Notice

The U.S. Environmental Protection Agency through its Office of Research and Development partially funded and collaborated in the research described here under Cooperative Agreement No. CR-821906 to Rice University. It has been subjected to the Agency's peer and administrative review and has been approved for publication as an EPA document. The document contains copyrighted material on pages: 22, 23, 29, 30, 31, 32, 33, 34, 35, 36, 40, 42, 43, 44, 47, 48, 49, 50, 51, 52, 53, 54, 55, 56, 57, 58, 59, 60, 61, 62, 63, 64, and 65. Mention of trade names or commercial products does not constitute endorsement or recommendation for use.

All research projects making conclusions or recommendations based on environmentally related measurements and funded by the Environmental Protection Agency are required to participate in the Agency Quality Assurance Program. This project was conducted under an approved Quality Assurance Project Plan. The procedures specified in this plan were used without exception. Information on the plan and documentation of the quality assurance activities and results are available from the Principal Investigator.

Foreword

The U.S. Environmental Protection Agency is charged by Congress to protect the Nation's land, air, and water resources. Under a mandate of national environmental laws, the Agency strives to formulate and implement actions leading to a compatible balance between human activities and the ability of natural systems to support and nurture life. To meet these mandates, EPA's research program is providing data and technical support for solving environmental problems of today and building a science knowledge base necessary to manage our ecological resources wisely, understand how pollutants affect our health, and prevent or reduce environmental risks in the future.

The National Risk Management Research Laboratory is the Agency's center for investigation of technological and management approaches for reducing risks from threats to human health and the environment. The focus of the laboratory's research program is on methods for the prevention and control of pollution to air, land, water, and subsurface resources; protection of water quality in public water systems; remediation of contaminated sites and ground water; and prevention and control of indoor air pollution. The goal of this research effort is to catalyze development and implementation of innovative, cost-effective environmental technologies; develop scientific and engineering information needed by EPA to support regulatory and policy decisions; and provide technical support and information transfer to ensure effective implementation of environmental regulations and strategies.

This report presents a discussion of the application of the first- and second-order reliability methods (FORM and SORM, respectively) to groundwater transport and remediation, and to public health risk assessment. Using FORM and SORM allows the formal incorporation of parameter uncertainty in the analysis of such applications. The report shows the advantages of the reliability methods over currently available simulation methods, such as the Monte Carlo Simulation method. Special attention is also given to the stochastic sensitivity results obtained as an integral part from the reliability analysis. Numerous examples and case studies are given to illustrate the method's application. The report concludes with an outlook of possible future efforts needed in this research area. It is published and made available by EPA's Office of Research and Development to assist the user community.

Subsurface Protection and Remediation Division
National Risk Management Research Laboratory

Abstract

Failure to rigorously accommodate physical parameter uncertainty in groundwater transport models casts serious doubts on our ability to accurately delineate the contaminant plume at a given site. This failure could also considerably reduce the possibility of success of the remediation scheme intended to clean up a plume within the specified time.

In this research, the probability that a contaminant leaking from a waste source will exceed some predetermined target level at a downgradient well is estimated, along with the sensitivity of this probability to the basic uncertainty in input parameters. The relevant parameters are assumed random with prescribed probability distributions.

We present a probabilistic modeling tool based on first- and second-order reliability methods (FORM and SORM) to account for parameter uncertainty in groundwater contaminant transport and remediation. The methodology is applied to analytical groundwater models to provide a simple screening tool for the assessment of contamination and remediation. In addition, numerical-based reliability models are developed to account for aquifer spatial heterogeneity and correlation structure in more complex systems.

In the analytical phase, the program PROBAN was used for the probabilistic analysis. Results indicate that the greatest impact on the probabilistic event is due to basic uncertainty in seepage velocity. However, chemical-related and source-related parameter uncertainty were also found to be very important factors to consider. In the numerical phase, the finite-element code FLOTRAN was linked to the reliability shell CALREL. Hydraulic conductivity was treated as a spatial random field. Considerable saving in computational time was achieved by using a coarse random variables mesh with a finer numerical mesh. Series system reliability was used to analyze failure at several wells. Probabilistic assessment of plume containment was also provided.

FORM and SORM are powerful tools for the probabilistic analysis of groundwater contaminant transport and remediation. Examples given in this work are only samples of the variety of applications that FORM and SORM can address. Their use in areas such as probabilistic risk assessment should be of great potential and interest to regulatory agencies and groundwater professionals alike.

Section 1
Introduction

1.1 Uncertainty in Contaminant Transport Modeling

The uncertainty of the physical parameters in subsurface contaminant transport problems is ubiquitous. This is manifested in the basic heterogeneity of the aquifer formation and the uncertainty related to the chemical, physical and biological properties of the contaminant being released and transported. Furthermore, there is a great deal of uncertainty regarding the leaking source dimensions, concentration, leaking rate and duration. These parameters vary largely from one site to another and also exhibit great spatial variability within the same site.

In many applications, consideration of the uncertainty constitutes an integral part of the modeling process. The most evident example is the regulatory requirements established by the U.S. Nuclear Regulatory Commission (NRC), the U.S. Environmental Protection Agency (EPA), and the U.S. Department of Energy (DOE) to conduct performance assessment analyses in order to consider the uncertainty associated with the predictions of the performance of a geologic repository for a high-level nuclear waste (Eisenberg et al., 1987). In exposure risk assessment problems, the probabilistic approach is equally appealing, because it makes little sense to give a deterministic value for the risk associated with a given receptor due to the large uncertainty in exposure point concentration.

There are different sources of uncertainty that the hydrogeologist has to account for. Some of these are summarized in the following. *Modeling uncertainty* arises due to using a simplistic relationship to describe the actual behavior of a physical system and the idealization down to operational mathematical expressions. This can be quantified either by comparisons with other, more involved models that provide a more accurate representation of reality, or by comparisons with collected data from the field. Modeling uncertainty can be formally treated in a reliability context by introducing a random variable that describes the ratio between the actual and predicted model response or output.

Prediction uncertainty means that the reliability estimate depends on the state of knowledge that is available to the engineer at the time of analysis. Various factors could affect the model response which are not included in the analysis simply due to lack of knowledge. As the state of knowledge increases, our assessment of the reliability is refined, usually combined with an increased reliability index (Melchers, 1987). *Human factors* are the collection of errors that arise during data collection, recording, and analysis.

At field sites, data are collected, and statistical estimators (mean and higher order moments) are obtained, and a probability density function (PDF) is chosen to represent the distribution of each input random variable. Since collected data are usually inadequate and noisy, those PDFs are bound to be biased. This is often termed *statistical* or *information uncertainty* (Dettinger and Wilson, 1981). One way of alleviating this problem is to consider the parameters such as the mean and variance themselves as random variables to estimate how uncertainty of the statistical parameters propagate to the model response. Another solution is to collect more data and use a Bayesian approach to update the inferred statistics (Melchers, 1987).

The last type of uncertainty is that resulting from the inherent randomness of the medium variables under consideration. This is quite evident in the soil formations, for which properties such as hydraulic conductivity can span many orders of magnitude at the same site (Freeze and Cherry, 1979; Bakr et al., 1978). This type of uncertainty is irreducible, and is often referred to as the *inherent, intrinsic,* or *physical uncertainty* (Melchers, 1987; Dettinger and Wilson, 1981). Although the current research focuses on addressing the physical uncertainty, the approach is equally applicable to other types of uncertainty with the necessary modifications of the formulation.

1.2 Motivation

The aforementioned sources of uncertainty greatly affect the predictive ability of groundwater flow and contaminant transport models. Failure to rigorously accommodate physical parameter uncertainty in transport models casts

serious doubts on our ability to accurately delineate the contaminant plume at a given site on the one hand. On the other hand, it could also considerably reduce the possibility of success of the remediation scheme intended to clean up a plume within the specified time, simply because of the uncertainty related to the plume delineation.

Although a fair amount of research has been done in the area of uncertainty analysis of subsurface contaminant transport, many of the proposed methods are either of low applicability to actual field conditions, or computationally very intensive. For example, the classic Monte Carlo simulation method (MCS) is considered to be a very popular tool for the stochastic risk assessment procedure. MCS is general, its accuracy increases as the sample size increases and the results converge to the exact one. However, in cases where events are characterized by very low probability of occurrence, or when applied to a complex groundwater flow and transport model with large number of input random variables, MCS becomes computationally expensive. The number of samples required to estimate an event probability p is in the order of $100/p$ to get a coefficient of variation of the estimate of 0.10 (Bjerager, 1990). This means that in order to have a good estimate of a probability of 1×10^{-3} using MCS, roughly 1×10^5 Monte Carlo simulations are needed, which constitutes such a computational burden that might hinder the use of the methodology on the day-to-day tasks, especially for large scale field problems characterized by large number of input random variables with complex correlation structure. Note that very low probability events are not uncommon in contaminant transport problems, especially if the chemical is highly reactive, or if the soil is very tight or if it contains tight lenses in an otherwise permeable soil.

Moreover, other methods such as perturbation and spectral methods usually involve making restrictive assumptions about the problem domain (e.g., assuming infinite extent, or setting an upper limit on parameters variability), that may not be applicable when the random variables have large variances; which is usually the case in aquifer parameters (e.g., hydraulic conductivity). More discussions on the different stochastic analysis methods are given in Section 2. It is thus evident that there is a need for developing a computationally efficient, yet simple, methodology for the probabilistic analysis of contaminant transport in groundwater.

Furthermore, little work has been done in the area of aquifer remediation under uncertainty. The work that is most relevant is that of Wagner and Gorelick (1987) which addresses the optimal management policy for ground water under parameter uncertainty. With the very large spending on pump-and-treat remediation schemes in Superfund sites, and with frequent failure to meet cleanup levels, the issue of assessing the performance of a given remediation scheme under parameter uncertainty stands out as a topic that deserves utmost attention, since this will be of great help in designing aquifer restoration schemes, and analyzing their performance in light of the relevant parameters uncertainty.

1.3   Research Objectives

The objectives of this work can be summarized in the following:

1. Develop a computationally efficient, yet simple, probabilistic screening tool for the analysis of groundwater contamination that can take into account aquifer-related, source-related, and chemical-related parameter uncertainty.
2. Analyze the impact of physical parameters uncertainty in a framework that would not force us to make unrealistic and restrictive assumptions about the problem geometry and boundary conditions, or about the variability of the relevant parameters.
3. Identify the parameters and the associated variability that have the greatest effect on the probabilistic outcome. Some of the methodologies available to date can provide such information but only after an extensive amount of additional calculations. It is our objective to obtain such sensitivity measures at no additional computational cost.
4. Develop a rigorous numerical probabilistic model for the assessment of groundwater contamination. This would enable us to take into account more realistic case studies, where spatial variability of the aquifer parameters, material heterogeneity, and stresses on the aquifer in the form of pumping and/or injection can be considered.
5. Assess the impact of some numerical issues on the resulting probabilistic outcome. Issues such as the effect of correlation scale of the random field, the relationship between the correlation scale and the discretization level, the impact of material heterogeneity such as the presence of lower permeability regions, are a few of many important issues that one has to understand in order to fully, and properly, account for aquifer parameter uncertainty.

6. Analyze the probability of exceeding pre-determined target concentration levels at more than one location in the aquifer. This is needed in many case studies, where the plume should not escape beyond a site boundary, or when assessing the regulatory compliance at more than one well in the aquifer. In this instance, compliance at each point along the site boundary becomes necessary.

7. Develop a probabilistic tool to enable the rigorous assessment of the efficiency of containment/remediation schemes under parameter uncertainty, using a numerical transport model.

1.4 Report Outline

The report is composed of five sections, including this one. Section 2 presents the mathematical basics of the first- and second-order reliability methods (FORM, and SORM). Since the methods were originally developed in the field of structural engineering, the section attempts to present the theory in a groundwater contamination framework.

Section 3 illustrates the application of reliability methods in the development of an analytical probabilistic screening tool for groundwater contamination. Examples of the probabilistic analysis to conservative, as well as reactive, solutes are given. The performance of FORM and SORM is tested with comparison to that of the Monte Carlo simulation method.

Section 4, on the other hand, addresses more complex case studies. A numerical transport model based on the finite element method is utilized in developing the probabilistic model. The probabilistic model allows us to take into account spatial variability of the hydraulic conductivity, and test the effect of correlation scale, discretization level, and the presence of tight lenses on the probabilistic outcome. System reliability was also used to show the joint failure event when looking at more than one receptor well in the aquifer. An example of the analysis of plume containment efficiency under the effect of spatially variable hydraulic conductivity is also given.

Section 5 concludes this report with a summary of the results obtained in previous sections, along with recommendations for future research.

Section 2
Theoretical Background

2.1   Introduction

The first- and second-order reliability methods (FORM and SORM, respectively) were originally developed in the past 10-15 years to assess the safety of structural components and structural systems and are now widely used in the study of structural reliability problems. This section presents a brief review of the mathematical basis of the reliability analysis methods to the extent necessary to understand the subsequent formulation of the methodology. A full account of the reliability methods development and evolution can be found in Madsen et al., (1986), Der Kiureghian and Liu (1986), Melchers (1987), and Ditlevsen and Madsen (1996).

2.2   Basics of Component Reliability Concepts

In component reliability formulation the uncertain parameters involved in the problem describing the component of interest are represented by a set of n-random variables, $X = (X_1, X_2, ..., X_n)$. These are termed the *basic random variables* or *uncertain variables*. The *limit-state function* (also termed *performance function*) is a scalar function of the input random variables, g(X): $\mathbb{R}^n \to \mathbb{R}$. When the vector of random variables $\mathbf{X}$ has the realization $\mathbf{x}=(x_1, x_2, ..., x_n)$, then the value $g(x_1, x_2, ..., x_n)$ determines the *state* of the component for that particular realization.

The g-function is formulated with the convention that if $g(x_1, x_2, ..., x_n) > 0$, the component has *survived*, whereas if $g(x_1, x_2, ..., x_n) < 0$, then the component has *failed*. Consequently, the space $\mathbb{R}^n$ of the physical random variables is divided into two domains:

$$S = \{x; g(x) > 0\} \qquad \text{denotes the } safe \text{ domain, and}$$
$$F = \{x; g(x) < 0\} \qquad \text{denotes the } failure \text{ domain} \tag{2.1}$$

The n-dimensional hypersurface $\{x; g(x)=0\}$ is the limiting condition between failure and survival, and is termed the *limit-state surface.*

Note that the term *component* in this context means that there is a single mode of failure. To state it simply, the component of interest would either fail or survive. This is different from the *system reliability* formulation, however, where the system has more than one failure mode. This concept will be explained shortly.

The classic example of limit-state function definition in structural reliability is the "load-resistance" problem. In such a problem, the resistance of a given structural component, *R*, is assumed random, for example due to material imperfections. The load applied on the structural component, *L*, is also assumed random. Wind and earthquake loads are examples of such random loading. Now the limit-state function is typically formulated as follows:

$$g(R, L) = R - L \tag{2.2}$$

Therefore, realizations that cause the g-function to be negative indicate that the structural component has *failed* to withstand the applied load. On the other hand, realizations resulting in positive values of the g-function indicate a condition where the structure has *survived* in withholding the applied random load.

In groundwater contamination problems, on the other hand, the uncertain variables of interest can be categorized into aquifer-, source-, and chemical-related parameters. Aquifer-related parameters can include seepage velocity (or hydraulic conductivity), dispersivities in the *x*-, *y*-, and *z*-directions, soil porosity, soil bulk density, and fraction of organic carbon. Source-related parameters include source dimensions and concentration. Chemical-related parameters may include the characteristics of the chemical's sorption and biodegradation. For example, the distribution coefficient, and the parameters describing the kinetics of biodegradation can be considered uncertain.

If the interest is in assessing the potential of groundwater contamination risk due to a leaking source, the limit-state function is formulated as follows:

$$g(\boldsymbol{X}) = C_{target} - C(\boldsymbol{X}) \tag{2.3}$$

where C_{target} is the pre-specified threshold target concentration level at the receptor well, and $C(\boldsymbol{X})$ is the simulated value of the contaminant concentration at the well, taking into account parameters variability.

It is obvious that the events described by $\{g(\boldsymbol{X}) < 0\}$ and $\{C(\boldsymbol{X}) > C_{target}\}$ are equivalent. In other words, the *failure state* in this case means failure to meet regulatory standards regarding the contaminant of interest at the well within the required simulation time. Note that for a continuously leaking source, the contaminant breakthrough at the receptor well increases monotonically with time. Therefore once the target concentration at the receptor well is exceeded (and *failure* occurs), the concentration at the well will always be greater than the target value as time progresses and failure conditions will persist.

On the other hand, if the interest is in assessing the remediation efficiency of a certain remediation alternative, C_{target} is taken to be the pre-determined target cleanup goal that is required at a given water supply well, and $C(\boldsymbol{X})$ is the simulated value of the contaminant concentration at the well, after the remediation operation. In other words, the failure state in this case means failure to meet the required target cleanup goals at the given well location, using the proposed remediation technology (e.g., pump-and-treat) within the operation time available for site restoration.

2.3 Component Versus System Reliability

In *component reliability* problems, situations with a single failure mode are analyzed. As indicated earlier, examples include failure to meet regulatory concentration levels at a single receptor well in the vicinity of a hazardous waste site, or failure to meet the target remediation cleanup levels for a specific well at a contaminated site.

In *system reliability* problems, however, we consider the problem of evaluating the reliability of a system where the state is described by more than one limit-state function. This is important in exposure assessment situations where the interest is on more than one water supply well, or when assessing the performance of a remediation scheme based on the success to meet the target cleanup levels at a few points in the aquifer. In this case, the state of the system is described by the states of its components,

$$g_i(\boldsymbol{X}) = C_{target} - C_i(\boldsymbol{X}) \tag{2.4}$$

where limit-state function $g_i(\boldsymbol{X})$, $i = 1,...,n$, defines whether the target concentration C_{target} has been exceeded by the simulated concentration at any point $i, i = 1,...,n$, in the solution domain. The problem physics imply that *failure* of the system occurs if *at least* one of its components fails, that is, the system can be modeled as a *series system*. More discussion on the system reliability estimation is presented in Section 2.8.

2.4 The Probability of Failure

In our "load-resistance" example, *probability of failure* is defined as follows:

$$P_F = P[g(R, L) \le 0] = P[R \le L] \tag{2.5}$$

Whereas in the groundwater contamination/remediation situations, the probability of failure is given by the *n*-fold integral,

$$P_F = P[g(\boldsymbol{X}) \le 0] = P[C_{target} \le C(\boldsymbol{X})] = \int_{g(\boldsymbol{X}) \le 0} f_{\boldsymbol{X}}(x) \, dx \tag{2.6}$$

where $f_{\boldsymbol{X}}(x)$ is the joint probability density function of $\boldsymbol{X}$ and the integration is carried out over the failure domain. In other words, the failure probability is the probability of being in the domain of the *n*-dimensional space bounded by $g(\boldsymbol{X}) \le 0$.

A variety of factors complicate the direct estimation of this *n*-fold integral and prevent the use of the standard methods of integration. The first problem stems from the fact that for large problems, the integration is performed in a high-dimensional space, which makes the numerical integration very time consuming or even intractable. Hohenbichler et al. (1987) point out that for an *n*-dimensional integral, if *m* is the number of calls of the integrand per dimension, the computation time grows as m^n.

Another factor that complicates the estimation of the aforementioned probability integral is that in many cases the absolute value of the integrand is very small and therefore the effect of numerical inaccuracies can be considerably magnified (Breitung, 1991). Furthermore, problems arise due to the complex and algorithmic formulation of the

integration domain boundaries given by the *g*-function. This is the case when numerical solutions of the transport equation are obtained using the finite element or finite difference methods, such that a sequence of solutions of a large numerical transport problem is required to find a single point on the limit-state surface. In addition, problems arise due to the lack of information concerning the multivariate joint probability density function in many practical situations.

In addition to FORM and SORM, other methods exist for the approximation of the above integral. These include simulation methods (Bjerager, 1988), and hybrid methods combing simulations with FORM/SORM (Lin and Der Kiureghian, 1987).

2.5 FORM and SORM as Approximation Methods

The primary objective of the reliability methods is to overcome the aforementioned difficulties and to evaluate the multidimensional integral in (2.6). FORM and SORM are analytical schemes used to approximate the probability integral when the basic variables have strictly increasing continuous joint cumulative distribution functions.

FORM and SORM consist of a number of steps (Bjerager, 1990): (1) transformation of the basic variables, X, into the standardized and uncorrelated normal variates, U (2) determination of the most likely failure point in the standard space, (3) approximation of the limit-state surface in the standard space at the design point, and (4) computation of the probability of failure in accordance with the approximation surface selected in step (3).

2.5.1 Transformation to the Standard Normal Space

The first step in the reliability approach is to transfom the random vector, X, into the standard normal vector U with zero mean, unit variance and zero correlation using a non-linear one-to-one mapping, $U=T(X)$. This means that the original joint probability density function $f_X(x)$ is mapped into the standard normal density function

$$f_U(u)=\phi_n(u)=\frac{1}{(2\pi)^{n/2}}\exp\left(-\frac{1}{2}u^T u\right) \tag{2.7}$$

Such a transformation always exists for random variables having strictly increasing continuous joint cumulative distribution functions. The space of the basic random variables X is often termed the *x-space* or *physical space*. The transformed space is often termed the *standard normal space* or the *u-space*.

Jang et al. (1990) lists the advantages of the transformation into the standard normal space:

1. Probability density in the standard space is rotationally symmetric, that is, for all hyperplanes of equal distance from the origin, the probability content **p** of the half space away from the origin, is constant.
2. Since the probability density decays exponentially with square of the distance from the origin, integration at a linearization point in a standard space can approximate the probability of failure with good accuracy.
3. Closed form solutions for estimating the probability contents for simple sets in the standard normal space are readily available.

Figure 2.1 illustrates the transformation from the physical to the standard normal space for a simple two-dimensional case. The choice of transformation is dependent on: (1) the available level of statistical information, (2) whether the random variables X are normal, and (3) whether X is statistically independent. This is explained in the following.

2.5.1.1 The Hasofer-Lind Transformation

The simplest case is when the basic random variables X are uncorrelated and normally distributed. Here, the nonlinear transformation reduces to the affine Hasofer-Lind transformation of the form

$$u=L^{-1}D^{-1}\left(x-\mu_x\right) \tag{2.8}$$

can be used, where $D = \text{diag}[\sigma_i]$, and σ_i is the standard deviation of X_i, L is a lower triangular matrix resulting from the Cholesky decomposition of the correlation matrix $R = [\rho_{ij}]$, such that $R = LL^T$, and $\underline{\mu}_x$ is the mean vector of X.

2.5.1.2 The Diagonal Transformation

In case of statistically independent non-normal random variables, the non-linear mapping is reduced to the following diagonal transformation:
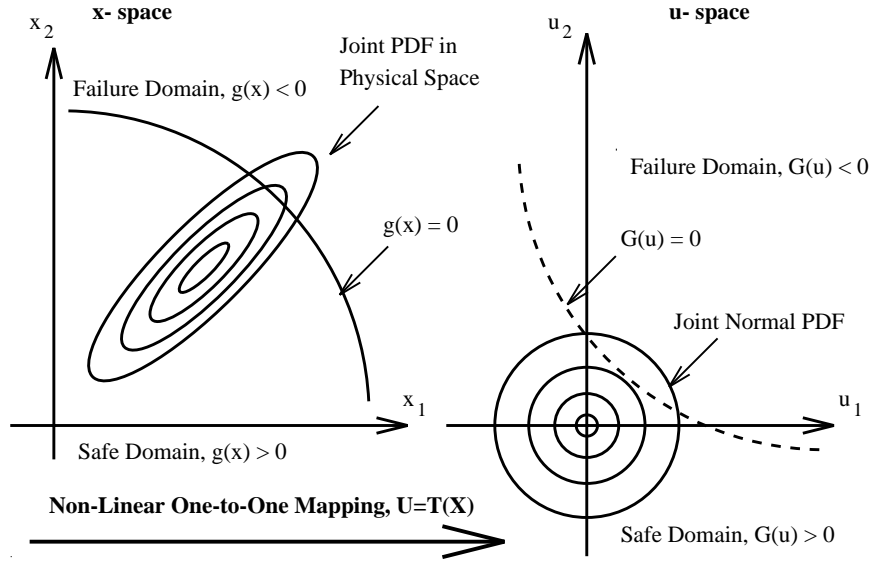

Figure 2.1   Mapping of the physical space into the standard normal space.

$$u_i = \Phi^{-1}\left[F_{X_i}(x_i)\right] \qquad i = 1, \dots, n \tag{2.9}$$

where $\Phi[\ ]$ is the standard normal cumulative distribution and $F_{Xi}(x_i)$ is the cumulative distribution function of X_i. This transformation is termed "diagonal" because each random variable X_i is transformed separately from the other variables.

2.5.1.3 The Nataf Transformation

In the special case of incomplete statistical information, where the marginal distributions and the covariances are known, the transformation into the standard normal space proceeds in two stages, following the Nataf model (Der Kuireghian and Liu, 1986). First, the basic random variables, X, are transformed into a space of correlated standard normal variates, Z, such that $Z_i = \Phi^{-1}\left[F_{X_i}(x_i)\right]$. The variates Z have a correlation matrix R_0. The second step consists of transforming the vector Z into the space of uncorrelated standard normal variates as follows:

$$U = \Gamma_0 Z \tag{2.10}$$

where Γ_0 is a lower triangular matrix resulting from the Cholesky decomposition of the correlation matrix of Z, i.e. $\Gamma_0 = L_0^{-1}$ in which $R_0 = L_0 L_0^{T}$. Elements of the matrix R_0 are the correlation coefficients, $\rho_{Zi\,Zj}$. These, in turn, are related to the correlation coefficients, $\rho_{Xi\,Xj}$ of the basic random variables, X, through the following implicit integral relationship (Der Kuireghian and Liu, 1986):

$$\rho_{x_i x_j} = \int_{-\infty}^{+\infty}\int_{-\infty}^{+\infty}\left[\frac{x_i - \mu_i}{\sigma_i}\right]\left[\frac{x_j - \mu_j}{\sigma_j}\right]\phi_2\left(z_i, z_j, \rho_{z_i z_j}\right)dz_i dz_j \tag{2.11}$$

where $\phi_2(z_i, z_j, \rho_{Zi\,Zj})$ is the bivariate normal density function of normal variates with zero means, unit variances, and correlation coefficient $\rho_{Zi\,Zj}$; μ_i and σ_i denote the mean and standard deviation of X_i, respectively. For each pair of marginal distributions, $F_{Xi}(x_i)$ and $F_{Xj}(x_j)$, and for a given correlation coefficient $\rho_{Xi\,Xj}$, the above equation can be iteratively solved to obtain $\rho_{Zi\,Zj}$. Liu and Der Kiureghian (1986a), however, provided a set of empirical formulae relating $\rho_{Zi\,Zj}$ to $\rho_{Xi\,Xj}$ for some known marginal distributions. This greatly simplifies the calculations and overcomes the tedious process of iterative solution.

2.5.1.4 The Rosenblatt Transformation

When complete statistical information, in the form of full joint probability distribution of *X*, is known, the Rosenblatt transformation (Rosenblatt, 1952) is used. This makes use of the successive conditioning (Melchers, 1987):

$$u_1 = \Phi^{-1}\left[F_{X_1}(x_1)\right]$$
$$u_2 = \Phi^{-1}\left[F_{X_2}|x_1(x_2|x_1)\right]$$
$$\dots$$
$$u_n = \Phi^{-1}\left[F_{Xn}|x_1\dots x_{n-1}(x_n|x_1\dots x_{n-1})\right]$$

(2.12)

where $F_{Xn}/X_1 \dots X_{n-1}(x_n/x_1 \dots x_{n-1})$ is the conditional cumulative distribution of X_n given $X_1 \dots X_{n-1}$, and all conditional distribution functions are assumed continuous. The transformation first transforms X_1 into the *u*-space. Then all conditional variables of X_2/X_1 are transformed into the *u*-space, and so on (Madsen et al., 1986). It should be noted that the Rosenblatt transformation is reduced to that in (2.9) when the basic random variables are mutually statistically independent. When the basic random variables are also jointly normal, the transformation reduces to the linear Hasofer-Lind given in (2.8).

2.5.2 Design Point Determination

The second step in the reliability approach (and a major task) is to determine the design point, which is a point on the limit-state surface in the *u*-space closest to the origin. The design point, ***u****, is of practical significance. In standard normal space, the contours of probability density are concentric spheres and the probability density decays with distance from the origin. Therefore, ***u****, which is the nearest point to the origin in the failure region, has the highest likelihood among all failure points. Hence, the design point is considered the *most likely failure point* in the standard normal space (Cawlfield and Sitar, 1987).

The design point, however, may not necessarily be the most likely failure point, if the underlying probability density functions of the basic random variables are unknown, and only incomplete statistical information is available. It should be noted that the design point in the standard normal space, ***u****, can be inversely mapped into its counterpart in the physical space, ***x****, to give a more physically meaningful interpretation. The design point, ***u****, is the solution of the following non-linear constrained optimization problem:

$$\text{Minimize} \qquad |\boldsymbol{u}|$$
$$\text{subject to} \qquad G(\boldsymbol{u})=0$$

(2.13)

The above optimization problem consists of finding the point that lies on the limit-state surface and has a minimum distance from the origin in the standard normal space. Several algorithms have been proposed for the solution of this problem. These include the HL-RF method, which was originally developed by Hasofer and Lind (1974) in second moment reliability analysis, and later extended by Rackwitz and Fiessler (1978) to include distribution information; the gradient projection method, the Sequential Quadratic Programming (SQP) method, and the modified HL-RF method (Liu and Der Kiureghian, 1986b).

For example, the HL-RF method is based on constructing a sequence of points, $\boldsymbol{u}_2, \dots, \boldsymbol{u}_n$, where $\boldsymbol{u}_1$ is an initial guess. The HL-RF method follows the procedure (Madsen et al., 1986):

$$u_{i+1} = \left[\alpha_i u_i + \frac{G(u_i)}{|\nabla u_i G(u_i)|}\right]\alpha_i^T$$

(2.14)

such that

$$\nabla_u G(u) = \left(\frac{\partial G(u)}{\partial u_1},\dots,\frac{\partial G(u)}{\partial u_n}\right)$$

(2.15)

is the gradient vector, and

$$\alpha_i = -\frac{\nabla_u G(u_i)}{\left|\nabla_u G(u_i)\right|} \tag{2.16}$$

is a unit vector pointing in the negative gradient direction.

The gradient vector can be estimated in terms of the gradient vector in the physical-space, $\nabla_x g(x)$, as follows:

$$\nabla_u G(u) = \{\nabla_x G(x)\} J_{u,x}^{-1} \tag{2.17}$$

where $J_{u,x}$ is the Jacobian of the transformation from the physical-to the standard-normal space. The HL-RF method starts from an arbitrary initial point, and the sequence usually converges to u^* and α^* in a few iterations.

Liu and Der Kiureghian (1991) list the criteria for comparing and assessing the different optimization algorithms for reliability analysis. These criteria are:

1. **Generality:** which refers to the different types of problems that the optimization method can solve.
2. **Robustness:** which refers to the power of a given optimization method to solve problems with the required accuracy.
3. **Efficiency:** which is measured by the effort required to solve a problem. This, in turn, is a function of the convergence rate of the optimization methodology.
4. **Capacity:** measured by the maximum number of variables that can be handled by the method. This is a direct function of the demand and supply of computer storage.

Liu and Der Kiureghian (1991) compared several optimization algorithms for reliability analysis. They concluded that the HL-RF method required the least amount of storage and computation in each iteration, and it converged within a few cycles. However, they reported some situations where the method can fail, and that introducing a merit function $m(u)$ to monitor the convergence of the sequence improved the robustness of the method.

From the previous discussion, we presented the solution of a non-linear constrained optimization problem to be an essential step in the reliability methods. Therefore, difficulties encountered in optimization problems would also prove problematic in the reliability analysis. Examples of situations giving rise to problems in the reliability analysis are when the limit-state surface is extremely complex; when the g-function is ill-posed; or if the limit-state surface contains many local minima. In such cases, the constrained optimization routine may converge to a *local* minimum instead of reaching the *global* one. Furthermore, if the finite difference method is used to approximate the gradient of a noisy limit-state surface, the optimization routine may fluctuate between a few points, and convergence may never be achieved.

In such cases, a number of procedures can be used to improve the optimization potential of reaching the global minimum. Using different starting points, the optimization method would be considered to have achieved the global minimum if it converges to the same point in every case. A noisy limit-state surface can be better handled by using a smoothing algorithm, or by using higher-order finite difference approximation to the gradients. If all fails, a non-gradient search procedure, such as the Nelder-Mead method, may be able to circumvent the problem of noisy gradients, although an extensive amount of additional function evaluations should be expected.

2.5.3 Limit-state Surface Approximation

The third step is the approximation of the non-linear limit-state surface in the u-space by an appropriate tangent surface at the point of smallest distance to the origin. This smallest distance, β, is termed the *reliability index* and is a measure of the reliability of the component under consideration.

In the first-order reliability method (FORM), the limit-state surface in the standard normal space is approximated by the tangent hyperplane at the design point.

Since the probability density in the u-space decays exponentially with the square of the distance from the origin, the primary contribution to the probability integral in (2.6) comes from the part of the failure region closest to the origin (see Figure 2.2). Therefore, the design point u^* is an optimum point at which to approximate the limit-state surface $G(U)=0$.

Although the first-order reliability method provides the results using a very small computational effort, the results can significantly depart from the "true" solution. This is usually the case when the limit-state surface has a significant curvature around the design point. Such cases occur when the basic random variables are of large scatter,
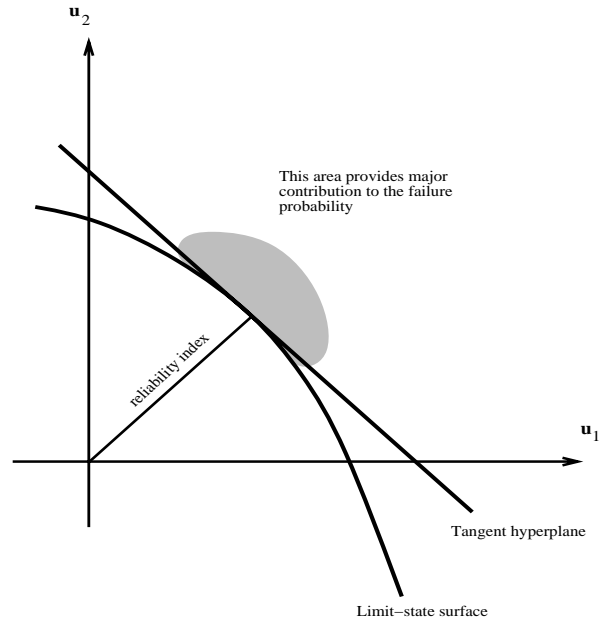

Figure 2.2   Region of major contribution to the failure probability (after Madsen et al., 1986).

or when the limit-state function is highly non-linear (categories in which most subsurface contamination problems fall). In such instances, the second-order reliability method (SORM) can be more effective, since it can account for the limit-state surface curvature in the standard normal space.

Bjerager (1990) reports that the first thorough study of SORM was done by Fiessler et al. (1979). They obtained the failure probability by approximating the failure surface at the design point in the standard normal space by a second-order surface. Both second-order Taylor expansion as well as curvature-fitted paraboloid approximation surfaces were analyzed.

Bjerager (1990) identifies the second-order Taylor expansion as more general than the paraboloid approximation method. However, due to the fact that it is not based on the geometrical properties of the failure surface, it lacks invariance with respect to the choice of the limit-state function. This is not the case for the geometrically-based paraboloid approximation method, which is invariant to the choice of the limit-state function. Consequently, the parabolic SORM is usually the preferred analysis method. There exists two paraboloid approximations in the literature, namely the curvature-fitted (Breitung, 1984; Tvedt, 1988), and the point-fitted (Der Kiureghian and Lin, 1987).

2.5.4 *Computation of the Failure Probability*

The final step in the FORM/SORM estimation of the *n*-fold probability integral given in (2.6) is to compute the failure probability corresponding to the approximating failure surface. It should be emphasized that FORM and SORM are full distribution methods, meaning that the full marginal and joint probability density functions can be incorporated, and the transformation from the *x*-space to the *u*-space is exact. Other methods often cited in the literature include FOSM, which refers to "Second Moment" methods, which can only incorporate the first two moments. Nevertheless, FORM and SORM can still be defined in a second moment context (Bjerager, 1990).

The first-order reliability index is given by the inner product

$$\beta = \alpha^* \boldsymbol{u}^* \tag{2.18}$$

where $\boldsymbol{\alpha}^*$ is the unit normal at the design point directed toward the failure region (Figure 2.3). The first-order approximation of the probability of failure is given by

Standard Normal Space
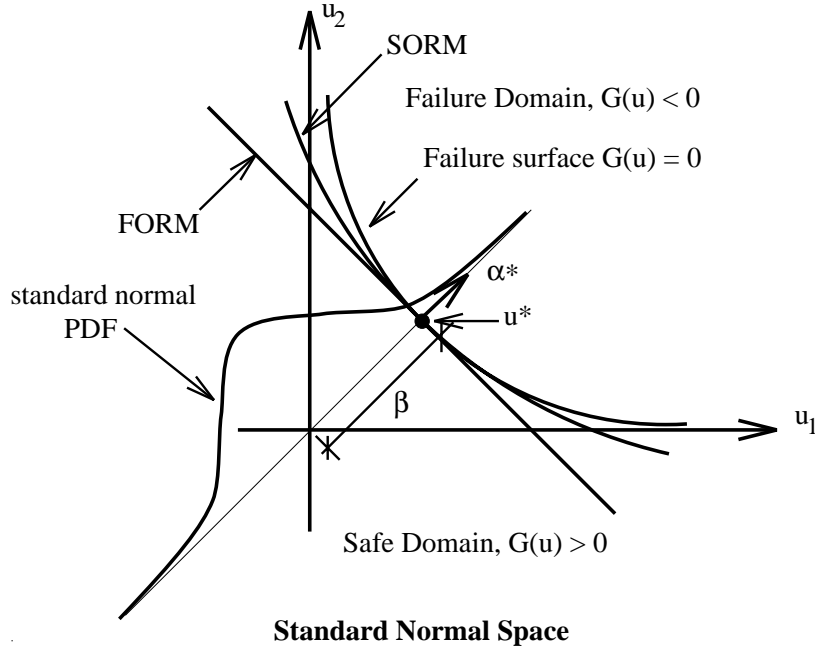

Figure 2.3 FORM and SORM approximations to the failure surface in the standard normal space.

$$P_F \approx P_F^{FORM} = \Phi(-\beta) \tag{2.19}$$

where $\Phi(\ )$ is the standard cumulative normal probability.

The estimation of the probability content of parabolic limit-state surface is an equally important step in the SORM analysis. The asymptotically exact result developed by Breitung (1984) had an appreciable impact on making SORM a practical method (Bjerager, 1990). The formula for second-order failure probability is given by:

$$P_{F\,asymptotic}^{SORM} \approx \Phi(-\beta)\prod_{j=1}^{q-1}\left(1+\beta\kappa_j\right)^{-\frac{1}{2}} \tag{2.20}$$

where κ_j are the q-1 principal curvatures at the most likely failure point, $\boldsymbol{u}^*$, in u-space, with the sign convention that curvatures are negative when the surface curves towards the origin. A numerical procedure to evaluate the integral was suggested by Tvedt (1988). This formula is asymptotically exact as β approaches infinity and the term $\beta \kappa_i$ remains fixed.

Tvedt (1988) provided an exact and numerically feasible result for SORM, thus making SORM a powerful tool for reliability estimates. His result is given for a parabolic approximation by:

$$P_F^{SORM} = \phi(\beta)\,\mathrm{Re}\left[i\left(\frac{2}{\pi}\right)^{\frac{1}{2}}\int_{t=0}^{\infty}\frac{\exp\left\{(t+\beta)^2/2\right\}}{t}\left[\prod_{j=1}^{q-1}\left(1-t\kappa_j\right)^{-\frac{1}{2}}\right]dt\right] \tag{2.21}$$

where $\phi(\ )$ denotes the standard normal probability density, κ_j are defined as before, and i is the imaginary number ($\sqrt{-1}$).

2.6 Sensitivity Measures

As an integral part of the first-order reliability method, the user is provided with measures of sensitivity of the reliability index and the first-order estimate of the failure probability with respect to the basic random variables, as well as to the parameters defining the probability distribution and the limit-state function. These sensitivity measures

identify the random variables or the deterministic parameters which have the greatest impact on the failure probability.

The simplest measure of sensitivity is the partial derivative of the reliability index, β, with respect to the coordinates of the design point in the standard normal space. This is given by:

$$\nabla_{u^*}\beta = \alpha^* \tag{2.22}$$

where

$$\alpha^* = -\frac{\nabla_{u^*}G(u^*)}{\left|\nabla_{u^*}G(u^*)\right|} \tag{2.23}$$

and

$$\nabla_{u^*}\beta = \left[\frac{\partial \beta}{\partial u_1}, \frac{\partial \beta}{\partial u_2}, ..., \frac{\partial \beta}{\partial u_n}\right] \tag{2.24}$$

The α^* vector, hence, gives a measure of the change in β when a given basic random variable is perturbed. Since the partial derivatives in (2.22) are estimated at the design point, they reflect only the sensitivity with respect to *small* changes in the random variables at that particular point. In other words, this vector gives an indication to measure relative importance of the standard variates u_i. Since $\boldsymbol{\alpha}^*$ is necessary for obtaining the design point, the aforementioned sensitivity measure is obtained with no additional computational effort.

Although $\boldsymbol{\alpha}^*$ is useful, the sensitivity of β with respect to the coordinates of the design point in the physical space would be more physically meaningful. Sensitivities with respect to changes in the coordinates of the design point in the physical space are obtained by the chain rules:

$$\nabla_{x^*}\beta = \left(\nabla_{u^*}\beta\right)J_{u^*,x^*} = \alpha^* J_{u^*,x^*} \tag{2.25}$$

where $\boldsymbol{J}_{u^*,x^*}$ is the Jacobian of the transformation from $\boldsymbol{x}$ to $\boldsymbol{u}$ evaluated at the design point. Since the values of $\nabla_{x^*}\beta$ are dependent on the units of $\boldsymbol{x}^*$, Der Kiureghian and Ke (1985) scaled the gradient vector by the matrix of standard deviations, providing the unit gamma sensitivity vector:

$$\gamma = \frac{\left(\nabla_{x^*}\beta\right)\boldsymbol{D}}{\left|\left(\nabla_{x^*}\beta\right)\boldsymbol{D}\right|} \tag{2.26}$$

where $\boldsymbol{D}$ is the diagonal matrix of standard deviations $\boldsymbol{X}$. Thus, the unit vector γ at the design point measures the scaled and normalized sensitivities of β with respect to the variation in the coordinates of $\boldsymbol{x}^*$. In other words, this vector provides a measure of relative importance of the *equally likely* changes of the basic random variable $\boldsymbol{X}$ on the reliability estimate.

Sensitivity vectors with respect to deterministic parameters in the limit-state function can also be obtained. Let $g(\boldsymbol{x}) = g(\boldsymbol{x},\eta)$, where $\boldsymbol{\eta}$ is a vector of deterministic parameters, Madsen et al. (1986) have shown that

$$\nabla_\eta\beta = \frac{1}{\left|\nabla_{u^*}G(u^*)\right|}\nabla_\eta g(x^*,\eta) \tag{2.27}$$

In this work, the target concentration level at the well, whether in a risk assessment scenario or during the assessment of remediation efficiency, would be a deterministic parameter. Hence the $\boldsymbol{\eta}$ sensitivity in that context would provide the sensitivity of the reliability index with respect to variations in the chosen target concentration. Hence, if the sensitivity with respect to target concentration is sought, and with the limit-state function formulation given in (2.3), it can be easily shown that:

$$\nabla C_{target}\,\beta = \frac{1}{\left|\nabla_{u^*}G\!\left(u^*\right)\right|} \tag{2.28}$$

since the term $\nabla_{\boldsymbol{\eta}}\,g(\boldsymbol{x^*},\boldsymbol{\eta})$ in this case which is equal to $\nabla C_{target}\,g(\boldsymbol{x^*})$ reduces to 1.0.

The choice of distribution parameters of each basic random variable can have a profound impact on the reliability estimate of the component of interest. For example, when considering the first-order decay coefficient describing the biodegradation of an organic chemical to be uniformly distributed, the choice of the upper and lower limits would have a significant impact on the probability of such a chemical to exceed the regulatory standards at a receptor well downgradient from a leaking source.

Such sensitivities can also be obtained during a reliability analysis. Let the joint probability density function of the basic random variables $f_X(\boldsymbol{x}) = f_X(\boldsymbol{x},\Theta)$, where Θ is a vector of the distribution parameters describing the basic random variables. The vector Θ could, for example, include the mean, standard deviation, and correlation coefficients of the random variables. Madsen et al. (1986) have shown that:

$$\nabla_{\Theta}\,\beta = \alpha^*J_T,\Theta \tag{2.29}$$

where J_T,Θ is the matrix containing the partial derivatives of the transformation $\boldsymbol{T}$ with respect to the parameters Θ, evaluated at the design point.

Cawlfield and Sitar (1987) indicate that the evaluation of (2.29) is cumbersome in general. This is because the partial derivatives of the transformation T with respect to the distribution parameters, Θ, are sometimes difficult to obtain.

The sensitivities of the first-order probability of failure are obtained by applying the chain rule to (2.19).

$$\nabla\eta P_F^{FORM} = -\phi\!\left(-\beta(\eta)\right)\nabla\eta\beta \tag{2.30}$$

and

$$\nabla_{\Theta}P_F^{FORM} = -\phi\!\left(-\beta(\Theta)\right)\nabla_{\Theta}\beta \tag{2.31}$$

2.7 Uncertainty Importance Factors

Additional valuable information to the parametric sensitivity factors is provided by the uncertainty *importance factors* of the reliability index. This indicates the importance of modeling the random variable X_i as a distributed variable rather than as a fixed valued variable, the median of the distribution being the fixed value.

For statistically independent variables, it has been shown (Madsen, 1988) that omission sensitivity factors (defined as the relative error in the first-order reliability index when a basic variable X_i is replaced by a deterministic number equal to its median $X_{i,m}$) are given by:

$$\frac{\beta\!\left(X_i = X_{i,m}\right)}{\beta} = \frac{1}{\sqrt{1-\alpha_i^2}} \tag{2.32}$$

It is therefore observed that the uncertainty importance factors, $100 \times \alpha_i^2$ as printed by PROBAN (Veritas Research, 1992b), give a measure of the relative importance of modeling the uncertainty of a basic random variable, X_i, with respect to the final probability outcome.

This concept naturally extends to higher dimensions. The relative error in the first-order reliability index of representing a group of m mutually dependent variables, $X_i, i=1,...,m$, by their respective medians is given by (Veritas Research, 1992a):

$$\frac{\beta\!\left(X_i = X_{i,m}, i = 1,...,m\right)}{\beta} = \frac{1}{\sqrt{1-\sum_{i=1}^{m}\alpha_i^2}} \tag{2.33}$$

14

Therefore, the uncertainty importance factors associated with a group of mutually dependent variables can be expressed by the quantity $100\sum_{i=1}^{m}\alpha_i^2$. In case $m=1$, the results of (2.33) reduce to that of (2.32).

Importance factors allow for the identification of the random variables which have the least impact on the final reliability outcome. Each of these variables can then be replaced, for all practical purposes, by a deterministic value, its median for example. Therefore, the importance factors are very useful in reducing the number of basic random variables in large size reliability models. Importance factors are further explored in Section 3.

2.8 System Reliability

In the preceding section, we have looked at cases where the state of the system is described by a single limit-state function, i.e., having a single "mode of failure". However, a situation can arise that necessitates the simultaneous consideration of several limit-state functions; for example, if we consider the probability that the contaminant concentrations at any of several points exceed a predetermined critical value. This is important in exposure assessment situations where the interest is on more than one point of human exposure in the aquifer, or when assessing the performance of a remediation scheme based on the likelihood of success to meet the target cleanup levels at every point in the aquifer. In this case, the state of the system is described by the states of its components:

$$g_i(X) = C_t - C_i(X) \tag{2.34}$$

where each limit-state function $g_i(X)$, $i=1,...,m$, defines whether the target concentration C_t has been exceeded by the simulated concentration at point i, $i=1,...,m$, in the solution domain.

By definition of the problem, *failure* of the system occurs if *at least* one of its components fails, that is, the system under consideration is a *series system*. Hence, the system failure probability can be expressed as

$$P_F^{system} = P\left[\bigcup_{i=1}^{m} g_i(x) \le 0\right] = 1 - P\left[\bigcap_{i=1}^{m} g_i(x) > 0\right] \tag{2.35}$$

The calculation of P_F^{system} is complicated due to the fact that the components $g_i(x)$ are usually statistically dependent since they share some of the same basic random variables. Upper and lower bounds on the probability of failure of a series system can be obtained from the individual component failure probabilities, P_{Fi}, and the joint failure probabilities in any two modes, P_{FiFj}. The uni-modal bounds make use of the P_{Fi} terms only, and are given by (Madsen et al., 1986):

$$\max_{i=1}^{m} P_{Fi} \le P_F^{system} \le \sum_{i=1}^{m} P_{Fi} \tag{2.36}$$

The bi-modal Ditlevsen bounds (Ditlevsen, 1979) make use of the individual modal failure probabilities and the joint failure probabilities in any two modes:

$$P_{F_1} + \sum_{i=2}^{m} \max\left\{P_{Fi} - \sum_{j=1}^{i-1} P_{Fi,Fj}, 0\right\} \le P_F^{system} \le P_{F_1} + \sum_{i=2}^{m} \left\{P_{Fi} - \max_{j<i} P_{FiFj}\right\} \tag{2.37}$$

The Ditlevsen bounds depend on the ordering of the failure modes (or components), F_1, F_2, ..., F_m, and different orderings may correspond to the largest lower bound and the smallest upper bound. Practical experience suggests that the failure modes (i.e., *g*-functions) be numbered in a decreasing order of P_{Fi} (Madsen et al., 1986).

The modal and joint modal failure probabilities P_{Fi} and P_{FiFj}, respectively, used in formulating the above uni- and bi-modal bounds were assumed to be exact failure probabilities. A first-order (FORM) approximation of these modal and joint modal failure probabilities are given by (Madsen et al., 1986).

$$P_{Fi} \approx P_{Fi}^{FORM} = \Phi\left(-\beta_i^{FORM}\right)$$

$$P_{FiFj} \approx P_{FiFj}^{FORM} = \Phi\left(-\beta_i^{FORM}\right)\Phi\left(-\beta_j^{FORM}\right)$$

$$+\int_0^{Pij} \phi_2\left(-\beta_i^{FORM}, -\beta_j^{FORM}, \rho\right)dp$$

(2.38)

In which ρ_{ij} denotes the correlation coefficient between the failure modes i and j linearized at their design point. This modal correlation coefficient is obtained as the inner product of the two unit normal vectors at the modal design points

$$\rho_{ij} = \alpha_i^* \cdot \alpha_j^{*\mathsf{T}}$$

(2.39)

The integral in (2.38) must be evaluated numerically. To avoid this numerical integration, Ditlevsen (1979) has proposed the following simple bounds on P_{FiFj}^{FORM}:

$$\max(p_1, p_2) \le P_{FiFj}^{FORM} \le p_1 + p_2 \qquad \text{if } p_{ij} > 0$$

$$0 \le P_{FiFj}^{FORM} \le \min(p_1, p_2) \qquad \text{if } p_{ij} < 0$$

(2.40)

where

$$p_1 = \Phi\left(-\beta_{Fi}^{FORM}\right)\Phi\left(-\frac{\beta_{Fi}^{FORM} - \beta_{Fj}^{FORM}\rho_{ij}}{\sqrt{1-\rho_{ij}^2}}\right)$$

$$p_2 = \Phi\left(-\beta_{Fi}^{FORM}\right)\Phi\left(-\frac{\beta_{Fj}^{FORM} - \beta_{Fi}^{FORM}\rho_{ij}}{\sqrt{1-\rho_{ij}^2}}\right)$$

(2.41)

By substituting the above bounds on P_{FiFj}^{FORM} in (2.37), the relaxed bi-modal bounds on P_F^{system} are obtained:

$$P_{F_1} + \sum_{i=2}^{m} \max\left\{P_{Fi} - \sum_{j=1}^{i-1} P_{FiFj,u}, 0\right\} \le P_F^{system} \le \sum_{i=1}^{m} P_{Fi} - \sum_{i=2}^{m} \max_{j<i}\left\{P_{FiFj}, l\right\}$$

(2.42)

in which $P_{FiFj,u}$ and $P_{FiFj,l}$ denote upper and lower bounds on P_{FiFj}, respectively.

Finally, a measure of the "system" reliability can be presented by reporting the system reliability index, given by

$$\beta^{system} = \Phi^{-1}\left(1 - P_F^{system}\right)$$

(2.43)

2.9 Monte Carlo Simulation Methods

In this work, verification of the first- and second-order reliability results is accomplished by comparing the reliability results to that obtained by the Monte Carlo Simulation method. The zero-one indicator-based Monte Carlo simulation method is used for that purpose. The method works as follows:

First, we define an *indicator function*, $I(\boldsymbol{x})$ such that:

$$I(\boldsymbol{x}) = \begin{cases} 1 & \text{if } g(\boldsymbol{x}) \le 0 \\ 0 & \text{if } g(\boldsymbol{x}) > 0 \end{cases}$$

(2.44)

Next, the Monte Carlo simulation estimates the probability of failure according to the following expression:

$$P_F = \int_{g(X)\le 0} f_X(\boldsymbol{x})dx = \int_{\boldsymbol{x}\subset \mathrm{IR}^n} I(\boldsymbol{x})f_X(\boldsymbol{x})dx = E\big[I(\boldsymbol{x})\big]$$

(2.45)

where $E[\ ]$ is the expectation operator. By performing N Monte Carlo simulations by random selection of the prescribed joint probability density of the vector X, the probability of failure is estimated as follows:

$$\hat{E}[P_F] = \frac{1}{N} \sum_{i=1}^{N} p_i \tag{2.46}$$

$$\hat{\sigma}^2[P_F] = \frac{1}{N(N-1)} \sum_{i=1}^{N} \left(p_i - \hat{E}[P_F] \right)^2 \tag{2.47}$$

where $p_i = I(\mathbf{x}_i)$ and $\mathbf{x}_i$ denotes the ith simulation. The stopping criterion for most Monte Carlo simulation procedures is when a threshold for the coefficient of variation of the estimate of P_F is reached. The coefficient of variation is given by:

$$c.o.v. = \frac{\hat{\sigma}[P_F]}{\hat{E}[P_F]} \tag{2.48}$$

It can be easily shown that:

$$\hat{\sigma}^2[P_F] = \frac{P_F(1-P_F)}{N}$$

$$\approx \frac{P_F}{N} \qquad \text{if } P_F \text{ is small} \tag{2.49}$$

which means that for small P_F, and for a stopping criteria of coefficient of variation of 0.1, the number of Monte Carlo simulations needed is about $100/P_F$.

Section 3

Analytical Probabilistic Groundwater Modeling

In this section, the first- and second-order reliability methods are applied to an analytical contaminant transport code. This phase of the work is intended as a first step in which the use of the reliability methods is tested on some simple case studies, such that the different aspects of the methodology are investigated, and the limitations are assessed. In this section, we are interested in the assessment of groundwater contamination risk due to the leaking of contaminants from a waste source, where the Horizontal Plane Source model of Galya (1987) is utilized to solve cases of non-reactive and reactive contaminant migration.

The use of the analytical transport code in this stage precludes the consideration of the spatial variability and correlation structure of the aquifer properties (e.g., hydraulic conductivity). This is because analytical models are usually simplistic models that cannot accommodate spatial variability in input parameters. Nevertheless, the intention in this part is twofold: (1) to perform a proof-of-concept type of study for illustrating the potential power of the reliability methods when applied to groundwater contamination problems; and (2) to develop a probabilistic tool that can provide general indication of contamination risk, along with sensitivity of the results with respect to the various basic sources of uncertainty, in a framework that can explicitly account for aquifer-related, source-related, and, in the case of reactive solutes, chemical-related parameter uncertainty. Spatial variability of aquifer properties is considered in Section 4.

3.1 Assessment of Groundwater Contamination

In order to assess the potential of groundwater contamination, the probability that a contaminant leaking from a waste source will exceed a threshold level at a well downgradient from the source is estimated, along with the sensitivity of this probability to the input random variables. The relevant parameters are assumed uncertain with prescribed probability distributions. These parameters can be grouped into the following three categories:

1. Aquifer-related parameters, such as:
    - hydraulic conductivity,
    - soil porosity,
    - soil bulk density,
    - fraction of organic carbon, and
    - longitudinal and transverse dispersivities.
2. Source-related parameters, which include:
    - source dimensions, and
    - source concentration.
3. Chemical-related parameters (in case of a reactive solute). For example, the organic carbon partitioning coefficient can be assumed uncertain. Furthermore, uncertainty in the reaction kinetics of the chemical can also be considered. For example if the biodegradation of the chemical under consideration is assumed to follow first-order kinetics, then first-order decay coefficient may be assumed uncertain.

3.2 Models Utilized

The uncertainty analysis of groundwater contaminant transport is developed by extending a deterministic semi-analytical contaminant transport model (Galya, 1987) to include the effect of parameter uncertainty, through linking it with the general purpose probabilistic analysis program PROBAN (Veritas Research, 1992b). A brief description of each model follows.

3.2.1 Horizontal Plane Source Model

The proposed methodology is tested using the Horizontal Plane Source model developed by (Galya, 1987), which is a three-dimensional, semi-analytical model that uses Green's function solutions, along with numerical integration to simulate uniform one-dimensional advective transport in the x-direction with three-dimensional dispersion in the x-, y-, and z-directions. It can incorporate retardation and first-order decay. The advection-dispersion equation of transport assuming a homogeneous and isotropic aquifer is given by

$$\frac{\partial C}{\partial t}+\frac{u}{R}\frac{\partial C}{\partial x}=\frac{D_x}{R}\frac{\partial^2 C}{\partial x^2}+\frac{D_y}{R}\frac{\partial^2 C}{\partial y^2}+\frac{D_z}{R}\frac{\partial^2 C}{\partial z^2}-\lambda C+\frac{M_s}{\theta} \tag{3.1}$$

where

C = concentration of contaminant [L^3/T]
u = seepage velocity in the x-direction [L/T]
t = time [T]
D_x = dispersion coefficient in x-direction [L^2/T]
  = $\alpha_x u$
α_x = dispersivity in x-direction [L]
D_y = dispersion coefficient in y-direction [L^2/T]
  = $\alpha_y u$
α_y = dispersivity in y-direction [L]
D_z = dispersion coefficient in z-direction [L^2/T]
  = $\alpha_z u$
α_x = dispersivity in z-direction [L]
M_s = mass source flux [M]
θ = porosity of soil matrix in aquifer
λ = first-order decay coefficient [T^{-1}]
R = retardation factor
  = $1+\rho_b K_d/\theta$
ρ_b = bulk density [M/L^3]
K_d = distribution coefficient [L^3/M]

Initial condition applied to solve the transport equation is given by

$$C=0 \quad \text{at} \quad t=0 \tag{3.2}$$

and the boundary conditions are given by

$$C=0 \quad \text{at} \quad y=\pm\infty \tag{3.3}$$

$$D_z\frac{\partial C}{\partial Z}=0 \quad \text{at} \quad z=0 \tag{3.4}$$

$$D_z\frac{\partial C}{\partial Z}=0 \quad \text{at} \quad z=H \tag{3.5}$$

$$C=0 \quad \text{at} \quad z=\infty \tag{3.6}$$

where H is the aquifer thickness. The three-dimensional analytical solution which gives the contaminant concentration at any point in space for an instantaneous release of a unit mass of contaminant is given by (Galya, 1987)

$$C=\frac{1}{\theta R}X_0(x,t)Y_0(y,t)Z_0(z,t)T(t) \tag{3.7}$$

where
T = degradation function
  = $\exp(-\lambda t)$ for first-order degradation and λ includes the effect of hydrolysis, biodegradation, and chemical reactions
X_0, Y_0 and Z_0 = Green's functions for the transport in the x-, y-, and z-directions, respectively.

Green's functions for a source extending from $-L/2$ to $L/2$ in the x-direction and from $-B/2$ to $B/2$ in the y-direction are given by Galya (1987) as:

$$X_0=\frac{1}{2L}\left[\text{erf}\frac{\left(\frac{L}{2}+x-x_s-\frac{ut}{R}\right)}{\sqrt{4D_x t/R}}+\text{erf}\frac{\left(\frac{L}{2}-x+x_s-\frac{ut}{R}\right)}{\sqrt{4D_x t/R}}\right] \tag{3.8}$$

where

L = width of source in x-direction
x = distance in x-direction to calculation point
x_s = distance in x-direction to center of source
erf = error function

and

$$Y_0 = \frac{1}{2B}\left[\mathrm{erf}\, \frac{\left(\frac{B}{2} + y - y_s\right)}{\sqrt{4D_y t/R}} + \mathrm{erf}\, \frac{\left(\frac{B}{2} - y + y_s\right)}{\sqrt{4D_y t/R}} \right]$$ (3.9)

where

B = length of source in y-direction
y = distance in y-direction to calculation point
y_s = distance in y-direction to center of source

For a source located at the top of an aquifer of infinite thickness:

$$Z_0 = \exp\left(-z^2/\left(4D_z t/R\right)\right)\big/\sqrt{\pi D_z t/R}$$ (3.10)

whereas for a source located at the top of an aquifer having a thickness H:

$$Z_0 = \frac{1}{H}\left(1 + 2\sum_{m=1}^{\infty}\exp\left(-\frac{m^2\pi^2 D_z t}{H^2 R}\right)\cos(m\pi z/H)\right)$$ (3.11)

Galya (1987) indicates that applying a convolution integral with respect to time provides for the concentration due to a continuous release at a rate $M(\tau)$ for any time, τ, following the beginning of release:

$$C = \frac{1}{\theta R}\int_0^{\tau} M(\tau)\, X_0(x, t-\tau)\, Y_0(y, t-\tau)\, Z_0(z, t-\tau)\, T(t-\tau)d\tau$$ (3.12)

where M = Mass released per unit time.

The aforementioned integration is carried out numerically, thus obtaining the concentration at any point downgradient from the source. Input to the model includes the seepage velocity, dispersivities in the x-, y-, and z-directions, soil porosity, aquifer thickness, first-order decay coefficient, organic carbon partitioning coefficient, soil bulk density, fraction of organic carbon, receptor location, along with the source location, dimensions, concentration and infiltration rate. The model can accommodate any number of sources with varying concentrations, and any number of receptor locations.

3.2.2 PROBAN

Physical parameter uncertainty is considered by linking the transport model to the general purpose probability analysis program PROBAN (Veritas Research, 1992b). PROBAN is a software package that is designed for sophisticated probabilistic analysis. It has a flexible input module, allowing for the definition of simple models as well as sophisticated models with complicated dependencies. It provides for a variety of methods aimed at different types of probability and distribution analyses, along with sensitivity measures. PROBAN comes equipped with a distribution library that contains more than twenty probability distributions. Thus the user can create any marginal probability distribution or joint density of the input random variables, by assigning the required distribution to the respective variables.

3.2.3 HPS-PROBAN Model

Figure 3.1 is a schematic presentation of the various elements involved in the combined HPS-PROBAN model. The probabilistic transport model can be applied as a "black box" without necessitating a great deal of knowledge of the reliability theory on the user's part. Input to the model include physical parameters uncertainty as well as deterministic parameters.

Physical Parameter Uncertainty — **Input Uncertainty Information** — **Probabilistic Screening Transport Model**

- aquifer–related
- source–related
- chemical–related

- joint multivariate probability density function
- mean, variance and correlation

- analytical transport model (HPS)
- probabilistic analysis program (PROBAN)

- assess groundwater contamination risk
- probablity of exceeding target concentration level
- limit–state function formulation
- relative "importance" of basic random variables
- design optimal site sampling
- assess data worth

Figure 3.1 Flow chart of the combined HPS-PROBAN analytical probabilistic screening model. (Reprinted from *Probabilistic screening tool for groundwater contamination assessment*, 1995, by M. M. Hamed, J. P. Conte, and P.B. Bedient with permission of Journal of Environmental Engineering, ASCE.)

Various levels of statistical information can be accommodated by the model. When only incomplete statistical information is available, the first two moments of each random variable are specified, without providing a specific probability distribution. If some, or all, of the random variables are correlated, this information can be readily incorporated into the model through correlation coefficients. When there is incomplete statistical information, only an "ad-hoc" estimate of the probability of failure can be obtained. On the other hand, if complete probability information is available, the input random variables are defined by their full joint density function.

The user is also prompted to formulate the limit-state function for the site-specific conditions, which identifies the performance criteria of the component being considered. It should be noted that the formulation is different in the case of continuous and instantaneous leaking sources, and differs depending on whether groundwater flow or contaminant transport is the primary focus of the study.

Once the limit-state function is formulated and the input variables are provided, the model applies the first- and second-order reliability methods to provide the user with the probability of failure at the receptor well, the reliability index characterizing the transport scenario, and the sensitivity of the reliability index (or the failure probability) to uncertainties in the basic random variables. The decision regarding the assessment of groundwater contamination risk can be made with the probabilistic outcome available. The sensitivity information can help the user assess the worth of available data and guide in future data collection protocols. Monte Carlo simulations of the failure probability, or

of the concentration at the receptor well, can be readily provided by the HPS-PROBAN model with minor modifications to the input file.

The interface between PROBAN and HPS is done using FORTRAN 77 user-defined subroutines, and the HPS-PROBAN is run on a SUN SPARCstation 2. In the FORM/SORM analysis, HPS is used at each iteration in the constrained optimization routine used to obtain the design point (as discussed in Section 2) to provide an estimate of the limit-state function for the current realization, x, of the vector of random variables, X. The search algorithm usually converges to a minimum in less than 20 iterations. To ensure that a global minimum is obtained, the user may choose to run the probabilistic model with different starting points, and check whether the algorithm converges to the same solution at each time.

3.3 Non-reactive Solute Transport

First, the methodology is demonstrated on a couple of cases of transport of a conservative (non-reactive) solute in groundwater. This means that the only mechanisms involved in the solute transport are advection and dispersion. The solute is assumed to undergo no chemical transformations, biological degradation, or sorption to the soil matrix. The source is assumed continuous. In the first of those two cases, a fewer number of random variables is considered. This will allow us to look into a number of parametric sensitivity analyses, and present them in a way that would be difficult with cases involving a larger number of random variables.

3.3.1 Limit-state Function Formulation

The problem of interest in this phase is to study the probability that the concentration of a given contaminant leaking continuously from a source exceeds a pre-determined target level at a downgradient water supply well during the simulation time of interest. Figure 3.2 shows a schematic of the case study setup. The formulation follows that of Cawlfield and Sitar (1988).

In the case of non-reactive solute, we look at the normalized target concentration at the receptor well, $(C(X)/C_0)$, where C_0 is the source concentration and $C(X)$ is the simulated concentration when parameter uncertainty is taken into account. Hence the limit-state function is formulated as follows:

$$g(X) = (C/C_0)_{target} - C(X)/C_0 \qquad (3.13)$$

where $(C/C_0)_{target}$ is the pre-specified normalized target concentration at the well.

Figure 3.2 Schematic of the case study setup. (Reprinted from *Probabilistic screening tool for groundwater contamination assessment*, 1995, by M. M. Hamed, J. P. Conte, and P.B. Bedient with permission of Journal of Environmental Engineering, ASCE.)

Component failure occurs when $g(\boldsymbol{x})$ (for a given realization $\boldsymbol{x}$, of the random variables) is less than zero; that is, when the normalized target concentration at the receptor well is exceeded. Note that this formulation is intended for a continuous source transport problem, in which case the concentration at the receptor well increases with time in a monotonic fashion. This implies that once the target concentration at the receptor well is exceeded (and *failure* occurs), the concentration at the well will always be greater than the target value as time continues to increase, and failure conditions will continue to prevail.

3.3.2 Inputs to the Case of Non-reactive Solute (Case 1)

The probability of failure at a receptor well that is 100 m downgradient from the source was studied, considering the seepage velocity, along with the dispersion characteristics of the aquifer as random variables. Input to the model includes deterministic parameters (Table 3.1) as well as random variables (Table 3.2). For the case of shifted-lognormally distributed variables, the mean, standard deviation, and the minimum values are given. Mean and standard deviation are given for the normally distributed variables.

Table 3.1   Deterministic Input Parameters for the Non-reactive Case (1)

Variable	Units	Value

horizontal dispersivity, α_y	m	0.2 of α_x
vertical dispersity, α_z	m	0.05 of α_x

SLN(mean, std. dev., lower limit): Shifted Lognormal N(mean, std. dev.): Normal

3.3.3 Results of the Case of Non-reactive Solute (Case 1)

Instead of performing the analysis for a single normalized target concentration, a set of such target concentrations was considered. In other words, the reliability problem is solved a number of times, varying the term $(C/C_0)_{target}$ that appears in Equation 3.13 at each time. Note that the probability distribution of the failure event under consideration can be obtained by varying the target concentration values and using the parametric sensitivity results with respect to limit-state function parameters. This gives a more flexible way of assessing the groundwater contamination risk at the receptor well for any selected target concentration value.

The analysis was done using both FORM and parabolic SORM as the probability analysis options. The results are shown in Figure 3.3. The decrease in failure probability as the target (C/C_0) increases is expected, since the probability of exceeding a high concentration value downgradient is usually less than that of exceeding a smaller value for a continuous source.

The deviation between FORM and SORM failure probabilities indicates the nonlinear nature of the limit-state function, and thus a second-order surface is expected to provide a better approximation of the failure surface at the design point in the standard normal space.

To generalize the analysis even more, the location of the receptor well was varied, in order to study the effect of both distance from the leaking source as well as the specified target concentration level (C/C_0) on the failure probability.
Figure 3.3 Probability of failure at a location 100 m downgradient from the leaking source.

Figure 3.4 illustrates the failure probability "surface" as a function of both the distance from the source and the normalized target concentration. Figure 3.5 shows horizontal "slices" in that surface, thus producing contours of equal failure probabilities, for the range of distances from source, and target concentration values of interest. The figures indicate that for a given target (C/C_0), the probability of failure decreases as the well distance increases, and that for a given well location, the probability of failure decreases with increasing the normalized target concentration. Although the results are qualitatively intuitive, the quantitative aspects could not have been obtained without the formal probabilistic computations described in the above formulation.

Various parametric studies can also be performed using the probabilistic program, to study the effect that the various distribution parameters of the input random variables have on the probabilistic outcome. An example is given below,
Figure 3.4 Failure probability surface at various well locations for different normalized target concentration levels.
Figure 3.5 Contours of equal failure probabilities for case 1.

where the mean value of the longitudinal dispersivity α_x is allowed to take on values in the range of 1.0 to 5.0 meters. The effect on the probability of failure at different downgradient locations is shown in Figure 3.6. The decrease in the probability of failure with the increase in the mean value of α_x is intuitive, since the higher the dispersivity in the x-direction, the higher the dispersivities in the y- and z-directions will become (because we considered α_y and α_z to be fully correlated to α_x). Therefore, the mass of contaminant will be dispersed on a larger volume, and the concentration at the well will decrease, thus reducing the probability of failure. Besides, the figure shows that the probability of failure decreases with distance from the source for the same value of mean longitudinal dispersivity. This is due to the fact that for larger distances from the leaking source, the spread of contaminant is greater than that at closer distances, and the probability of exceeding the designated normalized target concentration will be smaller.

Additional valuable information to the failure probability and the parametric sensitivity factors is provided by the *importance factors.* Those were explained in Section 2 and they indicate the relative importance of the uncertainty in each basic random variable.

Figure 3.7 shows the change in importance factors with changing the mean value of α_x along with the downgradient distance from the source. It is clear that in this case the probabilistic outcome is more sensitive to the uncertainty in the seepage velocity than the uncertainty in the dispersivity for the most part, and only when the mean value of the longitudinal dispersivity exceeds a value of about 4.0 m, and for distances greater than about 90.0 m from the source, the sensitivity to the uncertainty in the longitudinal dispersivity becomes significant. This result shows that for receptor locations away from the source, the effect of dispersion becomes noticeable, since at large distances from the source larger dispersivities would cause the contaminant to spread over a larger volume, reducing the concentration at the receptor location, hence decreasing the probability of failure. The results of the sensitivity analysis in this case are not intended to be general and will vary with the choice of problem configuration, prescribed probability distributions, and other pertinent factors. However, the methodology is applicable to all cases.

To study the effect of source strength, further analysis was performed considering the source initial concentration (C_0) to be a random variable, having a normal distribution, with a mean of 1.0 mg/L, and a coefficient of variation of 0.3, and still assuming the seepage velocity along with the longitudinal, transverse horizontal and vertical dispersivities to be random variables with the distributions given in Table 3.2. The analysis was carried out by estimating the importance factors of these random variables, for a range of normalized target concentrations, and for
Figure 3.6 The effect of the mean value of the longitudinal dispersivity α_x on the probability of failure at different downgradient locations.
Figure 3.7 The effect of the mean value of the longitudinal dispersivity α_x on the importance factors (upper surface represents seepage velocity, lower one represents dispersivity).

varying receptor well locations downgradient from the source. In this case, by target (C/C_0) we mean the concentration normalized with respect to the mean source concentration (which is equal to 1.0 mg/L).

Results are shown as a three-dimensional plot in Figure 3.8, indicating the paramount importance that the source strength uncertainty has on the reliability measure. It is clear from this plot that, for the range of distances studied, the source strength has such a significant impact on the reliability estimates, regardless of the location of the receptor well from the source. This is not the case for the importance of the seepage velocity and dispersivity, which are affected by the distance from the source. A vertical section of this figure at a distance of 60 m downgradient from the source is shown in Figure 3.9, which shows the greater sensitivity of the reliability index to the source strength uncertainties than to the uncertainty of the dispersivity or seepage velocity.

3.3.4 Inputs to the Case of Non-reactive Solute (Case 2)

The deterministic parameters to this case study are listed in Table 3.3. The probability of failure at a receptor well downgradient from the waste source is studied. The well is assumed to be screened from the water table to a depth of 2.0 m below the water table, hence the observation point is taken to be 1.0 m below the water table.

Input random variables to the case study are categorized into aquifer-related and source-related parameters and are listed in Table 3.4. Aquifer-related parameters include seepage velocity, dispersivities in the x-, y-, and z-directions, and soil porosity. Source-related parameters include the source dimensions parallel to the x- and y-axes. Probability density functions and relevant parameters for the aquifer-related parameters were obtained from the nationwide survey conducted by the EPA in 1988 (U.S. EPA, 1988), along with the 400-site survey conducted by Newell et al. (1990). The selection of the uniform probability distribution for the source dimensions is arbitrary. Since there is usually limited information on the extent of the source area, the uniform distribution, which implies equal likelihood of occurrence, is believed to conveniently describe the level of uncertainty related to the source dimensions. The basic random variables are assumed to be mutually statistically independent.

3.3.5 Results of the Case of Non-reactive Solute (Case 2)

The probability of failure at receptor wells at distances of 200 m and 400 m downgradient for a range of normalized target concentration levels are shown in Figure 3.10. First-order and curvature-fitted second-order reliability methods were used. The decrease in failure probability with target concentration increase is intuitive, since it is less probable for the solute concentration to exceed a high value at the downgradient well than a smaller value for a continuous source.

FORM and SORM failure probabilities were found to be in good agreement for low target concentration values (and hence for higher failure probabilities). However, FORM and SORM results depart from each other for large target concentration values (and lower failure probabilities), which indicates the appreciable non-linearity of the limit-state surface at the design point. In this case, a second-order method is expected to provide a better approximation of the failure surface at the design point since it accounts for the principal curvature of the limit-state surface in the standard normal space.

Figure 3.11 illustrates the effect of changing the normalized target concentration levels at the receptor well on the FORM and SORM reliability index for the 200 m and 400 m cases. Since there is a monotonic one-to-one relationship between the probability of failure and reliability index, the same trend of agreement at low normalized target concentration levels and discrepancy at large normalized target concentration levels is observed for the FORM and SORM results. The reliability index is a measure of the component reliability, such that it increases for decreasing probability of failure.

The discrepancy between the FORM and SORM results are further investigated by estimating the percent difference between the results for varying normalized target concentrations and distances from the source. The absolute value of the percent difference was estimated as follows:

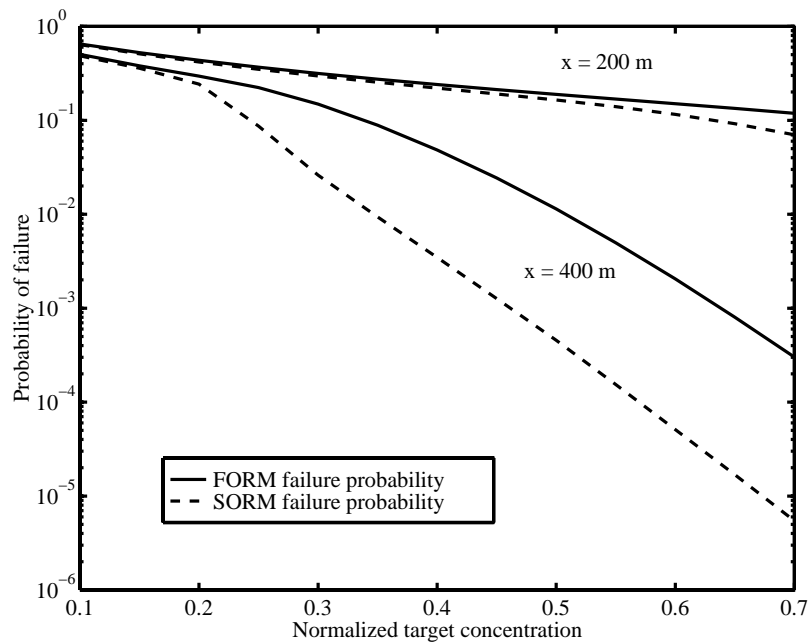

Figure 3.10 Effect of normalized target concentration levels on the probability of failure for the non-reactive case 2. (Reprinted from *Probabilistic screening tool for groundwater contamination assessment,* 1995, by M. M. Hamed, J. P. Conte, and P.B. Bedient with permission of Journal of Environmental Engineering, ASCE.)

Figure 3.11 Effect of normalized target concentration levels on the reliability index for the non-reactive case 2. (Reprinted from *Probabilistic screening tool for groundwater contamination assessment,* 1995, by M. M. Hamed, J. P. Conte, and P.B. Bedient with permission of Journal of Environmental Engineering, ASCE.)

$$\text{absolute percent difference} = \text{absolute}\left(\frac{P_F^{FORM} - P_F^{SORM}}{P_F^{FORM}}\right) \times 100 \qquad (3.14)$$

This is shown in Figure 3.12. FORM and SORM failure probabilities were found to be in good agreement for low target concentration values, or for high target concentration values at closer distances to the source. In other words, the agreement between the FORM and SORM results is good for cases with high probability of failures (above 10^{-1} for this particular case study and for the prescribed probability distributions). FORM and SORM results depart significantly from each other, however, for large target concentration values, or for small target concentrations at larger distances from the source, which indicates the appreciable non-linearity of the limit-state surface at the design point, in which case the use of SORM is warranted.

The previous discussion draws attention to an important issue regarding the choice of SORM versus FORM as the reliability analysis option. In many practical situations, FORM and SORM results would be in good agreement, provided that the limit-state surface at the design point in the standard normal space is nearly flat. On the other hand, when the limit-state function contains highly non-linear terms, or when the input random variables have an accentuated non-normal character, SORM can produce more accurate results than FORM. However, it should be recognized that SORM requires more computational effort than FORM. As discussed, in component reliability, the run time required for a FORM analysis grows proportionally with the problem dimensionality, n, whereas the additional computational effort needed for a SORM analysis grows with $n^2/2$. Consequently, the selection of the reliability method should be based on problem dimensionality, available computer resources, and the required level of accuracy. In other words, one should always conduct a careful trade-off analysis between computational and accuracy requirements. In this case study, the CPU times (user + system times) for FORM and SORM were on the order of one minute and two and a half minutes, respectively.

The change of the importance factors with changing normalized target concentration levels is shown in Figure 3.13. It is evident that over the range of target concentrations selected, and for the probability distributions prescribed for this case study, the probability of failure at the receptor well is most sensitive to the basic variabilities in the seepage velocity. Sensitivities with respect to z-dispersivity and source length, L_x, come next. The importance factors for the remaining variables were less than 1.0% and were not plotted. Hence, although the impact of seepage velocity on the probabilistic outcome is evident, the significance of the source-related uncertainty should also be recognized. When
Figure 3.12 Percent difference between FORM and SORM failure probabilities results for the non-reactive case 2. correlation between some of the input random variables was included, the resulting probability of failure was within about 3% of the uncorrelated case.

3.4 Reactive Solute Transport

As an example of transport of a reactive solute in the subsurface, the proposed methodology is applied to the case of transport of *o*-xylene. A continuous leaking source is also used in this case. The concentration at a well 100.0 m downgradient, and 1.0 m off the centerline (*x*-axis) is studied.

3.4.1 Limit-state Function Formulation

In this case study, we look at actual (as opposed to normalized) *o*-xylene concentration at the receptor well, resulting from the continuous leaking source. Note that *o*-xylene undergoes adsorption to the soil matrix and biodegradation in addition to advection and dispersion, hence the actual concentration of *o*-xylene at the receptor well will be much smaller than that of a similar leak of a non-reactive solute. The limit-state function for this case is formulated as follows:

$$g(X) = C_{target} - C(X) \qquad (3.15)$$

where C_{target} is the non-normalized *o*-xylene target concentration at the well.

3.4.2 Inputs to the Case of Reactive Solute

The deterministic parameters used in the case study are listed in Table 3.5 and the input random variables to the model are listed in Table 3.6.

The input random variables are classified into three categories: aquifer-related, source-related, and chemical-related parameters. Basic random variables are assumed mutually statistically independent.

First-order kinetics have been extensively used to describe processes like natural biodegradation, chemical reactions, and radioactive decay. For the purpose of this work, it is assumed that o-xylene undergoes natural anaerobic biodegradation by indigenous microorganisms following first-order kinetics. Due to changing depths of groundwater elevation and fluctuation in levels of nutrients and electron acceptors, there is uncertainty in the value of the first-order decay coefficient for the contaminant. This is taken into account by assuming the decay coefficient to be random. The choice of the range of equally likely values of the first-order decay coefficient used in this work takes into account actual rates for natural biodegradation reported by Wilson et al. (1993) for o-xylene. As for the organic carbon partition coefficient, K_{oc}, the range of values were obtained from the listed values given by Fetter (1993).

3.4.3 Results of the Case of Reactive Solute

The effect of changing the target concentration levels at the receptor well location on the probability of failure is illustrated in Figure 3.14. Both FORM and SORM (curvature-fitted) were used for the component reliability analysis. As was observed and explained in the non-reactive case there is a similar trend in decreasing the failure probability with increasing target concentration. For this application, FORM and SORM results agree reasonably well for the whole range. A similar trend was also noted in good agreement between FORM and SORM reliability index for the whole range of target concentration levels. This is shown in Figure 3.15. The effect of correlation between some of the input random variables in this case was similar to that of the non-reactive case, and the resulting difference in the probability of failure was within about 5% of the uncorrelated case.

The importance factors for a range of o-xylene target concentration levels is shown in Figure 3.16. It is clear that over the range of target concentration selected, and for the probability distributions prescribed for this case study, the probability of failure at the receptor well is most sensitive to the basic uncertainty in the seepage velocity, the first-order decay coefficient, the organic carbon partition coefficient, and, to a lesser extent, the source length L_x. Therefore, although the impact of seepage velocity on the probabilistic outcome is pronounced, the significance of the chemical-related and source-related uncertainty should be recognized and failure to account for these uncertainties would cast shadows of doubt over the risk assessment results. The importance factors for other variables were negligible (below 1.0%) hence they were not plotted. The apparent oscillation in the results are spurious numerical artifacts due to the fact that the level of accuracy of the reliability algorithm varies slightly with the level of target concentration levels resulting from the non-linear nature of the limit-state surface at the design point in the standard normal space. The trend of the true behavior of the solution, however, remains clear.
Figure 3.14 Effect of o-xylene target concentration levels on the probability of failure. (Reprinted from *Probabilistic screening tool for groundwater contamination assessment,* 1995, by M. M. Hamed, J. P. Conte, and P.B. Bedient with permission of Journal of Environmental Engineering, ASCE.)
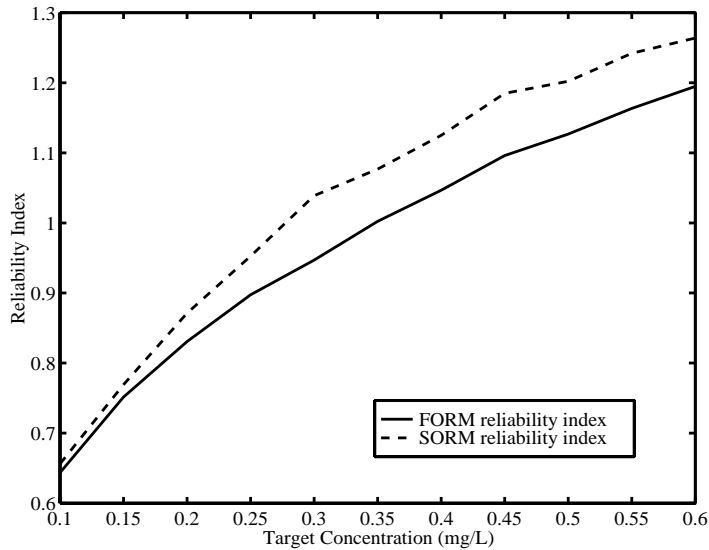

Figure 3.15 Effect of *o*-xylene target concentration levels on the reliability index.
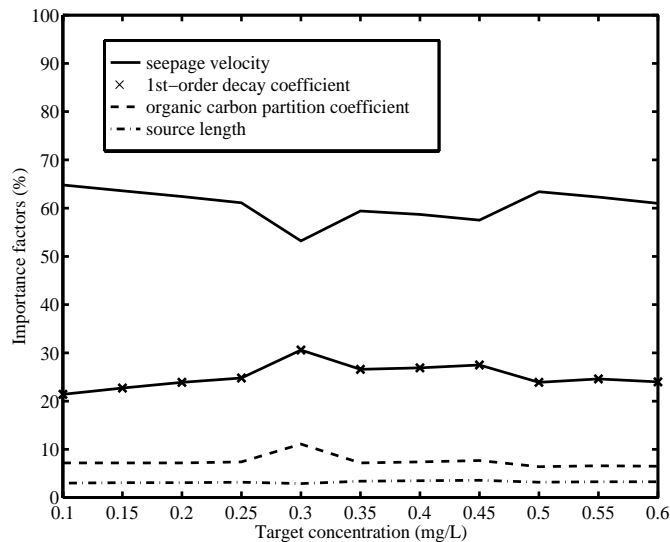

Figure 3.16 Effect of *o*-xylene target concentration on importance factors. (Reprinted from *Probabilistic screening tool for groundwater contamination assessment,* 1995, by M. M. Hamed, J. P. Conte, and P.B. Bedient with permission of Journal of Environmental Engineering, ASCE.)

In Figure 3.17, the failure probabilities obtained by FORM, curvature-fitted SORM, and the classic Monte Carlo simulation (MCS) are plotted for the well location described before, and for an *o*-xylene target concentration of 0.75 mg/L. The MCS and SORM results seem to be in good agreement. FORM results, however, depart from the "true" solution predicted by the ensemble mean of the large number of Monte Carlo simulations . It should be emphasized that 10,000 Monte Carlo simulations were required to get a reliable estimate of the probability of failure (i.e., a coefficient of variation of the estimate within the permissible limits, 0.02 in this case). FORM and SORM results were obtained in less than 20 iterations, and the required CPU time on a SUN SPARCstation 2 was on the order of
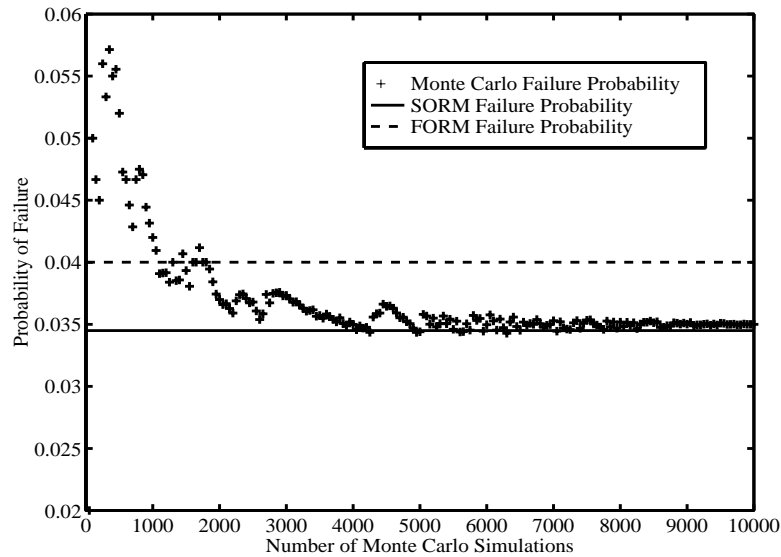

Figure 3.17 Comparison of FORM, SORM, and MCS estimate of the probability of failure for the o-xylene case study. (Reprinted from *Probabilistic screening tool for groundwater contamination assessment,* 1995, by M. M. Hamed, J. P. Conte, and P.B. Bedient with permission of Journal of Environmental Engineering, ASCE.)

two minutes and three minutes, respectively. The 10,000 Monte Carlo results, on the other hand, were obtained in about 60 minutes of CPU time on the same machine.

This clearly illustrates the power and computational efficiency of SORM through which the results can be obtained at a small fraction of the computational cost required for the classic Monte Carlo simulation results. The figure also indicates the inaccuracy of the FORM results in this case. Nevertheless, FORM results were obtained in a very short run time, hence it could be used to provide a first estimate of the failure probability. Alternatively, the FORM design point can then be used as the initial guess for the optimization routine used in SORM runs. The asymptotic convergence of the classic MCS is evident by the way the MCS estimate converges to the failure probability which is predicted by SORM.

Section 4

Numerical Probabilistic Groundwater Modeling

4.1 General

In this Section, we develop a probabilistic transport model based on a numerical groundwater contaminant transport code. The impetus for using the numerical transport code in this phase can be summarized in the following:

1. Numerical models allow for the consideration of more realistic problems, with complex boundary conditions and geometry.
2. They allow for the consideration of the spatial variability of the aquifer properties. In this case, the formulation is done in terms of *spatial random fields* as opposed to *random variables*. Spatial random fields describe variability in the parameters in addition to correlation structure between any two points in space.
3. It is possible, using numerical models, to examine a number of critical issues in modeling groundwater flow and transport problems. Examples include:
   (a) the effect of the discretization level of the solution domain on the accuracy of the results.
   (b) the effect of the ratio of the discretization scale to the integral scale of the aquifer on the solution accuracy.
   (c) the effect of material heterogeneity on the reliability of the groundwater system considered.
4. Numerical models allow for the analysis of problems where the aquifer is stressed by pumping and/or injection.

4.2 Selection of Numerical Transport Model

The selection of the numerical contaminant transport model, along with the reliability model should be carefully done in order to assure robustness and efficiency of the resulting probabilistic transport algorithm. The transport model chosen for this phase of the work is FLOTRAN developed by Clint Dawson at the Computational and Applied Mathematics Department (CAAM) at Rice University. The code is written in FORTRAN 77. The underlying theory of the solution is explained in Bell et al. (1988), and Dawson (1990, 1991, and 1993).

FLOTRAN is a recently developed finite element simulation tool for modeling unsaturated/saturated flow and contaminant transport in porous media. The code solves Richard's equation for flow combined with a system of advection-diffusion-reaction equations describing contaminant transport. It assumes a three-dimensional, logically rectangular domain, but allows for fairly general geometries by using smooth mappings between the logically rectangular domain and a rectangular computational domain. Therefore, we describe the algorithms used in the method in the context of brick-shaped elements.

FLOTRAN solves the governing flow equation using the mixed finite element method for spatial discretization and fully implicit time discretization. The mixed finite element method applied to flow equations has been described in numerous papers. The version employed herein is defined in the context of linear elliptic equations in Arbogast et al. (1998). In this method, hydraulic head and Darcy velocity are simultaneously approximated, with hydraulic head approximated using constants in each element. Numerical integration is used to reduce the finite element equations to a cell-centered finite difference scheme in head variables only. The implicit time discretization leads to a system of nonlinear finite difference equations. These equations are solved using a damped Newton method with linesearch backtracking to guarantee convergence from bad starting guesses (Dennis and Schnabel, 1983). The Jacobian equations which arise at each Newton step are solved using a preconditioned orthomin iterative procedure.

The Darcy velocities and moisture content computed from the flow are used in the system of transport equations for each contaminant species. These equations model the advection, diffusion, and chemical reactions of species in the system. Each equation is of the form

$$\frac{\partial \theta c}{\partial t} + \nabla \cdot (\mathbf{v}c - \mathbf{D}\nabla c) = g \tag{4.1}$$

where θ is moisture content, c is the contaminant concentration, $\mathbf{v}$ is the Darcy velocity, $\mathbf{D}$ is the diffusion/dispersion tensor, and g incorporates sources and sinks through wells and chemical reactions; g may be a function of several species in the system.

Equation (4.1) is solved numerically using a time-splitting approach. Given an approximation $C(t)$ to c at some time t, we advance to time $t + \delta t$ by advecting and diffusing $C(t)$, which gives an intermediate solution $\overline{C}(t + \delta t)$, then incorporating reactions using $\overline{C}(t + \delta t)$ as initial conditions. This ultimately gives $C(t + \delta t) \approx c(t + \delta t)$. This type of splitting has been analyzed in Wheeler and Dawson (1988), and has been adopted and modified by a number of other researchers, see, for example, Valocchi and Malstead (1992). The advantages of this approach are that the advection and diffusion of each component can be performed separately (and in parallel if desired), advection-diffusion and reactions can be modeled using appropriately-sized time steps, and different reaction models can be easily incorporated.

Advection and diffusion/dispersion are modeled using the Godunov-Mixed Method, developed and analyzed by Dawson and described in Dawson (1991, 1993). In this scheme a second-order accurate Godunov procedure (Bell et al., 1988) is used to approximate the advective flux $\mathbf{v}c$, and a mixed finite element method, similar to that used for the flow equation, is used to incorporate diffusion/dispersion. The resulting scheme is a cell-centered finite difference method for contaminant concentrations. The advective flux is incorporated explicitly in time, while the diffusion/dispersion step is implicit. By modeling advection explicitly and diffusion implicitly, a symmetric, diagonally dominant and positive definite system of equations is obtained at each time-step. This system is easily solved using Jacobi preconditioned conjugate gradient. Although contaminant concentrations are approximated by constants in each cell, the Godunov-Mixed Method developed is second-order accurate in space and first-order accurate in time at the center of each element. This has been observed both theoretically and computationally.

When nonlinear reactions are present, with reaction terms depending on a number of species, a system of ordinary differential equations must be solved after each component has been transported. This system is approximated using a second-order Runge-Kutta procedure, however, more sophisticated techniques may also easily be incorporated.

4.3 Selection of Reliability Shell

The general purpose reliability shell CALREL (Liu et al., 1989) is linked to the finite element program FLOTRAN. Experience with the analytical phase of the research showed that although PROBAN is a sophisticated and versatile probabilistic analysis program, it is better suited for analytical transport problems. This is mainly due to the extensive amount of preparation and interface programs that the user has to provide. Experience with CALREL, on the other hand, has established the advantages of using it with a numerical scheme, since it lends itself more easily to interface with numerical models with large numbers of input random variables.

CALREL is a general purpose reliability analysis shell that is designed to compute probability integrals as well as the sensitivities of estimates of the probability of failure with respect to deterministic parameters defining the probability distribution or the limit-state function. CALREL is modularized into a set of routines to perform:

1. First-order reliability analysis (FORM),
2. Second-order reliability analysis (SORM),
3. First-order sensitivity analysis,
4. First-order bounds for series systems,
5. Monte Carlo simulation, and
6. Directional simulation.

Input to the CALREL shell includes:

1. An analysis flag to determine whether component or system reliability is used.
2. The choice of the optimization method used in determining the design point, including:
   (a) HL-RF method,
   (b) modified HL-RF method,
   (c) gradient projection method, and
   (d) sequential quadratic programming method.
3. The statistical data for the random variables, this in turn includes:
   (a) Whether the variables are correlated or independent,

(b) Whether the variables are described by their marginal distributions and correlation matrix, or by conditional and marginal distributions and correlation matrix,

(c) The probability distribution of each random variable, and

(d) Deterministic parameters used for defining the limit-state function.

4. Type of reliability or simulation analysis to be performed.

4.4 FLOTRAN-CALREL Interface

Linking CALREL and FLOTRAN is done through the use of three user provided routines. The first routine, UGFUN defines the limit state function(s). In some instances, the user may choose to provide analytical derivatives of the limit-state function(s) with respect to the basic random variables. In that case, these analytical derivatives are coded in the second routine, UDGX. The third routine, UDD is used to provide for user specified probability distributions that are not available in the CALREL distribution library. However, since the random variables considered here follow either normal, lognormal, or uniform distributions, which are already available in the CALREL library, the UDD routine is not used in this work.

The interface between CALREL and FLOTRAN is done by considering the numerical transport code as a subroutine that is called using the UGFUN subroutine of CALREL. The combined model is used to calculate the probability of exceeding a certain target concentration, at the location and time specified by the user. By having a range of target concentration values, a cumulative distribution function (CDF) of the failure probability can be plotted, which shows the probability of having a concentration that is less than or equal to the corresponding target concentration. Using the finite difference method, one can derive the probability density function (PDF) by differentiating the CDF for the same range of target concentration values. An alternative way of deriving the PDF is by plotting the sensitivity values of the probability of failure with respect to the deterministic parameter (which is the target concentration in this case) with an opposite sign, since this is equivalent to the slope of the CDF at that value of the target concentration.

At each iteration in the process of determining the design point, UGFUN calls FLOTRAN to evaluate the limit-state function $g(x)$ and its gradient for a given realization of the discretized spatial random field x. The gradient which is required by the nonlinear optimization scheme is approximated using the central finite difference method. Thus, the ith element of the gradient matrix is approximated by

$$\frac{\partial g(X)}{\partial x_i} \approx \frac{g(x_i + \Delta x_i) - g(x_i - \Delta x_i)}{2\Delta x_i} \tag{4.2}$$

in which the step size Δx_i is chosen as a small fraction of the standard deviation of each random variable x_i. The combined FLOTRAN-CALREL code provides the probability of failure, reliability index, and sensitivity information.

Figure 4.1 illustrates the steps involved in this phase. The general layout of the flow chart is essentially of the same structure as the HPS-PROBAN flow chart, except for the step where spatial random fields are discretized. This is explained in the following sections.

4.5 Spatial Random Fields

In the following numerical probabilistic analyses, the hydraulic conductivity is modeled as a spatial random field, $w(s)$. It is assumed that the statistical information available on the aquifer property consists of pointwise (or marginal) probability distribution, $F_W(w)$, and the spatial correlation coefficient function, $\rho_{ww}(s_1, s_2)$ (i.e , second-order joint moments). Thus, it is a state of incomplete probability information which is made complete by assuming that the transformed random field, $V(s) = \Phi^{-1}[F_W w(s)]$, is Gaussian with zero mean, unit variance, and spatial correlation.

This probabilistic model is the random field version of the Nataf model defined in Section 2 for multiple random variables. The spatial correlation structure of the hydraulic conductivity is considered to be of the exponential type

$$\rho_{ww}(h) = \exp\left(\frac{-|h|}{\lambda}\right) \tag{4.3}$$

where $|h| = ||s_1, s_2||$ is the lag (separation) distance, and λ denotes the correlation length. This formulation assumes statistical isotropy, i.e., the correlation coefficient function depends only on the distance between spatial
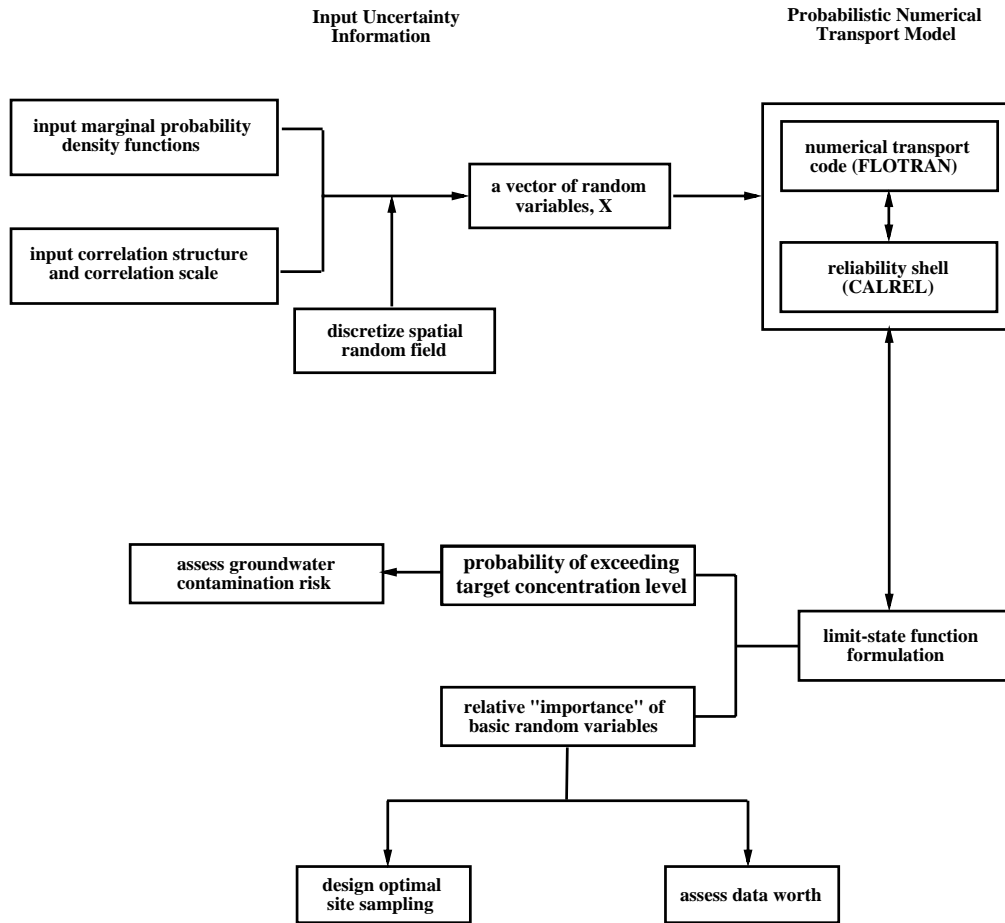

Figure 4.1 Flow chart of the numerical probabilistic transport model. (Reprinted from *Probabilistic modeling of aquifer heterogeneity using reliability methods,* 1996, by M. M. Hamed, P. B. Bedient, and C. N. Dawson, with permission of Advances in Water Resources.)

locations and is independent of direction. The correlation length is a measure of the rate of random fluctuations of a random field. It corresponds to the distance over which the correlation coefficient drops from 1 to e^{-1}=0.368. The exponential correlation function is used here since it has been shown to adequately describe the spatial correlation of the log-conductivity data (Bakr et al., 1978; Jang et al., 1994).

To perform a finite element reliability analysis of a system, it is required to discretize the spatial random field considered. This means that the spatial random field will be represented by an equivalent set of random variables. The random field discretization method employed in this study is the midpoint discretization method. Here, the random field values are defined at a finite set of discrete points, which corresponds to the midpoint (or centroid) of each finite element. Then the random field is represented in terms of a vector of random variables, X, the elements of which are correlated (Der Kiureghian and Ke, 1988). The correlation coefficient matrix is obtained directly from the correlation coefficient function $\rho_{ww}(h)$ and the separation distances between the centroids of the finite element.

Other types of correlation functions used in groundwater flow and transport problems are described by Cawlfield and Sitar (1987). Although only one correlation function is considered in this work, other types of correlation structure are provided for the sake of completeness. The forms are given for statistically isotropic functions:

- The linear correlation function is given by

40

$$\rho_{ww}(h) = \begin{cases} 1 - \frac{|h|}{\lambda} & \text{for } |h| \leq \lambda \\ 0 & \text{for } |h| > \lambda \end{cases} \tag{4.4}$$

- The squared exponential autocorrelation function is of the form

$$\rho_{ww}(h) = \exp\left(-\frac{|h|}{\lambda}\right)^2 \tag{4.5}$$

- The second-order autoregressive correlation function, on the other hand, is

$$\rho_{ww}(h) = \left(1 + \frac{|h|}{\lambda}\right)\exp\left(\frac{-|h|}{\lambda}\right) \tag{4.6}$$

- The spherical correlation function is given by

$$\rho_{ww}(h) = \begin{cases} 1 - \frac{3}{2}\left(\frac{|h|}{\lambda}\right) + \frac{1}{2}\left(\frac{|h|}{\lambda}\right)^3 & \text{for } |h| \leq \lambda \\ 0 & \text{for } |h| > \lambda \end{cases} \tag{4.7}$$

4.6 Applications

In Section 3, we presented the application of FORM and SORM to simple analytical probabilistic groundwater models. The developed models allowed for the assessment of the extent of groundwater contamination from a continuous leaking source at the screening level, accounting for aquifer-, chemical-, and source-related parameter uncertainty. Reliability methods were found to be very efficient in these types of analyses.

Jang et al. (1994) applied FORM and SORM methods to probabilistically model contaminant transport in one- and two-dimensions. They applied their code to estimate the probability of exceeding target concentrations at specific points, taking into account the spatial random variability of the input parameters, along with their spatial correlation. They concluded that the probability of failure increases as the correlation scale increases and approaches that obtained using the analytical transport model, which represents the transport in a perfectly correlated medium. The sensitivity analysis showed that the solution is most sensitive to hydraulic conductivity near both the source and target regions. They also found that the second-order reliability method, SORM, can handle large variance of the input parameters; something which is not possible with many of the current available techniques.

The work presented here extends the work in the sense that the formulation is similar, but more emphasis is given to issues like the analysis of failure at several wells in the aquifer, the use of reliability methods in plume containment and remediation, and the effect of the presence of a lower conductivity lens on the estimated reliability.

4.6.1 Symmetric and Asymmetric Target Wells

The limit-state function is given by

$$g(X) = C_{target} - C(X) \tag{4.8}$$

where C_{target} is the target concentration at the well and $C(X)$ is the simulated concentration taking into account the effect of parameters uncertainty. Figure 4.2 illustrates the case study setup. A non-reactive chemical leaking from the waste source is carried downgradient due to advection and dispersion to downgradient observation points, located symmetrically and asymmetrically as shown. The study area is 66.0 m by 42.0 m. The domain is divided into 11×7 grid blocks. Input parameters used in this case study are listed in Table 4.1.

The hydraulic conductivity is assumed to follow a lognormal distribution, with a mean of 5.0×10^{-3} cm/sec and a coefficient of variation of 1.0. The spatial correlation structure is assumed to follow an exponential pattern, with a correlation length of 18 m. Left and right constant head boundaries are set so that the resulting hydraulic gradient is 0.01.

The midpoint method is used to discretize the spatial random field into random variables. The latter are essentially the grid block hydraulic conductivities. Therefore, the number of random variables to be considered is 11×7=77. The target concentration level is taken to be 2.0 mg/L.

The design point, which is the realization of hydraulic conductivity at the most likely failure scenario at the observation well is shown for the symmetric observation well in Figure 4.3(a). It is clear that the grid block hydraulic

conductivities at the design point attain their maximum along the path lines connecting the source to the observation point.

Gamma sensitivities are shown in Figure 4.3(b) for the symmetric observation well. These show the scaled and normalized sensitivities of the reliability index with respect to equally likely changes in grid block hydraulic conductivities at the design point. Sensitivities are higher with respect to the hydraulic conductivity of the grid blocks at the source, the observation well, and along the streamlines connecting the two. Symmetry of the design point and sensitivities for the symmetric case are intuitive.

The design point and gamma sensitivities for the asymmetric observation well are shown in Figure 4.4(a) and Figure 4.4(b), respectively. In this case, the hydraulic conductivity at the design point is also at its maximum along the contaminant travel path. As for the gamma sensitivities, these are higher at the source, observation well, and along the

connecting region. Since the observation well is asymmetric with the source, the design point and gamma sensitivities are also asymmetric.

Sensitivity information is very useful in designing future sampling at the site, in the sense that samples should be collected from spatial locations where the sensitivity of the probabilistic event is the highest. This will help reduce the uncertainty regarding the probability of exceeding the pre-determined concentration levels at the target observation well.

Note that hydraulic conductivities at the design point in the asymmetric case are higher than that for the symmetric case. This is because in the symmetric case, the target concentration at the observation well is closer to the mean concentration. The mean contaminant concentration at the asymmetric well is 0.17 mg/L, as opposed to 1.93 mg/L for the symmetric well. Therefore, in order for the contaminant concentration at the well to exceed the target level of 2.0 mg/L, hydraulic conductivities have to be considerably higher than the mean. This is shown in Figure 4.4(a). The sign of the gamma sensitivities indicates whether the relationship between the reliability index and an increase in the design point is of direct or inverse proportionality. The previous findings are consistent with that of Jang et al. (1994).

Other valuable information that CALREL provides includes the delta parametric sensitivity information. Recall that the delta sensitivities are the scaled and normalized change in the reliability index due to change in the mean values of the random variables:

$$\delta_i = \left\{ \sigma_i \frac{\partial \beta}{\partial \mu_i} \right\} \tag{4.9}$$

where μ_i and σ_i are the mean and standard deviation of the basic random variable X_i, respectively.

Figure 4.3(c) shows the delta sensitivities for the symmetric case. Negative sensitivities along the contaminant travel path indicate a decrease in the reliability index as the mean value of the hydraulic conductivity in this region increases. This result is intuitive. An increase in the hydraulic conductivity in the grid blocks that exhibit negative delta sensitivity will cause more contaminant to reach the target observation well within the specified simulation time. Therefore, the probability of exceeding the target concentration level will increase, and the reliability index will decrease. The reverse is also true. Delta sensitivities for the asymmetric observation well are shown in Figure 4.4(c). The same discussion applies to this case.

Table 4.2 presents a comparison between FORM, SORM and Monte Carlo simulation results for the symmetric observation well for target concentration values of 2.0 and 5.0 mg/L. The stopping criterion for the Monte Carlo simulation method was a coefficient of variation of 5% of the simulated probability of failure. The failure probability at 2.0 mg/L is greater than that at 5.0 mg/L, as expected. This is due to the fact that there is a higher probability of exceeding a lower target concentration than a greater target concentration at a given point. Note also the inverse relationship between P_F and β. Since the reliability index is a measure of the reliability of the system, then the higher the failure probability, the lower the reliability index, and vice versa. This is shown in the Table.

The comparison shows that SORM results better match those of Monte Carlo simulation method than FORM results. FORM results, however, were obtained with a much less computational effort. The Monte Carlo simulation method

[§]   *on a SUN SPARCstation 2*
[†]   *Improved Breitung*

required a greater number of simulations as the failure probability decreases, as expected. This trend continues as the failure event departs from the bulk of the distribution, where an exceedingly larger number of simulations are required. This illustrates the computational burden one might expect to encounter when using the Monte Carlo simulation method for simulating very small probability events.

The effect of correlation scale, λ, on the probability of failure is shown in Figure 4.5 for the case where target concentration is 2.0 mg/L. Correlation scales ranging from 5 to 30 meters were studied, and the effect on the FORM probability of failure is reported. The figure shows that the probability of exceeding the target concentration increases as the correlation scale increases. Ideally, the probability of failure would approach that obtained using the analytical model, where the correlation scale approaches the problem domain length.

4.6.2 Effect of Material Heterogeneity

The presence of regions with hydraulic conductivities that are orders of magnitude lower than the prevailing formation is of prime importance in the analysis of transport through natural porous formations. Many sites exhibit such localized lenses of a much different permeability characteristics than the predominant aquifer material.

In the following case studies, hydraulic conductivity is assumed to follow a lognormal distribution. The mean value changes from one region to the other in the same case study, as well as from one case study to the next. Nevertheless, the coefficient of variation of the distribution is maintained at 1.0. The cases are numbered MH-1 and MH-2, where the notation MH stands for "Material Heterogeneity." It should be emphasized that in these case studies the location and extent of the macro-heterogeneity are assumed to be known. Although this information may not be available with certainty at many field sites, the modeling exercise is useful in illustrating the importance of gamma sensitivities for the probabilistic modeling of contaminant transport in the subsurface.

4.6.2.1 Case MH-1

First, we look at the effect of the presence of a block of lower hydraulic conductivity. Table 4.1 lists input data for the case study. Figure 4.6 shows this case study, where a region of 15 grid blocks is assumed to exist with a mean hydraulic conductivity of 5×10^{-4} cm/sec, which is an order of magnitude less than that of the remaining grid blocks (with a mean hydraulic conductivity of 5×10^{-3} cm/sec).

The probability of exceeding a target concentration of 5×10^{-4} mg/L at the target node is studied. The reason for choosing such a low target concentration is the fact that the average concentration when the low conductivity region is present is much less than the average concentration without it. In fact, the mean concentration at the target node is 2.45×10^{-4} mg/L. Hence, it is more convenient to assign a target concentration in this case that is of the same order of magnitude as the mean. The FORM probability of failure was calculated to be 0.2237, with a reliability index of 0.76. The design point, gamma, and delta sensitivities are shown in Figures 4.7, 4.8, and 4.9, respectively.
Figure 4.5   Effect of correlation scale on the first-order probability of failure (C_t=2.0 mg/L).

Figure 4.9 Delta sensitivities for case MH-1. (Reprinted from *Probabilistic modeling of aquifer heterogeneity using reliable methods*, 1996, by M. M. Hamed, P. B. Bedient, and C. N. Dawson with permission of Advances in Water Resources.)

Figure 4.10 which illustrates the contaminant concentration for this case study emphasizes the preferential pathways that the contaminant takes in order to circumvent the tight region. In other words, due to the reduction in the hydraulic conductivity in the indicated region, groundwater selects the path of least resistance, thus avoiding the high resistance from the low conductivity region.

Therefore, it is intuitive for gamma sensitivities to attain their maximum value above the lower conductivity region, as shown in Figure 4.8. The ease at which the contaminant would preferentially flow around the tight zone is dependent upon the hydraulic conductivity of the region above it. The negative delta sensitivities in the region above the tight zone indicate that the higher the hydraulic conductivity, the lower the reliability index, due to the increased flow.

4.6.2.2   Case MH-2

Next we consider the presence of (elongated) lower conductivity "lenses" in an otherwise highly permeable medium. Figure 4.11 shows the configuration considered. Lenses of tight formation (mean hydraulic conductivity of 5.0×10^{-5} cm/sec) are considered to exist parallel to the mean flow direction as indicated in the figure. Each lens is one block wide and three blocks long. Hydraulic conductivity for the remainder of the domain has a mean value of 5.0×10^{-3} cm/sec. The coefficient of variation of each random variable is maintained at 1.0. The probability of exceeding a target concentration of 2.0 mg/L at the observation well is obtained. FORM estimates the failure probability to be 0.118, with a reliability index of 1.19.

Figure 4.12 illustrates the design point, while Figures 4.13 and 4.14 show the gamma and delta sensitivities, respectively. In this case too, the contaminant bypasses the lower conductivity regions in an effort to find a more conductive and less "resistive" pathway. The sensitivities, consequently, illustrate the relative importance of the conductive regions in this case.

4.6.3 Effect of Mesh Overlay and Discretization

First, we look at the effect of the mesh discretization level on the accuracy of the estimated probability of failure. There are two meshes that we consider in any numerical reliability problem. The first is the mesh required for the solution of the transport equation by the finite element model, which we refer to as the *numerical mesh*. In addition, we must assign realizations of the random variables (hydraulic conductivity) to the individual grid blocks in the numerical mesh. This step is achieved by discretizing the spatial random field on a number of grid blocks, which is done by superimposing another mesh, called the *random variables mesh*. This concept is illustrated by a numerical example.

Figure 4.15 illustrates the setup for the case study, where Table 4.3 lists the problem configuration. In this case, we have a domain of 36.0 m on the side with the indicated boundary conditions. Here, the contaminant behaves conservatively, although any chemical reactions can be considered. In order to solve the contaminant transport equations using FLOTRAN, we discretize the domain into 12×12 grid blocks. This numerical grid is shown in Figure 4.15(a). Now in order to take into account the uncertainty in the aquifer material, we describe the hydraulic

conductivity by means of a spatial random field, using the exponential correlation function. We first look at the case where the same mesh is used for finite element and random field discretization (see Figure 4.15(f)).

The design point, gamma sensitivity, and delta sensitivity are shown in Figures 4.16, 4.17, and 4.18, respectively. The same patterns observed in the case study of Section 4.6.1 were also obtained in this case, where the design point and the sensitivities are highest along the contaminant travel path.

We next experiment with using two different levels of discretization for the numerical and random variables meshes. In other words, we use a coarse random variables mesh for the assignment of random variables, and a fine mesh for the solution of the transport equations using the finite element method. Numerous mesh discretization levels are studied. In all of these cases, the numerical mesh is maintained at 12×12.

Figure 4.15(b) illustrates the case of 4 random variables. This means that each 36 grid blocks contained in a single element of the random variables mesh will be assigned the same value of hydraulic conductivity. Figures 4.15(c) through 4.15(f) show the cases of 9, 16, 36, and 144 random variables, respectively. For the 144 variables case, each grid block in the numerical mesh is assigned a different, yet correlated, value.

Figures 4.19(a), 4.19(b), and 4.19(c) illustrate the effect of the number of random variables on the failure probability, reliability index, and the required CPU time on a SUN SPARCstation 2, respectively. It should be noted that the greater the number of random variables considered, the more accurate the estimate of the failure probability (and, reliability index estimate). Nevertheless, the resulting computational burden increases considerably. This is indicated by the increase in CPU time about 35 fold when the number of random variables is increased from 4 to 144. The trade-off between computational time and accuracy becomes a crucial issue.

Figure 4.19(d) shows the percent difference between the failure probability estimated at each case as compared to the "true" solution, assumed to be represented by the solution obtained with 144 random variables. If one considers the case of 16 random variables, the error in failure probability is only 5% where the saving in CPU time is 88%. Therefore, it is clear that using a random variables mesh that is coarser than the numerical mesh can result in considerable savings in computational effort without jeopardizing numerical accuracy. In this specific case study, fairly accurate results were obtained with 16 random variables, where the dimension of the grid block of the random variables mesh is 3 cells on the side; i.e. , $\Delta x = \Delta y =$ one-half the correlation scale. This finding is not general, and it depends on our choice of correlation type and scale, along with problem setup. However, the outlined approach can be used to identify the level of discretization that combines accuracy with computational efficiency.

Next, we explore the effect that the target concentration has on the probabilistic event. The design point for target concentrations of 3.0 mg/L was shown in Figure 4.16. The mean concentration at the well is 2.3 mg/L. This occurs when grid block hydraulic conductivities are at their mean value of 5×10^{-2} cm/sec. Hence, the figures show the design point for a case where the target concentration is greater than the mean concentration. The design point for a target concentration of 1.0 mg/L, which is less than the mean value, is shown in Figure 4.20.

It is interesting to see the difference in the design point for the two target concentration levels. When the target concentration is at 1.0 mg/L, which is less than the mean concentration, the realization of hydraulic conductivity which produces the most likely failure is *lower* along the stream tubes connecting the source to the well than the mean hydraulic conductivity. On the other hand, when the target concentration at the observation well is 3.0 mg/L, which is greater than the mean concentration, the realization of the hydraulic conductivity producing the most likely failure is *greater* along the stream tubes connecting the source to the well than the mean hydraulic conductivity.

Table 4.4 shows a comparison of the results for the two target concentration levels. The Monte Carlo results were obtained by the following procedure. The prescribed probability density function of the hydraulic conductivity is randomly sampled, so that the correlation structure is satisfied. With this realization, the transport model is run and

the *g*-function is obtained. At this point, another random sampling is performed, the transport model is run again, and another set of results is obtained. Enough Monte Carlo simulations are performed until the coefficient of variation of the ensemble of failure probability drops below 5%. The Monte Carlo simulations needed for the 1.0 and 3.0 mg/L were 1000 and 2500, respectively.

The comparison indicates that SORM results matched those of the Monte Carlo simulation method very closely, and bettered the match between FORM and the Monte Carlo results. Nevertheless, FORM results were obtained at less of a computational effort than that of SORM. The selection of the approximation method, therefore, becomes an issue of trade-off between computational efficiency and demand. Time saving is not very dramatic in this case, since the failure threshold is in the bulk of the distribution. Besides, the saving in computational time increases with decreasing failure probability. However, the reliability methods presented sensitivity information at no additional computational burden, which the Monte Carlo simulation cannot provide.

4.6.4 System Reliability Analysis

In many groundwater contamination applications, we are interested in studying the reliability of more than one component in the solution domain. For example, we may be interested in the probability that the contaminant will exceed a predetermined level at any point along a property boundary. The compliance with the regulatory standards at more than one receptor well in the aquifer of interest is another example. In these situations, the problem is formulated in a *system reliability* framework, in which several limit-state functions are considered, one for every *component* of interest.

As an example, consider the case where a contaminant source leaks chemicals into an underlying groundwater aquifer. Assume that there exists a number of downgradient points of human exposure (i.e., wells). In this case, we have several limit-state functions, one at each well. The formulation is similar to (2.34).

In general, a system can be idealized as a series system, a parallel system, or a combination of the previous two. The problem of groundwater contamination is posed in a *series system* format since failure of *any* of the components constitutes failure of the system. In other words, in a multiple well compliance example, if the concentration at any of the wells exceeds the predetermined target value, the system has failed.

As an application example, consider the probability of exceeding 2.0 mg/L at any of the three observation wells given in Figure 4.21. That is, the probability of failure to meet the 2.0 mg/L threshold after the 350 days simulation time is required. Table 4.5 lists the input data for this case study. In Table 4.6, the system reliability results are shown for first-order uni-modal, bi-modal, and relaxed bi-modal bounds. As expected for a series system, the system failure probability obtained is higher than the largest component failure probability ($P_{F_1}^{FORM}$ =0.385,

$P_{F_2}^{FORM} = P_{F_3}^{FORM}$ =0.224). The bi-modal bounds are narrower than the relaxed bi-modal bounds, which are, in turn, tighter than the first-order uni-modal bounds.

The correlation coefficient between the failure event at wells 1 and 2 is the same as that between wells 1 and 3 and equals 0.726. This means that failure to meet the target concentration of 2.0 mg/L at well 1 is closely related to the failure at well 2. A careful analysis of the physics of the problem explains this result. In order for the contaminant to exceed the target concentration at well 1, the grid block hydraulic conductivities at the design point should be high enough to allow easier and less resistive paths for the contaminant to reach the target well at the designated threshold value. The high conductivity realizations also allow for more contaminant to reach well 2, hence resulting in a large correlation coefficient between the probability of exceeding the target level at wells 1 and 2. The correlation coefficient between the failure events at wells 2 and 3 is 0.217, which is less than the correlation between wells 1 and 2. This is explained by the fact that wells 2 and 3 are separated by a greater distance than wells 1 and 2, hence their failure events are correlated at a smaller value.

Additional information gained from the system reliability analysis is the sensitivity of the system failure probability with respect to changes in the distribution parameters of the grid block conductivities. Figure 4.22(a) displays the sensitivities of the upper bi-modal bound on P_F^{system} with respect to changes in the local mean value of the hydraulic conductivities. The results indicate that the greater the mean hydraulic conductivity of the region along the flow paths, the greater the system failure probability, a behavior easily explained by the earlier discussion.

	Bounds on β^{system}	$0.182 > \beta^{system} > -0.075$

Next, we look at the series system reliability in which only wells 2 and 3 are included. In this case, the system failure probability bounds are given in Table 4.7. The system failure probability in this case is less than in the case with three wells, as expected. Figure 4.22(b) depicts the sensitivities of the upper bi-modal bounds of system failure probability with respect to changing the mean value of grid block conductivities for the 2-well case. The pattern in which the sensitivities behave is interesting. Mean hydraulic conductivities along the branching path leading to both wells 2 and 3 have the highest impact on the system failure probability. The negative sign indicates an inverse relationship between local mean conductivity and system failure probability.

When a lower conductivity lens is considered to exist between the two wells and in an orientation parallel to the mean groundwater flow direction (Figure 4.23), the first-order bi-modal bounds on system failure probability changes from 0.377 to 0.369. In other words, the presence of the lower conductivity lens affected the system reliability only slightly. However, the sensitivity of the system failure probability with respect to the local mean hydraulic conductivity in this case differs considerably from the case without the lens. This is shown in Figure 4.22(c).

4.6.5 Remediation/Containment under Uncertainty

The impact of parameter uncertainty on achieving remediation/containment goals is important. Failure to account for such uncertainty can dramatically hinder the efficiency of the remediation/containment scheme, creating significant economic ramifications. In this section, we present a reliability formulation to study the effect of the natural variability of the hydraulic conductivity on achieving a plume containment goal. The limit-state function is formulated as in (4.8), however, C_t in this context is the remediation/containment threshold or target concentration at a specific well. *Failure* in this case indicates failure to contain the plume from reaching the observation well, or failure to remediate the plume to the predetermined threshold level.

Figure 4.24 illustrates the problem setup. The aquifer's extent is 66.0 m on the side. A numerical grid of 11×11 is used to discretize the solution domain. The random field mesh used to discretize the spatial random field of hydraulic conductivity is assumed to coincide with the numerical mesh. That is, the number of random variables is $11 \times 11 = 121$, comprising the hydraulic conductivity in the center point of each grid block. Table 4.8 lists the input parameters for this case study. It should be noted that the hydraulic gradient is assumed constant throughout the case studies. The initial contaminant plume is shown in Figure 4.25.

It is assumed that a property boundary is located as shown in Figure 4.24. A pumping scheme is installed in such a manner so as to contain the plume from escaping into the neighboring property beyond the site boundary within the 30 day pumping period. The target concentration at the observation well is chosen, arbitrarily, to be 1.0 mg/L. In realistic applications, the target concentration and well location are chosen according to: (1) the type of contaminant, (2) land use at the neighboring property, and (3) risk estimation at the receptor well.

The numerical reliability model is used to estimate the probability of failure of the remediation/containment scheme. FORM failure probability and reliability index were found to be 0.743 and -0.655, respectively. This means that if a single, fully penetrating well at the middle of the domain is pumped at a rate of 1.26 L/s (20 gpm) for 30 days, there will be a 74% probability of failure to contain the plume from reaching the downgradient observation well at a concentration exceeding the target concentration of 1.0 mg/L. The negative reliability index simply means that the probability of failure exceeds 0.5. This is clear by an examination of the definition of the relationship between P_F and b given in (2.19).

**Figure 4.22** Sensitivity of the upper bi-modal bound on the system failure probability to the local mean hydraulic conductivity: (a) for the 3-well case, (b) for the 2-well case, (c) for 2-well with lower conductivity lens. (Reprinted from *Numerical stochastic analysis of groundwater contaminant transport and plume containment*, 1996, by M. M. Hamed, P. B. Bedient, and J. P. Conte with permission of Journal of Contaminant Hydrology.)

Next, the pumping rate is increased to 1.89 and 2.52 L/s (30.0 and 40.0 gpm), and the reliability analysis is repeated to study the effect of increasing the pumping rate on the failure probability. For the 1.89 L/s (30 gpm) case, FORM failure probability and reliability index are 0.41 and 0.227, respectively. Table 4.9 lists FORM, SORM, and Monte Carlo results for the 2.52 L/s (40.0 gpm) scenario. FORM and SORM results were in good agreement with that of the Monte Carlo simulation method. This good agreement in the reliability to that of the Monte Carlo results was observed for all of the case studies conducted. Thus, an increase in the pumping rate from 1.26 to 2.52 L/s (20.0 to 40.0 gpm) caused the failure probability at the observation well to drop from 74% to about 33%. The design point, gamma and delta sensitivities for this case study are shown in Figures 4.26(a), 4.26(b), and 4.26(c), respectively. It is interesting to see that the probabilistic event is most sensitive to hydraulic conductivities in the region downgradient from the pumping well. This is due to the fact that the more conductive this region is, the more "clean" water the pump is able to flush towards the observation well, and the better the containment becomes. This is indicated by the positive delta sensitivities in that region, which indicates a direct proportionality between the local mean value of the hydraulic conductivity in that region and the reliability index.

Next, we look at the impact of the presence of a lower conductivity lens downgradient from the pumping well, and upgradient from the observation well, as shown in Figure 4.27. The lens has a conductivity of 2.0×10^{-5} cm/s, which

Table 4.7 Results of the System Reliability Analysis for the 2-well Case Study (Reprint from *Numerical stochastic analysis of groundwater contaminant transport and plume containment*, 1996, by M. M. Hamed, P. B. Bedient, and J. P. Conte with permission of Journal of Contaminant Hydrology.)

is two orders of magnitude less than the prevailing hydraulic conductivity. When the pumping rate of 1.89 L/s (30.0 gpm) was applied to this case, the probability of failure to meet the target concentration of 1.0 mg/L dramatically increased to 0.985, with a reliability index of -2.12. This illustrates the significant impact that material heterogeneity and the presence of lenses have on the success of cleanup schemes. Table 4.10 lists FORM failure probability and reliability index for different pumping rates. For each pumping rate, the original case study, as well as that with the lower conductivity lens, are analyzed. The table indicates that failure to meet the target cleanup level increases significantly for the case with the lens. This emphasizes the importance of accounting for the material variability and heterogeneity when designing aquifer remediation systems. Failure to account for this

factor will reduce the chances of success to meet the predetermined target cleanup standards within the specified time.

Figures 4.28(a), 4.28(b), and 4.28(c) illustrates the design point, gamma, and delta sensitivities, respectively, for the case with the lens, and for a pumping rate of 5.68 L/s (90.0 gpm). Comparison of the trends in these figures with their counterparts for the original case (Figure 4.26) indicates that when the lower conductivity lens is present, the failure probability is most sensitive to the region downgradient from the pumping well, in addition to the region around the lens. This is another indication of the significance of careful site investigation to delineate the extent of heterogeneity present at the site before designing a remediation system.

Section 5

Summary and Conclusions

The uncertainty of the parameters describing the aquifer material, the chemical, and the leaking source have been the focus of many research efforts. This is indicated by the wealth of literature on stochastic hydrology in the past decade. This was motivated by the recognition of the impact that such uncertainty has on the predictive ability of groundwater fate and transport models. Most of the work presented so far has been structured around one of three methods: (1) classic Monte Carlo simulation method (MCS), (2) spectral analysis, and (3) perturbation theory. Furthermore, Sitar, Cawlfield, Der Kuireghian, and co-workers have pioneered the application of the first- and second-order reliability methods (FORM and SORM, respectively) in groundwater contamination problems (Sitar et al., 1987; Cawlfield and Sitar, 1988; Mok et al., 1993). A brief survey of some of the stochastic hydrogeology work was presented in Section 2.

In this work, a probabilistic approach for modeling groundwater contaminant transport and remediation has been presented based on FORM and SORM. The theory of the reliability methods has been reviewed to the extent necessary to understand the formulation. We looked at the use of analytical and numerical transport and remediation models for the probabilistic analysis of uncertainty in groundwater. The development of probabilistic models based on analytical transport codes have proved to be much easier and less computationally intensive than numerical-based probabilistic models. Numerical models, however, allowed us to look at the effect of spatial heterogeneity and correlation structure of the hydraulic conductivity, which is not possible with analytical models. The issue of trade-off between intensive computational effort to account for more complex cases versus lower cost analytical methods that give screening decisions within a few minutes becomes of great significance. In this section, we list the general conclusions of the work presented in preceding sections.

5.1 Probabilistic Analytical Transport Model

We have shown that FORM and SORM can be a potential alternative to the classical Monte Carlo simulation method when dealing with groundwater contamination events that have very small probability of occurrence, therefore requiring thousands of Monte Carlo simulations to provide reliable results. FORM and SORM were used to assess the probability that a given contaminant exceeds a certain target concentration level at a selected point in space and time in the solution domain and to provide the sensitivity of such a probabilistic event to the basic uncertainty in the input variables. Contamination scenarios with both reactive and non-reactive solutes were presented for demonstration purposes.

FORM and SORM results were compared and were tested against those obtained using the classical Monte Carlo simulation method. In selecting the analysis method, it should be emphasized that, in this work, SORM was more accurate than FORM, but computationally more expensive. The problems analyzed were fairly simple, hence computer time required for SORM was still very low (on the order of a few minutes on a SUN SPARCstation 2) and the use of SORM was warranted. However, for larger problems, and when using more complex numerical models (based on finite difference or finite element methods) this becomes a matter of considerable significance, and a careful trade-off analysis between computational effort and accuracy should be conducted to determine which approximation method to use. We also showed that FORM results are sometimes very different from SORM results, and in such cases, SORM analysis is warranted, in spite of its extra computational effort required.

The impact of the basic uncertainty in seepage velocity was identified. However, chemical-related and source-related parameter uncertainty are also important factors to consider in the probabilistic analysis of groundwater transport problems, and their importance should not be overshadowed by the aquifer-related parameter uncertainty.

5.2 Probabilistic Numerical Transport Model

Numerical solution to the transport equations was obtained using a finite-element model. This allows considering the spatial variability of the aquifer material, as well as more complex geometry and boundary conditions. Hydraulic conductivity was assumed to be spatially correlated, following an exponential auto-correlation function, and lognormal distribution.

Failure to meet target concentration level at a downgradient well was analyzed for a number of cases. The reliability analysis provides the design point, as well as gamma and delta sensitivities. The effect of lower conductivity regions, whether large blocks, a few elongated lenses, or many small scattered lenses, was considered. The sensitivity, as well as the design point obtained indicate that the flow lines circumvent the lower conductivity

regions, in an effort to produce the target concentration at the well. Sensitivity of the probabilistic event was highest with respect to hydraulic conductivities along the tortuous flow path that bypasses the tight lenses.

There are two types of meshes that the numerical probabilistic model utilizes: (1) a random variables mesh, and (2) a numerical mesh. The former is used by the mid-point method to discretize the spatial random field (the hydraulic conductivity). The numerical mesh, on the other hand, is required in the finite-element method to discretize the transport equation. We used a coarse random variables mesh superimposed on a fine numerical mesh, and found that considerable savings in computational effort can be obtained in this manner. The choice of the appropriate stochastic discretization level, however, needs some engineering intuition. In other words, a careful trade-off analysis between computational effort and numerical accuracy must be conducted in order to determine the spatial discretization level needed that would capture the stochastic features of the random field without much computational effort.

When analyzing the failure to meet the target levels at more than one location, system reliability was used. Series system formulation was used since failure to meet the pre-determined target concentration at *any* well results in the failure of the system. The joint probability of failure, as well as the correlation between individual failure probabilities, was obtained using reliability bounds.

The effect of spatial heterogeneity of the aquifer on containment/remediation was studied. Hydraulic conductivity was assumed to be represented by a spatial random field, and the probability of the plume escaping the site boundary was estimated. Furthermore, the relative importance of grid block conductivities was obtained. The use of analytical gradient is expected to alleviate some convergence problems we faced when looking at stressed aquifer conditions. Pumping and/or injection apparently causes the limit-state surface to be extremely non-linear and noisy, and the use of finite-difference to estimate gradients has resulted in failure in many cases to converge to the design point.

5.3   Recommendations for Future Research

Most of the reliability analysis software available to date use gradient-based optimization techniques to determine the design point. Examples include the HL-RF, SQP, and the gradient projection methods. The reason for using these methods is their superior convergence in the neighborhood of the optimum point. This is because the methods use, in the search, information on the gradients of the limit-state function with respect to basic random variables.

In the case of algorithmic formulation of the limit-state function, such as the work presented in Section 4, a finite-element routine is required to obtain any point on the limit-state surface. Therefore, the calculation of the required gradients can be very time consuming. Furthermore, numerical noise can render these gradients considerably inaccurate. If these factors are combined, together with a starting point that may not be in the neighborhood of the solution, the optimization routine can fail to find the design point.

Non-gradient search methods may be advantageous in cases where the limit-state function is highly noisy, since these methods do not use gradient information, but rather rely solely on functional evaluations. Examples of non-gradient search methods include the Nelder-Mead method (Press et al., 1989), or one of many available non-classical methods, such as genetic algorithms (GA) (Goldberg, 1989; Davis, 1991), simulated annealing (SA) (Kirkpatrick et al., 1983; Goffe et al., 1994), and evolution strategies and evolutionary programming (ES and EP) (Baeck et al., 1991; Baeck et al., 1993; Baeck and Schwefel, 1993).

Hybrid optimization methods that rely on a non-gradient search method to locate the neighborhood of the design point, combined with a gradient optimization method to accurately and efficiently determine the design point may also be another valid approach that may prove very useful in cases of noisy limit-state function.

The use of reliability methods in analyzing the effect of pumping on containing a plume within a site boundary was presented. Due to the fact that convergence to the design point was not always achieved due to noisy gradients, the estimation of analytical gradients for reliability-based remediation models is highly recommended.

The use of reliability Bayesian updating scheme can also be an important addition to the work presented here, since it allows updating the reliability estimates as more data becomes available from the site.

Finally, although FORM and SORM required a fraction of the computational effort needed by the Monte Carlo Simulation method, the CPU time necessary for solving large problems could still be extensive. The use of parallel computer architecture can be utilized to considerably reduce the computational time required. This will allow for the consideration of large dimensional problems without necessitating overwhelming CPU time.
