DISCLAIMER

This report has been reviewed by the Office of Drinking Water, U.S. Environmental Protection Agency, and approved for publication. Approval does not signify that the contents necessarily reflect the views and policies of the U.S. Environmental Protection Agency, nor does mention of trade names or commercial products constitute endorsement or recommendation for use.

FOREWORD

Many of the industrial Nations today face problems related to population, energy, and protection of the environment. In order to optimize use of the scientific and technical expertise from different countries, the Committee on the Challenges of Modern Society (CCMS) was created between the Allied Nations of the North Atlantic Treaty Organization (NATO). This international society of scientists strengthens ties among members of the North Atlantic Alliance and permits NATO to fill a broader social role with non-member countries. CCMS has been responding to the increasingly complex, technological problems facing modern society.

The Drinking Water Pilot Study was initiated by the U.S. Environmental Protection Agency (EPA) in order to address a broad spectrum of drinking water quality and health related issues. Six subject areas have been studied by a number of groups representing individuals from eleven NATO countries and three non-alliance countries with technical participation from many others. The conclusions and recommendations reached by the participants are hoped to allow national programs to focus on specific areas of water supply research and to bring out the most up-to-date technology and practices. However, the recommendations and conclusions do not necessarily reflect the policy of the U.S. or any other participating countries. The work of the Pilot Project has been covered in a summary report.

In addition three other major publications round out the work of the pilot study – two being reports of international symposia "Oxidation Techniques in Drinking Water Treatment". (CCMS-111; EPA-570/9-79-020) and "Adsorption Techniques in Drinking Water Treatment" (CCMS-112; EPA-570/9-84-005); and the third being this document. EPA has been proud and pleased to associate with such a fine group of scientists in this import work and hopes to see these relationships continued into the future.

FRAU PROFESSOR DR. GERTRUD MÜLLER

1919 - 1980

Frau Professor Dr. Gertrud Müller, Leitender Direktor and Professor, Abt. "Spezielle Umwelthygiene, Humanökologie und Gesundheitstechnik," Institute für Wasser-, Boden- und Lufthygiene des Bundesgesundheitsamtes, Berlin, Federal Republic of Germany, departed this world and the community of scientists on 30 April 1980, ending a long and outstanding career as a water and wastewater microbiologist and environmental hygienist. She was a recognized leader in her fields of endeavor in her own country and a frequent participant in international professional activities. Among her more than 200 scientific publications were several books that are regarded as classics in their fields. Those who knew and worked with her were invariably impressed by the enthusiasm and the positive approach with which she addressed whatever she did. We, her colleagues in the writing, compilation, and editing of Project Area III - Microbiology of the CCMS Pilot Study on Drinking Water Supply Problems, fondly dedicate this report of our work to her. She has been an inspiration to us in this undertaking and will surely continue to be one for our work in the years to come.

PREFACE

The Pilot Study on Drinking Water Supply Problems was performed under the auspices of the Committee on the Challenges of Modern Society, to examine problems of special concern to industrialized nations. Increasing technology has helped developed countries deal with some of the drinking water supply problems that still trouble less affluent nations, but other problems arising from industrialization and urbanization are just beginning to surface.

This report on the microbiology of drinking water was compiled by approximately 50 experts from 11 countries (cf. preceding list). Each of the seven topics comprising the report was led by a person from a different country, and most of the working groups were international in composition.

We intended to incorporate into this project all aspects of drinking water microbiology that have practical significance. We considered the entire continuum from the source water, through treatment and delivery to the consumer. We included organisms which may affect human health directly, those which may have an indirect influence (such as indicator organisms), and those which cause technologic problems in the provision of safe drinking water. Thus, the scope of our undertaking may well be broader than that of any previous project in the area of drinking water microbiology.

On the other hand, extreme breadth necessarily limits depth. We chose to try to define the problems, identify available solutions, and propose research that is required to produce solutions that do not yet exist. Both published and unpublished research results have been included; but we have often directed the reader to a review on some broad subject, rather than a multitude of older source articles. We have tried to produce a text which is useful and meaningful to a career microbiologist who may not be an expert on the aspects of drinking water microbiology. The summary of the report is directed to those with a less specialized technical background.

The seven topics are intended to cohere as much as possible, but the topic leaders have chosen a variety of formats on the basis of suitability to the kinds of material they had to present. The references cited are principally those which are likely to be available in technical libraries of industrialized nations.

Topic A, led by Dr. J. J. Nygård of Norway, deals with the microbiology of raw water. Groundwater and surface water are considered separately, and the report includes a survey of microbiologic experience with raw water in several countries.

Topic B, led by Prof. J. M. Foliguet with Dr. P. Hartemann and assisted by Dr. J. Vial, all of France, concerns the pathogens which are transmissible through drinking water. Following a survey of the properties of individual pathogenic species, the report addresses the general questions of sources, persistence, and infectivity of waterborne pathogens and the compilation of statistics on waterborne disease.

Topic C, led by Dr. R. S. Tobin of Canada, discusses indicator systems. This includes both indicators which are already established and in general use as well as others which are still at the research stage. Some are primarily indicators of fecal contamination, whereas others relate to different aspects of microbiologic quality. The discussion also includes techniques presently under study which are designed to be potentially more rapid or convenient and do not rely upon the growth of viable organisms.

Topic D, compiled by Mr. A. E. Greenberg of the United States from materials supplied by respondents in thirteen countries, concerns testing and standards for drinking water. Tables are used to make comparisons among nations as to their requirements or recommendations for sampling and testing procedures. Methods for determining coliforms and thermo-tolerant coliforms (<u>Escherichia</u> <u>coli</u>) are emphasized. The existence and effects of standards are compared.

Topic E, led by Dr. H. J. Kool of the Netherlands, addresses processes used in drinking water treatment. The effects of various unit processes are considered from the microbiologic standpoint. Where possible, effects on pathogens are contrasted with effects on indicator organisms.

Topic F, which concerns the distribution of drinking water, was written by Dr. N. P. Burman and Miss J. K. Stevens,

both of the United Kingdom. The discussion emphasizes
protecting the microbiologic quality of finished water
during storage and on the way to the consumers. Means of
preventing growth of organisms within the system as well as
contamination by organisms from without are considered.

Topic G, led by Prof. G. Müller of the Federal Republic
of Germany, deals with technological aspects of potable
water microbiology. One broad area of discussion concerns
the influence of microorganisms upon the structures or
functions of devices used in treating and distributing
drinking water. Another area is concerned with water held
in containers. These include drinking water reservoirs
aboard ships, or cans and bottles used either for commercial
or emergency use.

The summary which concludes the text of the report is
intended to be of value to both policymakers and the public.
It attempts to provide an overview, from the microbiologic
standpoint, of the technical and institutional problems
involved in providing a safe and quantitatively adequate
supply of drinking water from whatever raw water is avail-
able. It also emphasizes the need for continuing research
to fill the gaps in present knowledge.

INTRODUCTION

Throughout the course of history, the development of a safe drinking water supply has been crucial to the public health of nations. Drinking water is a necessity and approximately 2 liters/day are required to sustain life. Despite the body's many special mechanisms for conserving water, substantial quantities are lost each day and must be replaced promptly. Much of the replacement is derived from water that is present in food, some is a product of metabolism; the rest must be obtained by drinking water or other beverages, all of which contain water. Water must be drunk, even if what is available is unsafe, in the sense that drinking it may produce adverse effects upon health. Postponement of meeting the body's needs for beverage water can lead to extreme illness and death within a very few days. Because people have virtually no option but to drink the water that is available to them, it is a fundamental responsibility of governments to ensure a continuous supply of safe drinking water, to provide alternative sources, or provide for conservation.

Water does not occur in an absolutely pure state anywhere in the world. By and large, the chemical impurities in both ground and surface waters govern, through their chemistry, the kinds of native bacterial populations that ordinarily grow in the water. The organisms are generally found in low numbers and are of little public health consequence as long as the water contains minimal concentrations of organic, nitrogen, and phosphorus compounds as basal nutrients. Pollution of both ground and surface water supplies, much of which is domestic sewage, is becoming a serious problem for industrialized countries. These wastes not only contain pathogenic microorganisms, but also varying amounts of basal nutrients which can support the growth of various microorganisms and as a result, cause taste, odor, or fouling problems for some water supplies.

Historically, the agents causing typhoid fever, bacillary dysentery, and cholera have been of primary concern to the sanitary microbiologist and public health officials.

These diseases are only rarely observed now in industrial countries which efficiently practice modern means of water treatment and waste disposal. Other disease producing bacteria, viruses, and protozoa, including Giardia lamblia, are receiving attention probably because of our general awareness of the organisms in some source waters and our ability to recover them from the water. Attention has focused, too, on the opportunistic pathogens which are primarily saprophytic and can cause disease in debilitated individuals. These bacteria have the ability to multiply in situ and in distribution systems while the more fastidious bacteria, viruses, and protozoan cysts cannot compete in the aquatic environments.

Pathogens cannot usually be sought as a means of determining the microbiologic quality or safety of drinking water. Levels of pathogens in finished water and in highly protected source waters are essentially nil, most of the time, because pathogens are likely to be so fastidious that only highly specialized laboratory techniques may allow them to be detected. Therefore, bacterial species which are generally nonpathogenic, but are more readily cultivated in the laboratory, have come to be used as indicators of water quality and safety. Some of these indicators may be taken as evidence that water is contaminated with feces. Some of these indicators can show that water treatment has been inadequate or that an abnormal or undesirable situation exists, but none can be directly correlated with the presence of specific pathogens. Other indicator systems, some of which do not entail the growth of viable organisms from a sample, have been proposed to detect endotoxin or ATP or to provide results more rapidly than is possible by techniques presently in routine use. No microbiologic indicator system will serve all of these purposes, nor does any system serve even a single purpose perfectly. Nevertheless, the coliform indicator system has been used for many years in monitoring water quality and, with minor refinements, has stood the test of time reasonably well.

Routine testing for microbiologic indicators has been the traditional means of evaluating the safety and reliability of public water supplies for more than 80 years. Sampling and microbiologic testing procedures to determine drinking water quality have been established in every industrialized nation, yet the procedures used are not always the same. Potentially significant differences exist among nations as to where and with what frequency water samples are to be taken, how samples are to be tested when they

reach the laboratory, how the laboratory test results are to be interpreted, and what remedial action is appropriate when indicator test results exceed established norms. In comparing activities it is important to note that commendable and much-needed efforts are already under way toward standardizing microbiologic testing of water through a number of existing organizations.

Water for potable use must be taken from the best source available to the community. If the quality of the source does not meet appropriate criteria and standards for safety, treatment must be developed in order to protect the public health. Water treatment techniques are well established and sophisticated in industrialized nations. This supports the observation that waterborne disease is relatively rare in these countries, even though many of the suppliers are obliged to prepare drinking water from sources that are not ideal in purity. However, even procedures that have long been in use at a given location may have to be modified if raw water quality suddenly deteriorates, if the public that is served demands a higher degree of water purification than was previously practiced, or if reductions in the treatment costs, in terms of money or energy, are sought. As a result of long experience, we know the effects each of the major water treatment procedures are expected to produce upon the pathogens that may be present in the water and what effect changes in treatment may have on the indicator systems by which the quality of the water is monitored. Few unit processes in water treatment, other than disinfection, have been designed specifically to act upon the microorganisms present in the water. Therefore, reductions of pathogens as a result of these processes are largely fortuitous. Furthermore, a given unit process acts differently upon different classes of pathogens, so it is not at all surprising that bacterial indicators of sanitary significance may not be affected in the same way or to the same degree as particular pathogens. Information concerning treatment efficacy can aid in assessing the microbiologic effects of these water treatment processes and in predicting the results of changes that may be contemplated.

No matter how excellent the quality of drinking water may be when the treatment plant is finished, the responsibility of the water utility must extend to safe storage and distribution of the water to the service connection at the point where the water is used. Where proper distribution and storage facilities do not exist, they must be

built. Indeed, the epidemiologic record of disease out-
breaks involving public water supplies suggests that recon-
tamination of finished water during distribution is one of
the major problems confronting water supplies in all coun-
tries. Community distribution systems are inevitably com-
plex and have frequently been constructed in stages over
long periods of time, so that construction practices pres-
ently regarded as standard may be represented in only a
portion of an existing network. Use of substantial volumes
of water for firefighting, industrial applications, or the
sudden incidence of natural or manmade catastrophe, can
disrupt well-considered and established water distribution
procedures. Therefore, water distribution systems must be
adaptable to a variety of uses, and decisions for new
construction must be integrated into the overall land use plan-
ning exercise for the community.

Though the principal emphasis in this report has,
necessarily, been on the effects of water and of drinking
water technology upon microorganisms, it is also obvious
that some microorganisms are capable of significant effects
upon their immediate environment and that these effects must
be considered in discussing water treatment and dis-
tribution. Problem areas include the degradation of sur-
faces in contact with drinking water, as a result of organic
or inorganic reactions induced by microbes, and the influ-
ence of accumulated microbial cells upon the functions of
water treatment resins and on the mains through which water
is expected to flow. The technological problems which may
result from microbial growth during treatment and dis-
tribution of public water supplies are part of the task of
providing water to the consumer; however, drinking water, in
some situations, must be held in a static condition for
substantial periods of time. Two such applications are that
of supplying drinking water aboard ships and that of pack-
aging drinking water in containers for emergency use or for
commercial distribution. Each of these technological prob-
lems may appear to lie outside the traditional scope of
drinking water microbiology, but are included because they
are significant to the task of providing safe, palatable
drinking water to the consuming public.

This report on drinking water microbiology is, as was
previously stated, intended to treat the subject as broadly
as possible. Although it is clear that there are many
problems in water supply which are not of a microbiologic
nature,

it must be noted that microbes are probably the oldest form
of life and that they almost certainly originated in water.
Therefore, the human species, as a late and opportunistic
arrival on the face of the earth, must to some degree base
its strategies for survival upon understanding and learning
to deal with the interactions between microorganisms and
water. In this context, we trust that the report which
follows will contribute significantly to our collective
potential to survive.

A.   RAW WATER

The ultimate source of water in various freshwater environments is precipitation, be it rain, snow, or hail. From there, it evaporates, is transpired, runs off directly into streams, rivers, and lakes or it percolates through the soil to travel eventually into groundwater aquifers. As water makes its descent to the ocean, it may pass through both the groundwater state and the surface water state. The increasing demand for potable water to supply domestic and commercial needs has prompted many communities of the world to use new source waters, including those receiving wastewater from homes, communities, and industries (Dykes, et al., 1967).

As a rule any body of fresh water, whether or not it receives wastewater, contains a great number of microbes, among which may be bacteria, algae, protozoa, fungi, and viruses (including phages). Some of these microbes are indigenous to natural bodies of water whereas others are transient, entering the water from air or soil and, more significantly, from domestic or industrial wastewater. The presence, activities, and interactions of both indigenous and transient microbes are extremely important because they may affect the health of humans and other animals. The persistence of these organisms in any given water varies from hours to months and is influenced by a variety of environmental conditions (e.g., available nutrients, pH, temperature, presence of toxic substances, competition, predation, etc.). The complexity with which these factors interact is even greater if the body of receiving water is flowing, as in the case of a river.

Chemolithotrophs, as the name implies, obtain their energy from the oxidation of simple inorganic elements or compounds (i.e., ammonia, sulfur, reduced iron and/or manganese). Thus, all of these organisms play an important role in the cycling of the elements. Chemolithotrophic bacteria are divided into: (1) obligate chemolithotrophs (able to oxidize only certain specific inorganic substances as sources of energy but can derive their carbon from any of several

sources); (2) heterotrophic chemolithotrophs (can utilize several different sources for energy but are wholly restricted to carbon dioxide as their carbon source); and (3) mixotrophic chemolithotrophs (can obtain both energy and carbon from different sources).

The prevalence of chemolithotrophs is influenced by various factors. For example, nitrifiers (members of the family Nitrobacteraceae) are strict aerobes, preferring a pH slightly above 7.01. On the other hand, some sulfur-oxidizers require a pH of 1.0 to 3.5. Whereas the growth of some microorganisms is inhibited by the presence of organic compounds, others are mixotrophic and can function both as chemolithotrophs and as chemoorganotrophs (Alexander, 1971).

Chemolithotrophs play various important ecological roles within source waters. For example, Nitrobacteraceae convert ammonia to nitrite and nitrite to nitrate. Nitrate is a universal nitrogen source for green plants and, when present, stimulates the growth of aquatic weeds which, in turn, may temporarily immobilize the nitrate by removing it from circulation. However, the subsequent death and decomposition of such weeds within source waters result in taste and odor problems along with oxygen depletion.

Sulfur bacteria, such as members of the genus Thiobacillus, are facultative and as such, can thrive in aerobic as well as anaerobic environments [See Section G.4.c] They oxidize both reduced sulfur (such as hydrogen sulfide) and reduced iron (ferrous compounds). Their activities, therefore, are largely beneficial since reduced sulfur compounds (such as hydrogen sulfide) not only impart a distinctive odor to potable water, but may be toxic to animals, given sufficient quantities.

Members of the family Siderocapsaceae can deposit iron and/or manganese oxides on their capsules. Their presence in source water may be beneficial where large amounts of reduced iron and/or manganese (agents responsible for fouling of pipes) are also present and will, as a result, undergo biological oxidation [See Sections F.2 to 3 and G.4.b].

Chemoorganotrophs, more commonly referred to as heterotrophs, obtain energy from the oxidation of organic compounds. They include not only saprophytic, parasitic, and pathogenic bacteria, but also fungi and protozoa.

Whereas human or animal pathogens usually require rich nutrient substrates, aquatic saprophytic bacteria are less fastidious and can thrive in an environment with extremely low nutrient concentrations. They include both gram-negative nonsporeformers (members of the Spirillaceae and Pseudomonadaceae), and gram-positive cocci and endospore-forming bacteria (members of the Micrococcaceae and Bacillaceae). Some are sheathed (members of the genera Sphaerotilus, Leptothrix, Crenothrix, etc.); some possess appendages (Hyphomicrobium, Caulobacter, Gallionella, etc.). Several members of the sheathed and appendaged bacteria are well known among sewage and water treatment operators. For example, species of Gallionella have been responsible for plugging sand filters and other water treatment media [See Sections E.4 and G.2] (Warren, 1971).

Among the myriads of fungi, only a few species thrive to any extent in an aquatic environment. Those classes of fungi most prevalent in the aquatic environment (chytridiomycetes, hypochytridiomycetes, and oomycetes) do not appear to cause disease in man or other mammals (some chytrids may parasitize certain species of algae). However, saprolegnias, notably S. parasitica, have been known to cause a disease of fish and fish eggs and may cause significant economic damage (Alexopoulos, 1962).

Aquatic protozoa ingest minute algae and bacteria in addition to large quantities of organic debris found in their habitat; they are regarded as consumers or grazers. Of the five phyla (Mastigophora, Sarcodina, Ciliata, Cnidospora, and Sporozoa), the first three are thought to be indigenous to unpolluted waters. They play an important role in the aquatic environment as scavengers, but the majority are considered harmless to humans.

The occupancy of different niches, the cycling of elements, and the scavenger activities, all of which support a diversity of life forms and maintain the stability of the source water ecosystem, can be thrown off balance or drastically altered when increased volumes of untreated or inadequately treated wastewater are discharged into source waters (Cairns, 1977).

Most source waters, whether lake, reservoir, river, or groundwater will, at some point, receive wastewater from human activity (Fair and Morrison, 1967). Nearly 200 to 450 1 (50 to 100 gal) of wastewater are produced daily per individual in a developed country. These wastewaters are discharged to receiving bodies of water as untreated or

treated effluent. Wastes may be derived from domestic
sewage, from agricultural or industrial discharge, from
cesspool seepage or leachate, from a refuse disposal site,
or from wild animals and birds. The effect of effluent
discharge upon the receiving water, expressed in micro-
biologic terms or as BOD and suspended solids, varies with
the kind of wastewater, the treatment it has received, the
quantity discharged, and the dynamics of subsequent dilu-
tion. Understandably, the BOD or microbial content of
wastewaters derived from slaughterhouses and meat packing
plants is considerably different from wastewaters of paper
manufacture, and these are different from domestic waste-
waters (Tabor, 1976).

When large numbers of thermo-tolerant coliforms, fecal
streptococci, Clostridium perfringens, Bifidobacterium
bifidum, Bacteroides, Veillonella, and Peptostreptococcus
are encountered in a source water, they signify fecal pol-
lution [See also Sections C.1.c to e and D.4 to 5]. In
addition to human intestinal microbes, wastewater derived
from municipal sources may contain all of the indigenous
aquatic and soil microflora and -fauna. As a rule, the
great majority of microbes derived from wastewaters are
harmless chemoorganotrophic saprophytes. However, wastes
entering a waterway, whether treated or not, increase the
opportunities for contamination with disease agents.

The agents of typhoid fever, bacillary dysentery, and
cholera are members of the family Enterobacteriaceae, are
associated with wastewater, and are potentially transmissible
by contaminated drinking water [See Sections B.1.a(i),
(ii), and (vii)]. Outbreaks of gastroenteritis caused by
Yersinia enterocolitica [See Section B.1.a(iii)] have been
reported, and the organism is apparently more widespread in
source waters receiving wastewater than once thought (Highsmith,
et al., 1977a). Enteropathogenic or toxigenic strains of
Escherichia coli [See Section B.1.a(iv)] also have occurred
in source waters. Francisella tularensis (agent of tularemia)
[See Section B.1.a.(v)] is another pathogen associated with
surface water contamination on rare occasions (Safe Drinking
Water Committee, 1977).

Recently, gram-negative, antibiotic-resistant strains
of Pseudomonas aeruginosa (cause of melioidosis) have been
transmitted to humans via source water receiving wastewater
[See Section B.1.a(ix)]. The organisms are well known as
pathogens of both animals and plants. Antibiotic-resistant
species of Aeromonas (e.g., A. hydrophila) not commonly

identified as agents of human infection (but rather of certain species of fish and frogs) have been transmitted to humans via source waters contaminated by wastewater and have caused cases of acute cellulitis (Hanson, et al.. 1977). Populations of this organism in numbers as high as 10^5 to 10^6 cells per ml have been found in aquatic environments which receive wastewater [See Section C.2.h].

Other bacteria (e.g., Klebsiella pneumoniae, Corynebacterium diphtheriae, Streptococcus pyogenes, S. pneumoniae, and others), whose epidemiologic significance has been traditionally associated with food or air, have been isolated from improperly treated wastewater effluent. Pathogenic members of the orders Actinomycetales, Mycoplasmatales, Rickettsiales, and Chlamydiales might also be transmissible from wastewater to sources of drinking water. Similarly, raw water derived from surface water which receives human or animal waste (either raw sewage or effluent from improperly treated sewage) may be a potential source of the Legionnaires' disease agent, Legionella pneumophila. The agent was thought to be closely associated with water in an air-conditioning system or wind-blown dust from an excavation site close to the outbreak of the disease. However, further investigation revealed that L. pneumophila has been isolated from nonepidemic-related aquatic habitats including streams, lakes, and soil (Fliermans, et al., 1979).

More than 100 different enteric viruses have been isolated from the feces of infected humans in concentrations as high as 10^6 plaque-forming units (pfu) per gram. Raw sewage has yielded as many as 5×10^5 pfu per liter of enteric viruses (Buras, 1976). Since viruses are not altogether destroyed during wastewater treatment (though the majority will have been removed by coagulation, sedimentation, and filtration procedures) [See Section E], they may enter surface or groundwater via treated waste effluent (Wellings, et al., 1975) and find their way to another community's source water [See Sections B.1.b and B.1.d]. Viruses have been recovered recently from both treated and raw wastewater effluents; from soil receiving digested sludge; from lakes and rivers which receive treated sewage effluent (Gerba, et al., 1975a); and from estuaries in which water salinity may vary from less than 1 percent to 12 percent. Some of the more important viruses which occur in wastewater and other aquatic environments and might be transmitted by contaminated drinking water are enteroviruses, reoviruses, parvoviruses, hepatitis virus type A, adenoviruses, and gastroenteritis viruses [See Sections B.1.b and B.1.d].

Only free-living protozoa may flourish in unpolluted waters, so facultative or obligately parasitic protozoa may be considered as transient populations. Yet, both parasitic and facultatively parasitic protozoa produce cysts and trophozoites in their life cycles. Protozoan cysts are frequently found in human feces and therefore, also in wastewater [See Section B.1.c]. Hence, source waters receiving wastewater discharges may harbor forms of these protozoa. Most cysts resist disinfection by chlorine, bromine, or ozone; but the great majority are apparently removed by coagulation, sedimentation, or subsequent filtration. The majority of waterborne protozoan disease outbreaks in the U.S. have been associated with drinking water derived from surface waters receiving wastewater which was treated only by natural sedimentation and disinfection. More efficient treatment, including coagulation and sedimentation to remove cysts, followed by disinfection, must be used routinely when processing source water receiving wastewater, to avoid epidemics of amoebic dysentery, giardiasis, and meningoencephalitis [See Section E].

There is little information on the habitats of some potentially pathogenic microbes such as Mycoplasma, pathogenic yeasts, and other fungi (Safe Drinking Water Committee, 1977). However, fungi do not appear to be important causes of waterborne disease in man, though they are frequently incriminated as the cause of undesirable tastes and odors.

Certain pathogens are more virulent than others. Though virulence is a genetic trait, it is also related to infectious dosage (the number of pathogenic organisms required to cause infection) [See Section B.4]. For example, ingestion of a relatively small number of Shigella dysenteriae may cause acute disease, whereas exposure to a somewhat larger population of Vibrio cholerae is required to infect a susceptible individual. Pathogens also vary in that: some are able to donate or receive antibiotic resistance; some have traditionally been associated with foodborne or airborne disease; some contain in their cell walls lipid-polysaccharide complexes (endotoxins) that can produce illness; and some propagate or cause illness only under very special conditions [See Sections B and G.2].

Furthermore, there is nothing constant or necessarily predictable about the numbers and kinds of pathogenic microflora and -fauna associated with wastewater effluent. The numbers and kinds vary with the degree of treatment and disinfection, and these factors are subject to daily or even

hourly change. In addition, some pathogens are capable of resisting chlorination, or displaying a phenomenon known as aftergrowth [See Section F.2]; that is, multiplication within the receiving body of water. At one mechanical-biological treatment plant in Denmark, reduction of fecal and pathogenic organisms was found to be 90 to 99 percent, with the exception of <u>Clostridium</u> <u>perfringens</u> [See Section C.1.e], which was reduced by only 63 to 98 percent (Kristensen, 1974). <u>C</u>. <u>perfringens</u>, considered primarily a food-borne pathogen is virtually always present in raw sewage as well as in mechanically and biologically treated sewage effluent. For all of the reasons just mentioned, kinds as well as numbers of pathogens per volume of raw water must be determined before the potential health hazard of any source water can be assessed and the degree of treatment prescribed.

To summarize, microbes within source water that receives wastewater effluents are either indigenous or transient. These microbes include bacteria, algae, fungi, protozoa, and viruses. The bacteria may be further characterized on the basis of modes of obtaining energy, such as phototrophic, chemolithotrophic, and chemoorganotrophic; each set occupies a specialized niche in the aquatic ecosystem.

As is true of organisms indigenous to source water, the majority of microbes derived from wastewater are harmless saprophytes. However, as greater quantities and more diversified qualities of wastes are discharged to source waters, pathogens, whether obligate or opportunistic, are more likely to be present. Hence, it is the degree to which raw waters are contaminated with waste that determines, in large measure, the risk involved in producing finished water that is free of disease agents.

1. Microbiology of Groundwater

Historically, groundwater has been a source of relatively clean, high quality drinking water, needing little, if any, treatment. In contrast, surface water almost always has required some level of treatment as a result of ever increasing human interactions, in the form of industry, agriculture, aquaculture, recreation, sewage disposal, and other activities, with the hydrologic cycle. In many countries, pollution of surface waters has led to a decrease in their suitability for potable use or rendered them more costly and complicated to treat. The relative purity of groundwater has led to greater world reliance on this source for supplying potable water. On a global scale, groundwater sources appear to be much more plentiful than surface water sources [See Table A.1-1].

TABLE A.1-1

COMPOSITION OF THE HYDROSPHERE
AND RATE OF TURNOVER

Parts of the Hydrosphere	Volume[a] in Thousands of Cubic Kilometers	Rate of Water Turnover (Years)
World oceans	1,370,000	3,000
Groundwater	60,000	5,000[b]
(groundwater -- zones of active turnover)	4,000	330[c]
Polar ice caps	24,000	8,000
Surface water	280	7
Rivers	1.2	0.031
Soil moisture	80	1
Atmospheric vapor	14	0.027
Total hydrosphere	1,454,000	2,800

From Ilvovitch, 1977.

[a]In round numbers.

[b]Includes groundwater runoff to oceans bypassing rivers -- 4,200 years.

[c]Includes groundwater runoff to oceans bypassing rivers -- 280 years.

About 98 percent of Denmark's population obtains its drinking water from minimally treated or untreated ground-water. In the U.S., over 50 percent of the population receives its drinking water from groundwater sources, roughly half of which have been treated minimally or not at all. However, between 1946 and 1974, over 50 percent of all waterborne disease outbreaks in the U.S. were attributed to contaminated groundwater (Allen and Geldreich, 1975). One of the most important diseases spread via groundwater is hepatitis A [See Section B.1.b]. In a review of 48 hepatitis outbreaks occurring worldwide and involving 31,357 people, groundwater was implicated in 21 of these and involved 1,378 people (Taylor, et al., 1966).

Recent trends in land disposal of sewage effluent and sludge have prompted scientists and hygienists to examine possible new and adverse chemical and microbiological effects upon groundwater. Manure has been used extensively in agriculture for hundreds of years without any reported disease outbreaks resulting (except where excessive fertilization or cattle feedlot impoundments led to nitrate contamination). However, lately, many new methods have been used to dispose of wastes on land, which has consequently increased the volumes disposed there. Moreover, as sewage treatment methods improve, production of sludges will increase, resulting in greater impacts to the land and to aquifers below. The growing practice of groundwater recharge with wastewater is also of concern.

Volumes of wastewater produced in the year 2000 are expected to be ten to 15 times higher than those produced in 1970 (Ilvovitch, 1977). It therefore would appear that we are dealing with problems whose solutions will become increasingly urgent in the next few decades. The protection of our groundwater resources will become more important as our reliance on land disposal of wastes increases as an alternative to discharging them into surface water.

a. Definition of Groundwater. Water resources differ from other natural resources in that the hydrologic cycle and hydrosphere are two inextricably bound systems with one constantly exerting an influence over the other. Taking part in this cyclic continuum are oceans, ice caps and glaciers, lakes, streams, groundwater, and the atmosphere. Surface water and groundwater are in contact through river and lake beds. Most precipitation evaporates and returns to the atmosphere; a lesser portion returns to the sea through

streams and rivers; and only a minor part sinks into the ground and percolates through the soil system to become groundwater.

That water which percolates through the soil and stops its downward movement upon reaching an impermeable layer comprises the groundwater. Water in this zone fills the soil pores and flows horizontally. Because it has passed through the soil system, where processes such as ion exchange, adsorption, precipitation, and chemical alterations including biodegradation take place, groundwater will differ both chemically and microbiologically from surface water.

Above the groundwater is an unsaturated zone where water percolates both horizontally and vertically while some of it remains there held by adhesion and capillarity. It is in this unsaturated stratum that various physical, chemical, and biological activities take place which normally will determine groundwater quality. Climate, the depth and geochemistry of the unsaturated zone, and activities at the surface (such as waste disposal) are all major factors affecting groundwater quality.

Normally, groundwater is virtually free of organisms because they are filtered out or adsorbed to particles in the soil system. If there is sufficient soil depth, texture, structure, and biological activity, the groundwater should be of acceptable microbiological quality. On the other hand, more than 40 groundwater samples from deep aquifers in Jordan were found to contain coliforms; this was attributed to poor filtration of the overlying soil (Shehabi, 1976). The rate of groundwater turnover is much slower than that of surface water [See Table A.1-1] and therefore, once groundwater has become contaminated, it remains contaminated much longer. For this reason, the issue of waste disposal on land becomes that much more serious.

This groundwater discussion pertained to that which occurs in deep aquifers and did not take into account well water which may become contaminated with surface water when leaky covers are situated below surface level, or as a result of improper construction or placement.

b. Occurrence of Indigenous Microorganisms in Groundwater. Groundwater usually is extremely low in organic matter (or that which is present is in an unavailable form), and this combined with filtration in the unsaturated zone normally

precludes the presence of any organisms except possibly a few chemolithotrophic bacteria. These bacteria usually range in numbers between 20 and 50 per ml (Hvid, 1955). The ratio of chemoorganotrophs (also called chemoheterotrophs) to chemolithotrophs is a function of the organic content of the soil, which decrease with depth [See Table A.1-2]. The total numbers of microorganisms decrease with the depth of the soil, but below one meter, both the amount of organic matter and numbers of chemoorganotrophs are low while the proportion made up of chemolithotrophs rises. Samples taken from deep borings may be sterile or contain only chemolithotrophic bacteria, such as methane, sulfur, and/or iron bacteria.

The presence of methane in groundwater indicates activity of methane-generating bacteria such as Methanobacterium, which reduce carbon dioxide and organic acids to methane. Such bacteria may cause problems because methane is a nutrient source for certain slime bacteria which may grow in layers on filters, along pipes, and in containers (Völker, et al., 1977) [See Sections G.2 and F.3]. Sulfates, if present in groundwater, may be reduced to hydrogen sulfide by bacteria such as Desulfovibrio and thereby render the water unacceptable for potable use [See Sections F.2.d and G.4].

Iron and manganese bacteria, including the Sphaero-tilus-Leptothrix group and Gallionella, may be present in groundwater. These bacteria obtain energy by oxidation of ferrous and bivalent manganese compounds [See Section G.4]. Hydrogenomonas, which can oxidize molecular hydrogen to obtain energy, has also been recovered from aquifers (Hvid, 1955).

Samples taken from deep borings normally contain few, if any, chemoorganotrophic bacteria unless there has been some mixing with surface water resulting in availability of organic material. Danish investigators found anaerobic actinomycetes, clostridia, and anaerobic gram-positive non-motile cocci (unclear taxonomy) in samples from deep borings (Hvid, 1955). These cocci and actinomycetes are important in denitrification of nitrates in the unsaturated zone and as such, are instrumental in preventing occurrence of nitrates in groundwater. Also found within the groundwater in Denmark were nonsporeforming, motile, gram-negative, glucose-negative, and gelatin-positive bacteria (possibly belonging to the genus Vibrio) (Bonde, personal communication). Such bacteria may not always be detected by conventional methods and may propagate in slow moving or stagnant parts of the distribution system [See Section F.2].

TABLE A.1-2

CONTENT OF BACTERIA AND ORGANIC MATTER
AT DIFFERENT SOIL DEPTHS

Depth (cm)	Organic Matter (%)	Million Bacteria per Gram	
		Aerobes	Anaerobes
0-6	8.04	49.2	1.0
6-12	3.18	131.8	1.0
12-28	2.41	158.3	10.0
28-48	1.76	45.3	1.0
48-80	0.80	6.0	0.001

From Jepsen, 1972.

Bacteria also can propagate in water of initial potable quality that has been stored. Investigators in Norway stored groundwater with a potassium permanganate value of 1.5 at 22°C for 3 to 13 days, after which time original bacterial numerals of 2 per ml had swelled to over 100,000 per ml. However, such marginal levels of organic matter content would be highly selective for the less fastidious bacteria [See Section G.6].

Although fungi (of which about 200 genera have been isolated from soil) are more prevalent than bacteria in soil, very little is known about their presence in ground-water. Fungi, pathogenic to humans, also may occur in soil. All fungi are aerophilic and do not grow under strict an-aerobic conditions such as would occur in water-logged soil.

Protozoa, including flagellates, amoebae, and ciliates, may appear in the upper part of the unsaturated zone in numbers varying from 10^3 to 10^6 per gram of soil. However, owing to their size, they are readily entrapped within the soil matrix and prevented from entering groundwater.

c. **Fate of Organic Substances in Groundwater.** As a rule, undisturbed groundwater bears organisms and chemicals indigenous to that environment. But, accompanying the rapid increases in human populations have been more intense and varied uses of land and water. This has meant, in some instances, that groundwater may be derived in part from water percolated from surfaces to which treated or untreated sewage effluents have been applied. Or, it has led to the practice of disposing sewage effluent or sludge on land near sources of groundwater used in producing potable water. The extent to which these practices pose a threat to the safety of groundwater depends on the types and quantities of waste applied and on the climate and hydrogeology of the site.

Pollutants may enter the aquifer directly through crevices and fractures in the bedrock or through porous subsoil. They may percolate through shallow soils, or enter the aquifer during bank infiltration practices used in some areas for treating surface waters (Federal Ministry of the Interior, 1975) [See Section E.4]. Pollutants also may enter groundwater via deep injection wells used for under-ground storage or disposal of industrial or municipal waste-water or of septage. Toxic or obnoxious pollutants may enter the aquifer as a result of accidental spills during transport (Federal Ministry of Health, 1969); such events

can no longer be considered extremely rare. Once these substances enter groundwater, they may travel great distances and pollute uncontaminated water in nearby aquifers.

The fate of organic substances in groundwater depends largely on the presence of saprophytic microbes and on the availability of dissolved oxygen. Organic substances, when in the presence of sufficient available oxygen, may be oxidized or mineralized to such products as carbon dioxide, nitrate, and sulfate [See Figure A.1-1]. However, any aerobic biooxidation of organic substances in an environment such as an aquifer almost always depletes the supply of dissolved oxygen, thereby decreasing the oxidation-reduction potential of the water. Such conditions favor the microbial reduction of certain substances (e.g., ferric and tetravalent manganese ions, nitrate, sulfate, etc.) to a number of unacceptable products including ferrous and manganous ions, ammonium, nitrite, methane, hydrogen sulfide, and other reduced sulfur compounds (Schweisfurth and Ruf, 1976) [See Figure A.1-2]. These biogeochemical conversions are known to occur even in aquifers deep underground.

Reduced inorganic or organic substances in groundwater subsequently may be spontaneously (chemically) or microbially oxidized when the water is brought to the surface to be processed through a water treatment facility, for example. Here, various microorganisms such as species of Sphaerotilus, Leptothrix, Phragmidiothrix, Gallionella, and especially Crenothrix polyspora (Schweisfurth, 1974; Völker, et al., 1977) proliferate, producing abundant sheaths or slimes which may be encrusted with oxidized minerals. Sheaths and slimes not only discolor and impart tastes and odors to the water, but also cause considerable problems in treatment since they (especially slimes encrusted with iron or manganese) may plug sand filters and otherwise interfere with the treatment and distribution of drinking water [See Section E.4 and G.2 to 4].

d. New Trends in the Disposal of Sludge and Sewage Effluent. Opportunities for contamination of groundwater, including water in wells, seem to be tied closely to new trends in land disposal techniques. Increasing populations produce more wastes and at the same time withdraw more water for domestic, agricultural, and industrial purposes. As a result, more water is being converted to wastewater, only to be re-introduced into the hydrologic cycle where some will invariably end up as groundwater.

Hazards associated with septic tank systems, cesspools, and leaky sewage pipes have been known for a long time. Sewerage systems may lose influent to the surrounding soil; and, in fact, it is estimated that the wastewater arriving at the treatment plant is generally 20 percent to 60 percent lower than the amount originally supplied to the municipal system (Shuval, 1977). The reverse (infiltration) also has been known to occur with some regularity. Home septic systems that incorporate a sand-filled seepage pit or leach field for adsorption can be very effective in removing pathogens from the septic tank effluent; yet, many of these individual systems are poorly constructed, receive little maintenance, and become overloaded by the householder so that the domestic sewage essentially bypasses treatment. The potential hazard therefore is that poor quality sewage effluent may seep into groundwater supplies of the home or community.

Sewage effluent disposal to the land has, in recent years, been largely in the form of irrigation, wastewater treatment lagoons, infiltration ponds, and wastewater disposal in underground pits (Cleary and Warner, 1970). Volumes of irrigation water used in some countries are expected to double in the next 20 to 25 years. Such activities may modify water circulation patterns, soil ecology, and ultimately, groundwater quality. Heavy irrigation may cause stronger vertical seepage through soil increasing the potential for groundwater contamination (Kovacs, 1977).

Infiltration ponds are designed for disposal of sewage, but often are used for groundwater recharge besides. However, they should be viewed as waste treatment processes only, since seepage of pollutants to groundwater is a definite possibility, depending on geochemical conditions, climate, level of the water table, and infiltration rate of the wastewater (which can be rather high in some cases). Danish investigators found that the infiltration rate varied between 0.18 m per day during the first year to 0.05 m per day after a few years (Bonde, et al., in press).

The use of treatment lagoons is common, especially in semi-arid regions. Lagoons may be used in conjunction with conventional primary or secondary treatment, but may also be used exclusively to dispose of waste by evaporation, seepage, and direct re-use through irrigation (Klock, 1971).

In areas with a high water table and a low adsorption capacity of the unsaturated zone, the use of wastewater treatment lagoons or infiltration ponds may result in contamination of groundwater with fecal (including pathogenic)

and soil organisms. Moreover, where a sewage stabilization pond has been placed improperly over river alluvium or limestone sink holes, leakages into groundwater or an entire collapse of the pond is possible.

Alterations in the ecology of the soil and groundwater are possible with increased reliance on wastewater treatment lagoons and infiltration ponds. Such changes as the appearance of large numbers of iron and sulfur bacteria in aquifers have already been noted. More important are the potentials for changes in survival, propagation, and movement of pathogens. If pathogens survive longer in soil than the time it takes to pass from a treatment lagoon through the unsaturated zone, these organisms may gain entry into the groundwater. Creation of a new set of variables within soil and groundwater from new waste disposal technologies may change conditions enough that the previously applied principles will no longer hold true. Therefore, it is essential that more be known about factors affecting survival of intestinal microorganisms in soil and groundwater as compared to their survival in treatment lagoons and infiltration ponds.

e. Factors Affecting Survival in Soil and Groundwater. Survival of pathogens in soil and water is determined largely by: (1) species of microorganisms; (2) temperature; (3) sunlight; (4) rainfall; (5) pH; (6) soil type; (7) moisture and organic content of the soil; (8) microbial antagonisms (including production of antibiotics such as actinomycin and streptomycin), predation, and parasitism (bacteriophages); and (9) infiltration rates. Different organisms exhibit different survival rates in soil and water [See Tables A.1-3 to 5]. For example, mycobacteria and sporeformers survive longer than thermo-tolerant coliforms in soil. Climate also is a major factor in that survival is generally greater in winter than in summer [See Table A.1-3], and contamination of groundwater is much more likely during periods of heavy rainfall. Microbial antagonisms (especially from actinomycetes) are very important in the reduction of pathogenic bacteria, but appear not to be with viruses (Gerba, 1974).

Organisms at the soil surface are exposed to UV and desiccation and therefore are less likely to survive than those within moist soil. Less than 15 percent humidity greatly reduces virus numbers (Moore, et al., 1976). In general, bacteria survive longer in alkaline (limestone) than in acid (peat) soils. Irrigation with sewage effluent

TABLE A.1-3

SURVIVAL OF BACTERIA ON OR IN SOIL

Organism	Soil Type	Time of Year	Survival Time (Days)
Total coliforms	Surface soil	–	38

on soil and plant surfaces allows for direct exposure of
accompanying flora to UV light and for desiccation between
irrigation periods. Death rates under such conditions are
relatively high. Waste stabilization ponds, on the other
hand, protect microorganisms against exposure to UV and so
increase the likelihood of survival. The presence of organic
compounds also seems to increase survival of microorganisms.
For example, the data in Table A.1-6 suggest that indicator
bacteria survive for extended periods in soil to which
digested sludge has been applied.

Adsorption of viruses is influenced mainly by pH, the
type and concentration of cations, organic matter, and the
surface area of the soil particles. Clay soils or, to a
somewhat lesser extent, consolidated sands facilitate virus
adsorption. The efficiency of adsorption increases the more
acid the soil is or the greater the ionic strength is in the
suspending medium (obtained, for example, by adding calcium
chloride to the soil). Adsorption may be hindered or the
process reversed with high concentrations of organic matter.
Sites consisting largely of highly fractured rock or mix-
tures of gravel and sand are unacceptable for waste disposal
because viruses and other microorganisms may be transported
over long distances in such soils [See Table A.1-5].

In experiments using 250-cm columns of calcareous sand,
Lance and coworkers (1976) showed that reductions in the
ionic strength of the soil solution, from flooding with
deionized water, caused desorption and movement of viruses
through the soil (Lance, et al., 1976). However, most
viruses were re-adsorbed, and showed a peak concentration at
a depth of 10 cm, after flooding with sewage. It is evident,
from these and other data, that the best results are achieved
by alternating applications of sludge or sewage effluent
with dry periods and by avoiding disposal of wastes during
periods of heavy rain. If done correctly and at the appro-
priate site, land application of municipal wastewater or
sludge can be a highly satisfactory method of waste treat-
ment.

Once they have entered the groundwater, bacteria no
longer have to contend with UV light or microbial antago-
nisms and this, along with low temperatures of groundwater,
prolongs survival (E. coli has been found to survive up to
100 days in subsoil water: Gerba, et al., 1975) [See Table
A.1-4]. When sewage effluent was pumped directly into
aquifers, fecal streptococci and thermo-tolerant coliforms
were recovered at a distance of 33 m (Reviewed by Jepsen,
1972). Viruses, as well, persist longer in groundwater

which is clean compared to river or seawater where viral reductions are greater [See Section B.3]. Investigators recovered hepatitis A virus from a well situated 23 m (75 ft) away from a cesspool (Neefe and Stokes, 1945).

From tests made of treatment lagoons (Klock, 1971), it appeared that after about one week (a shorter time during the summer), only 1 percent of coliforms had survived; and only about .001 percent were viable after two weeks (Klock, 1971). Survival rates in infiltration ponds probably are the same. From this, one could surmise that a large majority of pathogens would be eliminated before reaching the soil. Nevertheless, when soil beneath infiltration ponds became saturated with sewage effluent, thermo-tolerant coliforms were recovered at a depth of four, but not eight, meters (Baars, 1957). Since infiltration ponds often are placed in areas of sandy soil, movement of organisms tends to be a problem.

By studying a sedimentation-infiltration pond system in operation for about ten years, researchers in Denmark were able to evaluate long-term consequences to underlying soil and groundwater (Bonde, et al., in press) [See Table A.1-7]. The system consists of two sedimentation ponds and four infiltration ponds receiving raw sewage on an infiltration surface equalling 10 m^2 per capita waste output. The depth to groundwater in the area is about 2 m and the soil is characterized as sandy. Average retention times were eight days in the sedimentation ponds and five days in the infiltration ponds. As can be seen in Table A.1-7, thermo-tolerant coliforms were isolated from all samples collected at a depth of 16.5 m beneath infiltration ponds. Colony counts at 20 and 37°C were quite high at all depths and the presence of P. aeruginosa in nearly all groundwater samples indicates probable occurrence of pathogenic bacteria in groundwater below these infiltration ponds.

f.   Occurrence of Endotoxins in Groundwater.   Gram-positive bacteria are the predominant bacterial microflora of soil, whereas gram-negative bacteria normally predominate in water. Irrigation and disposal of sewage water on soil consistently contribute enormous numbers of gram-negative bacteria, many of which are subsequently eliminated by antagonisms in the soil.

The confrontation in soil between the indigenous gram-positive soil bacteria and the gram-negative water bacteria may result in the release of endotoxins, which are produced

BACTERIA IN GROUNDWATER BENEATH INFILTRATION PONDS
SAMPLED IN JANUARY AND FEBRUARY OF 1977

BACTERIA	DEPTH (in meters)				
	1.9	2.5	4.5	9.5	16.5
Total coliforms	$5.4x10^3-2.2x10^4$ [a]	$>1.6x10^3-1.6x10^5$	$>1.6x10^3-1.7x10^4$	$>1.6x10^3-1.6x10^4$	$2.3x10^1-2.5x10^2$
Thermo-tolerant coliforms	$3.5x10^3-2.2x10^4$	$>1.6x10^3-5.4x10^4$	$>1.6x10^3-1.1x10^4$	$>1.6x10^3-1.6x10^4$	$8x10^0-4.3x10^1$
Colony counts at 20°C	$2.2x10^8-12.9x10^8$	$1.8x10^8-13.2x10^8$	$5.0x10^7-4.1x10^8$	$1.3x10^7-4.7x10^8$	$4.0x10^6-4.0x10^7$
Colony counts at 37°C	$6.0x10^6-4.4x10^8$	$1.0x10^7-4.5x10^8$	$9.0x10^6-1.3x10^8$	$4.0x10^6-9.6x10^7$	$1.0x10^6-4.6x10^7$
Fecal streptococci	$1.8x10^3-4.6x10^3$	$5.4x10^2-3.9x10^4$	$3.6x10^2-4.8x10^3$	$1.0x10^2-5.9x10^2$	$1.0x10^0-1.0x10^1$
Clostridium perfringens	$1.0x10^2-3.0x10^2$	$1.4x10^3-1.7x10^3$	$4.0x10^1-9.1x10^2$	≤ 200	≤ 100
Pseudomonas aeruginosa	+[b]	+	+	+	-
Coliphages	$2.0x10^1-3.5x10^2$	$2.0x10^1-5.4x10^2$	$1.0x10^1-9.2x10^2$	$8.0x10^0-5.0x10^1$	≤ 5.0

(BONDE, ET AL., IN PRESS)

only by gram-negative bacteria. Endotoxins may then travel from the unsaturated zone in the soil into the groundwater. Groundwater situated beneath infiltration ponds in Denmark and sampled at depths of from 1.9 to 16.5 m was found to contain endotoxins in amounts varying from 10^{-4} to 10^{-6} g per ml (Kristensen, 1978). Maximum endotoxin concentrations found during this study were over 10,000 times the minimum dose (2 ug endotoxin per kg body weight) needed to produce clinically measurable effects by parenteral injection in humans (Mikkelsen, 1977). Since they are toxic only if they enter the bloodstream, endotoxins in potable water pose special problems for production of solutions for infusion [See also Sections B.1.a(ix) and C.3.a].

g. Criteria for Evaluating Groundwater Quality. Groundwater supplies often are tested by the same microbiological criteria used for potable water (Allen and Geldreich, 1975). Though there are differences from country to country, most include tests for total and thermo-tolerant coliforms and colony counts at 21 and 37°C [See Sections C.1.a-c and D]. Tests made in the U.S. have demonstrated the presence of total and even thermo-tolerant coliforms in some community groundwater supplies [See Table A.1-8]. Yet, the apparent absence of coliforms does not necessarily ensure that pathogens, such as P. aeruginosa [See Sections B.1.a(ix) and F.3.b] and Y. enterocolitica [See Section B.1.a(iii)] are not present in the groundwater (Nemedi and Lanyi, 1971; Lassen, 1972).

There is very little information available on the spread of viruses in groundwater primarily because the most important groundwater-borne virus, the hepatitis A virus, cannot as yet be cultured in the laboratory and remains extremely difficult to study [See Section III.B.1.b]. Virus criteria for drinking water normally are not specified for routine drinking water analyses. Although, in a preliminary proposal submitted by the Commission of the European Communities in 1974, recommendations included a statement that enteroviruses should be absent in 10 l of drinking water, this was removed from the final Council Directive (Commission of the European Communities, 1975) [See Table A.1-9 and Section C.2.b]. It has been suggested that bacteriophages be used as an indicator of enteroviruses [See Section C.2.a]; but Gerba and coworkers (1974) state that removal of bacteriophages during percolation through soil is much greater than removal of enteroviruses.

Before improved indicator systems for assessing groundwater quality can be designed however, more needs to be

TABLE A.1-9

MICROBIOLOGICAL REQUIREMENTS FOR DRINKING WATER
IN THE EUROPEAN ECONOMIC COMMUNITY

Parameter	Volume of Sample (ml)	Guide Level (GL) Plate Count Agar	Maximum Admissible Concentration (MAC)		Multiple Tube Method
			Plate Count Agar	Membrane Method	
Total coliforms	100	–		0	MPN < 1
Thermo-tolerant coliforms	100	–		0	MPN < 1
Fecal streptococci	100	–		0	MPN < 1
Clostridium sp.	20	–		–	MPN < 1
Colony count (for water supplied for direct consumption)	1	10 (37°C)[a] 100 (22°C)[a]	– –		

[a] Values for disinfected water should be considerably lower at the point where it leaves the processing plant.

Footnote: In addition to the above analyses, microbiologic examinations should, in cases where warranted, include tests for Salmonella, enteroviruses, and coliphages. All finished water should be free of algae and parasitic protozoa and helminths.

known about soil-groundwater ecology and survival and movement of enteric organisms released to the soil via current waste disposal practices. Whether or not to establish quality criteria for chemolithotrophic bacteria is another matter to be considered. Chemolithotrophs, though not indicators of fecal contamination, are an important cause of operational difficulties at the treatment plant and in the distribution network.

     h. Protection of Groundwater. In an effort to divert some of the tremendous volumes of wastewater from discharging into rivers and lakes, many countries are turning to land disposal. At the same time, it is estimated that groundwater will, in the future, satisfy over 50 percent of drinking water needs (Ilvovitch, 1977). Although the soil acts as a buffer against groundwater contamination, just how far this protection can be counted on is not known given these new and intensified circumstances.

     Recommendations for protecting groundwater, submitted by the Commission of the European Communities (1979), make a distinction between pollution that occurs in the saturated zone and pollution that occurs in the unsaturated zone. Unfortunately, the proposed measures deal only with chemical and toxicological problems even though over 99 percent of outbreaks of waterborne disease are caused by microorganisms. Whereas it has been shown that groundwater beneath infiltration ponds need only be diluted less than 100-fold to fulfill chemical requirements (e.g., NH_4^+-N and anionic detergents) for drinking water, it must be diluted several thousand fold to satisfy microbiologoical requirements.

     Legislation enacted in Denmark for the protection of groundwater requires that a license be obtained prior to land disposal and specifies conditions under which land disposal of wastes may be considered. Containers whose contents could be construed as potentially contaminating cannot be placed in the soil. Seepage drains and cesspools must be at least 2.5 m above the water table; and wastewater percolation facilities must be no less than 300 m from the nearest water catchment. Pollutants in all such wastewaters must be easily biodegradable. It is recommended that, for municipal sewage effluent, the equivalent of one person's daily waste output be applied to 100 to 400 m^2 of farmland. One hectare is required for one day's disposal of 10 m^3 of dairy wastewater.

High groundwater quality is best maintained by intelligent preventative measures aimed at protecting the integrity of the soil-aquifer ecosystem. Primary treatment with disinfectants such as chlorine does not serve as an adequate substitute but rather, renders more complex the economic and technical props needed to produce a potable product.

i. <u>Conclusion and Recommendations</u>. Pollution of our groundwater supplies is one of the most serious problems confronting the 20th Century. In order to devise and implement means for safeguarding this resource, we need to know a great deal more about long-term effects to soil and aquifers from inundations with wastes. Besides studying altered conditions for survival, propagation, and transport of pathogens, water microbiologists should pay more attention to oxidation and mineralization processes and their effects on the growth of chemolithotrophic and chemoorganotrophic organisms. Also needed is more research into potential groundwater contamination with endotoxins and other biotoxins from land disposal activities. Finally, better indicator systems are sorely needed to take into account properties unique to soil-aquifer ecosystems.

2. <u>Microbiology of Surface Water</u>

In Western Europe, agricultural, industrial, and urban expansion have led to a four to five-fold increase in water consumption over the past 100 years. For Denmark, as for many countries, increased demands for potable water have necessitated turning to nontraditional raw water sources. Presently, Denmark derives over 90 percent of its water from groundwater, which accounts for 20 percent of the total groundwater formation and 3 percent of the total precipitation over the country's surface area. However, in order to avoid markedly lowering the water table, Denmark is now attempting to meet demands by exploiting its surface water resources to a greater extent than previously. At the same time, surface water is increasingly being used as a repository for chemical and biological wastes; this trend could put many municipalities, and even nations, on a disaster course if corrective steps are not taken soon.

a. <u>Occurrence of Microorganisms in Surface Water</u>. Bacteria in lakes and streams are either part of the aquatic community or they are of exogenous origin (runoff, waste effluent, animals, or aerosols). Whereas types and numbers

of the indigenous flora are influenced mainly by the avail-
ability of nutrients, light, pH, temperature, and dissolved
gases, most transient bacteria (e.g., indicators, pathogens,
and soil bacteria) live a more or less passive existence in
surface water, their survival rates being determined more by
negative factors including UV light, predation, microbial
antagonisms, and sedimentation [See Section B.3 and E.1].
Therefore, one may expect a rise in the indigenous popu-
lations and a reduction in transitory microbes during the
summer months. Conversely, winter temperatures tend to
prolong survival of indicators and pathogens while curbing
activity of the endogenous aquatic community. Heavy winter
rains can cause soil runoff in an unprotected watershed and
convey nutrients (that stimulate the growth of indigenous
flora) and soil bacteria and fungi (that may temporarily
mask actual bacterial numbers) to surface waters. However,
the effects are generally short-lived.

(i) Chemoorganotrophic Bacteria. Chemoorganotrophic
bacteria depend on organic matter for energy as a principal
carbon source [See Section A.Intro.]. Aquatic chemoorgano-
trophs differ from soil chemoorganotrophs in being mostly
gram-negative rods. Dominant surface water bacteria belong
to the Flavobacterium-Cytophaga, Achromobacter-Acineto-
bacter-Alcaligenes-Moraxella and Vibrio-Aeromonas groups and
to the genus Pseudomonas; and their occurrence in surface
waters is related to depth. Together these bacteria can
comprise up to 90 percent of colony counts in surface waters
(Druce and Thomas, 1970; Yoshimizu, et al., 1976).

Chemoorganotrophs in lakes usually are encountered in
numbers of around 10^2 to 10^3 per ml (at 20°C). In Scotland,
three lakes were found to contain respectively 5.6 x 10^3,
3.0 x 10^4, and 4.1 x 10^5 chemooorganotrophs per ml at 20°C
incubation. However, colony counts at 20°C can exceed 10^6
per ml in highly eutrophic lake water. Even highly oligo-
trophic lakes (with 1 mg per liter or less organic matter)
will have a colony count of around 10 per ml (Godlewska-
Lipowa and Jablonska, 1972); and finished drinking water has
been shown to contain nutrients sufficient for growth of
bacteria when stored in containers at a favorable tempera-
ture and in the absence of microbial antagonisms [See Section
G.6].

Colony counts on plate count agar at 20°C are often
subject to considerable variation depending largely on the
organic matter content. The more fastidious of the chemo-
organotrophs require a minimum of 10 to 100 mg of organic

matter per liter (Zo Bell, 1943) and the less fastidious will grow in water containing as low as (or lower than) 1 mg of organic matter per l. Benthic chemoorganotrophs, especially those in the upper 10 mm of sediment, occur in much higher numbers and are composed largely of gram-positive bacteria such as Micrococcus, Corynebacterium, Actinomyces, Bacillus, and Clostridium.

Colony counts in streams and rivers vary according to dilution from rainfall and pollution from wastewater. When dilution is low and pollution high, as often occurs with heavy irrigation, bacterial levels will be high and flow rates low. The same holds true for urban communities that remove more water than they replace or that replace it in the form of wastewater. Colony counts at 20°C usually are higher for rivers and streams than for lakes and are higher at 20°C than at 37°C incubation [See Table A.2-1]. Quality criteria for river water are given in Table A.2-2. [See also Sections C.l.a, C.4.h, and D.6].

Certain pathogens and indicator bacteria can grow in the presence of low nutrient concentrations. Both Enterobacter aerogenes and Escherichia coli grew at nutrient levels up to 50 times lower than those required by Streptococcus faecalis as long as conditions were aerobic (Zo Bell, 1943).

(ii) Chemolithotrophic Bacteria. Chemolithotrophic bacteria can grow in aquatic environments of purely inorganic content [See Section A.Intro.]. Soluble salts and carbon dioxide are often present from mineralization and other processes when organic matter has settled in the sediment, depriving chemoorganotrophs of a nutrient source. However, chemolithotrophs can thrive under such relatively clean conditions (Terney, 1973). Table A.2-3 lists some of the important chemolithotrophs, classified on the basis of their growth requirements. Chemolithotrophs are instrumental in the nitrogen and sulfur cycles and can oxidize reduced iron and manganese compounds. Though not responsible for disease, they often are responsible for operational problems at treatment plants and taste, odor, and color problems at the consumer's tap [See Sections F.3.b and G.4].

Nitrification is carried out in the benthos under aerobic conditions, primarily by two chemolithotrophs, Nitrosomonas and Nitrobacter. Denitrification is usually

TABLE A.2-1

COLONY COUNTS IN FOUR RIVERS OF CZECHOSLOVAKIA

River	Colony Counts (per ml)	
	20°C	37°C
Danube	6,200	1,800
March	7,500	2,800
Vah	2,200	330
Hron	6,100	740

TABLE A.2-2

RIVER WATER QUALITY AS DETERMINED BY
NUMBERS OF CHEMOORGANOTROPHS AT 22°C

Quality of Water	Chemoorganotrophs per ml
Pure river water	< 500
Relatively pure river water	5,000 - 10,000
Moderately polluted river water	25,000 - 50,000
Polluted river water	≤ 100,000
Highly polluted river water	≤ 1,000,000

From Daubr.er, 1972.

TABLE A.2-3

CLASSIFICATION OF CHEMOLITHOTROPHIC BACTERIA

Category	Genera and Species
Obligate chemolithotrophs	Nitrosomonas europaea, Thiobacillus thiooxidans, Thiobacillus thioparus, Thiobacillus neopolitanus, Thiobacillus denitrificans, Thiobacillus ferrooxidans
Mixotrophs	Hydrogenomonas, Micrococcus denitrificans, Thiobacillus intermedius, Thiobacillus novellus, Nitrobacter agilis
Heterotrophic chemolithotrophs	Desulfovibrio desulfuricans, Thiobacillus perometabolis

From Rittenberg, 1972.

the result of reductions by chemoorganotrophs such as pseudo-monads, although Paracoccus denitrificans (a facultative chemolithotroph), Thiobacillus denitrificans (a strict chemolithotroph), and a few other chemolithotrophs are denitrifiers. Levels of nitrogen and the form in which it enters surface water will influence the numbers of nitri-fying bacteria; in turn, relative numbers of nitrifiers and denitrifiers will decide the ultimate form nitrogen is to take: whether ammonia, nitrate, nitrite, or nitrogen gas which escapes to the atmosphere.

Sulfur, upon entering surface waters by way of the atmosphere or through wastewater discharge, sets in motion a number of microbial oxidations and reductions carried out by chemolithotrophic and chemoorganotrophic bacteria. These reactions can lead to the formation of various undesirable sulfurous compounds that not only produce bad tastes and odors, but that also can degrade concrete structures used for water storage and distribution [See Section G.4.b].

There may occur in surface waters both sulfur oxidizing and sulfate reducing chemolithotrophs. Thiobacillus species and Beggiatoa can oxidize sulfides, elemental sulfur, or thiosulfate to acceptable or unacceptable forms. Although all species of Thiobacillus, except T. denitrificans, are obligate aerobes, they inhabit primarily the benthic zone (in numbers as high as or higher than 10^6 per g: Fjerding-stad, 1969; Terney, 1973) and can oxidize hydrogen sulfide (which is found only in the oxygen-poor hypolimnion) to sulfuric acid. The presence of hydrogen sulfide may be due to a microbial decomposition of proteins or to the anaerobic reduction of sulfates (or other reducible sulfur compounds) carried out by the gram-negative chemoorganotrophs Desulfo-vibrio (nonsporeforming) and Desulfotomaculum (sporeforming). Counts of 10^6 Desulfovibrio and 10^5 Desulfotomaculum per gram have been found in bottom sediments in Denmark (Fjerding-stad, 1969). The thermophile Desulfotomaculum is respon-sible for hydrogen sulfide odors emanating from hot water tanks where conditions have become anaerobic.

In view of the problems caused worldwide by iron bac-teria in surface water, well water, and groundwater sup-plies, it is surprising that so little is known about actual numbers occurring in raw source waters. Biological oxi-dation of ferrous compounds to insoluble ferric compounds with consequent encrustations along pipes and in reservoirs and organoleptic changes in finished water, has been reported in Canada, the U.S., the U.K., Scandinavia, Australia,

India, and some African countries (Cullimore and McCann, 1977). In addition, iron oxide or iron hydroxide deposits on bacterial cell surfaces form a protective layer that can hamper the effectiveness of disinfection [See also Sections F.3 and G.3].

The chemolithotroph Thiobacillus ferrooxidans has been found in numbers as high as 10^6 per ml in iron-containing waters of Denmark (Fjerdingstad, 1956). Gallionella, Crenothrix, Clonothrix, Toxothrix, and Lieskeela are probably chemolithotrophic and aerobic or microaerophilic; and all have been isolated from surface waters (Cullimore and McCann, 1977). Iron bacteria known to be chemoorganotrophs are Sphaerotilus and Leptothrix, both of which can oxidize ferrous and manganous compounds. They have been isolated from both uncontaminated and contaminated iron-containing waters throughout the world.

Under acidic conditions, only the biological oxidation of iron is significant, whereas at a neutral pH, both biological and chemical iron oxidation can occur. Iron bacteria grow within a temperature range of 5 to 34°C if there is more than 0.2 mg of ferrous ions per liter and if the pH is within a range of 5.4 to 7.2. Some iron bacteria, notably Sphaerotilus, can utilize inorganic compounds for energy and carbon when the required vitamins also are present.

(iii) Phototrophic Bacteria. Photosynthetic organisms, primarily the aquatic bacteria, can inhabit surface waters. Included in this diverse physiological community are genera from the families Rhodospirillaceae (nonsulfur purple and brown bacteria), Chromatiaceae (sulfur purple bacteria), and Chlorobiaceae (green sulfur bacteria). Bacteria from these families oxidize reduced inorganic substances such as molecular hydrogen, hydrogen sulfide, elemental sulfur, or low molecular weight organics. The presence of iron seems important to their metabolism. They require a highly reduced or anaerobic environment in which to carry on anoxygenic photosynthesis (where free oxygen is not a by-product) and therefore occupy a stratum of minimal light penetration near the benthic zone (Buchanan and Gibbons, 1974).

In contrast, the cyanobacteria (or blue-green bacteria, formerly classified as blue-green algae) inhabit the aerobic zone and carry on oxygenic photosynthesis. Unlike the majority of anoxygenic phototrophs, cyanobacteria can fix

atmospheric nitrogen; hence, they can thrive in aquatic environments that lack a combined nitrogen source such as ammonia or nitrate. Their prevalence in oligotrophic, mesotrophic, and especially in phosphate-rich eutrophic bodies of water is attributed to these dual abilities to photosynthesize and to fix nitrogen. It is generally agreed that the growth of cyanobacteria is limited only by the availability of phosphates. Hence, any waters rich in phosphates, such as those receiving phosphate-laden waste-water, tend to accelerate the growth of the organisms.

Massive blooms of species from some genera (e.g., Anabaena, Oscillatoria, Microcystis, Lyngbya, Gleotrichia, Anacystis) have created considerable problems in water treatment facilities by clogging filters and imparting noxious tastes and odors (Benson-Evans and Williams, 1975) [See Section F.3.b]. Some of the cyanobacteria have also been reported to produce toxins that, if ingested, may cause gastrointestinal disturbances (Mackenthun, et al., 1967) [See accompanying section]. Some of the genera mentioned above have been used as indicator organisms for assessing the degree of eutrophication. Great numbers of fish inhabiting shallow waters have perished in winter as a result of frequent severe summer blooms: when the photosynthetic activity of aquatic plants is hindered due to reduced surface aeration and solar insulation (especially in the case of ice cover), dissolved oxygen is depleted as decomposing masses of cyanobacteria settle to the benthic zone.

(iv) Other Microorganisms. Numbers of algae, protozoa, and fungi occurring in a river or lake reflect its nutrient state. Predominant classes of algae occurring in lakes are the Chlorophyceae (green algae) and Bacillariophyceae (diatoms). Up to 100 species of algae have been found in lakes; yet, high diversities and low numbers of algae signify relatively clean conditions whereas low diversities and high numbers signify eutrophic conditions. Algae are photoautotrophs in the light, but can be chemoorganotrophs in the dark. Flagellates of the classes Euglenophyceae and Chrysophyseae are most often implicated as the cause of tastes described as bitter or sweetish and odors described as "fishy", "grassy", "musty", and "earthy" (Palmer, 1962). Freshwater protozoa include genera of the classes Flagellata, Ciliata, and Sarcodina, the latter containing in it the pathogens Acanthamoeba, Entamoeba histolytica, and Naegleria fowleri [See Section B.1.c].

Fungi, including yeasts, are chiefly soil organisms and their mostly accidental presence in water does not appear to affect significantly the quality of drinking water. Yeast cells normally comprise < 1 percent of the microbial flora, but may exceed this level in streams and rivers that receive effluent from certain industries such as breweries or metal works. Yeasts, predominantly Rhodotorula, Candida [See Section C.2.f], Cryptococcus, and Torulopsis were isolated from the St. Lawrence River (Canada) in numbers of from 0 to 9,500 cells per ml (Simard, et al., 1970). Also common to freshwaters are the fungi Trichosporon, Cladosporium, Endomyces, and Deboromyces (Buck, 1975; Daubner, 1972).

b. Lakes and Reservoirs. Lakes and reservoirs (which include any depressions of land created by natural causes, such as glacial and volcanic action, or through human effort, that retain water from rain, rivers, or springs) are the bodies of water most frequently used as sources of drinking water in the U.S. Yet, very little is known about the ecology of microorganisms, and even less about viruses, in such waters.

The waters in lakes and reservoirs, as a group, differ markedly in chemical composition and are frequently classified on the basis of nutrient content or degree of biological productivity. Biological productivity here refers to the amount of organic matter synthesized from inorganic substances through photosynthetic activity; and productivity, as a rule, is a function of the levels of nutrients (e.g., C, N, P, and S) present in the water. Oligotrophic lakes are those lakes relatively low in nutrients or relatively infertile in which nutrient recycling is of the autochthonous (self-nourishing) type. Eutrophic lakes, on the other hand, are productive lakes rich in nutrients of which the major portions are derived from the external environment (allochthonous). Lakes that fall between these two extremes are considered mesotrophic.

Microbial populations within oligotrophic lakes are rich in species diversity but low in numbers; in excessively eutrophic lakes, as a rule, there is less species diversity but a massive increase in the populations of a few species, as in the case of algal blooms. These few typically dominant species (of the genera Anabaena, Microcystis, Lyngbya, and Anacystis) are frequently referred to as index species of eutrophication or pollution.

Some of the major causes of accelerated eutrophication are the discharge of nutrient-rich effluents from sewage plants and septic tanks and of farm runoff. Obvious undesirable consequences of accelerated cultural eutrophication are an increase in turbidity, promotion of a toxic algal bloom [See Section A.2.c], excessive stratification of dissolved oxygen in the summer, or depletion of dissolved oxygen in the winter. Depletion of dissolved oxygen during the winter is attributable to aerobic decomposition of accumulated organic matter (e.g., dead algae and weeds) which removes dissolved oxygen from the water. Consequences of the depletion of oxygen include a drastic alteration in distribution of micro- and macrocommunities within the lake. Anaerobic digestion of sediment organic material by indigenous bottom-dwelling organisms (such as species of Desulfovibrio, Desulfotomaculum, Butyrivibrio , Selenomonas, Clostridium, etc.) generally results in production of reduced inorganic ions (e.g., Fe^{++} and Mn^{++}) as well as products that impart undesirable tastes and odors.

Most lakes and reservoirs serving as community water sources have characteristic zonation and temperature stratification. Most lakes are rimmed by a relatively shallow littoral zone where nutrient accumulation is highest; further offshore is the limnetic or photic zone where sufficient light is available for photosynthetic activities by primary producers (the phytoplankton), and a profundal zone where photosynthetic activities cease as a result of insufficient light penetration.

The bacteria within the littoral zone are largely representative of soil microflora, but conditions favor the survival of nutritionally nonfastidious gram-negative organisms. Among the notable bacteria frequently encountered here are oxygenic, nitrogen-fixing cyanobacteria (formerly known as blue-green algae); anoxygenic, photosynthetic bacteria (members of Rhodospirillales); chemolithotrophic nitrogen-fixing bacteria (members of Nitrobacteraceae); organotrophic bacteria (such as species of Pseudomonas, Aeromonas, Alcaligenes, and Flavobacterium); gram-positive bacteria (such as species of Bacillus, Micrococcus, Mycobacterium, and Corynebacterium); and various species of Actinomyces. The discharge of sewage effluent may add members of the family Enterobacteriaceae, such as species of Escherichia, Proteus, Enterobacter, Yersinia, and others, some of which may be pathogenic (species of Salmonella, Shigella, Vibrio, etc.).

The viability of pathogens, or of bacteria considered
as potential or opportunistic pathogens, is dependent on
such factors as available nutrients, temperature, and pH, as
well as biotic factors such as predation and antagonism.
The grazing of bacteria by protozoa, bacteriovorous bacteria
(Bdellovibrio), and bacteriophage in water may destroy
millions of bacteria. Further, antibiotic substances produced
by some microorganisms may destroy other species. The role
of cyanophages, which attack cyanobacteria, remains to be
evaluated. In addition, lakes rich in suspended solids may
harbor considerable numbers of epiphytes or peritrophic
bacteria (such as species of Caulobacter, Hyphomicrobium,
Seliberia, Thiodendron, Gallionella, Leptothrix, Crenothrix,
and Clonothrix). Some of these have been known to cause
considerable problems in the water treatment process, either
by fouling sand filters or imparting undesirable tastes and
odors.

Lakes that are sufficiently deep generally display
temperature stratification during summer. The region of
rapid temperature drop with depth is known as the thermo-
cline; water above the thermocline is called epilimnion, and
below, the hypolimnion. As a rule, the thermocline layer
prevents mixing of epi- and hypolimnion water during summer,
but in spring and fall when the temperature of the epilimnion
reaches approximately 4°C (the temperature at which water is
densest), the cold water begins to sink and causes extensive
mixing of both layers of water resulting in complete circula-
tion (holomixis). Lakes which turn twice a year are called
dimictic, but there are lakes which fail to turn (amictic),
ones which turn once a year (monomictic), or those which
turn constantly (polymictic). The last group of lakes are
rarely used as source water because they are either under
permanent ice cover or are located in colder regions.

As a rule, distribution of micro- and macroflora within
the lake ecosystem is neither constant nor necessarily
predictable except within wide limits. This is because the
conditions of the littoral zone change hourly, from week to
week, or season to season, as this region of the lake is
subject to the intrusion of sewage effluent, soil runoff,
and other external disturbances, such as wind and wave
action, utilization of the water by wild animals, and abstrac-
tion of water for various human uses.

The total number of microorganisms within the limnetic
zone may be a few hundred per milliliter during the quiescent
period, but the microbial population immediately after

circulation may reach a few million per milliliter. This change is primarily attributed to disturbance of the bottom sediment and upwelling of nutrients as a result of the circulation. The organic matter stirred up from the benthic zone temporarily furnishes a rich and varied pabulum. Numerous species of aerobic and facultative organisms (Bacillus, Micromonospora, Micropolyspora, Chromobacterium, and Flavobacterium) as well as some strict anaerobes (Bacteroides, Desulfovibrio, Desulfotomaculum, Sporosarcina, Clostridium, Methanobacterium, etc.) previously present in undetectable numbers may multiply enormously, frequently reaching millions per milliliter, and some previously numerous species may be suppressed by newly multiplying antagonistic species. The circulation may be accompanied by increased turbidity and the lakes with an excessively eutrophic condition may actually show an increase in BOD content as well as production of a noticeable hydrogen sulfide odor. Circulation may continue for a few days or weeks, depending on such factors as rate of water temperature change, average depth of the lake, etc.

Microbial communities in lakes and reservoirs are extremely complex and fragile. They are readily altered by internal as well as external influences. External influences not under local control, such as "acid rain", are of considerable concern in the deterioration of water quality especially in those lakes which lack a limestone base. However, cultural eutrophication of a lake is the single most important factor in the deterioration of water quality. Eutrophic lakes tend to promote the bloom of various algae, including toxigenic species; lengthen the viability period or even promote "aftergrowth" of undesirable bacteria; cause increased turbidity; and impart undesirable odors and tastes. The water derived from such lakes requires extensive and costly treatment. Thus, lakes and reservoirs serving as source waters must be protected from external influences that tend to deteriorate water quality.

c. Toxic Cyanobacteria in Raw Water Supplies. There are numerous reports about poisonings of livestock, pets, and wildlife by ingestion of waterblooms of cyanobacteria; and mounting evidence indicates that man may also be affected by toxic cyanobacteria through water supplies (Dillenberg and Dehnel, 1960). Outbreaks of human gastroenteritis which occurred in Charleston, West Virginia, and the area served by the Anacostia Reservoir near Washington, D.C., in the drought years of 1930 and 1931, were attributed to growths of cyanobacteria in the water supplies. The usual bacterial causes

of gastroenteritis could be excluded, but direct toxic effects of the cyanobacteria or associated bacteria were not clearly established.

Recent cases of cyanobacterial toxicity to humans have been reported by Dillenberg and Dehnel (1960) who described cases of human gastroenteritis resulting from the ingestion of heavy blooms of Anabaena, Microcystis, and/or Aphanizomen from a number of lakes and reservoirs in the province of Saskatchewan, Canada. The most convincing case cited in this review is of a physician who accidentally fell into a lake containing a heavy bloom of cyanobacteria and swallowed an estimated half-pint (250 ml) of water. A few hours later, he suffered stomach pains, nausea, vomiting, painful diarrhea, fever, headache, and pains in limb muscles and joints which lasted for two days. Samples of slimy green stool subjected to laboratory analysis for pathogens (including virus) revealed no Salmonella or Entamoeba, but many cells of Anabaena and Microcystis.

By isolating, growing, and testing (by intraperitoneal or oral administration to laboratory mice) cultures of the most common bloom-forming species (Anabaena flos-aquae [L.] de Breb., Microcystis aeruginosa Kutz. emend Elenkin, and Aphanizomenon flos-aquae [L.] Ralfs.) from a number of different lakes, ponds, and reservoirs, investigators have shown that there are toxic strains of these organisms. They have, in addition, been able to determine fully or partially the chemical structure of at least one toxin from one strain of each of these three species. A number of toxins from newly isolated strains of Anabaena flos-aquae have recently been described (Carmichael and Gorham, 1978), and a toxin from a new strain of Microcystis aeruginosa has recently been found. Slower-acting toxins produced by bacteria associated with these cyanobacteria have also been noted (Gorham, 1965).

Known strains of Anabaena flos-aquae produce four (perhaps six) toxins (Carmichael and Gorham, 1978). The first of these, called anatoxin-a, is an alkaloid with both pre- and post-synaptic neuromuscular blocking activity. Anatoxins-b and d are fast-acting and are suspected of being alkaloids. Anatoxin-c is slower-acting and is suspected of being a peptide.

The effects of a toxin produced by a new strain of Microcystis aeruginosa, called type c, are indistinguishable from those produced by anatoxin-c. Microcystin, the cyclic polypeptide toxin produced by Microcystis aeruginosa NRC-1,

affects the cardiovascular system and produces character-
istic lesions of the liver when administered by intraperi-
toneal injection or by the oral route to mice, guinea pigs,
rabbits, chickens, ducks, calves, and a lamb (Konst, et
al., 1965). Toxic mixed blooms of Aphanizomenon flos-aquae
and Microcystis aeruginosa produced signs that were indis-
tinguishable from microcystin poisoning (Gorham, 1965).
Since no cultures were successfully established, it could
not be decided whether the toxin came from the Aphanizomenon,
the Microcystis, or from both. Blooms of Microcystis toxica
Stephens have been reported to produce an alkaloid hepa-
totoxin of unknown structure.

An atypical strain of Aphanizomenon flos-aquae produces
an ichthyotoxin, called aphantoxin, which kills mammals
(Gentile and Maloney, 1969). It is a mixture of which one
component is, surprisingly, the known alkaloid saxitoxin.
Saxitoxin is the paralytic shellfish toxin which affects
man and is produced by the marine dinoflagellate Gonyaulax
catenella (Schantz, et al., 1975).

The question of whether or not toxins from cyanobacteria,
if present in raw water supplies in significant quantities,
would survive water purification practices has been considered.
Cases in the province of Saskatchewan of poisoning associated
with the presence of cyanobacteria led to tests for the
occurrence of toxic cyanobacteria in blooms of two impound-
ments that served as the water supply for three of the
province cities. Raw untreated water was either mildly or
fatally toxic as determined by intraperitoneal injections
into mice (Dillenberg and Dehnel, 1960). These same authors
reviewed tests conducted by Wheeler and coworkers in which
they found that toxins produced by Microcystis aeruginosa
blooms maintained their toxicity after the laboratory
equivalent of water purification processes, including alum
coagulation, filtration, chlorination, and activated carbon
treatment. Massive amounts of activated carbon were needed
to render the effluent non-toxic.

Gorham (1962) considered that two of the known cyano-
bacterial toxins, microcystin and anatoxin-a, would normally
be removed or inactivated by the usual water treatment
procedures. Moreover, the large doses and high percentage
(75 percent or higher) of toxic strain necessary to produce
symptoms in animals suggest that the comparatively small
amounts of toxins that might remain in a drinking water
supply after treatment probably would not be sufficient to
cause human poisoning.

One must also consider that strains of different species of cyanobacteria are capable of producing a great variety of toxins, individually and in mixtures. Since some are toxic to man, it could be that others, which may not be eliminated by standard water treatment practices, may also prove toxic. This suggests a need for a comprehensive study of the effects of water treatment practices upon toxins produced by different strains and species of cyanobacteria.

If one could select a set of representative water treatment practices to be evaluated as a model laboratory-scale process, the suggested investigation could proceed in three stages. For each of several known toxic strains of cyanobacteria, one would produce a mass culture and determine the extent of detoxification which resulted from the model process. Then one would concentrate naturally-occurring blooms of cyano-bacteria from raw water supplies and measure the amount of detoxification, by the model process, of those blooms which were found to be toxic. Finally, one would grow laboratory cultures from the toxic natural blooms and attempt to confirm the detoxification results more critically.

Such a study would go far towards evaluating the risk to man of consuming treated water produced from sources containing toxic cyanobacterial blooms. It would also help to identify specific treatment practices which are capable of detoxifying such source waters and to suggest possible improvements.

d. Sampling, Transport, and Microbiological Requirements for Raw Surface Water. A council directive submitted to the director of the Commission of the European Communities (Commission of the European Communities, 1975) has proposed that raw surface waters be monitored using microbiological parameters; and a more recent directive (Commission of the European Communities, 1978) has included suggestions for sampling protocol, frequency, and transport, along with ways to ensure analytic reproduceability [See Table A.2-4]. According to this proposal, samples are to be collected from a zone 50 cm below the surface and 50 cm above the bottom; or, if not possible, samples are to be taken at a depth midway between the surface and the bottom. These speci-fications are meant to ensure that samples will contain bacterial numbers that accurately reflect levels in the water phase and not those in resuspended sediment, from which much higher bacterial counts would be obtained. However, most saprophytic bacteria are concentrated in the few millimeters below the surface.

TABLE A.2-4

PROPOSED WATER QUALITY CRITERIA TO BE USED FOR
RAW SURFACE WATER SUPPLIES

Category of Raw Surface Water	Samples/Yr, for Population Served		Maximum Concentration Allowed			
	$< 10^5$	$\geq 10^5$	Coliforms/ 100 ml	Thermo-tolerant Coliforms/100 ml	Fecal Streptococci 100 ml	Salmonella
A1[a]	1	3	50	20	20	0/5 liters
A2[b]	2	6	5,000	2,000	1,000	0/1 liter
A3[c]	4	12	50,000	20,000	10,000	

[a] Surface water requiring only simple physical treatment (filtration) and disinfection.

[b] Surface water requiring physical and chemical treatment (coagulation, flocculation, filtration) and disinfection.

[c] Surface water requiring more extensive physical and chemical treatment (coagulation, flocculation, filtration, along with supplementary treatment such as active carbon) and disinfection with chlorine and possibly ozone.

(COMMISSION OF THE EUROPEAN COMMUNITIES, 1975 AND 1978)

On the other hand, strong correlations were found between presumptive total coliform MPN's in sediments and virus numbers in recreational coastal waters (Goyal, et al., 1978). Moreover, sediments can serve as a reservoir for enteroviruses which may become resuspended in the water phase during heavy rains (la Belle and Gerba, 1979). The microbiological quality of sediments also needs periodic evaluation, possibly by surveying sediment samples for coliforms and thermo-tolerant coliforms as well as fecal streptococci or Clostridium perfringens [See Section C.1].

As wastewater treatment practices become more complex, there is a greater possibility of reducing indicators without necessarily producing concomitant reductions in some of the more resistant organisms such as viruses and protozoa. Both viruses and parasites may persist for extended periods in water and are fairly resistant (especially parasites) to chlorine [See Section B.3, E.1, and E.5.a]. By not including tests for viruses, and perhaps certain parasites, the Commission of the European Communities proposal does not take into account consequences from contamination of surface water with treated wastewater.

Another pollution parameter not dealt with in the Commission's proposal is that of colony counts at 20 to 22°C, which would enable detection of psychrophilic organisms. Tests for these organisms could serve to indicate any heavy influx of organic and inorganic pollutants into surface waters [See Sections C.1.a and D.6]. Such an occurrence could give rise to algal and cyanobacterial blooms and could increase opportunities for biotoxin production. In addition, the presence of several potentially pathogenic bacteria, and others of special concern to the food industries, has been associated with these blooms (potentially pathogenic species of Aeromonas have been observed in large masses of dying algae: Simudi, et al., 1971). Species of Klebsiella, an opportunistic pathogen, are known to propagate in water containing wastes from textile, lumber, and sugar industries. Strains of these bacteria frequently are adapted to colder environments and are able to grow at temperatures ranging between 0 and 15°C [See Section C.2.d].

e. Protection of Surface Water. It is important to recognize the connection between surface water contamination problems and waste disposal problems. One will not be solved without the other, for even adequately treated surface waters have caused disease when recontamination occurred

during distribution. Out of 54,935 cases in the U.S. (1946 to 1970) attributed to surface water contamination, 8,992 of these were associated with "treated" surface water (Craun and McCabe, 1973).

Surface water, usually to a far greater extent than groundwater, is exposed to various kinds of contamination. In countries where the drinking water supply is derived from surface waters, measures to protect against chemical, physical, and biological deterioration need upgrading. Laws to protect surface water should be more restrictive and more specific; and they must be backed up with adequate provision for enforcement. The discharge (including sub-surface seepage) of raw or inadequately treated waste into raw source waters should be prohibited; and minimum distances from freshwater sources for disposal of wastes need precise delineation. Dogs and motor boats should not be allowed, nor is swimming acceptable in waters designated for potable use. Tight restrictions should be placed on camping, sailing, and other recreational activities in or around surface water sources [See also Section E.1].

However, no amount of regulation will eliminate all microbiological or chemical problems because surface waters will always be in unavoidable contact with wild animals, especially migratory birds, and because some organisms (e.g., cyanobacteria, Pseudomonas, Alcaligenes, Chromobacter, Acinetobacter, Vibrio, Aeromonas, Yersinia, and Bacillus) may continue to grow (albeit in lower numbers) after all waste discharge has ceased. The most difficult, yet the most critical, issue to deal with is that of initiating steps to curb entry of pollutants into surface waters. Beyond this, authorities can only ensure hygienic safety by conducting routine and appropriate analyses of raw source waters and by making sure that all surface waters used for drinking purposes receive complete and continuous treatment before distribution.

Programs for routine analysis should be selected on the basis of knowledge about: (1) what conditions favor propagation of pathogens, potential pathogens, and cyanobacteria; (2) what conditions favor production of undesirable compounds by chemolithotrophs (notably iron bacteria) and chemoorganotrophs; (3) types of information that can be obtained from microbiological examination of sediments; and (4) what hazards are associated with the presence of viruses, protozoan cysts, metazoan eggs, and endotoxins and other biotoxins in surface water. Mapping of waterborne disease

outbreaks [See Section B.5] should be carried out in con-
junction with microbiological monitoring, with special
attention paid to possibilities for growth of hitherto
unrecognized pathogens such as Yersinia enterocolitica [See
Section B.1.a(iii)], Campylobacter fetus [See Section
B.1.a(viii)], and Legionella pneumophila (Center for Disease
Control, 1978e). As different pathogens exhibit different
virulence in the host and different stabilities in the
aquatic environment [See Sections B.3 and B.4], the kinds as
well as numbers of pathogens in a given source water should
be determined prior to decisions about type and rigor of
drinking water treatment [See Section E].

All of these issues are part of one overriding concern:
that of finding ways, some of which have been discussed in
this report, to ensure that surface water used for drinking
purposes shall be protected, to the utmost extent possible,
from the discharge, runoff, or seepage of wastes.

3. Survey of the Bacteriological Quality of Raw Water
   Supplies from Nine Countries

An important consideration to be dealt with in Topic
Area A, and one which impinges on every other section of
Project Area III, concerns the differences from one water-
works to the next and from one country to the next, in
bacteriological quality of the raw water supply. The tables
and text that follow are the result of surveys taken of
waterworks facilities from nine developed countries (Norwegian
Institute of Water Research, 1980). In order to draw a
basis for comparison, the parameters chosen were total and
thermo-tolerant coliforms, the widely used and accepted
indicators of water quality.

One problem encountered was the variation among coun-
tries in methods for sampling and analysis [See Section D.1
to 5]. Another weakness of the study is that, except for
the Netherlands, Norway, and Sweden, information from water-
works in the various countries surveyed represents only a
small part of the total raw water supply and population
served. On the other hand, each country's national contact
for the drinking water microbiology project, who was respon-
sible for collecting data, was instructed to choose repre-
sentative raw water supplies wherever feasible. Though the
flaws in this study cannot be ignored, neither must the
reader discount the knowledge to be gained from this type of
study (one that no international organization has as yet
undertaken). It is hoped that documentation and comparisons

of raw water quality in the various countries participating in this survey will lead to improvements where warranted. Data were gathered principally from sampling and analyses of raw water during the year 1977, except in cases where no samples had been taken that year. Results were then requested for the previous or the following year.

a. Size of Waterworks, Source of Raw Water, and Sampling Frequencies. The number of people served by a waterworks will be reflected in the size of that facility [See Table A.3-1]. Thus, small waterworks predominate in Norway, most facilities in Sweden serve a medium-sized population, and the other countries surveyed (except France) presented data from waterworks, most of which serve > 20,000 people. Apparently all but one waterworks (UK) in this study serve > 1,000 people. Data from Norway and Sweden are the most complete, representing the majority of waterworks in these countries serving > 1,000 people.

Norway derives most of its drinking water from surface water sources. Although there are more suppliers of groundwater than of surface water in Sweden, a larger proportion of the population receives water from surface sources; likewise, in the Netherlands, 50 percent or more of the population uses surface-derived water [See Table A.3-2].

Whereas most waterworks in Sweden sample one to six times per year, the sampling frequency in Norway falls more evenly into all the categories listed in Table A.3-3. A large number of suppliers take no samples, but there also is a sizeable group of them that sample > 26 times per year. In Sweden, only groundwater may bypass routine monitoring and treatment, but this also can be true of some surface water supplies in Norway. Although epidemiological and environmental conditions in Norway appear stable, Norwegian regulations specify that treatment and routine bacteriological monitoring of all surface water supplies are required. One explanation for the apparent discrepancy is that many Norwegian waterworks have not yet received governmental licensing. The other countries (except France) reported high sampling frequencies, which probably is due either to the size of the waterworks or the level of pollution.

US	0	0	0	2	8	10

b. Bacteriological Quality of Raw Water Supplies.
Many surface water sources in Norway, and some in Sweden,
show high standards of bacteriological quality (Sweden tests
for total, but not for thermo-tolerant, coliforms). Except
for Canada, which reported relatively low coliform levels at
some waterworks, raw surface water in the other countries
surveyed appears to be of low bacteriological quality [See
Tables A.3-4 and A.3-5]. In contrast, but to be expected,
groundwater sources in most countries were of high bacterio-
logical quality (results from the FRG are based only on
tests for thermo-tolerant coliforms in groundwater) [See
Tables A.3-6 and A.3-7].

Most of the waterworks surveyed, in most of the countries,
reported extensive treatment of water prior to distribution
to the consumer. In cases where the raw water received only
minimal (aeration or microstraining whereby water is filtered
through finely woven fabrics of stainless steel to remove
suspended solids) or no treatment, the bacteriological
standards usually indicated water of potable quality [See
Table A.3-8]. Exceptions were noted for France, Norway, and
Sweden. All minimally treated or untreated source waters
reported for Canada, France, and the U.S., and most in
Sweden are derived from aquifers; in Norway, however, they
are derived largely from surface water sources.

c. Conclusion. This tabulation serves to point up
the large variation in raw water quality in the different
countries surveyed. Where the raw water quality is good,
sampling frequencies often tend to be low and the water
receives little or no treatment. However, infrequent sampling
and testing cannot be expected to alert a supplier quickly
to changes in conditions in the community or to a sudden
influx of contaminants into the water supply.

Countries such as Norway and Sweden, where waterworks
are numerous and predominantly of small or medium size, have
greater flexibility in finding means to supply safe, potable
water. At the same time, however, there is less centralized
control and uniformity of policy for managing and treating
raw water supplies.

Those countries fortunate enough to possess water of
high bacteriological quality are encouraged to enact policy
that will assure its continued excellence.

Sweden	35	3	2	18	58
US	3	0	0	0	3

[a]Minimum treatment -- microstraining or aeration.

4. Summary

As the use of water and the disposal of wastes become more diversified and intensive, those in positions of authority will be required to effect needed changes in resource management policy. In order to make correct decisions, a water supplier will have greater need of information about the impact of water from aspects of human activity, from the siting of waste discharges, meat processing plants, and stockyards, to the local incidence of disease.

Currently most drinking water is derived from surface water sources; but in many cases, deteriorating quality has led to the search for water, such as ground water, that is better protected from human activities. At the same time, the increasing use of soil in treatment and disposal of wastewater raises safety questions in that the dynamics of microorganisms in soil and groundwater are, as yet, imperfectly understood and are inadequately controlled by bacteriological monitoring of aquifers.

Each of these entities, surface water and groundwater, brings with it a distinctive ecological system that responds differently to inputs of waste at different seasons; hence, byproducts of microbial interactions with organic and inorganic matter can be vastly dissimilar, as can conditions for survival and propagation of indicators and pathogens. Surface water, although more vulnerable and more enriched with nutrients and aquatic flora, is essentially a hostile environment to human intestinal microorganisms. Groundwater, which usually occurs as a result of some form of soil filtration, is relatively free of microorganisms. However, once pollution of the aquifer has taken place, conditions favor the persistence of whatever organism initially gained entry. It is important, therefore, that water authorities regularly monitor groundwater, as is generally recommended for surface water, and that they be vested with some legal recourse to impose sanctions in the event of any infringement of regulations.

Where large populations receive their water from one central supplier there is an inherent susceptibility to total disruption of the water supply as a result of a war or natural disaster, especially if alternative raw water sources are limited. On the other hand, if circumstances such as war necessitated that many people gather where normally only a few people lived, it would be incumbent on the responsible agency to have on hand sufficient volumes of potable water.

A comparable problem, in terms of availability of potable water, arises whenever large numbers of people are assembled together at resort areas during holidays.

Protection of our source waters will require more than just good intentions if future generations are to receive from their governments a sufficient quantity of safe and palatable drinking water. Careful and appropriate micro-biologic monitoring along with prompt correction of problems are essential.

B.   MICROBIAL PATHOGENS TRANSMISSIBLE
BY WATER

Drinking water is a potential vehicle for pathogenic organisms if it becomes contaminated with human or animal feces. Fecal contamination can occur at the raw water source or anywhere along a distribution system. The presence of fecal contaminants in finished water can also result from accidental or routine inefficiency during the treatment and disinfection of a raw water. A result of such fecal contamination may be that the consumer will ingest some quantity of bacterial, viral, or parasitic organisms. The effects of these will depend both on the demographic and epidemiologic conditions, and on the overall numbers and virulence of the organism ingested.

The problem of transmission of microbial pathogens through drinking water has changed with time; our perception of the problem has also been changed by the development of new research results. Certain bacteria of fecal origin (e.g., Salmonella, Shigella, and Vibrio cholerae) are less prevalent than they once were, but are now more likely to have acquired some resistance to antibiotics. Other microorganisms, such as several of the enteric viruses, have been held in check over the last 25 years. However, there are those (such as the hepatitis A virus) which still pose problems that are far from being solved. Likewise, there appear to be more frequent occurrences of gastroenteritis in which the causative agent is undetermined but strongly suspected of being a virus. Parasitic protozoa, such as Giardia lamblia, also seem to be an occasional cause of waterborne gastroenteritis.

The most important epidemiolgic issue to be addressed by the developed countries is the extent to which various microorganisms can cause sporadic cases or inapparent infections in the consuming population via the water supply route. To be able to predict accurately, one must not only understand epidemiologic facts, but must also take into account conditions under which pathogens survive in water

and retain their capacity to infect. There are deficiencies in present information gathering systems and in methods for identifying the responsible waterborne agent. Therefore, if decisions are to be made on the basis of current epidemiological data, the limitations to this approach must be recognized.

Research on and detection of pathogenic microorganisms in polluted drinking water is hampered by various factors associated with waterborne spread of disease:

1. A mass infection leading to epidemic manifestations in the consumers is generally sporadic and isolated rather than regular and repetitive.

2. Several days or even weeks can intervene between contamination of the drinking water and appearance of the first symptoms of illness. By the time water is suspected of being the vehicle of transmission the pathogenic agents most often will have disappeared from the contaminated water.

3. Even when the causative agent remains present in the water, its numbers are usually quite low compared to total bacterial densities in the water.

4. It is often necessary to eliminate other interfering organisms present in the sample which could otherwise mask the presence of pathogens.

5. Finally, the choice of recovery methods must take into account probable stressed states of pathogens derived from a more or less hostile aqueous environment.

For all of these reasons, the following protocol is especially important when culturing for microorganisms in water:

1. Concentration of an appropriate volume of water sample.

2. Enrichment (in certain cases pre-enrichment) in specific liquid media and transfer to solid selective media.

3. Use of an optimal incubation temperature, chosen on the basis of the suspected causal agent.

The incidence of pathogenic organisms in drinking water, and the means by which information about them can be obtained, are the concerns of this section. Most papers in the first part, dealing with individual pathogens, are organized according to the format: (1) characterization and pathogenesis, (2) stability and sources, (3) epidemiology, and (4) detection methods.

1. Categories and Properties of Waterborne Microbial Pathogens of Humans

   a. Bacteria

   (i) Salmonella. The genus Salmonella is made up of gram-negative, nonsporeforming, generally motile bacilli having many biochemical reactions in common with other members of the family Enterobacteriaceae (Buchanan and Gibbons, 1974). It is a very large group consisting of 1,200 known serotypes, classified according to possession of O and H antigens. Biotypes, determined by different sugar fermentation patterns, or serotypes demonstrated to be resistant to antibiotics can serve as markers in epidemiological investigations. Plasmid transfers with various strains of Enterobacteriaceae over the last several years have conferred antibiotic resistance to certain of the Salmonella serotypes.

   All serotypes of Salmonella are pathogenic to humans, causing mild to acute gastroenteritis and very occasionally death. Typhoid fever, caused by S. typhi and paratyphoid fever, caused by S. paratyphi A or B are both enteric fevers that occur only in humans. The other Salmonella serotypes are responsible for foodborne intoxication accompanied by mild to acute gastroenteritis, but rarely death. Referred to as salmonellosis, these milder forms occur frequently in humans and wild or domestic animals.

   The organism grows either continuously or intermittently in the intestines of sick individuals or clinically healthy carriers and is excreted through the feces. Salmonella is excreted by infected individuals in the human population (exclusively so for S. typhi), by infected farm animals, by domestic pets, and by other warm-blooded animals in the wildlife population. The average number of individual humans excreting Salmonella at any given time will vary, from < 1 percent to 3.9 percent based on information from studies in several countries throughout the world [See Section B.2]. As a result, a large constant reservoir of

Salmonella exists in the environment, although accurate carrier rates are difficult to obtain since infected yet asymptomatic animals can be included among the healthy carrier population.

Salmonella densities, as well as the number of Salmonella serotypes present in sewage discharging to receiving waters, vary with the number of people served and the extent of community infection. Salmonella strains were regularly found in the sewage system of a residential area of 4,000 persons (Harvey, et al., 1969). A sewage collection network of 50 to 100 homes is considered by Callaghan and Brodie (1968) to be a minimal size for detecting salmonellae.

Streams, lakes, and rivers receiving discharges of meat processing wastes or effluents of untreated or ineffectively treated community sewage may contain substantial numbers of salmonellae (Geldreich, 1972). Researchers recently recovered 32 serotypes both from sewage effluent and from downstream sections on the Oker River, Germany (Popp, 1974). Kampelmacher and Jansen (1973) calculated that the Rhine and Meuse Rivers carried approximately 50 and seven million salmonellae per second, respectively [For persistence of Salmonella in water, See Section B.3].

Fish living in polluted water may ingest Salmonella and become vectors of pathogen transport. Salmonella presence in animal feed, notably fishmeal, is a case in point. Experiments with carp suggest that S. typhi survived for five to six days in the intestinal tract when the water temperature was 24 to 27°C, and for six to seven days at water temperatures of 1 to 5°C (Lee, 1972). When researchers sought evidence for possible Salmonella multiplication within the fish gut, they instead discovered a progressive die-off of S. typhi in intestinal material from carp and bluegill at water temperatures of both 10 and 20°C. However, substantial multiplication of S. typhimurium occurred in 72 h at 20°C in fecal material from both fish species (Geldreich and Clarke, 1966).

Drinking untreated, unprotected surface water presents the greatest risk to the consumer. S. typhi or S. paratyphi are the agents responsible for most waterborne outbreaks due to Salmonella contamination of water supplies; other salmonellae produce illness only after growth in food at ambient temperatures. Water supplies implicated in Salmonella outbreaks have included individual water systems, semi-public water systems, systems on passenger cruise liners, and small community municipal supplies. While large

municipal water supplies are not a common source of Salmonella outbreaks, the number of cases involved is often large and represents a major epidemic in the community.

The 1965 salmonellosis outbreak, traced to an unchlorinated water supply in Riverside, California, is to date the largest epidemic in modern times to be caused by salmonella contamination of a municipal water system. More than 16,000 people became ill, and three of them died (Boring III, et al., 1971). Negative coliform readings, reported prior to the outbreak may have been the result of suppression by high densities of non-coliform bacteria (Geldreich, et al., 1972). Müller (1964) found Salmonella in chlorinated drinking water that showed an absence of coliforms, yet had been contaminated with 100,000 l of floodwaters during distribution.

Properly constructed wells, located in high quality aquifers protected from surface contamination, generally afford a good untreated potable water supply free of microbial pollution. Unfortunately, not all wells meet such standards. Five cases of typhoid fever occurred in an area served by individual shallow wells drilled into a layer of river bed gravel. Septic tanks or cesspools were located nearby. In one instance, only 60 meters separated a well site from the home sewage disposal system of a known S. typhi carrier (Center for Disease Control, 1972).

If groundwater is subject to surface contamination, continuous disinfection of water abstracted for potable use is essential. Neglect of this critical requirement led to the largest reported outbreak of typhoid fever (210 cases) to occur in the U.S. since 1939. This outbreak occurred at a farm labor camp in Dade County, Florida (Pfeiffer, 1973). Engineering evaluations revealed that chlorination of the wells (known to have had a history of intermittent contamination) was interrupted and consequently the water supply became a vehicle of infection.

Distribution pipe slimes, rich in iron, manganese and organic materials, support the growth of Salmonella and E. coli (Woratz and Bosse, 1968). Researchers, investigating an outbreak of S. bareilly in a maternity hospital, isolated the organism from one-third of the water taps examined; and from all of the water storage tanks (Mendis, et al., 1976). Upon further examination, S. bareilly was found growing on the interior surfaces of water taps and on the walls of the water storage tanks. After the tanks and lines were cleaned and disinfected, no further evidence of Salmonella was found in the water system.

Salmonella occurs and can be anticipated in polluted water, but other organisms present during sampling can interfere with Salmonella detection. There is no single method that will ensure recovery of all Salmonella serotypes present in a given sample, so a combination of methods is necessary. Negative results by any method chosen do not necessarily imply the absence of all salmonellae nor the absence of other pathogens. There are presently no standardized methods for isolating Salmonella from water, although the Committee of the European Economic Community, the World Health Organization, and the International Standards Organization are working to establish standardized procedures. The following, therefore, presents summaries of procedures that may need modification to fit a particular set of circumstances.

Since Salmonella ordinarily occur in lower numbers than expected for sanitary indicator bacteria, it must initially be concentrated from large volumes of water samples. A qualitative analysis may be performed by submerging gauze swabs in flowing water, thus exposing the swabs to a large volume of water (American Public Health Assoc., 1976). After three to five days of submergence at the sampling site, the swab is retrieved, placed in a sterile plastic bag inside a container with ice, and sent to the laboratory for processing within 6 h after sample collection. The swab is not a perfect entrapment device since some salmonellae may pass through, others may desorb from the swab during exposure period, and the volume of water in contact with the swab is unknown. Furthermore, since the swab is submerged for several days, what results is a composite which does not reflect changes in or cycling of Salmonella densities at the sampling site.

The diatomaceous earth procedure often produces better results than the swab method when floating solids are present, such as in sugar beet effluents, paper mill wastes, and waters containing massive algal (and cyanobacterial) blooms. In this procedure, the water sample is filtered through a plug of diatomaceous earth to concentrate the organisms (Brezenski and Russomanno, 1969). Since known volumes of water or wastewater are filtered through the diatomaceous earth, the procedure provides a quantitative approach to salmonellae detection.

A membrane filter may be used to concentrate organisms, including salmonellae, from a water sample provided sample turbidity does not clog membrane pores and prevent filtration. Samples taken from suspect potable water supplies (including wells) can be anywhere from 100 ml to several

liters, depending on the concentration and characteristics of the suspended solids.

Using a cartridge filter permits 20 1 or more of sample to be filtered and is particularly applicable to waters that have low concentrations of organisms (Levin, et al., 1974). Water is drawn (under negative pressure) through a filter of borosilicate glass microfibers bonded with epoxy resin. After filtration, the filter cartridge is separated aseptically from the holder and placed in the enrichment broth. If high numbers of background organisms are present, this technique will not easily recover Salmonella. As with other filtration procedures, sample turbidity will slow the filtration rate. Pre-enrichment for Salmonella can be accomplished with buffered peptone water. Selective enrichment for Salmonella after concentration requires selenite, Rappaport, or tetrathionate broth. Selenite enrichment broth may be combined with dulcitol to improve selectivity for salmonellae. However, dulcitol selenite may retard the recovery of S. typhi, S. cholerae-suis, S. enteritidis biotype paratyphi A, and S. pullorum because these species ferment dulcitol slowly (Raj, 1966). Mannitol selenite broth has been recommended for isolation of S. typhi.

Tetrathionate and selenite broths may be modified by the addition of brilliant green dye to enhance selectivity for salmonellae other than S. typhi. However, tetrathionate broth is reportedly toxic to salmonellae at a temperature of 43°C (McCoy, 1962).

Salmonella strains have been further selected and separated from other bacteria in polluted water samples with a variety of enrichment media at various incubation temperatures. Because other bacteria in the sample may interfere with Salmonella detection, temperatures above 37°C have been used to inhibit the growth of background microorganisms. In general, most researchers agree that 41 to 42°C (preferably 41.5°C) is an optimum incubation temperature for recovery of the largest number of Salmonella in the enrichment procedure. However, since some salmonellae grow more vigorously at 35 to 37°C, parallel enrichment cultures at these temperatures may be performed when feasible; also, when isolating, purifying, or cultivating salmonellae for biochemical testing, a 35 to 37°C incubation temperature is recommended (American Public Health Assoc., 1976).

The fluorescent antibody (FA) technique can be used to screen rapidly for cultures taken directly from prior enrichment (American Public Health Assoc., 1976). This technique

requires careful interpretation of fluorescence; any posi-
tive FA results must be confirmed by the conventional bio-
chemical and serotyping techniques.

Pure cultures of Salmonella may be isolated from the
enrichment broths by streaking every 24 h for three days
onto the surface of selected differential plating media.
These media are: xylose lysine desoxycholate (XLD) agar,
brilliant green (BG) agar, xylose lysine brilliant green
(XLBG) agar, and bismuth sulfite medium. Because bacteria
other than salmonellae may grow and possibly interfere with
isolation and differentiation of suspect Salmonella strains,
using brilliant green agar at an elevated temperature of
41.5°C will reduce the number of these interfering or-
ganisms. However, the elevated temperature and this medium
may inhibit development of some Salmonella serotypes. After
incubation, the cultures are examined for typical colonies
of salmonellae which are then characterized biochemically
and serologically.

Biochemical reactions are used to characterize the
suspect Salmonella isolates recovered and permit a separa-
tion from closely related bacteria. Four major Salmonella
sub-genera can be differentiated by selecting tests to obtain
reactions for dulcitol, lactose, β-galactosidase, d-tar-
trate, mucate, malonate, gelatin, and KCN. Ordinarily,
salmonellae do not ferment lactose, sucrose, malonate, and
salicin, but do ferment glucose, inositol, and dulcitol.

These tests, using pure culture isolates, can be made
in single tube media, or in commercial multitest systems.
The multitest systems permit the examination of large num-
bers of isolates in a relatively short time. All ten-
tatively identified Salmonella isolates are then submitted to
serological confirmation.

To prepare for serological verification of Salmonella
strains, the pure culture isolate is transferred to a brain
heart infusion agar slant and incubated for 18 to 24 h to
insure maximum strain vigor. A range of polyvalent and
individual somatic or flagellar antisera should be used in
agglutination tests for determining Salmonella serotypes.

Especially when testing for Salmonella, the dedication
and skill with which the microbiologist conducts his ex-
aminations, and his critical review of culture reactions are
what determine the validity of the results.

(ii) <u>Shigella</u>. This genus is composed of a group of closely related gram-negative bacteria that cause mild to acute bacillary dysentery in man. These bacteria have many biochemical reactions in common with other members of the family <u>Enterobacteriaceae</u> to which they belong. In addition, they are non-motile, do not normally ferment lactose, yield positive methyl-red and negative Voges-Proskauer reactions, and do not grow on citrate medium (Wilson and Miles, 1975).

The <u>Shigella</u> genus is divided into four main subgroups based on a combination of biochemical and serological characteristics: Subgroup A (<u>Shigella dysenteriae</u> -- several serotypes), Subgroup B (<u>S. flexneri</u> -- several serotypes), Subgroup C (<u>S. boydi</u> -- several serotypes), and Subgroup D (<u>S. sonnei</u> -- one species or serotype). The shigellae are not particularly heat resistant and are killed by temperatures of 55°C in one hour. They are even more sensitive to higher temperatures and they will die within several hours when in moist stool specimens that have become acidic from bacterial growth. However, <u>Shigella</u> can survive for many days in clean, cool water.

All <u>Shigella</u> species cause bacillary dysentery (also called shigellosis) exclusively in humans and some primates. Infection normally is restricted to the intestinal tract and the incubation period is only 48 h. The organism enters the small bowel, multiplies, then proceeds to the terminal ileum and colon where it penetrates the epithelial cells and multiplies again. The result is inflammation, sloughing of cells, and ulceration. Dysentery is a disease of the large bowel and the mesenteric lymph nodes. Symptoms include fever and diarrhea characterized by watery feces tinged with blood, mucus, and groups of polymorphonuclear leukocytes. The case-fatality rate varies widely according to the age and general health of infected individuals and also the <u>Shigella</u> species involved. <u>S. dysenteriae</u> is the most dangerous, possibly because it produces a particularly cytotoxic exoenterotoxin not known to be produced by any of the other species (Hollister, <u>et al.</u>, 1955).

Infection is transmitted by the fecal-oral route. The organism may be present in enormous numbers in the feces of clinically ill persons, but it can also be spread by asymptomatic carriers as well as convalescents. <u>Shigella</u> has been isolated from clothing, toilet seats, and contaminated food; and flies are known to carry and spread infective material. Infection with <u>Shigella</u> occurs endemically in most communities and may be maintained by a few symptomless carriers in the absence of clinical cases.

Bacillary dysentery occurs most commonly during summer months in tropical countries where lower standards of hygiene increase opportunities for transmission by many routes. Many different serotypes generally are present in these areas with no single one playing a much greater role than any of the others. Water supplies in tropical countries tend to receive shigellae that are water-washed from many sources, whereas in developed countries, transmission by water is most often the result of contamination from one identifiable source. Stricter sanitation measures, proper sewage disposal, and public health standards enforced in the developed countries have led to a shift in peak incidence from summer to winter, as low temperatures favor survival of Shigella. One species, S. sonnei, predominates, probably because it can survive longer under adverse conditions (Feachem, 1977).

In the U.S., waterborne outbreaks of shigellosis have increased somewhat from 1961 to 1977, although shigellae are not often isolated from water and the organism poses no unique problems to the protection of water supplies. The majority of outbreaks were from inadequately maintained and monitored semi-public systems, especially those serving recreational areas that are in use for only part of the year. Fecal contamination and improper disinfection of a well, situated approximately 46 m (150 feet) from a septic tank, were blamed for an outbreak of shigellosis in Florida (U.S.) involving 1,200 people (reviewed by Craun, 1977). Thermo-tolerant coliforms were isolated from drinking water after 690 people became ill with shigellosis during passage aboard a cruise ship sailing from the U.S. The water was found to have been stored improperly and not given sufficient contact time with the chlorine disinfectant. (Reviewed by Hughes and Merson, 1975). An outbreak involving hundreds of cases occurred in 1977, in Germany, when a reservoir was contaminated with waste from a nearby water-flush toilet (Bohm, et al., 1978). These incidences serve to underscore that the lesson still to be learned in developed countries is that of increased vigilance, especially in connection with semi-public water supplies.

As with Salmonella, no standardized procedures have been established for isolating Shigella from water. Tentative methods, subject to modification, are offered in Standard Methods (American Public Health Assoc., 1975) and elsewhere. Concentration techniques described in Standard Methods are the same as those for Salmonella [See Section III.B.1.a(i)]. GN broth affords good enrichment for

Shigella while suppressing coliforms and fecal streptococci. The formulation includes dextrose and d-mannitol which are balanced to limit the growth of Proteus and encourage that of enteric pathogens. High concentrations of sodium citrate and sodium desoxycholate inhibit gram-positive organisms, and the latter ingredient is far less toxic to Shigella than brilliant green dye which is unacceptable for use with Shigella. Xylose lysine desoxycholate agar is a differential media suggested by Standard Methods for isolation of Shigella species when used in conjunction with GN enrichment broth. Finally, suspect colonies can be purified and subjected to various biochemical and serological procedures.

(iii) Yersinia Enterocolitica. Evidence of infections due to Yersinia enterocolitica has been mounting since the early 1960's, especially from the world's cold or temperate regions. Illness caused by this organism has been reported in recent years from North America, Japan, South Africa, and almost every European country. Some cases also have been noted in South America, North Africa, and the Middle East; and the disease probably would be found common in many other parts of the world if there were more laboratories in these areas capable of detecting the causative organism (Alonso, et al., 1976; Bottone, 1977; Toma and LaFleur, 1974).

(iii.1) Characterization of Y. Enterocolitica. The organisms comprising the genus Yersinia (Y. pestis, Y. pseudotuberculosis, and Y. enterocolitica), of the family Enterobacteriaceae, were formerly considered members of the genus Pasteurella. Although no consensus on the precise definition of Y. enterocolitica has been reached, it is described in general terms as a gram-negative, facultatively anaerobic, motile (below 30°C) coccobacillus. Mollaret and Thal (Buchanan and Gibbons, 1974) provide some biochemical differentiations among the three species. Y. enterocolitica has been divided into many serobio-, and phage-types; and these have all been classified into three or four groups based on DNA homology (Brenner, et al., 1976). However, it is more likely that this wide spectrum of types eventually will be separated into different, more precisely defined species. The most noteworthy characteristic of this bacterium is its stability and even growth down to temperatures as low as 4°C (optimum, 20°C) [See Section B.3.c]. Yersiniosis, caused by both Y. enterocolitica and Y. pseudotuberculosis, is thought to be contracted perorally; its appendicitis, mesenteric lymphadenitis, or acute terminal

ileitis. Y. enterocolitica has been isolated from lymph
nodes and feces of both sick and healthy humans along with a
growing number of animal species. Though there are human
and animal carriers, their role in the disease's trans-
mission is as yet undetermined.

(iii.2) Sources and Occurrence of Y. Enterocolitica.
Broadly speaking, the organisms that are classified Y.
enterocolitica fall into two main groups (Mollaret, 1976).
The first group causes typical illnesses and consists of
host-specific strains with constant and stable bio-, sero-,
and phage types. Predominant types within this group may
differ from place to place suggesting that incidences of the
disease in different areas of the world may have no epi-
demiological connection. For example, in Japan, Canada, and
most European and African countries, serotype 0:3 predomi-
nates. However, strains of this serotype belong to phage
type 8 in Europe and Japan; whereas in South Africa, these
strains are classified as phage type 8 or 9a; and phage type
9b is regarded as the "specific Canadian" type elaborated by
these strains (reviewed by Toma and LaFleur, 1974). The
serotype 0:9 predominates in Finland and serotype 0:8, which
predominates in the U.S., does not occur at all in Europe.

Sources of the infection have remained largely unknown.
The human serotype 0:3 has been found to occur in animals
(including pigs and household pets) suggesting a zoonotic
epidemiology; however, no clear connection between human and
animal infections has ever been established. In fact, there
is reason to believe that Y. enterocolitica infections occur
independently in humans and animals as a result of exposure
to an environmental source common to both (Mollaret, 1976).

Little has been written about the second group whose
occurrence and significance in different ecosystems is not
well understood. Strains of this group have been isolated
from small mammals (Kapperud, 1977), poikilotherms (Kapperud
and Jonsson, 1976), water (Harvey, et al., 1976), and food
(Morris and Feeley, 1976). They do not appear to require a
specific host and they vary widely in biochemical and anti-
genic characteristics. Humans and animals can carry them
with no clinical symptoms (Mollaret, 1976).

Different Y. enterocolitica types have been isolated so
frequently from untreated surface water in some areas that
they most likely represent part of the normal microbial
flora of the water and surrounding terrestrial environments

(Kapperud, 1977). Alternately, the same Y. enterocolitica biotype and/or serotype is readily recoverable in these areas from a wide range of animal species (including poikilotherms) indicating a nonspecific role in these ecosystems. Most of these organisms belong to the rather ill-defined second group and generally do not appear to act as pathogens. Although members of this group also have been isolated occasionally from people with diarrhea (Kapperud, 1977; Toma, 1973), their presence is probably only incidental.

(iii.3) Epidemiology of Waterborne Y. Enterocolitica Infections. Reports referring to waterborne Y. enterocolitica infections are few in number. Lassen (1972) described a case of violent gastroenteritis caused by Y. enterocolitica serotype O:13-7 in an 18 year-old woman. This same sero- and biotype had been isolated only a few days earlier from the well next to her house. Keet (1974) reported a septicemia in a 75 year old man from Y. enterocolitica serotype O:8, in which the source of infection was later traced to a mountain stream. He postulated that wild animals inhabiting a watershed may transmit the disease indirectly through the water to farm or domestic animals. In December 1975, waterborne gastroenteritis occurred in 41% of approximately 1,500 guests at a ski resort in Montana (U.S.). Although Y. enterocolitica was isolated from the unchlorinated well water, what, if any, role it played in the outbreak remains unclear (Center for Disease Control, 1975a).

It has been proposed that, to infect humans, Y. enterocolitica may require an intermediate period of multiplication at reduced temperatures (after passage through a vector) wherein the organism can reach infective levels. Such a "hot-cold" mode of transmission could account for the observed increase in cases of yersiniosis in colder climates and seasons (Bottone, 1977). Moreover, Y. enterocolitica grown at 37°C is less resistant to normal cellular bactericidal defenses than when grown at 20°C (Nilehn, 1973); this could explain why infection through direct person-to-person contact is relatively rare, and again, why an intermediate cold phase could be critical to its spread. If so, the life cycle for Y. enterocolitica would stand in sharp contrast to that of others in the family Enterobacteriaceae whose ability to be transmitted through water represents only an exceptional phenomenon.

There is no standard method for the isolation and enumeration of Y. enterocolitica in water. This microorganism is similar to other enteric bacteria except that it grows better at 25°C than at 36°C, and it is able to grow at

4°C.   For these reasons, a procedure analogous to those for
food examination has been proposed.   This method described
recently by Highsmith and coworkers (1977b) includes:
membrane filtration; liquid enrichment in M-Endo broth at
25°C and 36°C for 72 h and plating on Salmonella-Shigella
(SS) or MacConkey agar at 4°C for 14 to 21 days; isolation
on the same plating media or enrichment broth and incubation
at 25°C; biochemical identification of the lactose-negative
colonies on Triple Sugar Iron agar for urea and motility
determinations before further identification and typing.

(iv)   Enteropathogenic Escherichia Coli.   Transmission
of enteropathogenic E. coli through drinking water was
frequently reported during the 1950's (Monnet, et al., 1954;
Seigneurin, et al., 1955; and Lanyi, et al., 1959).

Certain enteropathogenic strains of E. coli are now
known to cause acute diarrhea, especially in infants, in
travelers to foreign countries, and in consumers of con-
taminated foods.   These organisms include 14 distinct an-
tigenic types, in addition to other recently implicated
strains, some of which are not serologically typable.

Disease may occur by either of (at least) two mech-
anisms: tissue invasion or toxin production.   When cells
penetrate the intestinal epithelium, the result is a syn-
drome like the bacillary dysentery caused by virulent Shigella
strains.   The second mechanism entails the production of
potent heat-labile or heat-stable enterotoxins which induce
cholera-like symptoms or a salmonellosis-like enteritis.   If
the organism colonizes the upper bowel it will manifest
enterotoxigenicity; but, it may be carried in the colon
without producing any harmful effects.   However, because
toxin production is a plasmid-borne trait, organisms of a
given serotype may or may not be toxigenic.

Of the 99 waterborne outbreaks of gastroenteritis
reported in the U.S. from 1971 to 1974, no causal agent was
identified in almost half of these incidents.   The extent to
which enteropathogenic E. coli was involved in these out-
breaks is largely unknown, primarily because serotyping of
isolates is not routinely performed during outbreaks.

Two of the best documented outbreaks took place in
Sweden in the autumn of 1965, one in a residential area of
Uppsala, and the other in the small community of Gimo situ-
ated 50 kilometers north of Uppsala (Danielsson, et al.,
1968).

Within a period of 14 days, 442 residents of Uppsala fell ill; 261 of them experienced the onset of symptoms during a two day peak. High coliform densities were discovered in the community's water supply. A rapid (2 to 8 h) preliminary screening technique, based on membrane filtration combined with fluorescent antibody staining (Danielsson, et al., 1968), was applied to water samples and identified three serotypes of enteropathogenic E. coli. Freshly collected water samples and enriched water samples (incubated at 37°C for 4, 6, and 14 h in nutrient broth) were filtered or centrifuged, and filter sections or sediment smears were stained with fluorescent antibody. In conjunction with this, fecal specimens from sick patients were serotyped according to conventional culture and serological procedures. Both water samples and fecal specimens were found to contain the same three serotypes 026:B6, 0128:B12, and 0111:B4 -- the latter serotype predominated in both fecal and water sources.

Only a few cases of gastroenteritis were reported for the community of Gimo, although the drinking water supply was also found to be highly contaminated with coliforms after a spell of heavy rains. Serotypes 026:B6, 0114:B?, and 0125:B15 were identified from samples subjected to Danielsson's membrane filtration and fluorescent staining technique. However, since no clinical specimens were collected for bacteriological examination, etiology could not be confirmed. Danielsson and coworkers (1968) cautioned that their rapid screening technique could yield false positive results due to serological cross reactions with other bacteria, and they advised that conventional methods be used for confirmation.

A large waterborne outbreak of illness caused by enterotoxigenic E. coli occurred in June and July of 1975, at Crater Lake National Park, U.S.A. (Rosenberg, et al., 1977). More than 200 staff members and 2,000 visitors to the park experienced prolonged diarrhea, cramps, nausea, and vomiting. Telephone surveys and questionnaires strongly associated the illness with ingestion of the park's drinking water, supplied by a shallow spring. The water supply, although chlorinated before distribution, was not routinely monitored for chlorine residuals once it had entered the distribution system. Later tests, using fluorescein dye, revealed that raw sewage from an overflowing manhole was contaminating the water.

Lactose-positive and -negative colonies, picked from cultured stool specimens, were tested for toxin production

using mouse adrenal tumor cell, Chinese hamster ovary tissue culture, and infant mouse assays (Rosenberg, et al., 1977). Of 120 patients examined, enterotoxigenic E. coli (exclusively serotype 06:H16) was isolated from 20 of them. The organism produced both heat-labile and heat-stable toxins. No Salmonella, Shigella, pathogenic vibrios, or Yersinia enterocolitica were recovered from either the spring water or from clinical specimens.

These investigators pointed out the relative insensitivity of current culture methods. They explained that the lack of recovery of enterotoxigenic E. coli from many fecal specimens was, in all probability, due to the pathogen's short duration (averaging less than four days) after diarrhea had ceased. Also criticized was the practice of testing only five to ten E. coli isolates randomly chosen from nonselective media. The serum antitoxin immunity test was held to work well only in areas where a particular pathogen, such as cholera, is endemic and/or introduced at high antigenic levels. This was not the case with the Crater Lake outbreak. The authors recommended intensive screening of a substantial portion of diarrheal fecal specimens for presence of the enteropathogenic agent. Once a predominant serotype of E. coli was shown to be enterotoxigenic by criteria listed earlier, the remainder of fecal specimens would then be tested serologically for the presence of that strain.

The definition of the coliform group includes E. coli, so enteropathogenic E. coli is unlikely to be present in water in which coliforms are undetectable; this relationship is far more direct than is usual between indicators and pathogens. However, even if E. coli is shown to be present, its enteropathogenicity can be determined only by highly refined techniques. The presence of enteropathogenic E. coli is not a great deal easier to monitor than that of several pathogens, including viruses, which may cause waterborne outbreaks of acute diarrhea.

(v) Francisella Tularensis. Tularemia is a zoonotic disease, transmitted to humans from blood-sucking arthropods, domestic animals, and primarily by a number of wild animal species, many of which lead semi-aquatic lives. It is this semi-aquatic existence of such susceptible hosts as voles, beavers, muskrats, and water voles that accounts for most waterborne outbreaks of the disease in humans. Tularemia is endemic on three, possibly four, continents and is ubiquitous throughout the northern hemisphere, including North America,

Europe (except the British Isles, Spain, and Portugal), the U.S.S.R., Turkey, and Japan (Hopla, 1974).

The causative agent, Francisella tularensis, is described as a tiny gram-negative, aerobic, singly occurring, non-motile, nonencapsulated, nonsporulating, bipolar rod requiring special media to which glucose and cysteine or cystine have been added. Historically, it has occupied several generic designations -- these being Bacterium, Bacillus, Brucella, and Pasteurella. But, the organism was finally placed in a genus by itself, Francisella, based on its small size and because it does not grow on simple nutrient media. Nonetheless, investigators in the U.K. generally refer to this pathogen as Brucella tularensis because of cross-reactions with agglutinating antigens of the genus Brucella. F. tularensis is killed by heating for 30 minutes at 50°C, but it can survive over three weeks at -14°C or after desiccation.

The disease occurs as an anginose-bubonic infection when contracted through ingestion (as opposed to inhalation or skin contact with animals), producing buboes and areas of necrosis in organs and tissues of man and animals.

It was first suggested that tularemia was transmissible through water in 1935 (Pollitzer, 1967). The first reported outbreak of waterborne tularemia, in which 45 people, all of whom drank from a small stream where F. tularensis was later isolated, came down with the disease was documented in 1936. Lesions observed on the mucosa of the tonsils and the oral cavity implicated water as the vehicle.

Most references to waterborne tularemia are integrated into a very extensive body of tularemia literature contributed by Russian workers in response to a series of explosive tularemia outbreaks which ravaged the U.S.S.R. in 1928 and over the next 30 years. Several investigators have directed their studies to the westward penetration of tularemia in Eastern Europe during and immediately after the Second World War. The disease had calamitous effects on the Soviet army beginning in 1941 and was traced to drinking water contaminated with rodent carcasses and excrement as a vehicle of infection.

Outbreaks of waterborne tularemia have been reported throughout the U.S.S.R. Leningrad was struck with about 200 cases in 1944 - 1945 of which 20 percent were shown to be waterborne (Pollitzer, 1967). Drinking water contaminated with infected rodent carcasses accounted for 22.8 percent of tularemia cases in White Russia (Pollitzer, 1967). Three river cities in Central and Eastern Siberia experienced

tularemia epidemics in the 1940's in which contaminated drinking water played an important role second only to that of insect and tick bites. It appeared that a peak in the epidemic was reached during the warmer months of June to September. Cases of waterborne tularemia have been reported for the southern part of the U.S.S.R., notably Armenia and Kazakhstan, where the anginosebubonic form of the disease was greatly in evidence. Investigation of outbreaks in Kazakhstan placed the blame on direct or indirect contact with water rats. The Altai Mountain region was also hit with tularemia in 1955 through 1957, reportedly from drinking water contamination (Pollitzer, 1967).

Recent cases of waterborne tularemia in northern Norway have brought about renewed interest in water as a vehicle of infection in the Scandinavian peninsula. Mair (1973) studied a series of what he termed otolaryngological manifestations of the disease involving hunters who drank from a mountain brook during a period of peak rodent (notably lemmings) populations. Short-term contamination of rural streams is the more common, well documented source of waterborne tularemia outbreaks, and is attributed to epizootics among semi-aquatic wildlife, mainly voles, beavers, muskrats, and water voles.

There is no standardized method for the examination of water for F. tularensis. The genus is characterized by growth requirements for cysteine or cystine; no growth is obtained on ordinary culture media. Semi-solid media which allow for slow growth, such as gelatinized egg yolk and media containing cysteine, glucose, and defibrinated rabbit blood (or serum) can be used. Identification is accomplished by means of biochemical tests.

(vi) Leptospira. The genus Leptospira is composed of finely coiled, spiral organisms including a number of strains that cause leptospirosis in humans and many animals. The organisms are of slender appearance, have numerous coils with bent or hooked ends, and are very actively motile. They do not stain well in conventional stains, but require special preparations.

At present, all leptospirae are grouped within one species, L. interrogans. L. interrogans is divided into two complexes: 1) interrogans, all strains that are pathogenic or parasitic; and 2) biflexa, free-living or water leptospirae that commonly occur in fresh surface waters. The

interrogans complex contains 18 serogroups and about 150 serotypes. The most important serogroups are: Icterohaemorrhagiae, Canicola, Hebdomadis, Pomona, Grippotyphosa, Autumnalis, Australis, Mitis, and Bataviae. More detailed studies are available (Fuchs and Burger, 1974). It was proposed in 1973 by the Leptospira subcommittee that these complexes be designated species: L. interrogans and L. biflexa.

Leptospirae can be grown on various media containing peptone and inactivated serum. They are aerobic, their optimal temperature is 28 to 30°C, and they grow well at pH 7.2 and 7.4. Reliable diagnostic methods are available, and most laboratories are equipped to distinguish leptospirosis from other diseases as well as to identify the specific serogroup responsible.

The leptospirae penetrate the surface epithelium of the host and enter the bloodstream, where they multiply and are carried to all organs of the body (hence, the diversity of symptoms). They finally settle in the convoluted tubules of the kidney and from there are excreted in the urine. Incubation time of the disease is usually from seven to 13 days. Symptoms may range from fever, headache, chills, malaise, vomiting, and muscular aches to very severe and even fatal illness including meningitis, encephalitis, haemorrhagic states, and infrequently, jaundice. Symptoms formerly ascribed to Weil's disease may be caused by all the pathogenic strains, depending on the virulence of the strain and on the reaction of the host. Severe cases may have fatality rates of as high as 50 percent (Turner, 1973).

The leptospirae are not particularly heat-resistant (Chang , et al., 1948) and are killed in 10 min at a temperature of 50°C. They are sensitive to desiccation, acid (such as gastric juice), and to disinfectants; and they are destroyed by bile. They do not tolerate high salt levels and are soon eliminated in polluted water or sewage. They can, however, withstand freezing for some time.

Leptospirosis is essentially a zoonosis that can occur in great numbers of domestic and wild animals depending on climate and availability of a food supply. The organism is maintained in the environment by both carrier and diseased hosts, and transmission is particularly favored by population explosions of animal carriers, especially rats. In temperate regions, animal hosts most likely to transmit disease to man are rats, dogs, and swine. Human exposure to

the disease has been from direct or indirect contact with urine from infected animals (Kathe, 1945; Müller, 1969a). Humans are considered to be a dead-end host, as person-to-person spread is rare. Mild anicteric forms are now recognized as more common than clinically severe icteric forms of the disease; consequently, human infection with pathogenic leptospirae may pass completely unnoticed.

In the U.S., the most likely sources of infection with Leptospira are surface water, dogs, rodents, cattle, and swine (Reasoner, 1977). However, infection by the water route is mainly the result of swimming in polluted ponds or creeks; or, in the case of miners, of walking through stagnant water infested with rodents. Warm (~22°C), slow moving streams of neutral or slightly alkaline pH provide an ideal environment that can prolong Leptospira survival for many weeks. Infection with Leptospira is primarily associated with certain occupations such as mining, dairy farming, and sanitary engineering. Only rarely is it associated with drinking water (Heath, et al., 1965), as in times of disaster such as during wars, when there has been a breakdown in sanitation and public health systems. In post-war Berlin, the incidence of the infection was very high (Becker, 1969).

The detection of Leptospira is made difficult by the competitive growth of other organisms and the need to differentiate between pathogenic and saprophytic strains. There is no standard method for isolating Leptospira from environmental sources, but a tentative procedure entails analysis of bottom sediments by concentration, enrichment in Fletcher's semi-solid medium containing 10 percent rabbit serum, and incubation at 30°C for six weeks. During incubation, the medium should be checked repeatedly for the appearance of leptospirae and for any culture contamination. Upon detection, the Leptospira isolates must be further characterized by various biochemical and serological tests (American Public Health Assoc., 1975).

(vii) Vibrio Cholerae. The genus Vibrio comprises a large number of species, only a few of which are of medical importance: V. cholerae and its biotype V. cholerae El Tor cause cholera exclusively in man; V. parahaemolyticus (a marine organism which typically inhabits estuaries); and nonagglutinable (NAG) vibrios can cause cholera-like disease or mild diarrhea in humans (Heiberg, 1935), but are not normally transmitted by the water route. Only under exceptional circumstances (e.g., contamination with surface water

due to leakage or cross-connections) can NAG vibrios be transmitted through drinking water. However, numbers sufficient to cause illness (10^5) are obtained only after subsequent enrichment in food (Müller, 1977a).

The genus is composed of polymorphic, gram-negative, nonsporeforming rods that are slightly curved, actively motile, and that possess a single thick polar flagellum. They are not fastidious and grow readily on a number of simple media which need only contain a balanced mixture of utilizable carbohydrate, inorganic nitrogen, sulfur and phosphorous sources, simple minerals, and an adequate buffer. Vibrios grow best between 30 and 40°C and at a pH near neutrality. They are classified according to their biochemical reactions in tests that include slide hemagglutination, Voges-Proskauer test, polymyxin-B sensitivity, and resistance or susceptibility to Mukerjee's group IV cholera phage (Finkelstein, 1973; Wilson and Miles, 1975). Two major serotypes, Ogawa and Inaba, and one rarely encountered serotype, Hikojima, are recognized in both V. cholerae and the El Tor biotype.

The vibrios are sensitive to heat, sunlight, and drying; and they are especially intolerant of acid but are able to withstand alkalinity up to pH 10.2. They survive well at low temperatures and can persist for weeks in cool, pure drinking water. The El Tor biotype seems hardier than the classical Vibrio biotypes and can survive longer in nature (Finkelstein, 1973).

Cholera, whether caused by classical V. cholerae biotypes or the El Tor biotype, produces the same clinical symptoms of profuse diarrhea, leading to rapid loss of fluid together with loss of bicarbonate, sodium, potassium, and chloride ions. In severe cases, this can be accompanied by a drop in body temperature and blood pressure, followed by prostration, kidney failure, and death. Untreated case fatalities are over 60 percent, but death always can be averted by early medical intervention. The time of incubation is anywhere from a few hours to six days. Infection is confined to the gastrointestinal tract, and formation of enterotoxin is what triggers host response. Diagnostic procedures are standardized throughout the world, and laboratories can easily identify the disease if alerted to the possibility of cholera and suitably equipped.

Fecally contaminated water is the primary vehicle of cholera transmission, although vibrios are also spread by a

multitude of other routes including food, soiled clothing, flies, and direct person-to-person contact. Extremely high numbers of cholera vibrios can be found in human feces and vomitus. The disease has a high rate of secondary spread when there is contact with sick individuals who shed the organism in enormous numbers, particularly during the first days of illness. Generally, the number of inapparent infections or mild cases greatly exceeds that of severe cases by a factor of ten up to several hundred. Major determinants of this ratio are levels of hygiene and nutrition, occurrence of other enteric infections (which can permit vibrios to pass unharmed through the gastric juices), and quantity of vibrios ingested [See Section B.4]. The carrier status is presumed to be transitory; but, especially in patients over 50 years of age, prolonged infection in the gall bladder has caused chronic and intermittent shedding (Zwadyk, 1976).

Cholera is still one of the most severe and contagious of infections, having spread to over 171,000 people in 42 countries since 1961. In 1971, it became clear that the El Tor biotype was responsible for this seventh recorded cholera pandemic. The agent has been widely disseminated due to a high frequency of unrecognized El Tor infections. The disease has characteristically been sporadic and endemic in areas of poor hygiene and warm humid climates (Barua, 1970; Feachem, 1977; Felsenfeld, 1967; and Mosley, 1970). However, isolated cases have been reported in Czechoslovakia, Spain, France, Portugal, Australia, New Zealand, Sweden, the U.K., and the U.S., mainly from importation through tourism (Finkelstein, 1973).

Crabs caught in a Louisiana (U.S.) lake caused six known cases of cholera in 1978 (Center for Disease Control, 1978c). Water sampled from the lake and from sewage of a nearby town showed presence of the Inaba serotype as did clinical specimens from patients. Except for these and a single case in Texas, the U.S. has had no reported cases of cholera since 1911.

During the last century, when standards of hygiene were lower, Europe suffered from several devastating epidemics. However, it is now well understood that the spread of cholera can be arrested quickly and entirely by adequate sewage and water treatment, together with prompt detection and treatment of cases and carriers. Moreover, a healthy and well nourished population is unlikely to succumb to infection with $\underline{V}$. cholerae, particularly that caused by the El Tor biotype.

Methods for isolating vibrios from water have not been standardized. Sampling procedures have included the use of membrane filters, gauze pads, and grab devices. Enrichment in alkaline peptone water at pH 8.4 or in taurocholate tellurite peptone water at pH 9.2 yielded good results after incubation initially for 4 to 6 h at ambient temperatures ($\sim$ 25°C) and then for 18 h at 37°C (Colwell and Kaper, 1977). Enrichment cultures were streaked onto TCBS agar and suspect colonies were screened by testing for presence of oxidase. Further differentiation was achieved by biochemical and serological testing.

(viii) _Campylobacter_. _Campylobacter_ is a small, gram-negative, curved or spiral-shaped rod possessing a long, single polar flagellum at one or both ends of the cell. It has a characteristic corkscrew type of motility, is micro-aerophilic, and grows easily on a conventional culture medium at 37°C in a special atmosphere of 5 percent oxygen, 10 percent carbon dioxide, and 85 percent nitrogen (Smibert, 1978). Included in this genus are pathogens for both humans and animals as well as saprophytic forms normally occurring in the oral cavity, reproductive organs, and intestinal tract.

The organism was initially observed as the agent of infectious abortion in cattle and was named _Vibrio fetus_. However, because its G + C content is much lower than that of members of the genus _Vibrio_, and because it does not ferment or oxidize carbohydrates, _V. fetus_ has been reclassified as _Campylobacter fetus_. Of the three species -- _C. fetus_, _C. sputorum_, and _C. fecalis_ -- only _C. fetus_ is pathogenic for man.

In addition to causing abortion and sterility in cattle and sheep, _C. fetus_ ss. _jejuni_ and _intestinalis_ also may cause gastroenteritis in humans, cattle, sheep, and swine. Human infections with _Campylobacter_ can lead to gastro-intestinal disease characterized by abdominal pains, diarrhea, malaise, headache, and fever lasting from one to four days. All age groups and both sexes appear to be equally susceptible to infection. The organism inhabits the genitourinary and intestinal tracts and is excreted in the feces.

In several studies, _Campylobacter_ was isolated from stools of 4 to 8 percent of patients with diarrhea -- an isolation rate comparable to those of the more commonly recognized enteric pathogens such as _Salmonella_ [See Section

B.l.a(i)] and Shigella [See Section B.l.a(ii)] (Butzler, et al., 1973; Skirrow, 1977; Steel and McDermotts, 1978; and Pai, et al., 1979). Campylobacterial gastroenteritis with diarrhea has been described in Rwanda (Africa) (De Mol and Bosmans, 1978), Canada (Laboratory Centre for Disease Control, 1978), and the U.S. (Center for Disease Control, 1978).

Feces from infected humans, animals, and fowl may contaminate surface waters destined to be used for drinking water supplies. If such source waters were inadequately treated, viable Campylobacter cells could theoretically gain entry to finished water. The exact mode of transmission to humans is unknown, but contaminated food and water probably serve as major vehicles (Joklik and Willett, 1976).

The best evidence for waterborne transmission of this organism to humans came from an outbreak in Bennington, Vermont (U.S.) (Center for Disease Control, 1978b). During two weeks in May 1978, 2,000 of the town's 10,000 residents became ill with gastroenteritis. An epidemiologic investigation showed a strong association between gastroenteritis and consumption of water from the town supply. C. fetus ss. jejuni was isolated from individuals with diarrhea by culturing fecal samples obtained from rectal swabs. In this case, water samples taken from several areas of the town showed no residual chlorine. The report went on to state that investigators were seeking evidence for contamination from wild and domestic animals within the watershed.

Prior to the Bennington outbreak, isolation of this pathogen was occasionally successful only if blood from an infected individual was cultured (King, 1962). Later, a procedure for isolating Campylobacter from stools was described by Butzler and coworkers (1973). Also, a selective growth medium containing vancomycin, polymyxin B, and trimethoprim was described in England by Skirrow (1977). Both media require incubation at 43°C and microaerophilic culture conditions. Failure to isolate Campylobacter is more often the result of improper atmospheric adjustment than an incorrect choice of growth media. The organism also has been grown using Albimi Brucella broth (Pfizer Diagnostics, Flushing, N.Y.), supplemented with 10 percent animal blood. This formulation is used either as a semi-solid broth (0.16 percent agar) or a solid medium. Because it is microaerophilic, Campylobacter will grow only within the upper first few millimeters of a semi-solid growth medium.

At present, there are no standard methods for detecting Campylobacter in water. When such methods become available

for routine use, it will then be possible to determine the significance of <u>Campylobacter</u> in water as it relates to outbreaks of waterborne gastroenteritis.

(ix) Opportunistic Pathogens. Several other micro-organisms present in water can cause disease infrequently, and almost always under unusual circumstances, either in abnormal hosts or in situations where the normal flora have been supplanted. These organisms are called opportunistic pathogens and are ubiquitous in nature, very resistant in water, can grow with only a few nutritional requirements, and are able to accept and transfer plasmids which carry the determinants for resistance to antibiotics. Concentrations of opportunistic pathogens found in drinking water are not normally sufficient to lead to infection in a healthy consumer.

The endotoxins produced by these agents, however, pose a significant health hazard to the hospitalized, immuno-depressed patient who might suffer from septicemia, wound infection, urinary infection, or be in an otherwise weakened state. Also susceptible are post-operative patients, individuals being treated with immunosuppressive or antineo-plastic agents, cancer or leukemia patients, newborn babies (especially when premature), and the very old and infirm.

The organisms are most frequently transmitted by contact with material, water, disinfectants, cleansing fluids, or via intravenous therapy; airborne spread occurs less frequently. These modes of transmission are to be distinguished from the definite possibility of self-infection, whereby the host, being in a weakened state, may become susceptible to the growth of an organism that is already present in the body in low numbers. Of all hospitalized patients, 5 to 18 percent can be expected to have contracted an infection from opportun-istic pathogens; the risk is higher in hospital wards using more technical equipment, for example, in emergency care or neurosurgery.

The dangers resulting from bacterial metabolites, such as pyrogens, should not be overlooked; and problems caused by these organisms may extend to households and to scientific laboratories, where de-ionizer and soft water units have been shown to contain gram-negative bacteria. Opportunistic pathogens also have been found growing in humidifiers and ventilation plants.

Opportunistic pathogens whose presence in water can be anticipated include the following bacteria:

- Pseudomonas species, especially P. aeruginosa, present special problems in stored water and with medical procedures and equipment that use water, such as dialysis units, water baths, sprinkler heads, scrub sinks, and others (to be discussed further at the end of this section).

- Aeromonas hydrophila has been found in feces from healthy individuals and those suffering from diarrhea, in domestic animal feces, and in drinking water (Annapurna and Sanyal, 1977). This bacterium has drawn increased attention recently because of its ability to cause infection in man, animals, fish, and reptiles, and because it produces enterotoxins. Antibiotic-resistant species of Aeromonas, including A. hydrophila, not commonly identified as agents of human infection (but rather of certain species of fish and frogs), have been transmitted to humans via source water receiving wastewater and have caused cases of acute cellulitis (Hanson, et al., 1977). Populations of this organism in numbers as high as 10^5 to 10^6 cells per ml have been found in aquatic environments which receive wastewater.

- Edwardsiella tarda has been isolated from human patients and is associated with gastroenteritis. It is harbored in the intestines and can cause septicemia (Koshi and Lalitha, 1976).

- Flavobacterium can cause meningitis, bacteremia, or septicemia. It is composed of a variety of species, some of which tolerate high levels of chlorine, are resistant to antibiotics, and can produce pyrogenic metabolites (Colwell, et al., 1978).

- The genera Klebsiella [See Section III.C.2.d], Enterobacter, and Serratia of the tribe Klebsiellae have been recovered from human feces and water. They are able to grow in water, are often resistant to antibiotics, and can cause urinary infections or septicemia.

- The genera Proteus and Providencia of the tribe Proteae can infect the urinary tract and cause bacteremia in debilitated patients. They are found in the feces or urine of infected individuals.

- Citrobacter and Acinetobacter can cause infections of the digestive tract or produce bacteremia or septicemia in debilitated persons.

Staphylococcus aureus, Bacillus cereus, and Clostridium species are unable to multiply in water, but can cause illness (notably diarrhea) after incubation and growth in food to which contaminated water was added.

P. aeruginosa has received the greatest attention in its role as an opportunistic pathogen and also was the first organism to be described as such. Pseudomonas species (pseudomonads) are gram-negative bacilli, straight or curved, and are motile with polar flagella. They are strictly aerobic, but denitrifying species do exist. They are chemoorganotrophs and some are facultative chemolithotrophs [See also Section A].

P. aeruginosa is a bacillus of 1 to 3 um in length and 0.4 um in diameter, with a polar flagellum. It is ubiquitous in nature and may actively reproduce in potable and distilled water to populations as high as 10^7 per ml (Carson, et al., 1975). This bacterium has few requirements and can grow with only carbon as its energy source in a broad range of temperatures (4 to 42°C) and pH (5 to 8). P. aeruginosa is ordinarily a strict aerobe but can grow under anaerobiosis, utilizing nitrates or arginine as electron acceptors. The identification of P. aeruginosa includes determining its production of pyocyanin on King's medium and some biochemical characteristics, for example, as proposed by Brodsky and Cieben (1978). Strains can be differentiated on the bases of the antigens and pyocyanins that they produce, as well as by phage typing.

P. aeruginosa can cause illness, especially in immunodepressed patients. Ingestion or contact with large amounts of P. aeruginosa in water can cause enteric, eye, ear, and upper respiratory tract infections. The enteric infections are most often manifested as stomach upsets and nausea, but they are not usually reported to medical practitioners. To

become infected, a consumer must be weak (very young or old or immunodepressed) and ingest an effective dose (Hunter, 1947). The eye, ear, and upper respiratory tract infections often cause relatively long-term symptoms, as reported by Hoadley (1977).

A very important problem associated with P. aeruginosa is its increasing resistance to antibiotics (Van Dijck and Van der Vorde, 1976). This resistance is extrachromosomic and the plasmid can code for multiple resistances (Leclerc, et al., 1977a). These plasmids can be passed to the human enteric bacilli that occur with P. aeruginosa in water. P. aeruginosa can also be very resistant to antiseptics.

Even though the pathogenicity of P. aeruginosa is determined more by the patient's state of resistance than by any inherent virulence, the possibility of creating conditions for this microorganism to proliferate in distribution and plumbing systems must be considered. About 10 percent of the healthy human population are carriers and can eliminate P. aeruginosa in feces (Hugh and Gilardi, 1974). This organism can survive in raw water and can be present in drinking water with a frequency varying from 1 or 2 percent to more than 50 percent, depending on the quality of the water (potable or not potable) and the type of water treatment practiced. P. aeruginosa may also persist and grow in water for extended periods and so is frequently found in the absence of coliforms; one study reported that half of the finished water samples containing P. aeruginosa lacked coliform bacteria (Nemedi and Lany, 1971).

For all these reasons, consideration should be given to possible incorporation into routine drinking water analyses of tests for the presence of P. aeruginosa [See Sections F.2 to 3 and G.6], since suitable methods exist for its enumeration [See Section C.2.c].

b. Viruses. Viruses are ultramicroscopic intracellular parasites, incapable of replication outside of a host organism. They consist of a nucleic acid genome enclosed in a protective protein coat and some viruses have lipid-containing outer envelopes. They have been classified on the basis of their size and shape, the composition of their nucleic acid (single or double stranded DNA or RNA), and by their antigenic properties.

Large numbers and diversities of bacterial, plant, and animal viruses may be present in both polluted and unpolluted waters. Most of these viruses are harmless to humans;

they may, however, be economically damaging to agriculture and certain industries such as breweries and dairies.

The viruses of greatest concern are those of human origin which are capable of infecting and causing disease in humans. In general, they are shed in the feces and are known as the human enteric viruses. The most important groups of human enteric viruses will be discussed below. The virus particles (virions) in all these groups are roughly spherical, acid-stable, and lack envelopes [See Table B.1.b-1]. These viruses may cause symptoms in the digestive tract (vomiting and diarrhea), generalized symptoms such as fever, and occasionally respiratory illnesses; some of the more virulent enteric viruses may affect the central nervous system (meningitis or poliomyelitis) or the liver.

(i) Pathogenesis of Viruses. Infectivity resides in the nucleic acid portion of the virus particle. When a suspension of infectious particles is inoculated into a culture of susceptible cells, the particles are engulfed by, or penetrate, host cells, and the cells produce progeny virus. Death of the host cells often results as the viruses continue to replicate.

Infection usually takes place after viruses are ingested, possibly in contaminated water or food. They can pass unharmed through the stomach and infect cells lining the lower alimentary canal. Infection may also start in the throat or, in some cases, in the upper respiratory tract and then spread downwards to the gastrointestinal tract.

The severity of the disease depends on the health and immune status of the patient and on the virulence of the virus. Fortunately, symptoms are negligible or even nonexistent with the majority of infections, even for the most virulent strains of virus. Diagnosis can often be difficult as one virus may cause a variety of symptoms in different patients and different viruses may produce the same symptoms.

(ii) Occurrence and Stability of Viruses. Because they are excreted through the feces of an infected individual, human enteric viruses are the ones most often encountered at sewage treatment plants, and therefore, they are the ones most likely to be released to environmental waters. To a lesser extent, viruses may enter wastewaters from other sources such as blood and urine. Additionally, animals

HUMAN ENTERIC VIRUSES THAT MAY BE PRESENT IN CONTAMINATED WATER

Virus Group (Size and Composition)	Number of Types	Disease or Symptoms Caused	Host Range for Natural Infection	Principal Cultivation Methods
ENTEROVIRUS (About 20-30 nm diameter. Single-stranded RNA in a protein shell)				
Poliovirus	3	Poliomyelitis, meningitis, fever	Man	Human and monkey cells
Coxsackievirus A	24	Herpangina, respiratory disease, meningitis, fever	Man	Newborn mice, human cells
Coxsackievirus B	6	Myocarditis, congenital heart anomalies, meningitis, respiratory disease, pleurodynia, rash, fever	Man	Newborn mice, human and monkey cells
Echovirus	34	Meningitis, respiratory disease, rash, diarrhea, fever	Man	Human and monkey cells
New enteroviruses	4	Meningitis, encephalitis, respiratory disease, acute haemorrhagic conjunctivitis, fever	Man	Human and monkey cells
HEPATITIS VIRUS type A (probably an enterovirus)	1	Infectious hepatitis	Man	No known method except possibly in marmosets and chimpanzees
GASTROENTERITIS VIRUS (possibly an enterovirus)	2	Vomiting and diarrhea	Man	No method available

Virus Group (Size and Composition)	Number of Types	Disease or Symptoms Caused	Host Range for Natural Infection	Principal Cultivation Methods
ROTAVIRUS (About 70 nm diameter. Double-stranded RNA in a single or double protein shell	?	Vomiting and diarrhea, mainly with children	Human infants and calves	Limited replication in pig kidney, continuous monkey kidney, and human embryo kidney
REOVIRUS (About 75 nm in diameter. Double-stranded RNA in a double protein shell)	3	Not clearly established	Man	Human and monkey cells
ADENOVIRUS (About 70-80 nm in diameter. Double-stranded DNA molecule in a protein shell)	>30	Respiratory disease, eye infections	Man	Human cells
PARVOVIRUS (Small diameter. Single-stranded DNA molecule)				
Adeno-associated	4	Not clearly established but associated with respiratory disease in children	Man and some domestic animals	Human embryo kidney cells coinfected with adenovirus

contribute viruses to water, but as yet viruses from this source do not appear to present a public health hazard.

Over 100 different enteric viruses are known to be shed in human feces [See Table B.1.b-1], and new ones are still being discovered. They are often excreted in very large numbers, $> 10^6$ per gram of feces, and $> 5 \times 10^5$ per liter have been found in sewage. Shellfish that are grown in waters contaminated with sewage effluent can bioaccumulate enteric viruses, including the virus of hepatitis A. Viruses may be harbored as long as two months or more in shellfish digestive tracts after all indications of water contamination have ceased.

The human enteric viruses, in general, are stable in an acid environment and in cold temperatures. They are resistant to bile, ether, and chloroform; but they are sensitive to heat, desiccation, and to various oxidants. All are relatively stable outside the host organism, and some can persist in water over long periods of time. As a result, human enteric viruses have been recovered from water long distances from the initial point of contamination.

(iii) Human Enteric Viruses Likely to be Recovered from Water. Viruses of concern to water authorities are those capable of causing major epidemics, as happened in New Delhi in 1955 - 1956 when the water supply became grossly contaminated with sewage, spreading infectious hepatitis to 28,000 people (Viswanathan, 1957). Yet, except for the hepatitis A virus, the public health significance of human enteric viruses in water remains unclear due possibly to the inapparent or latent nature of viral infections and the difficulty of detecting waterborne viruses.

(iii.1) Enteroviruses. These viruses comprise an acid-stable subgroup of the picornaviruses. Human enteroviruses include the polioviruses, the coxsackieviruses groups A and B, and the echoviruses [See Table B.1.b-1]. In addition, several new members (yet to be fully classified) recently have been discovered. Members of the picornavirus group contain single-stranded RNA and are further characterized by the absence of a lipid-containing envelope, average 28 nm size (most subgroups), and increased thermal stability in the presence of divalent cations.

The polioviruses are the most widely studied because they are easy to culture and they include vaccine strains that are safe to handle. Still, they are the most potentially dangerous of the enteroviruses, causing the major crippling disease of infectious origin.

Polioviruses are transmitted primarily through direct contact with pharyngeal secretions or feces of an infected individual. The seasonal peak incidence of poliomyelitis is in the summer and fall (as is true for most all of the enteroviruses) although sporadic cases do occur in any month of the year. In recent years, however, occurrence of poliomyelitis has been reduced significantly by the use of highly effective vaccines. Nevertheless, the virus has not been eliminated from the community, and vaccination programs must be maintained to prevent the resurgence of a susceptible group of children.

Infection with poliovirus and probably most of other enteroviruses normally confers lifelong immunity against the infecting virus strain (this is the basis of the live attenuated vaccine). The older a person is before becoming infected, the more severe his symptoms are likely to be. In many developing countries where sanitary conditions tend to be poor, waterborne spread of polioviruses and other enteroviruses almost certainly occurs. There, infection usually takes place early in life with severe symptoms being few and limited to young children. However, in developed countries where more hygienic conditions prevail, infection may be delayed leading to a greater proportion of serious disease in older age groups. This pattern, characteristic in developed countries, has been observed with poliovirus and can be expected with other viruses.

Eight outbreaks of poliomyelitis, which occurred during the period of 1900 - 1953, in Europe and North America, were attributed to transmission by water, however, Mosley (1967) believed that only one of them was adequately documented. In this instance, 45 cases of poliomyelitis occurred among families living in a cluster of temporary houses on the outskirts of Lincoln, Nebraska (U.S.) in June and July of 1952. The water supply was known to have wide fluctuations in pressure, and vacuum breakers were missing from a number of the toilets.

Where sanitation is good, the oral-oral spread of poliovirus may be more important than the fecal-oral route. For this reason and others mentioned earlier, water would

not appear to be involved with the transmission of polio-viruses in developed countries.

The other enteroviruses are less well known, particularly the group A coxsackieviruses. They also can cause serious illnesses [See Table B.1.b-1] but, like the polioviruses, usually only in a small proportion of those infected (generally, poliovirus causes significant central nervous system disease in only 1 percent or less of those infected).

The most common of the diseases associated with enterovirus infections may well be aseptic meningitis: over 3,000 cases of this disease were reported in the U.S. during 1974. The disease can be paralytic, mimicking poliomyelitis; however, the cases are generally not as severe as those caused by the polioviruses (reviewed in Safe Drinking Water Committee, 1977). Many of the infections are so mild as to escape clinical recognition; others produce encephalitic manifestations and transient paresis. Aseptic meningitis also occurs most frequently in late summer and early autumn, but its incidence tends to be sporadic rather than epidemic. It is possible that the viral agents of meningitis might be transmitted via water, but there have been no documented instances of this as yet.

Although large numbers of enteroviruses have been isolated consistently from fecally contaminated water, only a few reports have implicated water as the vehicle of transmission. This may be due to lack of suitable detection methods and difficulty in demonstrating disease incidence epidemiologically. Or, it could be that the viruses recovered from sewage were the consequence of viral infection in a population rather than the source. The ambiguities surrounding the question of cause or effect with respect to virus occurrence in water will be elaborated on later in the discussion.

(iii.2) Hepatitis A Virus. Hepatitis A is the only form of viral hepatitis known to be transmitted through water and it is also the most prevalent waterborne disease attributable to a specific etiologic agent. Its spread, via sewage-polluted water, is well documented due to its clear-cut symptomatology and the explosive nature of its occurrence. It is therefore considered the most important viral disease transmitted through water.

The virus particle is apparently small enough to be either an enterovirus or a parvovirus and buoyant density studies suggest that it resembles an enterovirus. Its nucleic acid composition has not yet been determined. The agent seems to withstand acidity and heat, but perhaps not more than what the enteroviruses will endure. Though chimpanzees (and perhaps other primates) are infected accidentally on occasion, the only natural host of the virus seems to be man. Transmission is predominantly fecal-oral.

The incubation period of the disease in humans ranges generally from 15 to 50 days, with a median of 28 days. Some people shed the virus in their feces as early as seven days before onset of symptoms; others may transmit the virus without ever becoming perceptibly ill. Anorexia, nausea, and vomiting are seen in most cases; and jaundice is common but certainly not universal. Laboratory diagnosis is often based on demonstration of abnormally high levels of glutamic oxalacetic and glutamic pyruvic transaminases (SGOT, SGPT) in the patient's blood serum. The carrier state does not seem to be prolonged; the virus is usually absent from feces after the symptoms have abated and serum transaminase levels have become normal.

The hepatitis A virus has caused several serious epidemics and numerous small outbreaks in various parts of the world, some of which have been attributed to the consumption of polluted water or contaminated shellfish. Hepatitis A has been epidemiologically implicated in 66 waterborne outbreaks from 1946 to 1975, but its incidence in developed countries does not appear to be increasing. Moreover, the occurrence of hepatitis A as a whole (of which waterborne spread makes up only a small fraction), has shown a downward trend since 1971, in the U.S. Of the 22 waterborne outbreaks associated with municipal systems, three resulted from either inadequate or interrupted disinfection and five were related to the use of contaminated, untreated surface or groundwater. Half (eleven) of the outbreaks traced to municipal systems occurred as the result of contamination of the distribution system, primarily through cross-connections and back-siphonage (Craun, 1978) [See Section F.4].

Attempts to culture the hepatitis A virus in cell lines have consistently failed so that all available evidence about its transmission by polluted drinking water has been obtained from epidemiological surveys. Human volunteers and chimpanzees have, however, been infected with the virus, and

recently developed methods employing immune electron microscopy (IEM) have afforded some progress. These investigations indicate that the hepatitis A virus may soon be classified as an enterovirus. If so classified, the hepatitis A virus could be expected to react to water treatment and purification processes in a manner similar to the other enteroviruses [See Section E.].

(iii.3) Gastroenteritis Viruses. Another group of small viruses potentially transmissible through water, some of which may in fact be enteroviruses, are called gastroenteritis viruses. Included in this heterogenous group are the Norwalk agent and the related Montgomery County and Hawaii agents, rotaviruses, astroviruses, coronaviruses, caliciviruses, the W agent, the cockle virus, and the Ditchling agent [See Section B.1.d]. These have all been detected in diarrheal feces by direct electron microscopy. They do not replicate in routine cell cultures, although some have been shown to replicate to some extent in particular cells (reviewed by Madeley, 1979).

Gastroenteritis is probably the most common waterborne disease in developed countries and was reported to have involved 45,255 cases in 178 outbreaks between 1946 and 1970 within the U.S. (Craun and McCabe, 1973). Gastroenteritis epidemics of viral origin are known to be spread by personal contact; and it seems reasonable to suspect that many waterborne gastroenteritis outbreaks might stem from the same etiologic agents. [See Section B.1.d.]

(iii.4) Rotaviruses. These viruses are related to the reoviruses and belong to the same family, Reoviridae. They have been shown to be antigenically related to viruses of similar morphology isolated from various animal species; but they are antigenically distinct from reoviruses and orbiviruses. Rotaviruses are primarily associated with gastroenteritis in children.

Characterizations of rotaviruses have been made possible by the use of electron microscopy, and recent investigations suggest the possibility of more than one human serotype (reviewed by Madeley, 1979). The viruses have been concentrated and purified from fecal extracts for biochemical and biophysical characterization. Rotaviruses are described as being 70 nm in diameter and appear to contain double-stranded RNA and a protein component with eight

distinct polypeptides observed by electrophoresis. Particles with single- and double-shelled capsids have been detected at bouyant densities of 1.36, and 1.37 g/ml in cesium chloride gradients (Rodger, et al., 1975).

The route(s) of transmission of rotaviruses associated with diarrheal disease in infants and children has not been identified, although direct person-to-person spread has been indicated in some hospital nurseries. In temperate climates, infections with rotaviruses increase during the cold winter months; and at peak times, rotaviruses have been observed in fecal specimens of as many as 90 percent of young hospital patients. A few studies have indicated that adults may also be infected with rotaviruses, usually resulting in relatively mild gastroenteritis. The isolation of rotaviruses from U.S. students who experienced "travelers' diarrhea" while attending a Mexican university and from a community-wide outbreak in Sweden suggests that water transmission of the agent should be considered (Bolivar, et al., 1978; Lycke, et al., 1978). Rotaviruses may be excreted in very large numbers (up to 10^9 per gram of feces -- Madeley, 1979) and they are almost certain to be present in polluted water, but there is presently no suitable method for their detection at low concentrations [See also Section B.1.d].

(iii.5) Reoviruses. Reoviruses are members of the Reoviridae and share a number of properties with the enteroviruses (e.g., spherical shape, lack of an envelope) -- only reoviruses are larger and possess double-stranded RNA cores [See Table B.1.b-1]. They are unusual in that they infect a wide range of animals; furthermore, they have been recovered from persons with a wide variety of illnesses including upper and lower respiratory tract disease, gastrointestinal disease, steatorrhea, exanthems, and some central nervous system diseases. Although they have been found to be highly infectious and have been isolated frequently from sewage and contaminated water, their etiologic role in man has not been established (Horsfall and Tamm, 1965).

(iii.6) Adenoviruses. Adenoviruses are icosahedral and contain double-stranded DNA [See Table B.1.b-1]. At least 28 types are recognized and many serotypes have been isolated from human sources. The adenoviruses resemble enteroviruses only in their resistance to ether and absence of a lipid-containing envelope.

Members of this group generally are considered to be respiratory viruses; they can infect the upper respiratory tract as well as the intestines, typically without evidence of disease. Adenoviruses are often shed for prolonged periods in the feces of young children. They have been isolated frequently from stool specimens, sewage, and contaminated water. Curiously, only a few of those seen in feces by electron microscopy have yielded to culturing in cell lines.

The adenoviruses produce sporadic infections in the general population which tend to be highest in the colder months; but, overt disease is rare. Although they occasionally appear to have been involved with outbreaks of diarrhea, reports of their transmission through water have been connected only with outbreaks of conjunctivitis in persons frequenting swimming pools. Adenoviruses are readily inactivated by free chlorine at levels commonly used to protect water supplies; hence, they should be entirely absent from adequately disinfected drinking water.

(iii.7) Adeno-Associated Viruses. The adeno-associated viruses are members of the parvovirus group and, as such, are the smallest of animal viruses, some having diameters of as little as 19 nm. They are polyhedral, lack a lipid-containing envelope, and contain one molecule of single-stranded DNA. Buoyant density studies have placed them between 1.38 and 1.46 g/ml in cesium chloride. They comprise four known serotypes which have been found to chiefly infect the lower animals such as rats, mice, cats, dogs, swine, and birds; however, infectivity appears dependent on concurrent infection with adeno- or (less readily) herpesviruses. By themselves, the adeno-associated viruses are not known to cause any symptoms. They have, however, been recovered in association with childhood respiratory diseases.

These viruses are quite stable outside of the host organism and can withstand heat at 60°C for at least 1 h. They are highly resistant to many physical and chemical agents and are unaffected by ether, chloroform, and anionic detergents.

Since they have been isolated from feces together with adenoviruses, they are almost certain to be present in fecally contaminated water, although no method for their detection in water is currently available for confirmation.

There are, at present, insufficient data on these viruses for determining their pathogenicity and hence, for judging what, if any, threat they might pose if ingested with drinking water.

(iv) Methods for Detecting Viruses in Water. As more and more water is used to receive waste discharges and run-off from domestic, agricultural, industrial, and recreational uses, the opportunities for fecal, and therefore viral, contamination will increase accordingly. Most enteric viruses are shed in large numbers in the feces of infected persons, although it should be noted that the majority of people in industrialized nations are not infected with enteric viruses on any given day. Because viruses multiply only within susceptible host cells, they cannot increase in sewage. Their numbers are further reduced as a result of sewage treatment, dilution, natural inactivation, and water treatment practices [See Section E.]. Therefore, barring gross contamination of finished water, only low numbers of virus, if any, are likely to occur in properly treated supplies.

(iv.1) Concentration Techniques. The possible presence of only very low numbers of virus necessitates applying highly efficient methods, including a preliminary concentration step, to demonstrate and quantitate any viruses present. Some source waters may contain viruses at such low levels that sample volumes of 400 l or more would be required to enable them to be detected.

Adsorption methods employing glass microfibers (Jakubowski, 1974) and glass powder (Sarrette, et al., 1977) appear promising for handling large volumes of water containing few viruses. Concentration with glass microfibers permits sampling of 2,000 l or more of water and is recommended as a tentative procedure in Standard Methods (American Public Health Assoc., 1975). Many of the enteroviruses can be adsorbed at pH 3.5 to 4.5 in the presence of $AlCl_3$ followed by elution with a protein solution at pH 9.5 or 0.05 M glycine buffer at pH 11.5. Excellent reviews of these methods have been published (Foliguet, et al., 1973; and Sobsey, 1976).

Raw water containing suspended matter and organic substances may require more conservative analytical procedures, such as the aqueous polymer two-phase separation

technique described in <u>Standard Methods</u> (American Public Health Assoc., 1975). If enteric viruses are entrapped in fecal clumps, special procedures must be employed to disrupt the clumps, releasing the virus.

(iv.2) Cell Culture Techniques. Human enteric viruses, if they will replicate at all in the laboratory, must do so in primate cells, although no one cell culture will accommodate all of the various enteric viruses capable of propagation in cell lines. Therefore, selection of host cell systems will, of necessity, be a compromise between what one expects to find, what one knows will yield to culturing, and what costs one can afford.

Enteroviruses, reoviruses, and some adenoviruses can be detected by conventional cell culture techniques using human primary amnion or fetal cells (such as embryonic kidney) and suckling mice. For the coxsackieviruses A, all but three of the 24 types are isolated only in suckling mice. Human diploid embryonic lung cells were used successfully to recover 31 echoviruses (reviewed in Safe Drinking Water Committee, 1977). Unfortunately, there are yet many known enteroviruses that have no known tissue culture hosts. Likewise, there is no laboratory host system for detection of the virus of hepatitis A.

Neither are there cell culture systems for detecting gastroenteritis viruses, although rotaviruses will replicate, to a limited extent, in pig kidney, continuous monkey kidney, and in human embryo kidney (reviewed by Madeley, 1979). The Norwalk, Montgomery, and Hawaii agents, along with rotaviruses, adenoviruses, caliciviruses, the W agent, cockle virus, and the Ditchling agent are detectable, when present in patients' stools at high enough levels (at least 10^{-6} pfu per g feces), using electron microscopy.

Adenoviruses can be cultured only in human cells, and adeno-associated viruses are cultured on human embryo kidney cells concurrently infected with adenoviruses. Quantitation of adeno-associated viruses is thereby handicapped by the necessary inclusion of a helper virus to induce infectivity.

(iv.3) Virus Identification Techniques. Serologic methods for virus identification can be based on serum

neutralization or antigen-antibody interactions. The antigen-antibody tests (comprising immunofluorescence and immuno-enzymatic procedures) yield results sooner than the visible cytopathic effects required for interpretation of serum neutralization tests. However, these immunochemical techniques have not been adapted to use pooled antisera and so, unlike serum neutralization tests, they require as many individual reactions as there are virus types to be identified.

(v) Public Health Significance of Viruses in Drinking Water. The presence of viruses, pathogenic to humans, in groundwater, streams, rivers, and lakes, is certain. The majority of these emanate from domestic sewage but are present in widely fluctuating numbers, anywhere from no viruses per 100 ml to over 45,000 viruses per 100 ml of sewage (Gerba, et al., 1975a). The season, hygienic level of the population, and incidence of disease in a particular community are the major determinants of viral presence, and these factors all are subject to change.

Except for the occurrence of waterborne hepatitis A, however, there is little evidence to connect the presence of enteric viruses in water with incidence of viral disease. Although isolated regularly from sewage and environmental waters, the picornaviruses have not been demonstrated, epidemiologically, to cause disease by this route. Conversely, those outbreaks of gastroenteritis that have been traced to water have not been shown to be of viral origin.

If the epidemiologic data on transmission of hepatitis A through water are representative, it may be useful to consider the kinds of circumstances which have led to water-associated outbreaks of this disease. The overwhelming majority of reported waterborne outbreaks of hepatitis A were attributable to untreated or inadequately treated water supplies. In the case of semipublic and private water supplies, the fault lay usually with sewage contamination of the source coupled with little or no treatment. With large municipal supplies, the problem usually was one of cross-connections or back-siphonage during distribution. The solutions to these obvious deficiencies are straight-forward and attainable.

On the other hand, it is believed by some that viral infections may be spread insidiously by way of continual low level transmission through water. It is the nature of most

viral diseases that they elude the epidemiologist in his
quest for definitive data. Many viruses can cause inap-
parent or latent infections which go unrecognized until
secondary person-to-person spread finally leads to overt
disease in scattered, virtually untraceable pockets of the
population. One case in point is the picornaviruses, the
majority of which cause subclinical infection much more
frequently than overt disease.

Inadequacies in current water treatment techniques have
been demonstrated on several occasions when viruses were
isolated from conventionally treated potable supplies which
had received treatment adequate to remove bacterial patho-
gens (Berg, et al., 1975; Jenkins and Mendia, 1967; Hoehn,
et al., 1977). Whether the extremely small numbers of viruses
that manage to get through into drinking water are suffi-
cient to initiate infection in a community, or whether other
modes of transmission play a much more prominent role in
disseminating them , is not yet known.

Virus interactions with tissue cultures and with the
intact host do not appear to be entirely comparable, although
such comparisons have been made. There is evidence to
suggest that anywhere from a few to a great number of viral
particles must be present to account for one tissue culture
dose (TCD) -- that quantity of virus required to produce in
a tissue culture an infection that is perceptible on the
basis of cytopathic effect, plaque formation, or some other
manifestation. The number of virus particles corresponding
to a TCD sometimes ranges in the thousands but is always
greater than one. Although tissue cultures vary in their
susceptibility to any given virus, it is clear that the
process by which animal viruses initiate infection is inher-
ently inefficient; there is no known system in which every
single animal virus particle succeeds in initiating infec-
tion. The number of viral particles that equals a TCD
varies with the cell line as well as with the virus; the
laboratory procedures used to make these determinations
impose further uncertainties. Finally, host cells in culture
may not be strictly representative of intestinal cells in
vivo; hence, experiments which try to relate TCD's mani-
fested in cell lines to human infectious doses have produced
quite disparate results.

Infection and disease are not synonomous. Viral infec-
tions may be highly prevalent when the incidence of viral
disease is low. The occurrence of disease among infected
persons is strongly dependent upon the individual hosts'

susceptibilities. A detailed summary of this topic is presented by the Safe Drinking Water Committee (1977).

For all of the reasons outlined above, reported levels of viral contamination in water cannot be used directly to assess the risk to human health. If surveillance programs were equipped and staffed to detect virus infections, there would be an increased likelihood of tracing sources of viral disease. However, such an approach would be almost impossible to implement because of the considerable expense and personnel time it would consume. Studies to determine virus levels in drinking water, in conjunction with epidemiologic surveys of viral disease in the community, are sorely needed. Epidemiologists and public health laboratories must have available to them the expertise for conducting extensive virologic studies whenever disease is suspected of being waterborne and the etiologic agent is unknown. Until information gathered from such investigations is forthcoming, the public health significance of small numbers of viruses in drinking water will remain undetermined.

(i) <u>Entamoeba histolytica</u>. This protozoon causes amebic dysentery as well as such other clinical manifestations as diarrhea, abscesses of the liver (or less commonly of the lung or brain), and skin ulceration. It can also cause chronic infections with minimal symptoms, or the organism may act as a commensal within its asymptomatic host carrier. Amebiasis (infection with <u>E. histolytica</u>) occurs world-wide; and dysentery epidemics are, by and large, waterborne -- usually the result of poor sanitation.

(i.1) Characterization and Pathogenesis. Entamoebidae is the only exclusively parasitic family in the order Amoebida; and <u>E. histolytica</u> (referred to in some American literature as <u>Endamoeba</u>) is the only true pathogen among five species of amebae which parasitize the human intestine. Two other members of the genus <u>Entamoeba</u>, <u>E. coli</u> and <u>E. hartmanni</u>, are harmless intestinal parasites, the latter morphologically resembling <u>E. histolytica</u> and easily confused in clinical diagnoses.

<u>E. histolytica</u> exists in both the actively growing trophozoite (9 x 11 um or 18 x 25 um) and dormant, thick-walled cyst (6 to 8 um or 12 to 15 um in diameter) states, as do the other intestinal amebae (except <u>Dientamoeba fragilis</u> which exists only as a trophozoite). The organism

is not infectious when passed in the feces of patients with acute dysentery, owing to its occurrence at this time as a fragile trophozoite. However, once lodged in the host, trophozoites can attack the walls of the intestine, feeding characteristically (but not exclusively) upon red blood cells. They may penetrate the intestinal lining, causing intense inflammation and ulcers (amebic dysentery). They may also gain entry to the lymph and blood vessels and then be carried to the liver, lungs, brain, and other organs where abscesses will result. Cysts are passed in the feces of asymptomatic carriers or of patients with chronic or mild cases of amebiasis; in this way, they may spread the disease.

As early as the 1940's, most researchers agreed that other factors beyond the solitary presence of E. histolytica were needed to provoke an infection (Chang, 1948). When axenic E. histolytica cultures were administered to gnotobiotic guinea pigs, no symptoms were apparent. However, animals whose intestines harbored either E. coli or A. aerogenes developed ulcerations after receiving the pathogen (Phillips, et al., 1955). The importance (but not the exact role) of an accompanying bacterial flora was realized: one proposed mode of mixed etiology was supposed to involve a profound anaerobiosis occurring as a result of disturbance to the normal bacterial flora (Chang, 1948). Such anaerobiosis would ostensibly favor penetration of the mucosa by E. histolytica. In its vegetative stage (trophozoites), E. histolytica is extremely fragile and is killed in 35 min at 45°C, in 2 to 5 h at 32°C, in 6 to 12 h at 25°C, and in 18 to 96 h at 15°C. The cysts are more resistant, being able to survive in the environment for three to four days at 25°C and more than four weeks in slightly alkaline water.

Although the U.S. Center for Disease Control has, in the last decade, received from 2,000 to 3,000 annual reports of symptomatic amebiasis (Center for Disease Control, 1977c), none since 1953 has been waterborne. Those which did occur prior to 1953 involved sewage contamination of water supplies that primarily serviced private distribution systems. It is clear that cross-connections or back-flow of sewage into water supply lines must be prevented in order to preclude transmission of E. histolytica through drinking water [See Section F.4]. No waterborne outbreak of symptomatic amebiasis has been reported in Western Europe during the 1970's.

(i.2)   Effects of Treatment Practices.   In the U.S., improved sanitary sewerage systems have been largely responsible for the curtailment of waterborne amebic dysentery. Also important has been the introduction of coagulation [See Section E.2] and filtration during water treatment. Sand filtration of water [See Section E.3] removes nearly all cysts, and diatomaceous earth filters remove them all. Data on survival of E. histolytica exposed to iodine [See Section E.5.d] are summarized in Figures B.1.c-1 and 2. The parameter of cysticidal residual used in these calculations is defined as that concentration required to kill 99.999 percent of cysts. High pH decreases the cysticidal activity of chlorine [See Section E.5.a], bromine, and iodine. But at pH 4, a bromine residual of 1.5 ppm produced 99.9 percent cyst mortality, whereas 5 ppm iodine residual and 2 ppm chlorine residual were required for the same results under the same conditions. Ozone, applied at 0.5 ppm, can kill 97 to > 99 percent E. histolytica cysts suspended in tapwater (Newton and Jones, 1949) [See Section E.5.b]. Also, heating to 52°C for 2 min destroys E. histolytica cysts (Chang, 1950); and drying causes instantaneous death (Chang, 1948). Finally, water storage for four weeks at 10°C and for one week at 20°C destroys cysts.

There is at present no standardized method for detecting E. histolytica in water. Various methods for concentrating by filtration have been recommended. Detection is essentially accomplished by careful microscopic examination of concentrated or unfiltered water samples that have or have not been stained. However, laboratory diagnosis for E. histolytica is often difficult and requires highly specialized procedures.

(ii)   Giardia Lamblia.   This protozoon infects the small bowel and causes prolonged diarrhea and several other intestinal symptoms. It is the most frequently diagnosed parasitic pathogen in U.S. public health laboratories; moreover, giardiasis appears to be emerging as a major waterborne disease, having been responsible for 14 waterborne outbreaks in the U.S. between 1965 and 1975, 12 of which occurred between 1971 and 1974 (Horwitz, et al., 1976). It was not until 1966 that water was recognized as a vehicle of giardiasis transmission, and since that time, increased awareness on the part of physicians may have accounted for the more frequent reporting of outbreaks.

FIGURE B.1.c-2

RELATIONSHIP OF CONTACT TIME TO CONCENTRATION OF I_2 AND HOI
FOR DESTRUCTION OF 99.9% OF CYSTS, VIRUSES, AND BACTERIA AT 18°C
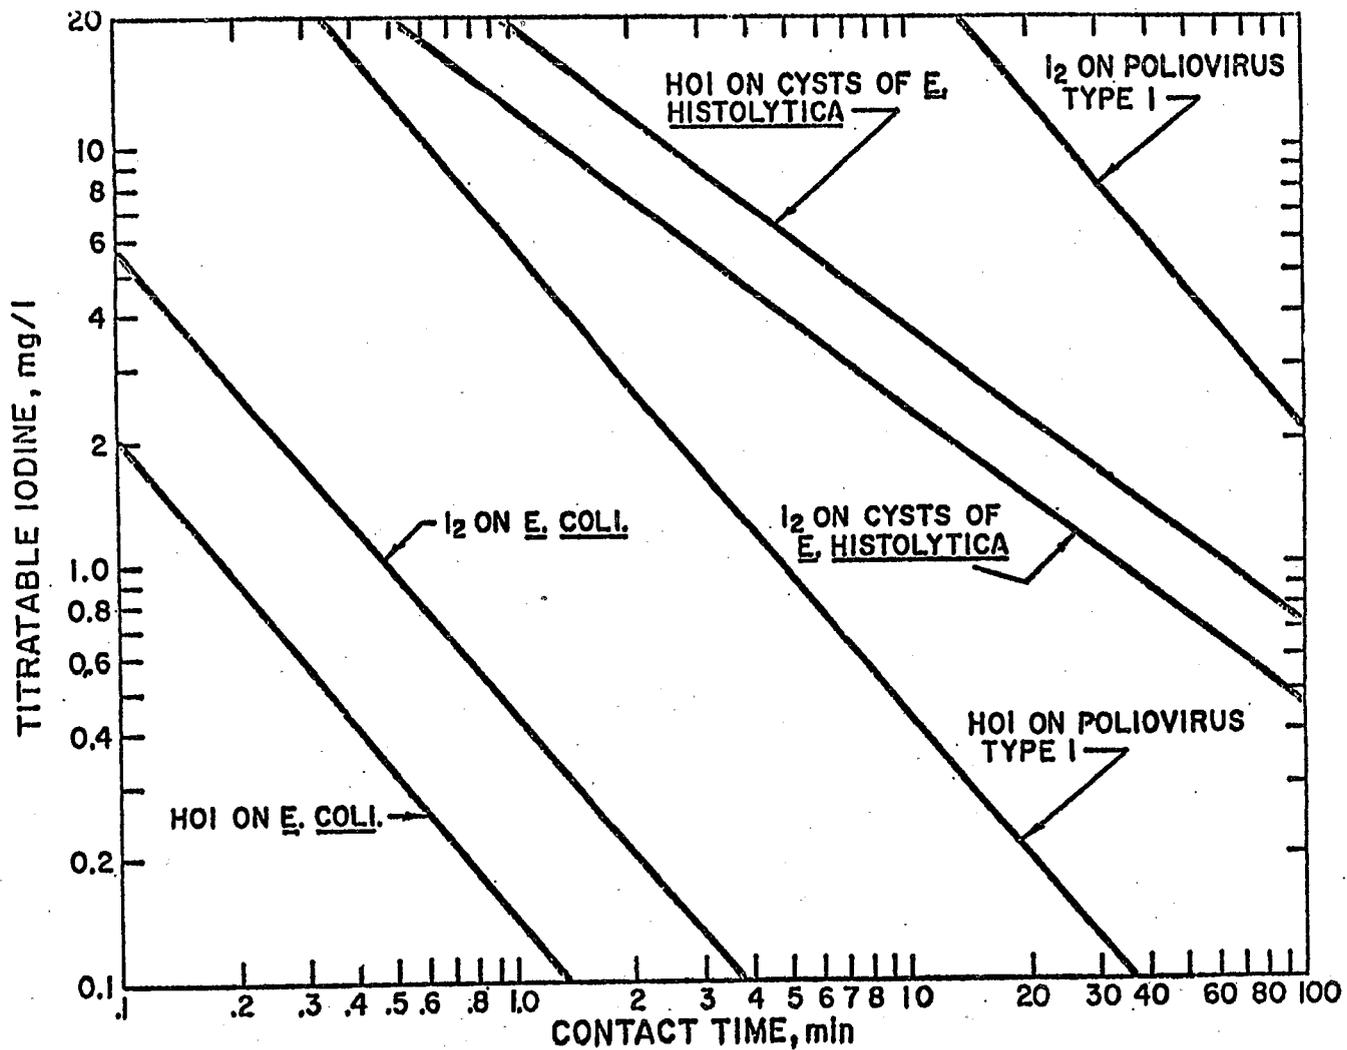

(ii.1) Characterization and Pathogenesis. The flagellate G. lamblia exists as both trophozoite (9 to 18 um x 6 to 9 um) and cyst (9 to 12 um x 5 to 8 um). After being ingested as cysts, the organisms quickly develop into infectious trophozoites, coating the mucosa of the duodenum and upper jejunem and often causing such changes as flattening of villi and roughing of mucosal surfaces; the flagellate bodies may imbed deeply in the villi (Burke, 1975; Nath, et al., 1974). The large number of trophozoites lining the mucosa interferes mechanically with absorption (especially of fats) and enzyme activity, and this can lead to weight loss, malnutrition, and anemia. Symptoms, which include chronic diarrhea, steatorrhea, and abdominal cramps, are generally more severe in children (especially those with any immunodeficiency) than in adults.

(ii.2) Epidemiology. Beavers were implicated as the source of a waterborne giardiasis outbreak which took place in Camas, Washington (U.S.) in 1976, which included 128 confirmed cases in a population of 6,000 people (Dykes, et al., 1977). Beavers, but not coyote, opossums, nutrias, or porcupines, were found to be carrying G. lamblia cysts which were recovered from both raw and finished surface waters. The beavers inhabited a pond bordering a heavily used state park and were within foraging distance of water intakes for Camas [See also Section B.2]. A similar epidemic occurred a year later in Berlin, New Hampshire (U.S.) where at least 205 residents (an attack rate of ∿ 25 percent) were confirmed to be ill with giardiasis. Sewage contamination of one raw water source was demonstrated, and unrestricted public access to the other source provided opportunity for fecal contamination (Center for Disease Control, 1977c). Beavers trapped nearby were found with intestinal lesions produced by Giardia trophozoites.

The first laboratory confirmed (using pathogen-free beagle dogs) outbreak of giardiasis in the U.S., also the largest outbreak to date, involved an estimated 5,300 persons (in a population of 46,000) in Rome, New York; 359 of the cases were clinically confirmed (Shaw, et al., 1977). Raw mountain stream water from the heavily wooded, sparsely populated watershed had routinely shown low coliform counts over a two-year period, but very high total bacterial counts were recovered from water in the distribution system. This led investigators to conclude that raw water, though not contaminated with human sewage, was insufficiently chlorinated during treatment. However, they went on to caution against reliance on chlorine for destroying Giardia cysts.

Every U.S. outbreak involving municipal water supplies, except one, has been associated with surface water sources where disinfection was the only treatment. The one exception occurred in Aspen, Colorado in 1965 and 1966 (Moore, et al., 1969). Wells provided the town's water, but old, broken and leaking sewer lines passing close by served as the source of contamination.

(ii.3) Effects of Treatment Practices. G. lamblia cysts are not destroyed by chlorination at dosages and contact times commonly used in water treatment [See Section E.5.a], nor do closed pressurized filtration systems afford adequate protection, as was evidenced in the Camas outbreak. Beyond ensuring against opportunities for fecal contamination, water treatment regimes should include coagulation [See Section E.1], sedimentation [See Section E.2], and filtration [See Section E.3]. When aluminum sulfate was applied to water maintained at usual pH levels and turbidities encountered at a water treatment facility, 99.999 percent of suspended Giardia cysts were removed. The addition of calcium and/or magnesium salts to aid floc formation is recommended for very cold or very soft waters. Filters should be of adequate depth and the rates of filtration and back-flushing should be adjusted to ensure entrapment of cysts and to prevent turnover or channeling of the filter.

Proper maintenance is essential. The greatest risks will occur in water systems that use only disinfection and in contamination of water in the distribution system by sewage from broken lines or from cross-connections. More study is needed to define the conditions required for destruction of G. lamblia cysts.

Concentration techniques, using microporous filters, for recovery of G. lamblia cysts are based on established methods for concentrating viruses. When culture methods become available for inducing G. lamblia to excyst, propagate, form trophozoites, and encyst in one complete life cycle, the organism will then be accessible for closer scrutiny and possible eradication as a waterborne agent of disease.

(iii) Naegleria Fowleri. The facultatively parasitic ameba, Naegleria fowleri, has, in the recent past, been recognized as one of two agents (also Acanthamoeba) responsible for causing primary amebic meningoencephalitis (PAM), mostly in children and young adults -- a disease which is usually

fatal within three to seven days. The organism is a free-living ameba, ordinarily found in water, soil, and decaying vegetation. There is no evidence of any person-to-person transmission; instead, the infection appears to take hold, in most instances, when water containing N. fowleri cysts enters through the nose, usually as a result of swimming in fresh water lakes, swimming pools, or hot springs. Though associated with recreational waters, the ameba has more recently been isolated from tapwater in connection with incidences of PAM (Safe Drinking Water Committee, 1977).

(iii.1) Characterization and Pathogenesis. The first two known cases of PAM occurred in 1962, in Orlando, Florida (U.S.), but the causative agent was not definitely identified until several years later when a Naegleria species was isolated from cerebrospinal fluids grown on inorganic agar seeded with coliform bacteria (Butt, 1966; Butt, et al., 1968).

The genus Naegleria belongs to the family Schizopyrendae, of which N. fowleri (which has been successively named N. fowleri, N. aerobia, and N. invades by different investigators) is the only species known to be pathogenic. The ameba measures approximately 8 - 15 um and has a spherical nucleus and one or more lobate pseudopodia. It exists either as a cyst or a trophozoite; the latter becomes flagellated after a few hours in water. Trophozoites are indistinguishable from those of the nonpathogenic N. gruberi in freshly prepared specimens. Both species have a conspicuous centrally located nucleolus and are slightly smaller than E. histolytica; they must be differentiated by serological tests.

Pathological findings indicate that, once insinuated into the nasopharynx, the ameba can "chew" its way from the roof of the nose through the cribiform plate into the cranial cavity. A phospholipase-like enzyme of the ameba can decompose syringomyelin in a chemically defined medium; this enzyme is probably the means by which the ameba can penetrate the olfactory mucosa and find its way into the brain through the olfactory nerve plexus (Chang, 1978). Extensive demyelination of the white matter in the central nervous system has also been attributed to the action of this enzyme. The typical syndrome comprises fulminating meningoencephalitis with severe frontal headache, nausea, vomiting, high fever, nuchal rigidity, and somnolence, with death on the fifth or sixth day.

(iii.2) Sources and Occurrence. Cases of PAM have been reported in Australia, Czechoslovakia, the U.K., Ireland, Belgium, New Zealand, India, Africa, and the U.S. As of 1974, there were 64 cases reported worldwide, most have occurred during the hottest time of the year. In South Australia, infection is believed to have occurred as the result of school children washing their noses with ameba-laden tap water (Fowler and Carter, 1965). In Czech-oslovakia, a swimming pool (and possibly a stream) was the source of infection (Cerva and Novick, 1968); a swimming pool and thermally polluted stream served as vehicles of infection in Belgium. All cases in the southeast U.S., except one, were traced to swimming in lakes; in California, two victims had a history of swimming in a creek fed by a hot spring. An extensive survey of lakes in the Orlando, Florida (U.S.) area (Wellings, et al., 1977) revealed the presence of N. fowleri in 12 out of 26 lakes examined (single sample). Moreover, viable cysts, identified as Naegleria and Acanthamoeba species, have been found in eight of 15 finished water samples in a survey of large city supplies across the U.S. (reviewed in Safe Drinking Water Committee, 1977).

Increasing eutrophication and thermal pollution of water are likely to enhance the growth of N. fowleri. However, evidence of its rather widespread presence has not been associated with widespread occurrence of PAM. In fact, there has been no case in Czechoslovakia since 1968, in Australia since 1972, in Belgium since 1973, and in New Zealand since 1975. Other unknown factors may be important accompaniments to the occurrence of infection and should be investigated in view of the disease's high fatality.

(iii.3) Persistence. Little is known about the sta-bility of N. fowleri cysts and trophozoites. Cysts very likely are resistant to chlorine [See Section E.5.a] as are those of other parasitic amebae; therefore, emphasis should be placed on coagulation [See Section E.2] and filtration [See Section E.3] processes to remove these organisms from waters in which they may be proliferating.

(iv) Acanthamoeba Species. Acanthamoeba, also associ-ated with PAM, is the most widely distributed, free-living ameba in all types of fresh water and in sewage effluents (Chang, 1971a).

This facultative parasite measures 10 - 25 um and has multiple, spine-like filiform pseudopodia. Cysts have a double layered wall and, upon aging, give a wrinkled appearance from retraction of the inner wall. Acanthamoeba is able to grow axenically on ordinary media such as tryptic digest soy broth or even peptone solution; in contrast, Naegleria generally requires the presence of living bacteria, tissue culture cells, fresh tissue, or fetal calf serum.

Species of Acanthamoeba were formerly classified within the genus Hartmanella (Singh, 1953). There are still problems in the differentiation of individual species due to morphological and cultural similarities and because single strains oftentimes exhibit morphological variability, even under the same growth conditions (Chang, 1971a). Species must therefore be classified on the basis of serology. Acanthamoeba cysts are extremely resistant to chlorine [See Section E.5.a], drying, and freezing.

Experimental evidence indicates that all Acanthamoeba species, except A. palestinensis, are at least mildly pathogenic. Infection does not occur through any specific portal of entry; rather, the organism is believed to be a secondary invader taking advantage of abrasions, ulcers, or other infections initiated by other organisms (Chang, 1971a). When an ulcer is well established, the amebae may consume all the bacteria and feed on the exudate and cell debris. Acanthamoeba has been implicated in PAM cases of patients who were debilitated or undergoing immunosuppressive therapy.

Like Naegleri fowleri, Acanthamoeba species have been isolated from tapwater in association with PAM cases (reviewed in Safe Drinking Water Committee, 1977). However, their presence in finished drinking water seems unlikely to lead to PAM in the consumer. Acanthamoeba is detected by microscopic examination of the water sample.

(v) Helminths (Worms). In the U.S., metazoan parasites that may be transmitted by ingestion of water are limited to a few intestinal nematodes (roundworms) and even fewer trematodes and cestodes (flatworms). Of the nematodes, the following merit consideration: Ascaris lumbricoides (the stomach worm), Trichuris trichura (the whipworm), Necator americanus, Ancylostoma duodenale, A. brasiliense (hookworms), and Strongyloides stercoralis (the threadworm). Cestodes of

public health significance are <u>Hymenolepis nana</u> (the dwarf tapeworm) and <u>Echinococcus granulosus</u> (the dog tapeworm).

Eggs of the intestinal nematodes originate from feces and may be shed directly into surface waters or indirectly through surface water run-off or drainage from polluted soil where conditions would favor development of infective larvae. In order to infect, a hookworm larva normally must penetrate the host's skin, most commonly as a result of walking barefoot on polluted soil. However, infection can also be acquired through penetration of oral mucosa by waterborne larvae which, in the case of <u>Strongyloid</u> larvae, have been found in drinking water as well as on leafy vegetables (Strong, 1944). The guinea worm <u>Dracunculus medinensis</u> is a nematode that develops as an infective larva in copepods, usually <u>Cyclops</u>. Humans can become infected by drinking water containing the larvae, and eggs may subsequently exit through the feet as a result of wading. <u>D. medinensis</u> is not endemic in the U.S.

Due to the complex life cycle of trematodes, infection occurs and is endemic only in areas where the appropriate intermediate snail host is present. Most cestodes that parasitize humans require vertebrates (cattle, swine, fish) as intermediate hosts. Cestode life cycles are relatively simple and the organisms are more widely disseminated in nature, particularly <u>Hymenolepis nana</u> and <u>H. diminuta</u>. <u>H. nana</u> is a tapeworm of man, but can incidentally infect rats and mice; <u>H. diminuta</u> is a tapeworm of rats and mice, but occasionally is found in humans. Water contaminated with human feces or rat droppings may serve as the vehicle of transmission, and athe fully embryonated eggs are infective upon ingestion.

Eggs of most parasitic helminths are large, about 50 um in diameter or larger, and being heavier than water they are easily removed by standard water treatment processes that include storage, coagulation, sedimentation, and filtration [See Sections E.1 through 3]. However, the infective larvae of hookworms and threadworms are highly motile and can sometimes move through sand filters. Consequently, sand filtration and flocculation have not proved to be adequate safeguards against these larval forms. They are also much more resistant to disinfectants than are enteric bacteria, viruses, or even protozoan cysts. If such larvae are suspected in drinking water, heating to boiling is the only safe measure. On the other hand, the chances of obtaining a

serious worm infection via drinking water are extremely slim considering that: (1) eggs and most larvae settle out in water; and (2) each egg or larva develops into only one worm in the host, and this inability to replicate, coupled with the enormous dilution effect in water, makes transmission through drinking water highly unlikely. Such conditions of relative safety do not, however, apply to wells polluted with surface water nor to systems that use chemical disinfection as the sole treatment.

Since hookworm and threadworm larvae are about the same size as the harmless free-living adult nematodes (0.75 to 1.0 mm long, 40 to 60 um wide) and since these latter are frequently found in water supplies and breed well in slow sand filters, there are opportunities for mistaken identity. The harmless, free-living nematodes include members of the genera <u>Cheilobus</u>, <u>Diplogaster</u>, <u>Diplogasteroides</u>, <u>Trilobus</u>, <u>Aphelenchus</u>, and <u>Rhabditis</u>. They normally inhabit the soil, and if present in wastewater influent, will flourish during aerobic sewage treatment such as by trickling filters or activated sludge. Effluents from such treatment plants, upon entering receiving waters, may contain large numbers of these organisms. Sand filters used to process raw water for drinking purposes may become infested with these organisms, which ultimately will be carried through the distribution system to the consumer. Nevertheless, it should be borne in mind that these nematodes are a subject of concern only insofar as they reportedly produce a gummy substance, small quantities of which confer an unpleasant taste to finished water.

The only effective way to remove both the parasitic hookworm and threadworm larvae and the free-living nuisance nematodes from water is to chlorinate heavily, allowing at least 2 to 4 h contact time to immobilize them prior to flocculation and sand filtration. Nematodes are detected by filtering the water sample through a woven nylon strainer of 25 to 30 um pore diameter, then pipetting in phosphate buffer to dislodge them and finally examining the sample microscopically.

d. <u>Gastroenteritis of Undetermined Etiology</u>. Gastroenteritis, resulting in nausea, vomiting, and diarrhea, accounts for over half the reported cases of waterborne disease. The cause of illness cannot be determined in the majority of these cases.

Many causes of gastroenteritis are possible: among them, only the infectious agents are transmitted, with any frequency, by contaminated water or food. Fecally contaminated water is a likely source of these agents since diarrhea is one of the major symptoms of gastroenteritis. Indeed, sewage contamination of drinking water supplies has produced the largest number of documented cases of waterborne disease. Such contamination often results in explosive outbreaks of acute gastroenteritis affecting a large percentage of the individuals who ingest the water.

When gastroenteritis of undetermined etiology occurs in otherwise healthy individuals, it is generally self-limiting; and in the majority of cases, there is no need for medical attention. However, outbreaks that occur among malnourished or otherwise weakened persons can lead, especially when they occur repeatedly, to more serious consequences; as a result, this disease is considered to be a major cause of infant mortality, particularly in the tropics.

(i) Categories and Properties of Agents of Gastroenteritis. Many of the infectious agents which sometimes cause waterborne gastroenteritis are discussed in other sections of this report. Those most often incriminated are enteric bacteria of the genera Salmonella and Shigella [See Sections B.1.a(i) and (ii)], perhaps because these are often the only organisms sought in laboratory investigations of waterborne outbreaks. More extensive investigations may also include testing for enteric viruses [See Sections B.1.b and C.2.b], enteropathogenic E. coli [See Section B.1.a(iv)] and the cysts of Entamoeba and Giardia [See Section B.1.c]. Nonetheless, even when laboratories do thorough tests of diarrheal stool specimens and water samples they usually fail to identify an etiological agent. The illness in such outbreaks is often called "acute infectious nonbacterial gastroenteritis" (AING) if bacteria-free fecal extracts from affected individuals cause gastroenteritis when ingested by volunteers. The agents causing AING therefore were often presumed to be viruses, although laboratories were (and still are) unable to cultivate these presumed viruses. It is only recently that means have been developed for identifying some of the viruses responsible for AING. Most of the viruses that can be isolated from feces by standard cultural methods are not agents of gastroenteritis, but may, however, cause a variety of other symptoms [See Section B.1.b].

(i.1) Parvovirus-Like Agents of Gastroenteritis. A breakthrough in identifying AING agents came in the early 1970's when viral particles were detected in connection with a gastroenteritis outbreak that had a 50 percent attack rate at a school in Norwalk, Ohio, U.S. (Kapikian, et al., 1972). The outbreak was characterized by nausea, vomiting, and stomach cramps, and symptoms typically persisted for 12 to 24 h. Secondary cases occurred in 32 percent of family contacts.

The viral particles were seen by means of immune electron microscopy (IEM) in fecal extracts from a volunteer who had ingested stool filtrates from an outbreak victim. The well from which the school's water was obtained was suspected, but could not be definitely incriminated because the IEM method is not sensitive enough to detect viral particles in environmental samples. The virus was called the Norwalk agent and was characterized as a parvovirus-like 27 nm particle similar in appearance, but unrelated serologically, to the virus of hepatitis A.

Further investigation has revealed similar particles in stool specimens from two separate family outbreaks of AING, one in Montgomery County (U.S.) and the other in Hawaii (U.S.) (Thornhill, et al., 1977). The Montgomery County (MC) agent was found to be antigenically similar and the Hawaii (H) agent dissimilar to the Norwalk agent, suggesting that more than one type of parvovirus-like agent may be associated with AING. This conclusion is supported by work conducted in England where parvovirus-like particles designated "W", Ditchling, and cockle agents were associated with two distinct gastroenteritis outbreaks (Appleton and Buckley, 1977; Appleton and Pereira, 1977). These viruses are similar in morphology, size, and density, but are antigenically dissimilar to the Norwalk agent. They show considerable similarities to enteroviruses and may soon be classified as such. The cockle agent is of special interest because shellfish, the probable vehicle of transmission, were taken from water where sewage pollution was known to occur (Appleton and Pereira, 1977).

(i.2) Rotavirus. A second category of viral agents associated with gastroenteritis also was identified in the early 1970's. Reovirus-like particles were visualized in fecal extracts from infants and young children experiencing diarrheal illness (Bishop, et al., 1973). They were also reported by Riley to be the cause of several non-bacterial diarrheal outbreaks (reviewed in Craun, 1979). These particles have been found worldwide in association with diarrheal disease in infants and young children. They have been

isolated from as many as 75 percent of children with gastro-
enteritis (Madeley, 1979). Infections appear to be more
common during colder winter months. The incubation period
is about 48 h and the disease is short-lived; viruses are
seldom isolated after the eighth day. Infection normally
leads to long-lived immunity.

These viruses are now generally called rotaviruses,
although they have also been referred to in the literature
as orbiviruses, duoviruses, reovirus-like agents, and infan-
tile gastroenteritis viruses. The human rotavirus, like the
parvovirus-like agents, has not yet been isolated in labora-
tory cell cultures. However, it is often excreted by in-
fected individuals in concentrations sufficient to be de-
tected by direct electron microscopic examination of fecal
extracts [See Section B.1.b].

(i.3) Other Viruses and Bacteria Associated with
Gastroenteritis. In addition to parvovirus-like particles
and rotaviruses, other yet unidentified viruses have been
visualized by electron microscopy of diarrheal stools.
These include particles resembling coronaviruses, myxoviruses,
astroviruses, adenoviruses, and caliciviruses, ranging in
diameter from 28 to over 100 nm.

Electron microscopy studies have revealed the presence
of adenoviruses in feces, while normal cultural methods
yielded negative results. The presence of these adeno-
viruses has occasionally been associated with mild outbreaks
of gastroenteritis (Flewett, et al., 1975). However, it is
difficult to assess the extent to which the illness can be
attributed to the virus because these viruses have commonly
been isolated, using both cultural methods and electron
microscopy, from healthy persons. It is not known why some
of these viruses apparently cannot be cultured, nor is it
clear whether or not the nonculturable strains are of dif-
ferent serotypes.

There is still considerable confusion in identifying
viruses in feces, especially when variations in methods,
possible artifacts, and the presence of bacteriophages are
considered. Furthermore, all of these viruses have been
isolated from healthy persons as well as from those with
gastroenteritis and, on some occasions, more than one virus
has been present. Therefore, the role of these agents in
AING is unclear at present, but it would appear that AING
might have several viral causes.

Investigations by the U.S. Public Health Service on waterborne outbreaks of acute gastroenteritis have indicated that parvovirus-like agents are most likely responsible for many of these episodes in the U.S. However, the nonbacterial nature of AING outbreaks is sure only in those instances where the disease has been transmitted to volunteers in bacteria-free filtrates of diarrheal stool. The recent association of Yersinia enterocolytica [See Section B.1.a(iii)] and of Campylobacter fetus [See Section B.1.a(viii)] with waterborne gastroenteritis outbreaks in the U.S. (Craun, 1976; Center for Disease Control, 1978b) must also be kept in mind. These bacteria are more difficult to cultivate in the laboratory than are the more familiar enteric bacterial pathogens and tests for their presence are not routinely conducted. For this reason they may sometimes be responsible for outbreaks that are mistakenly designated AING.

(ii) Conclusion and Recommendations. Now that electron microscopic and serologic procedures are available to detect them, it is clear that there are indeed viruses capable of causing AING. As more information is forthcoming, many once unidentified infectious agents will probably be classified as identifiable viruses. For example, infections now known to be caused by rotaviruses can no longer be referred to as "gastroenteritis of undetermined etiology." The incidence of gastroenteritis viruses in humans and in water and wastewater might be determined better if laboratory means of cultivating these agents could be developed. Meanwhile, culture procedures capable of isolating the less-frequently suspected bacterial causes of gastroenteritis should be employed in investigating all waterborne outbreaks.

2. Sources of Waterborne Pathogens

The reservoirs for microbiological diseases transmissible to man, consist of man himself as well as both domestic and wild animals (including some poikilotherms). The microorganisms responsible for causing disease generally are excreted in the feces or urine, whereupon they may gain access to water. If drinking water treatment is inadequate or lacking altogether, these organisms may pass freely into water en route to the consumer, thereby engendering a risk of infection and possibly disease [See Section E].

The human intestines are the source of most of the
bacteria [See Section B.1.a], virtually all of the viruses
[See Sections B.1.b and B.1.d], and the great majority of
protozoan and metazoan parasites [See Secton B.1.c] which
can be transmitted through water to man. Nonhuman sources
are significant for a few waterborne pathogens, as is seen
in Table B.2-1.

 a. The Role of Man. Pathogenic microorganisms are
excreted not only by individuals with clinical symptoms, but
also by asymptomatic carriers. The average number of
individual humans excreting Salmonella at any given time
will vary from < 1 percent to 3.9 percent according to
studies conducted in several countries throughout the world
[See Section B.1.a(i)]. In a great number of cases, these
people were outwardly healthy yet excreted about 10^6 organ-
isms per gram of feces.

 Enteric viral infections are common in children, espe-
cially those under five years of age. The high frequency of
occurrence is obscured by the fact that only a small percent
of those infected manifest serious disease. Prior to the
introduction of the poliovirus vaccine, it was estimated
that only one of every 1,000 children infected with the wild
virus contracted paralytic disease (Melnick and Ledinko,
1951). A similar ratio probably exists for many of the
other enteric viruses, therefore, an indication of the
prevalence of enteric viruses in a community must be deter-
mined from viral excretion data. A recent study conducted
in Seattle, Washington (U.S.) indicated a rate of virus
isolation in feces (excluding poliovirus) of 2 to 4 percent
among family members selected for the study (Cooney, et
al., 1972).

 Poliovirus isolates were eliminated from the evaluation
because they were assumed to be primarily of vaccine origin.
Gelfand and colleagues (1957) in earlier work in Louisiana
found that as many as 16 percent of the healthy children
included in their study were excreting other than polio-
viruses during the summer months. They also found excretion
rates to be inversely related to socio-economic status.
Interestingly, Chin and coworkers (1967) were able to demon-
strate the presence of vaccine strain poliovirus in sewage
when as few as 0.3 percent of the local population has received the
live-virus vaccine shortly prior to the examination of the
sewage. The Seattle study also found that children less
than one year of age had an average of 1.5 enteric viral
infections per year which dropped to 0.58 for those two to

TABLE B.2-1

SOURCES OF WATERBORNE PATHOGENS

five years of age and fell considerably lower for those over
five [See also Sections B.1.b and B.1.d].

Protozoan cysts are passed in the feces of asymptomatic
carriers or patients with chronic or mild cases of amebiasis.
Patients with acute dysentery shed trophozoites that are
non-infectious. Asymptomatic carriers of the protozoon E.
histolytica usually outnumber those with symptomatic ame-
biasis. In the U.S., where the 1976 carrier rate for E.
histolytica was 0.6 percent (Center for Disease Control,
1978a), there is evidence of one clinical case for every 500
carriers. Horster (1943) reported that many German soldiers
who developed amebic dysentery in association with bacillary
dysentery [See Section III.b.1.a(ii)] in North Africa had
been E. histolytica carriers for years before in Germany.
Likewise, Wenyon (1947) hypothesized that the 1933, Chicago
epidemic of amebic dysentery was, in fact, an outbreak of
bacillary dysentery in a population with a high rate of E.
histolytica carriage. The source, in this outbreak, was
traced to cross-connections between sewage and water lines
in a hotel (Bundesen, et al., 1936).

Among populations exposed in three separate waterborne
outbreaks of amebic dysentery, the percentage of asympto-
matic persons passing cysts was quite high: 57 percent of
those exposed were found to be carriers in the 1953, South
Bend, Indiana (U.S.) epidemic (Offutt, et al., 1955); 62.9
percent in the Chicago epidemic (Hardy and Spector, 1935);
and 50 percent in the 1947, Tokyo Mantetsu-apartment-building
outbreak (Ritchie and Davis, 1948). Of these subclinical
carriers, only a small fraction developed clinical symptoms
[See also Section B.1.c(i)].

G. lamblia occurs throughout the world, especially in
areas of poor sanitation. In 1948, G. lamblia was estimated
to be present in 7.2 percent of the world's population,
based on 84 stool surveys. Giardiasis is endemic and primar-
ily asymptomatic in the Canadian arctic and has been reported
in as high as 72 percent of Greenland populations. Cur-
iously, Canadian travelers overseas have a relatively high
rate of frank giardial illness and experienced a 59 percent
morbidity in a recent outbreak among tourists to Leningrad
(Center for Disease Control, 1976a). Whether those tourists
who were stricken did not have prior exposure, or whether
other factors such as variation in virulence were involved,
remain matters for speculation and further study. Leningrad
tapwater was implicated in a series of outbreaks among U.S.
tour groups which visited Leningrad between 1969 and 1973,
and which experienced a 23 percent (324 ill) attack rate
[See also Section B.1.c(ii)].

It is not known whether there are carriers for Naegleria
fowleri [See also Section B.1.c(iii)]. Acanthamoeba species
have been recovered from the respiratory tract of healthy
individuals and have been found in eye infections (Sotelo-
Avilo, 1974; Nagington, 1974). They have also been isolated
from throat cultures of asymptomatic children home from camp
where activities included swimming [See also Section
B.1.c(iv)]. Man can become an intermediate host in the life
cycles of nematodes and other helminths and be severely or
minimally infected, depending on geography and climate [See
also Section B.1.c(v)].

b. The Role of Domestic Animals. Many waterborne
human pathogens can be excreted by either sick or apparently
healthy animals, such as domestic pets or farm animals.
Excellent reviews are given by Reasoner (1977, 1978).

The incidence of Salmonella in dogs ranges from 6.9 to
18 percent; cats, 6.0 to 13.6 percent; pet turtles, 7.3 to
20 percent; and pet birds, 8.3 percent. Studies of large
groups of clinically healthy farm animals indicate that
Salmonella carrier rate may vary from 1 to 15 percent for
sheep, 0.1 to 17 percent for cattle, 2 to 35 percent for
pigs, 2 to 4 percent for goats, 22 to 29 percent for chickens,
and 0.7 to 37 percent for ducks and geese.

It is well known that enteropathogenic E. coli can
cause intestinal disturbance in domestic animals, especially
in pigs; it also can be present without any symptomatology.
This organism's ability to exchange plasmidic resistance
factors with pathogens such as Salmonella and Shigella
heightens the disease risk for individuals in close prox-
imity to domestic animal carriers, but there is at least
some evidence that enteropathogenic E. coli strains do not
pass readily from one host species to another [See also
Section B.1.a(iv)].

Yersinia can be derived from pets, cattle, and more
frequently, from pigs [See also Section B.1.a(iii)].
Francisella tularensis has been identified in dogs, cats,
sheep and horses [See also Section B.1.a(v)]. Studies
reviewed by Reasoner (1977) reported the isolation of Lepto-
spira from pet dogs (42 percent), cattle (1.2 and 59 percent),
pigs (43 and 70 percent), horses (5 - 74.6 percent), sheep (7
and 65 percent), and goats (25 percent). These animals can
become carriers after inapparent or acute infections and
shed the bacteria in their urine [See also Section B.1.a(vi)].
Human carriers of Vibrio cholerae serve as the source of new

cases of cholera; and the role of animals, if any, seems to be minimal [See also Section B.1.a(vii)]. It has been suggested, however, that in the absence of human carriers, intermittent excretion of vibrios by cows and chickens may be a source of new infections. Campylobacter fetus can originate from cattle, sheep, pigs, and poultry [See also Section B.1.a(viii)]. Likewise, all opportunistic pathogens, especially the Enterobacteriaceae, can be found in domestic animals [See also Section B.1.a(ix)].

Man is thought to be the only important reservoir for members of the human enteric viruses. However, viruses that appear to be human viral serotypes have been isolated from the feces of domestic animals (Grew, et al., 1970; Graves and Oppenheimer, 1975). It is assumed that these animals are ony passive shedders of viruses ingested via grossly contaminated food or water and that the viruses do not multiply in these hosts. Rotaviruses may be an exception to this viewpoint. Serologically related rotaviruses have been isolated from the feces of children, calves, piglets, mice and foals having acute gastroenteritis (Woode, et al., 1976). The role of these animals in the natural transmission of rotavirus disease in man has not been explored. In fact, the role of domestic and wild animals in the transmission of enteric viral disease to man has not been extensively studied, and further work in this area is needed.

Horses, cows, pikas, and sheep were found to be infected with Giardia species, according to unpublished animal surveys conducted in Colorado in 1975 and 1976. Since only one of two Giardia species infects humans, and since sources for these animal infections were undetermined, data from this survey raise more questions than they answer, such as:

- Which Giardia species was involved?

- Was there one source (perhaps domestic sewage) or multiple sources?

- Were there any cross-transmissions?

G. lamblia of human origin has been shown to be highly infectious for dogs (Craig and Faust, 1964), and has been successfully transmitted from man to rats (Hegner, 1930). Conversely, the organism appears to be transmissible from dog to man (Padchenko and Stolyarchuk, 1969). Giardiasis has recently been found to be apparently prevalent in various species of psittacine birds, but any cross-infectivity to humans has yet to be determined (Panigrahy, et al., 1979).

c. The Role of Wild Animals. Wild animals can serve as important reservoirs of some waterborne pathogens. For example, the carrier incidence of Salmonella in grain fed pigeons ranges from 1.4 to 3.8 percent. The occurrence of Salmonella in 6.9 to 26 percent of various species of seagulls may be directly related to their scavenger activities in garbage refuse and ocean dumping sites [See also Sections B.1.a(i) and E.1]. Among cold-blooded animals -- notably snakes, turtles, and lizards -- a high incidence of Salmonella (12.7 to 46 percent) may be due to feeding on dung-associated insects or on infected rodents or small birds.

Y. enterocolitica has been identified in several wild mammals including deer, hare, primates, rodents, foxes, rabbits, and wild birds. Contact with feces appears to be the major transmission route. F. tularensis has been identified in rodents, rabbits, voles, muskrats, beaver, deer, foxes, moles, wild birds, and many species of arthropods. There is no good evidence that animal hosts maintain carrier states; however, Bell (1975) demonstrated that rodents with a tularemia-induced nephritis chronically shed bacilli -- a matter of great theoretical interest. Leptospira interrogans has been identified in mice, opposums, field voles, badgers, rats, and squirrels. They constitute a major reservoir for this organism. It has been suggested that contaminated shellfish have served as sources of human infection with Vibrio cholerae (reviewed by Zwadyk, 1976). Campylobacter fetus has been isolated from birds and rats. As yet, there are insufficient data for ascertaining the role of wild animals in disseminating opportunistic pathogens. It appears that wild animals are not involved in the spread of human enteric viruses (including reoviruses and rotaviruses). Giardia lamblia has been recovered from deer, elk, marmots, raccoons, coyotes, beavers, and muskrats.

3. Persistence and Death of Pathogens in Water

Water is a hostile environment to most human pathogens which, once introduced, will die at varying rates. This discussion will deal mainly with factors that influence this death rate. The available data are sparse and scattered in the literature. Moreover, much of the data cannot be directly compared because the experimental protocols differ. An excellent review on the spread of pathogens through water was prepared by Geldreich (1972). As the present work is mainly directed towards drinking water, attention will be directed primarily to intestinal pathogens. In addition,

some data on indicator bacteria will be included to eluci-
date mechanisms of survival or inactivation.

     a.   Death of Bacteria. Before discussing the various
factors that influence the death of pathogens in water, it
will be necessary to consider the phenomenon of death itself.
This is best done by citing Postgate (1976) who, in a very
instructive paper, pointed out that death of a microbe is
not the result of aging as it is in macrobes. A microbial
cell divides and its contents live on indefinitely; death
will occur only as the result of an environmental stress.
Death is usually diagnosed retrospectively. That is, a
population is exposed to a recovery medium, incubated, and
those cells that do not divide to form progeny are con-
sidered to be dead. A marginal state exists between life
and death, wherein a cell will grow in one recovery medium,
but will fail to grow in another. As a consequence the
bacterium will be counted as dead, or alive, depending on
the experimental procedure.

     In food microbiology, the term "sublethal injury" has
been introduced to describe this phenomenon. General prin-
ciples for the recovery (resuscitation) of sublethally
injured bacteria have been developed and are reviewed by van
Schothorst (1976). Several effects, not directly related to
the aqueous environment, will influence the observed death
rates in experimental systems. First, a dense population
will die more slowly than a sparse one. This is partly
because dying bacteria leak small molecules which not only
protect neighbors from stress, but can actually be metabo-
lized for further growth. Second, the use of inappropriate
diluents can sensitize microorganisms to experimentally
applied stresses. Even mild stresses which would normally
elicit no reaction could, after an organism was exposed to
an overt stress, have a marked effect. For example, E.
coli became sensitive to warming at 50°C for 5 min after
being starved for two weeks or more in stream water (Klein
and Wu, 1974). This suggests that the pour plate method,
which entails a certain amount of heat shock when the melted
agar contacts the organisms, may be unsuitable for the
enumeration of starved bacteria. On the other hand, no
increased sensitivity to heat was observed for Aeromonas
after starvation. Third, the use of different media, incu-
bation temperatures, etc., will result in the recovery of a
different proportion of the sublethally damaged bacteria.
Also, the presence in the medium of a limiting nutrient that
was lacking in the environmental system may lead to death in
part of the population.

b. **Factors that Influence the Death of Bacterial Pathogens.** It has long been recognized that bacterial death is influenced by a number of factors (Rudolfs, et al., 1950a), some of which will be considered here.

In general, death rates increase with increasing temperatures (McFeters, et al., 1972; Mitchell and Starzyk, 1975; and Verstraete and Voets, 1976). Death rates in summer are higher than in winter, not only because of higher temperatures but possibly from the action of sunlight. Even though close correlations between the death rate and insolation or ultraviolet solar radiation have been found, it is impossible to distinguish between the direct effects of sunlight and the many indirect effects such as heating, promotion of algal growth, etc. (Verstraete and Voets, 1976; Calkins, et al., 1976) [See Section E.1].

It is well known that pathogens prefer conditions close to neutrality and survive best between pH values of six and eight. High acidity or alkalinity are deleterious, and sudden changes in pH from neutrality to either acidity or alkalinity accelerate the death rate considerably. Hanes and coworkers (1964) performed detailed studies and confirmed the earlier evidence that indicator bacteria survive better under aerobic than under anaerobic conditions.

The role of nutrients in bacterial survival in water is complex. High nutrient levels (as would occur in sewage effluent or fecal suspensions) may prolong survival (Tannock and Smith, 1971) or even promote bacterial growth. On the other hand, nutrients can also encourage the growth of bacterial predators (Kittrell and Furfari, 1963). Low nutrient levels will generally result in bacterial reductions as has been shown in numerous papers. Wuhrmann (1972) stated that pathogen multiplication is negligible in environmental waters where nutrients are sparse, although Cherry and coworkers (1972) found Salmonella in 44 percent of apparently unpolluted waters. This could have been a consequence of the high Salmonella carrier rates in birds and wild animals [See Sections B.1.a(i) and B.2].

The ecosystem of a receiving water has an inherent capacity to restore conditions to their previous norm. One important mechanism is predation by protozoa such as Vexillifera (Mitchell, 1972) and Colpoda steinii (Drake and Tsuchiya, 1976), and another is competition and antagonisms from the indigenous aquatic flora. Bacteriophages are frequently mentioned as important contributors to bacterial

die-off but no data have been published to confirm this hypothesis. Algae and cyanophages can elso enhance bacterial death by a number of poorly understood mechanisms, including production of antibacterial substances (also true with higher plants), changes in pH, and limitation of carbon dioxide (reviewed by Davis and Gloyna, 1972). Filtration or autoclaving (the more efficient of the two), of raw river water removed its bactericidal effect on Shigella flexneri (Mohadjer and Mehrabian, 1975). Another indirect indication for the role of predators is the influence of stream morphology. In general, death rates in small streams (with a great surface-to-volume ratio) will be greater than those in large streams (Kittrell and Furfari, 1963; Wuhrmann, 1972).

c. Survival of Bacterial Pathogens in Water. The following data were obtained by investigators using different experimental procedures and are not meant to be construed as a basis for quantitative comparisons between pathogens.

The survival of Salmonella after having entered a receiving water depends upon several conditions. Salmonellae were regularly detected in surface water up to .25 km downstream from a wastewater treatment plant, but never at sample sites 1.5 to 4 km downstream (Kampelmacher and van Noorle Jansen, 1976). In this case, dilution was the main factor in reducing bacterial numbers. Salmonellae, transported by stormwater through a wastewater drain at a University of Wisconsin experimental farm, were isolated regularly .8 km downstream of a swimming beach (Claudon, et al., 1971).

Laboratory experiments suggest that cold water and available nutrients in wastes are critical to Salmonella persistence. When S. typhimurium was held in samples of river water, 90 percent reduction took place in 13 days at 5°C, five days at 20°C, and two days at 30°C (Ahmed, 1975). Ruys (1940) isolated Salmonella typhi from water in winter but not in summer. Studies of ice covered rivers showed survival times of from four to seven days (Spino, 1966; Davenport, et al., 1976).

Salmonellae were isolated during September from the Red River of the North, 36 km downstream of sewage discharges from Fargo, North Dakota, and Moorhead, Minnesota (U.S. Department of Health, Education, and Welfare, 1965). By November, salmonellae were found 100 km downstream of these

two cities. High levels of bacterial nutrients entered the river under ice cover during a January peak in sugar beet processing and accompanying waste discharges. Salmonella strains were then isolated 118 km downstream (or four days' flow time) from the nearest sources of warmblooded animal pollution. Similarly, water samples taken from the Vltava and Danube rivers, polluted with sugar beet wastewaters, supported Salmonella growth even when diluted 1,000-fold at 20°C and 30°C (Adamek, et al., 1977).

On the other hand, Shrewsbury and Barson (1952) conducted experiments which showed that Salmonella survives longer in pure water than in water containing dissolved inorganic substances. They inoculated 5×10^8 and 10^9 S. typhi per ml into tapwater, distilled water, and normal saline. Samples were kept in daylight at temperatures between 7.2 and 35°C (mean, 21.1°C) under aerobic conditions. Viable organisms were recovered for up to 211 days in tap water, up to 443 days in distilled water, but only up to 153 days in normal saline.

Shigella flexneri survived more than a month at -8°C in tap water, but untreated river water was bactericidal for S. flexneri at 4 to 6°C and 23 to 25°C (reviewed by Reasoner, 1977).

Whereas most bacterial pathogens appear to show some similarity in survival rates in water, the stability of Y. enterocolitica in water differs considerably from that of the other Enterobacteriaceae. Y. enterocolitica is better able to survive in nature than are other human pathogens because it prefers lower temperatures (~20°C optimum). It has been hypothesized (Kristensen, 1977) that the ability of Y. enterocolitica to multiply at 4°C may explain its apparent increased occurrence in industrialized countries where refrigeration is used extensively. Dominowska and Malottke (1971) found that Y. enterocolitica survived longer in autumn and winter than in spring and summer, and that it survived for as long as 157 days in water free of other microorganisms. Krogstad (1974) found that during the first few hours and days in water, Y. enterocolitica and E. coli were reduced at nearly the same rate, but that Y. enterocolitica survived longer than E. coli at low temperatures. In seawater held at 15°C, the survival time was nearly the same for Y. enterocolitica serotype 0:3, Y. enterocolitica of the type frequently isolated from water (and showing an atypical rhamnose-positive reaction), and E. coli (Kristensen, 1977).

But, at 6°C, both Y. enterocolitica types persisted considerably longer than E. coli. Schillinger and coworkers (1978) found that Y. enterocolitica survived longer, compared to E. coli, in oligotrophic stream water at temperatures of 5.0 to 8.5°C. On the other hand, Y. enterocolitica died at a faster rate than E. coli in a continuous flow of chlorinated tap water.

Y. enterocolitica has also been shown to grow under low nutrient conditions. Highsmith and coworkers (1977) reported growth of Y. enterocolitica in sterile distilled water at 4, 25, and 37°C, but not at 42°C. Optimum growth was at 25°C. After 18 months of storage at 4°C, the flasks still contained 10^6 cells per ml.

According to Hopla (1974), whether or not tularemia organisms persist in water over long periods has not been satisfactorily resolved. Hopla described tests performed by Bell wherein he found that F. tularensis isolated from streams grew poorly or not at all when incubated at stream temperatures. Parker and coworkers (reviewed in Hopla, 1974) recovered F. tularensis over a 16-month period in certain areas of northwestern U.S. and postulated that specific properties of mud and water enhanced the organism's survival potential.

Enteropathogenic E. coli, unlike the non-pathogenic E. coli types, does not appear to survive long in water; whereas E. coli can persist in water for over 60 days, enteropathogenic E. coli dies within ten days, and this may be why it is very rarely isolated from environmental waters (Müller, 1967).

Survival of Leptospira is enhanced by temperatures of 22°C or above and a neutral to slightly alkaline environment [See Section B.1.a(vi)]. Vibrio cholerae survives best at low temperatures, but only at a neutral or alkaline pH [See Section B.1.a(vii)]. There is no information as yet on the survival of Campylobacter [See Section B.1.a(viii)] in water, nor are there any precise quantitative data for survival of opportunistic pathogens in water [See Section B.1.a(ix)].

The most promising types of experiments comparing pathogen survival in water appear to be based on the membrane filter chambers described by McFeters and coworkers (1974). Table B.3-1 summarizes results from these experiments on survival of different bacteria in well water at 9.5

TABLE B.3-1

COMPARATIVE DIE-OFF RATES OF
FECAL INDICATOR BACTERIA AND ENTERIC PATHOGENS

Bacterial Species	Half-Time (Hours)*
Aeromonas	no death
Shigella	22 - 27
Enterococci	22
Salmonella enteritidis ser. paratyphi D	19
Coliform bacteria	17
Salmonella enteritidis ser. paratyphi A	16
Salmonella enteritidis ser. typhimurium	16
Streptococcus equinus	10
Vibrio cholerae	7
Salmonella typhi	6
Streptococcus bovis	4
Salmonella enteritidis ser. paratyphi B	2

*The time required for a 50% reduction in the initial
population.

Taken from: McFeters, et al., 1974.

to 12.5°C. In particular, the longevity of Shigella species is striking and should be of concern to water hygienists.

In recent years, several workers have shown that bacteria can sustain sublethal injury after starvation in the aqueous environment. Hoadley and Chang (1974) found counts of P. aeruginosa, S. faecalis, and E. coli on selective media to be consistently lower when these organisms were suspended in tapwater than when they were suspended in stream water or 0.1 percent peptone water (both containing ∿550 mg per 1 of organic carbon). Bisonnette and coworkers (1975; 1977) studied the effect of environmental stress using membrane filter chambers. Both survival and death of E. coli and S. faecalis were found to be dependent on water quality as reflected by differences between eight sampling points. In general, the percentage of sublethally injured bacteria increased with time. Resuscitation for 2.5 to 3 h in enriched Trypticase Soy Broth was sufficient to restore the cell's ability to grow in selective media. Andre and coworkers (1967) noted that both colony size and morphology of Salmonella and Shigella grown on SS agar changed with increased exposure to water. Sublethal injury does not only manifest itself in the growth characteristics of a bacterial cell, but in many biochemical characteristics as well, including reduced oxygen consumption and dehydrogenase activity (Daubner, 1975). Oger and coworkers (1976) starved different Salmonella serotypes in river water and found that antigenic properties of the bacteria disappeared after two weeks at a survival of approximately 0.5 percent.

d. Persistence of Viruses in Water. Virus persistence in water has been the subject of a number of reviews. Clarke and colleagues (1964) reviewed the early literature that was published after the introduction of tissue culture techniques. A more recent summary of results appears in Table B.3-2.

There is no difference in opinion among the various authors on the role of temperature: lower temperatures favor persistence, whereas virus inactivation is accelerated at higher temperatures. The following features also are generally agreed upon: (1) viruses persist longest in distilled or deionized water; (2) viruses persist longer in autoclaved drinking water than in autoclaved river water; (3) viruses persist longer in water heavily polluted with sewage, in autoclaved and filter-sterilized river water, in tap water, and in distilled water than they do in untreated

TABLE B.3-2

PERSISTENCE OF SOME ENTEROVIRUSES IN WATER

Type of Water	Viruses	Estimated Days before 99.9% Titer Reduction at a Temperature of		
		4 – 6°C	15 – 16°C	20 – 25°C
Sea or estuary	Coxsackie B1, B3	90	8 – 14	2 – 28
	Echo 6	30 – 88	15 – 16	4 – 15
	Polio 1, 2, 3	30 – 130	8 – 15	2 – 8
River	Coxsackie A2, A9, B3, B5	10 – 75	8	2 – 8
	Echo 6, 7, 12	15 – 60	15	3 – 16
	Polio 1, 2, 3	19 – 75	8 – 45	3 – 20
Impounded fresh	Coxsackie A9, B3	6 – 18	–	3 – 6

Deionized or distilled	Coxsackie B1	–	–	5
	Echo 6	–	–	14

Modified from Akin et al., 1977.

environmental water, regardless of temperature; and (4)
, enteroviruses persist longer than E. coli in water.

Apart from the seeming paradox of prolonged survival in
water heavily polluted with sewage, the evidence suggests
that the cleaner the water, the longer the survival time
[See also Sections B.1.b and C.2.a to b].

e. Survival of Parasites in Water. Recently, a
cesspool in Amersfoort (Netherlands) was uncovered that had
been in use at a monastery around the year 1600. The mate-
rial was almost free of bacteria, except for some anaerobic
sporeformers, but it contained large numbers of Ascaris and
Trichuris eggs (van Knapen, 1978). Although none of these
eggs were viable, this observation indicates that parasitic
eggs are very stable. The same holds true for parasites in
water, as concluded by Rudolf and coworkers (1950b). Both
protozoan cysts, such as those of Entamoeba histolytica, and
parasitic eggs can still retain their infectivity for weeks
or even months in water (reviewed by Geldreich, 1972) [See
also Section B.1.c].

f. Conclusion. The fate of pathogenic organisms in
water is subject to a great many influences including
temperature, nutrients, pH, indigenous and accompanying
flora, and a number of others. Furthermore, some pathogens
under certain conditions persist longer in water than the
standard bacterial indicators. Therefore, once a source
water has been contaminated, specific treatment to remove
pathogens is warranted; it is not enough to rely solely on
natural die-off during storage.

4. Infectivity of Waterborne Pathogens

The presence of a viable, pathogenic microbe in drink-
ing water is always undesirable, but it does not always
guarantee that infection, and especially disease, will
result if someone drinks the contaminated water. There is a
paucity of information concerning the infectivity of water-
borne pathogens. Information that is available is mainly
based on controlled feeding studies of healthy unstressed
volunteers and probability of illness studies by Dudley and
coworkers (1976). Dudley's work indicated that if a person
were to swallow 506 S. typhosa, there would be a 0.0051
percent probability that illness would ensue, and that if

219 <u>S. typhosa</u> were swallowed, the probability of illness occurring would be .0003 percent.

For the present purpose, an ideal study would have been one in which a fully virulent infectious agent was administered to a large number of human volunteers representing a broad range of ages, if not states of health. The agent should have been administered with drinking water and the dose determined in terms of some absolute unit such as viable bacterial cells, viral particles, or protozoan cysts. Each recipient should have been observed carefully to determine whether infection (as contrasted to illness) occurred and, if illness resulted, the length of the incubation period and the duration and severity of the symptoms. A few studies with human subjects may have met one of these stipulations -- almost none seems to have met more than one. Obviously, there is a great need for research in this area. Unfortunately, it is extremely difficult to determine absolute numbers of agents such as virus particles in an administered dose; and it is virtually inconceivable that infants or the elderly would be used in this type of research, especially as recipients of virulent infectious agents.

The probability that a given agent will cause infection if ingested with drinking water is, almost certainly, a function of the dose; however, the mathematical nature of the function is not known and may well not be the same for all kinds of infectious agents. Mathematical rigor, in the analysis of results of studies to date, is discouraged by uncertainties in the measurement of administered dose. It seems safe to say that the probability of becoming infected is a function of dose ingested, but it is by no means clear that the probability of becoming overtly ill is enhanced by ingesting some dose greater than that which would have produced infection. If an agent is competely attenuated, no multiple of the infectious dose should produce disease. If an agent is virulent, the probability that it will produce disease may be a function of ingested dose, of host factors, or of a combination of the two. Inasmuch as most studies with human subjects have looked only for illness or only for infection, depending on the agent studied, the gaps in present knowledge are not surprising.

The data given in Table B.4-1 have been compiled by Bradley and Feachem (1979) and are presented on the premise that some information is better than none. The studies from which these numbers derive are inevitably subject to the limitations discussed previously, so the data must not be

TABLE B.4-1

MEDIAN PERORAL INFECTIVE DOSE OF
WATERBORNE PATHOGENS CITED IN THIS SECTION

	Quantity Needed to Infect 50% of Human Volunteers
BACTERIA:	
Salmonella	$\approx 10^6$
Shigella	$10^2 -- 10^4$
Yersinia	10^6 or more
Enteropathogenic E. coli	$>10^6 -- 10^7$
Francisella tularensis	?
Leptospira	$<10^2$
Vibrio	$10^4 -- 10^6$
Campylobacter	?
Opportunistic pathogens (Pseudomonas)	?
VIRUSES:	
Enteroviruses	$<10^2$
Hepatitis A virus	$<10^2$
Rotavirus	$<10^2$
PARASITES:	
Entamoeba histolytica	10^5
Giardia lamblia	10^5

Taken from: Feachem et al, 1978.

taken too seriously either as absolute or relative pre-
dictors. A look at research on peroral virus infection
illustrates these points.

There have been a few published studies regarding the
infectivity of ingested poliovirus (reviewed by Safe Drinking
Water Committee, 1977), but none on pathogenicity. Each was
done with oral poliomyelitis vaccine virus and was subject
to the criticisms that: (1) the attenuated virus may not be
representative of "wild" types occurring in water and waste-
water; and (2) the quantities of virus administered to the
human subjects were measured in tissue culture infectious
doses, rather than in numbers of particles, so that all of
the results are expressed in relative terms. The results of
the various studies appear to differ by as much as a factor
of 100,000 in the relative infectivity of virus in the body
and in tissue cultures. Nothing in these findings rules out
initiation of an infection, either in a tissue culture or in
the body, by a single virus particle: they do suggest that
the probability of this happening is quite small in a tissue
culture and smaller still in the human body. There are no
data available on the relationship of viral dose to patho-
genesis.

The incidence of waterborne disease in most indus-
trialized nations appears to be quite low. The potential
practical use of further studies with human subjects would
be to allow more accurate assessment of the risk to public
health associated with a given level of a pathogen in drink-
ing water. In theory, an accurate set of risk assessments
could be used by a government to array its public health
resources in a way that would minimize transmission of
infectious diseases by all routes, including the water
vehicle. However, it must be recognized that there are at
least two limitations to applying data on the infectivity of
waterborne pathogens in this way. First, the data cannot be
used to justify intensification of water treatment so as to
reduce the concentration of a pathogen to some tolerable
level: the presence of pathogens is not tolerable at any
level, though there are, of course, practical limits to what
can be done to ensure their complete absence. Second, most
known outbreaks of waterborne disease have resulted from
episodes in which the water produced during some short
period had not received any treatment or in which properly
treated water became contaminated by raw sewage during
distribution: in such instances the outbreak results from
the incident, and the precise level of contamination with
the pathogen is not a preeminent concern. In summary, there

is a need for more information concerning the peroral infec-
tivity of waterborne pathogens, but it is clear that such
information can produce only limited changes in the practice
of drinking water treatment and distribution and that it is
unlikely to lead to testing water for pathogens rather than
indicators in routine surveillance.

5. Epidemiology of Waterborne Infectious Diseases

An infectious disease should be designated "waterborne"
only if water has, in fact, served as the vehicle of trans-
mission for the infectious agent. A distinction should be
made between waterborne diseases and water-associated diseases.
Describing a disease as waterborne in a general sense implies
that water is a principal means of its transmission. The
role played by water in the transmission of certain infec-
tious agents has been overstressed at times to the point of
being quite unrealistic (Henderson, 1968).

This discussion concerns the epidemiology of waterborne
diseases, that is to say, the rates of infection and character-
istics of the diseases principally associated with waterborne
transmission in developed countries. There is a great
difference between the situations in developed and developing
countries. In many developing countries worldwide, more
illnesses and deaths result from sheer lack of availability
of water in quantities sufficient for personal and household
hygienic uses than from impurities in drinking water. These
deficiencies in quantity or availability, along with malnutri-
tion and lack of medical care, are responsible for the millions
of deaths ascribed annually to diarrhea and enteritis, which
are water-associated, but much less commonly waterborne.

In developed countries, the quantity of water available
for drinking and hygienic purposes is sufficient; the
nutritional status and medical care are generally good, and
the incidence of waterborne disease is low, due to more than
a century's progress in sanitation. The epidemiological
data all agree that there has been a dramatic regression of
classical waterborne disease. For example, in the U.S. in
1908, 40 percent of the typhoid was transmitted via drinking
water, compared to 1.4 percent between 1946 and 1964.

There is an important further distinction to be made
between the waterborne diseases transmitted by drinking
water and contaminated drinking water. Contaminated drink-
ing water is drinking water, having been made potable accord-
ing to accepted hygienic standards, that is later contami-
nated accidentally with wastewater. Such contamination

accidents have the potential of producing epidemics that include thousands of cases; whereas the extremely low numbers of infectious agents that might be present in uncontaminated drinking water, after proper treatment and disinfection, are unlikely to produce an appreciable incidence of disease. A third possibility is that untreated or inadequately treated water has been distributed still carrying significant levels of pathogens that were present in the source waters; as will be shown, substantial outbreaks have occurred in this way.

a. Reported Outbreaks of Waterborne Infectious Diseases. The classic and traditional waterborne diseases -- typhoid fever, bacillary dysentery, and cholera -- have declined considerably in the developed countries. Development of methods for treatment and disinfection of drinking water, as well as construction of wastewater treatment facilities, has made it possible to safeguard against contamination of drinking water with bacteria of fecal origin, except in a few extraordinary cases. Hence, in the developed countries the majority of bacterial disease outbreaks reportedly associated with water consumption have not arisen from a state of endemicity in the population, rather, they have occurred as small localized outbreaks resulting from a temporary deficiency in water treatment or distribution.

Infectious diseases are generally declining in relative importance in developed countries; most of the infectious diseases which are still prominent are not transmitted by the fecal-oral route and are thus unlikely to be waterborne. Whereas bacterial diseases known to be waterborne are definitely less prevalent, the same may not be true for viral diseases. Hepatitis A, which is sometimes transmitted through water, shows a fairly constant overall incidence in the U.S. for the past several years (Center for Disease Control, 1977a). Laboratory methods by which the viral etiology of some gastroenteritides can be confirmed are so new that trends in annual incidence cannot be examined. A fundamental difficulty in comparing the incidence of diseases is that all of them tend to be underreported, in varying degrees, to the agencies that are charged with compiling statistics. This applies to diseases in general and to waterborne diseases in particular.

(i) Incidence in the U.S. The most complete data on waterborne disease are those reported for the U.S. by the Center for Disease Control and the Environmental Protection

Agency (Craun, 1978). During the period 1971 through 1975, 123 waterborne outbreaks, resulting in almost 28,000 cases of illness and perhaps two deaths, were documented in the U.S. [See Table B.5.a-1]. The three largest outbreaks involved municipal water systems: Sewickley, Pennsylvania (5,000 cases of gastroenteritis) in 1975; Rome, New York (4,800 cases of giardiasis) in 1974; and Pico Rivera, California (3,500 cases of gastroenteritis) in 1971.

The mean annual number of waterborne outbreaks reported in the U.S. during 1971 through 1975, was 25. This is twice as many outbreaks as the mean annual number reported during the period 1951 through 1970, and equals the mean annual number reported during the period 1920 through 1936. The reason for this apparent increase in number of outbreaks is difficult to ascertain but is thought to be primarily the result of increased reporting and surveillance activities.

An etiologic agent was implicated in only 49 percent of the outbreaks (including just 36 percent of the cases) from 1971 through 1975. Among these, 12 outbreaks (511 cases) were attributed to chemical poisoning. Outbreaks of infectious diseases included 21 (4,062 cases) caused by the Enterobacteriaceae (shigellosis, typhoid, other salmonellosis, and enterotoxigenic E. coli), 14 outbreaks (368 cases) of hepatitis A, and 13 outbreaks (5,136 cases) of giardiasis.

(ii) Water Systems Involved in Outbreaks. Water systems may be classified as municipal, semipublic, or individual. Municipal water systems are defined as public or investor-owned water supplies that serve communities. Individual water systems are those used exclusively by single residences or by persons traveling outside of populated areas. Semipublic water systems, located in areas not served by municipal systems, are developed and maintained for a group of residences (e.g., subdivisions and trailer parks) or at locations where the general public has access to drinking water (e.g., industries, camps, parks, resorts, institutions, and hotels).

The 123 waterborne outbreaks were classified by type of water system [See Table B.5.a-2]. More outbreaks occurred in semipublic water systems (57 percent) than municipal systems (30 percent) or individual systems (13 percent); however, outbreaks in municipal systems affected an average of 504 persons compared to 129 persons per outbreak in semipublic and nine persons per outbreak in individual systems. Therefore, most of the illness (67 percent) resulted from outbreaks in municipal systems.

TABLE B.5.a-1

WATERBORNE DISEASE OUTBREAKS IN THE U.S., 1971-1975

	1971	1972	1973	1974	1975	Totals
Outbreaks	19	29	26	25	24	123
Cases of illness	5,182	1,638	1,774	8,356	10,879	27,829

From Craun, 1978.

TABLE B.5.a-2

WATERBORNE OUTBREAKS IN THE U.S.,
1971-1975, BY TYPE OF SYSTEM

	Outbreaks	Cases of Illness
Municipal systems	37	18,633
Semipublic systems	70	9,058
Individual systems	16	138
	123	27,829

From Craun, 1978.

(iii) Deficiencies Leading to Outbreaks. Outbreaks of waterborne disease can also be classified on the basis of the kinds of deficiencies in the water supply system that led to transmission of the causal agent. This has been done, for a longer period of U.S. experience and with water supplies categorized simply as public or private, in Table B.5.a-3. One finds again that the greatest number of outbreaks and the greatest number of cases do not necessarily coincide. Whereas contaminated groundwater accounts for the majority of outbreaks (52 percent) and cases (47 percent) involving private systems, most outbreaks (40 percent) involving public supplies resulted from distribution deficiencies, but the most cases (45 percent) associated with public supplies resulted from treatment deficiencies.

It is extremely difficult to attribute disease contracted as a result of consuming contaminated drinking water directly to the discharge of treated wastewater. Communities that knowingly take their drinking water supplies from contaminated (or potentially contaminated) sources normally expend greater efforts to remove microbial pathogens that are expected to be present. The study of outbreaks is seldom sensitive enough to implicate specific sources of pollution, though they are likely to be the same as some of those that give rise to shellfish contamination. That is to say, the discharge to surface waters of untreated or inadequately treated wastewater always carries with it at least some potential for transmission of disease.

b. Risk Assessment. In addition to investigations of outbreaks, the data gathered as a result of epidemiologic surveys can be used as a basis for estimating risks. In some countries, groups such as the Center for Disease Control, Atlanta, Georgia (U.S.) collect data on many notifiable diseases, including several listed previously. Although this type of surveillance suffers from the problem of incomplete reporting, it can be useful in identifying trends and may also be of help in determining the order of magnitude of various risks of disease. These risks can be expressed alternatively as cases per 100,000 population, as percent of population affected, or as a probability of illness in a single individual at risk. The time dimension is normally one year.

TABLE B.5.a-3

DEFICIENCIES RESULTING IN OUTBREAKS OF WATERBORNE DISEASE IN U.S.

Cause	Public Supply Outbreaks	Public Supply Cases	Private Supply Outbreaks	Private Supply Cases	Total Outbreaks	Total Cases
Untreated surface water	19	7,363	38	1,349	57	8,712
Untreated ground water	19	24,402	188	10,816	207	35,218
Treatment deficiencies	35	36,972	64	7,522	99	44,494
Distribution deficiencies	60	12,246	22	994	82	13,240
Miscellaneous	17	1,155	52	2,436	69	3,591
Total	150	82,138	364	23,117	514	105,255

From Center for Disease Control, 1976b, 1977b ; Craun and McCabe, 1973; Craun, et al., 1976.

During the period from 1967 through 1976, 36 to 51 cases of enteric disease per 100,000 population were reported annually (Center for Disease Control, 1977a) (these included amebiasis, aseptic meningitis, hepatitis A, leptospirosis, poliomyelitis, salmonellosis, shigellosis, and typhoid fever, the agents of which may infect perorally after having been shed with feces or urine). About half of the cases were hepatitis A. Even if the reported cases only represent one out of 20 actual cases (Marier, 1977), it is likely that each year less than 1 percent of the U.S. population contracts infectious disease that is characterized as being spread by fecal-oral route. This compares to the rates observed in eastern Europe where reporting is thought to be much more complete (Szmuness and Dienstag, 1971). In 1974, Czechoslovakia reported a rate of about 290 cases per 100,000 population; Poland, 245; and Yugoslavia, 360 (World Health Organization, 1977). Estimates of the proportion of enteric disease that is waterborne range from about 1 to 33 percent (Mosley, 1967; Singley, et al., 1975), so the probability of contracting waterborne infectious disease in any year might range from 0.0001 to 0.0033 per person.

Over the past 30 years there have been over 100,000 reported cases of disease associated with water supply deficiencies [See Table B.5.a-3], or an average of approximately 3,500 cases per year. If one out of 20 are reported, as assumed previously, then this represents 70,000 actual cases or a probability of 0.0003 (1976 U.S. population = 214 million) which is within the range estimated above. For illustrative purposes assume that there are 10^5 cases per year in the U.S. This figure can then be compared to average water consumption in the U.S. It has been estimated that the average person drinks about 1.6 l of water per day (Safe Drinking Water Committee, 1977) which yields a national consumption figure of 1.2×10^{11} l per year. This leads to the estimate that there is less than one case of infectious disease for every 1,000,000 l of water consumed in the U.S. It would seem that U.S. water supplies are quite safe in terms of microbial hazards, although this admittedly represents ⸱ ⸱ a social judgment.

The purpose of the preceding exercise is to demonstrate that absolute values for risk can be estimated from general disease statistics, albeit not with a great deal of confidence. However, one can gain an idea of the magnitude of the problem in this way. The drawback to this approach is that the value obtained is insensitive to change because of

the high level of uncertainty. There is also no way of knowing what portion of the risk can be attributed to individual sources of infectious agents, such as effluents, although the outbreak record may eventually prove helpful in that regard.

Another approach to determining the risk associated with a given source of infection is to study specific populations that are most likely to be exposed to the hazard. Ideally, the level of the exposure is determined so as to be able to relate it to the observed response. That is to say, it should be possible to demonstrate a dose-response relationship. For sewage and effluents as a source, a declining order of probable exposure to infectious agents might be by way of: occupational exposure in sewers, occupational exposure in sewage treatment plants, shellfish consumption, beach pollution, land irrigation, and drinking water contamination. Studies intended to relate the frequency of enteric disease to some of these modes of exposure are now in progress.

c. Special Problems in Epidemiology of Waterborne Disease. At least two cases of infectious disease must have occurred before an outbreak can be considered to have taken place and a common source of the infectious agent sought. Except in unique circumstances, such as a case of chemical poisoning in which the chemical was identified in the water, a single case cannot be recognized as having been caused by drinking water. The waterborne outbreaks reported above are those in which drinking water has been implicated epidemiologically as the vehicle of transmission of the illness. In most of the outbreaks, the water was found to be bacteriologically or chemically contaminated. Nevertheless, the etiologic agent of the illness was identified in only about half of the reported outbreaks.

(i) Proving Transmission via Water. It is rare that a simple epidemiologic study can, of itself, develop proof of a cause and effect relationship. The strongest proof, of course, is that provided by the time sequence whereby removal of a suspected cause is followed by a reduction in the illness. Even here, however, it may be difficult to insure that an effect will be seen if the disease has a long latent period. False positive results, in the sense that not every event that follows an action has surely been caused by that action, have also to be anticipated.

In that epidemiologic studies are done with people having multiple activities and living in a complex world, many things affect the outcome of exposure to an infectious agent. The essence of a valid epidemiologic study is to compare an exposed group to an unexposed group in which all important factors other than exposure are identical. To find an appropriate control (unexposed) group which meets these needs is sometimes very difficult when the factor to be studied is drinking water. A truly comparable control group may be very difficult to identify when almost everyone is "exposed"!

Furthermore, the nature of a disease may of itself impose difficulties in undertaking prospective studies. For example, the movements of the study population become important problems when investigating a disease with a relatively long incubation period, such as hepatitis A.

In order to prove, irrefutably, that drinking water has acted as a vehicle in transmitting a particular disease agent, it is necessary to: (1) be relatively certain of the presence and levels of potentially pathogenic bacteria or viruses occurring in finished water (taking into account the limits of current techniques); (2) recover these agents from the water; (3) have accurate knowledge of the minimum infectious dose (i.e., to know at least approximately, the numbers of organisms one must ingest to provoke infection and disease); and (4) increase the probability of detecting sporadic and isolated illness in a population by conducting well-planned prospective studies.

(ii) Virus Transmission. The majority of hepatitis A and viral gastroenteritis outbreaks reported have been associated with drinking water supplies which, for reasons of poor management or inadquate or interrupted disinfection, became contaminated with fecal waste. There have not been any reported manifestations of enteroviral disease where the water in public distribution met conventional bacteriological standards of water quality. In view of this epidemiological void, three hypotheses have been offered: (1) either there is no waterborne transmission of virus at all (however, this seems unlikely, given the presence of viruses in wastewater, in surface water, and even in groundwater); (2) the impact to public health of virus transmission through water is negligible; or (3) the current inadequacy of methods of epidemiologic investigation has prevented the gathering of substantial evidence in support of viral transmission through water.

Assumptions have been made that lead to the estimate
that one tissue culture infectious unit (TCIU) per 400,000 l
would be the maximum level of viruses likely to be present
in drinking water under currently accepted treatment and
sanitary standards (Environmental Protection Agency, 1978).
At this concentration, the residents of a typical city of
100,000 population would be exposed to about 100 TCIU of
viruses each day in the water used for domestic purposes
based on U.S. average community use of 640 l per person per
day and 69 percent residential use (Murray and Reeves,
1977). If we assume that an "average" person drinks about
one l of tap water per day, under the circumstances outlined
above, one TCIU of virus in infectious condition would be
ingested with water by a single individual in the typical
city about every four days. The number of cases of clinical
disease that would result from the infections produced by
this level of ingestion is unknown but would most likely be
several orders of magnitude lower than the frequency of
ingestion. Factors important in the manifestation of clini-
cal disease from viral ingestion include: (1) the immune
state of the consumer as a result of previous exposure to
the virus; (2) the number of viral particles required to
produce infection; and (3) the virulence of the virus (i.e.,
the disease:infection ratio).

It is probable that current methods (or the current
absence of methods) for obtaining epidemiologic information
about a population would not allow detection of waterborne
disease occurring at this level. Only in exceptional cases
(e.g., when wastewater contamination of a supply is substan-
tial) will numbers of affected consumers be sufficiently
high to register epidemiologically as having resulted from a
common source.

It also has been suggested that sporadic cases of viral
disease may be transmitted indirectly by water supplies.
That is, even though the levels of pathogens found in water
may not cause disease, they could produce infections which,
in turn, are spread through close contact of the infected
individuals (Berg, 1973). However, these cases should not
be considered as waterborne if there is a probability that
the diseased individual could have contracted the infection
elsewhere, nor should it be assumed that intervention with
the water route of transmission will necessarily reduce the
incidence of disease.

Berg (1967) has indicated that it may be impossible to prove, by current epidemiologic methods, that focal viral infections are contracted from water and then spread in a community by person-to-person contact. However, he concludes that, given the uncertainties inherent in the situation, future decision-making must err, if at all, on the side of safety. This point is certainly well taken, but it is also true that decision-making should not take place outside the context of the total picture of community health, including the kinds of illnesses that are really occurring in the population and the kinds of preventive measures (including those unrelated to water) that are most likely to exert a significant beneficial effect. Inasmuch as it may be impossible to demonstrate that focal waterborne infections do or do not occur, the controversy remains unresolved and may be expected to continue so for some time to come.

(iii) Parasites. Amebiasis has long been a major concern, both as regards public health in general and drinking water safety in particular. Certainly there have been enough incidents of Entamoeba histolytica transmission by water to show that the problem is a real one. However, another significant problem that is now being perceived in the U.S. and may be present, though undetected, in other developed countries is that of endemic and sometimes epidemic giardiasis [See Section B.1.c(ii)]. The total incidence of giardiasis in the U.S. may exceed that of amebiasis, but the figures are difficult to compare because amebiasis is a notifiable disease, whereas giardiasis is not (Center for Disease Control, 1977a). There is no doubt that transmission of Giardia lamblia through water is significant in the U.S. As was reported above for the period 1971 through 1975, waterborne outbreaks recorded in the U.S. included 13 of giardiasis with 5,136 cases (Craun, 1978). This was more cases than were attributed to any other waterborne agent, or even to the entire group of Enterobacteriaceae combined. Perhaps significantly, this case total compares to no reported outbreaks of waterborne amebiasis.

Reported outbreaks of waterborne giardiasis in the U.S. appear to have resulted primarily from use of surface water for drinking, after no treatment at all or only chemical disinfection by small municipal or semipublic water systems. Giardia cysts are relatively resistant to disinfection. However, Giardia-free water can probably be produced consistently by complete water treatment, including at least coagulation and sedimentation followed by some form of sand Filtration before disinfection. Giardia contamination may not be a problem in groundwater from well-protected sources,

but any surface water should probably be suspected, inasmuch as contamination may sometimes derive from feral, nonhuman reservoirs as well as from wastewater containing human feces. For various reasons, it seems likely that waterborne giardiasis will eventually be shown to occur in other industrialized nations besides just the U.S.

(iv) Antibiotic Resistance in Bacteria. A current major concern with regard to bacteria in drinking water relates to their increasing resistance to antibiotics. Bacterial cells are endowed with a remarkable capacity for accepting genes of other strains, for incorporating these traits, and then transmitting them. Antibiotic-resistant enteric bacteria comprise 0.01 percent to 1 percent of the total flora present in feces (in the absence of antibiotic therapy); they make up 10 percent of cells isolated from urban wastewater, 50 percent of cells recovered from river water, and 82 percent of cells isolated from drinking water (Leclerc, et al., 1977a). It would seem, therefore, that over the years, antibiotic-resistant bacteria have been diffused to and concentrated in water, which might be explained in terms of a strong selective pressure in the aquatic environment. The hypotheses offered to explain this are that antibiotic-resistant bacteria enjoy a selective advantage, or that resistance is transferred directly from one strain to another in water; neither has yet received a direct experimental test.

It appears that in order to determine the seriousness of the risk to public health due to increased antibiotic resistance in waterborne bacteria, it would be necessary to perform a survey calling for collaboration between epidemiologists and public health specialists, water authorities, doctors, pharmacists, and diagnostic clinicians who see patients and isolate organisms responsible for producing disease manifestations. Such a survey ought to take into account the total population of one geographic area. Physicians should report all cases of confirmed infectious illness, especially when symptoms include diarrhea. Pharmacists should record all medicines prescribed to clients for treating infectious illness or diarrhea. Clinical diagnostic laboratories should list organisms isolated from patients on the basis of their antibiotic resistances. For their part, water authorities should analyze water for more than just the standard indicators of pollution. Finally, epidemiologists should seek better ways of ascertaining the role of water in the spread of disease within a population. However,

without substantial financial support and good collaboration among these professions, such a survey could not be conducted.

    d.   <u>Modeling and Monitoring</u>. An epidemiological model is a conceptual system that operates by resembling the natural course of a disease and its transmission. It incorporates major epidemiological factors that determine the dynamics of the spread of infection. A model necessarily represents a simplification of natural processes; nevertheless, if properly constructed it can simulate the natural evolution of an epidemic or an endemic situation, thus permitting the study of the disease dynamics and the effect of deliberate interventions on the natural course of transmission of the infection and hence, on the incidence of the disease (Cvjetanovic, <u>et al</u>., 1978).

Observations of epidemics of infectious diseases led epidemiologists to the conclusion that they present some regular features and that there must be some definite principles that determine the evolution of infectious processes. Efforts have therefore been made to express, in precise quantitative terms, time-related changes in the dynamics of infections and to formulate a mathematical theory of epidemics. One of the general principles of the mechanism of epidemics was established in 1927 by Kermack and McKendrick in mathematical terms when they formulated their theory of the initial "threshold of density" of susceptible populations as the determining factor in epidemics.

Later models have been proposed for individual diseases on the basis of general theories (stochastic, catalytic, and deterministic models) which are excellently reviewed by Cvjetanovic and coworkers (1978). Some of these models can be applied to diseases transmitted partly though water as well as by food. These models are constructed by identifying categories of individuals and factors that play a well-defined and important role in the dynamics of the disease. In order to make the model relatively simple and manageable it is desirable to eliminate unimportant factors and retain only those that significantly influence the epidemiological processes. It is obvious that the models must be based on the natural history of the disease and should be an expression of that history. The aim of the model construction is to arrive at a system that is able to "mimic" the natural processes, such as the past outbreaks and trends of disease, and thus to simulate various real or hypothetical situations.

(i)   Potential for Modeling Waterborne Infectious
Disease.   The word "model" can take on many meanings.   Even
when it is clear that one is referring to a mathematical
model, the great variety and complexity of models may still
make the definition unclear.   To many, modeling may seem to
be a mathematician's art, interesting, but not very practi-
cal.   Yet all models have one thing in common: they are
attempts to represent reality and as such (if they are
logically constructed) may be extremely useful in inferring
information about real situations.

To be useful to decision-makers, a mathematical model
must incorporate the following features: (1) it must be
clearly defined; (2) the assumptions made in its construc-
tion must be clearly stated; (3) those variables which have
the greatest impact on its output must be identified (sensi-
tivity analysis); (4) data inputs must be carefully selected;
and (5) it must be validated (Breidenbach, 1976).   As a
modeler tries to describe large areas, his model can become
very complex; but as long as he adheres to the above tenets,
the model should still be understandable to those policy
makers who must use it.   One of the major advantages of
modeling is that it promotes the systematic collection and
organization of information.   On the other hand, if modeling
is to have any practical value, representative field data
will have to be collected in quantities sufficient to yield
unbiased estimates for use in the model.

A major reason for the apparent difference in the
incidence of a disease between areas   is often the variation
in the efficiencies of passive reporting systems.   Several
studies have indicated that from 60 to 90 percent of the
clinical cases of hepatitis are not reported to health
authorities (Center for Disease Control, 1975b; Koff, et
al., 1973; Levy, et al., 1977; Liao, et al., 1954; Marier,
1977).   During nonepidemic periods as few as 10 percent of
the actual cases may be reported (Tolsma and Bryan, 1976).
However, with the advent of screening for the hepatitis B
surface antigen and the availability of immunoglobulin
prophylaxis, it is likely that a higher percentage of cases
will be reported in the future (Bernier, 1975).   Inasmuch as
reporting of even notifiable diseases is clearly inadequate,
there is an obvious need for alternate, active methods of
gathering data for use in epidemiologic modeling and risk
assessment.

(ii) Dose-Response Relationships. One of the more basic approaches to estimating risk is the dose-response relationship which predicts the percent of a population likely to exhibit a specific response (e.g., infection, disease, or death) when exposed to a given dosage of a disease agent. Once this type of information has been obtained for representative populations, all that is necessary to assign risk is to measure the level of exposure to a given agent among the subject population. Further, if the sources of the agent are known, then the risk from each of these sources can be determined. However, there are several limitations to this approach: (1) there are many potential disease agents to be evaluated; (2) there can be a wide range of undesirable responses (for example, variety and intensity of symptoms); (3) it is difficult to measure the concentration of some disease agents; and (4) acquisition of the needed data normally requires experimentation on human beings of varying backgrounds, which has become a visible ethical problem (Katz, 1972).

The response to infection is normally acute and generally can be classified into the various states of: infection, disease, and death. Not all infections result in disease which, in the idealized form, means that the dose-infection curve represents lower doses than the dose-disease curve for a given percent response. The vertical difference between the two curves is a measure of the proportion of the infections that result in disease (for hepatitis A, this ratio is about 1:5 to 1:20). However, it cannot always be shown that a dose larger than that required to cause infection is necessary or more likely to produce disease. At present, very few cases of enteric disease result in death.

(iii) Monitoring Methods. There are, of course, active means of gathering needed data without having to challenge human subjects with infectious agents:

- Monitoring is an integrated system of making observations on health and environmental factors, and of scrutinizing, storing, and retrieving these data for specified purposes of protecting and improving human health.

- Health Surveillance is the closely associated system of collating and interpreting data collected from monitoring programs (and from any other relevant sources) with a view to the detection and evaluation of health problems so as to provide a basis for remedial action.

In addition, monitoring may often prove a valuable tool
for the epidemiologist endeavoring to relate exposure to
response in order to elucidate the causes of widespread
diseases or to explain changes in the total disease and
mortality patterns. In regard to vital statistics such as
births and mortality, monitoring is already established in
all developed and in many developing countries throughout
the world, but two-thirds of the world's population still
lack adequate birth and death registration. Communicable
diseases are subject to surveillance, with the object of
alerting public health authorities, even at the stage of
suspicion, to take preventive action. Although highly
developed computerized systems have been designed to provide
the quickest possible warning, simpler systems can be devised
to suit the needs and capabilities of the country.

It is possible, in looking at environmental hazards, to
study a population of children. They tend to remain in the
same area at least for a certain known period of time and
since they usually go to school near their homes, it is
relatively easy to determine the effect of an environmental
factor.

The ultimate in this approach is to study a target
population with a history of weak immunologic defenses, one
that is easy to keep under surveillance, and one for which
the source of drinking water is strictly controlled -- that
is to say, a population of infants attending child care
centers. By studying a population whose drinking water
consumption is restricted to bottled water exclusively, and
barring any person-to-person spread, one can obtain a good
picture of the impact of a water sample on the health of the
consumers.

In comparing different groups of the population exposed
to environmental hazards, it is extremely important to
choose appropriate control groups. In considering an environ-
mental hazard in an industry, for example, it is possible to
examine illness or morbidity among husbands and wives, using
the wives as controls. It is unlikely that they will be
exposed to the same occupational hazards as their husbands,
whereas both are likely to be exposed to the same environ-
mental hazards in their homes.

It is also possible to compare data from epidemiologic
surveys of two geographic areas with populations of roughly
equivalent size and activity; one in which the drinking
water is of poor quality and the other using water of high

quality. By noting whether there has been any increase in the sale of antidiarrheal medications, one can obtain valuable data without requiring that there be notification of disease through official channels. The special merit of this approach is that it does not require direct, conscious participation by the populations that are included in the study.

Otherwise, whatever population is chosen, it is important to investigate that population as completely as possible. Information on those who do not participate is essential; they may, for example, have refused because they are ill or because they fear the consequences of having the disease discovered. Significant bias may be introduced in this way if adequate precautions are not taken.

Once the population has been defined and the variables to measure have been decided, the next step is to collect the necessary information. One method of doing this is by using a questionnaire. This is usually better than a clinical history, which may not identify and record in a repeatable way what the individual actually says. The importance of using a standardized questionnaire has been amply demonstrated; whatever questionnaire is used, it is vital that the sensitivity, specificity, and precision of the individual questions be validated. Interviewing techniques must also be standardized.

Physiological tests are another possible method of obtaining the necessary information. Such tests must be simple and if possible cheap to administer, acceptable to those who receive them, and must produce accurate and repeatable results. They must also be "sensitive" (give a positive finding in those who have the condition under investigation) and "specific" (give a negative finding in those who do not). Physiological tests, capable of direct and rapid assessment of the functional state or normality of any member of a study population, would obviously be of great help in minimizing the subjective aspect of an epidemiologic study. Unfortunately, such tests may not always be readily applicable to studies of enteric diseases. If they were, they would yield results well suited to the application of the threshold, or no-permissible-adverse-health-effects, approach that is the basis for all national regulations establishing drinking water quality standards. That is, exposure limits based on bacteriologic indicators in water are set at levels where no adverse health effect to consumers can be anticipated. This is feasible because the

relationship between the pathogenic bacteria and classical microbiological indicators is fairly well known, but may be insufficient for waterborne diseases because of the low correlation between the presence of bacterial indicators and viruses in water, as will be discussed in Topic C.

e. Summary. An extensive record of waterborne outbreaks of disease in the U.S. indicates that most such incidents have resulted from the use of untreated or undertreated water and from episodes of contamination of drinking water. Inasmuch as comparable records do not seem to be available from other countries, it is not entirely certain that the U.S. experience is typical of other industrialized nations. Better reporting, and recording, of disease outbreaks in other countries would certainly be desirable.

There is continuing concern about the possible incidence of sporadic illness in the consuming public, especially as a result of viruses that might be present at extremely low levels in finished drinking water. Existing systems of compiling disease statistics are passive in the sense that the compilers must wait and hope that clinicians who observe waterborne illnesses will report them. Alternate, active approaches to gathering information on waterborne disease are needed: several possible methods have been discussed in this section.

Meanwhile, decisions regarding drinking water safety and public health must be made with the information that is now available. The epidemiologic record (at least of the U.S.) appears to make a strong case for complete treatment and disinfection of drinking water. "Worst-case" assumptions may lead to predictions that a certain amount of disease will be transmitted even by completely treated water. The public interest may instead lie in determining the validity of these predictions through better epidemiologic work than in devising new water treatment techniques in hopes of solving a problem that has not yet been proven to exist.

6. Summary

Drinking water may transmit pathogenic organisms if it becomes contaminated with human or animal feces. Fecal contamination may occur at any point from the raw water source to the ends of the distribution network. If the

pathogens thus introduced are not subsequently removed or destroyed, a result may be that the consumer will ingest some quantity of bacterial, viral, or parasitic organisms. Geographic and epidemiologic conditions, as well as the overall numbers and virulence of the organism ingested, determine the result of such an incident.

a. <u>Microbial Pathogens</u>. The transmission of microbial pathogens through drinking water in industrialized nations has changed with time. Some of the most historically significant waterborne pathogens (notably those that cause typhoid fever, bacillary dysentery, and cholera) have been on the decline in recent years. Other bacteria, all of the enteric viruses, and the protozoon, <u>Giardia lamblia</u>, have evoked more concern of late, probably due instead to greater awareness and better reporting than because they present a greater threat than previously. This trend is associated with the development of better methods of detecting potential waterborne pathogens in clinical specimens and, in some cases, in water samples.

The genus <u>Salmonella</u> is a very large group consisting of 1,200 known serotypes that are pathogenic to humans, causing mild to acute gastroenteritis and very occasionally death. Typhoid fever, caused by <u>S. typhi</u>, and paratyphoid fever, caused by <u>S. paratyphi</u> A or B, are both enteric diseases that occur only in humans. The other <u>Salmonella</u> serotypes are responsible for foodborne illnesses accompanied by mild to acute gastroenteritis, but rarely death. These milder forms are referred to as salmonellosis and occur frequently in humans and wild or domestic animals.

Salmonellae are excreted by infected humans (exclusively so for <u>S. typhi</u>), farm animals, domestic pets, and warm-blooded wild animals. <u>Salmonella</u> strains were regularly found in the sewage system of a residential area of 4,000 persons. Streams, lakes, and rivers receiving discharges of meat processing wastes or effluents of untreated or inadequately treated community sewage may contain substantial numbers of salmonellae. Fish living in polluted water may ingest salmonellae and become vectors of pathogen transport. Drinking untreated, unprotected surface water presents the greatest risk to the consumer. There are presently no standardized methods for isolating salmonellae from water. Since these microorganisms ordinarily occur in lower numbers than those of sanitary indicator bacteria, they must initially be concentrated from large-volume samples of water.

The Shigella genus is divided into four main subgroups.
All species cause bacillary dysentery (also called shigel-
losis) exclusively in humans and some primates. Infection
is transmitted by the fecal-oral route: shigellae have been
isolated from clothing, toilet seats, and contaminated
foods. Infection with Shigella occurs endemically in most
communities and may be maintained by a few symptomless
carriers in the absence of clinical cases. Stricter sani-
tation measures, proper sewage disposal, and public health
standards enforced in the developed countries have led to a
shift in peak incidence from summer to winter, as low tem-
peratures favor survival of Shigella. As with Salmonella,
no standardized procedures have been established for iso-
lating Shigella from water.

Evidence of infections due to Yersinia enterolitica has
been mounting since the early 1960's, especially from the
world's cold or temperate regions. Yersiniosis is thought
to be contracted perorally. Y. enterocolitica has been
isolated from lymph nodes and feces of both sick and healthy
humans and of a growing number of animal species. Different
Y. enterocolitica types have been isolated so frequently
from untreated surface water in some areas that they most
likely represent part of the normal microbial flora of the
water and surrounding terrestrial environments. Reports
referring to waterborne Y. enterocolitica infections are few
in number. Moreover, Y. enterocolitica grown at 37°C is
less resistant to normal cellular bactericidal defenses than
when grown at 20°C; this could explain why transmission of
infections through direct person-to-person contact is
relatively rare, and again, why an intermediate cold phase
could be critical to its spread. If so, the life cycle of
Y. enterocolitica would stand in sharp contrast to that of
others in the family Enterobacteriaceae, which are trans-
mitted through water less frequently than by contact. There
is no standard method for the isolation and enumeration of
Y. enterocolitica in water.

Transmission of enteropathogenic Escherichia coli
through drinking water was frequently reported during the
1950's. Certain enteropathogenic strains of E. coli are now
known to cause acute diarrhea, especially in infants, in
travelers to foreign countries, and in consumers of contami-
nated foods. The definition of the coliform group includes
E. coli, so enteropathogenic E. coli is unlikely to be
present in water in which coliforms are undetectable; this
relationship is far more direct than is usual between indica-
tors and pathogens. However, even if E. coli is shown to be

present, its enteropathogenicity can be determined only by highly refined techniques.

Tularemia is a zoonotic disease transmitted to humans from blood-sucking arthropods, domestic animals, and primarily from a number of wild animal species, many of which lead semi-aquatic lives. The causative agent, _Francisella tularensis_, can be contracted through ingestion and may produce buboes and areas of necrosis in organs and tissues of man and animals. Outbreaks of waterborne tularemia have been reported throughout the U.S.S.R. Recent cases of waterborne tularemia in northern Norway have brought about renewed interest in water as a vehicle of infection in the Scandinavian peninsula. There is no standardized method for the examination of water for _F. tularensis_.

The genus _Leptospira_ is composed of finely coiled spiral organisms, including a number of strains that cause leptospirosis in humans and many animals. Leptospirosis is essentially a zoonosis that may involve domestic and wild animals in great numbers depending on the climate and available food supply. The organism is maintained in the environment by both carrier and diseased hosts, and transmission is particularly favored by population explosions of animal carriers, especially rats. Human exposure to the disease has been from direct or indirect contact with urine from infected animals. Infections with _Leptospira_ are primarily associated with certain occupations, such as mining, dairy farming, and sanitary engineering. It is associated with drinking water only rarely, when there has been a breakdown in sanitation and public health systems. There is no standard method for isolating _Leptospira_ from environmental sources.

The genus _Vibrio_ comprises a large number of species, only a few of which are of medical importance: _V. cholerae_ and its biotype _V. cholerae_ El Tor cause cholera exclusively in man; _V. parahaemolyticus_ and nonagglutinable (NAG) vibrios can cause cholera-like disease or mild diarrhea in humans, but are not normally transmitted by the water route. Cholera, whether caused by classical _V. cholerae_ biotypes or the El Tor biotype, produces the same clinical symptom, profuse diarrhea. Fecally contaminated water is the primary vehicle of cholera transmission, although vibrios are also spread by a multitude of other routes including food, soiled clothing, flies, and direct person-to-person contact. Cholera vibrios originate from human feces or vomitus. The disease has characteristically been sporadic and endemic in areas of poor hygiene and warm humid climates. However, isolated

cases have been reported in Europe, and the U.S., mainly from importation through tourism. Methods for isolating vibrios from water have not been standardized.

Campylobacter was initially observed as the agent of infectious abortion in cattle; it also may cause gastroenteritis in humans, cattle, sheep, and swine. The organism inhabits the genitourinary and intestinal tracts and is excreted in the feces. Feces from infected humans, animals, and fowl may contaminate surface waters destined to be used for drinking water supplies. If such source waters were inadequately treated, viable Campylobacter cells could, theoretically, gain entry to finished water. At present, there are no standard methods for detecting Campylobacter in water. When such methods become available for routine use, it will then be possible to determine the significance of Campylobacter in water as it relates to outbreaks of water-borne gastroenteritis.

Several other microorganisms present in water can infrequently cause disease, and almost always under unusual circumstances, either in abnormal hosts or in situations where the normal flora have been supplanted. These organisms are called opportunistic pathogens; Pseudomonas aeruginosa is a most notable case in point, along with some Enterobacteriaceae. Opportunistic pathogens are ubiquitous in nature, very resistant in water, and can grow with only a few nutritional requirements. Concentrations of opportunistic pathogens found in drinking water are not normally sufficient to lead to infection in a healthy consumer. Another very important property of these microorganisms is their great ability to accept and transfer plasmids which carry determinants for resistance to antibiotics.

Opportunistic pathogens present in drinking water include the following bacteria: Pseudomonas species, Aeromonas hydrophila, Edwardsiella tarda, Flavobacterium, Klebsiella, Enterobacter, Serratia, Proteus, Providencia, Citrobacter, Acinetobacter and Staphylococcus aureus. Examination of drinking water for the presence of Pseudomonas should be incorporated into routine analyses of the water since suitable methods exist for the enumeration of P. aeruginosa.

Viruses are ultramicroscopic intracellular parasites, incapable of replication outside of a host organism. Great numbers and varieties of bacterial, plant, and animal viruses may be present in both polluted and unpolluted waters. The viruses of greatest concern are those of human origin, which

are capable of infecting and causing disease in humans. In general, they are shed in the feces and are known as the human enteric viruses. Infection usually takes place after viruses are ingested, possibly in contaminated water or food. Except for the hepatitis A virus, the public health significance of human enteric viruses in water remains unclear due possibly to the apparent or latent nature of viral infections and the difficulty of detecting waterborne viruses.

Human enteroviruses include the polioviruses, the coxsackieviruses groups A and B, and the echoviruses. Although large numbers of enteroviruses have been consistently isolated from fecally contaminated water, only a few reports have implicated water as the vehicle of transmission. Hepatitis A is the only form of viral hepatitis known to be transmitted through water, and it is also the most prevalent waterborne disease attributable to a specific etiologic agent. The incubation period of the disease in humans generally ranges from 15 to 50 days, with a median of 28 days. Some people shed the virus in their feces as early as seven days before onset of symptoms; others may transmit the virus without ever becoming perceptibly ill. Attempts to culture the hepatitis A virus in cell lines have consistently failed, so that all available evidence about its transmission by polluted drinking water is obtained from epidemiological studies. Another group of small viruses potentially transmissible through water, some of which may in fact be enteroviruses, are called gastroenteritis viruses. Rotaviruses are primarily associated with gastroenteritis in children. Because rotaviruses may be excreted in very large numbers, they are almost certain to be present in polluted water; there is presently no suitable method for their detection at low concentrations. Reoviruses, adeno-viruses, and adeno-associated viruses can also be found in water.

Because viruses multiply only within susceptible host cells, they cannot increase in sewage. Their numbers are further reduced as a result of sewage treatment, dilution, natural inactivation, and water treatment practices. Therefore, barring gross contamination of finished water, only extremely low numbers of viruses, if any, are likely to occur in properly treated supplies. Large samples of water must be tested to enable detection of whatever low level of viruses might be occurring in any given source water. Adsorption methods employing glass microfibers and glass powder appear promising for handling large volumes of water containing few viruses. Until further information is forthcoming, the public health significance of small numbers of viruses detected in drinking water will remain undetermined, and it should be noted again that the hepatitis A virus cannot be detected in water.

Certain species of protozoa are now an increasing cause of waterborne disease. Entamoeba histolytica causes amebic dysentery, as well as such other clinical manifestations as diarrhea, abcesses of the liver, and chronic infections with minimal symptoms. Improved sanitary sewerage systems have been largely responsible for the curtailment of waterborne amebic dysentery. Another protozoan, Giardia lamblia, now appears to be emerging as a major causative agent of waterborne disease. It was not until 1966 that water was recognized as a vehicle of Giardia transmission; since that time, increased awareness on the part of physicians may have accounted for the more frequent reporting of outbreaks. The overriding point to be emphasized is that outbreaks involving municipal water supplies are associated with surface water sources where disinfection was the only treatment. G. lamblia cysts are not destroyed by chlorination at dosages and contact times commonly used in water treatment. Naegleria fowleri has been recognized as one of the agents responsible for causing primary amebic meningoencephalitis (PAM). Acanthamoeba is also associated with PAM; like Naegleri fowleri, Acanthamoeba species have ben isolated from tap water in association with PAM cases. Metazoan parasites that may be transmitted in drinking water are limited to a few nematodes and helminths whose presence in water is only incidental to their life cycles. Standard chlorination is not effective against parasitic or nuisance-causing metazoa discussed in this section. Well-regulated flocculation, sedimentation, and filtration practices afford reliable protection against their occurrence in finished water.

Many causes of gastroenteritis are possible, including bacteria, viruses, and other unknown agents. The illness in such outbreaks is often called "acute infectious nonbacterial gastroenteritis" (AING). It is only recently that means have been developed for identifying some of the viruses responsible for AING, such as parvovirus-like agents, rotaviruses, and particles resembling coronaviruses, myxoviruses, astroviruses, adenoviruses, and caliciviruses.

b. Sources of Waterborne Pathogens. Reservoirs of diseases transmissible to man are man himself, as well as domestic and wild animals. The microorganisms responsible for causing disease generally are excreted in the feces or urine, whereupon they may gain access to water. If drinking water treatment is inadequate or lacking altogether, these organisms may pass freely into water en route to the consumer, thereby engendering a risk of infection and possibly

disease. Pathogenic microorganisms are excreted not only by individuals with clinical symptoms, but also by asymptomatic carriers.

c. <u>Persistence and Death of Pathogens</u>. Water is a hostile environment to most human pathogens which, once introduced, will die at varying rates depending on factors that influence this death rate: temperature, pH, nutrients, and predation. Under certain conditions, some pathogens persist longer in water than the standard bacterial indicators. Therefore, once a source water has been contaminated, specific treatment to remove pathogens is warranted; it is not enough to rely solely on natural die-off during storage.

d. <u>Infectivity of Waterborne Pathogens</u>. The presence of a viable pathogenic microbe in drinking water is always undesirable, but it does not always guarantee that infection, and especially disease, will result if someone drinks the contaminated water. There is a paucity of information concerning the infectivity of waterborne pathogens. The probability that a given agent will cause infection if ingested with drinking water is, almost certainly, a function of the dose; however, many other factors can affect the answer of the ingestor (immunity, nutrition, intestinal flora, intercurrent illnesses).

e. <u>Epidemiology of Waterborne Infectious Diseases</u>. The epidemiology of waterborne diseases in developing countries deals simply with the infection rates and characteristics of the diseases principally associated with waterborne transmission. However, in developed countries, the quantity of water available for drinking and hygienic purposes is sufficient; the nutritional status and medical care are generally good; and the incidence of waterborne disease is low, as a result of more than a century's progress in sanitation. Contaminated drinking water (water that is ordinarily treated so as to be safe to drink, but is accidentally contaminated by wastewater containing feces) is an important vehicle for epidemic outbreaks because of its potential for mass transmission. On the other hand, drinking water that is treated and disinfected so as to contain only a few residual microorganisms might produce only a barely perceptible or imperceptible rate of disease in the consuming population. More recorded outbreaks have been

associated with semipublic water systems than with muni-
cipal or individual systems; however, outbreaks from muni-
cipal systems have affected more people than those from
semipublic or individual systems.

In some countries, an agency collects data on many
notifiable diseases, including several previously listed.
Although this type of surveillance suffers from the problem
of incomplete reporting, it can be useful in identifying
trends and may also be useful in determining the order of
magnitude of various risks of disease. During the period
from 1967 through 1976, in the U.S.A., 36 to 51 cases of
enteric disease per 100,000 population were reported annually.
About half of the cases were hepatitis A. Even if the
reported cases only represent one out of 20 actual cases, it
is likely that each year less than 1 percent of the popu-
lation contracts infectious disease that is characterized as
being spread by the fecal-oral route. Estimates of the
proportion of enteric disease that is waterborne range from
about 1 to 33 percent, so the probability of contracting
waterborne infectious disease in any year might range from
0.0001 to 0.0033. Absolute values for risk can be estimated
from general disease statistics, but not with a great deal
of confidence. One can gain an idea of the magnitude of the
problem, however. The drawback to this approach is that the
value obtained is insensitive to change because of the high
level of uncertainty. Another approach to determining the
risk of a given activity is to study specific populations
that are most likely to be exposed to the hazard. Ideally,
the level of the exposure is determined in order to relate
it to the observed response (dose-response relationship).

The record of waterborne outbreaks, even though they
are underreported, reveals the most common deficiencies in
water supply systems. Contaminated groundwater accounts for
the majority of outbreaks involving private systems, whereas
water distribution deficiencies are the most common causes
among municipal systems. It is extremely difficult to
associate the discharge of treated wastewater with disease
contracted as a result of consuming contaminated drinking
water. It has been suggested that sporadic cases of viral
disease may be indirectly transmitted by water supplies.
The importance of the so-called "focal infection" (caused by
ingestion of water containing extremely low level of virus)
in the spread of enteric viral disease in a community has
been neither proven nor disproven. This is mainly because
epidemiological research methods are not sufficiently sen-
sitive to determine whether or not "waterborne focal in-
fections" occur. In most of the reported outbreaks, the

water was found to be bacteriologically or chemically con-
taminated. An etiologic agent is determined in about 50
percent of the incidents, but the rate of reporting is very
low.

In any individual, the result of ingesting an infec-
tious agent with water will depend on a great many factors.
It is rare that a simple epidemiologic study can, of itself,
develop proof of a cause-effect relationship. The purpose
of an epidemiologic study is to compare an exposed group to
an unexposed group in which all factors other than exposure
are identical. Finding an appropriate control (unexposed)
group that meets these needs is sometimes very difficult
when the factor to be studied is water. The nature of the
disease sometimes imposes further difficulties in prospec-
tive studies, as in the case of hepatitis A, where the long
incubation period affords much opportunity for subjects to
move about before becoming ill. Efforts have, therefore,
been made to derive precise quantitative expressions for
time-related changes in the dynamics of infections.

Models are attempts to represent reality, and as such,
may be extremely useful in inferring information about real
situations if they are logically constructed. To be useful
to decision makers, a mathematical model must incorporate
the following: (1) it must be clearly defined; (2) the
assumptions made in its construction must be clearly stated;
(3) those variables which have the greatest impact on its
output must be identified (sensitivity analysis); (4) data
inputs must be carefully selected; and (5) it must be vali-
dated. One of the major advantages of modeling is that it
promotes the systematic collection and organization of
information.

It is possible, in looking at environmental hazards, to
use a population of children. They tend to remain in the
same area at least for a certain known period of time and,
since they usually go to school near their homes, it is
relatively easy to determine the effect of an environmental
factor, such as pathogens present in drinking water.

7. Recommendations

    1. It is not to be expected that community water
        suppliers will invariably start with pure
        source water, treat and disinfect it appro-
        priately, and distribute it through a flawless

network. Even where source water is protected, as is true of many groundwaters, disinfection is recommended. This is especially important where finished water is to be stored rather than being used immediately.

2. Aftergrowth of opportunistic pathogens during distribution of finished water should be prevented by maintaining a chlorine residual throughout the distribution network, especially in large systems.

3. More sensitive methods for the detection of waterborne pathogens need to be developed, along with epidemiologic techniques to afford a more precise understanding of the effects of these agents on public health. Especially needed are well-planned prospective epidemiologic studies that are capable of establishing a valid causal relationship between the public water distribution system and the incidence of infection (and not only overt disease) in the consuming community.

4. Other situations in which it would be appropriate to test for pathogens in distribution water are: (a) after contamination is found to have occurred; (b) to trace the source of an outbreak; and (c) in analyzing disinfectant efficiency.

5. Better techniques must be developed for the detection and enumeration of all viruses that may be present in drinking water. Studies are needed to determine the quantities of waterborne viruses that must be ingested to produce infection and disease. Given the lack of correlation between viruses and the bacterial indicator systems, more research on the antiviral effectiveness of various water treatment processes is needed.

6. Epidemiologic surveillance networks should be established to determine the incidence of infections in populations of drinking water consumers, with an eye to either strengthening or relaxing specific standards.

C. INDICATOR SYSTEMS FOR MICROBIOLOGICAL QUALITY AND SAFETY OF WATER

Good quality drinking water should be free of potentially harmful organisms and substances. Although this continues to be the main concern of drinking water microbiology, there is much more to the quality of drinking water, by present-day standards, than mere harmlessness. Today's good quality drinking water should be of acceptable color, odor, taste, and (if possible) temperature, and should be prepared and distributed under continuously controlled microbiological conditions.

In the present context, "indicator systems" are defined as quality control methods for water procurement, treatment, and distribution, even when these are not directly related to the presence of potential pathogens. In the broad sense, consideration has been given to methods which range from the traditional reliance on fecal indicators, to methods for recovering other more fastidious organisms, to those which employ chemical and physical means of determining microbial populations and activities.

There are few established routine methods for detecting human pathogens in drinking water due to the large diversities and low numbers encountered in potable waters. Since most of the important waterborne human pathogens are of fecal origin, tests for determining the presence of organisms normally found in human feces provide a means for alerting the microbiologist to any potential hazard from pathogens in the water. These tests for recovering normal fecal organisms, which occur in far greater quantities, need not be as sensitive and specific as methods which measure pathogens directly.

There is always room for improvement in the methods for ensuring the absence of pathogens from drinking water. However, we also intend to consider here microbiologically-based methods for the control of all phases of drinking water quality. Some of these methods are well established and routinely used in water testing while others are in

various experimental stages. Some may only be applied in special cases.

Probably no indicator system will be found ideal for all of the possible applications. Some may seem most appropriate for daily quality control; others may be most useful in measuring gradual deterioration in water quality over the long term. Some of the rapid or automated methods may find widespread application in determining water quality during emergencies such as cross-connections or line breaks. Other automated methods may be better applied to on-line monitoring of water quality.

This section will discuss both the theoretical bases of indicator systems and improvements in testing technology in an effort to evaluate their present and future roles in ensuring the quality and safety of drinking water.

1. Established Viable Indicator Systems

The indicator systems in this category are the classical microbiological parameters of water quality which have proved useful for indicating the presence or potential presence of pathogens originating from fecal sources. It is generally agreed that a good indicator of these types of pathogens should fulfill the following criteria:

- It should be present and occur in greater numbers than pathogens.

- Any potential it may have for growth in the aquatic environment should not surpass that of pathogens.

- It should yield characteristic and simple reactions enabling, as far as possible, the unambiguous identification of the group.

The indicators in this group are dealt with in terms of their ability to satisfy these criteria and the extent to which they will continue to be relied upon, in the coming years, as the primary microbiological indicator systems of water quality.

a. **Colony count.** The colony count (also referred to as standard plate count, total microbial count, viable count, water plate count, total bacterial count, aerobic mesophilic viable bacteria, etc.) measures the number of

aerobic and facultative anaerobic heterotrophic bacteria in
1 or 0.1 ml of water that form colonies on nutrient medium
at a specified incubation time and temperature. Nutrient
media used and time and temperature of incubation vary from
country to country [See Section D.6]. Colonies formed with
this method do not represent all bacteria in the sample
since no single growth medium will accommodate the nutri-
tional requirements of all bacteria. Also, strict anaerobes
and slower growing bacteria are missed by this method.
Clusters or chains of bacteria or bacteria adsorbed to small
particles do not necessarily yield colonies that were devel-
oped from each bacterium contained in such groupings.

Plates are incubated at 35 to 37°C for 24 to 48 h,
favoring bacteria adapted to the body temperature of warm-
blooded animals, or at 20 to 22°C for 48 to 72 h, favoring
saprophytic bacteria which may be capable of causing opera-
tional disturbances in water treatment and distribution.
Organisms able to grow at 20°C are found in tap water in
much higher numbers than organisms that grow at 35°C. This
is partly because the adverse conditions inherent in any
water environment, such as lack of nutrients and sub-optimal
temperatures, would tend to select for bacteria of little or
no public health significance [See Section B.3].

The vast majority of bacteria are of this latter cate-
gory and take part in virtually all cycles of nature: in
the self-purification processes that occur in surface water,
in antagonistic reactions among different species, and in
the mineralization of organic matter (e.g., ammonia to
nitrite, to nitrate), to name a few [See Section A]. Al-
though the genera of bacteria detected by the colony count
method may not be pathogenic to healthy humans, many of
these organisms can produce acute or chronic infections in
special cases -- for example, during medical therapy [See
Section B.1.a(ix)]. Bacteria other than coliforms also are
important because they can hamper filtration efficiency at
the treatment plant [See Sections E.4 to 5] and their pres-
ence in large numbers often signifies a deterioration in
finished water quality brought on when, for example, changes
in pressure in a distribution system cause a release of
microorganisms from dead ends and other protected sections
[See Section F.2].

(i) Media Used for the Colony Count. Various nutrient
media used in the colony count differ mainly with respect to
the solidifier -- gelatin, agar, or silica gel. All nu-
trient media have to be enriched with some form of peptone

and meat or yeast extract, the type and concentration of which influence the number of developing bacteria [See also Section D.6].

Agar media contain either yeast or meat extract and differ mainly in the quality of peptone used and in the presence, in some cases, of glucose. However, the incorporation of glucose entails an additional analysis and calls for a number of precautions during sterilization in order to avoid hydrolysis of the sugar. For this reason , the European standardization committees INSTA and CEC do not recommend glucose media for the colony count technique (Commission of the European Communities, 1977).

Gelatin, sometimes used in conjunction with gelose, contains meat extract with or without sodium chloride. The gelatin is a nutrient for gelatin-liquifying bacteria, and as such, will influence the colony count. Thus, gelatin not only provides a quantitative measure, but also distinguishes certain "nuisance" bacteria, such as green-fluorescent pseudomonads [See Section C.2.c] and other bacteria that liquify gelatin rapidly. Gelatin nutrient media should be incubated only at 20°C, since they will liquify again at higher temperatures. Gelatin combined with agar in nutrient media can be incubated at 37°C and enables differentiation between bacteria that liquify gelatin and those that do not. Selective counting of gelatin liquifiers is accomplished after determination of the colony count by placing 5 ml of ammonium sulfate solution on the nutrient medium and counting colonies that become surrounded by clear halos after a few minutes. Silica gel retains its gelling properties regardless of variations in quality, but is not commonly used, mostly from lack of familiarity and consequent difficulty in preparing.

Studies compared yeast extract with meat extract at 37 and 20°C and found a more rapid development at 37°C and higher bacterial numbers at 20°C using the yeast extract. Numbers were either the same or lower when glucose was added (Commission of the European Communities, 1977). In addition, results from pour plates using plate count agar (American Public Health Association, 1976) were in agreement with peptone yeast extract medium, proposed by the ISO (Commission of the European Communities, 1977).

(ii) Method for Determining Colony Counts. Very simply, the procedure entails mixing the sample, then transferring 1.0 or 0.1-ml volumes of diluted or undiluted sample

into culture plates, and adding 10 ml of melted nutrient medium. The covered plates are swirled in a motion describing a figure 8, are allowed to solidify (within 10 min) on a level surface, and are then incubated. Colony counts are recorded from plates containing 30 to 300 colonies, and counts are made using a Quebec counter or a counter that gives equivalent magnification and illumination. Densely grown colonies may be counted by taking an average of the colony numbers within 1 cm^2 at six different sites on the dish, provided the colonies are evenly distributed.

The colony number is calculated by using the formula:

$$ab/c = G$$

where a = number of colonies counted per cm^2; b = area of the culture dish in cm^2; c = volume of the water sample transferred into the dish, in ml; and G = number of colonies per ml of the water sample. The colony count is expressed as a number per 1 ml of sample water, to not more than two significant digits. The colony number should be recorded along with information on type of culture medium and incubation time and temperature applied. Numbers of gelatin liquifiers, if determined, also are reported [See Section C.4.h].

(iii) Applications of the Colony Count. The colony count is not, by itself, an indicator of fecal pollution [See Sections C.1.b to d]. However, when used routinely to monitor water supplies -- at least every three months -- it can provide baseline data on the general bacterial population and aid in assessing the degree of bacterial pollution of that supply. It is an especially valuable tool, when used in conjunction with other tests, for assessing the purity of a possible new raw water source.

Used as part of routine analyses, the colony count would reveal any changes in the bacteriological quality of finished water in storage reservoirs and distribution systems. Colony counts taken repeatedly at specific sites in a water treatment plant, at different times of the year, and at various points throughout the distribution system offer a valid procedure for maintaining ongoing quality control [See also Section C.4]. Application of this method would indirectly limit the occurrence and level of Pseudomonas, Flavobacterium, and other secondary pathogenic invaders that could be harmful in a hospital environment [See Section B.1.a(ix)]. It would, in addition, serve to monitor the

effectiveness of chlorine throughout the distribution network. Also, it would alert water authorities to any deterioration in filtration efficiency at the treatment plant or sediment accumulation in the distribution network with consequent build-up of bacteria.

Many filter media (e.g., charcoal, polysterol, and asbestos) and ion exchange resins used in the home and elsewhere have been known to support large increases in bacterial populations (Müller and Herzel, 1973) [See Section G.2]. The colony count method is well suited as an indicator of such disturbances.

A sudden increase in the colony count from a given source can serve as an early indication of contamination. Indeed, sudden increases in colony counts which had been low for several years have, in the past, indicated the sources of waterborne outbreaks in the FRG. Such an increase in the colony count occurred prior to the typhoid fever outbreak in Hannover in 1926 (Mohrmann, 1927), the cause of which was flooding of untreated well water with heavily contaminated river water. High colony counts were observed in distribution system water before it was found to be positive for E. coli and total coliforms. Some 40,000 people became ill with nonspecific gastroenteritis ("water disease") [See Section B.1.d] two weeks before the first cases of typhoid fever were reported. The same observations were made during the typhoid fever outbreaks at Pforzheim in 1919 and at Gelsenkirchen in 1889.

Large populations ($\sim$1,000 per ml) of noncoliform genera, including Pseudomonas, Bacillus, Streptomyces, Micrococcus, Flavobacterium, Proteus, and various yeasts can suppress the growth of coliform bacteria below detectable levels. This may well have been the reason that coliform readings were negative just prior to a salmonellosis outbreak involving 16,000 cases in Riverside, California (U.S.) [See Section B.1.a(i)]. The colony count, used in conjunction with coliform tests, would reveal such interferences by noncoliform bacteria and thereby afford a more accurate interpretation of results.

(iv) Recommended and Mandatory Maximum Limits. Opinion varies in different countries as to the necessity or value of incorporating total microbial counts into routine water quality surveillance programs [See Section D.6]. Even in places where these tests are routinely performed, water

quality criteria will differ with respect to maximum allow-
able concentrations, evaluation of the counts, and the kind
of water that shall be characterized by the count (Müller,
1977b) [See Table C.1.a-1]. Except for bottled water (which
has legal limits imposed of 1,000 colonies per ml) [See
Section G.6], all other types of drinking water in the FRG
are subject only to recommended guidelines; however, German
drinking water law specifies the method by which the colony
count is to be conducted (Aurand, et al., 1976).

The colony count is not a required test in the U.S.,
but many health departments, water supply agencies, and
local jurisdictions observe limits commonly applied within a
range of 100 to 500 colony-forming units per ml. Geldreich
(reviewed in Safe Drinking Water Committee, 1977) proposed
that a 500 per ml limit (at 35°C for 48 h) be placed on the
colony count and that immediate investigations of water
treatment and distribution systems be undertaken whenever
this limit was exceeded. The U.S. government has acknow -
ledged the importance of the colony count in recommendations
of the National Academy of Sciences, entered into the Federal
Register (Environmental Protection Agency, 1977): "It [the
colony count] is, however, a valuable procedure for asses-
sing the bacterial quality of drinking water.... The SPC
[colony count] has major health significance for surface-
water systems that do not use sedimentation-flocculation-
filtration, and chlorination, and for those systems and
[sic] do not include chlorination."

(v) Summary. The colony count is not a substitute for
total coliform measurements of the sanitary quality of
potable water. However, if it is used in conjunction with
other tests, bacterial numbers and types determined by this
method can provide an integrated picture of conditions upon
which to base decisions for further microbiological testing,
epidemiological surveys, and repair or upgrading of treat-
ment plants and distribution systems.

b. Total Coliforms. The relationship between the
ingestion of polluted water and the occurrence of certain
diseases has been recognized since the beginning of recorded
history. Even before specific agents had been detected,
epidemiologists were able to show that some human activities
could give rise to disease. Von Fritsch's observation in
1882, that the presence of Klebsiella pneumoniae and K.
rhinoscleromatis signified fecal contamination, and Escherich's

TABLE C.1.a-1

COLONY COUNT CRITERIA FOR VARIOUS TYPES OF WATER
IN SEVERAL EUROPEAN COUNTRIES

Country	Maximum Allowable Numbers/ml	Incubation Temperature	Type of Water
Poland	25	--	--
Czechoslovakia	20	37°C	Public supply
	100	20°C	Public supply
	100	37°C	Well water
	500	20°C	Well water
Yugoslavia	10	37°C	Treated water
	100	37°C	Raw groundwater
	300	37°C	Raw surface water
Romania	20	--	Public water supply for 70,000 customers
	100 to 300	--	Other supplies
Switzerland	100	--	Raw water entering works
	300	--	Raw water during distribution
	20	--	Treated water immediately after treatment
	300	--	Treated water in the distribution system

TABLE C.1.a-1 -- Continued

Country	Maximum Allowable Numbers/ml	Incubation Temperature	Type of Water
Spain	50 to 65	37°C	Good quality finished water
	100	37°C	Tolerable quality finished water
Netherlands, Sweden, GDR	100	20°C	--
Fed. Republic of Germany	20 (recommended)	$20 \pm 2°C$	Disinfected water
	100 (recommended)	$20 \pm 2°C$	All other kinds of drinking water
	1,000 (recommended)	$20 \pm 2°C$	Water tanks
	1,000 (mandatory)	$20 \pm 2°C$	Bottled water
France, Austria, UK, Greece, Israel, Italy, Netherlands, US	--	--	No recommended or mandatory values

isolation of Bacillus coli (Escherichia coli) from feces in 1885, mark the beginning of the science of sanitary water bacteriology.

During the next twenty years, investigators were quick to recognize the difficulties in isolating pathogens compared to the relative ease in isolating B. coli from polluted waters (Heathman, et al., 1936). Before the turn of the century, Theobald Smith had observed that the presence of B. coli in water must be due to fecal discharges. Survival studies indicated that B. coli persisted longer in water than did the typhoid bacillus, the most feared pathogen of the day (Heathman, et al., 1936) [See also Sections B.1.a(i), B.3, and E.1]. Thus, the rationale for the use of B. coli as an indicator of the sanitary quality of water was established, being based on: its regular association with feces; its presence in water in numbers greater than those of pathogens; and its superior survival capabilities. In 1905, when the first edition of Standard Methods of Water Analysis was issued by the American Public Health Association, B. coli was recommended for use as an indicator of the bacteriological condition of water supplies.

There are several operational definitions of the coliform group. These differ in a number of procedural details [See Sections D.2 to 3]; but all tend to result in the inclusion of organisms from the genera Escherichia, Klebsiella, Enterobacter, and Citrobacter, not all of which are of fecal origin. For example, in North America, the 14th edition of Standard Methods for the Examination of Water and Wastewater (American Public Health Association, 1976) defines the total coliform group as: all aerobic and facultative anaerobic, gram-negative, nonsporeforming, rod-shaped bacteria that ferment lactose with gas formation within 48 h at 35°C; or, all organisms that produce a colony with a golden-green metallic sheen within 24 h on an Endo-type medium containing lactose. Members of the coliform group also are motile by peritrichous flagellation or immotile, they reduce nitrate ions to nitrite ions under anaerobic conditions, and they are oxidase-negative, a feature which distinguishes them from Aeromonas. These definitions are not to be regarded as identical but rather, as indicative of organisms roughly equivalent in sanitary significance.

The total coliform group is used today in many countries to indicate the microbial quality of raw and finished drinking water [See Sections D.2 to 3], and apparently this indicator system continues to ensure, with very few exceptions, that drinking water shall be safe for human consumption.

(i) Isolation Methods. Two standard methods are available for coliform determinations: the multiple tube fermentation procedure and the membrane filter technique. In the multiple tube fermentation procedure, tenfold dilutions of the water to be tested are inoculated into tubes containing the appropriate medium (five tubes per dilution). Dilution is unnecessary, however, for drinking water examination because of the expected low bacterial counts, so it is possible to set up 1 x 50 ml and 5 x 10 ml samples. The presence of gas (and acid) after incubation for 48 h at 35 or 37°C constitutes a positive presumptive test for coliforms and must be followed by confirmatory procedures. Results are reported as a most probable number (MPN). The MPN is a statistical estimate of the number of bacteria that, more probably than any other number, would give the observed result; it is not an actual count of the bacteria [See Section D.3].

The membrane filter (MF) technique has, in recent years, largely replaced the multiple tube fermentation procedure for the routine examination of drinking water. However, the multiple tube fermentation method is still of value when conditions render the membrane filter technique unusable (e.g., for water that is very turbid or heavily populated with noncoliform organisms capable of growth on the medium), and as a reference standard procedure.

The MF technique became accepted in bacteriological water analysis when it was demonstrated to be capable of producing results equivalent to those obtained by the multiple tube fermentation procedure. With the MF technique, the water sample is passed through a filter of 0.45 um pore diameter; the filter is placed on an appropriate selective/ differential medium and incubated for 24 h, after which time the coliform colonies are counted. The technique allows for large quantities of non-turbid water to be examined, thus increasing sensitivity and reliability while markedly reducing time, labor, equipment, space, and material needed [See Section D.2]. A current area of controversy with the MF technique concerns the variable performance of filters in the recovery of coliforms. Brown (1973) reported that numbers of E. coli were 15 to 18 percent less on filters than on standard plate cultures. He attributed the discrepancy to lack of nutrients. Variation also has been ascribed to differences in filter sterilization procedures, surface pore size, and the source of coliforms (Sladek, et al., 1975; Tobin and Dutka, 1977).

(ii) Evaluation as an Indicator. There are several serious problems with the general use of total coliforms as indicator organisms (except when testing finished drinking water). Total coliforms can grow in water of rather low organic matter content as well as in low temperature water such as cold mountain streams. They have been recovered in soil, on vegetation, in forest and farm products, and in many other environments (Geldreich, et al., 1964) including those almost untouched by humans. Although these organisms clearly are not specific for fecal pollution, they are considered by some to be preferable to thermo-tolerant coliforms [See Section C.l.c] as quality indicators for finished water because of their greater resistance to disinfection. Lin (1977) and others have shown that the total coliform group is more abundant and relatively more resistant to chlorine and other stresses than are thermo-tolerant coliforms, and thus it serves as a more stringent measure of water quality. If total coliforms are detected in finished water their presence should not be ignored, but should signal an investigation of the type and source of pollution. There have been a few documented cases in which pathogenic organisms were isolated from water that was negative for coliforms (Dutka, 1973). This may have been due to inhibition of the coliforms by other microorganisms, a phenomenon known to occur when colony counts at 35°C exceed 500 per ml (Geldreich, et al., 1972) [See Section C.l.a].

(iii) Conclusion. The total coliform group was one of the first indicator systems used and is still used in many surveys. It has limited value as a direct indicator of fecal pollution in raw source waters because of the ability of some coliforms to multiply readily in the environment and because of the methodological difficulties involved. Hence, it is more appropriate to monitor raw water for the presence of E. coli or thermo-tolerant coliforms [See Section C.l.c], and to test finished water for the presence of total coliforms which serve as a sensitive indicator of disinfection inadequacy or problems during distribution. It is used in many countries as the primary microbiological test for evaluating the quality of finished water and may continue to be for some time to come, or at least until easier, faster, and more sensitive indicator systems are well established [See Sections C.2 to 4].

(iv) Summary. The total coliform measurement is one of the oldest and most frequently used methods in sanitary microbiology. It enumerates bacteria of the genera Escherichia, Klebsiella, Enterobacter, and Citrobacter. Since some of these bacteria are not restricted to fecal origin, their presence should not be construed as a specific indication of contamination with fecal or pathogenic organisms, but rather, as a cause for further investigation. On the other hand, the total coliform group is more resistant to chlorination and environmental stresses than many other indicators, and so continues to be preferred by many water authorities as the primary indicator system for evaluating the microbiological quality of finished water.

c. Thermo-Tolerant Coliforms and Escherichia Coli. For many years, the total coliform group [See Section C.1.b] served as the main indicator of water pollution. However, because many of the organisms in this group are not limited to fecal sources, methods were developed to restrict the enumeration to those coliforms which are more clearly of fecal origin. A modified method devised by Eijkman (1904) called for a higher incubation temperature and this was refined further to distinguish what are known as thermo-tolerant coliforms (also referred to as fecal coliforms; it was the consensus of this working group that the descriptor "thermo-tolerant" is more accurate and more representative of the thinking of scientists in the participating countries) (Hajna and Perry, 1943; Geldreich, et al., 1958). This indicator group has all the properties of the total coliform group and, in addition, is able to ferment lactose with the production of gas in 24 h at 44.5°C (American Public Health Assoc., 1976). In general, this test enumerates organisms of the genera Escherichia and Klebsiella. Klebsiella [See Section C.2.d] may derive from nutrient-rich, non-fecal sources; a further procedural refinement permits testing specifically for E. coli.

E. coli is the only member of the coliform group that unquestionably is an inhabitant of the intestinal tract; hence, it has come to be the definitive organism for demonstrating fecal pollution of water. E. coli has the definitive properties of all members of the coliform group [See Section C.1.b], but possesses the following additional

characteristics: production of acid and gas from lactose at 44°C, glutamic acid-decarboxylase activity [See also Section C.4.e], no pigmentation on nutrient agar during an incubation of eight days (20°C), inability to utilize citrate as a sole carbon source, negative cyanide test, no urea or gelatin decomposition, positive methyl red reaction, and negative Voges-Proskauer reaction. Most of the strains form indole from tryptophan contained in tryptone broth and produce acid and gas from glucose at 44°C. It must be understood that not all these tests are carried out for routine water analyses, so the bacteria enumerated could perhaps be best described as "presumptive E. coli".

E. coli meets the criteria of a valid fecal indicator in that: it is present in the intestine in numbers larger than those of enteric pathogens; it behaves similarly to enteric pathogens within the aquatic environment; and it is less susceptible than most enteric pathogens to treatment or disinfection procedures. The presence of E. coli in a water supply indicates contamination with fecal material from warm-blooded animals such as birds and humans. One must assume that, if E. coli has gained access to a waterway, enteric pathogens also may have entered this water. Indeed, results from recent epidemiological studies (Cabelli, et al., 1976) show a higher statistical relationship between presence of E. coli and incidence of gastrointestinal illness than other members of the Klebsiella-Enterobacter-Citrobacter group.

(i) Methods for Enumerating Thermo-Tolerant Coliforms and E. Coli. Since it is impossible in water investigation to test all characteristics essential for identifying species, simplified procedures have been developed. These must be followed precisely, for any deviation from the prescribed procedure (e.g., use of a different nutrient medium) may invalidate the results.

Methods used in various countries for enumerating thermo-tolerant coliforms are essentially high temperature modifications of the total coliform tests. As with the total coliform test, there are two methods for enumerating thermo-tolerant coliforms -- the membrane filter technique [See Section D.4] and the multiple tube fermentation procedure [See Section D.5] -- upon which are based two separate (but hygienically equivalent) definitions. The IMViC tests

(indole, methyl red, Voges-Proskauer, and sodium citrate) are often used to differentiate between coliform isolates, particularly to determine the presence of E. coli (American Public Health Assoc., 1976). In the FRG, as in several other countries [See Sections D.4 to 5], there are very specific protocols for identifying E. coli (Müller, 1977b). Here, E. coli is differentiated from coliform bacteria by means of tryptone broth cultures according to the following procedure.

A single colony of a pure culture is inoculated into tryptone broth; after the culture becomes slightly turbid (4 to 7 h), it is inoculated into the following nutrient media: ammonium-citrate agar slant (the material should be distributed homogeneously on the agar slope), glucose broth, lactose broth, nutrient agar plate, and Endo agar plate. All nutrient media, including tryptone broth, are then incubated for 20 $\pm$ 4 h -- glucose broth at 44 $\pm$ 0.5°C in a water bath, the other nutrient media at 37 $\pm$ 1.0°C in an air incubator. After incubation, the Endo and nutrient agar plates are examined to determine whether all colonies show the same morphology. If not, fresh Endo agar plates must be inoculated from well isolated single colonies picked from the nutrient agar plate, and then incubated.

If a pure culture is present on the nutrient agar plate, the cytochrome oxidase test is performed by putting two to three drops of dimethyl-p-phenylenediamine on the colonies. The reaction is considered positive if the colonies turn blue within 1 to 2 min; if there is no color change, the reaction is negative. A positive cytochrome oxidase reaction means that colonies are not coliform bacteria (they may well be Aeromonas [See Section C.2.h] or Pseudomonas [See Section C.2.c], and no further testing is required. A negative cytochrome oxidase reaction and a positive reaction in lactose broth (i.e., gas and acid production) confirms the presence of coliform bacteria in the water sample. If acid is detected (brom cresol purple indicator turns from purple to yellow) without gas being present, the lactose broth is incubated another 24 h (48 h total elapsed time) and checked for gas, the presence of which is considered a positive result. If the result of the lactose broth culture is negative, there are no coliform bacteria present and no further tests are indicated. When coliforms are found to be present, the following biochemical

reactions are performed to determine the presence of E. coli:

1. Glucose Broth. If gas and acid are detected after incubation at $44 \pm 0.5°C$ (indicator changes from purple to yellow), the reaction is considered positive; no gas production, whether or not acid is present, indicates a negative result.

2. Tryptone Broth. Several drops of indole reagent are added to the incubated broth and the tube is agitated gently. The reaction is considered positive if a red surface layer forms in the culture within 1 to 2 min. If the surface layer remains yellow, the reaction is negative.

3. Ammonium Citrate Agar Slant. If visible colonies appear on the culture medium or if the indicator has changed from green to blue (even without detectable growth), the reaction is positive. Otherwise it is considered negative.

E. coli is confirmed to be present in the water under investigation by positive results in glucose broth (gas production) and in tryptone broth (indole positive), and by negative results on ammonium citrate agar.

(ii) Evaluation of Thermo-Tolerant Coliforms and E. Coli as Indicators. Recent research has confirmed the validity of the thermo-tolerant coliform test as an indicator of the potential presence of enteric pathogens in water. It has been shown that the frequency of Salmonella detection in water is related to the density of thermo-tolerant coliforms (Geldreich, 1970; Van Donsel and Geldreich, 1971). At thermo-tolerant coliform densities of 1 to 200 per 100 ml, Salmonella was detected in 28 percent of water samples examined; this frequency rose 85 to 98 percent in waters with thermo-tolerant coliform counts above 2,000 per 100 ml. Studies on survival in river water (Mitchell and Starzyk, 1975), well water (McFeters, et al., 1974), and septic tank effluent (Calabra, 1972) have shown that thermo-tolerant coliforms persist longer than salmonellae [See Sections B.3 and E.1]. Because they are more specific for fecal contamination, thermo-tolerant coliforms and E. coli are preferred over total coliforms for monitoring raw water for the potential presence of pathogens [See also Section C.1.b]. E. coli also is preferred in several European

countries for use in monitoring finished drinking water [See Section D].

(iii) Conclusion. Thermo-tolerant coliforms and E. coli are valuable indicators of fecal pollution in many situations where total coliforms are less applicable because of their widespread occurrence in the environment. When the means are available, E. coli is a preferred indicator for raw water because it excludes most of the Klebsiella organisms [See Section C.2.d] which may or may not originate from fecal sources. Because of its unrivaled specificity for fecal pollution, E. coli also is used for routine monitoring of finished drinking water, even though it is somewhat less resistant than total coliforms to chlorine and other disinfectants.

(iv) Summary. Coliform organisms can be further subdivided into thermo-tolerant coliforms (those capable of growth at 44°C) or E. coli, one of the principal species making up the thermo-tolerant coliform group. These latter two indicators are considered more specific for fecal pollution than total coliforms and are preferred for monitoring raw water quality. They also are the primary indicators used for finished water in several countries.

d. Fecal Streptococci. The three most commonly employed indicator groups for establishing the presence of sewage in a water supply, are total coliforms, thermo-tolerant coliforms, and fecal streptococci. All three groups occur in feces and feces-polluted waters in greater numbers than pathogens and fit all the other criteria for a valid indicator system [See Section C.1.Intro.]. However, drawbacks to total coliforms as indicators in raw water have been noted, due to their presence in the environment remote from any fecal pollution, and growth in nutrient-enriched waters [See Section C.1.b] (Clausen, 1977; Geldreich, 1970). Thermo-tolerant coliforms, a more restricted subgroup of the total coliform group, occur only in association with feces and thus are a better indicator of raw water quality. However, thermo-tolerant coliforms are more sensitive to conditions outside the animal intestinal tract than total coliforms, and possibly some pathogens including viruses, and thus may be subject to excessive die-off [See Section C.1.c].

Fecal streptococci serve as an index of fecal pollution of raw water and may provide valuable supplementary data when used in conjunction with thermo-tolerant coliforms. A ratio of thermo-tolerant coliforms to fecal streptococci can be used to identify the source of pollution as being either human- or nonhuman-derived. This is possible because humans have greater numbers of thermo-tolerant coliforms than fecal streptococci in their feces, whereas the reverse is true of other warm-blooded animals. In addition, the fecal streptococci are more resistant than coliforms to disinfection, are capable of longer survival in the environment, and do not exhibit aftergrowth, as is true of the coliforms. The fecal streptococci should therefore be considered a valuable indicator group for raw water quality when used as an adjunct to thermo-tolerant coliforms.

Fecal streptococci originate in the intestinal tracts of warm-blooded animals and are discharged with feces. They are easily detected in water because of characteristics which readily separate the fecal streptococci from other groups of bacteria including other gram-positive cocci. The fecal streptococci belong to the family Streptococcaceae and include catalase-negative, non-motile, gram-positive cocci that are indifferent to oxygen (Buchanan and Gibbons, 1974). The term fecal streptococcus in this discussion, as well as in most of the literature, is used as a synonym for Lancefield's group D streptococcus, but these terms are not precisely equivalent. Streptococci (e.g., S. mitis and S. salivarius and the group Q streptococci of fowl) other than those possessing the group D polysaccharide antigen between their cytoplasmic membrane and cell wall may occur in feces and thus may also be termed fecal streptococci (Clausen, et al., 1977); however these are not the streptococci that originate in the intestinal tracts of most warm-blooded animals. The group D streptococci (or fecal streptococci of sanitary significance; American Public Health Association, 1976) include:

Group D Streptococci

Streptococcus faecalis
Streptococcus faecalis variety liquefaciens
Streptococcus faecalis variety zymogenes

Streptococcus faecium
Streptococcus faecium variety durans
Streptococcus faecium variety casseliflavus

Streptococcus bovis

Streptococcus equinus

The first two species and their varieties are termed the "enterococci" and are the fecal streptococci that may be of human origin. In addition to these two species, feces of nonhuman warm-blooded animals also contain varying concentrations of S. bovis and S. equinus (Geldreich and Kenner, 1969) [See Table C.1.d-1]. The latter two species have been associated with pollution involving meat processing plants, dairy wastes, cattle feedlots, duck farms, and runoff from livestock pasture land (American Public Health Association, 1976; Geldreich, 1970); the detection of either of them indicates that the source of pollution is from animals other than humans.

(i) Isolation Methods. As is true for coliform testing, determinations of fecal streptococcus densities in water may be done by the multiple tube fermentation procedure or the membrane filter procedure. The mechanics and comparisons of these two general procedures are described elsewhere [See Section C.1.b]. In addition, fecal streptococci may be detected by a pour plate procedure (American Public Health Association, 1976).

The most probable number (MPN) method for determining fecal streptococcus concentrations, like the procedures for total or thermo-tolerant coliforms, includes both a presumptive and confirmed step (American Public Health Association, 1976). In the U.S., the presumptive medium used is azide dextrose (AD) broth. Replicate sets of three or five tubes of the medium are inoculated with tenfold dilutions of the water sample and incubated at 35°C. Growth constitutes a positive test after either 24 or 48 h of incubation. All tubes demonstrating turbidity are transferred to ethyl violet azide (EVA) broth. Growth in EVA, after 24 to 48 h of incubation at 35°C, is confirmed evidence of the presence of fecal streptococci. The MPN is taken from the number of positive EVA tubes.

Although the media in the U.S. for the multiple tube procedure have been adopted as part of their standard method (American Public Health Association, 1976), other media may be substituted for AD and/or EVA. Kibbey and coworkers (1978) have achieved higher fecal streptococcus recoveries when substituting KF streptococcus (KFS) agar (Geldreich and Kenner, 1969) or m-Enterococcus (ME) agar for EVA in the confirmed procedure, following incubation in either AD, KFS broth, or ME broth. The combination of KFS or ME presumptive broths followed by KFS or ME agar as the confirmed media

From Geldreich and Kenner, 1969.

have yielded the greatest number of streptococcal isolates (Kibbey, et al., 1978). The use of ME medium, however, has been discouraged by the American Public Health Association (1976) due to its poor recoveries of S. bovis and S. equinus; whereas these two species may be recovered on KFS medium (Clausen, et al., 1978).

The use of membrane filtration (MF) or agar pour plates for fecal streptococcus detection is recommended over the MPN procedure because recoveries on the MF and pour plate media are higher and less affected by interfering organisms, and greater numbers of false positive reactions occur in the AD/EVA broth MPN system (American Public Health Association, 1976). Also the MPN method using AD/EVA broths detects only the enterococci (Clausen, et al., 1978). For the MF procedure, filters are incubated on KFS agar at 35°C for 48 h, at which time all dark red to pink colonies (due to the reduction of the tetrazolium salt indicator) are counted (American Public Health Association, 1976). Turbid waters or chlorinated effluents cannot be analyzed by the MF procedure and one of the other methods must be employed.

An alternative method to either the MPN or MF method for fecal streptococcus detection is a pour plate procedure (American Public Health Association, 1976). The procedure should be used preferentially over the MF technique for those samples containing few fecal streptococci associated with significant turbidity. The only disadvantage to this procedure is that the sample volume that may be tested is usually limited to 1 ml. Two media have been recommended for use in the U.S.: KFS agar and Pfizer selective enterococcus (PSE) agar. Surface and subsurface colonies produced by fecal streptococci after 48 h of incubation at 35°C are dark red to pink. Few nonfecal streptococcus colonies will be observed on KFS agar because of the selectivity of the medium (American Public Health Association, 1976). Stream samples may sometimes contain gram-positive soil organisms that may grow on this medium, such as Corynebacterium or Bacillus species (American Public Health Association, 1976). Other false positive organisms reported to grow on this medium include: Pediococcus, Lactobacillus, and Staphylococcus (Clausen, et al., 1977); but none of these organisms reduce tetrazolium and thus, will not form a red colony. Fecal streptococci on PSE agar produce brownish-black colonies with brown halos, due to the formation of iron salts of hydrolyzed esculin, after 24 h of incubation at 35°C. The only gram-positive cocci that will grow and exhibit esculin hydrolysis are the group D streptococci. Listeria monocytogenes,

the only other organism capable of both growth and esculin hydrolysis on PSE agar, shows only pinpoint colonies at 24 h, and coloration of the colonies is less marked with Listeria than with the fecal streptococci (American Public Health Association, 1976). The advantage of PSE agar over KFS agar is the shorter incubation time of 24 h for PSE agar as compared to 48 h for KFS agar. Unfortunately PSE agar does not lend itself to use with the MF technique unless a PSE agar overlay is added after the MF has been applied to the medium. The overlay allows visualization of esculin hydrolysis directly above the colonies without having to turn over the plate to see the blackening of the medium under the MF (Clausen, et al., 1977).

All the media used for the detection of fecal streptococci are dependent on the inclusion of the metabolic inhibitor, sodium azide, which poisons hemeporphyrin components (e.g., the enzyme catalase and the cytochromes of the respiratory chain) of cells. Because the fecal streptococci lack any porphyrin-containing enzymes or coenzymes, they survive in the presence of this poison, whereas any aerobic or facultative anaerobic organisms should be completely inhibited.

Although the detection of fecal streptococci is relatively straightforward, and the selective media which are recommended yield few false positives, their speciation is extremely tedious and several different taxonomic schemes have been proposed (American Public Health Association, 1976; Buchanan and Gibbons, 1974; Geldreich and Kenner, 1969; Kibbey, et al., 1978) which have led to considerable confusion. The results of any identification are determined by the taxonomic scheme which is employed (Kibbey, et al., 1978). Characteristics of the enterococci used in most identification schemes include: growth at 10 and 45°C, growth at pH 9.6, tolerance to 60°C for 30 min, tolerance to 6.5 percent NaCl, growth in 40 percent bile broth, and reduction of 0.1 percent methylene blue. To identify the varieties of enterococci and to separate out S. bovis and S. equinus, other biochemical tests must be employed.

(ii) Evaluation as an Indicator of Raw Water Quality. The fecal streptococci are a diverse group of organisms that have variable fecal origins and survival characteristics; they include several biotypes of limited sanitary significance (Geldreich, 1970; Geldreich, 1979). Usually the detection of fecal streptococci in water denotes fecal pollution; but if they were to be used as the sole indicator

system, the existence of strains that have an environmental origin should be noted. S. faecium variety casseliflavus is described by Mundt and Graham (1968) as being plant-derived and possessing a yellow pigment (unlike other streptococci). It occurs in high numbers on vegetation, but rarely in association with fecal material (Mundt and Graham, 1968), although it also has been reported to be of human origin (Ator and Starzyk, 1976). It appears to be a transitional organism that has properties of both S. faecalis and S. faecium (Ator and Starzyk, 1976). S. faecalis variety liquefaciens also occurs in the environment in association with plants, insects, and certain types of soil, in addition to occurring in animal feces in high proportions (American Public Health Association, 1976 ; Clausen, et al., 1977; Geldreich, 1970). Geldreich (1970) has found high numbers of this organism in unpolluted wells, perhaps due to contamination of the wells by soil or insects. An atypical biotype of S. faecalis capable of starch hydrolysis may be isolated in association with vegetation, but rarely from feces. Recovery of the starch-hydrolyzing strain is uncommon from water, soil, insects, or warm-blooded animals. Group D isolates of human origin, by contrast, were found not to hydrolyze starch (Clausen, et al., 1977).

The plant-associated streptococci of nonfecal origin closely resemble the streptococci of fecal origin (Kibbey, et al., 1978), and low numbers of certain biotypes (e.g., S. faecalis variety liquefaciens) are present even in good quality waters free of fecal pollution (Geldreich, 1970); although in waters from vegetable-processing plants their numbers may be increased. Therefore, if high numbers of fecal streptococci are detected in the absence of thermo-tolerant coliforms, misinterpretation may be avoided if the species of the fecal streptococci are determined, so as to learn whether environmental rather than enteric varieties are involved.

Fecal streptococcus densities may be best used in association with thermo-tolerant coliforms as a ratio used to assign the probable source of waste discharge as being either human or from farm animals and wildlife. Fecal streptococcus densities are significantly higher than thermo-tolerant coliform densities in all warm-blooded animal feces except for those of humans as shown in Table C.1.d-1 (Geldreich and Kenner, 1969). In human feces, the thermo-tolerant coliform to fecal streptococcus ratio is always greater than four, whereas ratios for all other warm-blooded animal feces

are always less than 0.7. However, this ratio is influenced by die-off and is only valid at the waste outfall or during the first 24 h after discharge into the receiving waters (Geldreich and Kenner, 1969). Due to environmental factors such as death, survival, or aftergrowth, the proportions of fecal streptococci and thermo-tolerant coliforms in water may be altered (Geldreich, 1979).

Table C.1.d-1 illustrates the distribution of the fecal streptococci in warm-blooded animals including man. S. bovis and S. equinus do not occur in the feces of humans and therefore are considered specific indicators of nonhuman animal pollution; however, S. bovis and S. equinus are the indicator organisms most sensitive to rapid die-off outside the animal intestinal tract (Geldreich, 1970; Geldreich, 1978; Geldreich and Kenner, 1969). After 24 h at either 10 or 20°C water temperatures, less than 10 percent of S. bovis can be recovered, and even shorter survival times are seen with S. equinus (Geldreich and Kenner, 1969).

Although limited survival of S. bovis and S. equinus occurs when outside the intestinal tract, survival of the other fecal streptococci in the environment is greater. During favorable temperatures and in waters with high electrolyte contents, survival of fecal streptococci is enhanced (Geldreich, 1970; Geldreich, 1978). S. faecalis and S. faecalis variety liquefaciens persist longer in water than either thermo-tolerant coliforms or Enterobacter aerogenes (Clausen, et al., 1977). Unlike the total or thermo-tolerant coliforms, the fecal streptococci rarely mutiply in polluted water, with the exception of the naturally-occurring S. faecalis biotypes that may replicate in vegetable processing wastewaters (Clausen, et al., 1977; Geldreich, 1978). Fecal streptococci are also more resistant to chlorine, and populations surviving disinfection are not as subject to aftergrowth as are total and thermo-tolerant coliforms. The apparent resistance of fecal streptococci to disinfectants and adverse environmental conditions is probably due to the clustering of the organism in chains: in a reaction with a disinfectant, all cells of a chain or cluster must be destroyed, or the surviving cells will again manifest growth of the chain or cluster (Berg, 1978). With the extended survival of the fecal streptococci beyond that of total or thermo-tolerant coliforms, and because they are heavily clumped, they more closely parallel survival of the enteric viruses (Berg and Metcalf, 1978; Clausen, et al., 1977; Kenner, 1978). Similar rates of destruction for both fecal streptococci and enteric viruses have been observed in mesophilic digested sludge, raw fresh waters, and possibly may occur in ocean waters (Berg and Metcalf, 1978; Kenner, 1978).

(iii) Conclusions. Like the total and thermo-tolerant coliforms, the fecal streptococci may be used as fecal pollution indicators in water because all three of these groups are present in the feces of humans and warm-blooded animals in higher concentrations than pathogens and also are present in feces-contaminated waters. In raw water, fecal streptococci are less numerous than total coliforms, which are ubiquitous in nature and do not necessarily indicate fecal contamination. Although the fecal streptococci occur in low numbers within environmental sources not necessarily associated with feces, their presence in high numbers, especially if thermo-tolerant coliforms also are present, indicate fecal additions have occurred. Because of the environmentally-associated biotypes, S. faecalis variety liquefaciens, the atypical S. faecalis, and S. faecium variety casseliflavus, it is important to include thermo-tolerant coliform densities with fecal streptococcus densities to determine whether fecal pollution actually has occurred, and to define the polluting source by the thermo-tolerant coliform to fecal streptococcus ratio.

Because fecal streptococci are not often found associated with plants in pristine environments, it appears that plant populations of fecal streptococci originate from a fecal source and establish a reservoir which then may be spread to other vegetation (Clausen, et al., 1977). To compensate for the low levels of the naturally occurring biotypes, fecal streptococcus densities of less than 100 per 100 ml should be considered of little sanitary significance (Geldreich, 1970; Geldreich, 1978).

Unlike the total coliforms, the fecal streptococci rarely multiply in polluted waters, but survive in waters, especially those containing levels of high electrolyte, at favorable temperatures (Geldreich, 1970; Geldreich, 1978). Although the two species occurring in the feces of nonhuman warm-blooded animals (i.e., S. bovis and S. equinus) survive for only short periods in the environment, the other fecal streptococci (i.e., the enterococci) have much greater survival capabilities outside the animal host than either S. bovis or S. equinus and also as compared to either total or thermo-tolerant coliforms.

Due to the species-specific survival characteristics and ubiquitous distribution of certain biotypes in the environment, it is not recommended that the fecal streptococci be used as the sole fecal pollution indicator. Other fecal indicators should be used concurrently if using the

fecal streptococci to investigate water quality (American Public Health Association, 1976). Improved assurance of the microbiological safety of raw water can be gained by using both the thermo-tolerant coliforms and fecal streptococci as fecal pollution indicators.

e. Sporeformers

(i) Definitions and Source of Indicators. Anaerobic (genus Clostridium) and aerobic (genus Bacillus) spore-forming species can be applied as indicators of pollution in the examination of drinking water. Bacillus species often constitute a considerable part of the colonies counted on plates, especially at 37°C; these organisms can accumulate in sand filters, and a sudden increase in numbers can indicate a breakthrough of the filter. However, an increased number of aerobic sporeformers may also indicate specific pollution (Schubert, 1975a); and the species demonstrated may give an indication as to the source, B. licheniformis being associated mainly with sewage; B. cereus, B. megaterium, and B. sphaericus with soil; and B. brevis with filter sand (Bonde, 1977).

The enumeration of anaerobic sporeformers (clostridia) is based either on counting all sulfite-reducing clostridia that grow at 37°C or on a specific count of C. perfringens.

A short definition of C. perfringens applicable in water quality examination is: gram-positive, anaerobic, sporeforming (although spores are infrequently seen), non-motile rods, which reduce sulfite to sulfide, give stormy fermentation on milk, produce lecithinase, hydrolyze gelatin, ferment sucrose but not mannitol, and do not form indole. Demonstration of sulfite reducers necessitates pasteurization of the sample to avoid interference from non-sporeforming organisms (Vibrio, Salmonella, Arizona, Edwardsiella, Citrobacter, Proteus mirabilis and P. rettgeri) that can form H_2S from inorganic or organic sulfur compounds. A wide variety of clostridia can reduce sulfite at 37°C (Bonde, 1962), including C. perfringens, C. sporogenes, C. feseri, C. fallax, C. septicum, C. sphenoides, C. bifermentans, C. parasporogenes, C. botulinum, C. oedematiens, C. roseum, C. tertium, and C. cochlearium. Not all of these species are as suggestive of fecal pollution as C. perfringens, which on the other hand is often capricious with regard to sporulation and might in some instances be

lost or suppressed by the other sulfite reducers. The
aerobic sporeformers B. polymyxa and B. macerans have some-
times been mentioned as sulfite reducers, but this has not
been confirmed (Bonde, 1977).

Applying selective media and procedures, combined with
incubation at 48°C, reduces the number of species enumerated
to five, of which C. perfringens is more important in pol-
luted waters than the other four species (C. bifermentans,
C. feseri, C. sporogenes, and C. tertium), all of which
generally grow more slowly.

(ii)   Sources and Significance of C. Perfringens in
Water Examinations.   Bonde (1962) gives a review of the
classification, production of toxins, and pathogenicity, as
well as of the occurrence in soil, water, and sewage of this
organism.   The most controversial point is whether this
organism is really ubiquitous and mainly found as spores in
nature, or dependent upon pollution and found as vegetative
forms in the neighborhood of the source of pollution.

Before 1900, C. perfringens was considered to be pri-
marily a fecal and pathogenic organism and, as such, to have
greater indicator significance than the coli bacteria.
Pollution by sewage could be detected at a ratio of 1:500,000
by means of the "enteritidis test" (for C. perfringens)
which was 25 times more sensitive than chemical tests.
Wilson and Blair (1925) considered the demonstration of
cells in the negative form to be particularly valuable, and
stressed that C. perfringens is an organism of indisputably
fecal origin that is of great importance for the detection
of intermittent and occasional pollution.   Many others (cf.
survey by Bonde, 1962) considered a test for C. perfringens
to be a valuable supplement to other examination methods.
Windle Taylor (1958) emphasized that when water is satis-
factory from a sanitary point of view according to all
other criteria, it has never been possible to demonstrate
the presence of C. perfringens, and that this organism is a
particularly useful indicator in cases where the coli-aero-
genes group fails.

Willis (1956) expressed more negative assessment of
C. perfringens as an indicator after finding this bacterium
in large numbers in soil samples from areas around bore-
holes.   He also found poor correlation between counts of
coliforms and of C. perfringens and showed that filter sand
contained this organism in great numbers.   He concluded from

his counts of vegetative cells that C. perfringens is able
to multiply in tapwater. Windle Taylor (1958) also found
C. perfringens in samples of filter sand, vegetative cells
being predominant. However, considering that waterbearing
strata are subject to contamination and that defects in sand
filters are common, it is surprising that such adverse
interpretations are made from these findings.

C. perfringens is also very important in water samples
because it may cause "false positives" in the lactose fermen-
tation test for coliforms more frequently than any other
single organism, sometimes in nearly half of the samples.
Windle Taylor (1958) considered this species a predominant
cause of false positive results in testing filtered and
chlorinated waters: C. perfringens accounted for 22.7
percent of the total of 32.6 percent false positive reactions.

Bonde (1962) did not find a regular correlation between
counts of C. perfringens and E. coli, but stressed that such
a correlation should not be expected. The initial numbers
of both species are functions of fecal pollution, but the
ecology, persistence, and survival of the two differ mark-
edly. C. perfringens and E. coli must both be considered
fecal organisms and are excreted together with potentially
pathogenic organisms. On the whole, the counts of thermo-
tolerant coliforms are usually greater, by a factor of about
100, than counts of C. perfringens regardless of whether the
latter are done with nonpasteurized samples or as counts of
spores. In some cases, however, C. perfringens may give
higher counts tnan E. coli and may even be present despite
negative tests for E. coli in as much as 46 percent of
tapwater samples, whereas among water samples in general
that contain E. coli, 85 percent lacked C. perfringens
(Bonde, 1962).

Those opposed to the use of C. perfringens as an indi-
cator have suggested that its numbers, in samples, are too
small to be useful. However, improved methods now often
reveal higher numbers of C. perfringens than of E. coli
(Bonde, 1962).

(iii) Enumeration Techniques. Several methods and
media are available for C. perfringens counts (Bisson and
Cabelli, 1979; Bonde, 1962; British Department of Health and
Social Security, 1969; Hirn and Raevuori, 1978; Windle
Taylor, 1958). The methods differ mainly in using media
that are liquid or solid and rich or lean in nutrients, in
incubation at 37°C or at 45 to 48°C, and in pasteurization

of the inoculum or not. Liquid media are used for most
probable number methods and solid media are used for colony
counts.

An improved version of the Bonde pour-tube method uses
a lean medium (meat extract 1 percent, peptone 1 percent,
agar 0.75 percent, pH 7.2, in 10-ml amounts in tubes to
which is added 2 ml 1 percent anhydrous sodium sulfite
solution, two drops of 5 percent ferrous alum, and 5 ml
inoculum). Ten tubes of pasteurized (at 80°C for 5 min) as
well as of nonpasteurized samples are incubated at 48°C for
24 h. Based on a study of about 13,000 counts and confir-
mation by gram stain, motility, stormy fermentation-reaction,
and fermentation of mannitol, colonies that had attained a
size of more than two mm were confirmed as C. perfringens
in more than 90 percent of cases, except in samples from
polluted fresh water courses (75 percent). Lack of confir-
mation was, in most cases, due to failure to grow and not to
the presence of other sulfite-reducers. The method can,
therefore, be applied with good results as a presumptive
test without confirmation. The same medium can also be used
with membrane filters laid onto it.

(iv) Conclusions. Enumeration of C. perfringens
compares to the requirements for an ideal indicator system
as follows:

1. An indicator bacterium must always be present
    when pathogenic organisms are present. C.
    perfringens is a fecal organism and will be
    excreted together with possible enteric patho-
    genic organisms.

2. It must be present only when the presence of
    pathogenic organisms is a possibility. This
    rigorous requirement is not fulfilled by any of
    the known indicator species; Bonde (1977) has
    shown that C. perfringens is widespread but
    not ubiquitous, so it meets this criterion as
    well as other established fecal indicators.

3. It must be excreted in greater numbers than the
    pathogenic organisms. This appears to be true
    of C. perfringens now that the methods devel-
    oped are yielding numbers comparable to those
    for E. coli in feces.

4. It must be more resistant, both to disinfectants and to hostile aqueous environments, than the pathogens. This condition is fulfilled by C. perfringens to a greater extent than by any other indicator.

5. It must display characteristic and simple reactions during growth, enabling rapid and, preferably, unambiguous identification; this is the case with C. perfringens.

6. The growth of the indicator bacterium should be independent of other species in the presumptive medium. This requirement is fulfilled by C. perfringens in sulfite-alum agar at 48°C.

C. perfringens may be preferable to E. coli as an indicator when examining samples that may contain substances toxic to microorganisms, including samples of chlorinated water, and in the examination of samples for which transportation problems are such that the samples cannot be analyzed within 12 h of collection. In all single examinations and all first examinations of untreated water, determinations of C. perfringens should be added to the usual tests. This species may be an especially valuable indicator in exceptionally hot or cold climates.

(v) Summary. Anaerobic, sporeforming clostridia can be applied as indicators of pollution in the examination of drinking water: the species of choice for this purpose is C. perfringens. Techniques for the enumeration of this fecal organism have been so refined as to allow them to be used with as much sensitivity as the methods for E. coli, in most cases. In general, good correlations are not found, nor are they expected, between C. perfringens and E. coli in environmental samples. C. perfringens is evidently widespread, but not ubiquitous in the environment; its detection in water must be considered evidence of fecal contamination.

2. Proposed Viable Indicators

For any of several reasons, the organisms in this group are not presently included under the designation, "established viable indicators." In some cases, the detection method is

too complex or time-consuming, or too recently developed. Not enough is known about some of the organisms to enable correct interpretation of results in all situations. Whatever drawbacks currently preclude their use may or may not be subject to revision in the future. The following critical evaluations will attempt to discern their utility and scope of application as indicators in light of the latest data.

      a.   <u>Coliphages</u>. Twort in 1915, and d'Herelle in 1917, were the first to report bacterial lysis caused by a virus. d'Herelle named these viruses "bacteriophage" (i.e., bacteria-eating); the name is frequently shortened to "phage."

Phages, each of which are specific for a single species of bacterium, have been isolated from fresh and seawater, as well as from wastewater. Those which attack <u>Salmonella</u>, <u>Shigella</u>, <u>Pseudomonas</u>, <u>Staphylococcus</u>, <u>Vibrio</u>, and other bacteria are described in the literature, as are phages that attack yeasts and cyanobacteria.

Best characterized are the "coliphages" (phages which infect <u>E. coli</u>), especially the T-phages; others designated MS_2, f2, and $\phi X174$ have also been studied extensively. Coliphages are shed at high levels by humans and other warm-blooded animals and are present in the feces whether or not enteroviruses are.

The coliphages are not usually specific as to the species of animal in whose feces they occur, but they are quite selective as to which strains of <u>E. coli</u> they will infect. This specificity is determined by the coat protein (e.g., the tail structures in the case of the T-phages) of the virus particle, which must attach to a homologous receptor on the surface of the bacterial cell before the viral nucleic acid can be injected into the host. Only those coliphages that express themselves overtly (i.e., carry out a full replicative cycle) in cell culture can be used as indicators. Those that do not cause cell lysis within the 6 h incubation period -- lysogenic phages -- are not useful indicators.

The presence of coliphages (shed in all human feces) indicates that fecal material, possibly containing surviving pathogenic enteroviruses, is present. Since at least some coliphages are more resistant to environmental conditions and chlorination than most enteroviruses, the elimination of

the latter can be assumed to have occurred if these coliphages cannot be found. Coliform (especially thermotolerant coliform) bacteria are not considered good indicators of enteroviruses because they are much less resistant than enteroviruses to environmental conditions and chlorination (Scarpino, et al., 1972). Detection of waterborne coliphages is easier than enteroviruses because:

1. They are present in greater numbers than enteroviruses in fecal material and therefore, in sewage; and

2. They can be isolated and counted by relatively simple means, and in less time than is required for enteroviruses. Coliphage enumerations can often be accomplished within 4 to 6 h, whereas seven or eight days are required for enterovirus enumerations (Kott, et al., 1978b).

(i) Coliphage Enumeration Techniques. The agar layer method (Adams, 1959) provides an accurate means of enumerating coliphage, and does so within 24 h. The sample is inoculated directly onto a bacterial lawn grown on soft agar (or mixed together with the sample and molten agar) in petri plates, and plaques are counted. However, a preliminary concentration step must be applied before this technique can be used with large volumes of water containing small numbers of bacteriophage.

The most probable number (MPN) method has been used successfully for animal virus tissue culture enumerations and could detect coliphage in fresh water, seawater, and wastewater in numbers as low as two plaque-forming units (pfu) per 100 ml when E. coli B was the host strain (Kott, 1966). This technique has, accordingly, been recommended for use with larger volumes of up to one liter of water and provides for enrichment of phages. It calls for inoculation of sample into a 5-tube, 3-dilution series, using double and single strength Phage Assay Base (PAB) broth (Fisher Scientific Co., Pittsburgh, Pa.) as the enrichment medium. Culture tubes are incubated for 16 h at 35°C after which time a loopful from each tube is transferred to freshly seeded host E. coli plates and incubated for 6 h at 35°C. Results are computed from coliform MPN tables (Kott, 1966). Although the MPN method can be used with any E. coli strain, the best results in the cited study were obtained when E. coli B served as host.

(ii)   Preparatory Concentration Techniques.   Several
techniques are available for concentrating viruses, includ-
ing phages, which occur in water at extremely low levels
[See also Section III.C.2.b]. Gilcreas and Kelly (1955)
used alum flocculation and obtained almost 99.99 percent
isolation of coliforms and coliphages; they accordingly
recommended it for concentrating coliphages. Preformed
flocs of aluminum hydroxide, aluminum phosphate, and calcium
phosphate are generally used for the concentration and
isolation of a great variety of viruses, and have been
routinely employed as a step in drinking water treatment.

Sorber and coworkers (1972a) found that the polelec-
trolyte (PE) 60 (a cross-linked copolymer of isobutylene
maleic anhydride) adsorbed 100 percent of T2 coliphage from
large volumes (up to 18 l) of water. These same authors
(1972b) employed asymmetric cellulose-acetate membranes
(commonly used in reverse osmosis) to collect coliphage T2
and poliovirus from large volumes of water.

Bachrach and Friedmann (1971) used a polyethylene
glycol and dextran sulfate 2-phase system as well as zone
centrifugation in sucrose gradients to isolate T-even and T-
odd coliphages. When acid precipitation was employed, good
recoveries were obtained with T2 and T4 phages, but not
with T3 and T7 phages due to their susceptibility to the
acid.

The method found most suitable for recovering low
coliphage numbers from large volumes of water entails adsorp-
tion of the phage to a cellulose nitrate membrane filter
after increasing the electrolyte concentration (for better
adsorptive capacity) by adding 0.1 M $MgCl_2 \cdot 6H_2O$ to the
sample. The sample is filtered through a 50 mm^2 membrane of
0.45 um pore size (or larger membranes if over 20 l are
applied); phages are eluted with 10 to 15 ml of 3 percent
beef extract (pH 9.0). The eluate is examined either by the
direct plaque count or by the MPN method (Vajdic, 1970).
E. coli B host cultures were used with this method.

(iii)   Occurrence and Persistence of Coliphage and
Enterovirus in Different Water Sources.   Types and numbers
of coliphages present will vary depending on the source of
the water to be tested -- whether taken, for example, from
stream water, wastewater effluent, or a sewage lagoon.
Therefore, the most appropriate bacterial host strain will
depend on which coliphage types are likely to predominate,

depending upon their relative resistance to environmental (and disinfection) stresses, among other factors. Although most investigators use host bacterial strains susceptible to the T-phages, only 11 percent of hundreds of E. coli (differentiated by IMViC) strains isolated demonstrated susceptibility to the T-series. Moreover, the RNA bacteriophages f2 and MS_2 are more resistant than the other coliphages to chlorination.

Vaughn and Metcalf (1975) studied the presence of coliphages in an estuary polluted with sewage effluent. By testing samples with three host E. coli strains over a three-year period, they found that the dominant coliphage type shifted from one year to the next; this suggested that a host system selected on the basis of past experience might prove ill-suited to present needs. Their studies also revealed that coliphages were capable of multiplying in polluted estuarine waters containing susceptible host cells. They suggested that, due to the potential for coliphage replication in certain waters, coliphages might not always be used reliably to indicate the presence of enteric viruses in water. Cleaner quality waters, however, may show no such multiplication because coliphages infect and replicate only in growing cells and only under very restrictive conditions of pH, temperature, and more.

Ratio of coliphages to enteroviruses also vary among water sources. A three-year study of wastewater effluents found that while the comparatively small number of enteroviruses underwent seasonal fluctuations, the comparatively large number of coliphages ($\sim 10^3$ to 10^4 times as many) remained steady (Kott, et al., 1978a). However, levels of both poliovirus 1 and coliphage f2, isolated from an experimental oxidation pond, remained stable over a period of several months; following oxidation pond treatment the coliphages exhibited higher resistance to chlorination. Sewage lagoons appeared to reduce enteroviruses and coliphages to approximately the same degree (about two orders of magnitude). But, when poliovirus 1 (strain LSc) and coliphage f2 were kept in tapwater and oxidation pond samples in the dark at room temperature, the poliovirus was totally inactivated in < 150 days in both sample waters, whereas the f2 remained viable for over 300 days in both samples [See also Section E.1.d]. Creek and stream waters often contain coliforms, coliphages, and enteroviruses: there may be from 10 to 10^7 times as many coliphages as enteroviruses present. Poliovirus survived < 217 days in dry sand, whereas coliphage persisted for several hundred days. In effect,

the physical and chemical quality of the water will influ-
ence, to a much greater extent, the numbers of enteroviruses
recovered than it will the numbers of coliphages.

(iv) Summary. Coliphages (phages that infect E.
coli) are indicators of the possible presence of entero-
viruses in water because they are shed in the feces of
humans and warm-blooded animals and may be more persistent
than enteroviruses under adverse conditions (including
disinfection). Coliphage numbers may range from a few per
liter in streams and rivers to as many as 10^6 per ml in
wastewater (where there has not been substantial dilution).
Coliphages can be quantified directly by the plaque tech-
nique if numbers are high; low numbers necessitate use of
the MPN method; either technique may be preceded by some
method for concentrating the phages. The simplest method
is that of adsorption to a cellulose nitrate membrane filter
followed by elution in a small volume of fluid. Using
coliphages to indicate the absence of enterovirus from
drinking water is inexpensive, does not require a high level
of operator skill, and yields results within 24 h. There
are, however, circumstances under which coliphage detection
may not accurately indicate the presence of enteric viruses.

b. Vaccine Polioviruses. A criticism frequently
leveled at the microbiologic indicators of water quality
presently in use today, is that their occurrence is poorly
correlated with the incidence of human enteric viruses in
water (Berg and Metcalf, 1978). The assertion may be true,
but the criticism is not entirely valid, for indicators now
in general use are expected to signal a variety of undesir-
able conditions without necessarily being absolutely related
to the presence of any one specific pathogen. If one wants
an indicator specifically to predict the incidence of human
enteric viral pathogens, the indicator in question should
always be present when these pathogens are present (Berg,
1978). The nonpathogenic, vaccine strains of the polio-
viruses are human enteric viruses and might thus serve as
specific indicators of the virologic safety of water
(Katzenelson, 1976).

More than 100 different virus types may be encountered
in waters contaminated with human wastes, although only the
hepatitis A virus has been demonstrated to be transmitted by
water (Berg and Metcalf, 1978; Katzenelson, 1978; Melnick,
et al., 1978). Most commonly encountered in water are the

enteroviruses (polioviruses, echoviruses, and coxsackie-
viruses); but the reoviruses, adenoviruses, hepatitis A
virus, and gastroenteritis viruses may also be present [See
Sections B.1.b and B.1.d] (Center for Disease Control,
1978d; Katzenelson, 1978; and Melnick, et al., 1978). The
concentration of such viruses in feces-contaminated water
depends upon the number of infected individuals in the
population, independent of the incidence of clinical symp-
toms.

The concentration of any virus, once introduced into
water, can only remain at the initial level or decline
(Berg, 1978; Katzenelson, 1978). Viruses do not replicate
outside a susceptible living host, whereas indicator bacte-
ria can multiply in nutrient enriched waters and thus, exag-
gerate the perceived risk of viral contamination (Berg, 1978;
Geldreich, 1978). Enteric viruses are also more resistant
to environmental extremes and to disinfection, so that
enteric viruses may persist in water long after all indi-
cator bacteria have been eliminated (Berg, 1978; Berg and
Metcalf, 1978; Katzenelson, 1976; U.S. Environmental Protec-
tion Agency, 1978). These are general reasons that the
occurrence of bacterial indicators cannot always be used to
signal the presence of viruses in water, as has been demon-
strated by outbreaks of hepatitis A resulting from con-
sumption of shellfish grown in contaminated surface waters
that were believed to be free of total coliforms (Berg and
Metcalf, 1978; Portnoy, et al., 1975). The presence of
viruses in water may best be monitored using a viral indi-
cator group.

In comparison to the traditional coliform indicators of
water quality, the concentration of viruses in wastewater is
quite low. Estimates of 100 to 400 virus units per liter in
the U.S. (U.S. Environmental Protection Agency, 1978) and
100 to 10,000 per 100 ml in other countries (Fattal and
Nishmi, 1977; Katzenelson, 1978) have been reported. After
wastewater treatment and dilution in the environment fol-
lowed by exposure to environmental extremes, the con-
centration of the remaining viruses in the water supply
will be still lower. Thus, it is difficult to estimate the
extremely low numbers of viruses that might occur in drinking
water.

Given the many types of viruses that may enter water,
the detection of any single viral pathogen is a formidable
task, and the detection of a great range of virus types
would be too complicated for routine laboratory analyses.

What is needed is a simple, reliable virus indicator system that consistently occurs in feces-contaminated waters and would dependably serve notice of the presence of viral pathogens.

In countries using the live trivalent oral polio vaccine (TOPV), the predominant enteric viruses isolated from sewage have been the three serotypes of the vaccine poliovirus (Fattal and Nishmi, 1977; Katzenelson, 1976; Katzenelson and Kedmi, 1979; U.S. Environmental Protection Agency, 1978). These virus isolates are shown to be vaccine-associated on the basis of the presence of distinctive genetic markers. Vaccine-derived poliovirus is assumed to be nonpathogenic, although of 142 cases of poliomyelitis reported in the U.S. from 1970 to 1978, 44 have been vaccine-associated; thus, the vaccine virus may be pathogenic for a small susceptible portion of the population (U.S. Environmental Protection Agency, 1978). The vaccine virus should not exhibit seasonal fluctuations in concentration, whereas the occurrence of wild viruses peaks in the late summer and early fall (Fattal and Nishmi, 1977; Katzenelson, 1976; U.S. Environmental Protection Agency, 1978).

Vaccine polioviruses are hardy, safe to handle, and easy to enumerate in the laboratory, whereas simple cell culture recovery systems for many other viruses are non-existent. Because they are convenient laboratory tools, much is known about their survival in the environment, their responses to disinfectants, and methods for their recovery from environmental sources. It is for these reasons that the vaccine-derived polioviruses are attractive candidates to serve as viral indicators. Other investigators (Melnick, et al., 1978) also have realized the value of using the readily demonstrable enteroviruses as indicators.

The major disadvantage of using a virus system for determining water safety is the time involved in performing virological assays, which usually takes more than 24 h and often requires three to seven days after a 24 to 48 h concentration step (Katzenelson, 1976). If polioviruses are to serve as useful indicators, a more rapid detection method is required. A proposed method uses the fluorescent antibody (FA) technique which identifies the virus after 18 to 24 h (Katzenelson, 1976). With the FA method, poliovirus antigens can be demonstrated after 6 to 9 h, but quantitative results require the complete 18 to 24 h incubation. An improvement of the original FA method incorporates tragacanth gum into the micro tissue culture medium, analogous to the

incorporation of agar into the plaque assay medium (Kedmi and Katzenelson, 1978). The resulting increase in viscosity allows the resolution of closely spaced plaques (preventing overlapping of neighboring plaques) and eliminates scattering of infected cells. Thus, a more accurate enumeration of plaque-forming units is achieved.

In countries routinely administering the TOPV to infants, in three to four challenges during the first year of life, a constant seeding of wastewater occurs (Berg and Metcalf, 1978; Katzenelson, 1976; Katzenelson and Kedmi, 1979; U.S. Environmental Protection Agency, 1978). The vaccine virus, like the wild virus, replicates in the human intestinal tract and is shed in high numbers (10^5 to 10^6 plaque-forming units per g of feces) for several weeks after the initial administration. Vaccine-derived poliovirus should thus, be expected to occur consistently in the sewage of countries using the live attenuated virus.

In one study (U.S. Environmental Protection Agency, 1978), vaccine-derived poliovirus could be isolated from sewage when as few as 0.3 percent of the local population were vaccinated. In Israel, viruses were isolated from sewage at different locations; among the 489 isolates, 74 percent of those identified were polioviruses. However, in Hungary only 19 percent of the identified viral isolates were vaccine-strain polioviruses (Palfi, 1971). In this study, poliovirus was the prevalent type found in sewage only after the compulsory polio vaccination campaigns were carried out during the winter months. Reoviruses were isolated throughout the year, but were isolated in highest concentration only after excretion of the vaccine virus ceased. The same pattern was observed with other wild viruses, suggesting that vaccination of populations with live polioviruses alters the incidence of wild viruses within a population. This observation may be due to the very rapid destruction of cells, by polioviruses, during enumeration assays (Palfi, 1971) or to the displacement of other virus types in the human population. Administration of live vaccine virus also alters the ratio of indicator bacteria to viruses entering sewage (Berg and Metcalf, 1978). Intermittent vaccination programs would cause poliovirus predominance only seasonally, whereas continuous vaccination programs, as in the U.S. and Israel, should cause poliovirus to predominate throughout the year (Berg and Metcalf, 1978).

In Israel, where TOPV is administered year-round, raw sewage samples from both large cities and small communities were analyzed for poliovirus (Katzenelson and Kedmi, 1979).

In this study, poliovirus was isolated from only 50 percent of the samples assayed. Negative results may have occurred because the wastewater contained a low concentration of polioviruses that was beneath the limit of sensitivity of the investigators' detection system. Detectable viruses were absent not only in small communities where the infant population could be expected to be low, but also in the large communities that had a significant number of infants who had received the TOPV.

In order for vaccine polioviruses to serve as indicators for enteric viruses, they must be present in all waters receiving fecal discharges. Although vaccine-derived poliovirus is isolated from sewage more often than other viruses, it is not always present (as is true of E. coli) in detectable quantities; therefore, negative test results would not guarantee virus-free water (Katzenelson, 1976). Vaccine polioviruses could not be expected to serve as suitable indicators in small communities lacking a significant infant population, in countries administering TOPV only seasonally, or in countries and communities using a killed virus vaccine instead of TOPV. However, the vaccine-derived polioviruses would have been expected to predominate in raw sewage from large cities in Israel, where the vaccine is in continuous use. The inability to detect vaccine polioviruses in many of such samples suggests that this potential indicator system is not predictably better correlated, compared to others already in use, with the incidence of human enteric viruses in water (Katzenelson and Kedmi, 1979).

Summary. Vaccine polioviruses are prevalent in receiving waters in areas where live trivalent oral polio vaccine is used for immunization. These viruses have been considered for use as indicators of human pathogenic enteric viruses. They are frequently detected in sewage, but recent data suggest that there are significant numbers of cases where no polioviruses were detectable in raw sewage in urban areas where the oral polio vaccine was in constant usage. As a result, the vaccine polioviruses do not appear to offer increased reliability over conventional bacterial indicators for enteric viruses in water.

c. Pseudomonas Aeruginosa. Within the genus Pseudomonas, the species of concern to public health is P. aeruginosa [See Section B.1.a(ix)]. The most common diseases

caused are eye, ear, nose, and throat infections, although general infections and septicemia are also possible (Caselitz, 1966). Given the opportunity to multiply in foods, P. aeruginosa may cause diarrhea after ingestion of the contaminated food (Caselitz, 1966; Kubota and Liu, 1971). Since this organism can grow under low nutrient concentrations (i.e., in distilled water), it warrants consideration for use in routine monitoring of finished water.

P. aeruginosa has been defined by a working group of the International Standards Organization as:

> "Gram-negative, non-sporing rods which are oxidase and catalase positive; capable of growth at 42°C, but not 4°C; usually produces a water-soluble, fluorescing pigment; exhibits oxidative metabolism as indicated by the Hugh and Liefson test; reduces nitrate beyond the stage of nitrite, and produces ammonia from the breakdown of acetamide; gelatin is liquified, casein is hydrolyzed, but starch is not hydrolyzed. Pyrocyanine is produced by more than 90 percent of strains."

The ecology of P. aeruginosa is not well known. Although the organism is found, regularly, in surface waters that receive wastewater effluents (mainly of urban origin) [See Sections A.Intro. and A.2.a], it is not clear whether this is necessarily the source of all P. aeruginosa. Recovery of Pseudomonas biotypes in areas untouched by humans indicates that environmental factors alone may support and even favor mass development of P. aeruginosa. Results from groundwater surveys show that P. aeruginosa is rarely found in undisturbed groundwater and that the presence of P. aeruginosa nearly always indicates contamination by surface water (Hoadley, 1977; Schubert and Blun, 1974a; Schubert and Scheiber, 1975). In addition, the organisms are not frequently found in groundwaters infiltrated with surface water or river water, which suggests that they are effectively eliminated during passage through the soil (Schubert and Blun, 1974a; Schubert and Scheiber, 1975) [See also Section A.1.e].

(i) Enumeration Methods. The most probable number (MPN) method is routinely used to enumerate P. aeruginosa, with enrichment either in nutrient broth containing malachite green dye incubated at 37°C (Schubert and Blun, 1974b) or in asparagine broth incubated at 35 to 37°C (American Public Health Association, 1976). Enrichment in Drake's medium 10

also has been shown to yield good results (reviewed by Hoadley, 1977). From there, cells are streaked onto a selective medium (MacConkey's agar, cetrimide agar, etc.), and finally identified by tests for fluorescein formation (on King's medium A) and/or pyocyanin formation (on King's medium B) as well as ammonia production from acetamide (which is of particular importance with apyocyanogenic strains (Schubert, et al., 1975).

Several membrane filtration methods, based on the mPA medium of Levin and Cabelli (1972), are in current use. The mPA medium contains antibiotics to reduce background growth (sulfapyridine, kanamycin, nalidixic acid, and acidione) along with indicator systems to distinguish P. aeruginosa from colonies that ferment lactose, sucrose, and xylose, and produce hydrogen sulfide. Membrane filters are placed on the agar medium and plates are incubated at 41.5°C for 48 h. A recent modification of this procedure, known as mPA-C (Brodsky and Ciebin, 1978), allows presumptive identification of P. aeruginosa within 24 h at an incubation temperature of 41.5°C.

(ii) Evaluation as an Indicator. Pseudomonas is an organism worthy of attention in the area of finished drinking water, largely because it has been found capable of growth along portions of the distribution system, particularly under conditions of low water flow and where dead end pipes are situated [See Sections F.2.a and F.3.a]. Treatment processes such as ion-exchange systems [See Section G.2] and many filtering devices [See Section E.4], in addition to situations where warm water flows through some types of plastic tubing or containers, can be especially favorable to the growth of Pseudomonas. It has been suggested (Labonde and Festy, 1979) that, in certain cases (e.g., in bottled water, in epidemiological studies, in new homes, in high risk areas, and in water destined for therapeutic purposes), drinking water should be monitored for Pseudomonas.

(iv) Conclusions. P. aeruginosa is a potential pathogen, especially if ingested in high numbers, as can occur after enrichment in foods. Therefore, it must be considered undesirable in drinking water and should be absent from sample volumes of at least 100 ml of finished water. The presence of P. aeruginosa in drinking water almost always can be traced either to direct contamination by surface

water or to dissemination from a primary locus of contami-
nation to other parts of the distribution system, reser-
voirs, or treatment facilities.

(v) Summary. Pseudomonas aeruginosa is an important
opportunistic pathogen of humans. It may or may not be of
fecal origin in water, but it can grow even at low nutrient
levels, sometimes reaching high numbers under favorable
conditions, some of which have been described here. Methods
for the detection of Pseudomonas are sufficiently developed
that the organism should be routinely monitored in high risk
areas, in the distribution system, and in water destined for
therapeutic use.

d. Klebsiella. The genus Klebsiella is a member of
the family Enterobacteriaceae and is composed of non-
sporeforming, non-motile, capsulated gram-negative rods
(Ørskov, 1974).

Some species of the present genera Klebsiella and
Enterobacter, with IMViC type --++, were traditionally
classified as Aerobacter aerogenes. Later, the motile
strains were designated Enterobacter (including A. aero-
genes), while the non-motile organisms were placed in the
genus Klebsiella. Another major difference between Entero-
bacter and Klebsiella is that the latter lack ornithine
decarboxylase.

According to the Edwards and Ewing classification,
which is widely accepted in the U.S. (especially in the
clinical laboratory), the klebsiellae are divided into three
species: K. pneumoniae, K. ozaenae, and K. rhinosclero-
matis. This classification has been adopted by Bergey's
Manual of Determinative Bacteriology, (Buchanan and Gibbons, 1974);
however, alternate classification systems exist. The type species
K. pneumoniae, is the predominant species isolated from environmental
sources and is identified in 95 percent of clinical Klebsiella
isolates in the U.S.

Biochemical procedures for differentiating K. pneu-
moniae are discussed elsewhere (Gellman, 1975; Dufour and
Cabelli, 1976; Vlassoff, 1977). This organism is char-
acterized as a non-motile rod that ferments lactose with the
production of gas and does not decarboxylate ornithine. Its
typical IMViC reaction is --++. Other tests useful for its
identification are urease (slow +), H_2S (-), oxidase (-),

gelatin liquefaction (-), KCN (+), lysine decarboxylase (+), arginine dihydrolase (-), and esculin hydrolysis (+).

Klebsiella isolates may be classified, serologically, on the basis of their heat-labile capsular (K) and heat-stable somatic (O) antigens. Presently, there are 72 known capsular serotypes and five O antigens. Rennie and Duncan (1974) found that biotypes and serotypes vary independently so that the two methods, used in conjuction, distinguish among more types than either method used alone.

Klebsiellae are widespread in normal humans and animals, but are also known to be opportunistic pathogens capable of causing infections when normal host defenses are weakened (Bagley and Seidler, 1978; Gellman, 1975). Furthermore, since the advent of antibiotic therapy, these organisms have shown increasing resistance to antibiotics because of their ability to accept and transfer plasmids (R factors) which carry determinants for multiple drug resistance.

(i) Sources of Klebsiella in the Environment. Klebsiella may originate from vegetable as well as animal sources (Duncan and Razzell, 1972). Klebsiella of animal origin, in the environment, most frequently derives from feces, but not all fecal samples yield Klebsiella. On the other hand, colonization of the human intestines, so that Klebsiella predominates, is a known, but abnormal phenomenon (Dufour and Cabelli, 1976; Knittel, et al., 1977; Vlassoff, 1977).

Regardless of its ultimate source, Klebsiella is ubiquitous in the environment (Dufour and Cabelli, 1976; Knittel, et al., 1977; Seidler, et al., 1977; and Vlassoff, 1977). These organisms are commonly associated with living trees and have been found in samples of water, soil, needles, and bark from different forest environments, including virgin forests of British Columbia. High densities of coliform bacteria, predominantly Klebsiella, can be found in pulp and paper mill effluents. Other carbohydrate-rich nutrient sources such as waste effluents from sugarcane, sugar refining, and kelp processing also yield high numbers of Klebsiella, far outnumbering the E. coli population. Significant numbers of Klebsiella have been isolated from a variety of market vegetables and seeds, dairy products (with positive coliform counts), and pet turtles.

The ability of Klebsiella to grow in nutrient-rich waters may be the cause of its frequent predominance over

E. coli in surface waters receiving wastewater discharges (Dufour and Cabelli, 1976; Seidler, et al., 1977). The capsule on the Klebsiella cell seems to impart some relative chlorine resistance, so that Klebsiella may predominate over E. coli in chlorinated water derived from raw water in which E. coli was the more numerous (Ptak, et al., 1973).

Total coliform counts exceeding U.S. federal regulations were detected by Seidler and coworkers (1977) in public and private drinking water systems that utilized redwood storage tanks. The coliform isolates were most often identified as K. pneumoniae and Enterobacter species. E. coli was isolated only rarely and was most likely due to more immediate fecal contamination. It appeared to the authors that specific nutrients in wood, trees, vegetables, and other plant matter selectively support coliforms of the tribe Klebsiellae.

(ii) Significance of Klebsiella in Water Bacteriology. Given the definition of the genus, virtually all Klebsiella organisms will yield a positive result in the total coliform test [See Section C.1.b]. Not all klebsiellae give a positive result in the thermo-tolerant coliform test [See Section C.1.c], apparently because some cannot grow at 44.5°C, however, most thermo-tolerant coliforms other than E. coli are Klebsiella (Dufour, 1977). Those klebsiellae which can grow at 44.5°C and are thermo-tolerant coliform-positive are not necessarily of fecal origin. Nevertheless, those which have been selected or adapted to growth in low temperature environments tend to be negative in the fecal coliform test (Naemura and Seidler, 1978), so there is a measure of correlation between the test result and fecal origin.

Members of the genus Klebsiella are not reliable indicators of sanitary qualilty or fecal contamination of water, for they do not meet several criteria of ideal indicator organisms. Detection of Klebsiella in water is more probably indicative of certain types of industrial pollution. Many studies have demonstrated high densities of Klebsiella, and few E. coli, in wood processing and other nutrient-rich effluents that were not known to have received human or animal wastes. Therefore, high coliform or fecal coliform counts in waters receiving such industrial effluents (unless sanitary wastes from the plant are included) should not be considered indicative of the presence of other microbial pathogens. Alternately, it has been suggested that

nutrients arising from vegetable material may selectively favor multiplication of the klebsiellae and that this could mask the presence of other fecal organisms (Dufour and Cabelli, 1976; Seidler, et al., 1977). Klebsiella may also inhibit the growth of other bacteria (Ptak, et al., 1973).

Klebsiella, used in conjunction with thermo-tolerant coliforms or E. coli, can be a useful indicator for monitoring certain industrial discharges and their receiving waters. Primary isolation methods, by which members of the genus Klebsiella can be enumerated and differentiated for this purpose, are obviously needed. Proposed media and methods have been reviewed by Vlassoff (1977). Sufficient data, on which to base a selection, are not yet available.

(iii) Conclusion. The widespread presence of Klebsiella in the environment is well known. Although carried by many healthy individuals, members of the genus Klebsiella are opportunistic human and animal pathogens and have become increasingly important as the cause of nosocomial infections. Some Klebsiella strains, readily recovered from environmental sources, have been found to be indistinguishable from clinical isolates when tested biochemically, serologically, and for their ability to grow at elevated temperatures (44.5°C) (Bagley and Seidler, 1978).

As is the case with any opportunistic pathogen, both a compromised host and a sufficient number of organisms are necessary for infection to occur. There is, as yet, no epidemiological evidence to connect the incidence of Klebsiella in drinking water or recreational waters with occurence of human disease.

The klebsiellae cannot be considered reliable indicators of fecal pollution because: (1) they are not always present or found in high numbers in feces; (2) they are found in large numbers in certain industrial wastes; (3) they are ubiquitous in the environment; and (4) they are able to multiply in nutrient-rich effluents.

The klebsiellae are not thermo-tolerant coliforms; thus, since a large proportion are able to grow at 44.5°C, there has been some controversy about the validity of total and thermo-tolerant coliform tests which include these organisms. Insofar as the organisms detected are recognized as members of the genus Klebsiella, their presence is most likely to signify high nutrient levels in receiving waters or to give evidence of inadequate treatment of industrial wastes.

(iv) Summary. The genus Klebsiella is a member of the coliform group, Klebsiella pneumoniae being the species most predominant in both environmental and clinical isolates. In spite of its significance as a secondary pathogen, it is not entirely suitable as a fecal pollution indicator because: it is not always found in large numbers in feces; it is often found in large numbers in certain industrial wastes; and it is able to multiply in environmental waters rich in carbohydrates.

e. Bifidobacterium. Bifidobacterium, previously known as Lactobacillus bifidus, may have the necessary characteristics of an ideal bacterial indicator of fecal pollution in raw water (Evison and James, 1975). Bifido-bacteria derive exclusively from feces and so, would occur only where there has been fecal contamination. Moreover the organisms are present only in very high numbers of 10^9 to 10^{11} per gram of feces in humans (Levin, 1977; Cabelli, 1979) and occur, though in markedly lower numbers, in some warm-blooded animals, especially pigs. Both coliforms and E. coli are now recognized as being capable of regrowth in warm, organically polluted waters; conversely, under these same conditions, numbers of fecal streptococci tend to decline rapidly. Bifidobacteria, on the other hand, are anaerobic organisms with fairly specific growth requirements and thus, are highly unlikely to find all the conditions necessary for regrowth in raw waters.

Members of the genus Bifidobacterium have posed clas-sification problems in the past and the nomenclature has been very confused. However, in the most recent edition of Bergey's Manual of Determinative Bacteriology (Buchanan and Gibbons, 1974), the genus has been divided into eleven clearly defined species on the basis of fermentation reac-tions with eleven carbohydrates. B. bifidum, B. adoles-centis, B. infantis, and B. breve are regularly associated with human feces; B. longum, and perhaps B. pseudolongum, may also be isolated from human feces, but are more often found in feces of lower animals, as are B. thermophilum and B. suis; B. asteroides, B. indicum, and B. coryneforme are associated only with insects.

Bifidobacteria are defined as anaerobic, nonspore-forming, non-motile, gram-positive, thick, pleomorphic rods. They may exhibit branching bulbs, clubs, coryneforms, buds, spheroids, and bifurcated Y and V forms when freshly iso-lated from fecal sources. However, their morphology is

related to nutritional conditions and may be affected by exposure in an aquatic environment and by composition of the culture medium. A calcium deficiency has been said to encourage pleomorphism, but culturing on normal laboratory media, such as MRS broth (De Man, et al., 1960) or differential reinforced clostridial media (DRCM), greatly reduces pleomorphism. Although young cultures of bifidobacteria are gram-positive, cultures older than four days gradually become gram-variable or even apparently gram-negative (Buchanan and Gibbons, 1974). The organisms also are catalase negative, do not reduce nitrates, and produce mainly lactic and acetic acid, but not gas, from glucose fermentation.

(i) Methods for Enumerating Bifidobacterium. Several media have been proposed for isolating Bifidobacterium from water, but only two are in use at present. Both of these media are used with membrane filters, which allows concentration of the sample, as may sometimes be necessary in the case of raw water. The more fully defined isolation medium is based on that proposed by Gyllenberg and Niemela (1959), but has been modified considerably and improved (Bhoonchaisri, 1979)(MGN-Modified Gyllenberg and Niemela medium).

The isolation medium [See Table C.2.e-1 for formulation] is prepared in two parts. After Part A is melted and cooled to 45°C, Part B is added in proportions of 10 ml Part B to 90 ml Part A. Raw water samples are filtered through cellulose nitrate membrane filters (0.45 um pore diameter, 47 mm filter diameter), the membranes are placed on the solidified medium in incubation tins, and incubated at 37°C for three days. Bifidobacterium colonies appear pink to red and are raised, with a diameter of 0.5 to 1.5 mm. They also will grow equally well in conventional anaerobic jars or in jars containing gas generator packets.

A second medium, YN-6, has been proposed by Resnick and Levin (1977) [See Table C.2.e-2 for medium formulation and preparation]. Membrane filters are incubated, anaerobically, for two days at 37°C. Bifidobacterium colonies will measure 1 to 2 mm in diameter and appear light to dark green, convex, glistening, and smooth.

Colonies from either MGN or YN-6 medium can be identified to the generic level by a simple series of tests.

TABLE C.2.e-1

MODIFIED GYLLENBERG AND NIEMELA MEDIUM FORMULATION

Part A

Lactose	10.0 g
K_2HPO_4	5.0 g
$(NH_4)_2SO_4$	4.0 g
Cysteine hydrochloride	0.4 g
$MgSO_4 \cdot 7H_2O$	0.2 g
Tween 80	1 ml
$FeSO_4 \cdot 7H_2O$	0.01 g
NaCl	0.01 g
$MnSO_4 \cdot 4H_2O$	0.007 g
Nalidixic acid	0.007 g
Biotin	5 ug
Riboflavin	250 ug
Pantothenic acid	500 ug
Neutral red	0.1 g
Oxoid agar No. 3	12 g
Distilled water	900 ml

Adjust pH to 6.5. Portion out in 90 ml aliquots. Autoclave at 121°C for 15 min.

Part B

Ascorbic acid	10 g
Distilled water	100 ml

Adjust pH to 6.5. Sterilize by pressure filtration through membrane filter of 0.45 u pore diameter

(GYLLENBERG AND NIEMELA, 1959: BHOONCHAISRI, 1979)

TABLE C.2.e-2

YN-6 MEDIUM FORMULATION AND PREPARATION

Yeast extract	20 g
Peptone	10 g
Lactose	10 g
Casamino acids	8 g
Sodium chloride	3.2 g
Brom cresol green	0.3 g
Distilled water	1 liter

Boil all ingredients for 10 min and cool. Add cysteine hydrochloride (0.4 g), Nalidixic acid (80 mg), adjust to pH 6.9, add agar (15 g) and autoclave at 121°C for 15 min. Cool to 60°C, add 1 ml stock Neomycin (2.5 mg/ml) and dispense into incubation tins.

(LEVIN, 1977)

Colonies are grown on solidified DRCM medium and Gram stained
(Gram +), spore stained (negative), tested for motility
(negative), aerotolerance (negative), and catalase activity
(negative). They also are grown in MRS-nitrate broth to
check for nitrate reduction (negative). Species of bifido-
bacteria are identified by their carbohydrates fermen-
tations. Purified isolates are inoculated into MRS-sugar
broths that have been modified by replacing 2 percent glu-
cose with other carbohydrates. Positive fermentation is
indicated by acid production (chlorophenol red indicator),
but no gas production. The isolates are divided initially
into four groups, on the basis of arabinose and gluconate
fermentation, as in Table C.2.e-3. Identification
within groups is achieved by additional tests for lactose,
ribose, xylose, mannitol, and starch fermentation (Levin,
1977; Bhoonchaisri, 1979).

(ii) Comparative Evaluations of Proposed Bifido-
bacterium Culture Media. Results obtained when raw water
was examined for Bifidobacterium differ according to the
isolation medium used. When the MGN and YN-6 media were
compared, using the same sample, the MGN medium yielded
higher counts of confirmed Bifidobacterium than the YN-6
medium. Although the YN-6 medium showed higher initial
colony counts, a larger proportion of these were aerotolerant
(non-Bifidobacterium) organisms. Bhoonchaisri (1979) also
showed that the incorporation of a reducing agent (0.05
percent cysteine hydrochloride) into the sample diluent in-
hibited the growth of Bifidobacterium.

(iii) Evaluation of Bifidobacterium as an Indicator of
Fecal Contamination. Studies of Bifidobacterium in fecal
specimens from humans have shown that the population is
higher and more constant than E. coli or fecal streptococci
across all age and ethnic group boundaries (Drasar, 1974;
Evison and Morgan, 1978). To quote Cabelli (1979), "Of all
the indicator systems, Bifidobacterium appears to be the one
most exclusively associated with human, as opposed to lower
animal, fecal wastes." It seems that this group may offer
potential as a means of distinguishing human from animal
pollution and may be very useful, for example, in deter-
mining whether domestic waste has entered a stormwater
system.

Studies with pure cultures of B. bifidum, B. adoles-
centis, and B. pseudolongum have demonstrated clearly that

TABLE C.2.e-3

Groupings of <u>Bifidobacterium</u> species

Group	Arabinose	Gluconate	Species
I	+	+	<u>B</u>. <u>adolescentis</u>, <u>B</u>. <u>asteroides</u>, and <u>B</u>. <u>coryneforme</u>
II	+	-	<u>B</u>. <u>longum</u>, <u>B</u>. <u>pseudolongum</u>, and <u>B</u>. <u>suis</u>
III	-	-	<u>B</u>. <u>bifidum</u>, <u>B</u>. <u>breve</u>, <u>B</u>. <u>infantis</u>, and <u>B</u>. <u>thermophilum</u>
IV	-	+	<u>B</u>. <u>indicum</u>

bifidobacteria are unlikely to multiply in raw waters (Evison and Morgan, 1978) because: very little growth occurs above or below the extremely narrow temperature range of 30 to 40°C; no growth can occur above 7 percent atmospheric oxygen; and maximum growth rates can occur only in the presence of high concentrations of proteins or carbohydrates.

One problem that has become apparent in recent studies is that the Bifidobacterium isolation media are not as selective when used with surface waters as they are for sewage samples. Gram-positive rods are commonly found in surface waters and are able to grow on the selective media, so further development of the media is required to overcome this interference.

A further problem, yet to be resolved, is that of the survival potential of bifidobacteria in the aquatic environment. Evison and James (1975), and Opara (1978), found that survival of bifidobacteria was equal to, and sometimes greater than, survival of E. coli in laboratory tests. However, Resnick and Levin (1977), and Cabelli (1979), have suggested that survival of bifidobacteria is poor in the aquatic environment. A possible explanation for this discrepancy might be that the YN-6 medium used by these latter authors contains high concentrations of antibiotics which may interfere with recovery of attenuated bifidobacteria.

(iv) Summary. The genus Bifidobacterium offers potential as a fecal indicator of raw water quality because it derives exclusively from feces (with high numbers in human feces and low numbers in animal feces) and it does not multiply in water (narrow temperature range, low tolerance of dissolved oxygen, high nutrient requirements). Better selective media are urgently needed in order to study the distribution and survival characteristics of the Bifidobacterium group in raw water.

f. Candida Albicans. Candida albicans is a dimorphic yeast which can be differentiated from other fungi by its formation of germ tubes and chlamydospores (Ahearn, 1974). The former are elongated cell extensions with no constrictions at the point of origin and are induced when young cells are incubated for 1 to 3 h, at 37°C, in calf serum. Chlamydospores are large, thick-walled, refractile bodies formed on pseudomycelia produced by growth of C. albicans on corn meal or oxgall agar or other appropriate media, at 22 to 26°C.

Although other species of Candida (viz., C. tropicalis, C. parapsilosis, C. guilliermondii, C. krusei, C. pseudotropicalis) are involved in human infection (Ahearn, 1978), C. albicans (syn. C. stellatoidea) is by far the most frequently encountered. While classical pathology involves oral, vaginal, and skin loci (Winner and Hurley, 1964), more recent awareness of the role of C. albicans as a serious opportunistic human pathogen has led to the increasing frequency of reports of systemic infections affecting a wide variety of internal organs (Kashkin, 1974; Ahearn, 1978).

(i) Sources of C. Albicans in the Environment. Human feces contain C. albicans in numbers ranging up to 10^4 per g while its occurrence in raw sewage may be as high as 25,000 per l, although a few thousand per l is more common (Buck and Bubucis, 1978). In addition, large numbers of C. albicans are shed by individuals with active cases of diaper rash or vaginitis caused by the yeast. In the latter case, it is estimated that over two million cases of vulvovaginitis of C. albicans etiology occur annually in the U.S. (Ahearn, 1978). Increasing numbers of infections can be correlated with the popularity of oral contraceptives.

The organism is known to occur in domestic and farm animals, although little information is available for these hosts. Feces of beagle dogs contain 10^3 - 10^5 cells per g, and over 10^6 per g have been recorded from pigeons. C. albicans also occurs in sea gulls and marine mammals (dolphins, porpoises, etc.) although no quantitation has been recorded.

Englebrecht and coworkers (1977) found yeast densities of up to 400 per l in chlorinated sewage effluent. They showed that C. parapsilosis, C. krusei, and other yeasts had a high chlorine resistance compared with coliforms. C. albicans has also been isolated frequently from chlorinated ($\sim$ 0.3 - 0.5 mg per l) aquarium water containing marine mammals (J.D. Buck, unpublished data), and chlorine tolerance has been noted (Jones and Schmitt, 1978). The organism is capable of surviving in natural seawater, in situ, for at least six days (Buck, 1978).

(ii) Significance of C. Albicans in Water Microbiology. From the above, it is clear that C. albicans occurs in natural environments; but little is known concerning maintenance of infectivity and infective dose. Since there is no

direct evidence of candidiasis in humans as related to the
consumption of water, C. albicans probably does not repre-
sent a public health threat in drinking water, although
McCabe (1977) suggests the possible use of yeasts as indi-
cators of drinking water quality, based on their chlorine
resistance. Bonde (1977) includes "Candida, and yeasts"
among agents of waterborne diseases. Brisou (1975) has
noted increased incidence of vaginal infections in women
using polluted recreational waters. With the necessity for
recycling water in some areas, potential microbiological
problems must be considered (Lund, 1978). Environmental
stress may have a profound effect on the ability to recover
indicator bacteria (Bissonnette, et al., 1975). Some reports
are available on the occurrence of pathogens in water in
which no thermo-tolerant coliforms were detected (Bonde,
1977; Berg, et al., 1978). In fact, the concept of bio-
indicators is being reexamined (Hoadley and Dutka, 1977;
Pipes, 1978).

(iii) Enumeration of C. Albicans. The definition of
C. albicans is clear-cut, unlike that of total and thermo-
tolerant coliforms, fecal streptococci or other indicator
groups. A standard description and characterization is
provided by van Uden and Buckley (1970). In addition, a new
method for detection and enumeration of C. albicans (Buck
and Bubucis, 1978) has been incorporated into the Environ-
ment Canada Microbiology Methods Manual for the Analysis of
Waters, Wastewaters, and Sediments and will soon undergo
testing in accordance with the American Society for Testing
and Materials (ASTM) prior to eventual establishment as a
standard procedure. The method has proved useful for assess-
ing bathing water quality (Sherry, et al., 1979).

(iv) Recommendations for Future Research. The sig-
nificance of C. albicans in raw and finished water would be
better understood if some additional research were done.
More should be known of the rate at which C. albicans is
shed in feces of normal humans and animals and of the role
of sea gulls and other birds as sources of this organism in
water. Second, the effects on C. albicans from sewage
treatment (including chlorination), temperature, salinity,
pH, industrial wastes, etc., need further study. It would
also be well to determine whether sediments in drinking
water collection basins concentrate or protect C. albicans,
as occurs with coliforms. Finally, ratios between densities

of C. albicans and accepted bioindicators should be measured
for as many situations as possible.

(v) Summary. Candida albicans is a yeast derived from
the feces of humans, animals, and birds. Although this
organism has not yet been implicated in any drinking water
disease outbreaks, it has emerged as a significant opportun-
istic human pathogen with common occurrence in environmental
and wastewaters. Therefore, it would be prudent to occa-
sionally monitor for Candida albicans in raw and finished
water. A membrane filter method is now available that is
suitable for these analyses.

g. Vibrio. Vibrio species are widely distributed in
aquatic environments. Recent studies have shown that Vibrio
cholerae, Vibrio parahaemolyticus, and other pathogenic
vibrios are found in brackish water and estuarine habitats
(Colwell, et al., 1977). Cholera has long been recognized
as a waterborne disease; the infectious agent enters water,
directly from the infected host or indirectly via waste-
water, from areas in which are found clinical cases of
cholera, persons in the incubation stage, or healthy car-
riers. The first documented outbreak of cholera in the
U.S. since 1911 (Center for Disease Control, 1978c) has
brought into focus the potential for cholera outbreaks in
those geographical areas hitherto considered cholera-free
because of the assumption that good sanitation practices and
high standards for waste treatment provide protection for
the community. Two newly described groups, the lactose-
positive and Group F vibrios, have been found to be asso-
ciated with disease in man. Thus, the potential health
hazard of Vibrio species, transmitted via the water route,
has been well documented and there is now a recognized need
to consider vibrios as potentially useful indicator organisms
of water quality.

(i) Taxonomy of the Genus Vibrio. The description of the
type species, V. cholerae of the genus Vibrio, is as follows:
short, curved or straight rods, single or united into spirals,
that grow well and rapidly on the surfaces of standard culture
media, are asporogenous and gram-negative, and produce L-lysine
and L-ornithine decarboxylases, but not L-arginine dehydrolase
or hydrogen sulfide (Kligler iron agar). The overall deoxyri-
bonucleic acid (DNA) base composition is about 48 ± 1 percent

guanine plus cytosine. V. cholerae includes strains that may or may not be hemolytic, may or may not be agglutinated by Gardner and Venkatraman O group I antiserum, and may or may not be lysed by Mukerjee V. cholerae bacteriophages I, II, III, IV, and V (Buchanan and Gibbons, 1974; Sebald and Veron, 1963).

V. cholerae strains are grouped into 53 serotypes, based on possession of O antigens. However, the non O-I vibrios, termed NCV, NAG, or non O-I of Heiberg groups I and II, also have been implicated in cholera-like diseases. In addition to the difficulties in assessing potential pathogenicity of the non O-I V. cholerae, Vibrio species often are confused with species of other genera such as Aeromonas, Spirillum, Plesiomonas, and other related groups. A table of features useful in separating these genera has been published elsewhere (Colwell, and Kaper, 1977).

(ii) Enumeration Methods. In order to enumerate Vibrio species in water, enrichment must be done prior to enumeration. For this MPN procedure, a three dilution, five-tube replication series in which 1 liter and 100 ml volumes of water are filtered, is recommended. The volumes employed will vary according to the species of Vibrio (viz. V. parahaemolyticus, V. anguillarum, etc.) and the numbers in which they are present in the sample. The filters are placed in 50 ml of alkaline peptone broth after filtration is completed (Colwell and Kaper, 1977). A third dilution is obtained by inoculation of a 10-ml sample into 10 ml double-strength alkaline peptone broth containing 10 g per 1 peptone (Difco Laboratories, Detroit, Michigan), 10 g per 1 sodium chloride (NaCl), pH 8.4. After inoculation, the enrichment flasks are incubated at ambient temperature (∿ 25°C) for 6 to 8 h, followed by 18 h incubation at 35 to 37°C, yielding a combined incubation period of approximately 24 h. The cultures should be streaked onto TCBS agar (Baltimore Biological Laboratories, Div. of Bioquest, Cockeysville, MD) at 6 h and after overnight incubation. Plates should be heavily inoculated from enrichment cultures and incubated at 35°C for 18 to 24 h. V. cholerae typically appear as large, smooth, yellow colonies, slightly flattened, with opaque centers, and translucent peripheries.

For slide agglutination and other identification procedures, colonies should be picked from TCBS and transferred to gelatin neopeptone agar containing no added NaCl. The gelatin neopeptone agar plates should be incubated at 35°C for 18 to 24 h. Gelatinase positive strains that are

also oxidase positive can be tested with polyvalent O group I antiserum by slide agglutination. Non O group I strains should be tested for lysine and ornithine decarboxylase, arginine dehydrolase, and other selected characteristics (Colwell and Kaper, 1977).

Several enrichment broths for V. parahaemolyticus have been suggested. A modification of the arabinose, ethyl violet broth of Horie and coworkers, containing (in g per l): peptone (Difco Laboratories Inc., Detroit, Michigan), 5.0; beef extract (Difco), 3.0; NaCl, 30.0; bromothymol blue, 0.03; ethyl violet, 0.001; and galactose, 5.0, pH 9.0, yields good results (Kaper, et al., 1979). After incubation for 24 h at 37°C, the enrichment broth cultures are streaked onto TCBS and incubated at 37°C for 24 h. Blue-green colonies typical of V. parahaemolyticus can be picked to Brain Heart Infusion Agar for further testing. See Colwell and Kaper (1977) for recommended differentiating features.

Because of their halophilic nature, the lactose positive and Group F vibrios must be cultured on heart infusion agar, which usually contains 0.5 percent or more NaCl, or on a suitable marine agar. Enrichment may be achieved, in the case of the lactose-positive vibrios, by using a marine salts solution (Kaneko and Colwell, 1978) with lactose added as a fermentable carboyhydrate in a properly buffered medium. Enrichment methods for both the lactose positive and Group F vibrios, however, have yet to be fully documented.

(iii) Significance of Vibrio Species as Water Quality Indicators. With the geographically widespread occurrence of cholera and cholera-like disease, it is clear that Vibrio cholerae and related vibrios are of immediate, practical interest to public health authorities responsible for water quality. The diagnosis of vibrio-induced disease has increased in recent years, due, in part, to greater awareness of the potential pathogenicity of Vibrio species.

The primary indicator organism for water quality has long been E. coli, the presence of which is considered to signify fecal contamination and the presence of potentially pathogenic bacteria. In contrast to E. coli, however, V. cholerae, V. parahaemolyticus, and the lactose-positive and group F vibrios have been demonstrated to be pathogens and are associated with foodborne disease and wound, ear, and eye infections in man. It would be very useful to develop a "Vibrio Index" for raw quality assessment based on total

vibrio counts. The evidence available to date would suggest that when the total count of vibrios is elevated, the presence of the pathogenic vibrio species is more probable and the human risk factor much greater. The significance of large numbers of vibrios in the aquatic environment, both freshwater and marine, has yet to be determined, so no absolute limits can be set at this time. It is necessary to point out that a correlation between standard pollution indices and numbers of Vibrio species in water or food has not been documented. Quite to the contrary, it has been shown that no relationship exists between the counts of V. parahaemolyticus and E. coli in estuaries. Thus, periodic analyses for Vibrio in raw waters could be a useful adjunct to routine water analyses.

(iv) Conclusions. Vibrios are a potential health hazard in the environment, although their fate and role as pathogens in finished drinking water is largely unknown. In order to determine levels in the environment and to determine whether or not a possibility of this pathogen in finished drinking water exists, the periodic analysis for total vibrios is considered useful.

(v) Summary. Vibrios are geographically widespread pathogens not necessarily associated with fecal pollution. Recent outbreaks of cholera and other Vibrio-associated illness have indicated that these pathogens have significant health implications. Methods for their enumeration are available for freshwater and estuarine species. The presence of large numbers of vibrios in a water sample suggests that pathogenic species of Vibrio may also be present. Inasmuch as established microbial indicator systems are poorly correlated with the incidence of pathogenic vibrios, a Vibrio-specific test affords the only potentially valid basis for predicting the presence of these pathogens [See also Section B.1.a(vii)].

h. Aeromonas. The genus Aeromonas includes straight, gram-negative, facultatively anaerobic rods that closely resemble members of the Enterobacteriaceae, but instead, are included in the family Vibrionaceae (Buchanan and Gibbons, 1974). Unlike the enterics, Aeromonas is motile by means of a polar flagellum; and, more important diagnostically, it is cytochrome oxidase positive. For these reasons, it resembles Pseudomonas; however, the metabolism of Aeromonas is

fermentative as well as respiratory. Like Pseudomonas, it is also capable of utilizing high molecular weight substrates such as proteins (e.g., casein and gelatin), deoxyribonucleic acids, starch, dextrin, and glycerol (Buchanan and Gibbons, 1974; Lennette, et al., 1974). Aeromonas occurs in uncontaminated waters as well as in sewage and sewage-contaminated waters. The organism may be pathogenic for humans, other warm-blooded animals, and cold-blooded animals including fish (Buchanan and Gibbons, 1974; Lennette, et al., 1974). Because of its consistent occurrence in appreciable, but variable, numbers in raw and treated sewage and sewage contaminated waters, the use of Aeromonas as a potential indicator of raw water quality has been considered (Cabelli, 1977).

Among the three species belonging to the genus Aeromonas, only A. hydrophila and A. punctata, as well as their subspecies, are of sanitary importance. Only these two species occur as free-living organisms in water, whereas A. salmonicida and its subspecies are fish pathogens that do not occur in surface waters, unless associated with infected fish. Several subspecies of A. hydrophila and A. punctata may be pathogenic not only for fish, amphibians (e.g., frogs), and reptiles (e.g., snakes, turtles, and alligators), but also for warm-blooded animals including humans, mice, and guinea pigs, when the organisms are ingested or enter the body through a wound; however, only A. hydrophila, subspecies hydrophila, is of concern to human health (Buchanan and Gibbons, 1974; Lennette, et al., 1974; Schubert, 1967a). This organism has been isolated from a wide variety of specimens of human origin, including blood, wounds, ulcers, pus, throat swabs, urine, bile, and feces of persons with diarrheal disease, as well as from normal stools (Lennette, et al., 1974); however, the organism is isolated from feces of normal individuals only infrequently, and then only in low numbers (Cabelli, 1977). Cases of dysentery caused by A. hydrophila have been documented (Annapurna and Sanyal, 1977) [See Section B.1.a]. Dysentery caused by Aeromonas-like organisms may also be due to Plesiomonas shigelloides (formerly Aeromonas shigelloides). The genus Plesiomonas, and its single species, P. shigelloides was created for those organisms resembling Aeromonas, but lacking some essential features of the genus. This includes the possession of a restricted carbohydrate metabolism and the absence of the enzymes diastase, DNase, lipases, and proteinases. Also P. shigelloides has multiple polar flagella grouped into a tuft, rather than possessing a single flagellum (Buchanan and Gibbons, 1974; Lennette et al., 1974). P. shigelloides has been isolated from the

feces of humans and other mammals, and was responsible for
causing two known outbreaks of acute infectious gastro-
enteritis. It has also been found in association with
Shigella in persons with dysentery; in fact, some strains of
P. shigelliodes possess an O-antigen identical to Shigella
sonnei (Buchanan and Gibbons, 1974; Lennette, et al., 1974).

(i) Enumeration Methods. Membrane filtration using
DSF medium (Schubert, 1976) is capable of detecting A.
hydrophila and A. punctata in drinking water. The multiple
tube method employing Rimler-Schotts medium has been exten-
sively used to enumerate A. hydrophila in natural waters
(Schotts and Rimler, 1973).

Aeromonas is not fastidious in its growth requirements,
and abundant growth occurs on nutrient agar and blood agar.
Aeromonas grows on the differential-selective media used for
coliform plating, such as eosin-methylene blue (EMB) agar,
MacConkey agar, and Salmonella-Shigella (SS) agar, mimicking
coliform colonies, and occasionally on brilliant green agar
producing colonies resembling Salmonella (Hendricks, 1978;
Lennette, et al., 1974; Mack, 1977). The oxidase test is a
rapid and easy means to distinguish the Aeromonas colonies
from the coliform or Salmonella colonies, and its use is
thus of cardinal importance in total coliform detection
procedures (Mack, 1977).

(ii) Evaluation as an Indicator. Because A. hydro-
phila and A. punctata are capable of degrading high molecular
weight organic wastes such as starches, lipids, and proteins,
their enrichment occurs in waters that have received waste-
water additions. Massive multiplication of Aeromonas has
been noted to occur even in pipes draining household wastes
(Schubert, 1967b).

In raw sewage, it is not uncommon for Aeromonas concen-
trations to reach 10^6 colony-forming units per ml. During
primary treatment their numbers are not reduced, but a
significant decline in their numbers occurs during secondary
treatment, the degree depending on the biological treatment
method employed (Schubert, 1967c). Reductions in the numbers
of Aeromonas could possibly be used to indicate the extent
of pathogen removal during treatment of wastewaters and in
the final effluent. It has been shown that the elimination
of Aeromonas correlates well with the elimination of Sal-
monella and other pathogens (Schubert and Schäfer, 1971).

From these and other results, it appears that the enumeration of Aeromonas from treated sewage effluents may be used as an index to determine whether pathogens remain in the wastewater. Its detection from surface waters or ground-waters indicates sewage contamination of that water.

Once introduced into water, Aeromonas may grow on the organic pollutants contained in the wastewater. Growth of Aeromonas has been reported to occur on filters at potable water treatment works as well as in other locations containing sufficient organic material (Hendricks, 1978) [See Sections E.3 and 4]. The detection of high numbers of Aeromonas has been reported to be a reliable indicator of the degree of contamination of a water source with organic wastes (Schubert and Schafer, 1971).

The proportions of aerogenic to anaerogenic subspecies of A. hydrophila may also be used to evaluate the degree of wastewater contamination. Table C.2.h-1 describes the sub-species of the two important Aeromonas species from the standpoints of their aerogenicity and their distributions in raw waters (Buchanan and Gibbons, 1974).

In wastewaters, or in waters containing wastewaters and solid wastes, the Aeromonas population consists almost entirely of the anaerogenic varieties, with very few aerogenic organisms isolated. The reverse is true of good quality surface waters in which Aeromonas densities are low, but of those organisms isolated, 95 to 98 percent are aerogenic (Schubert, 1975b). In groundwaters, aerogenic Aeromonas varieties are found at the surface, whereas the anaerogenic varieties occur in deep or undisturbed areas (Schubert, 1976).

Studies of the water from river bank infiltration wells demonstrates that the proportion of aerogenic aeromonads increases with increasing distance from the point of application, so that as purification of the river water occurs by passage through the soil, the population of Aeromonas shifts from predominately anaerogenic to predominately aerogenic (Schubert, 1976). Thus, the isolation of anaerogenic aeromonads from raw water indicates contamination with inadequately treated wastes.

Aeromonas resembles coliforms in all respects except that it possesses polar flagella and is cytochrome oxidase positive (Buchanan and Gibbons, 1974; Hendricks, 1978; Lennette, et al., 1974). During total coliform isolation,

TABLE C.e.h-1

DISTRIBUTION OF AEROGENIC VERSUS ANAEROGENIC AEROMONAS IN WATER

	A. Hydrophila Subspecies			A. Punctata Subspecies	
	Hydrophila	Anaerogenes	Proteolytica	Punctata	Caviae
Gas produced from:					
glucose	+	-	-	+	-
glycerol	+	-	-	-	-
Isolated from:					
uncontaminated water	+	-	ND^a	+	-
contaminated water	-	+	ND	-	+

^{a}No data available.

229

the lactose-positive, aerogenic strains of Aeromonas are also recovered, since the multiple tube test detects gas production. Therefore, the presence of Aeromonas elevates the apparent total coliform concentration (Leclerc, et al., 1977b; Mack, 1977). In the FRG, coliform analysis of drinking waters revealed that 30 percent of the samples having positive presumptive tests also contained Aeromonas (Leclerc, et al., 1977b). Thus, it is essential to distinguish these organisms from coliforms. Unfortunately, Aeromonas differentiation from coliforms is neglected in the current standard procedures for total coliform testing used in the U.S. (Leclerc, et al., 1977b).

(iii) Conclusions. Aeromonas is a saprophytic organism that occurs in both marine and fresh waters. Its presence in raw waters does not signal any significant health hazard; however, these organisms are opportunistic pathogens especially if ingested in large quantities (e.g., after enrichment in foods, although as yet few food-related diseases due to Aeromonas or the closely related Plesiomonas have been reported). High numbers of Aeromonas also are undesirable in bathing waters, for they may act as opportunistic pathogens if they gain entry into the body via a wound.

Because Aeromonas is a potential pathogen, it must be considered undesirable in drinking waters. Aeromonas is generally sensitive to disinfection treatments, so its presence in finished waters indicates inadequate disinfection or subsequent contamination [See Section F.2.a]. As an indicator of finished water quality, Aeromonas detection has no advantages over the detection of total coliforms.

Aeromonas survives in environmental waters considerably longer than E. coli or most coliforms. However, because it is capable of aftergrowth, as is true of some members of the total coliform group, but not of E. coli, Aeromonas detection may falsely signify contamination with sewage. Small numbers of aerogenic Aeromonas are common in groundwater, at the surface, and in contaminated surface waters, so they do not connote any hazard to public health; whereas anaerogenic Aeromonas varieties are predominant in wastewater and their detection indicates contamination of the water with sewage. Because the current Aeromonas enumeration methods do not distinguish aerogenic from anaerogenic varieties, detection of Aeromonas could lead to false condemnation of a raw water.

The aerogenic varieties, although present in smaller quantities than the anaerogenic types, are already being

detected along with total coliforms in the MPN total coli-
form procedure, and all types are probably isolated when
using the membrane filtration procedure. Thus, it seems
that the easiest way of determining the presence of Aero-
monas would be to do an oxidase test following total coli-
form isolation. The most important feature of Aeromonas is
that its presence may yield inaccurately elevated estimates
of coliform densities, so any total coliform detection
procedure should also include the oxidase test to determine
their presence. Because of its natural occurrence in the
environment, potential for aftergrowth in nutrient-enriched
water, and confusion with total coliforms, Aeromonas would
not be a very specific indicator of sewage discharge or
pathogen occurrence; where raw water quality is concerned,
Aeromonas should be considered as a general indicator in
relation to nutrient discharge.

(iv) Summary. Some members of the genus Aeromonas,
particularly A. hydrophila and A. punctata are potential
pathogens that are widely distributed in the environment.
They thrive in heavily contaminated waters, particularly
those derived from kitchen wastes. The anaerogenic varieties
are common to contaminated waters, therefore, their presence
may be considered an indicator of the degree of organic
contamination of raw waters. However, because Aeromonas is
capable of aftergrowth in environmental waters, its detec-
tion may exaggerate or falsely signal a public health hazard.
Because Aeromonas is very sensitive to disinfection, its
presence in drinking water is an indication of inadequate
treatment or a breakdown in the distribution system. Due to
its similarity with the total coliforms, Aeromonas, if
present, will be detected along with them and may even
constitute a significant proportion of the detected total
coliforms. The extent to which this occurs may be deter-
mined with the aid of the oxidase test.

If for some reason, drinking water is to be used without
disinfection, aerogenic Aeromonas may cause false positive
results in both the multiple tube and membrane filter total
coliform tests with water that is not unsafe. Anaerogenic
Aeromonas seen in the membrane filter coliform test with
such samples would, in fact, signal a hazard. No Aeromonas
should be present in finished drinking water that has been
disinfected, so both false (due to Aeromonas) and true
positive results in the total coliform test are significant
with such samples. In a sense, the presence of Aeromonas
augments the sensitivity of the total coliform test for
finished drinking water.

3. Other Indicators of Microbial Quality

Three relatively new biochemical methods have been employed to determine water quality. They do not measure microbial numbers directly, as do the indicator systems presented in the previous two sections. Instead, microbial numbers are determined indirectly in the case of Limulus lysate and adenosine triphosphate; these tests for fecal sterols serve as a chemical index of fecal pollution. Although these methods certainly must be measured against the more traditional microbiological indicator systems, their validity as indicators ultimately must be decided on the basis of their own merits.

a. Limulus Amebocyte Lysate. Limulus amebocyte lysate (LAL) is an aqueous extract of blood cells (amebocytes) from the horseshoe crab, Limulus polyphemus (Levin and Bang, 1969). LAL forms a clot or becomes turbid when incubated with lipopolysaccharides (LPS), also known as endotoxins, which are components of the cell wall of all gram-negative bacteria.

An elevated LPS or bacterial biomass concentration in a water sample does not, by itself, constitute a health hazard to a normal, healthy human. However, an elevated LPS or bacterial biomass level indicates contamination of a water source by gram-negative bacteria and in certain areas, for example, near sewage outfalls, may indicate the presence of potentially pathogenic bacteria (Evans, et al., 1978) [See also Sections A.1.f and B.1.a(ix)]. LAL currently is used to detect and quantitate endotoxins in a variety of solutions by a technique commonly referred to as the LAL or LPS test (Watson, et al., 1977).

The LPS test has been modified for use in determining bacterial biomass in aquatic environments (Watson, et al., 1977). The concentration of LPS in a sample is measured before and after centrifugation at $10,000 \times g$. The level of LPS that is free (in the supernatant after centrifugation) is subtracted from the total LPS (in the sample before centrifugation) to determine how much LPS was bound to cells. Finally, the bacterial biomass is obtained by multiplying the concentration of bound LPS by a factor of 6.35 (Watson, et al., 1977) to obtain the grams of bacterial cellular carbon in a given volume of water.

(i) Methods of Reading the LPS Test. The LPS test can be read either by a clot or a spectrophotometric method.

With the clot method, 0.1 ml of the sample is added to 0.1 ml of the LAL and incubated for 1 h at 37°C. If a firm clot is formed after incubation, the test is considered positive. This can be applied as a quantitative test by reacting an LPS standard, prepared in twofold serial dilutions, with LAL. The endpoint of the test is the lowest LPS concentration that will trigger clot formation of LAL. Appropriate twofold dilutions of the water sample also are made and reacted with LAL. The highest dilution in which clotting occurs is multiplied by the sensitivity of the LAL to obtain the LPS equivalents in the test water, expressed as ng per ml.

The clot method is easy to perform and requires minimum operator skill. However, it does not allow for exact quantitation of LPS in a water sample; instead, this can be done using a spectrophotometer by the method of Watson and coworkers (1977). In this method, 0.2 ml of LAL is added to a 1.0-ml portion of the sample. For freshwater samples, dilutions should be made with pyrogen-free distilled water, whereas seawater dilutions are made with a 3 percent pyrogen-free sodium chloride solution. After incubation for 1 h at 37°C, the samples are gently mixed by rotary agitation and the absorbance of each read in a spectrophotometer at 360 nm.

A standard curve is generated by incubating LAL with known concentrations of LPS in a dilution series that can range from 0.1 to 100 pg per ml. The limits of the range vary according to the sensitivity and range of linearity of the particular LAL preparation used. The concentration of LPS can then be determined by making serial dilutions of the sample and reacting these with LAL. LPS concentrations in samples are determined by comparing their absorbance readings with those found in the linear region of the standard curve.

(ii) Evaluation of the LPS Test as an Indicator of Water Quality. Some studies have demonstrated the presence of LPS in raw and finished water. DiLuzio and Friedman (1973) detected LPS in 16 of 18 finished water samples using an insensitive assay with a detection limit of 10 ug per ml (the two negative drinking water samples came from artesian wells). When the positive samples were measured for endotoxin content by taking serial dilutions, they were found to contain LPS levels of between 1 and 10 ug per ml. Raw surface water, used as a drinking water source, was tested

in the same study and found to have LPS levels of 20 to 400 ug per ml. In other studies (S. Watson, unpublished results), LPS levels of between 1 and 10 ng per ml were found in finished water of Woods Hole (Massachusetts, U.S.).

A number of samples of drinking water and renovated wastewater from advanced wastewater treatment plants was analyzed by Jorgensen and coworkers (1976). Drinking water, sampled from ten cities in the U.S., had LPS concentrations ranging from < 0.625 to 500 ng per ml. When the processes employed by the water treatment plants were examined, no association was found between use of activated charcoal and high endotoxin levels. But, high LPS levels were found in the effluents of five out of eight advanced wastewater treatment plants surveyed, and positive results did corre-spond with those plants that treated with activated carbon [See Section E.5]. One of the other three wastewater treat-ment plants, in which only low endotoxin levels were re-vealed, also used activated carbon, but followed it with breakpoint chlorination [See also Sections E.2 and F.2.a]. One plant, which employed a reverse osmosis unit as the final treatment step, produced water containing no detect-able LPS. As more and more water is being reclaimed due to limited water resources in the world, application of ad-vanced wastewater treatment for producing potable water will increase.

Evans and coworkers (1978) used a spectrophotometric assay with tapwater and found the sample to contain 1.19 ng per ml of LPS, of which 1.10 ng per ml was free LPS and 0.09 ng per ml was bound or cell-associated LPS. They also used this assay with several environmental samples to determine the correlation between endotoxin levels and bacteriological parameters. The correlation coefficients between bound LPS and the other parameters were: coliform (0.907), enteric bacteria (0.946), gram-negative bacteria (0.934) and hetero-trophic bacteria (0.952) [See also Sections C.1.a to c and D]. Whether all environmental water exhibits this high correlation, and whether the same holds true for drinking water, has not been established.

(iii) Potential Applications of the LPS Method. The LPS method could be applied in long-term routine monitoring and also as an emergency method to determine whether there has been an increase or decrease in gram-negative bacteria in raw or finished water. Another application for which this test may be particularly well suited pertains to the

increased use of granular and powdered activated carbon in the treatment of drinking water to remove organic compounds. Since bacteria are likely to grow on the adsorbed organic material, the LPS assay could prove useful for monitoring bacterial growth [See Project Area II.b]. Likewise, this assay could serve as a fast and simple method for determining, periodically, the LPS or bacterial levels in home point-of-use water treatment devices, such as activated carbon and reverse osmosis units [See Section G.2]. Even though these devices are known to eventually foster bacterial growth if not properly maintained (Wallis, et al., 1974), their use in the home has increased. Commercially available LAL kits could easily be adapted to serve as convenient household monitors.

The endotoxin assay will not replace coliform and colony counts or other methods routinely used to survey bacterial populations in municipal water supplies [See Sections C.1.a to c]. However, it could serve as a fast and convenient additional technique for measuring parameters related to public health [See also Section C.4.g]. The values could be used to indicate long-term trends, reveal differences from city to city, or rapidly determine sources of contamination in emergency situations, even in the field, if necessary.

(iv) Summary. The LAL or LPS assay for LPS quantitation is fast, accurate, and inexpensive. LPS, a component of the cell wall of all gram-negative bacteria, is of potential harm to humans and other animals only after entering the bloodstream. However, the LPS concentration in a volume of water is directly related to the level of gram-negative bacteria contained in that water. Thus, the LPS test has considerable potential for use in monitoring raw and finished water for the presence of gram-negative bacteria or endotoxin, including assessing bacterial contamination due to growth on activated carbon filters. It also could be of great assistance in evaluating the efficacy of advanced wastewater treatment employed as a means of producing potable water.

b. Adenosine Triphosphate. There have been many attempts to quantify cellular components in an effort to estimate cell numbers and, in this manner, to develop a nonspecific, quantitative indicator of biota in drinking water. Most of these attempts have been less than successful because of the difficult problem of distinguishing among

compounds present in viable, active cells and those present in dead cells or detrital material. Adenosine-5'-triphosphate (ATP) is a compound which, to a large extent, circumvents this problem. ATP shows good potential as a non-specific indicator of viable organisms in drinking water because it is: (1) present in all living cells; (2) rapidly hydrolized by cellular enzymes upon cell rupture or death; and (3) relatively constant in proportion to the biomass of many studied organisms.

A figure of 0.4 percent of total carbon is usually applied when determining the ATP content of a cell; hence, the total carbon is estimated as 250 times the ATP mass. Although this represents a moderate concentration within the organism, direct chemical analysis of ATP is not usually possible because the numbers of organisms most often encountered in drinking water are low.

The most commonly used method to determine ATP levels is the firefly luciferin-luciferase assay. ATP is extracted from the cells and reacted with firefly lantern luciferin and luciferase, in the presence of magnesium ions and at the proper pH (which depends on the extractant used). This reaction results in the production of light and may be shown as follows:

$$E + LH_2 + ATP \xrightarrow{Mg^{2+}} E \cdot LH_2 \cdot AMP + PP$$

$$E \cdot LH_2 \cdot AMP + O_2 \longrightarrow E + AMP + CO_2 + h\nu + T$$
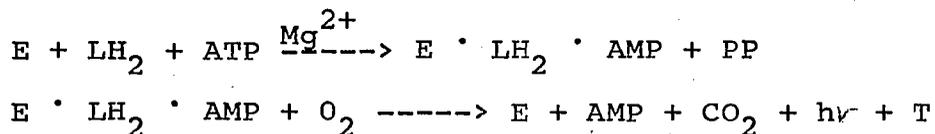

where E is the enzyme luciferase, LH_2 is reduced luciferin, AMP is adenosine-5'-monophosphate, PP is pyrophosphate, $h\nu$ is light, T is thiazolinone (which is decarboxylated reduced luciferin). The light emitted when ATP is injected into the enzyme reaction mixture rises in intensity quickly and then decays exponentially. Both the maximum intensity, measured as peak intensity, and the total light output are proportional to the amount of ATP added, as long as it falls within a range of 1×10^{-9} to 2×10^{-2} g per l.

(i) Methods for extracting and quantifying ATP. When testing environmental samples, extracting ATP from microorganisms and stabilizing it can become more difficult. Not only can the growth rate and physiological state of cells from various sources affect the content per cell of ATP, but also the extraction process itself may alter final ATP readings.

The extractant must be capable of immediately inactivating intracellular and extracellular ATPases and phosphatases, which can otherwise decrease the ATP concentration within a few seconds (Tobin, et al., 1978). It must also be capable of efficiently extracting the ATP from the large variety of cells which may be encountered. Both organic materials (such as humic substances) and inorganic cations often associated with drinking water (such as Ca^{++}, Mg^{++}, Al^{+++}, Fe^{++} and Mn^{++}) may interfere to varying degrees, depending on the method of extraction used. A judicious choice of extractants will usually prevent such interference (Tobin, et al., 1978).

Extractants include tris-(hydroxy methyl)-aminomethane (Tris) buffer, sulfuric acid, nitric acid, dimethyl sulfoxide, glycine buffer, phosphate buffer, and many others. Of the most commonly used extractants, boiling alkaline (pH 10) glycine buffer, containing magnesium-ethylene-diamine-tetraacetate, offered the most efficient combination of extracting ATP (in the presence of organic and inorganic constituents) and stabilizing it (Tobin, et al., 1978). When automated systems were employed to concentrate the sample and extract ATP, the use of nitric acid afforded adequate stabilization (Picciolo, 1977; 1978). The most common extractant currently in use for environmental samples is boiling Tris buffer (American Public Health Assoc., 1976). It is the basis of one of the original extraction techniques (Holm-Hansen and Booth, 1966), and one on which much of the ATP data is based.

The enzyme reaction and apparatus for detecting and measuring luminescence have been fairly well established. Several types of photometric equipment are commercially available which quantify ATP by integrating the light output over a period of less than 1 min, or by determining the peak light output during the first few seconds of the reaction, or both. Other equipment, such as liquid scintillation counters, fluorometers, and reaction-rate analyzers may also be used to quantify the light output.

Perhaps the greatest problem with using the bioluminescent method for determining ATP levels in drinking water is the need to concentrate the sample sufficiently. The linear range of ATP detection for a typical photometer is down to about 10^{-12} g ATP under ideal sample conditions. The average bacterium has been variously estimated to contain 3×10^{-16} g ATP (Picciolo, et al., 1977a), or from 2 to 40 x 10^{-16} g ATP, depending upon growth phase (Hamilton and Holm-Hansen, 1967). If the value of 3×10^{-16} g ATP per cell is

used, it can be calculated that a minimum of 3×10^3 cells would be required to evoke a quantitative response under ideal conditions. If the maximum acceptable level is 500 cells per ml of finished water, then it is necessary to make estimates based on this critical quantity, and therefore concentration of the sample usually is required.

A recent report (Picciolo, et al., 1978) compared several methods of concentration which included centrifugation; in-line membrane filtration; radial- and tangential-flow, flat-surface membrane concentration; and hollow fiber membrane filtration. Only the hollow fiber membrane filtration procedure (modified for backwashing) provided adequate concentration and recoveries. A commercially available unit, with a filter area of 10^4 cm, was capable of concentrating the sample 600-fold with up to 88 percent recovery after backwashing steps had been performed. This unit offers good potential for determining levels of bacteria which one may find in tapwater. Unfortunately, the method has yet to be tested extensively on actual tapwater.

(ii) Evaluation of ATP as an Indicator. Few studies have as yet been performed on finished water, and more often pertinent data obtained from raw water studies are used for drinking water analyses. One study has been reported briefly (Rexing, 1977) in which the luciferase ATP method was used to replace the tedious microscopic counting of algae, and to verify chlorination efficiency on drinking water. Raw water was filtered through a 3.0 um membrane filter which was then submerged in boiling Tris buffer. ATP levels were usually about 10^{-7} g per l and increased to about 10^{-6} g per l during a Cyclotella bloom. It was demonstrated that most of the algae which passed through the treatment system were killed and were, therefore, not positive for ATP; in this instance, then, the method was not suitable for monitoring total algal counts in finished water. A free chlorine residual of 1.6 mg per l caused at least a 99 percent decrease in the biomass, as measured by the luciferase ATP method. Surface water of Lake Ontario was shown, in a limited study (Afghan, et al., 1977), to harbor an average of 5×10^{-5} g ATP per l.

Although no extensive studies have been made of the ATP content of drinking water, some comparisons between bacterial estimates calculated from a model plate count system, and those from an ATP system, have been made (Picciolo, et al., 1977a). In this study, E. coli cultures were diluted in

0.9 percent NaCl or dechlorinated tapwater. The results were linear from 10^5 to 10^9 bacteria per ml by both methods, and the ratio between plate counts and counts estimated by ATP content did not differ from 1 at the 5 percent confidence level. However, when treated effluents from a pilot sewage treatment plant were analyzed, the luciferase-measured ATP indicated bacterial levels of 1.8 times the number obtained by viable plate counts. This was likely attributable to residual ATP in viable cells which were debilitated to the point of being unable to undergo cell division under the culture conditions used.

A limited study on the ATP content of a municipal tapwater in Canada (J. Cairns, unpublished data) showed 11 x 10^{-9} g per l (range of five values was 5.3 x 10^{-9} to 16 x 10^{-9} g per l) and after passing through a 0.6 um polycarbonate (Nuclepore) filter, the ATP content was reduced to 3.7 x 10^{-9} per l (range was 2.5 x 10^{-9} to 6.3 x 10^{-9} g per l). While this would indicate the potential of about 10^4 bacteria per ml, it has been shown that chlorine-stressed coliforms, thermo-tolerant coliforms, and total heterotrophic bacteria are much more reduced in ability to grow on their respective media than the decrease in ATP would indicate (Cairns, et al., 1979). Thus, it is improbable that this number of bacteria would be found by standard colony counts.

These results point out a problem which has yet to be resolved: that is, the effect of stress on the ATP content of organisms and on their ability to divide. It appears that in some stress situations, organisms lose their ability to divide, and the ATP decreases to a minimum level which may be a maintenance or survival value (Dawe and Penrose, 1978). A systematic study should be made of the effects of chlorine on the total microbial population in water, so that the interpretation of data will more closely reflect actual conditions.

(iii) Potential Applications of the ATP Method. The luciferin-luciferase assay has been shown to be a reliable nonspecific method for the analysis of the viable bacteria in water. Because of its potential to enumerate microorganisms in water, it may become useful in supplementing total plate counts in water, especially when applied as an on-line system to signal any changes in water quality at a water treatment plant. It may also be employed during emergencies when the rapid analysis of samples is required,

for example, in the event of disruption of a water main or gross bacteriologic contamination of samples.

Presently, the major problem with the ATP assay is the requirement for concentration in order to quantify the bacteria in water. Progress in this area has been made with the use of hollow fiber filters, which should enable the technique to be used routinely in the near future. A system of semi-automatic filtration and analysis, both in one apparatus (Picciolo, et al., 1977b), would seem to lead the way to rapid and accurate determinations. Some studies have been initiated on the use of immobilized enzymes in the performance of the ATP assay (Lee, et al., 1977). The use of immobilized enzymes may increase the potential for automation and economy of reagents.

The combination of flow concentration and immobilized enzyme reactors in close proximity to phototubes could significantly increase the number of samples processed and lower the cost per assay. It may be possible to have an automated sampling system which monitors raw water input and finished water output, and which alerts the waterworks operator to any unusual changes in values for either of the two. Long-range trends in the quality of water should be monitored closely by the use of retrospective data analyses, and any trends noted in the deterioration of water quality should evoke appropriate corrective steps.

(iv) Summary. ATP is a compound present in all living cells and is degraded rapidly upon cell death. The luciferin-luciferase assay for ATP can be used for analyzing the approximate numbers of microorganisms in water. The reaction is valid between about 10^3 to 10^9 bacterial cells and generally requires large concentration factors for the low densities of bacteria encountered in drinking water. Concentration can be achieved by means of hollow fiber filters to about 600 times with up to 88 percent recoveries. The principal applications of the ATP analysis are in monitoring algal content and removal in raw water, and in determining total bacterial numbers and disinfection efficiencies in finished water. Other potential uses are analyzing samples during main breaks and monitoring long-term changes in treatment and in the distribution system.

c. Fecal Sterols. Coprostanol or coprosterol (5β-cholestan-3β-ol) is the major fecal sterol of man, comprising

40 - 60 percent of the total neutral sterols excreted.
Studies to date, identifying it in sewage and surface waters,
have lent support to proposals that it be considered for use
as a fecal marker of water pollution -- especially pollution
of the type associated with industrial or wastewater treated
discharges (Murtaugh and Bunch, 1967; Smith, et al., 1968;
Smith and Gouron, 1969; Kirchmer, 1971; Tabak, et al.,
1972; Dutka, et al., 1974; and Wun, et al., 1976). If
coprostanol were confirmed to originate only in the feces of
man and higher animals, as is generally believed the case,
then it would be a highly specific chemical indicator. And,
being a chemical indicator, coprostanol analysis would have
the advantage over bacterial indicators of requiring less
preparation and processing time. Furthermore, various
purification processes applied to drinking water or simple
passage through soil in the case of groundwater, can remove
fecal organisms without removing some of the associated
fecal material. Testing for coprostanol could be useful in
this regard, especially in connection with drinking water
analyses. However, more definitive information is needed
before coprostanol analysis of water quality could be per-
formed routinely.

(i) Cholesterol Reduction to Coprostanol. The reduction
of cholesterol to coprostanol and the various factors affecting
such a transformation in biological systems have been studied
by many workers. Earlier investigations have been documented
in several reports (Gould and Cook, 1958; Hoffman, 1970;
Kirchmer, 1971). It has been shown that the hydrogenation
of cholesterol to coprostanol is mediated by microorganisms
in the large intestine of man and higher animals. Apparently,
this is the only source of the 5β-stanol. Recently, an
anaerobic gram-positive eubacterium, having an absolute
requirement for Δ^5-3β-hydroxy steroids, was isolated from
human feces and from rat intestinal contents (Eyssen, et
al., 1973; and Sadzikowski, et al., 1977). This diplobacillus
reduced the 5, 6-double bond of cholesterol, campesterol, β-
sitosterol, and stigmasterol, yielding the corresponding 5β-
saturated derivatives. When cholestanone (4-cholesten-3-
one) and coprostanone were incubated with this organism, the
carbonyl and the 3-oxo groups of these molecules were reduced
to a 3β-hydroxyl group (Eyssen, et al., 1973). Using dual
labeled cholesterol as a tracer, Parmentier and Eyssen
(1974) concluded that the major pathway for the conversion
of cholesterol to coprostanol in the animal intestine involved
the intermediate formation of 4-cholesten-3-one followed by
a reduction.

(ii) Coprostanol Removal During Sewage Treatment. A wastewater plant which employs an activated sludge process will produce an effluent low in or free of coprostanol (Murtaugh and Bunch, 1967; Smith, et al., 1968; and Smith and Gouron, 1969). This removal was believed to be mainly physical (Smith, et al., 1968). However, by comparing coprostanol degradation rates in chlorinated versus un-chlorinated sewage effluent, Kirchmer (1971) concluded that coprostanol removal by the activated sludge process was due principally to biodegradation. C. K. Wun and coworkers (unpublished data) detected unusually high levels of copro-stanol in the activated sludge. They found coprostanol breakdown to occur at a much slower rate when sewage was combined with sterilized (membrane-filtered) fresh water and seawater than when combined with unsterilized (unfiltered) water. It is likely that both physical and biological processes are at work removing coprostanol during activated sludge treatment.

(iii) Environmental Effects on Coprostanyl Degra-dation. The rate of coprostanyl ester degradation is essen-tially the same as that of free coprostanol. Coprostanyl esters are present in large amounts in feces (approximately 30 percent of the total coprostanol), and the ratio of the steryl esters to the total sterols was found to be 10 - 15 percent in sewage samples (Kirchmer, 1971). Using radio-isotope labeled coprostanyl palmitate, Wun, Walker, and Litsky (unpublished data) found that the ester bond was rapidly hydrolyzed resulting in 80 percent degradation during one to three days of any environmental exposure. This rapid hydrolysis may occur under aerobic conditions in the sewer system prior to the treatment plant, and may account for the low ratio of steryl esters to sterols found in raw sewage samples.

(iv) Agreement between Coprostanol and Other Accepted Criteria. In an attempt to establish fecal sterol criteria and standards, efforts have been made to correlate cop-rostanol concentrations with other accepted water quality standards. Tabak and coworkers (1972) reported that copro-stanol concentrations in non-chlorinated polluted water correlated well with fecal coliform densities in the same locations. Other investigators obtained contrasting results (Kirchmer, 1971; Dutka, et al., 1974; Dutka and El-Shaarawi, 1975; and Wun, et al., 1976). Kirchmer (1971) postulated that fluctuations in bacterial populations (from chlori-nation and from additional coliforms released in waterfowl feces) might explain why no clear relation could be shown

between coprostanol and bacterial densities. Singley and coworkers (1974) reported a linear relationship with a coefficient of determination (r^2) of 0.977 between coprostanol and total organic carbon (TOC) in sewage samples. Results of correlating the coprostanol concentration with biochemical oxygen demand (BOD) and chemical oxygen demand (COD) were less satisfactory.

(v) Significance of Coprostanol in Water. The unique characteristics of coprostanol recommend its use as a chemical index for water quality determination. It appears that the only source of this chemical is the feces of man and higher animals. It is biodegradable and can be removed from sewage by adequate treatment. Studies have also shown that coprostanol concentrations correlate closely with the extent of fecal pollution (Murtaugh and Bunch, 1967; Smith and Gouron, 1969; Kirchmer, 1971; Tabak, et al., 1972; and Wun, et al., 1976). Coprostanol, as opposed to coliforms, remained unaffected by wastewater chlorination, heat, and toxic industrial discharges; hence, coprostanol quantitation was seen to overcome many flaws inherent to coliform analyses (Kirchmer, 1971; and Tabak, et al., 1972). The relative stability of coprostanol is especially significant in view of current trends of rapid industrial development and the increasing emphasis on disinfection of raw and treated wastewater.

Because of its tolerance of environmental rigors, coprostanol might also be used for monitoring the source, course, and extent of fecal pollution in the ocean or brackish waters where bacteriological evidence is often doubtful. It also offers promise as a method for analyzing the distribution and mixing dynamics which occur when, for example, sewage effluent enters river water, or when sewage polluted surface water infiltrates into groundwater. Examinations of water that reveal the presence of fecal sterols, but no fecal bacteria, still indicate fecal pollution. Conversely, when indicator bacteria are present, but fecal sterols are not detected, this may indicate bacterial regrowth or infiltration, rather than fecal pollution, although degradation of the sterols must also be considered.

(vi) Coprostanol Analysis. The routine procedure for estimating coprostanol levels in water consists of hexane extraction, clean-up by thin layer chromatography (TLC), and

subsequent analysis by gas-liquid chromatography (GLC) (Murtaugh and Bunch, 1967; Smith, et al., 1968; Smith and Gouron, 1969; Kirchmer, 1971; Tabak, et al., 1972). The TLC clean-up procedure has been considered necessary for all surface water samples regardless of concentration (Murtaugh and Bunch, 1967; and Tabak, et al., 1972). However, processing samples through an alumina micro-column affords a more efficient clean-up procedure (Dutka, et al., 1974). The TLC clean-up can also be omitted if a sample containing > 1 ug of coprostanol per l is washed instead with acetonitrile saturated with hexane (Kirchmer, 1971).

In earlier studies of coprostanol quantitation, analysis included mild alkaline hydrolysis and/or preparation of trimethylsilyl ether derivatives (Murtaugh and Bunch, 1967; Tabak, et al., 1972). Results reported by Kirchmer (1971) suggest that omission of these time-consuming processes does not significantly affect coprostanol identification and quantitation. Later findings led to elimination of the saponification step, resulting in analysis of only the free sterol (Dutka, et al., 1974; Wun, et al., 1976; 1978).

Although the hexane liquid/liquid partitioning procedure was satisfactory for coprostanol extraction, it required an excess of reagents and was often further complicated by emulsion problems (Murtaugh and Bunch, 1967). In addition, much of the coprostanol present in heavily polluted areas is bound to particulate matter (Kirchmer, 1971; Wun, et al., 1978). Switzer-House and Dutka (1977; 1978) have shown that, in most samples, > 70 percent of the fecal sterols are associated with the pellet after centrifugation. Hexane's immiscibility with water may protect the fecal sterols, trapped within aggregates, from contact with the solvent. Under such circumstances, fecal sterols are unlikely to be extracted completely (Wun, et al., 1978). A column method has been developed which employs XAD-2 polystyrene polymeric resin for extracting coprostanol from water (Wun, et al., 1976; 1978). This method has been shown to be effective and avoids the excessive use of chemicals. However, adsorption and desorption are pH-dependent; the solvent must be dried repeatedly due to traces of water in the acetone eluate. Recently, the column technique has been improved by using XAD-1 non-ionic resin -- chemically similar to, but more porous than, XAD-2. Results indicate that XAD-1 resin eliminates the need for adjusting pH. Rapid drying of the eluate may be accomplished by means of a basic methanol

partial clean-up step added to the new column procedure.
This entails displacing water in the column with methanol
prior to elution (Wun, Rho, Walker, and Litsky, unpublished
data). The use of benzene during elution, however, is
undesirable for routine testing and a more acceptable solvent
to remove the fecal sterols from the resin is now being
sought.

(vii) Comparison of Coprostanol, Cholesterol, and
Coprostanone as Indicators. Three of the neutral steroids
found in the feces of man and higher animals -- namely,
cholesterol (5-cholestan-3β-ol), coprostanol (5β-cholestan-
3β-ol), and coprostanone (5β-cholestan-3-one) -- have been
suggested as potentially useful chemical indicators of fecal
pollution in water (Murtaugh and Bunch, 1967; Smith, et
al., 1968; Tan, et al., 1970; and Dutka, et al., 1974).
Although cholesterol constitutes a major component of the
fecal sterols, it is also present in eggs, milk, lard, and
wool grease (Murtaugh and Bunch, 1967). Except in specific
instances, this sterol does not specifically indicate fecal
pollution. In addition, cholesterol seems to be widely
distributed at its limit of solubility in seawater (Smith
and Gouron, 1969). Coprostanone, on the other hand, is
usually a minor component of feces, being present at about
one-tenth the concentration of coprostanol. It was suggested
that coprostanol may be readily oxidized to coprostanone in
the environment and that this ketone is, in effect, a more
stable chemical indicator (Dougan and Tan, 1973). However,
environmental contaminants interfered less in the detection,
by means of gas liquid chromatography, of coprostanol,
rather than coprostanone (Wun, Walker, and Litsky, unpub-
lished data).

(viii) Conclusion. Coprostanol satisfies the generally
accepted criteria for a good indicator of fecal pollution.
To employ this fecal sterol for the practical assessment of
water quality, however, more work is needed. Although this
chemical appears to originate from the intestine of man and
higher animals, it has been found to occur in the feces of
chickens and in tissues of other animals (Kirchmer, 1971);
also, seaworms obtained from sewage-polluted seawater may
excrete large amounts of coprostanol in their feces (Wun,
Walker, and Litsky, unpublished data). High concentrations
of coprostanol have been shown to absorb onto sewage partic-
ulates, as do viruses. Hence, it is likely that by ingesting

and concentrating these contaminated particulates, various aquatic organisms have been responsible for the high levels encountered. Whether lower animals concentrate coprostanol exclusively by ingestion, or whether they also harbor microorganisms which can transform cholesterol to coprostanol, remains to be learned. Two procedures, hexane liquid/liquid partitioning and polystyrene polymeric resin column extraction, are presently available for coprostanol isolation from waters. Gas-liquid chromatography is commonly used for quantifying this fecal sterol.

Coprostanol is biodegradable; nonetheless, Dutka and coworkers (1974) recovered high concentrations of this sterol at a substantial distance from fecal sources, suggesting a possible resistance to biodegradation. More studies are needed to determine how coprostanol is degraded and how various environmental factors affect decomposition rates. Also needed are studies to ascertain coprostanol persistence and baseline levels in surface waters and in sediments.

(ix) Summary. Coprostanol is the major fecal sterol of humans, comprising 40 to 60 percent of the total neutral sterols excreted. This compound can be concentrated from water and quantified by gas-liquid chromatography in a relatively short time. It is considered a good indicator of fecal pollution because it can be biodegraded during adequate sewage treatment, but is unaffected by chlorination, heat, and toxic industrial discharges; hence it overcomes some inherent problems of conventional bacterial indicators. Further testing of this method is required to obtain more baseline levels in the environment and to ascertain the factors affecting coprostanol persistence.

4. Potentials for Mechanization, Automation, and Shorter Read-Out Times

As water becomes increasingly more subject to reclamation and pollution, and owing to the limited resources available for microbiologic analyses of water, the direction taken in analytic procedures inevitably will be toward large-scale economies. Some of the more successful of these approaches are those that automate, simplify, or otherwise modify the methodology to enable the work to be more precise and accurate, and the results to be obtained more quickly. Increasing the productivity of a method often means that more samples can be taken, thus, increasing the degree of

certainty of results. The methods presented here range from improved versions of established methods to completely new approaches to water microbiology.

a. Radioactive Isotope Methods. Methods in chemistry, especially clinical biochemistry, have evolved rapidly during the last 20 years. Autoanalyzers as well as chromatographic and electrophoretic equipment have become an integral part of most diagnostic laboratories, enabling rapid and accurate chemical analyses. Radioimmunoassay has become an essential, sensitive tool for diagnosing various viral diseases and assaying simple molecules, including hormones.

However, progress in microbiology over the past 30 years has been slow. Diagnostic procedures have not changed significantly. Most of the conventional methods are based on the physiological properties of the various bacterial strains, especially their ability to ferment certain carbohydrates or to metabolize specific amino acids. The sanitary quality of drinking water is still usually determined by counting coliform bacteria, which serve as indicators of fecal contamination [See Sections C.1.b to c].

Methods currently practiced in some countries, for detecting coliforms, entail membrane filtration followed by the fermentation of carbon sources such as lactose [See Sections D.2 and 4]. Biochemical changes become apparent only after a prolonged (minimum 24 to 48 h) incubation to permit the growth of large numbers of the indicator (it takes 1.7×10^9 coliforms to produce 1 mm^3 of gas -- Levin, 1963). Thus, contaminated samples of drinking water may already have been consumed before public health officials are apprised of the danger and can institute corrective action. More rapid coliform detection methods are needed so that, ideally, bacteriological results would be obtainable within 6 h or less. There is also a need for semi- or fully-automated systems for rapid on-line coliform detection in water treatment plants or at strategic monitoring points in the distribution system [See also Sections C.4.c to g].

Radioactive isotopes have been used, extensively, to study biochemical changes, including bacterial fermentations. These techniques are much more sensitive than the conventional bacteriological procedures; therefore, it is not surprising that labeling compounds with ^{14}C to help detect, quantify, or identify contamination indicators was

first proposed more than twenty years ago. Unfortunately, despite its merits, this approach has not received the attention which it deserves and is not widely employed for routine microbiological monitoring. There are two applicable radioactive isotope methods, one based on fermentation; the other, based on isotope incorporation.

(i) Fermentation Method. This approach makes use of known biochemical properties of the various bacterial strains. Levin and coworkers (1956) used ^{14}C-labeled lactose broth to utilize the coliform's ability to metabolize lactose, unlike soil organisms which show no β-galactosidase activity. They reported that this method gave presumptive evidence of coliforms in water in 1 h. Other carbon sources including [^{14}C]glucose and [^{14}C]sodium formate have also been tried, but since these reactions lack specificity, they cannot be used to identify or quantify coliforms.

The sensitivity of the assay can be markedly increased by including additional nutrients in the medium, thereby enhancing bacterial multiplication which in turn contributes to the fermentation process. As in the standard procedures, inhibitors can be added to the isotope-containing medium, rendering it selective. Thus, adding bile salts prevents the growth of soil bacteria but permits that of coliforms. In addition, raising the temperature from 37 to 42°C (as has been suggested) increases the uptake of labeled carbohydrate, along with other enzymatic reactions, thereby accelerating $^{14}CO_2$ production.

The radioisotope procedure was modified further with the introduction of membrane filters for concentrating bacteria in large volumes of water. This modification permitted the detection of two to ten coliforms within 6 h (Bachrach and Bachrach, 1974; Reasoner and Geldreich, 1978). The radioisotope procedure has limitations, however, in that it does not permit the exact quantitation of an indicator. The rate at which coliforms ferment carbohydrates may be affected by their previous environmental exposure or handling. Starvation, lack of nutrients, or toxicity of membrane filters may decrease the initial rate of $^{14}CO_2$ release, producing a nonlinear $^{14}CO_2$ curve when [^{14}C]lactose is the carbon source. This may result from a lag in the induction of β-galactosidase production [See also Section C.4.g].

(i.1) Detection Techniques. Two techniques for collecting and measuring radioactive CO_2 are: (1) trapping $^{14}CO_2$ on filter papers or by hyamine injection, and counting with a Geiger-Muller or a scintillation counter; and (2) continuous monitoring of the $^{14}CO_2$ by flushing the cultures with gas, and counting with an analogue recorder connected to an ionization chamber (Deland and Wagner, 1969).

(i.1.1) Trapping $^{14}CO_2$. Various means have been employed to trap the released $^{14}CO_2$. The reaction is usually carried out in a sealed test tube or container which is shaken in a water bath. Filter papers containing either barium hydroxide (Levin, 1963) or potassium hydroxide are attached to the lid of this container. The reaction is usually stopped by injecting acid, which also releases the radioactive CO_2 trapped in the solution (in the form of carbonate when the pH of the medium is high). The filter papers containing the radioactive CO_2 are then transferred to scintillation vials and assayed for radioactivity by liquid scintillation spectrometry (Bachrach and Bachrach, 1974), or dried and counted with a Geiger-Muller counter.

An alternative method, which may be more precise, uses rubber stoppers to support center wells (K-882320, Kontes Glass Co., Vineland, New Jersey, U.S.) into which hyamine is injected (Bachrach and Bachrach, 1974). The reaction is stopped in the same manner as above, and the center wells are transferred to scintillation vials and counted. In principle, this radioisotope technique can be modified to monitor potable water quality automatically, as suggested by Pijck and Defalque (1963) and Reasoner and Geldreich (1978).

(i.1.2) Continuous Monitoring of $^{14}CO_2$. This approach has the advantage of being automatic and permitting continuous monitoring of radioactive CO_2 (Morello, 1975). It should, however, be pointed out that accurate results can be obtained only when bacteria are grown in an acidic medium to prevent trapping the CO_2 in the medium.

There are several commercially available instruments which afford continuous automatic monitoring. The best known is the BACTEC system (Johnston Laboratories, Cockeysville, Maryland) which represents an important advance in the field of automation for microbiology. It was originally designed to detect bacteria, automatically, in blood cultures and to test for sterility, but it may easily be used to monitor water quality.

With the BACTEC system, the sample is injected into a culture medium containing a ^{14}C-labeled substrate. Thereafter, the culture vial is attached to a cylinder of gas (containing 10 percent CO_2), connected to an ionization chamber, and incubated at the required temperature. At the start of the cycle, needles, which have not yet descended into the culture vial, are heated to sterility; and the pressure in the ionization chamber is lowered to about 1/2 atm. The needles then descend into the culture vial; gas from the cylinder is forced through a sterilizing filter into the vial and then swept out into the ionization chamber, where any radioactive CO_2 is counted.

(ii) Isotope Incorporation Method. The fermentation methods just described are quite sensitive in that, a single coliform bacterium may metabolize many molecules of the radioactive carbohydrate; the amount of evolved radioactive CO_2 is a function of cell number, incubation time, and temperature. Yet, these methods do have drawbacks. "Inactivated" coliforms, which are unable to multiply (due to chemical or physical water treatment), may still ferment the carbohydrate. To avoid inclusion of these in the results, alternative procedures have been proposed. Incorporation methods measure bacterial growth, usually to the exclusion of inactivated microorganisms. Khanna (1973) used a radiometric assay, based on the synthesis of macromolecules, wherein he incubated bacterial cells with ^{32}P and measured the amount of isotope incorporated into cellular nucleic acids. At the end of incubation, cells were collected on Whatman No. 40 filter paper, washed, dried, and their radioactivity determined. This procedure has been used for quantitating E. coli cells.

Radioactive phosphorus is not the only isotope which can be used for incorporation studies. Radioactive sulfur has been used in attempts to detect extraterrestrial life (Levin, 1968). This isotope may easily be used to quantitate coliforms in water. Using radioactive phosphorous or sulfur has the advantage that these isotopes may be obtained at high specific activity (unlike radioactive amino acids, purines, or pyrimidines), facilitating labeling and quantitation of bacteria. However, they may present a health hazard because they emit relatively high-energy β particles; in addition, their short half-lives may lead to practical difficulties. Since sulfur isotopes would be incorporated into bacterial proteins and phosphorous isotopes, into

nucleic acids, they would permit the detection of bacterial growth, but could not be used, as such, for the identification of specific bacteria.

This procedure clearly requires modification before it can be applied directly to water quality control. Soil bacteria behave like coliforms in that both groups incorporate the radioactive elements. Therefore, inhibitors should be added to the growth medium to permit selective growth. Bile salts and related compounds probably would permit the growth of coliforms while inhibiting the multiplication of any bacteria not in the family Enterobacteriaceae.

Tritium-labeled amino acids, carbohydrates, or purines are usually not suitable for incorporation studies. These isotopes cannot be obtained at sufficiently high specific activities; therefore the assay is not very sensitive. On the other hand, iodinated amino acids may be used and would probably permit the detection of bacteria even in small numbers.

(iii) Application. Both the fermentation and incorporation methods provide means of testing for sterility and, as such, could be applied to water samples after chlorination or other treatment.

As mentioned earlier, radioactive lactose may be used to differentiate between coliforms and soil bacteria. Other radioactive carbohydrates may similarly be used and may help in classifying indicator types. Related biochemical properties of specific bacterial strains should also be considered. E. coli, for example, shows lysine decarboxylase activity, and releases radioactive CO_2 when incubated with [1-^{14}C]lysine (labeled at the carboxyl group). In this way, E. coli may be differentiated from other Enterobacteriaceae; when this test is run concurrently with [^{14}C] lactose or [^{14}C]glucose incubations, total coliform or total bacterial levels, respectively, may be ascertained.

Incorporation studies may be used to test the sensitivity of the organisms to various agents. Any decrease in isotope incorporation in the presence of the drug would be a sensitive indication of growth inhibition. By monitoring isotope incorporation, in parallel cultures incubated aerobically and anaerobically, one may identify aerobic and anaerobic bacteria.

(iv) Conclusions. The radioactive isotope method, applied either to bacterial fermentation or isotope incorporation, is a useful tool for the early detection, quantitation and identification of microorganisms in water. It can be automated and applied as an on-line system to signal any changes in water quality. The fermentation of radioactive substrates offers a means of differentiating E. coli from other coliforms, and coliforms from soil bacteria, but it does not necessarily distinguish between viable and inactivated organisms. Enzymatic reactions can be accelerated by certain modifications to increase radioactive CO_2 output, although initial rates of $^{14}CO_2$ production are not always linear due to metabolic lag periods or previous environmental exposure. Isotope incorporations permit easy, accurate coliform quantitation, but do not identify specific bacteria. The use of membrane filters permits detection of sparse bacterial numbers in large volumes of water. The procedures are sensitive and permit the detection of two to 20 coliforms within 6 h.

(v) Summary. There are two radioisotope methods applicable to drinking water microbiology: one based on fermentation, the other based on isotope incorporation. The fermentation method utilizes the ability of bacteria to metabolize specific ^{14}C-labelled compounds, whereby the $^{14}CO_2$ released can be trapped and quantified. A judicious selection of substrates, inhibitors, and reactions will enable detection of specific groups such as coliforms.

b. Impedance Methods. The impedance technique offers potential as an automated, rapid, and non-specific indicator of viable microorganisms, analogous in several ways to the use of ATP [See Section C.3.b]. Both detect only viable microorganisms, and the response of both is a function of the number of viable organisms present. No work, however, has been published on the use of impedance for microbiological monitoring of drinking water, although this technique has been applied to microbiological problems in a number of other areas.

The impedance technique has been applied to several problems of practical importance in clinical microbiology, food microbiology, wastewater management, and environmental monitoring. Using this method, clinical microbiologists can screen rapidly for: microorganisms' tolerance of, or susceptibility to, antibiotics (Ur and Brown, 1974, 1975a;

Cady, 1978); clinically significant populations ($< 10^5$ per ml) in urine samples as a means of diagnosing bacteriuria (Cady, 1978); evidence of infection in blood samples (Hadley and Senyk, 1975); and pathogen characterizations and identifications, such as for <u>Neisseria gonorrhoeae</u>, by simultaneous impedance responses to multiple substrates and media (Hadley and Senyk, 1975; Cady, 1978). The impedance technique can be used to measure the rate of microbial sulfate reduction in pure cultures of anaerobic sulfate reducing bacteria and in estuarine sediment samples (Oremland and Silverman, 1979).

(i) Principles Underlying the Use of Impedance. When microorganisms in an aqueous medium metabolize, they generate a complex series of reactions whereby higher molecular weight substrates are converted by extracellular enzymes to lower molecular weight compounds. These, in turn, are metabolized at or within cell surface structures, or they are metabolized internally. Also, other lower molecular weight organic and inorganic compounds are transported into the cell, often accompanied by an influx or efflux of inorganic ions. Eventually, metabolic products of lower molecular weight, including gases, accumulate in the aqueous environment outside the cell. As a result of microbial growth, electrically charged molecules and ions in the water will change in species and increase in concentration over time.

If an electric current is passed through the solution between two electrodes, a decrease in resistance (with direct current) or impedance (with alternating current) will occur as ions and electrically charged molecules increase in concentration and relative mobility. Reactions also will occur at or near the surface of the electrodes when charged molecules or ions are attracted to or adsorbed on the electrode surface, causing the electrode to act as a capacitor. Thus, the entire system can best be visualized as a circuit containing both a resistor and a capacitor in series. These concepts are discussed more extensively by Cady (1978). Other discussions on principles and applications in microbiology may be found in Cady (1975), Cady and coworkers (1978), Ur and Brown (1974; 1975a,b), Hadley and Senyk (1975), Munoz and Silverman (1979), Silverman and Munoz (1979), and Oremland and Silverman (1979).

A certain minimum number of growing microorganisms must be present before a detectable impedance signal will be

delivered. When numbers lower than the minimum are present, there will be a lag period of no detectable change in impedance signal, until populations reach the minimum detectable size -- among the bacteria, this number is generally 10^6 to 10^7 per ml. The lag period, or detection time, is inversely proportional to the number of viable microorganisms present at zero time and can be as short as one hour for an inoculum of 10^5 to 10^6 cells, or as long as 18 h for one cell (Cady, et al., 1978; Ur and Brown, 1974, 1975a; and Silverman and Munoz, 1979).

(ii) Instrumentation. Two commercial instruments are available at present for measuring impedance changes generated by microbial metabolism. The Bactometer is available from Bactomatic, Inc., Palo Alto, California, U.S., and the Bactobridge (formerly called the Strattometer) can be obtained from T.E.M. Sales, Ltd., Crawley, Sussex, U.K., or from Koniak and Partners, Ltd., Geneva, Switzerland.

The Bactobridge, described by Ur and Brown (1974), employs a matched pair of borosilicate glass capillary cells 30 mm in length and 2 mm internal diameter, plated at both ends with a gold coating. One cell, used as the reference, is filled with a sterile nutrient medium, while the sample cell contains nutrient medium inoculated with the sample. Both cells are inserted into the Bactobridge where, in order to avoid extraneous effects on impedance, a constant temperature is maintained to within 0.1°C. A 10 KHz sinusoidal alternating current, maintained below 0.5 volts, is passed through both cells in a bridge circuit. The bridge circuit is balanced initially using a 10 turn 1 Kohm potentiometer. Thereafter, any impedance imbalance in the bridge circuit, due to microbial metabolism, in the sample tube is amplified, rectified, and recorded continuously on a chart recorder. The only signal obtained, therefore, is that which relates to the activity of the microorganisms. The use of the Bactobridge in microbiology was described by Ur and Brown (1974; 1975a,b).

The Bactometer, described by Cady (1975; 1978) and Cady, et al. (1978), detects growth by measuring the increase with time in the electrical impedance ratio, R_Z, between an inoculated sample vial and an uninoculated sterile reference vial (both vials contain nutrient medium), according to the relation:

$$R_Z = Z_{ref} / [Z_{ref} + Z_{sample}],$$

where Z_{ref} and Z_{sample} are the impedance of the reference and sample vials, respectively. In theory, the impedance

ratio at zero time should be 0.5000 with identical solutions in the sample and reference vials. As cells grow and metabolize and the impedance of the inoculated sample declines accordingly, the R_z will approach 1.0000. In practice, initial impedance ratios ranged from 0.4500 to 0.5500 (Silverman and Munoz, 1979). More detailed descriptions of the Bactometer and the theory and practice of impedance ratio measurements of microbial growth and metabolism have been published elsewhere (Cady, 1975; Cady, 1978; and Hadley and Senyk, 1975).

The Bactometer model 32 accepts up to 32 sample/reference pairs in four modules of eight pairs each. The instrument generates an alternating current of either 400 or 2,000 Hz, passes it through the electrodes of a sample/reference pair every 3 sec, reads the impedance ratio, then indexes automatically to the next pair. A complete cycle of 32 sample/reference pairs is read every 96 sec. The impedance ratio output for each pair is recorded on individual channels of a 32-channel strip chart recorder and displayed simultaneously on the face of the instrument. The Bactometer also converts the impedance ratio data into a form readily stored in a computer for subsequent processing. A variety of disposable sample/reference tubes is available, with total volumes ranging from 2 ml per tube up to 100 ml or more, complete with stainless steel electrodes.

(iii) Evaluation of Impedance in Microbiology. All species of bacteria, yeasts, and fungi tested, that produce visual evidence of growth in broth cultures, generated a detectable impedance signal. Included are many species important in public health, such as Escherichia coli, Streptococcus faecalis, Klebsiella pneumoniae, Pseudomonas aeruginosa, Salmonella enteritidis, Staphylococcus aureus, and Shigella species. Lists of microbial species that have been detected by the impedance technique were published by Cady (1978) and Cady and coworkers (1978).

A selective medium was introduced into multiple sample units of the Bactometer 32 to provide a rapid, single-step most probable number method for enumerating fecal coliforms in sewage treatment plant final effluents (Munoz and Silverman, 1979). A linear relation was found between the $\log_{10}$ of the number of fecal coliforms in the inocula of sewage treatment plant effluents and the detection time by the impedance technique. This permitted the preparation of standard curves of $\log_{10}$ thermo-tolerant coliforms, plotted

against detection time, for determining the number of fecal coliforms in wastewater directly from the detection times. Thermo-tolerant coliform counts obtained with this method were in excellent agreement with counts obtained by the standard MPN procedure (Silverman and Munoz, 1979).

Detection times determined for varying numbers of microorganisms in frozen vegetables correlated with numbers determined by the standard plate count method. This enabled detection times by the impedance technique to be employed in screening frozen vegetables for unacceptable levels of bacterial contamination (Cady, 1978).

(iv) Application of the Impedance Technique to Drinking Water Analysis. One problem common to all methods for detecting and enumerating microorganisms in drinking water is that of low numbers per unit volume. With respect to the impedance technique, strategies can be employed to overcome the problem. By accepting multiple samples, the Bactometer 32 should be able to perform a single-step MPN enumeration, as was demonstrated for thermo-tolerant coliforms in waste-water (Munoz and Silverman, 1979). Sample bottles and vials of up to 100 ml or more capacities are available, so that it should be possible to use larger sample volumes (i.e., greater than the 1 ml maximum in agar plating techniques) for relating detection times to numbers of microorganisms in a sample. Alternatively, methods for concentrating organisms could be employed; for example, collecting them on membrane filters, incubating the filters in an appropriate medium, and relating numbers to detection time.

Specificity can be incorporated as part of the impedance technique by the judicious use of selective media, tempera-tures, antibiotics, etc., when particular genera or species are sought. The impedance technique should prove useful particularly in cases where sample turbidity precludes the use of membrane filter techniques or standard plate counts. Turbidity will not affect microbial generation of an impedance signal, nor interfere with its detection. Finally, the instrumentation, commercially available, provides automated and simultaneous analyses of multiple samples, affording more frequent microbiological monitoring. In addition, its capacity for computer data storage and processing provides users with the opportunity for obtaining retrospective analyses of long-term trends in microbial types and numbers within a water supply.

(v) Summary. Metabolic processes and products of bacterial growth measurably decrease the resistance of an electrical current passing through the growth medium. In this way, the impedance method can be used to detect all viable organisms present in a sample. Selection of appropriate media and growth conditions will enable detection of a specific group of organisms or even one species. The method is extremely sensitive and can yield results in as little as one hour for highly polluted water, or in up to 18 h or longer for a single cell. Although the impedance method has been employed with several bacterial species of public health and sanitary significance, it has not yet been extensively tested for use with drinking water.

c. Automated Sampling, Plating and Incubation. Even though much is now known about water pollution, the problem continues to grow with industrialization and urbanization of society. The bacteriological control of drinking water quality is indispensible in this context; but methods presently used for the purpose have shortcomings, in that sampling is periodic, transporting of samples imposes additional quality control problems, and results represent a static image of a dynamic system. Variations in the bacteriological quality of a water supply may result from human activity, but also from that of wildlife [See Section B.2], and from climatic [See Section B.3] and geologic [See Section A] changes. An ideal method would take into account changing conditions and make possible the determination of a most probable contamination risk.

A logical solution may lie in the application of continuous sampling at selected sites at a water source, at the treatment plant, and along the distribution network [See also Sections 4.a to e]. Although continuous sampling is attainable with conventional manual methods, particularly the membrane filtration technique [See Sections C.1.b to c, C.4.f, C.4.h, D.2, and D.4] greater potential could be realized with the development of automated sampling and analytic equipment. Since these may be installed at a sampling site, the use of such devices would obviate the need for transport.

Several conventional techniques could also serve as a basis for automated procedures, although some obviously would lend themselves more readily than others to automation. Thus, the multiple tube fermentation technique [See Sections C.1.b to c, D.3, and D.5] would require extensive adaptation for use with automated equipment, which would not be practical. The membrane filtration technique, on the other hand, holds

more promise.   This technique has been simplified for use as a manual procedure, but not as applied to automation.

A laboratory prototype model for automated sampling and bacteriological analysis has been developed and was exhibited at the Symposium on Rapid Methods and Automation in Microbiology, held in Stockholm in 1973.   The apparatus is divided into three components: a vessel through which water is pumped, continuously, from the source to be tested; a compartment for storing 24 culture plates of a suitable solid medium; and an incubation chamber.   The prototype works on a direct current of 6 V.   It is equipped with a transformer and can run on the main supply.   It also is connected to a battery for auxiliary power, should the main current fail.

Water, entering continuously into the first container, is aspirated at preset intervals of 15, 30, or 60 min for inoculation onto the culture plates.   As each culture plate is transferred from the storage compartment to the incubation chamber, the lid is removed, and a measured dose (may be adjusted to any volume between 0.2 and 2.0 ml to permit testing of up to 48 ml of water in each series) of sample water is swept evenly over the medium.   A rinse cycle with fresh water follows each inoculation to avoid any bacterial transfer to consecutive samples.   The inoculated plate passes to the incubation chamber, which may be set at 22, 30, or 37°C.

This model was initially devised for use in the event of a catastrophe or war.   However, the advantages to be gained from such a system during normal times are many.   Soon-to-be-published results from pilot studies using this prototype have demonstrated the efficacy of automated bacteriological monitoring of water from different sources.   An industrial adaptation of the prototype, incorporating the latest developments in electronics and automation, might enable a wide variety of individual water analyses.

Work is now in progress to increase the versatility of the model.   For example, ways are being sought to incorporate the detection of anaerobic sporeformers, such as Clostridium perfringens, and to permit dilution of samples of highly contaminated water or concentration of samples for analysis of finished water.

d.   Automated Plate Counting.   One of the most slow, tedious, and routine laboratory procedures practiced today is the counting of certain groups of organisms or total numbers of colony-forming units for water quality assessments or ecological investigations.   Raw, as well as finished, water contains indigenous and exogenous microorganisms in constantly changing numbers [See Section A] and studies of the bacteriological quality or population dynamics of a water source usually entail extensive quantification. Depending on the purpose of the investigation and the microbial composition and density of the sample, counts generally are taken on spread plates, pour plates, or membrane filters [See Sections C.1 and D].

Automated colony counting instruments, recently developed and made available, promise to reduce the monotony that comes with manual counting and help greatly in microbiological testing by the spread plate, pour plate, and membrane techniques if the operational characteristics are fully understood.

(i)   Principle of Automated Counting.   The instrument usually consists of a viewing monitor and an electronic counter.   A high resolution television (tv) camera functions as a rapid scanning light detector that recognizes signals from a bright field/dark field light source moving horizontally in parallel lines over the culture plate.   The camera is connected to an electronic circuit with a counter and a digital readout.   Usually, a tv monitor is also connected to present an enlarged picture of the culture plate.   This magnified view makes it easier for the operator to fix the electronic window precisely on the area to be counted.

The position and size of the window, as well as its shape (circular, square, or rectangular) are all adjustable. Adjustments for colony size and optical density (referred to as sensitivity) also are manually set so that any object exceeding that threshold setting will be counted.   Appearing on the monitor screen will be an illuminated marker dot superimposed over the object to be counted, enabling the operator to check for a correct threshold setting that will tune out smaller particles and debris and count all colonies. The automated counter usually can be connected to a computer for easy data handling and storage.

(ii)   Sensitivity and Accuracy.   What will constitute the smallest detectable size depends on the magnification of

the camera lens, the number of lines in the scanning pattern, the spot diameter, and the level of contrast between the colony and the plate. The contrast level, in turn, is determined, in large measure, by the type of illumination employed.

Since what is recognized by the counter is the difference in light intensity between the background and the colony, the opacity of the agar and, therefore, the type of illumination applied is of major importance.

There usually are three types of illumination from which to choose. Reflected light is used with membrane filters or spread plates that contain opaque or colored agar media such as blood or chocolate agar. Membrane filters also can be counted using reflected light, but only ungridded filters are acceptable since grid marks may interfere with detection and produce inaccurate counts. Gridded filters serve only as a guide in manual counting and should, if possible, be avoided when using the automated counting device.

Transmitted light is preferable when the medium used is relatively transparent (as with pour plates) and the contrast normal. Colonies near the bottom of the dish that are low in contrast may not be counted, but applying an underlay of sterile agar usually will overcome this effect. Use of transmitted light also permits counting of plaques [See Section C.2.a], lipolytic zones, and the like, when cleared spots contrast with the agar by > 20 percent. Detection is possible at lower contrast with an auxiliary dark field illuminator.

With an ordinary 50 mm lens, objects measuring about 0.2 mm can be counted if the contrast level approaches 100 percent. If the contrast is low, the colony must be at least 0.4 mm in diameter. This was demonstrated in an earlier evaluation (Goss, et al., 1974) in which colonies could be counted manually after 18 h, having attained a mean diameter of 0.17 mm; but they were detectable by automated counting only after 48 h, when they had reached a mean diameter of 0.31 mm. With a 75 mm lens, colonies 0.1 to 0.2 mm in diameter (approximately the limit of resolution for the human eye) are readily detectable.

(iii) Correcting for Variables. Automated counts would tend to be somewhat lower than manual counts without

application of a correction factor. This calibration adjust-
ment takes into account distortions or error from colonies
that overlap or that are masked at the periphery of the
plate.

Overlapping or clustered colonies separated by < 0.3 mm
will be counted as multiple or single units depending on
their orientation to the scan lines. It is possible, how-
ever, to calculate the probable frequency of colonies spaced
< 0.3 mm apart if the original sample was homogenous and
distributed uniformly over the medium. This is because the
frequency with which colonies cluster increases in propor-
tion to the bacterial density of the sample (Goss, et al.,
1974; La Grange, et al., 1977; Miller, et al., 1975). Once
determined by experimental manipulation and set on the
machine, this correction factor will adjust the count auto-
matically, but it should be applied only within a range of
50 to 500 counts since densities above or below are subject
to variation from other factors.

(iv) The Spiral Counter. A special type of automated
counter has been developed for use with the spiral plate
method. Here, a small volume (35 ul) of sample is deposited
on the surface of a rotating agar plate in decreasing amounts
from the center to the edge, forming an Archimedes spiral.
The method enables the counting of a single plate for samples
having a 10,000-fold range of bacterial concentrations
(Gilchrist, et al., 1973). Counting is accomplished with a
laser electronic counter, designed to record a preset number
of colonies that have developed from the edge to the center
of transparent plates. If the plate contains more than the
preset number, the counter stops and displays the area in
which the count is made. The count per milliliter is then
determined from a calibration curve (Donnelly, et al.,
1976). This method is of potential value for counting
colony-forming units from different quality waters where the
total count exceeds 1,000 per ml.

(v) Agreement with Manual Counting. Good correlations
have been obtained in published comparisons using pure
cultures (Brusick, 1978; Fruin and Clark, 1977; Goss, et
al., 1974), mixed flora of human origin (Goss, et al.,
1974), cultures from dairy products (Fruin and Clark, 1977;
LaGrange, et al., 1977), and cells forming plaques from
antibody production (Katz, et al., 1977). There apparently
have not been any published accounts comparing organisms

from raw water or slower growing organisms. Nevertheless, the 14th edition of Standard Methods (American Public Health Association, 1975, p. 911) states with regard to automatic counters: "Their use is acceptable if evaluation in parallel with manual counting gives comparable results."

(vi) Advantages and Disadvantages of Automated Counting. The major advantage of automated counting is the savings afforded in time and labor. Counting time, including manual adjustments and allowance for any operator error, is less than one-third that of manual counting. Automated counting also minimizes manual count variations due to carelessness, fatigue, or other factors leading to human error or to differences in technique. Several unpublished studies have been made on this subject, including one by the American Public Health Association, in which it was found that for 95 percent of the manual counts, differences between technicians counting the same plates varied by $\pm$ 24 percent.

Scratches, irregularities in the agar, air bubbles, dust particles, and particles from the sample may be counted with both transmitted and reflected light, giving mistakenly high numbers. When illumination is by transmitted light, stacking ridges and marks such as finger prints on the petri dish can interfere with the count. Dust particles on the camera lens also may interfere. These problems are most evident with plates containing few colonies (Fruin and Clark, 1977), very small colonies, or with plates requiring adjustment to a high sensitivity. Adjusting the colony size or re-adjusting the sensitivity control to tune out smaller particles and irregularities usually will overcome these interferences. This is not always possible, however, with small colonies. Instead, a zero count can be taken for the freshly poured, spread, or filtered plates before incubation, and then subtracted from the final count. Here, it is necessary to put the plates in the same fixed position so that any scratches or elongated particles hold the same orientation, as before, to the scanning lines.

The automated counter does not distinguish between colonies of different color. Therefore, only if the background flora are quite minimal, as with the thermo-tolerant test [See Section C.1.c], should automated counting be used. Otherwise, with tests such as that for total coliforms [See Section C.1.b], where background growth is more developed, automated counting is of limited value.

Plates with mold colonies, filamentous bacteria, or surface spreaders are not well suited for use with automated equipment and should be counted manually. Anaerobic cultures incubated on spread plates may be a problem, since many of these colonies normally have a very low contrast, along with a tendency to spread at times.

(vii) Applications of Automated Counting. Automated counting is useful for all types of studies with pure cultures, and for many others using mixed cultures where the total number of colonies is to be counted. Differentiation of colonies by aspects other than size, however, is less applicable.

Automated counters can be used with spread plates and pour plates and with ungridded membrane filters (when tests are highly selective). Since cleared zones also can be counted when the dark field illuminator is used, automated instruments probably can be employed for enumerating coli-phages and cyanophages from different quality waters [See Section C.2.a]; or they might serve in studies of bio-chemical differentiation, for example, with quantification of cleared zones of lipolytic organisms. An auxiliary camera mounted on a photomicroscope enables objects to be counted automatically. The automated counter also can be connected to a computer programmed for statistical compi-lations to speed handling of the numerous data entries.

(viii) Summary. Although the applications of auto-mated counters are many, it is still the operator and not the machine who make the judgments. The automated counter is no more than a useful tool in the laboratory that can help to release the technician from boring, repetitive, and time-consuming work. The high resolution television cameras with high quality lenses are used to count colonies as small as 0.1 mm in diameter, and can be used with transmitted or reflected light. The major advantages over manual methods are the greater speed and lower cost of automated counting. The major disadvantage is the inability of the device to differentiate between colonies and other objects in the same size range or to distinguish colors. Advances in data processing methods speed up the handling of the voluminous data generated.

e. Automatic Enzymatic Methods. Current techniques for the bacteriological monitoring of finished water have

been of value in combating waterborne epidemics, but are not
without shortcomings. Some of these shortcomings may be
overcome by a recently developed, automated method which is
based upon the Technicon auto-analyzer. Current water
sampling and analytical practices entail a series of dis-
jointed, lengthy steps including sample transport and prep-
aration, as well as multi-phased laboratory procedures.
This not only invites mistakes, but permits only inter-
mittent sampling and analysis. Moreover, the coliform test,
on which monitoring of finished water is based, has proved
liable to misinterpretation.

The major advantages of the new apparatus are its
automated and continuous performance, its ability to be
installed at the water treatment site, and its increased
sensitivity to the detection of E. coli (an indicator of
well established significance). This selectivity for E.
coli is accomplished by the introduction of a glutamate
solution under strictly controlled conditions of pH and
temperature. E. coli was shown to carry on continuous
biosynthesis of glutamic acid decarboxylase (GAD), and
surveys of various bacterial species encountered in water
indicate that GAD production is limited to E. coli, Shigella,
Proteus rettgeri, P. hauseri, and Clostridium species (Leclerc,
1967; Leclerc and Catsaras, 1967). Shigella is only rarely
recovered from water and poses no problems of interference.
From the authors' experience, P. rettgeri and P. hauseri are
always associated with E. coli and occur in polluted water.
Clostridium species are unable to survive aerobic conditions
imposed in this analytical method. Therefore, the test is
highly specific for E. coli and exclusively so for fecal
contamination.

(i) Sampling and Culturing Mechanism. The entire
apparatus is shown schematically in Figure C.4.e-1. It
operates on the basis of continuous and sequential flow by
means of a peristaltic pump. A 3-way valve (constructed in
a T-shape to eliminate problems of contamination arising
from dead volume) enables attached silicone feeder tubes to
separately draw up water sample and culture medium [See
Figure C.4.e-2], after which these are mixed.

To compensate for the low volume of flow dictated by
this model, a hollow fiber ultrafiltration unit was designed
to reduce an initial 100 ml volume to 5 ml (Trinel and
Leclerc, 1976). The Technicon auto-analyzer can, in this
way, accommodate 120 water samples of 100 ml each (or 12 l)
daily, accomplishing analysis of 100 ml every 12 min.

P_{ll}:   T-valves

The growth medium is a buffered lactose broth (BLB) which selectively cultures for any E. coli present in the sample [See Table C.4.e-1]. The consistent and selective growth of fecal coliforms (especially E. coli) on BLB medium is achieved by, and contingent upon, strict adherence to a pH of 6.8 (using phosphate buffer) and a temperature of 41°C. Soil and water coliforms (e.g., Citrobacter and Enterobacter) do not grow well in this medium, and the growth of aquatic bacteria (e.g., Pseudomonas, Aeromonas, and Acinetobacter) is greatly inhibited. Research by Trinel and Leclerc (1976) indicated that this medium was more sensitive and efficient in promoting the growth of E. coli than conventional techniques.

Phthalate HCl-buffer, a disinfectant which is introduced between sample volumes, both sterilizes passages and separates one water sample from another, thereby preventing any cross contamination of consecutive samples. Yet, once diffused into the medium, phthalate buffer takes on the pH of the medium and imparts no harmful effects to incubating cultures. The continuous circulation of microorganisms throughout the system makes the issue of disinfection a critical one. Phthalate HCl-buffer (0.047 $\underline{M}$ at pH 2.4) appears, from results of experiments conducted in our laboratory, to offer an effective means of decontamination.

The mixture of sample and medium next enters a coil of glass tubing maintained at 41°C in a water bath. Incubation proceeds for approximately 12 h, during which time sterile air is bubbled through to provide oxygen for bacterial growth.

(ii) Glutamic Acid Decarboxylase (GAD) Detection. As the culture medium leaves the incubation coils, all gaseous fermentation products are bubbled off and the remaining liquid is diluted with sterile water from which all carbon dioxide has been removed. Sulfuric acid, added after 25 min, liberates evolved carbon dioxide which is recovered and measured by a colorimetric response with phenolphthalein reagent. Results are recorded as colony forming units (cfu) per 100 ml, permitting a detection accuracy of one or less than one E. coli per 100 ml.

(iii) Summary. An apparatus has been devised which is particularly suited to the on-site (i.e., treatment plant, reservoir, or water main) sampling and analysis of water

TABLE C.4.e-1

supplies. It operates continously and automatically, thereby eliminating manual procedures and providing for uninterrupted monitoring. Daily water volumes of 10 to 20 l may be analyzed within 12 to 13 h using ultrafiltration. The technique employed is highly sensitive to and specific for E. coli, as measured by the presence of carbon dioxide evolved from the biosynthesis of GAD.

f. Rapid Thermo-Tolerant Coliform MF Method. Temporary disruptions to the water supply (e.g., water treatment plant failure, line breaks in a distribution network, or other natural or man-made disasters) create an urgent need for methods that permit rapid assessment of the sanitary quality of the water. The 7-h membrane filter fecal (thermo-tolerant) coliform test (M-7h FC) provides results equivalent to those obtained using the conventional 24-h thermo-tolerant coliform procedure employed in the U.S. [See Section C.1.c] and can thus serve as a rapid, preliminary read-out while awaiting the 24-h test results. Accordingly, the M-7h FC test offers a means of detecting gross contamination of potable water in emergency situations, permitting more rapid responses and decisions by public health or other officials.

(i) Principles Applied to this Method. The M-7h FC test uses a lightly buffered lactose-mannitol based medium that contains an acid-sensitive indicator system (Reasoner, et al., 1976). To lessen the adverse effect of higher temperatures upon recovery of thermo-tolerant coliform organisms which may have been stressed by disinfectants, the incubation temperature has been reduced to 41.5°C (Van Donsel, et al., 1969). During 7 h of submerged incubation, thermo-tolerant coliforms ferment lactose to acid, causing the color of the indicator to change from purple to yellow. The thermo-tolerant coliform colonies typically appear yellow against a purple background; all yellow colonies are counted as thermo-tolerant coliforms.

(ii) Medium Preparation and Procedure. The medium may be obtained from Difco or prepared in the laboratory [See Table C.4.f-1]. It can be prepared in bulk quantity by mixing the dry ingredients and storing in a clean jar in a dry, warm place, or in a dessicating chamber to prevent absorption of moisture from the air. The medium is prepared for use by adding the appropriate quantity of the mixed dry

medium to the required volume of laboratory quality distilled water. The medium is then heated to boiling to dissolve the agar. The final pH of the prepared medium should be adjusted to 7.3 ± 0.1 using sterile 0.1 N NaOH or 0.1 N HCl. Plates are prepared by dispensing 5 to 6 ml of the melted M-7h FC agar into small (50 x 12 mm or 60 x 15 mm) petri dishes and allowing the agar to solidify. The prepared plates can be stored in the dark at 2 - 8°C for up to two weeks.

Water samples are tested by passing an appropriate volume (up to 100 ml) through a membrane filter [See Section C.1.c]. Membrane filters are then placed on the agar plates (taking precautions to avoid trapping any air bubbles), put inside watertight plastic bags, inverted, and submerged in a 41.5°C water bath for 7 h. Plates with 20 - 60 yellow colonies are counted using a binocular wide-field dissecting microscope. Colonies are recorded as numbers per 100 milliliters.

(iii) Accuracy and Verification of Results. Results from a study of thermo-tolerant coliform differentiation (Geldreich, 1975) showed that 94.3 percent of the yellow colonies from the 7-h medium verified as thermo-tolerant coliforms; when the same samples were analyzed by the 24-h thermo-tolerant coliform method, 93.7 percent of the blue colonies verified as thermo-tolerant coliform. These data indicate that both media measured essentially the same population of bacteria. Both the 24-h and the 7-h tests underestimate the actual thermo-tolerant coliform density.

(iv) Summary. A 7-h membrane filtration method for thermo-tolerant coliforms (M-7h FC) has been developed that is suitable for determining gross contamination of potable water in emergency situations. It gives results equivalent to the conventional 24-h thermo-tolerant coliform test routinely used in North America. After 7 h of incubation, thermo-tolerant coliforms appear yellow against a purple background. About 94 percent of the yellow colonies can be verified as thermo-tolerant coliforms.

g. Presence Absence Test. Routine analyses of drinking water samples from municipal distribution systems traditionally have been designed to quickly signal the presence and numbers of total coliforms. Initially, most laboratories used the most probable number (MPN) procedure for

this function [See Section D.3.]. However, MPN analyses are rather time-consuming, and the incubation period can extend up to four days before numerical results are available.

The membrane filter (MF) technique [See Section D.2] was introduced in the late fifties as an alternative to the MPN procedure. This technique yields results approximately equivalent to the MPN procedure, but it does so within a 24-h period and requires less preparation. In addition, numerical results from the MF method have been more consistent among samples from the same location.

Sudden, unexplainable instances of pollution occurring in a distribution system and leading to disease outbreaks are relatively rare. Aside from main breaks or equipment failure in the treatment plant, water quality deterioration in a distribution system is more likely attributable to a gradual process of microbial degradation, engendering bacterial slimes, corrosion, or encrustation [See Sections F.2 to 3 and G.2 to 4]. Distribution systems may, in fact, exert their own influences upon finished water, producing conditions whereby slower growing debilitated bacteria or pollution indicators of non-fecal origin may become established. This microbial activity will produce sediments and tubercles that reduce flow rates [See Section G.3], and will create a need for increased chlorination to prevent regrowth and to afford adequate disinfection.

The presence-absence (P-A) test is a simple, inexpensive procedure for the rapid, qualitative detection of fecal indicators (e.g., _Escherichia coli_), as well as indicators of marginal water quality (i.e., slower growing, debilitated bacteria and water bacteria which cause sliming and fouling of distribution systems). The test, as such, would be advantageous to laboratories with limited time and resources. This method, in use for over ten years by the Ontario Ministry of the Environment Laboratories (Canada), supplies results satisfying the criteria enumerated above when used on drinking water samples submitted daily or weekly. Since 90 percent of the samples are ordinarily free of pollution indicators, there is no need to provide quantitative results for each sample.

(i) Procedure for Conducting the P-A Test. Fifty or 100 ml of drinking water samples are added to double or triple strength MacConkey (MacC) broth (respectively) contained in P-A bottles with inverted durham tubes. Samples

and medium are mixed so as not to permit any stratification of the concentrated medium which would inhibit growth. The P-A bottles are incubated at 35°C for four days and checked every 24 h for acid production (with or without gas), as evidenced by the color yellow. If, after three or four days of incubation, only a slight acid reaction is apparent, cultures should be checked for the presence of <u>Staphylococcus</u> (see below).

Pollution indicator types are determined by inoculating presumptive-positive cultures into confirmatory media, diagrammed in Figure C.4.g-1 and described previously (Clark, 1969; Clark and Vlassoff, 1973). Most laboratories will find that the initial confirmatory tests provide sufficient information for assessing the sanitary quality of the water. However, further taxonomic tests may be applied to isolated cultures if more definitive information is required.

Tests for confirming fecal and total coliforms are easily performed. Only fecal coliforms produce gas in the EC broth at 44.5°C; but both fecal and total coliforms produce gas in the EC broth at 35°C; and both produce lactose fermenting colonies on MacC agar. If lactose fermenting colonies are evident on MacC agar, but gas is not seen in either of the EC broth tubes, the organisms are anaerogenic coliforms (debilitated coliforms which have lost the ability to produce gas from lactose fermentation), or aeromonads. <u>Aeromonas</u> can be readily distinguished from anerogenic coliforms by streaking on a non-carbohydrate medium such as Nutrient-Gelatin agar, and performing an oxidase test on 24 h colonies. If a good growth of only non-lactose fermenters appears on MacC agar, these colonies should be identified further with taxonomic tests.

Gram-positive organisms, including <u>Staphylococcus</u>, <u>Micrococcus</u>, and <u>Bacillus</u> sp. are frequently present when gram-negative organisms are absent from any of the other confirmatory media. When grown on Mannitol-Salt agar, <u>Staphylococcus</u> produces convex, yellow colonies surrounded by a yellow zone. <u>Micrococcus</u> types usually produce white or colorless colonies with no evidence of mannitol utilization. Some <u>Bacillus</u> species which produce mucoid, yellow colonies may be distinguished with a Gram stain.

Although <u>Pseudomonas aeruginosa</u> grows vigorously in P-A bottles and may dominate in mixed cultures, its presence may go unnoticed because of its inability to ferment lactose. It

will, however, be noticed if, for coliform confirmation, the organism is streaked onto MacC agar plates. P. aeruginosa can be detected and differentiated using Drake's broth (Drake, 1966), incubated at 41.5°C. Each day for four days, tubes are checked for any fluorescent growth. Cultures from positive tubes are inoculated onto Skim Milk agar, or onto Milk agar which is prepared in the laboratory according to the Brown and Foster modification (American Public Health Assoc., 1975), and incubated at 35°C for 24 h. P. aeruginosa hydrolizes casein, producing typical green colonies.

Fecal streptococci, when present alone in P-A bottles, produce acid with no gas, but the same is also true for anaerogenic coliforms or aeromonads. To confirm the presence of fecal streptococci, cultures are inoculated into Ethyl Violet Azide (EVA) broth and onto Enterococcus (Entero) agar.

Clostridium perfringens reacts in either of two ways in P-A bottles: it may produce abundant gas and acid in the MacC broth, thus resembling a coliform reaction; or, it may produce abundant gas, but confer a bleached, pale, greenish tinge to the medium. A stormy fermentation in Skim Milk broth is usually conclusive for C. perfringens, but a doubtful reaction should be checked with a Gram stain.

All media described in this section (except Drake's broth) may be obtained commercially from Difco. Use of the various confirmatory and taxonomic test media is not rigid. All laboratories have their own favorite media and procedures for confirming and identifying the pollution indicators described above. Even Lauryl Tryptose or Lactose broth may be substituted for MacC broth if a Brom-Cresol-Purple indicator is added at the rate of 0.01 g per l; although Lauryl Tryptose broth is somewhat more inhibitory than MacC broth, requiring sometimes an extra 24 h to develop a presumptive-positive reaction.

(ii) Interpreting Quantitative and Qualitative Results. Since most laboratories cannot run quantitative analyses for all the indicator bacteria, they may achieve an acceptable compromise by conducting a quantitative analysis for total coliforms with the MF technique; and by testing for the presence of all other indicator bacteria with the P-A method. When the P-A method is employed in conjunction with the MF coliform method, 50 ml sample volumes are used in each test. The P-A procedure, when applied by itself, calls for 100 ml

sample volumes. The following is a recommended procedure for handling results:

1. If the MF plate has a sheen colony count of greater than ten per 100 ml and the P-A bottle shows an acid reaction with or without gas, then the MF count is taken as the final result and the P-A bottle is discarded.

2. If the MF plate produces no sheen colonies, the P-A bottle should be incubated up to four days before discarding. If acid with or without gas occurs, confirmatory tests should ensue to identify the indicator group present.

3. If the MF plate has a sheen colony count, but the 24 h P-A bottle shows little or no reaction, several sheen colonies should be picked off and confirmed. (This type of result is frequently presumptive for Aeromonas organisms.) The P-A bottle should be kept for the remainder of the incubation period in case later presumptive results need confirming.

The above procedures will provide a quantitative result for total coliforms and a qualitative result for all the other indicator bacteria. At least 5 percent of the samples showing no total coliforms by the MF technique will be demonstrated by the P-A test to contain them. Thus, by substituting the P-A test for routine analyses and by applying the MF total coliform test only to random portions (15 - 25 percent) of sample blocks, quantitative data will be available if, at any time, the P-A test results should indicate pollution in part or all of the distribution system. Moreover, since many water suppliers find no total coliforms in 95 percent or more of water samples tested throughout the year, the money expended to run quantitative analyses for each sample may not be justifiable, particularly when the P-A method can provide more information at less cost.

(iii) Generic Distribution of Organisms Isolated from Raw and Finished Water by the P-A Test. Table C.4.g-1 lists organisms recovered from raw and finished surface water samples. Cultures isolated from presumptive positive P-A bottles were identified or characterized according to the scheme in Figure C.4.g-1. Usually 85 percent of these presumptive-positive cultures from both raw and finished

TABLE C.4.g-1

water sources proved to be coliforms. Other indicators were recovered less often, their presence being more a function of water source and nature of pollution. Most, but not all, of the colonies isolated from MacC agar plates were lactose fermenters. Those few which didn't ferment lactose, but which predominated on a culture plate, were picked along with the others for identification.

The use of Enterotubes and Oxyferm tubes (Hoffman-La Roche, Ltd.), according to the scheme in Figure C.4.g-1, afforded a more extensive determination of coliform genera. E. coli was most often isolated from raw water samples, but declined the most following water treatment. Alternately, isolation frequencies for other coliforms varied little from raw to finished water sources. While Enterobacter cloacae was more frequently isolated following water treatment, other Enterobacteriaceae were isolated as often from one source as from another.

Though E. coli was most often isolated from raw water samples, it showed the greatest reductions following water treatment. E. coli [See Section C.1.c] has been recognized as the indicator most closely associated with and representative of fecal pollution in drinking water; hence, its presence signifies the potential presence of pathogenic organisms such as Salmonella [See Section C.1.c]. Nonetheless, the results in Table C.4.g-1 demonstrate that though the presence of E. coli indicates fecal pollution, its absence does not necessarily indicate water safety after treatment. In contrast, any of the other coliform genera can be used to measure water treatment efficiency, but not to measure fecal pollution.

Klebsiella pneumoniae [See Section C.2.d] has also been isolated on a number of occasions from drinking water samples and is sometimes the organism responsible for positive fecal coliform tests. Its presence was therefore anticipated, but not in the relatively high numbers and unvaried isolation frequencies noted between raw and drinking water samples. From these results, and in view of the evidence that K. pneumoniae is more often associated with pulp and paper mill and other industrial effluents, its use as an indicator of fecal pollution is not recommended.

Recovery of Aeromonas [See Section C.2.h], also identified in these tests, signifies a deterioration in water treatment or along distribution lines, and it should, therefore, be included as an indicator of water treatment efficiency. However, this organism is often indistinguishable

from coliform colonies when the MF technique is used for analysis. Unless Aeromonas is differentiated, the water will be considered contaminated with fecal pollution, whereas slime deposits in water mains may instead be supporting entrenched Aeromonas populations. This organism is associated with nutrient-rich waters which receive heavy soil run-off's and it is also found as the predominant organism in certain groundwater supplies.

These generic tabulations should not be interpreted to represent all drinking and raw water sources; nor should they be taken to reflect year-round populations. More pollution indicators are detected in summer and fall months when distribution systems carry warmer water which may afford opportunities for regrowth. At other times, pollution indicators will be detected more frequently because of periodic treatment deficiencies at an individual facility. In the event of any such abnormalities, waterworks operators should be alerted so that they may step up disinfection.

(iv) Understanding P-A Test Results. P. aeruginosa [See Sections B.1.a(ix) and C.2.c] and S. aureus are both potential pathogens and their detection is cause for concern, especially since they may be established along portions of the distribution system. Most healthy individuals may not be affected by ingesting small numbers in drinking water, but there may be those who are susceptible to infections by these bacteria.

When fecal streptococci are isolated in association with total or fecal coliforms, the water is probably contaminated with fecal material. However, isolation of fecal streptococci by themselves may indicate marginal treatment of the water supply. Because many species in this group tend to be host specific, proper interpretation may call for species identification.

Staphylococcus epidermidis and Micrococcus species were isolated (Clark, unpublished data) when no other pollution indicators were detected in water samples. They were found to be protected from disinfection by slime deposits in water mains and reservoirs. Their detection may have no sanitary significance, but rather, should signal that some portion of the distribution system needs attention due to deteriorating conditions.

Total coliforms are employed in North America as the primary indicator of finished drinking water quality [See Sections D.2.g and D.3.f]. However, it is useful to make a

distinction between aerogenic and anaerogenic coliforms when discussing water of deteriorating quality. Among the coliform genera, variability exists within each genus, ranging from no fermentation of lactose to fermentation of lactose at 44.5°C with the production of gas. Depending on the length of time and degree of treatment that intestinal organisms have had in water, their physiological reactions could be altered so that they no longer respond exactly as typical strains. The detection of aerogenic coliforms sometimes indicates that the water supply received no treatment, whereas the detection and differentiation of anaerogenic coliforms may indicate unsatisfactory water treatment or insufficient chlorine residuals. The significance of anaerogenic coliforms has not been fully investigated because some MPN procedures do not use a pH indicator and thus, rely mainly on gas production to detect coliforms. MF techniques fail to distinguish non-lactose fermenting variants of the coliform genera, and do not differentiate between aerogenic and anaerogenic variants.

Clostridium perfringens has been shown to occur more frequently in distribution systems during winter and spring when seasonally colder waters reduce the efficiency of chlorine disinfection and aid survival of _C. perfringens_ in the distribution system. This organism has been shown to build up in sand filters whereupon it may detach and be passed along through the distribution system.

When good quality water is delivered through well maintained and disinfected distribution systems, water samples taken from anywhere along the distribution route will be free of the pollution indicators described here. However, if good quality water passes through pipelines and reservoirs which have been allowed to deteriorate, pollution indicators will continue to appear in water samples; albeit, they may be of genera quite different from those usually associated with fecal sources. The point to be emphasized is that because of certain ecological factors in distribution systems, particular types of organisms, whether gram-positive or -negative, may become the resident flora. By using simple, rapid, and reliable test procedures to determine which pollution indicators are becoming established, remedial action can be, taken before a crisis develops (Ontario Ministry of the Environment, 1976).

(v) Summary. The P-A test provides a simple, effective means of assessing water quality for the routine surveillance of distribution systems. A full range of

taxonomic tests would not be required on a routine basis, as the confirmation tests specified would be sufficient to assign most of the organisms to one or more indicator groups. Differentiation of the coliform genera, other than E. coli, would not likely be very helpful in determining whether the water was safe to drink. However, if coliforms, aeromonads, or any of the other indicators are detected, with any degree of frequency, in consecutive samples or sample blocks, this signifies problems within the distribution system. Either the walls of water mains are not being adequately protected from slime deposits, or factors such as warmer water and available nutrients are inducing regrowth of such organisms within the distribution system.

h. **Membrane Filter Procedure for U.S. Standard Plate Count.** The method presented here produces results closely parallel to those achieved with the standard plate count (SPC) used in the U.S. [See Section C.1.a]. The membrane SPC (M-SPC) method is offered as a substitute for the SPC and, as such, would be used (in conjunction with standard coliform analyses) to measure changes in the bacteriologic quality of potable water passing through water supply distribution systems or point-of-use treatment devices.

(i) Advantages of Using Membrane Filters. The M-SPC procedure would have a marked advantage for the enumeration of bacteria in potable waters by allowing the examination of sample volumes larger than one milliliter, thereby drastically increasing the statistical acceptability of results heretofore obtained with the SPC method. A membrane filter procedure would have the additional benefits of savings in time, incubator space, equipment, materials, and labor (Clark, et al., 1951). Also, colony pigmentation develops more readily on the membrane filter, and individual colonies may be easily picked for further identification. The only factors potentially restrictive of this procedure are sample turbidity and spreading of colonies on the filter surface. Colony density on the filter can be controlled by adjusting sample volumes appropriately.

(ii) Medium Preparation and Procedure. The M-SPC medium utilizes a general enriched formulation consisting of three conventional nutrients: peptone, gelatin, and glycerol. It may be obtained, in dehydrated form, from Difco (glycerol must be ordered separately), or prepared in the laboratory [See Table C.4.h-1]. Rehydrate the gelatin, peptone, and agar in distilled water; then heat to

TABLE C.4.h-1

M-SPC MEDIUM FORMULATION

Gelatin	25.0 g
Peptone	20.0 g
Agar	15.0 g
Glycerol	10.0 ml
Distilled water	1000 ml

boiling. Cool to 45 - 50°C and adjust to pH 7.0 with 1 N NaOH. Then, add glycerol and autoclave for 5 min at 121°C. Pour medium into petri plates with tight fitting lids [See Section C.1.b], and store between 2 and 10°C.

An appropriate volume of water sample (100 - 500 ml or more) is passed through a membrane filter [See Section C.1.b], the filter is then placed (taking precautions to avoid trapping any air bubbles) on an M-SPC agar plate. Plates with filters are incubated at 35°C for 48 to 72 h to achieve maximum colony size. An incubation temperature of 35°C is selected, to conform with procedures specified in the U.S., for determining a "standard" plate count in potable water (American Public Health Assoc., 1976). Membranes selected for counting should contain between 20 and 200 bacterial colonies. All colonies are counted with the aid of a wide-field dissecting microscope, 10 - 15X magnification, and recorded as numbers per one milliliter.

(iii) Agreement Between the SPC and M-SPC Methods. The mean SPC/M-SPC ratio for 164 drinking water samples was 1.099, indicating that the two procedures very closely approximate one another (Taylor and Geldreich, in press). In point of fact, the geometric mean ratio was 0.501, revealing the inclusion of a few unusually high ratios in the field data. That is, 120 of the individual samples registered ratios of less than one, indicating that the M-SPC procedure provided higher counts than the SPC procedure approximately 75 percent of the time. It remains to be seen whether results of the two methods will correlate as closely when applied to a greater number and variety of field samples.

(iv) Summary. A membrane filtration method has been developed that gives results closely parallel to those achieved with the U.S. standard plate count. The method is designed to replace the pour plate technique, and as such, to measure changes in the distribution system or in passage through point-of-use water treatment devices. In addition to increased volumes of water that can be tested, the method allows savings of time, space, and equipment. Colony pigmentation develops better on the membrane filter, and the colonies may be easily picked for identification.

i. Epifluorescence -- Total Cell Count. The direct counting of bacteria with a microscope is a technique with a

long history. As traditionally practiced, it has entailed concentrating bacteria by filtering 2 ml of sample water through a membrane. Bacteria trapped on the filter are stained. Then, the filter is dried and rinsed; finally, what are supposed to be bacteria are counted with the aid of transmitted light. Direct counting has never been popular because most bacteria in environmental waters are so small that identifying them from small dots required an act of faith. However, recent improvements in both membrane filters and microscopes have resulted in easier and more reproducible methods of direct counting. The epifluorescence direct count method is a rapid and simple way to determine total numbers of bacteria in water [See Sections C.3.b and C.4.b].

By employing direct counting methods, investigators have observed high numbers of bacteria in all water sources sampled: the Great Lakes and coastal oceanic waters may have about 10^6 bacteria per ml (Zimmerman and Meyer-Reil, 1974); mountain lakes or open ocean waters contain about 10^5 cells per ml; even distilled water, stored for a month in the laboratory, may have as many as 10^6 cells per ml (Daley and Hobbie, 1975). Sewage polluted water has been found to contain as many as 10^8 cells per ml (Straskraba and Straskrabová, 1969).

Bacteria will grow in any suitable water, including most distilled water. Rather high numbers of bacteria, over 10^6 per ml, have been found in drinking water (although no controls were run for presence of residual chlorine or effects from storage) [See Section G.6]. Bacteria are capable of growth during distribution where finished water does not contain a sufficient chlorine residual. Though generally not hazardous to health, these organisms may cause a number of technical and nuisance problems [See Sections C.4.g, F, and G.2 to 4] and may not be enumerated efficiently using plate count agar.

Most bacteria seen with epifluorescence do not grow well under laboratory conditions, although up to 90 percent of these same organisms are, according to autoradiographic studies, actively taking up substrates (such as sugars and amino acids) from solution (Hoppe, 1976). Therefore, direct counting using epifluorescence can remedy deficiencies in total bacterial enumerations, though it is not specific for pathogens or indicator organisms, and should only be used to supplement or replace non-specific plate count techniques.

(i) Materials for Direct Counting with Fluorescence Microscopy. A variety of dyes have been successfully used for staining samples prior to counting; they all provide adequate contrast, but none is specific for bacteria. Fluorescein isothiocynate (FITC) has been used (Fliermans and Schmidt, 1975), as has euchrysine (Jones, 1974), but acridine orange (AO) is the most widely accepted (Hobbie, et al., 1977). The usual final concentration is 0.01 percent AO.

Polycarbonate membranes, such as those produced by Nuclepore, have a very flat surface that retains all the bacteria on top of the filter. Although cellulose filters also retain all of the bacteria, many are trapped inside the filter where they cannot be counted. The polycarbonate membranes used in this procedure are 25 mm in diameter and have straight-through cylindrical pores with a diameter of 0.2 um. A 0.1 um porosity filter can also be used but at this diameter, the filtering rate is greatly reduced. The filter is stained before use by soaking 2 to 24 h in a solution of 2 g irgalen black (a competitive stain) in one liter of 2 percent acetic acid (Hobbie, et al., 1977).

A variety of microscopes have been used with success. Most manufacturers now make an epifluorescence attachment and have light filters especially for AO (e.g., Zeiss, Leitz, American Optical, Olympus, Nikon). A quartz halogen lamp is satisfactory, but a mercury lamp may give a higher intensity if necessary.

(ii) Method for Direct Counting with Fluorescence Microscopy. A few drops of a fluorescent dye are added to a water sample. It is convenient to place a 2.0-ml subsample in a small test tube and to add 0.2 ml of 0.1 percent AO (in distilled water). After the sample is held for one minute, it is filtered through a polycarbonate membrane. Filtering less than 2 ml does not permit an even distribution over the filter surface; therefore, dilution water may be added so that the total quantity filtered is 2 ml. When bacterial numbers are low, larger sample volumes can be filtered. Placing the polycarbonate membrane on top of a cellulose membrane filter during filtration helps to produce a more uniform distribution of cells.

While still damp, the membrane is placed on a glass slide, and immersion oil is added. Then, a cover slip is put on top, and more immersion oil added. Bacteria are counted,

using epi-illumination, within one hour or several hours (depending on type of water sampled) after preparation.

The epi-illuminated microscope allows a wet filter to be counted because the illuminating light comes from above; it also provides very intense light because the objective lens of the microscope acts as the condenser. As a rough guide, 2 ml of most raw water will yield about 90 bacteria per field when a 90X or 100X objective is used. Usually, one quarter of each of ten randomly chosen fields is counted, for a total of 200 to 400 cells. Because bacteria will readily grow in every kind of water, including distilled water, the numbers found by this technique are likely to be large and may reach 10^6 cells per ml.

With this method, bacteria are seen as fluorescent spots against a dark background. In some cases, dividing cells, rods, or spirilla can be seen. However, indicators or pathogens cannot be separated from the abundant naturally occurring bacteria. In most cases, bacteria can be differentiated from debris because bacteria take up more stain (when kept at a relatively low concentration, AO interacts with the nuclear material of bacteria) and appear more regular in shape. That these small brightly fluorescing foci are bacteria was verified by the good agreement of their numbers with scanning electron microscope counts (Bowden, 1977) and with indirect measures of bacteria such as the lipopolysaccharide content of the sample (Watson, et al., 1977)(See Section c.3.a).

The water sample (and the AO too) can be preserved with formaldehyde at a final concentration of 2 to 4 percent and stored for at least two months. Permanent slides can be produced with the Zimmermann (1977) technique.

(iii) Potential Applications for Use with Drinking Water. Epifluorescent direct counts have not been used on finished drinking water. However, this method offers potential for use in tracing breaks in supply systems, or in monitoring the overall quality of water supply sources. Pollution in a water supply may cause an increase in total cell numbers of 10 to 100 times.

By conducting a series of studies of bacterial numbers at different points in the treatment and distribution system, waterworks microbiologists could determine general levels and employ epifluorescence counting for quick assessment of the quality of water. Likewise, this technique could be

used for rapid tracing of breaks in lines and other similar
emergencies. Further evaluation of this type of application
is recommended.

Another possible approach could be based, not on total
numbers of bacteria, but on the size of individual cells.
Most bacteria in unpolluted waters are tiny, 0.2 to 0.4 um
in diameter, whereas bacteria in extremely productive or
organically polluted waters grow to diameters of up to 1 um.
Whether a richer nutrient source brings about increased
sizes in the initial flora, or whether different organisms
predominate under polluted conditions, is not yet known.

(iv) Summary. Bacteria in water can rapidly be counted
(within 15 minutes of sampling) by staining with a fluores-
cent dye such as acridine orange, concentrating by filtra-
tion through a polycarbonate membrane, and viewing with an
epifluorescent microscope. Because the technique is not
specific for indicator or pathogenic organisms, it can be
used only to supplement or replace non-specific plate count
methods used for investigating the quality of finished
water. It may be valuable for monitoring the quality of
supply waters or for obtaining rapid analyses of line breaks
or other emergency situations.

5. Summary

The indicator systems in this section are extremely
varied, ranging from fecal indicators and pathogens to
biomass estimates, including new, faster, and automated
methods to increase speed and sampling efficiency. It is
clear that not all of these organisms or techniques have the
same health and sanitary significance, nor are they all
applicable to the same types of waters.

It seems evident that the "classical" fecal indicator
organisms have served rather well in preventing transmission
of human disease by drinking water and shall continue to be
used for some time to come. Total coliform enumeration, for
example, is of limited value in the determination of raw
water quality, but is a sensitive method for determining
finished water quality and treatment adequacy. Total coli-
forms in drinking water do not necessarily reflect fecal
contamination, but their presence should alert the respon-
sible agency to a possible problem, and action can then be
taken to find the cause and correct it as necessary. Thermo-
tolerant coliforms (fecal coliforms) or Escherichia coli and
Clostridium perfringens, on the other hand, can be employed
for both raw and finished drinking water. The presence of

any of these organisms in finished water should be an immediate cause for concern and should be followed by resampling and corrective measures. Their level in the raw water is generally considered valuable in determining the type and degree of treatment required. Obviously, the greater the degree of contamination of the raw water, the more safeguards (perhaps both intensified treatment and stepped-up testing of the finished water) will be required to protect the consumer. Clostridium perfringens is a particularly hardy organism because of its ability to form disinfectant-resistant spores; it may thus be of value in determining the adequacy of water treatment and filtration. Fecal streptococci are of limited value in monitoring finished water quality, except when gross contamination occurs, but are used extensively for raw water. The judicious use of this indicator can greatly assist in determining the source, distance, and time of pollution of the raw water, when the studies are done in conjunction with other indicators such as thermo-tolerant coliforms.

Since this group of fecal pollution indicators is so important and routinely used, any procedural modification that reduces cost, speeds up the analysis, or reduces the labor involved is considered an improvement. For this reason, the 7-h membrane filtration fecal (thermo-tolerant) coliform test appears to be a valuable method, especially for emergency use, such as when finished drinking water is found to be polluted as a result of main breaks or cross contamination with sewage pipes. The presence-absence test is applicable to finished water only; it quickly and cheaply screens out all coliform-free samples, so that the positive samples can be given more detailed analysis. Both the automated sampling and plating methods and the automated plate counting methods could be applied in specific settings for these organisms. At present, they are not widely used, but further improvements in automation and data handling, as well as the increased costs for personnel to carry out routine analyses, will eventually make them more attractive. Other methods presented here, that show potential for thermo-tolerant coliform indicators, are radioisotope methods, impedance methods, and enzymatic methods. Each of these has been tested to a limited extent, to determine levels of coliforms or Escherichia coli and may have more widespread application in the future. They represent the application of physical and chemical technology to the field of drinking water microbiology, an endeavor that must be encouraged.

The analysis of fecal sterols is emerging as a promising indicator that eliminates some of the drawbacks of fecal

bacteria indicators. The fecal sterols display many adsorption and elimination properties similar to viruses and bacteria, but additionally, are not affected by most disinfection processes, by elevated temperatures, nor by toxic effluents. Further work is required to determine their ultimate applicability.

Certain other organisms are considered here, as indicators, because of their applicability in certain problem areas and their properties as pathogens or opportunistic pathogens of susceptible humans. Pseudomonas, Klebsiella, and Aeromonas are common opportunistic pathogens in water and are able to multiply under relatively low nutrient conditions, sometimes causing problems in the distribution system. It is worthwhile to monitor for these organisms occasionally, or when there is a known problem. Their health significance in low numbers in finished water is not well established, but their presence indicates potential problems in the treatment or distribution system and should stimulate more intensive sampling and investigation. The presence of Klebsiella in raw waters is often the result of its growth in carbohydrate-enriched waters, and its effect as a positive bias on total coliform and thermo-tolerant coliform counts is well known. Vibrios are becoming increasingly important as pathogens in the marine and estuarine environment, as is Candida albicans in the fresh-water environment; both warrant further study in reference to drinking water quality. Bifidobacteria show extremely good promise as a fecal indicator and are receiving increasing attention: the problem at this time is the lack of adequate methods for measuring them.

In addition to the presence of fecal material and human pathogens in water, there is concern for the general bacterial population in tapwater. General bacteria are usually present in much larger numbers, in both raw and finished waters, than organisms of health and sanitary significance, and they may have important consequences. First, when present at levels greater than 500 per ml, they greatly diminish the ability to detect total coliforms in the water, thereby adversely affecting the accuracy of that method. Second, increases, particularly sudden ones, in total bacterial colony counts may signal a change in water treatment efficacy, distribution problems, or other sources of contamination even before the traditional fecal indicators can signal such a change. They are also useful to determine bacterial growth in point-of-use water treatment devices. Plate count methods vary as to procedure, media, and incubation temperature; a new membrane filter method is described

that is more versatile and economical than some of the pour-
plate or spread-plate methods. Two other possible mechanisms
exist to determine numbers of bacteria in water: direct
counting and biochemical measurements. The epifluorescence
method has the distinct advantage of being very fast and can
be particularly useful in emergency situations. Among the
biochemical methods, measurement of ATP is probably the one
most often used, although concentration methods are required
for low bacterial levels in finished drinking water. The
Limulus lysate assay is much more sensitive, and can easily
detect the low levels of lipopolysaccharides derived from
the cell walls of gram-negative bacteria in tapwater.
Further research is required to ascertain how these methods
relate to the more common plate count methods.

The problem of an adequate indicator system to signal
the presence of human enteric viruses in water is one that
has not been resolved. Bacteriological indicators of fecal
pollution are not always adequate for this purpose because
of the greater ability of viruses to resist environmental
extremes and disinfection processes. Concentration, elution,
and cell culture techniques do not exist for all of the
viruses known to be transmitted in water, so it is impos-
sible to detect them all even if it were economically
feasible to do so. Vaccine polioviruses are a logical
enteric virus indicator because of their relative abundance
in waters in areas where trivalent oral polio vaccine is
used. Present data leave some doubt, however, as to the
adequacy of polioviruses for this purpose, for they are not
detected in waters with the frequency that would be pre-
dicted on the basis of the numbers of persons excreting
them. Coliphages, on the other hand, are found in much
larger numbers and are not dependent upon the use of vac-
cines in the population. The ideal host for this method,
and the actual relationship between the occurrence and
survival of these bacterial viruses and human viruses is
still open to question. Thus, until the basic question of
virus indicators is settled, routine analysis of drinking
water for fecal pollution indicator bacteria and the main-
tenance of sound water treatment and disinfection prac-
tices must be relied upon to ensure the virological quality
of the water.

The list of indicator systems considered here is not
exhaustive; there are many others that could have been
included. Some of those selected, however, are among those
most firmly established, others are among the most promising,
and still others are among the most interesting. It becomes

evident very early that even though the field of water microbiology is by no means new, there is still no best indicator system for every situation, nor is there ever likely to be one. Each situation may require one or several microbiological tests that can be selected from the ever-changing array of indicator systems.

6. Recommendations

    1. Colony counts should be used in conjunction with total coliforms to assess finished water quality and to monitor for any changes in water quality along the distribution system. A limit of 500 colonies per ml at 35°C should be considered for finished water, to reduce problems with detection of total coliforms due to interference from non-coliforms.

    2. Membrane filtration media for total coliform enumeration should be developed to replace those requiring the dye, basic fuchsin, in view of the impending shortage of this dye.

    3. Membrane filter methods for detecting Escherichia coli should be improved to permit faster and simpler enumerations with disinfected water.

    4. Better selective media and methods should be developed for recovery of bifidobacteria in raw and finished water. Bifidobacterium should be studied, extensively, in its role as a fecal indicator.

    5. Studies should be carried out to determine sources of Candida albicans (e.g., humans, birds, animals, etc.). Also needed are studies to determine the survival rates of C. albicans in water treatment and disinfection processes. In addition, the relationship, if any, between densities of C. albicans and classical indicators should be determined. Finally, the role of sediments in concentrating C. albicans in drinking water collection basins and other receiving waters should be evaluated.

6. The significance to human health of vibrios present in raw source waters should be determined.

7. Attention should be given to the use of immobilized enzymes and other rapid methods for determining adenosine triphosphate (ATP) levels.

8. Studies should be carried out to determine the mechanism by which coprostanol is degraded in water and what the effects are from environmental factors. Coprostanol persistence and baseline levels in surface waters and sediments should be determined.

9. The impedance method should be further refined to make it sufficiently sensitive and fast for on-line analysis of finished water.

10. Automated sampling and plating devices should be improved to enable detection of anaerobic sporeforming organisms. Concentrators for these devices need to be developed so that assays may be sensitive enough for use with finished water.

D.   TESTING AND STANDARDS

Tests to assess the microbiological quality of drinking water rely largely on the recovery or enumeration of coliform bacteria, thermo-tolerant coliform bacteria, or Escherichia coli and, in some instances, aerobic heterotrophic bacteria. Formal standards of drinking water quality usually are based on numerical values derived from specified test procedures.   While it may be assumed that coliform or thermo-tolerant coliform bacteria are identical and unaffected by national boundaries, differences in test procedures may produce differences in results because, in part, the definitions are functional and depend on the analytical procedures used.   To evaluate these differences, a survey was conducted among the participant nations to identify analytical techniques and water quality standards.   To simplify the data gathering and reporting and to make possible direct comparisons in definitions and techniques, the information has been summarized in a series of tables [Tables D-1 to D-6].   Although these tables are largely self-explanatory, some general comments are necessary.

The questionnaire was prepared in English and was keyed to the practices used in the U.S. as described in Standard Methods (American Public Health Association, 1976).   This led to some difficulties of interpreting the questions and may have resulted in inappropriate responses.   One major area in which this problem consistently occurred was that of quality assurance.   The term quality assurance usually is understood as an assessment, statistical or otherwise, of the quality of the product.   What was not clearly understood was the nature of the product.   Thus, some respondents dealt with water quality as indicated by standards, while others responded in terms of quality control within the laboratory. Although it was intended that this latter subject be addressed, it frequently was not.   Irrespective of the information provided herein, it is clear that control of personnel, procedures, materials, etc. in the laboratory, is of paramount importance, but often is not dealt with officially.   Excellent

guides to quality assurance practices in health laboratories
in general (Inhorn, 1978) and in drinking water laboratories
(Environmental Protection Agency, 1978) are available.

An additional difficulty lies in the occasional absence
of a formal national methodology or in the failure of some
laboratories to conform to the national methodology. This
problem is compounded by the continuing evolution of laws
and regulations so that changes in procedures are constantly
underway. Hopefully, the tables summarize the officially
accepted techniques whether or not they are in current use.

1. Sampling and Sample Storage

Table D-1 summarizes the data obtained for sampling
frequency, sample size, and sample storage. Generally,
sampling of both raw and treated water is not required (except in
the Netherlands, Norway, and Sweden), and primary control of
bacteriological quality of water is attempted through col-
lecting and analyzing samples from distribution systems.
Typically, the required frequency of sampling is a function
of the population served or the volume of water distributed
by a water system. The required sample size varies from 50
to 800 ml with the average being about 200 ml. Although many
European countries require refrigeration of water samples
not analyzed within 3 to 4 h, this is not mandatory in
Canada unless sample transit times exceed 24 h, nor in the
U.S., where ambient water temperature is acceptable provided
no sample awaiting analysis exceeds a 30 h limit. Replies to
the questionnaire indicated a consensus of opinion that a
temperature above freezing, but less than 10°C, probably is
adequate. Despite the recognition that holding samples,
even though they may be chilled, may affect the bacterio-
logical content of the samples [See Sections E.1 and G.6],
storage of up to 36 h (Sweden) is permitted. Problems of
sample transport clearly influence the maximum holding time
and every effort must be made to keep the time to a minimum.

2. Total Coliform Testing, Membrane Filter Technique

Table D-2 summarizes the data obtained with respect to
the definition of total coliform bacteria and the analytical
details used for the membrane filter technique. Two types
of definitions are used: one is based on specific phy-
siological and morphological characteristics of the organisms
(aerobic or facultatively anaerobic, rod-shaped, gram-nega-
tive, nonsporeforming); the other definition is based di-
rectly on the analytical technique used (organisms producing
a typical sheen on a defined medium). Some definitions,

9.	Water quality standard, specify	No coliforms/ 100 ml	Undisinfected surface water: good < 1/100 ml; not fit for use > 30/ 100 ml; disin- fected surface water; good < 1/100 ml; not fit for use > 2/100 ml; in a year 80% of samples should be good	No E. coli/ 100 ml; coliforms: good < 2/ 100 ml tolerable > 2 - < 10/ 100 ml unsuitable > 10/ 100 ml		Treated water: no coliforms/ 100 ml; in practice, the standard is not always obtainable in the distribu- tion system, and the fol- lowing stand- ards apply: in a yr, 95% of samples coliform free; no samples > 10/100 ml; no coliforms in 2 successive samples	1/100 ml as arithmetic monthly mean, 4/100 ml in < 1 sample if < 20 samples/ month; 4/100 ml in 5% of samples if > 20 samples/ month

additionally, include the negative cytochrome-oxidase reaction (Canada, FRG, and U.K.). Other definitions are derived from liquid enrichment culture procedures that specify the production of gas or acid and gas from a medium containing lactose (FRG, France, Netherlands, and U.K.). Irrespective of the formal definition, all countries generally have a common understanding of the term total coliform bacteria.

Sample size is relatively uniform at 100 ml, although 50-ml samples are occasionally specified or permitted. With two exceptions (Norway and Spain), analysis of replicate sample portions is not required and diluted samples are not routinely analyzed. In the event that sample dilutions were necessary, as would occur with highly contaminated raw or untreated waters, there is no consensus with regard to type of diluent used. Distilled water, tapwater, normal saline, Ringer's solution at 1/4 normal strength, 0.1 percent peptone water, or phosphate buffered distilled water are all used.

The membrane filter itself is relatively standardized at a diameter of 47 or 50 mm with a pore diameter of 0.45 um. It is most commonly purchased sterile; if not, it is boiled for 5 to 20 min or sterilized by autoclaving for 10 min at 121°C.

With only one exception (Canada), every country uses a single-step rather than a two-step (enrichment and transfer to final medium) procedure. The single-step medium may be liquid (M-Endo broth or 0.4 percent Teepol broth) or solid (LES Endo agar, Endo agar, Chapman agar, or 0.4 percent Teepol agar). In the two-step procedure, which is seldom used in drinking water testing, lauryl tryptose is used as the enrichment medium. Media are sterilized by steaming for 30 min on three consecutive days (Greece and U.K.), heating to boiling (for M-Endo broth) or autoclaving at 120 to 121°C for 15 or 20 min. Incubation, most commonly, is for 20 to 24 h at 35 or 37°C, although several countries use two-step incubation (Greece and U.K. -- 4 h at 30°C, then 14 to 16 h at 35 to 37°C; Netherlands -- 6 h at 25°C, then 12 h at 37°C).

The specified appearance of the coliform colony is a function of the medium used. For Endo-type media, a metallic sheen and/or a red color is required; with Teepol media, coliform colonies appear yellow; and with Chapman agar, coliforms appear yellow to orange. Colonies on membranes
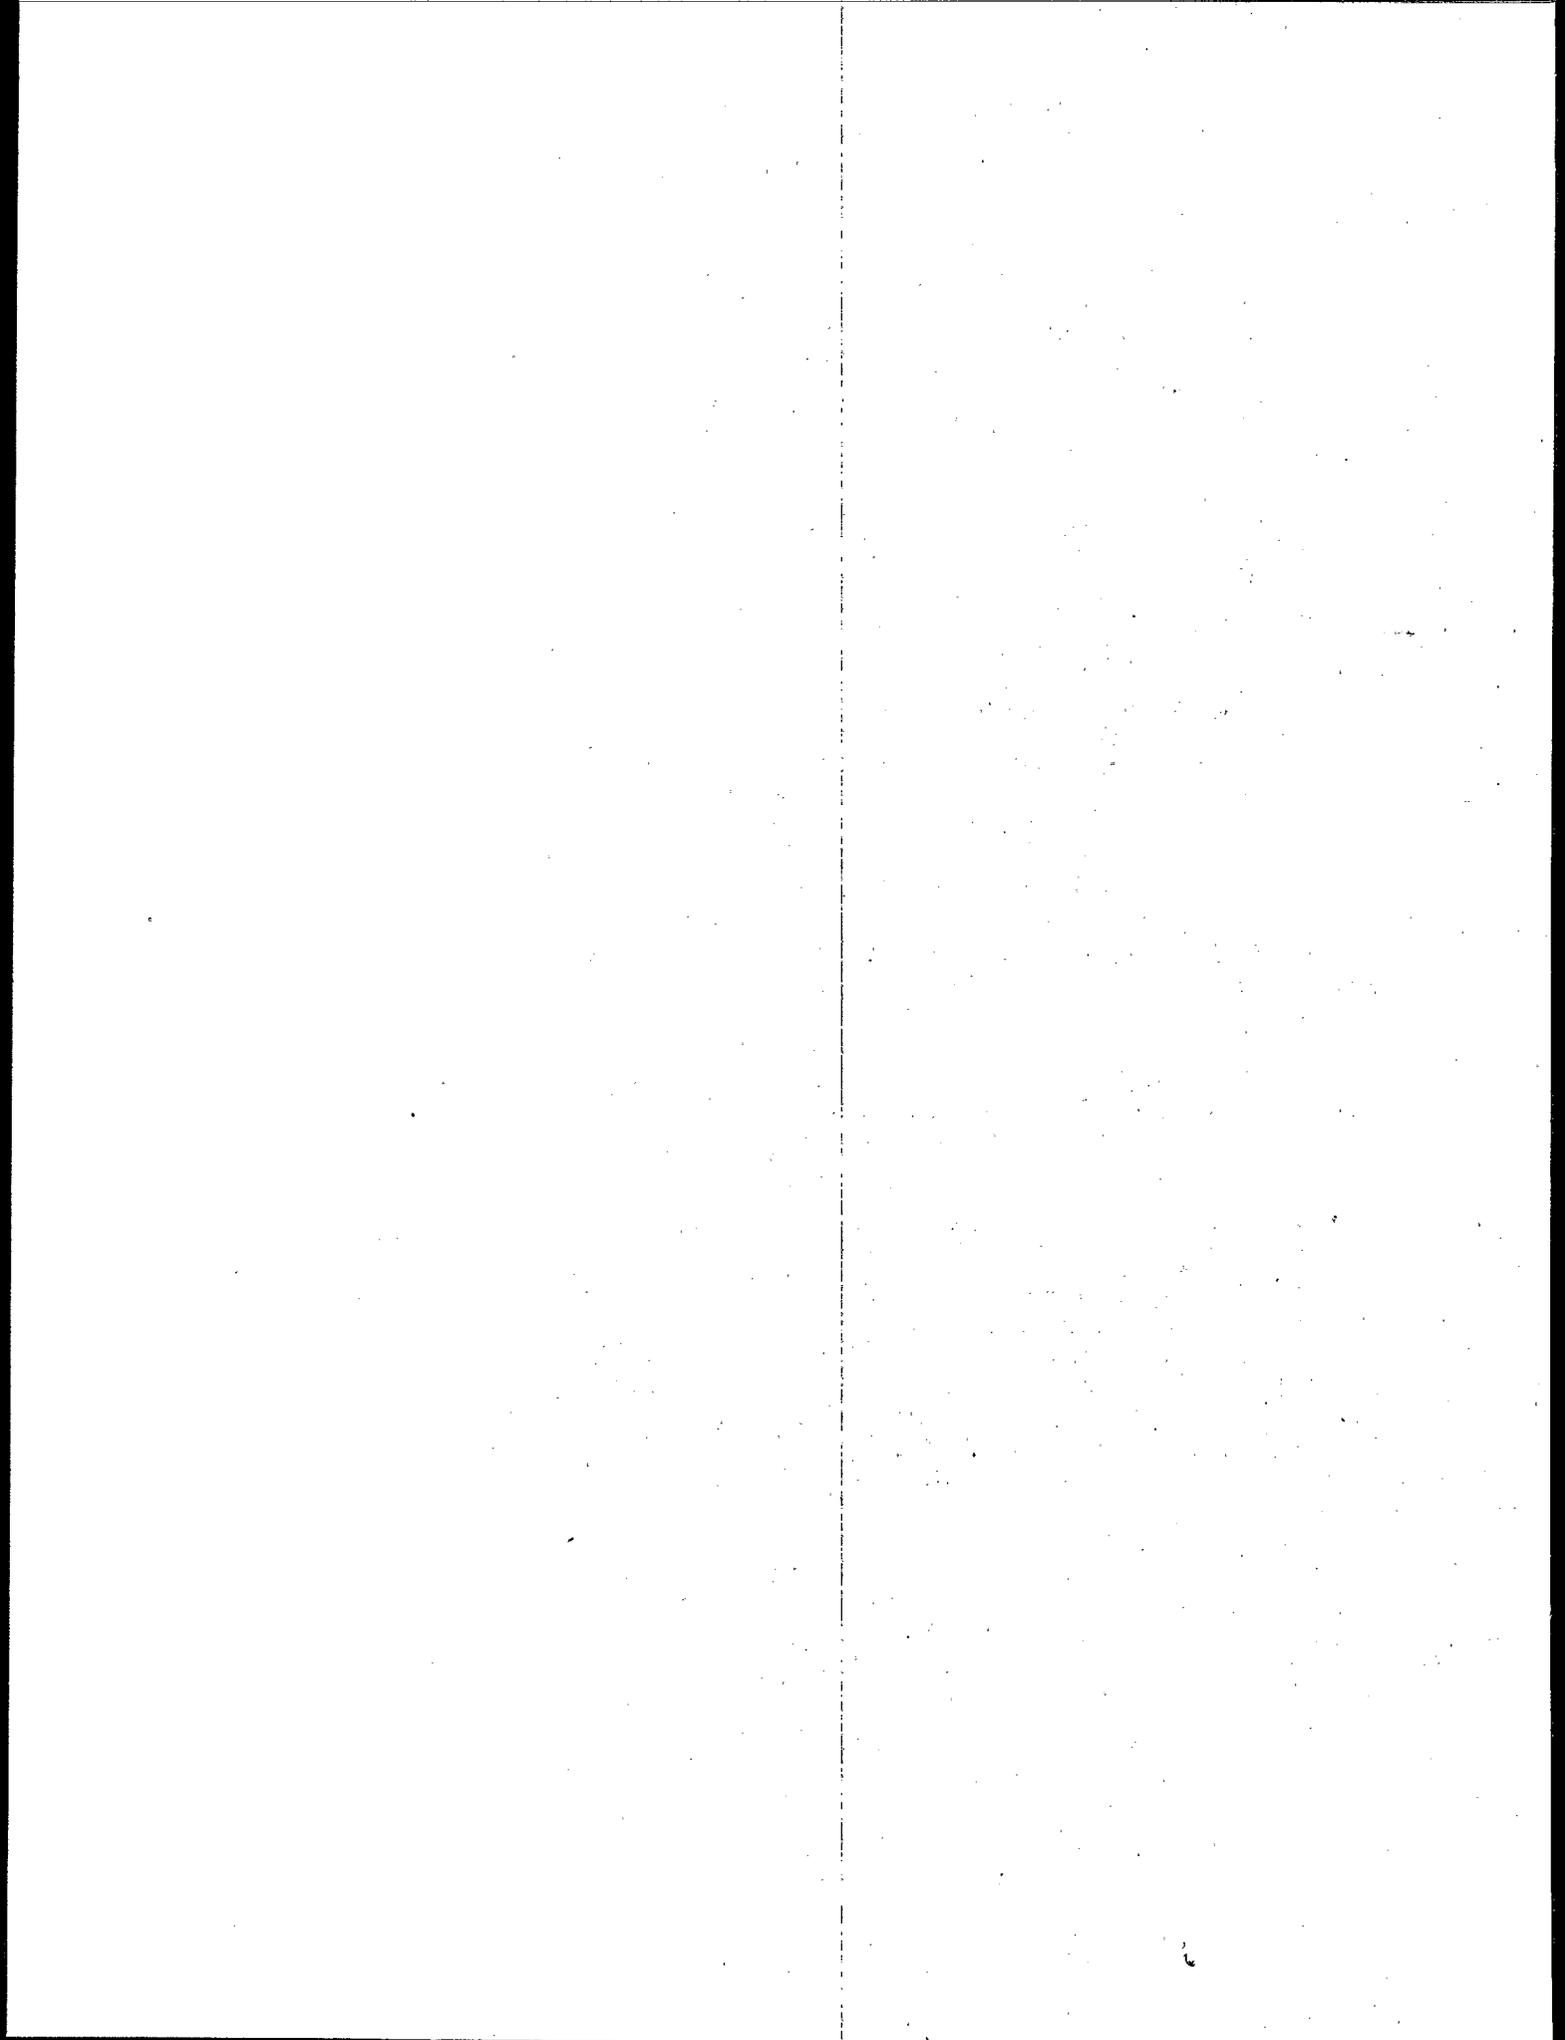

may be examined with or without magnification. Results uniformly are reported as a number per 100 ml.

Verification of coliform colonies is interpreted by the use of additional tests such that the colony identified as a coliform on the membrane filter conforms to the above definition of coliform bacteria, except where the practice is to confirm the colony as E. coli which has a different significance. The simplest procedure for verifying coliforms involves transfer to lactose-containing media (lauryl tryptose broth and/or brilliant green bile broth) and the demonstration of gas after up to 48 h incubation at 35 to 37°C. Lauryl tryptose broth and brilliant green bile broth are not used for coliform verification in the U.K., on the premise that an inhibitory agent is unnecessary where the inoculum is from a single (and presumably pure) colony. More involved techniques include determination of cytochrome-oxidase activity and citrate utilization as well as gram stain. Verification usually is not required.

The criterion for the bacteriological acceptability of water is the absence of coliform bacteria (in 100 ml) [See also Section C.1.b]. Because of procedural and statistical complications, this is variously stated as < 10 coliforms per 100 ml, < 1 coliform per 100 ml, etc. Most countries include in their standard the sampling frequency, how frequently coliforms are found, and an absolute coliform number. The membrane filter procedure is not formally specified in several countries (Greece, Israel, Italy, and Sweden) and appears not to be used officially in Italy and Sweden (Sweden has proposed its use as an official procedure).

3. Total Coliform Testing, Multiple Tube Technique

Table D-3 parallels Table D-2 for total coliform testing, but by the older multiple tube technique rather than the newer membrane filter procedure. The definitions of coliform bacteria are comparable to those given in Table D-2, but are restricted to organisms producing gas or acid and gas from a medium containing lactose.

The simpler procedures require testing of five 10-ml or five 100-ml portions of the sample (Canada and U.S.). All other countries use various combinations of sample volumes and tubes per dilution such as ten 10-ml, five 1-ml and one 0.1-ml portions (France); five 10-ml, one 1-ml, and one 0.1-ml portions (Israel); and five 100-ml, five 10-ml, and five

Water quality standard	90% of samples in consecutive 30 days negative; no coliforms in 2 consecutive samples; no sample with MPN > 10/100 ml	Coliforms should be absent in 100 ml	Coliforms should be absent in 100 ml; no E. coli/100 ml	See Table 2, #9	See Table 2, #9	Good: < 2/100 ml; repeat sampling: 3-10/100 ml (if positive, check for fecal coliforms); > 10/100 ml, repeat sampling immediately	Coliforms and thermo-tolerant coliforms should be absent in 100 ml

	Netherlands		Norway	Spain	Sweden	UK	US
8. Water quality standard	See Table 2, #9	See Table 2, #9	See Table 2	Clean water; suitable < 1/ 100 ml; un- suitable > 10/100 ml	See Table 2, #9	10 ml sample: < 10% tubes positive/month 100 ml samples: < 60% tubes positive/month	

[1] MPN = Most probable number derived from tables in Standard Methods (American Public Health Assoc., 1976). 14th edition, pages 923-925.

[2] Method of choice = Membrane filter technique.

[3] Unofficial confirmation uses brilliant green bile broth. Official procedure requires confirmation of E. coli (gas in bile broth and indole production, both at 44 ± 0.5° or isolation and identification of all coliforms (by streaking on EMB and incubating at 30° for 24 or 48 hours followed by IMViC tests).

1-ml portions (Sweden). If diluted samples are required, the diluents mentioned above are used.

For the presumptive test, lactose or lauryl tryptose broth are most commonly used, although several countries use chemically defined media (minerals modified glutamate broth -- Greece and Netherlands; improved formate lactose glutamate broth -- U.K.). All countries except Norway (which uses triple-strength) use double-strength presumptive medium for sample portions of 10 ml or more. For the confirmed test, brilliant green bile broth is most common except where Endo agar (FRG), MacConkey agar (Greece and Israel), or lactose ricinoleate broth (U.K.) are used. EMB or Endo agar, lactose or lauryl tryptose broth, and nutrient agar are used for the completed test. Media are sterilized by autoclaving at temperatures as high as 121°C for 15 min (Canada, Israel, Italy, Netherlands, and U.S.) and 120°C for 20 min (France and Spain) and at temperatures as low as 110°C for 15 min (Norway and Sweden).

With the presumptive test, samples are usually incubated for up to 48 h at 35 or 37°C; in the FRG, only a 24 h incubation at 37°C is required; in France and Spain incubation may be at 30°C. Likewise for the confirmed test, incubation is typically for 48 h at 35 or 37°C except for Israel (24 h at 35°C).

A presumptive-positive tube is defined as one in which gas has been produced; if the medium contains a pH indicator, gas and acid production both are required for a positive result (FRG, Greece, Netherlands, Norway, Sweden, and U.K.). Gas production is the characteristic of a positive confirmed test in all countries using a liquid confirmation medium. Results are reported either as coliforms present or absent, percentage of tubes positive, or most often, as the most probable number (MPN) per 100 ml.

The completed test is used for coliform verification and is comparable to verification in the membrane filter procedure. It is not typically required, at least not for all positive samples. As with membrane filter verification, it is sometimes defined in terms of E. coli presence (FRG, France, Norway, and U.K.) by such tests as indole production at 44°C, gas production from lactose at 44°C, or the IMViC series.

The water quality standards are comparable to those described above under the membrane filter technique [See also Section C.1.b].
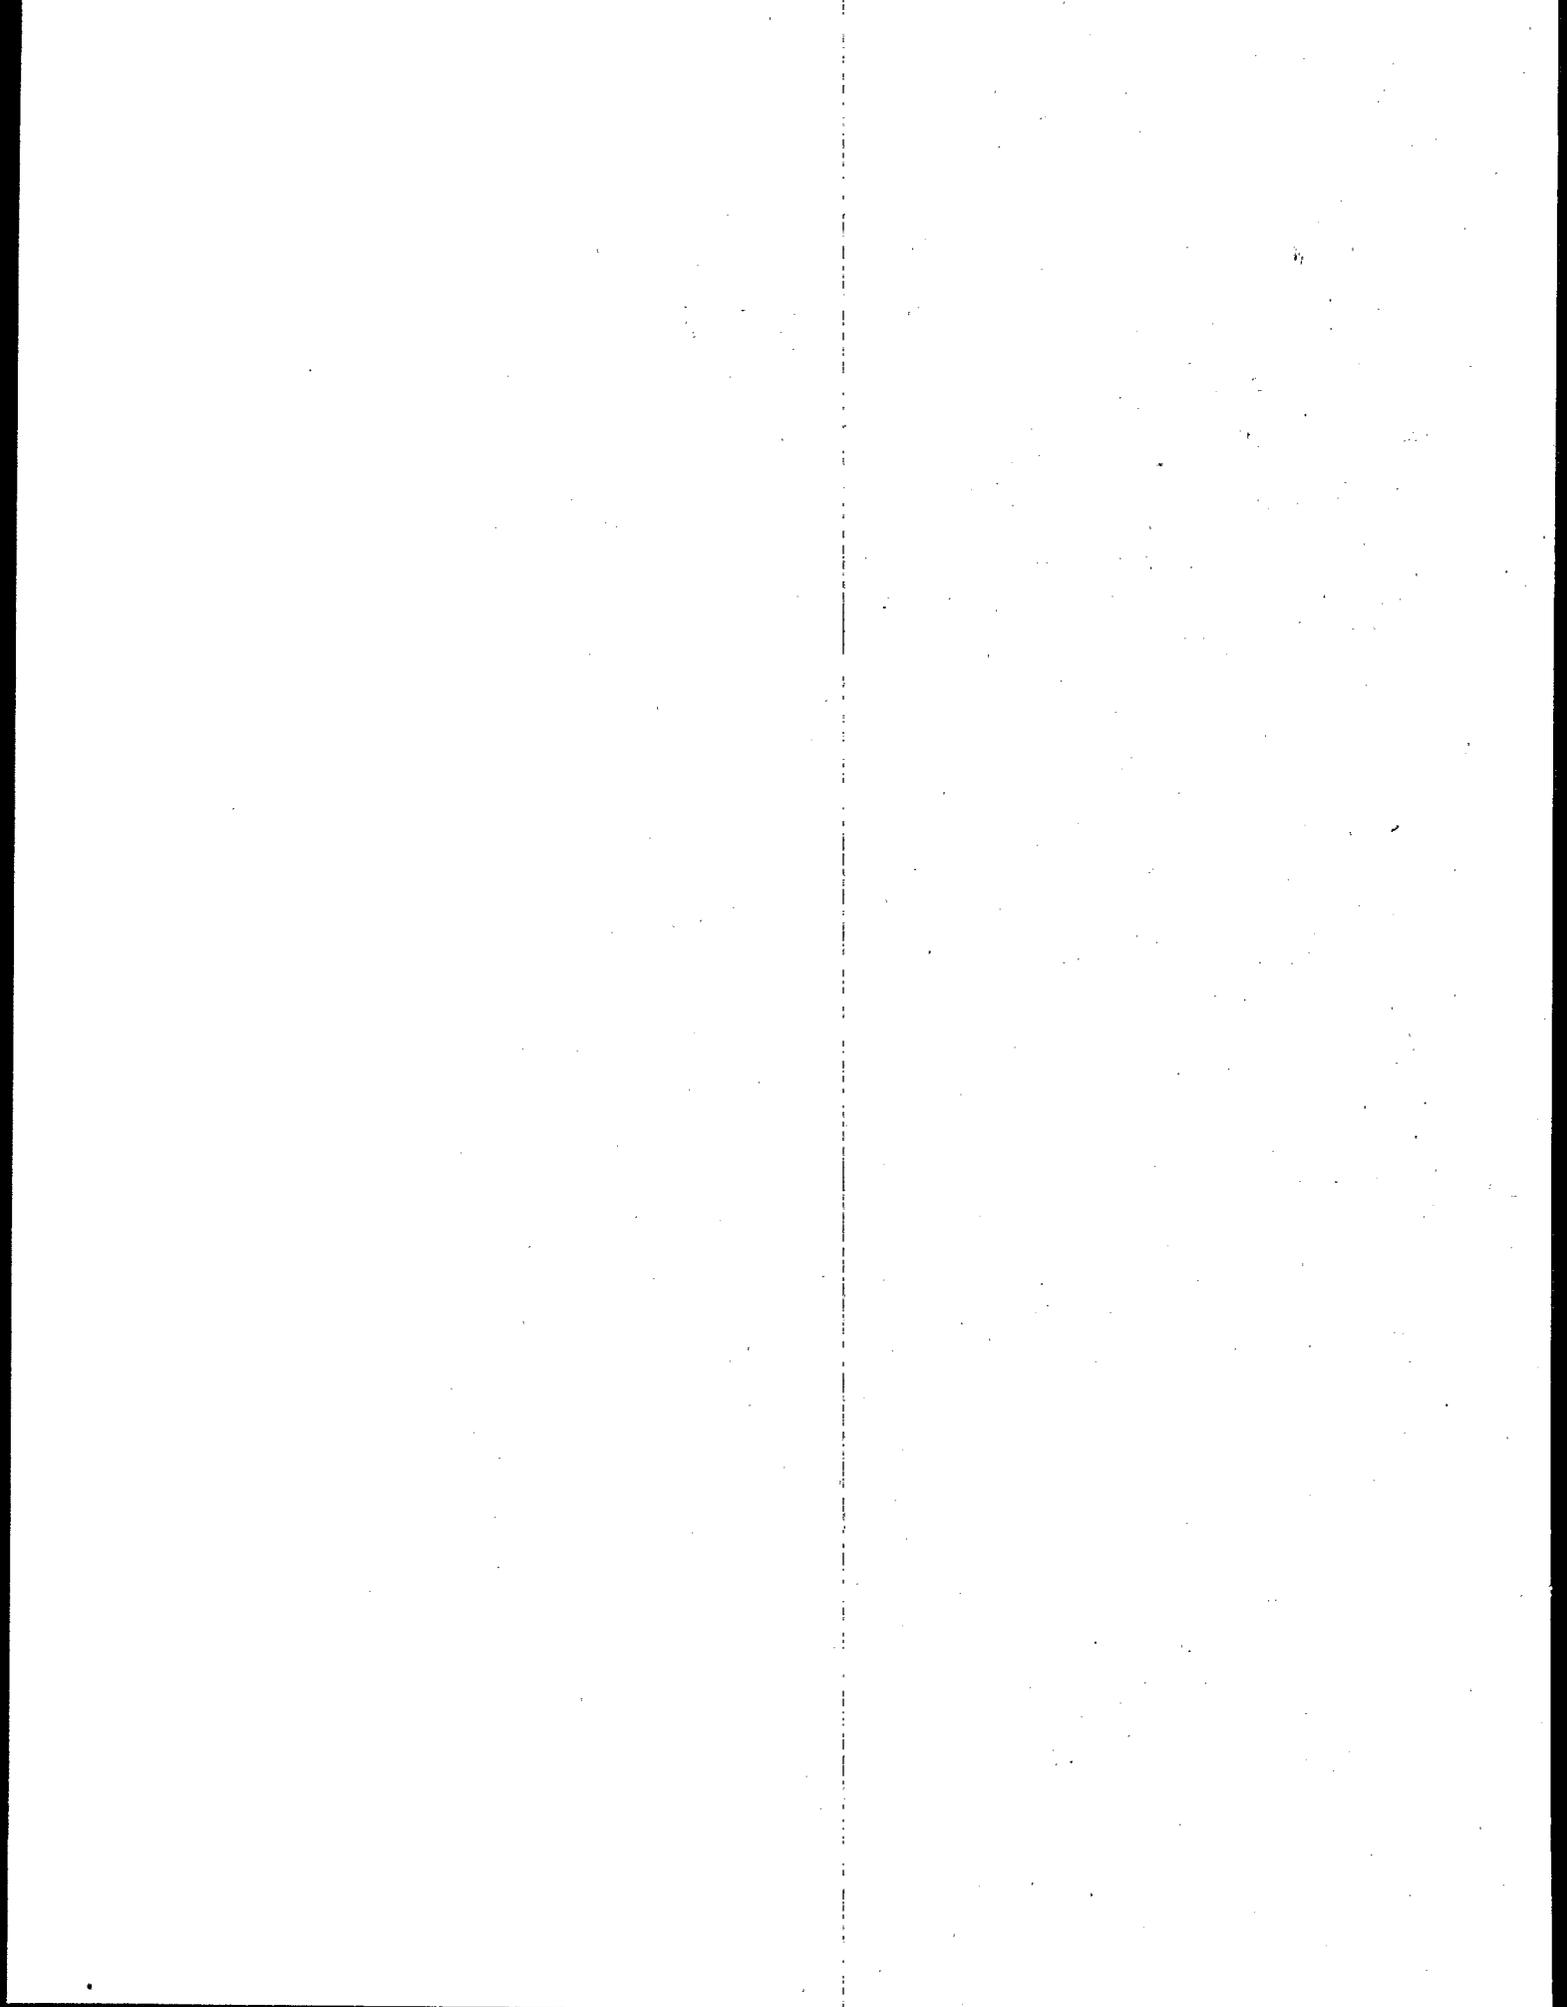

4. Thermo-Tolerant (Fecal) Coliform Testing,
    Membrane Filter Technique

Table D-4 summarizes the data obtained for the defi-
nition of thermo-tolerant (fecal) coliform bacteria and the
analytical details used for the membrane filter technique.
The term "thermo-tolerant" is defined as that portion of the
coliform group capable of producing gas from lactose within
24 h at a temperature around 44.5°C. Several countries use
the term "fecal" coliforms to convey the same information.
Others, the U.K. and the FRG for example, do not base analyses
for sanitary significance on the demonstration of fecal
origin by the ability of coliform bacteria to ferment lactose
at an elevated temperature, but rather, test specifically
for E. coli.

Where the membrane filter method is used, analytical
details are identical to those given in the section on total
coliform testing except that the medium is M-FC broth (Teepol
agar for Denmark) and incubation is at 44.0 or 44.5°C for
24 h; or, in the case of the Netherlands, incubation is 6 h
at 25°C, then 12 h at 44°C; and for Denmark and the U.K.,
incubation is 4 h at 30°C, then 14 to 18 h at 44°C. Thermo-
tolerant coliform colonies will appear blue (or yellow on
Teepol agar).

The total coliform test appears to serve as a primary
criterion in determining the microbiological quality of
finished drinking water. However, tests for thermo-tolerant
coliforms, or for E. coli, are specified in various coun-
tries for evaluation of raw water, of untreated water in
distribution, and even for finished water [See Section
C.1.c].

5. Thermo-Tolerant (Fecal) Coliform Testing,
    Multiple Tube Technique

Table D-5 parallels Table D-4. The generalizations
made above are equally applicable here. The definitions of
thermo-tolerant coliform bacteria are comparable to those
given in Table D-4, although there are some added analytical
steps that are more specific for E. coli than for thermo-
tolerant coliforms as a whole (gas production at 44°C and
negative oxidase and urease reactions).

Except for Italy and Sweden, which make direct inocu-
lations, those countries using the tube technique use it as
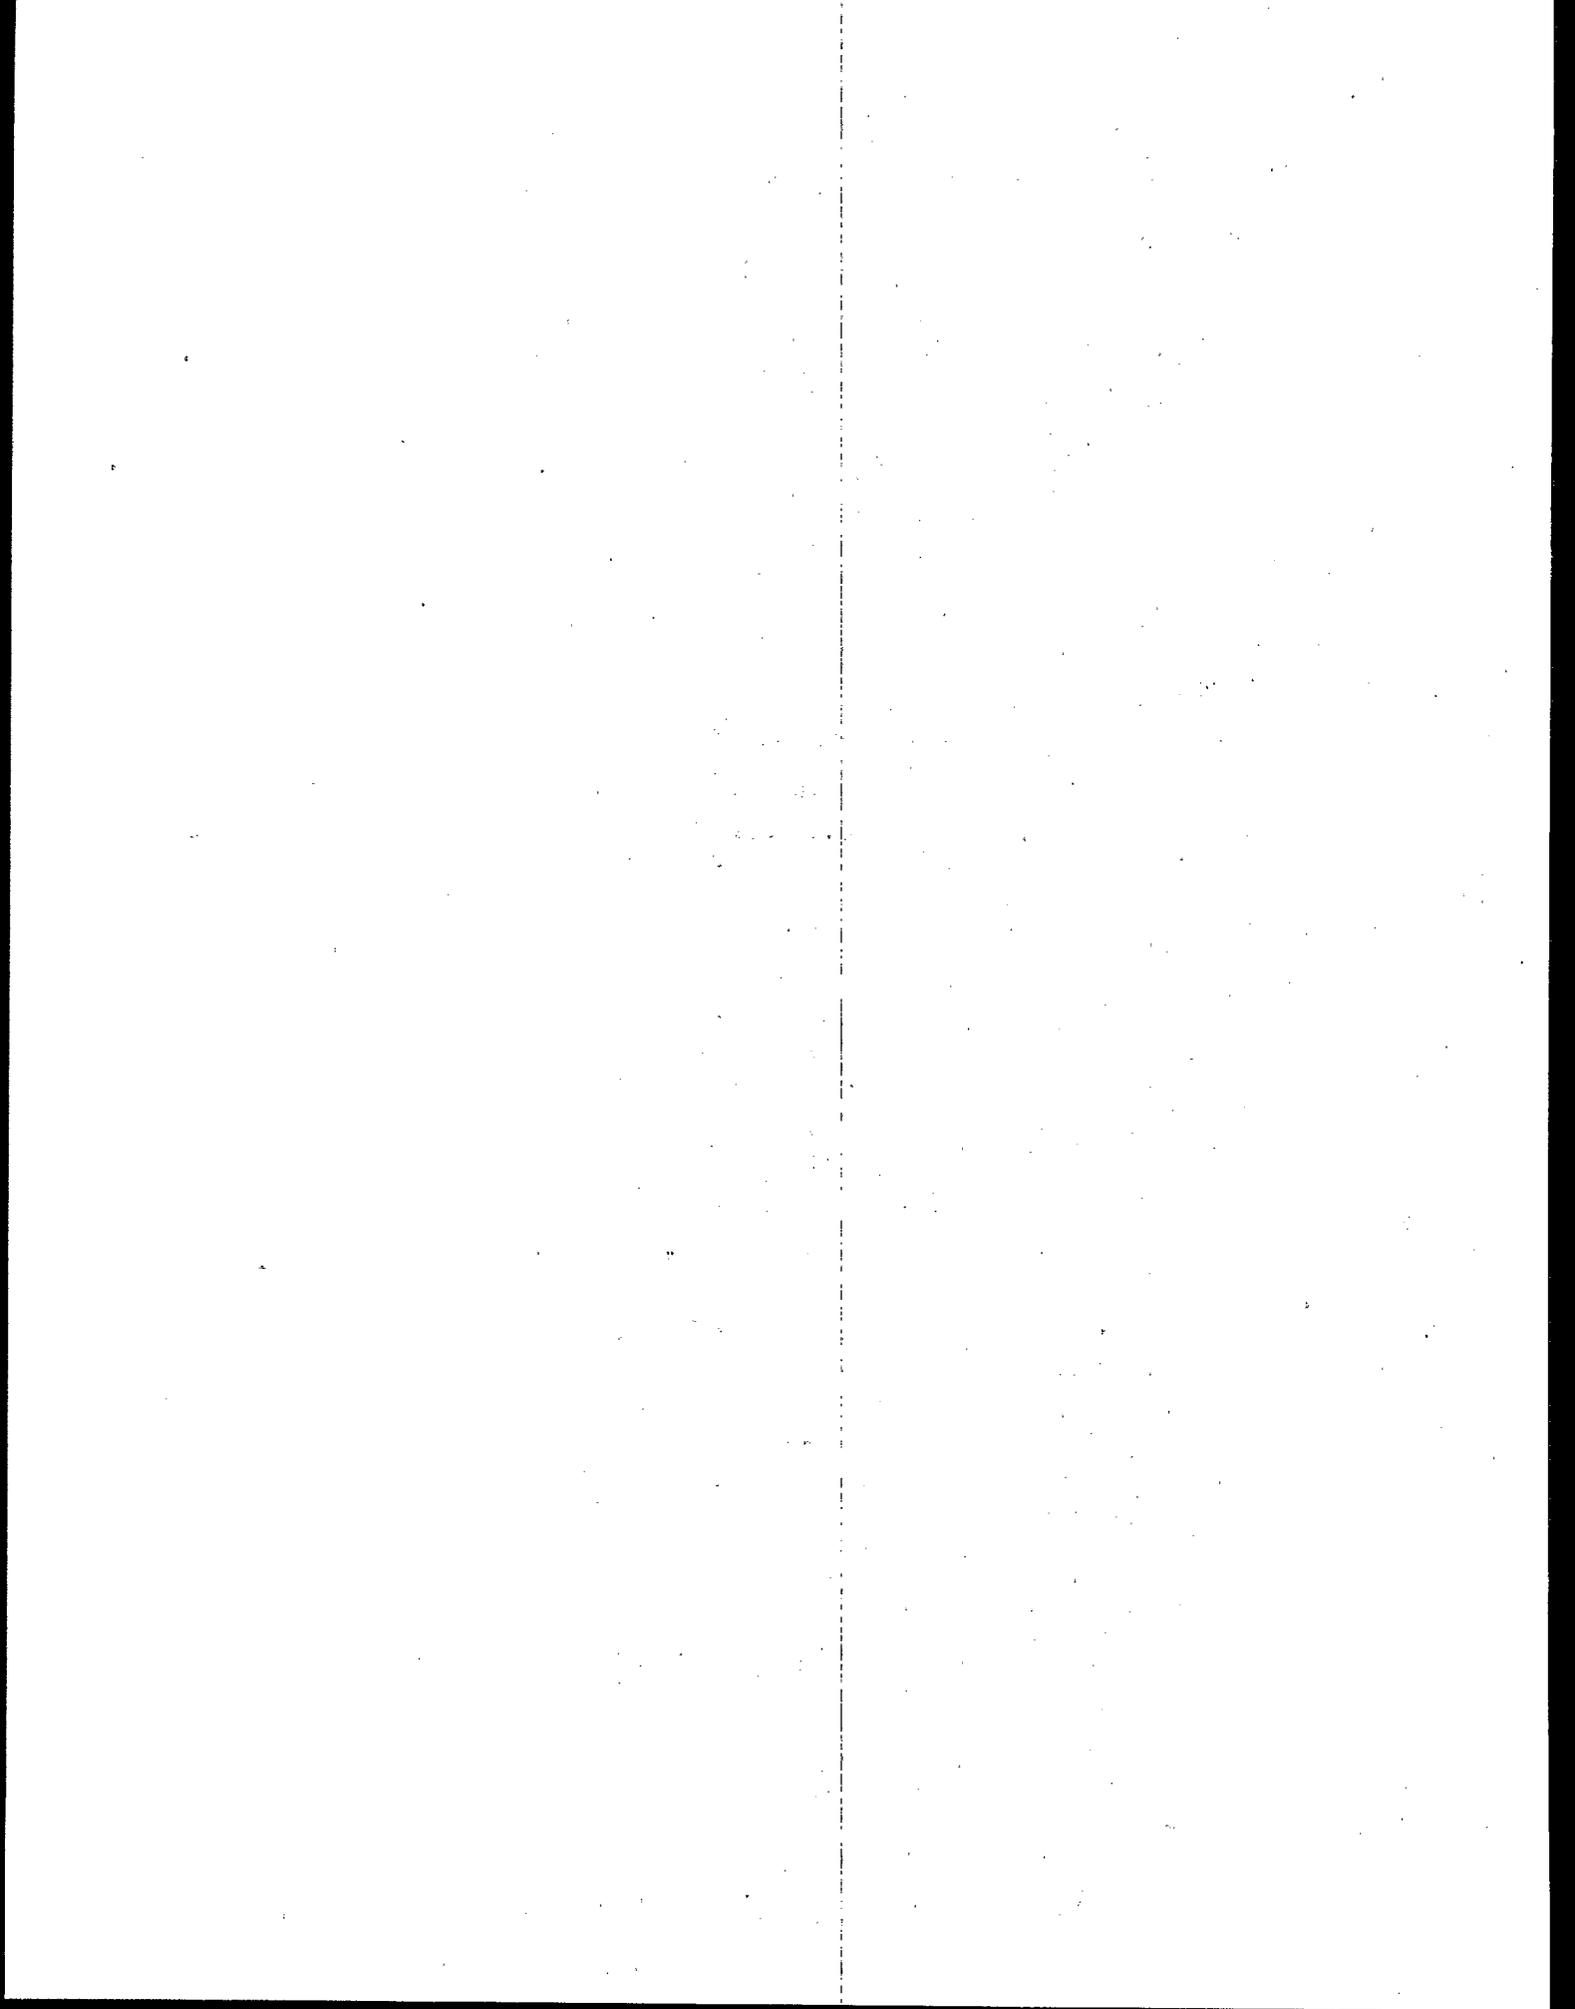

TABLE D-4

THERMO-TOLERANT (FECAL) COLIFORM TESTING, MEMBRANE FILTER TECHNIQUE, DRINKING WATER ANALYSIS

a confirmatory test following the standardized total coliform presumptive test. Brilliant green bile broth or EC medium are usually used with incubation for 24 h at 44.5°C (Canada, Israel, Italy) or 44°C (U.K.); or an incubation of up to 48 h at 44°C (France, Greece, Netherlands, and Sweden). Gas from lactose and indole production (France, Greece, and the U.K.) is the typical positive reaction [See also Section C.1.c]. In Sweden, samples are incubated in lactose broth at 44°C and a confirmatory step normally is not done.

6. Colony Count

Table D-6 summarizes the data obtained on the definition of the colony count and the analytical details used. The term colony count is not uniformly used. Other terms include standard plate count, microorganism or total microbial count; aerobic or mesophilic viable bacteria, and others. Irrespective of the term employed, what is understood is the number of bacterial colonies produced per ml of water under defined conditions of medium and time, temperature of incubation, and magnification for counting. There is considerable diversity of these defined conditions as will be seen below.

Where the procedure is formally used, it is always on the basis of a pour plate technique using, at most, a 1-ml sample, typically with duplicate plates made per sample volume. As already indicated, there is no uniformity in selecting dilution water.

The media generally used are based on extracts of beef or yeast and various peptone breakdown products, solidified by agar. This variety of natural organic substances leads to nonuniformity from medium manufacturer to manufacturer and even from lot to lot when prepared by the same manufacturer. When medium diversity (planned or unplanned) is coupled with different incubation times and temperatures -- varying from 48 to 72 h at 20°C (FRG, France, Norway, and U.K.) to 48 h at 22°C (Sweden), to 48 h at 32°C (Israel), to 24 to 48 h at 35 or 37°C (Canada, France, Greece, Italy, Netherlands, and U.K.) -- it becomes clear that results among different countries cannot be directly comparable. On the other hand, it is likely that any of these national methods would identify gross differences in water quality. This suggests that, unless there is a considerable collection of data within a country, the colony count is difficult to use as part of the water quality standard. That only Canada, the FRG, Norway, and Sweden incorporate such a count into formal standards supports this point of view [See also Section C.1.a].

7. Miscellaneous

The questionnaire on laboratory practices and bacterio-
logical standards also included a seventh set of questions,
in response to which came a tremendous diversity of replies
that could not be presented as tables.

The first of these questions asked about the kinds of
laboratories (national, provincial, municipal, university,
water utility, and nongovernmental or commercial) and their
numbers in each country. Because of different national
administrative arrangements, it is impossible to generalize
about the kinds of laboratories analyzing water. The
number of laboratories involved relates both to the role
played by the central government in water quality control
and, more importantly, to the size of the country. In
Israel and Greece, for example, there are fewer than ten
laboratories; whereas in the U.S. there are thousands of
water laboratories, many of them at water utilities.

Other questions dealt with control of water labora-
tories and the use of standards of laboratory quality. In
most countries, there is no formal system of technical super-
vision or direction for water laboratories, nor are there
formal standards by which the acceptability or general
quality of laboratory services are judged. It is assumed,
however, that internal and interlaboratory quality control
are achieved through good laboratory practices. In Sweden,
laboratories are controlled by the National Board of Health
and Welfare and each analyst is required to have a personal
authorization although, in practice, authorization is
required only of the supervisor. Comparable authorization
for the laboratories is under consideration. In the U.S.,
each laboratory must be approved by the state in which it is
located.

Responses to questions concerned with interpreting
laboratory results and acting on laboratory findings were
varied: interpretation of results and initiation of cor-
rective action are carried out by the water analyst, a water
engineer, or a health authority. No consistent pattern was
evident.

8. Summary and Conclusions

Bacteriological assessment of drinking water quality is
typically based on the coliform group of bacteria. Less
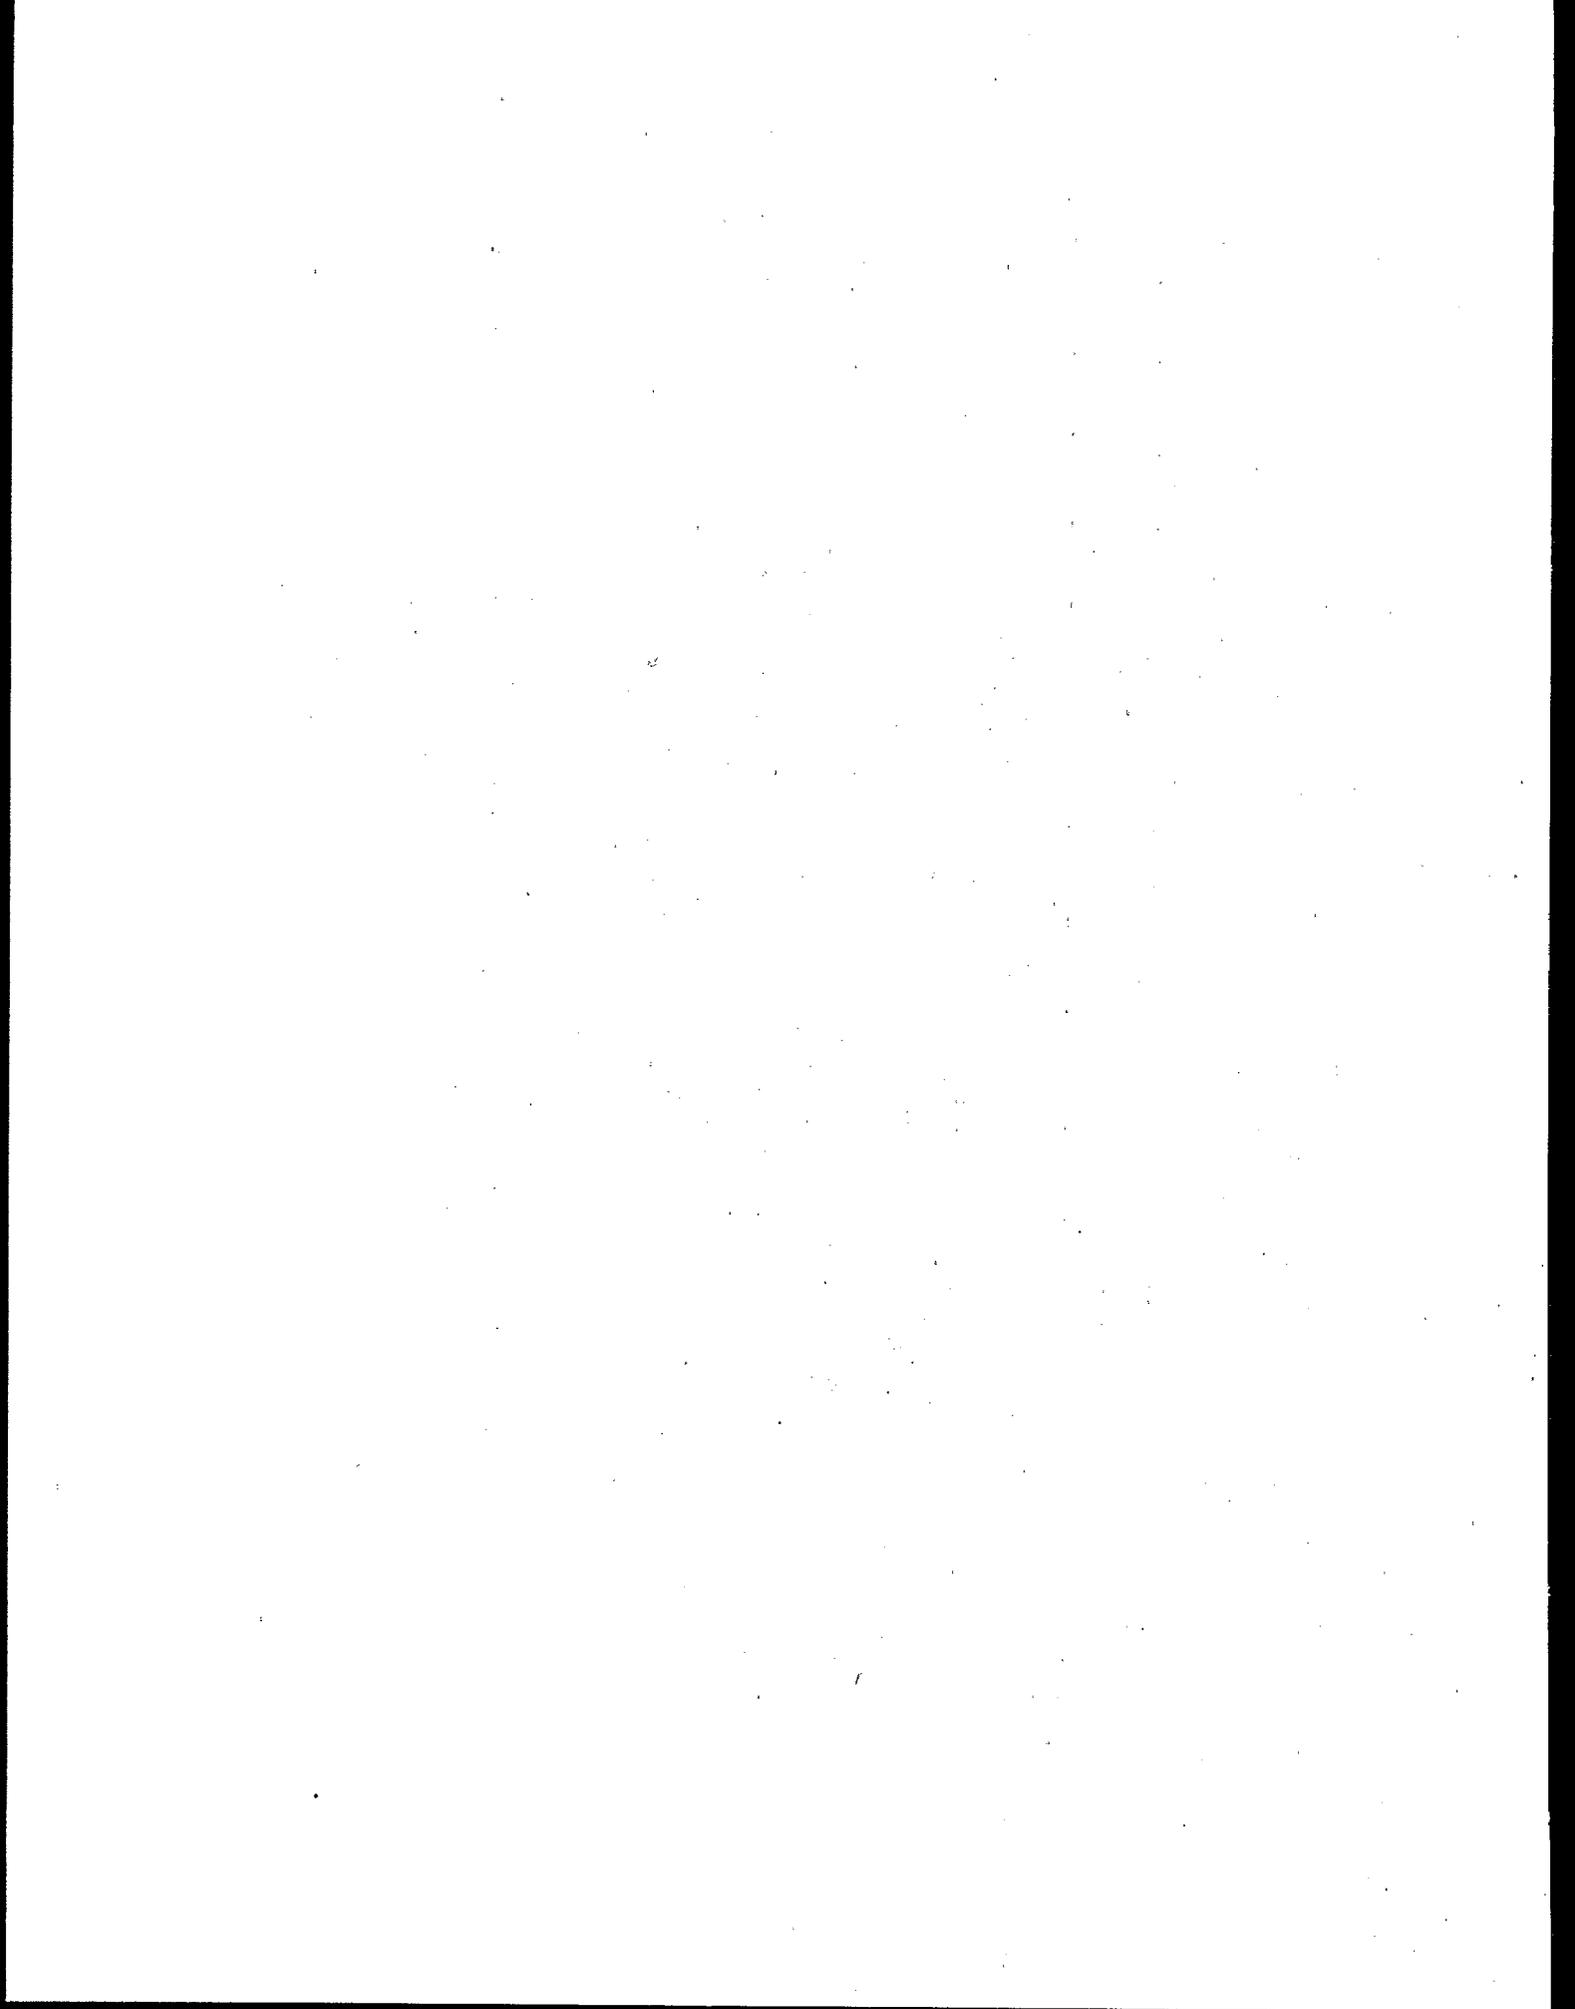

frequently, standards are based on thermo-tolerant coliform
bacteria or even E. coli. Still less often, a count of
aerobic heterotrophic organisms is required.

The analysis for coliform or thermo-tolerant coliform
bacteria may be conducted either by the multiple tube tech-
nique, with results reported as a most probable number (MPN)
per 100 ml, or by the membrane filter procedure,which yields
a colony count. The least methodological diversity exists
for the total coliform test even though there is no uni-
versally accepted medium or procedure. It may be concluded,
however, that the specified procedures, when correctly
followed, will provide closely comparable results.

Tests for thermo-tolerant coliforms are more varied,
most notably in the time and temperature of incubation. The
significance of these differences probably is slight.

The least uniform test is that made for the colony
count. Here, differences in media and incubation procedures
may yield markedly different results and comparisons across
national boundaries may be impossible, although the extreme
case of a very high count would be identified irrespective
of the procedure used.

Despite the existence of formal standards of water
quality, there are seldom formal standards of laboratory
quality; that is, formal laboratory quality control programs,
such as in the U.S., seldom exist. It may be concluded that
this subject is most in need of attention.

9. Recommendations

1. Greater efforts should be made at the national
    and international level to obtain maximum
    comparability of data by the use of uniform
    analytical methods. The procedures of the
    European Economic Community appear most suitable
    for universal adoption.

2. The absence of formal laboratory quality as-
    surance programs should be remedied. Proce-
    dures to establish quality assurance should be
    developed by national laboratories and enforced
    at all water laboratories. Likewise, the
    responsible national body should insure that,
    without exception, all laboratories within a
    country are using the adopted methods.

3. An adequate water testing program, using uniform
   methodologies that are under close quality as-
   surance, cannot guarantee distribution of safe
   water to all consumers. Laboratory analyses
   merely assess the quality of water being dis-
   tributed. It is essential, therefore, to have an
   integrated water program wherein the water author-
   ity takes action to correct deficiencies exposed
   by laboratory testing. The procedures should be
   formalized in such a way that laboratory infor-
   mation can be transmitted to the appropriate
   authority and corrective action instituted.

E. MICROBIOLOGY OF WATER TREATMENT AND DISINFECTION

The ever increasing need for potable water has led to reliance on low quality surface water sources which necessitate intensified and improved treatment practices. Waterborne disease outbreaks resulting from insufficient treatment of microbiologically contaminated water have been well documented. Therefore, in order to prevent the transmission of diseases through water, it is of the utmost importance that treatment practices be properly chosen and carefully applied from the raw source water to the final product.

This section will evaluate several standard processes used in the treatment of drinking water [See Table E. Intro-1] in terms of their effects upon the microbiology of the water. Emphasis will be placed on enteric bacteria, in their role as indicators, and on viruses. Estimates will be made, on the basis of recent pilot studies and experiments, of the overall safety to consumers achieved through the application of these respective treatment procedures. Not included here are microbiologic processes for nitrification of water from surface sources [See the report of Project Area II: Advanced Treatment Technology] and for denitrification of groundwater.

1. Storage Reservoirs

The storage of raw water in large, open reservoirs can provide both quantity and improved quality of the finished water. Storage reservoirs serve as an important supply under drought conditions and also as a safeguard against polluting substances which may be present in a river. If toxic materials are spilled or discharged into the river, the intakes can be closed until the harmful substances have passed downstream. Provided that the storage reservoir is of sufficient volume, it will serve as a buffer against any sudden deterioration of the influent quality. This buffering action is particularly important where contamination may be intermittent.

TABLE E.INTRO-1

SCHEME OF TREATMENT
FOR THE PREPARATION OF DRINKING WATER

Treatment	1	Reservoir storage
	2	Dune infiltration
	3	Coagulation
	4	Sand filtration
	5	Activated carbon
	6	Disinfection

a. Physical and Biological Factors. Surface waters may be purified by a treatment process consisting of several stages, the first of which is storage. Storage immensely improves the physical, chemical, and microbiological quality of the source water which is particularly important when this is a river polluted with sewage effluent. Loss of turbidity is perhaps the most striking improvement in that particulate matter, along with adhering microorganisms, will sediment out.

Sunlight has a lethal effect on bacteria and other microorganisms, and high coliform mortalities have been shown to occur in seawater during daylight hours (Gameson and Saxon, 1967). Radiation of the shortest wavelength (ultra-violet and the blue end of the visible spectrum) is bactericidal and its lethal potency is approximately proportional to its intensity. Except when algal and cyanobacterial blooms interfere, sunlight penetration is enhanced by the reduced turbidity obtained from sedimentation.

It is well known that higher temperatures increase microbial metabolism, leading to accelerated die-off rates of indicators and pathogens. A rise in water temperature will also increase predator activity. Certain protozoa are particularly active bacterial feeders, as can be seen at a sewage effluent outfall where ciliates abound and help reduce the vast numbers of bacteria. Among the somewhat larger animals, rotifers and members of the genus Daphnia are important predators of bacteria. The latter frequently graze on and remove large numbers of E. coli from reservoir water [See Section A.2]. The minute Bdellovibrio bacteriovorus can grow on gram-negative bacteria by penetrating the cell wall and multiplying within the cell. It is highly motile, can rapidly clear dense suspensions of gram-negative bacteria, and can grow equally well on live or dead cells (Guelin, et al., 1967). Bacteriophages (bacterial viruses) cause lysis of bacteria cells, but are only able to develop on actively growing bacteria. Since intestinal bacteria, such as E. coli, are not capable of multiplying in reservoir water, death from coliphage infection may be minimal [See Section C.2.a].

Although lethal to some microbes, antibiotics (produced by actinomycetes and fungi) and toxins (produced by cyanobacteria) probably play a minor role in reducing numbers of enteric bacteria whose populations are, in most cases, already greatly diminished by the lack of available nutrients, competition, and predation. The stresses exerted

by an entrenched and well adapted aquatic community render the reservoir an unfit environment for enteric bacteria.

According to Holden (1970), "it is impossible to assign the exact importance of each factor in the self-purification of water," because of the large number of agents operating simultaneously. It is obvious that different climates will have varying influences -- areas of high temperature combined with sunlight being strongly bactericidal in clear water.

b. Effect of Storage on Indicator Organisms. Thermotolerant coliforms (i.e., E. coli and other fecal coliforms) are the prime indicators of fecal pollution [See Section C.1.c]. E. coli is present in the intestine of man, animals, and birds and outnumbers the pathogens by millions to one in sewage. Its reduction can be traced through the various stages of water treatment, but is largely accomplished during storage. The following pertains to the effect of storage as carried out by the Metropolitan Water Division of the Thames Water Authority, U.K., and special reference will be made to these storage reservoirs.

Approximately two-thirds of London's water supply is obtained from the Thames River and one-sixth from the Lee River, with the remainder derived from underground sources. Numbers of E. coli are regularly monitored in both these rivers at the intakes to many of the storage reservoirs. Water is stored in the large reservoirs of the Thames Valley for periods of seven to ten weeks depending on demand, whereas in the Lee Valley the retention period is considerably less. The percentage reductions of E. coli during storage were computed from quarterly figures for the years 1971 to 1976 (Metropolitan Water Board, 1971-1973b; Thames Water Statistics, 1976). Though they varied by season, these losses remained considerable throughout.

During spring and summer, many 100 ml samples collected from reservoir outlets contained no E. coli, whereas only three reservoir samples taken in autumn and winter were free of E. coli. Storage reservoirs in the Thames Valley reduced E. coli by 95.7 to 99.8 percent in the spring, and by 90.7 to 99.7 percent in the summer. At these seasons, sunlight, temperature, and biological factors would be exerting their maximum influence. In the autumn, E. coli reductions during storage varied from 77.8 to 98.1 percent and in the winter, from 85.7 to 98.2 percent. It is noteworthy that the lowest

reductions for each season occurred in a reservoir which utilizes mixing jets to prevent thermal stratification. Storage reservoirs in the Lee Valley exhibited smaller seasonal fluctuations in E. coli removal, most likely because of their shorter retention times as compared to those in the Thames Valley. However, as in the previous cases, the lowest removal (84.3 percent) occurred in the autumn; winter reductions were > 91.8 percent, and spring and summer storage removed > 95.2 and 93.4 percent, respectively.

The storage-induced decline in bacterial numbers was studied in a small reservoir in the Lee Valley (Poynter and Stevens, 1975). The reservoir was filled with a mixture of water from the Thames and Lee Rivers, and then closed. The water was sampled weekly during the autumn of 1974 and showed the greatest decline in E. coli, 95.8 percent, within the first week. In the following eight weeks, low numbers of E. coli were isolated, suggesting that feces from birds and animals and/or rainfall runoff from reservoir banks were the contaminating source. When a sample of this reservoir water was inoculated in vitro with strains of E. coli (recently isolated from the Thames River and from feces), at a level of 260 E. coli per 100 ml, and stored in the dark at 15 to 16°C -- the rate of decline was logarithmic, ending with near extinction (E. coli absent from 100 ml) within 11 days.

Many coliforms present in feces can survive better than E. coli outside the body. Many are widely distributed in nature and may gain access to water from non-fecal sources. Under certain circumstances, they may multiply on decaying vegetation, wood, or other materials [See Section C.2.d]. Three weeks after copper sulfate was added to a storage reservoir to control a spring growth of diatoms, there was evidence of coliform growth in the secondary slow sand filter beds (Burman, 1961). Coliforms are usually reduced considerably, but less so than E. coli, during storage. In the previously described study of the small storage reservoir in the Lee Valley (Poynter and Stevens, 1975), coliforms decreased by 85 percent in the first week, but required two weeks to be reduced by 90 percent (the decline of E. coli was almost 96 percent by the end of the first week). During the remaining seven weeks, coliform reductions fluctuated between 92 and 99.5 percent.

The term fecal streptococci [See Section C.1.d] applies to the Streptococcus faecalis-faecium-durans group (enterococci) and the S. bovis-equinus group (i.e., they all belong to Lancefield's serological group D). The reported die-off

rates of fecal streptococci and fecal coliforms in natural waters (Geldreich and Kenner, 1969; Kjellander, 1960; McFeters, et al., 1974) can be summarized as S. bovis-equinus group > fecal coliforms > S. faecalis-faecium group. S. faecalis is abundant in human feces, whereas S. faecium is widespread in both man and animals. Thus, in a storage reservoir where the water source is a sewage polluted river, streptococci may be isolated in the absence of E. coli. However, when water samples from the Lee River were stored in clear glass bottles of 2.8 l capacity, in the dark or in the light, the observed die-off rates of fecal streptococci were similar to or greater than those of E. coli (Burman, et al., 1978). In these samples, the major source of fecal pollution was considered to be treated sewage effluents.

Clostridium perfringens [See Section C.1.e] is present in feces in much smaller numbers than either E. coli or the fecal streptococci. It differs from these organisms in that it produces spores which are resistant to adverse conditions and, therefore, better able to survive for extended periods. The presence of C. perfringens in a source water indicates fecal contamination and, in the absence of coliforms, suggests that the contamination occurred at some remote time. The die-off rate of these organisms in a storage reservoir would be slow, although sedimentation may account for apparent reductions of spores adhered to particulates.

Storage may also act to reduce considerably the number of bacteria able to form colonies on yeast extract agar at 37°C (and, to a certain extent, of those which form colonies at 22°C). The Lee Valley reservoir study (Poynter and Stevens, 1975) showed a 50 percent decline the first week, and a 72 percent decline the second week, in colony counts on plates incubated at 37°C for 24 h. However, due to the incidence of algal blooms there may be a considerable increase in colony counts at both 37°C and 22°C, which may occur during or after the algal blooms as was shown in the Dutch storage reservoir "De Grote Rug" (Kool, 1977). Peaks of bacterial numbers also coincided with peaks of algal activity in a Thames Valley reservoir, U.K. (Price and Valadon, 1970). Thus, under certain conditions, bacterial increases, rather than decreases, will take place in a reservoir.

c. Effect of Storage on Bacterial Pathogens. All drinking water supplies should be free from pathogens, such as those responsible for typhoid, paratyphoid, dysentery,

cholera, bacterial or viral gastroenteritis, and infectious hepatitis [See Section B]. For practical purposes, typhoid fever, cholera, and infectious hepatitis are regarded as exclusively human diseases, while the other diseases may be of human or animal origin. The agents of all these diseases are discharged in the excreta (feces or urine) of patients or carriers. Thus, if these diseases are prevalent within a population, the causative agents will be present in sewage; and if this sewage is discharged to a river which is used to supply a reservoir, the presence of such pathogens can be expected.

The effect of storage on Salmonella typhi (the agent of typhoid fever) was investigated some 70 years ago by Houston. His "Reports on Research Work" (Houston, 1908-1911) dealt with several experiments, the first of which involved 18 samples of river water, six each from the Thames, the Lee, and the New Rivers. Each of the 4 l samples was inoculated with a single strain or a mixture of different strains (27 in three of the experiments) of S. typhi, some of which had been recently isolated from typhoid patients. The inoculated river water samples were stored in the dark at temperatures ranging from 8 to 20°C. The numbers of S. typhi organisms added to the samples ranged from eight to 40 million per ml, and counts were made at weekly intervals. The decline was especially rapid in the first week, the reduction amounting to more than 99.9 percent in practically all experiments. However, S. typhi could still be recovered from 100 ml of water, in some experiments, during the eighth week of storage. Later, Houston carried out further experiments on much larger volumes (1.6 m^3) of Thames River water. He noted that temperature greatly affected the viability of S. typhi, survival being considerably longer at low temperatures. As a result of his work, he concluded that "an adequately stored water is a safe water."

Experiments were carried out in the U.S. (Jordan, et al., 1904) in which river, lake, or canal water was inoculated with S. typhi. The inoculated water was enclosed in permeable sacs made of celloidin and parchment to allow dialysis, and these sacs were suspended in flowing river, lake, or canal water. Under these conditions, designed to simulate those in nature, the majority of S. typhi perished within three to four days. The experimental results of Thresh and coworkers (described by Holden, 1970) are in general agreement with those of Houston, especially with regard to the sudden initial decrease of S. typhi in polluted waters. Though samples contained only five organisms

per ml of river water, both S. typhi and S. paratyphi decreased considerably in the first four days and were absent from 1 l after three weeks' storage in the dark at 10 to 15°C.

While typhoid fever, which is exclusively a human disease, rarely occurs in the U.K., Salmonella-induced gastroenteritis is comparatively widespread among humans and animals [See Section B.1.a(i)]. Storage experiments were carried out by Fennell and coworkers (1974) on the survival of S. typhimurium in reservoir water. Two outlet samples of reservoir water (pH 7.3) were tested; one was naturally contaminated with 25 salmonellae per l and the other was inoculated with S. typhimurium (isolated from the reservoir during the previous week), to yield a count of 120 per l. Ten l volumes of water were stored at approximately 5°C in the dark. At the end of the first week of storage, the reduction was approximately 50 percent and after two weeks, 75 percent. By the middle of the third week, salmonellae were difficult to isolate and at the end of the third week, the count was only one per l. Storage at the low temperature of 5°C (at pH 7.3) probably accounted for the comparatively small reduction (50 percent) in the first week. When inlet water with a pH of 5.6 was inoculated with 120 S. typhimurium per l, death occurred more rapidly, reaching a 95 percent reduction by the end of the first week, and a 99 percent reduction after two weeks. After 17 days of storage, no salmonellae could be isolated. In contrast to these results with S. typhimurium, Cohen (1922) demonstrated that the death rate of S. typhi was minimal within a pH range of 5.0 and 6.4. A change in pH from 5.4 to 3.8 accelerated the death rate by almost a hundredfold, while a similar change in pH on the alkaline side increased the death rate about four to fivefold. It is clear from these examples that both pH and temperature are important to the survival of Salmonella [See Section B.1.a(i)].

Gulls feeding on domestic sewage, either at the sewage works, at effluent outfalls, or at refuse disposal sites and subsequently excreting Salmonella elsewhere, represent a widespread problem. Muller (1965) collected more than 1,000 fecal samples from gulls in Hamburg around the area of the biggest sewage works, on bridges and pontoons in the port of Hamburg, and in the streets of the city; 78, 66, and 28 percent of these samples, respectively, were positive for Salmonella. In such widely separated areas as Hamburg, Venice, and Tanganyika, approximately 30 percent of pigeon feces contained Salmonella, whereas 16 percent of duck feces

in Hamburg carried the pathogen (Muller, 1965). During a thirteen-month survey of a storage reservoir in Yorkshire, U.K. (Fennell, et al., 1974), Salmonella was isolated from 52 out of 111 water samples from the reservoir, but never from the inlet water of the catchment area. The number of roosting gulls was at a maximum in December and the bacteriological quality of the reservoir water deteriorated markedly during the winter. There was a close correlation between the number of gulls and the degree of contamination with Salmonella, E. coli, and fecal streptococi all of which are excreted in large numbers by gulls. There was no correlation between the number of gulls and presence of Clostridium perfringens, since these organisms occur only in small numbers in gull feces. The presence of large birds, in high numbers on open storage reservoirs may pose a serious problem either from direct fecal discharge and/or from rainfall run-off along contaminated banks.

There have been few reports in the literature of the isolation of Shigella from river water, sewage, and sewage effluent; and this has generally been associated with the organism's poor stability outside the human body. However, the failure to isolate Shigella from polluted water may instead be due to unsuitable selective isolation techniques. Shigella has a longer generation time than many of the competing organisms, and this complicates the use of an enrichment medium [See Section B.1.a(ii)].

Cholera has been practically non-existent within the U.K. for more than 70 years, but prior to that period epidemics occurred at intervals. Houston (1909) carried out a series of 18 experiments on the survival of Vibrio cholerae in raw river water (six each from the Thames, the Lee, and the New Rivers) similar to those he conducted with S. typhi. The initial inoculations numbered from 70,000 to 13 million per ml of water, and samples were stored in the dark at temperatures ranging from 7 to 18°C. The cholera vibrios died out very rapidly; and in all 18 experiments, there was a reduction of at least 99.9 percent within one week. None could be isolated from 100 ml of water after three weeks, and negative results were obtained after two weeks in over half the experiments. Survival was longest in samples receiving the most massive inocula. The survival of a very small fraction of organisms, which is more resistant, is not uncommon and may be correlated with the initial number of cells in the inoculum. Houston interpreted his results as indicating that cholera vibrios were "even less hardy" than

typhoid organisms and that the storage time required to protect reasonably well against typhoid fever was more than sufficient for cholera [See Section B.1.a(vii)]. Cholera is endemic in India, and cholera vibrios have been found to perish only a few hours after entering certain rivers, such as the Ganges and Jumna (Holden, 1970). This is due to factors such as high temperature and the presence of an established predator population sustained by frequent fecal inputs. Conversely, the survival of enteric organisms is now known to be more prolonged in pure than in polluted water.

    d. <u>Effect of Storage on Enteroviruses.</u> Reservoir storage causes a marked reduction in virus levels. From December 1974 to March 1975, water samples from the river intakes to the storage reservoirs in the Thames and Lee Valleys were compared with the outlet water from these re- servoirs (Slade, 1977). Virus numbers in the River Thames ranged from 12 to 49 plaque-forming units (PFU) per liter, and in the Lee River, 0.8 to 11.8 PFU per liter. Large numbers of enteroviruses are frequently isolated during the winter months; the Thames River normally has more viruses than the Lee River. The virus numbers, after storage in the Thames Valley reservoirs, varied between 0.00 and 9.73 PFU per liter. The latter result was high and no other exceeded 1.93 PFU. Numbers after storage in the Lee Valley reser- voirs ranged from 0.00 to 1.00 PFU per liter.

    Temperatures of the stored water in the Slade study at the time of sampling ranged from 5 to 7°C, and the results can be compared to those of Poynter (1968) who also studied virus inactivation in water from the Lee River. He found that at a temperature of 5 to 6°C, more than nine weeks of storage were required for 99.9 percent inactivation of polio- virus type 3; but at temperatures of 15 to 16°C, 95 percent inactivation occurred in seven days and 99.75 percent in less than 15 days [See also Section B.1.b]. These results, which are sufficiently similar to the results obtained for enteropathogenic bacteria, uphold the value of storage reservoirs as a highly desirable method of safeguarding water supplies when the source is a polluted river.

    As a result of his research, Houston concluded that 30 days of storage, prior to filtration, should suffice to provide a safe water. However, this is not always practical and "it is now generally agreed that inflow-outflow arrange- ments which ensure at least ten days of retention in the

storage reservoir are practical methods of eliminating between 75 and 99 percent of the excremental organisms" (Holden, 1970). In temperate regions, the greatest reductions occur in spring and summer, and the least reductions in autumn and winter, especially during prolonged cold weather. At a water temperature of 4 to 8°C, a retention time of about 75 days was required for a 99.9 percent reduction of enteric viruses (Kool, 1979).

e. Recreational Use of Reservoirs. In some developed countries, there is now an increasing awareness of the amenities (connected) with open storage reservoirs. They may be stocked with fish, such as trout, and so attract fishermen. They may also be used for boating and by sailing clubs. Power-driven boats (apart from those involved in rescue) should be excluded to avoid any accidental spillage of oil or other toxic substances. Swimming (or any total immersion) should likewise be prohibited. Large numbers of people visiting a reservoir would dictate the need for adequate nearby toilet facilities. Provided that these and other safeguards are strictly carried out, storage reservoirs may serve as areas for recreation, as well as for storage and purification.

f. Summary. All the evidence indicates that storage reservoirs are invaluable as a primary stage in the treatment of fecally polluted river water. However, the advantages of storage may be lessened (or even lost) where the water is subsequently contaminated by waterfowl, such as gulls, or is used as a recreational facility without proper precautions.

2. Coagulation

This section will present and discuss data on the removal of bacteria, enteric viruses, and parasitic cysts by coagulation with aluminum and iron salts followed by sedimentation. Most studies cited here report effects of coagulation with raw surface water or secondary effluent, but others, in which raw wastewater was tested, were also included in order to provide more complete coverage.

Coagulant dosages, stated for compounds in which the water of hydration obviously was present, were reduced accordingly; otherwise, the concentrations are shown as reported. For example, in studies where aluminum sulfate had been the coagulant used, the concentration indicated

was reduced for this report by a factor of 0.486 (18 waters
of hydration) to convert to $Al_2(SO_4)_3$. In cases where
ferric sulfate or ferric chloride was used without desig-
nation of the water of hydration, the concentration reported
in the study was used here. However, some studies may have
neglected to include the waters of hydration in reporting
concentrations of ferric compounds, in which case, the
actual concentration of active compound would have been less
than that reported here.

a. Removal of Bacteria. Data on the removal of bac-
teria by coagulation and sedimentation have been taken
primarily from early studies since this subject has drawn
little attention in the current literature [See Table E.2-1].
Gehm (1944) obtained reductions in colony counts of 97
percent from raw sewage to which 60 mg per l of $FeCl_3$ had
been added, although only 77 percent of B. coli (now E.
coli) were removed. When 40 mg per l of $FeCl_3$ was applied,
colony counts were reduced by about 20 percent, although 50
percent of the E. coli were removed under similar conditions.

Early studies (Streeter, 1927, 1929) reported
average bacterial removals obtained at full-scale water
treatment plants on the Ohio River and Lake Erie [See Table
E.2-1]. Reductions at the Ohio River plants averaged 83
percent for both colony counts and E. coli, but only 46
percent for colony counts and 76 percent for E. coli at the
Lake Erie plants. Turbidity was reduced by about the same
percentages as were bacteria. However, only three of the
seven Ohio River plants employed flocculation, of which only
one allowed more than 6 min of detention time (20 min). Of
the four Lake Erie plants, only two used flocculation.

Later studies (Cummins and Nash, 1978) made at the
Cincinnati, Ohio treatment plant showed that when 12.6 mg
per l of $Al_2(SO_4)_3$ were added to Ohio River water and then
allowed to settle for 48 h in open reservoirs, 97 percent of
total coliforms were removed [See also Section E.1]. When
the effluent water was coagulated with 6.8 mg per l of
$Fe_2(SO_4)_3$ and allowed to settle for 4 h, only 42 percent of
the initial 2,400 coliform bacteria per 100 ml were removed.
The latter procedure more nearly typifies actual treatment
plant operations, but the former offers evidence of the
advantages to be had from longer sedimentation with its
increased opportunities for bacterial die-off.

Results vary widely in the few available reports on
removal of bacteria by coagulation and sedimentation. The

342

widely quoted laboratory study by Chang and coworkers (1958a) reported bacterial removals of 99 percent or more, but these figures have not been substantiated in other reported data. Streeter (1927, 1929) reported bacterial removals of 46 to 83 percent at full-scale treatment plants. Cummins and Nash (1978) reported total coliform removals of 42 percent.

The lack of recent reports on the removal of bacteria by this process is probably due to the widespread reliance on prechlorination dating from the late 1930's and early 1940's, with the result that attention was diverted from the capability of coagulation for removing bacteria. With the recent interest in decreasing prechlorination of water to reduce trihalomethane concentrations, the potential that coagulation offers for removal of organisms takes on new importance. Additional studies are needed to determine the effects that variations in pH, coagulant type and dosage, temperature, and other water characteristics would have on the removal of different bacteria.

b. Removal of Viruses. Poliovirus 1 and coxsackievirus A2 are the only enteric viruses for which data on removal by coagulation and sedimentation are available [See Table E.2-2]. Several studies conducted at large pilot plants reported relatively high reductions from influent containing low virus titers [Table E.2-2]. These studies indicate that viruses present in relatively low concentrations should be reduced by approximately 90 percent or more with coagulation. Chang and coworkers (1958a,b) reported that variations in the type of coagulant and temperature had minor effects on the removal of coxsackievirus A2, although an increased coagulant dose did increase removal. Data from other investigators (Guy, et al., 1977) support the observation that there is little difference in virus removals between the use of $Fe_2(SO_4)_3$, $FeCl_3$, or $Al_2(SO_4)_3$.

Although the coagulation process is relatively non-specific in its capacity to remove small particles, prudence dictates that generalizations based on tests made with only poliovirus 1 and coxsackievirus A2 be validated with studies using a spectrum of the enteric viruses.

c. Removal of Parasitic Protozoa and Metazoa. Cysts of protozoa and eggs of metazoa are heavier than bacteria and viruses and will settle in quiescent water. Helminth eggs are quite heavy and settle rather rapidly. The data

presented in Table E.2-3 indicate that the removal of para-
sitic protozoan cysts by coagulation and sedimentation
should be 90 percent or more under optimum conditions.

    d.   <u>Conclusions</u>. The few reports available on removal
of bacteria indicate that reductions will vary from 50 to 97
percent with coagulation carried out on a plant scale.
Removal of parasitic cysts should exceed 90 percent, although
this also is based on only a few reports. Additional
studies, therefore, are needed to verify the removal effi-
ciencies obtained with bacteria and parasitic cysts, espe-
cially as these are affected by variations in pH, coagulant
type and dosage, temperature, and different quality waters.

    The application of sufficient quantities of either
ferric or aluminum salts should result in 90 to 99.999
percent reductions in enteric viruses. However, these
predictions are based only on results from coagulation
studies with poliovirus 1 and coxsackievirus A2 and should
be confirmed by tests made with other representative enteric
viruses.

3. <u>Sand Filtration</u>

    One of the treatment processes often used for water
purification is filtration through sand, soil, or dunes
(Baker, 1934; Burman, 1962; Burman, 1978; Graveland and
Hrubec, 1976; Kool, 1979; Robeck, <u>et al.</u>, 1962). Filtration
is a process whereby raw water is passed through a porous
matrix to remove suspended and colloidal impurities and,
frequently, to change the chemical characteristics of the
water and reduce the levels of microorganisms present [See
also Sections E.3 to 4 and G.2].

    Removal of constituents from the water is accomplished
by a combination of physical and biological processes, the
most important of which are mechanical straining, sedimen-
tation, adsorption, electrostatic binding, and microbial
activity. Filtration through sand, as it is practiced today
in drinking water treatment, can be divided into three
types: rapid sand filtration, slow sand filtration, and
dune or bank infiltration.

    James Simpson is acknowledged as the first to introduce
slow sand filtration into Europe, at the Chelsea Waterworks
Company (one of the suppliers of London's drinking water at
the time) in 1829. A cholera outbreak [See Section B.1.a(vii)]

in Germany in 1892, involving water from the Elbe River,
demonstrated the efficiency of this treatment in removing a
pathogen. The outbreak occurred in Hamburg, where water of
the Elbe was drunk untreated, but not in nearby Altona,
where the water was drunk only after slow sand filtration.

This section discusses the physical and biological
processes that are involved during sand filtration, the
problems that may arise during operation, and the capacities
of such a treatment for removing organisms. The concept of
this presentation is based on a paper by Huisman and Wood
(1974).

a. Physical Processes. Particles of suspended matter
too large to pass through the interstices between the sand
grains are removed by the action of mechanical straining.
This process takes place almost entirely at the surface of
the filter, where water first enters the pores of the filter
bed. As filtration continues, pore openings become smaller
from the deposition of suspended matter, enabling straining
of progressively smaller particles. A mat eventually de-
velops as more material accumulates on top of the filter
bed, and this also increases the efficiency of the straining
process. When flocculation occurs within the filtration
bed, the aggregated particles may be retained at greater
depths of the bed. Bacteria, viruses, other microorganisms,
colloidal material, and other substances smaller than the
pore spaces are not, however, removed by mechanical strain-
ing.

Sedimentation is largely responsible for the removal
of colloids, small particles of suspended matter, and bac-
teria. Here, the interstices between the sand grains serve
as minute sedimentation basins, along the sides of which
suspended particles settle. Smaller and lighter particles
are only partly removed, although flocculation accompanying
further downward movement of the water will slightly in-
crease sedimentation efficiency with depth. Truly colloidal
matter cannot, however, be removed in this way.

Adsorption can take place in either of two ways. The
simplest is when suspended particles collide with and adhere
to the sticky gelatinous coating formed on the sand grains
by previously deposited bacteria and colloidal matter. Of
greater influence is the active promotion of adsorption by
physical attraction between two particles of matter (Van
der Waals forces), and still more important is the electro-
static attraction between opposite electrical charges
(Coulomb forces) [See Section A.1.e].

b. Biological Processes. Biological activity is the action of microorganisms living on and in the filter bed which produce chemical and physical, as well as biological, changes in the quality of water. The protozoa, metazoa, and bacteria inhabiting the filter bed include many organisms (often in quite high numbers) not commonly detectable in the raw water [See Section A]. The intensity of their activity is a function of infiltration rate; that is, the slower the flow, the longer the detention and the more important becomes the role of the filter bed flora in the treatment process. Biological activity, therefore, counts heavily in slow sand filtration and artificial recharge. In these systems, the greatest biological activity occurs near the filter surface (Kool, 1976). Their influence on the physical, chemical, and biological properties of the water arises mainly from activities of nutrient utilization and predation.

(i) Nutrient Utilization. Many bacteria and fungi in the filters are able to derive needed energy and nutrients from the numerous organic compounds, of various origins, that are dissolved in the raw water. These compounds are incorporated into cell mass, degraded to intermediate compounds, or mineralized entirely to carbon dioxide, water, and inorganic salts. Some organic compounds are less readily utilized than others by microorganisms in the filter bed. On the other hand, some bacteria can adapt rather quickly to new compounds to which they were not previously exposed. This has been demonstrated with various phenols. Within a few days after exposure to 8 to 10 mg per liter of phenols added to the raw water, organisms in the slow sand filter had adapted so as to be able to metabolize and remove all of the phenol (Metropolitan Water Board, 1971-1973a). Organic compounds present in raw water are usually pollutants and action upon them by the filter bed flora inevitably results in improved water quality (Zwaagstra, 1978).

(ii) Predation. The development of a large mixed microbial flora in response to organic nutrients present in the raw water results in the growth of predators. The antagonism between predators and nutrient utilizers does not, however, reduce the activity of nutrient utilizers. On the contrary, it is more likely to maintain an ecological equilibrium that stabilizes the activity of all the organisms in the community (Waksman, 1937).

Predators may include bacteriophages, the bacterium Bdellovibrio bacteriovorus, protozoa (including amoebae, flagellates, and ciliates), and metazoa such as rotifers and the larger oligochaetes (Metropolitan Water Board, 1971-1973a; Reijnen, 1973) [See also Sections A.2, B.3, and E.1]. Bacteriophages, like other viruses, require living and growing host cells, in which to replicate, and this results in the lysis of the host cell. The tiny bacterium Bdellovibrio makes use of its very active motility to embed itself in the host bacterium where it multiplies, causing lysis of the host cell. It has been found in sewage effluent, surface waters, filter beds, and soil (Reijnen, 1973). It is not known whether protozoan predation significantly alters bacterial numbers and activity in slow sand filters (Dornedden, 1930; Reijnen, 1973).

All of these predators feed primarily on the saprophytic microorganisms growing in the filter bed, but also will feed on intestinal bacteria and other organisms of public health significance that may be present and thereby improve the bacteriological quality of the raw water.

(iii) Effect of Temperature. Every microorganism grows best at its own optimum temperature [See Section B.3]; mixed communities in an aquatic environment probably exhibit optimum activity at around 20 to 30°C. At higher temperatures, there is less diversity of species, whereas lower temperatures retard metabolic rates and hence, growth and activity. It follows that during prolonged cold weather, slow sand filters will be less effective, as is evidenced in temperate regions where the chemical and bacterial quality of the filtrates changes with the seasons. This suggests that slow sand filters would be less effective in countries with extremely cold and prolonged winters, not to mention problems of cleaning beds during freezing weather.

Temperature exerts a great influence over the fate of pollutants, as in the case of ammonia. Ammonia can be utilized by some bacteria as an energy source. Nitrosomonas oxidizes ammonia to nitrite and Nitrobacter oxidizes nitrite to nitrate [See Section A]. This process is dependent on temperature and slows rapidly below 6°C (Huisman, unpublished data) even after only a short period of exposure; for example, when beds are drained for cleaning during a cold night, the ammonia oxidizing capacity takes several weeks to recover.

c. <u>Rapid Sand Filtration.</u> Flow rates during filtration are usually measured linearly as the vertical flow of water from the top, down through the sand. Rapid sand filters are ordinarily filled with medium to coarse sand (grain size 0.5 to 1.5 mm or larger) and have vertical flow rates of 5 to 10 m per h for free surface filters, and up to approximately 20 m per h for pressure filters enclosed in watertight steel cylinders. Impurities in the water are deposited deep in the bed of a rapid sand filter because of the high flow rates and the large size of the sand grains. The rapid clogging that results from the high flow rates necessitates cleaning at intervals of hours to a few days (Graveland and Hrubec, 1976).

d. <u>Slow Sand Filtration.</u> With slow sand filtration, water is passed down by gravity through a constructed layer of fine sand (usual grain size of 0.15 to 0.4 mm). Filtration rates vary from about 0.1 to 0.4 m per h, although rates of up to 0.8 m per h have been used experimentally (Metropolitan Water Board, 1971-1973a). After a few weeks to a few months of operation (depending on the quality of the raw water), particulates that have accumulated on and in the bed will begin to reduce the flow so that filtration rates cannot be maintained. However, because the sand is fine, clogging takes place only at the very top of the sand, and cleaning is accomplished simply by removing the top 1 to 3 cm of sand.

e. <u>Artificial Recharge.</u> With artificial recharge, water is passed through naturally occurring dunes or river banks at flow rates lower than those obtained with slow sand filtration. For example, in the Netherlands, water is infiltrated through dunes at velocities of up to 0.2 m per day and through river banks at rates of 0.1 to 0.5 m per day (Graveland and Hrubec, 1976). At times, detention of the infiltrated water may be very prolonged, and anaerobic conditions may develop, leading to the microbial production of off flavors and odors. As with slow sand filtration, particulate matter gradually accumulates on and in the filter bed, reducing flow rates; hence, beds must be cleaned periodically (every two to five years for dune infiltration) by the same procedure carried out for slow sand filters.

f. <u>Characteristics of the Raw Water.</u> The biological nature of dune, bank, and slow sand filtration implies that

some organic content is required in the water to encourage
the necessary bacterial population to bring about purifi-
cation. The methods are, therefore, unlikely to be satis-
factory with waters that contain no organic matter and where
all turbidity is due to mineral matter. Raw waters high in
turbidity due to suspended mineral matter and low in dis-
solved organic substances are unlikely to be much benefitted
by these processes. Neither is it advisable, in the case of
dune and slow sand filtration, to filter highly turbid
waters without some preliminary treatment to avoid the need
for frequent cleaning. Dune and slow sand filtration can
best be employed in a dual arrangement of preliminary fil-
tering through a conventional rapid sand filter. The higher
quality water obtained from this primary filtration extends
the cleaning interval required for subsequent slow sand
filters and should enable faster filtration rates without
significant silt penetration.

g. Algal Growth. Algae can cause filtration problems.
Growth of unicellular algae in storage reservoirs [See Sec-
tion E.1] results in an increase in particulate matter which
has to be removed either on the primary or secondary filters,
or both. From the filtration management standpoint, this
requires more frequent cleaning and backwashing of filters,
particularly the primary ones. Algae can also grow in
uncovered filters or filter beds which are exposed to light,
especially filamentous algae during the summer months (Metro-
politan Water Board, 1967-1968). Even when a good quality
water is infiltrated, algal growth is supported if the
water contains a high phosphate load, especially with a
rapid infiltration rate (Hrubec, 1975). Where filamentous
algae are a problem, they must be removed promptly when a
filter is drained for cleaning, lest they begin to compost
and raise temperatures sufficiently to support growth of
undesirable organisms such as E. coli (Metropolitan Water
Board, 1969-1970a).

The temperature and the phosphate content of raw water
usually are not subject to control, but all algal growth on
filters can be prevented by excluding light. A roof or
shade may suffice; however, a completely enclosed building
over the filters offers the further advantages that it
permits the filters to be cleaned even during extremely
cold or wet weather and that it excludes birds that might
pollute the filters (Graveland and Hrubec, 1976; Metro-
politan Water Board, 1969-1970b and 1971-1973a) [See Section
F.1.b].

h. <u>Maintenance of a Steady State</u>. It should be clear from the foregoing that dune, bank, and slow sand filtration are unique ecological systems of which the microbial types and distribution are subject to change with changing conditions, especially changes in filtration rate and raw water quality.

Sudden changes in filtration rates can cause deterioration in efficiency [See also Section G.2]. This is because, with very slow filtration, most microbial degradation and removal of nutrients takes place in the upper layers; whereas, with faster rates, nutrients penetrate deeper and consequently, microbial activity occurs at greater depths. Any abrupt rate change would remove nutrient deposition away from access by the established filter bed flora.

Another cause of perturbation is leaving the filter bed full of water when it is not in operation. At very slow flow rates, or when there is no flow, the demand inherent to the system can use up all available oxygen, causing a drastic change in the microbial flora and resulting in the production of some objectionable compounds.

When a bed is drained for cleaning, the bacterial micro-environment changes completely. Instead of receiving a steady flow of water containing nutrients, the interstices of sand become filled with air. Bacterial metabolism becomes more oxidative, and bacterial gums and other attachment substances are used as nutrient sources. Bacteria that previously were attached to the sand grain surface tend to be released so that when filtration recommences, they are washed out into the filtrate (Metropolitan Water Board, 1969-1970a). The longer the interruption in filtration and the higher the temperature, the greater the contamination of the filtrate. It is important, therefore, that beds be kept out of use for cleaning for as short a period as possible, especially in the summer months, and that former filtration rates be resumed as soon as possible. Beds returned to use at their maximum filtration rates within 24 h show no deterioration in efficiency (Metropolitan Water Board, 1971-1973a).

i. <u>Removal of Microorganisms by Dune, Slow, and Rapid Sand Filtration</u>. Sand filtration of water removes microorganisms by physical and biological processes as has already been discussed. Filtration and adsorption were studied to determine their influence on virus retention (Goldschmid, et al., 1972; Lefler and Kott, 1974). Adsorption on sand

was found to be strongly enhanced in the presence of cations, such as those of calcium and magnesium, and fresh sand was demonstrated less retentive of viruses than conditioned sand. Viruses could be eluted from the particles by raising the pH or by reducing the ionic strength of the water (Goldschmid, et al., 1972; Lefler and Kott, 1974; Nestor and Costin, 1971; Wellings, et al., 1975) [See Section A.1.e].

A dune infiltration system in the Netherlands was examined for its capacity to remove bacteria and viruses (Hoekstra, 1978; Kool, 1978). Tests in which raw surface water was infiltrated through sand dunes produced the following results: > 99.99 percent of the colony count (at 22 and 37°C), > 99.9 percent of coliphages, and > 99 percent of thermo-tolerant and total coliforms were removed. The somewhat lower percentages for coliphage and coliform removal, compared to that of the colony count, were due to a relatively small number of coliphages and coliforms present in the raw water before filtration. None of these organisms were detected in samples of 1,000 and 100 ml after filtration. Therefore, it is likely that coliphages and coliforms would exhibit the same high removal rates as those obtained for the colony counts. These high removals of > 99.99 percent are in agreement with Robeck and coworkers (1962) who observed that seepage through unsaturated sand reduced poliovirus levels by > 99.99 percent. The capacity of slow sand filtration to remove viruses was investigated by Robeck and coworkers (1962) who obtained a 96 percent removal of poliovirus. Poynter and Slade (1977) also showed that this process was efficient for removing enteroviruses.

Factors that adversely affect removal of microorganisms during sand filtration are low temperatures, high flow rates, insufficient sand depth, and filter immaturity. The importance of temperature was demonstrated by Burman (1962) who reported that during cold weather, only 41 percent of E. coli and 88 percent of total coliforms were removed by slow sand filtration. Poynter and Slade (1977) reported that the lowest poliovirus reduction of 98.25 percent was obtained at 5°C and at a flow rate of 12.0 m per day; whereas, at a standard rate of 4.8 m per day and at 11°C, poliovirus was reduced by 99.999 percent [See also Sections B.1.b, B.1.d, and C.2.b].

Bacteria are not retained quite as efficiently as are the enteric viruses in slow sand filters. Total coliforms were reduced by 96.3 to 99.5 percent, and slightly lower

reductions were obtained for E. coli and colony counts at 22°C (reductions of the colony count at 37°C were lower yet). Results from a 12-year study of slow sand filtration showed that reductions in total coliforms and colony counts varied from 70 to 98 percent when an infiltration rate of 5 m per day was used (Hoekstra, 1978) [See also Sections C.1 and D].

Only marginal reductions of microorganisms are possible with rapid sand filtration. Robeck and coworkers (1962) showed that not more than 50 percent of polioviruses could be removed with this step, and in other studies removal of enteric viruses and bacteriophages fluctuated between 0 and 98 percent (Berg, et al., 1968; Guy, et al., 1977).

Less information is available on the removal during infiltration of pathogenic protozoa such as Entamoeba histolytica and Giardia lamblia, and metazoan parasites such as Ascaris lumbricoides and Schistosoma. Results of Baylis (1936) and a review in the report of the Safe Drinking Water Committee (1977) indicate that most of these organisms can be removed by sand filtration, although Rivas (1967) reported that, in some cases, sand filters do not remove Schistosoma cercariae. Nevertheless, mechanical means of clarifying water, such as sand filtration, are important as antiparasitic measures, especially when one considers that the protozoan cysts are resistant to usual residual chlorine concentrations maintained in the distribution system [See Section B.1.c].

j. Conclusion. When the available data on the various sand filtration processes are compared, it becomes clear that artificial recharge in the ground, through river banks and in sand dunes, is one of the most effective treatments for removing microorganisms from raw water. Slow sand filtration is also well suited for removing enteric viruses and is slightly less so for bacteria.

The efficiency of water purification in slow sand filters is a function of raw water quality and is adversely affected by low temperatures, excessive flow rates, inadequate sand depths, and immaturity of the filter. The mechanisms by which bacteria and viruses are removed in the sand are not yet clear, but both organisms seem to respond in the same way to the cleaning process, whereby the viruses are removed more efficiently than the bacteria. Rapid sand filtration is not efficient enough to serve alone for the

removal of viruses and bacteria, thus, it should be used only in combination with other treatments, such as slow sand filtration and flocculation.

Areas with the needed soil configurations or the requisite land area and sand to build filters, would find artificial recharge or slow sand filtration a very simple, practical, reliable, and inexpensive method for removing microorganisms from raw water. The level of efficiency falls, however, in cold climates.

4. Activated Carbon Filtration

Activated carbon filtration has proved to be extremely useful for the treatment of drinking water and is almost indispensable with water from surface sources. However, the microbiological quality of water treated by activated carbon filtration has often failed to meet legal requirements because of high colony counts measured by the German Standard Procedures. Bacteria can actively contribute to the improvement of water quality during activated carbon filtration [See the reports of Project Area II: Advanced Treatment Technology]. The microbiology of activated carbon filtration for the treatment of drinking water is poorly understood because testing, to date, has been done according to German Standard Methods that were devised to guarantee safe water rather than to characterize the microbial community.

The present discussion addresses the numbers, kinds, and metabolic activities of bacteria in activated carbon filters for drinking water. The numbers of microorganisms can be determined accurately only by separating them from the carbon (e.g., with a standard household mixer) and culturing them on a rich medium incubated at 25°C for seven or more days to accommodate the long generation times of some of them. Bacteria, in a study by Klotz and coworkers (1976), were identified according to Bergey's Manual of Determinative Bacteriology (Buchanan and Gibbons, 1974). The metabolic activities of the bacteria were assessed by comparison of a sterile and a nonsterile activated carbon filter. Biocidal substances were not effective, so activated carbon filters were autoclaved and operated with filter-sterilized water. The activities of the bacteria could not be determined solely on the basis of CO_2 production or O_2 consumption during the passage of the water through the filter beds because some purely chemical oxidation of organic substances adsorbed to active carbon also takes place.

a.   Numbers and Kinds of Microorganisms. It proved
impossible in practice to produce, by means such as the use
of silver-impregnated carbon or frequent back-washing of
filters, water that had low enough colony counts to meet
German Standards after activated carbon treatment. Colony
counts in the activated carbon filters examined ranged from
10^7 to 10^8 bacteria per g of wet material and were stable
for several years if the treatment processes remained
unchanged. Bacterial numbers were a function of the treat-
ment processes, especially those affecting the degradability
of organic substances. Bacterial numbers were minimally
affected by the use of different types of activated carbon
and apparently not at all by seasonal variations, including
changes of temperatures between 5° and 25°C.

The activated carbon filtrate gives colony counts of
about 10^4 per ml of water, but is otherwise satisfactory
when examined according to the German Standard Methods.
Activated carbon filters can be compared to chemostats in
that the rate of flow has a direct influence on microbial
development.

Although numbers of bacteria found on the activated
carbon and in the filtrate were relatively constant, the
proportions of organisms in each of the two phases are
governed by events occurring on the boundary surfaces of the
water-carbon system. Examination by scanning electron
microscopy reveals that the space on the carbon surface is
only partially occupied by bacteria. In the middle range of
concentrations, the adsorption of bacteria is governed by
the isotherm equation of Freundlich. The equilibrium of
adsorption in a beaker in the laboratory is reached only
after 24 h and is influenced by the ionic composition of the
aqueous phase and by whether the bacteria are dead or alive,
but evidently not by variations of temperatures normally
encountered in drinking water treatment.

A great variety of bacteria, among which 26 species
from 12 genera could be identified, was found in the acti-
vated carbon filtrate. As expected, most species identified,
was found in the activated carbon filtrate. As expected,
most species identified belonged to the genus Pseudomonas,
which is characterized by a very adaptable metabolism [See
also Sections A.2.a to b, B.1.a(ix), C.2.c, F.2.a, and F.3].
Next most prevalent was the genus Bacillus. Fungi and
yeasts are encountered only rarely and do not seem to be of
any importance.

b. **Microbial Metabolism on Activated Carbon and Its Effects on Water Quality.** Activated carbon adsorbs organic substances and desorbs them slowly, so they serve as a sustained source of nutrients for bacteria associated with the carbon. The resulting stimulation of bacterial growth apparently increases with increasing diameter of the carbon grains, negating the adverse effect of the reduction in surface area that goes with larger grain size. Adsorption increases the local concentration of the organic substances, which enhances the probability that they will be degraded. Even substances toxic to the bacteria are more susceptible to biological degradation once they have been adsorbed to the carbon.

Most of the organic substances removed in treating water by activated carbon filtration are removed by adsorption rather than biological degradation. In a recent study, the total reduction of organic substances (measured by COD, $KMnO_4$-reaction, and UV-adsorption) by non-sterile activated carbon filtration was found to be 80 percent (while the material still had very nearly its initial high adsorptive capacity) of which the part attributable to bacterial activity was approximately 4 percent. As the adsorptive capacity of the carbon declines with use, the part of removal of organics attributable to bacterial activity rises considerably. The changes of O_2 and CO_2 content that take place during filter passage are mainly produced by bacteria; only one-third is caused by purely chemical reactions.

Bacteria act most efficiently upon the most easily degraded substances: 60 percent of the removal of easily degradable substances (expressed as BOD_2) is effected by bacteria, whereas only 17 percent of the more resistant substances (expressed as BOD_{20}) is degraded by bacteria. It is important that the more easily degradable substances be eliminated by bacteria, for the biologically active carbon filter quite effectively eliminates substances which can give rise to aftergrowth within the distribution system [See Section F.2]. In addition, bacterial activity produces something of a regeneration of the carbon, thus prolonging the period of its usefulness. In general, the microbiological degradability of organic substances will be diminished by chlorination and enhanced by ozonation [See Section F.2.a].

c. **Conclusions.** The bacterial activity that takes place in activated carbon filters is supported by organic substances adsorbed to the carbon (Klotz, 1978; Klotz, et al., 1975, 1976a, 1976b; Werner, 1978, 1979). The more

readily degradable substances are used by the bacteria in the filters, extending the useful life of the carbon and reducing the capacity of the treated water to support microbial aftergrowth during distribution. A suggested adverse effect on consumer health, from bacteria and their derivatives in the treated water, has yet to be substantiated.

5. Disinfection

a. Chlorination. Since the beginning of the 20th century, chlorine has been one of the most widely used and thoroughly studied of chemical oxidants employed in drinking water disinfection. This paper discusses the various reactions between chlorine and water constituents, in terms of the important parameters governing these reactions and their ultimate effects on microorganisms. Also described is the mechanism by which chlorine acts upon the biota present in water.

(i) Chlorine Dissociation in Water. Chlorine, when added to water in the gaseous state or as sodium hypochlorite, initially hydrolizes to form hypochlorous acid:

1. $Cl_2 + H_2O \rightleftharpoons HOCl + H^+ + Cl^-$

2. $NaOCl + H_2O \rightleftharpoons HOCl + Na^+ + OH^-$
At pH 5, all chlorine occurs as hypochlorous acid, but as the pH increases, more hypochlorous will dissociate forming hydrogen and hypochlorite ions. Below pH 5, and at a concentration of > 1,000 mg per l, chlorine may be present in the elemental state (Cl_2) (White, 1972). The chemical species thus formed -- Cl_2, HOCl, and OCl^- -- are called free residual chlorine and their occurrence in water can be summarized as:

Cl_2 + HOCl at pH < 6 and HOCl + OCl^- at pH > 6.
Temperature affects the equilibrium of the reaction, as expressed by the dissociation constant (KD) according to the following relation:

$KD = 2.6 \times 10^{-8}$ mole per l at 10°C

$KD = 3.7 \times 10^{-8}$ mole per l at 25°C

Thus, a rise in temperature increases the dissociation of hypochlorous acid.

Depending on the level and nature of pollution in a water supply, chlorine will react partially or totally, by oxidation or substitution, with organic and inorganic constituents of the water. In the case of iron, for example, chlorine reacts with ferrous ion and converts it to the ferric form:

$$2FE^{++} + HOCl + 5H_2O \longrightarrow Fe(OH)_3 + Cl^- + 5H^+$$
Soluble manganese compounds are similarly oxidized:

$$Mn^{++} + HOCl + H_2O \longrightarrow MnO_2 + Cl^- + 3H^+$$
Both of these metal compounds will precipitate out. With anions such as nitrites, sulfides, and sulfites, the following reactions take place:

$$NO_2^- + HOCl \longrightarrow NO_3^- + Cl^- + H^+$$

$$HS^- + HOCl \longrightarrow S^0 + Cl^- + H_2O$$

$$SO_3^{--} + HOCl \longrightarrow SO_4^{--} + Cl^- + H^+$$
At pH's > 8, chlorine occurs principally as hypochlorite ions and gives the following reactions:

$$CN^- + OCl^- \longrightarrow CNO^- + Cl^-$$

$$S^{--} + 4OCl^- \longrightarrow SO_4^{--} + 4Cl^-$$
Ammonia reacts with chlorine to produce inorganic chloramines according to a sequence of reactions that begins (at pH's up to 8.3) with the formation of monochloramines:

$$NH_3 + HOCl \longrightarrow HN_2Cl$$
The second stage proceeds as an equilibrium reaction between mono and dichloramine:

$$NH_2Cl + HOCl \rightleftharpoons NHCl_2 + H_2O$$
Finally, trichloramine is formed in the third stage:

$$NH_2Cl + HOCl \longrightarrow NCl_3 + H_2O$$
These reactions are dependent on pH, temperature, contact time, and the initial ratio of chlorine to ammonia. Chloramines will convert to form elemental nitrogen if the ratio

of chlorine to nitrogen exceeds 7.6:

$$2NH_3 + 3Cl_2 \longrightarrow N_2 + Cl^- + 6H^+$$
and in some cases, nitrates will, instead, be the product formed.

Organic chemicals with functional groups similar to ammonia (e.g., urea, amino acids, proteins, and other amines) react with chlorine to produce organic chloramines:

$$RNH_2 + HOCl \rightleftarrows RNHCl + H_2O$$

$$RNHCl + HOCl \rightleftarrows RNCl_2 + H_2O$$
Chlorine linked with nitrogen is called combined residual chlorine. The sum of free residual chlorine ($HOCl$ and OCl^-) and combined residual chlorine determines the total residual chlorine; it is this total residual chlorine that constitutes the germicidal potential available in chlorine disinfection.

All of these reactions may occur in succession during water treatment [See Figure E.5.a-1]. Zone 1 of the curve in Figure E.5.a-1 occurs with low quantities of chlorine added to water. Here, chlorine will combine immediately with reduced mineral compounds. Higher chlorine inputs result in the formation of chloramines and some organo-chlorinated compounds (Zone 2). Further addition of chlorine causes a loss in total residual chlorine due to the oxidation of chloramines (Zone 3). When sufficient chlorine has been added to react with all the chlorine-consuming chemicals in the water, the breakpoint will be reached, during and after which chlorine forms free residual chlorine, the same as would occur in pure water (Zone 4). Reactions with other chemical constituents of a particular water source that may lead to the formation of toxic or even carcinogenic compounds are discussed in Project Area IIA of this Pilot Study.

(ii) Parameters Affecting the Disinfection Efficiency of Chlorine. How efficiently chlorine will disinfect depends on the microbial composition of the water, the chlorine dose applied, the contact time, and the chemical form taken by the chlorine. The chemical form of chlorine, in turn, depends on the pH and temperature of the water, along with the amounts and types of dissolved organic and inorganic substances present.

FIGURE E.5.a-1

DIAGRAMMATIC REPRESENTATION OF COMPLETED
BREAKPOINT REACTION
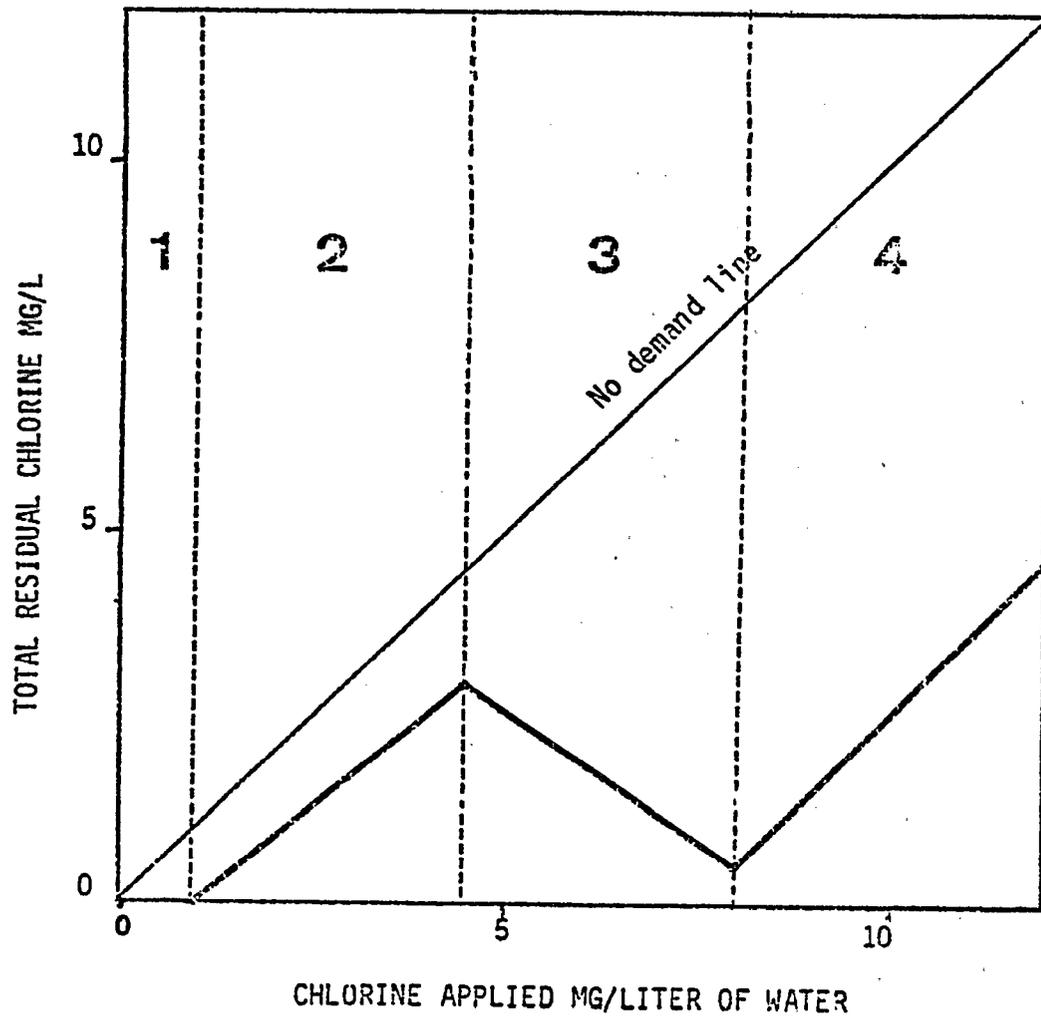

The following discussion takes into account only that chlorine which occurs as a residual during and after break-point chlorination. These chemical forms exert different germicidal effects. Feng (1966) proposed the following order of disinfecting efficiency:

$$Cl_2 > HOCl > OCl^- > NHCl_2 > NH_2Cl > R-NHCl$$
Morris (1967) measured the effects of HOCl, OCl^-, and NH_2Cl on various microorganisms and constructed a table of le-thality coefficients for making comparisons [See Table E.5.a-1]. His results reiterated that HOCl > OCl^- > NH_2Cl. These studies confirmed earlier results of Butterfield and coworkers (1943) who found that at pH 10.7, when most of the chlorine would dissociate to form hypochlorite ion, a 60-fold increase in contact time was required to inactivate E. coli and S. typhi over that required at pH 7, when the greater fraction of chlorine would be HOCl. In similar studies, it was found that increasing the pH from 7 to 8.5 for poliovirus 1 (Weidenkopf, 1958) and from 8.8 to 9 for adenovirus 3 (Clarke, et al., 1956) extended the inacti-vation time sixfold.

Although the bactericidal and virucidal superiority of HOCl over OCl^- has since been demonstrated by others (Engel-brecht, et al., 1978; Scarpino, et al., 1974), inconsistent results were obtained with poliovirus (Scarpino, et al., 1974) which were thought to be due either to direct effects of pH (Morris, 1970) or to the presence, in the medium, of mineral ions (Engelbrecht, et al., 1978; Kuzminski, et al., 1970). Indeed, Engelbrecht and coworkers (1978) have shown that the presence of potassium chloride accelerated polio-virus 1 inactivation by hypochlorous acid. Because, unlike the poliovirus, E. coli inactivation by hypochlorite ions was not enhanced in the presence of potassium chloride, it would seem likely that it is the potassium choride, more than the hypochlorite ions, that was responsible for pro-ducing greater poliovirus inactivation.

It is commonly agreed that chloramines are less effec-tive disinfectants than free chlorine against bacteria (Butterfield, 1948; Esposito, et al., 1974; Siders, et al., 1973), viruses (Esposito, et al., 1974; Lothrop and Sproul, 1969; Siders, et al., 1973) [See Table E.5.a-2], and proto-zoan cysts (Chang, 1971b; Stringer, et al., 1975). More-over, the organic chloramines disinfect even less efficiently than the inorganic chloramines (Feng, 1966; Kjellander and Lund, 1965; Nusbaum, 1952). Hence, for optimal disinfection,

TABLE E.5.a-1

[a]Concentration of compound multiplied by contact time (mg/l) (min).

free chlorine should be present in the water. Free chlorine, inorganic chloramines, and organic chloramines all have their own characteristic oxidation potentials, which also affects the efficiency of disinfection [See Table E.5.a-3].

Chlorine may be applied at the end of the treatment process so that a residual will be maintained throughout the distribution system. In this way, aftergrowth is prevented [See Section F.2.a] and as long as the residual remains detectable, it ensures that no contamination has occurred during distribution. As yet, no alternative has been found to provide an equivalent measure of protection during distribution [See also Project Area IIA].

(iii) Effects of Chlorine Dose and Contact Time on Disinfection Efficiency. The relationship of the concentration of free available chlorine to the time required for destroying a certain portion of microorganisms is expressed by the empirical equation:

$$c^n t_p = k$$

where c = disinfectant concentration, t_p = the time required for obtaining a constant percentage destruction of microorganisms, n = the Van't Hoff order of the reaction (or coefficient of dilution), and k = a calculated constant that represents an organism's relative resistance to a given disinfectant. For example, Fair and coworkers (1968) calculated values for an elimination of 99 percent of an initial population by HOCl (for which $n = 0.86$):

$$c^{0.86} t_p = 6.3 \text{ for coxsackievirus A2}$$

$$c^{0.86} t_p = 1.2 \text{ for poliovirus 1}$$

$$c^{0.86} t_p = 0.098 \text{ for adenovirus 3}$$

$$c^{0.86} t_p = 0.24 \text{ for } \underline{E. \ coli}$$

When n is > 1, the efficiency of the disinfectant decreases rapidly with dilution. When n < 1, the efficiency of disinfection is based principally on contact time. When $n = 1$, the efficiency of disinfection is based equally on concentration and contact time.

It is difficult to review the literature for this type of information because of insufficient reporting of experimental conditions. However, from more recently published

TABLE E.5.a-3

THE OXIDATION-REDUCTION POTENTIAL OF CHLORINE IN WATER

Reaction	Redox Potential at 25°C
$Cl_2 + 2e^- \longrightarrow 2Cl^-$	+ 1.39 V
$HOCl + H^+ + 2e^- \longrightarrow Cl^- + 2H_2O$	+ 1.49 V
$OCl^- + 2H_2O + 2e^- \longrightarrow Cl^- + 2OH^-$	+ 0.94 V

accounts in which data were expressed as concentration x
contact time (C x t) [See Table E.5.a-2], it can be seen
that the different forms of chlorine vary markedly in their
abilities to inactivate E. coli and poliovirus 1.

(iv) Sensitivity of Microorganisms to Chlorine. Under
ideal conditions, the destruction of a microbial population
theoretically can be predicted on the basis of Chick's law
(Morris, 1975), given that one disinfectant unit acts on one
single target site. This relation is written:

$$N = N_o C^{-at}$$

where N is the number of surviving microorganisms; N_o is
the initial number of microorganisms; a is the slope of the
inactivation curve; and t is the contact time. However, in
practice, discrepancies between laboratory experiments and
field assays have been noted with vegetative bacteria
(Carson, et al., 1972), bacterial spores (Bond, et al.,
1973), E. histolytica (Stringer, et al., 1975), and lab-
oratory and indigenous enteroviruses (Block, et al., 1978).
It would seem possible, therefore, that factors such as
aggregation, adsorption, and microbial resistance to a dis-
infectant, acquired over time, might limit the usefulness of
calculations when applying Chick's law.

Bacteria may aggregate in the presence of naturally
occurring polysaccharide polymers (Harris and Mitchell,
1975) or they may adsorb to hydroxides in the water (Carlson,
et al., 1975). Moreover, viral particles have been shown to
aggregate spontaneously   in distilled water (Floyd and Sharp,
1977) or in the presence of di- or trivalent ions (Floyd
and Sharp, 1978). This clumping of bacteria (Carlson, et
al., 1975; Poynter, et al., 1973) and viruses (Berg, 1964)
limits diffusion of the oxidant, thereby decreasing the
disinfection rate (Sharp, et al., 1975), which could explain
the persistence of infectious particles in treated water
(Engelbrecht, et al., 1978; Lovtsevich, 1973).

Turbidity also limits disinfectant action because
microorganisms will adhere to suspended matter (Hoff, 1978).
E. coli persisted several hours in turbid water to which
chlorine had been added (Tracy, et al., 1966). Likewise,
adding bentonite decreased the chlorine inactivation of
coliphage MS_2 (Stagg, et al., 1977), although decreased
disinfectant efficiency was not observed when kaolinite and
aluminum oxide were tested with coliphage T7 and poliovirus
1 (Boardman and Sproul, 1977) [See also Sections C.2.a to
b].

Beside the enhanced resistance to disinfectants afforded bacteria and viruses that are adsorbed to suspended matter or aggregated in clumps, sensitivity to chlorine differs from one microbial group to another and, in some cases, within the life cycle of one species. Indicators and pathogens most commonly isolated from water (e.g., E. coli, Klebsiella, Salmonella, Shigella, and Pseudomonas) show similar resistance to chlorine. Salmonella species [See also Section B.1.a(i)] are not exceptionally resistant to chlorine and should be controlled effectively by proper application of disinfectants. The same holds true for Francisella tularensis (Gotovskaia and Mogaram, 1945) [See Section B.1.a(v)] and most of the other bacterial pathogens.

However, there are other microbes whose resistance to chlorine exceeds that of the coliform group; these include spores of clostridia and of aerobic bacteria, enteroviruses, yeasts, acid fast bacilli, and cysts of protozoan pathogens. It is well established that enteroviruses are more resistant than E. coli to chlorine (Butterfield, 1948; Engelbrecht, et al., 1978; Weidenkopf, 1958) [See Table E.5.a-3] although there are no data for the hepatitis A virus. Yet, even among the enteric viruses, there is variation in resistance to chlorine. When water of zero chlorine demand and 0.5 mg per l free residual chlorine was held at 2°C, the time needed to inactivate 25 human enterovirus types ranged from 2.7 min for reoviruses to > 120 min for coxsackievirus A (Liu, 1978). Grouped according to their resistance to chlorine, viruses compare with E. coli in the following order: poliovirus > coxsackievirus > coliphage MS_2 > E. coli. Moreover, viruses may be gradually selected for resistance to chlorine after repeated sublethal exposure (Bates, et al., 1977). In similar studies, Shaffer (1978) found poliovirus, all of serotype 1, to exhibit varying sensitivity to chlorine.

A review by Engelbrecht and Greening (1978) compared data which, although collected under different experimental conditions, nevertheless serve to indicate that Mycobacterium fortuitum, M. phlei, and Candida parapsilosis [See Sections A.2.a and C.2.f] are more resistant than poliovirus to chlorine.

Data on survival of Entamoeba histolytica [See Section B.1.c(i)] exposed to free chlorine, ammonia, and chloramines are summarized in Figures E.5.a-2 and 3. The parameter of cysticidal residual used in these calculations is defined as that concentration required to kill 99.999 percent of cysts. From the curve in Figure E.5.a-2, it is clear that ordinary

SLOPE $= \dfrac{E}{2.3nR} = \dfrac{E}{4.575}$

$E = 2{,}750 \times 4.575$

$\quad = 12{,}500$ calories
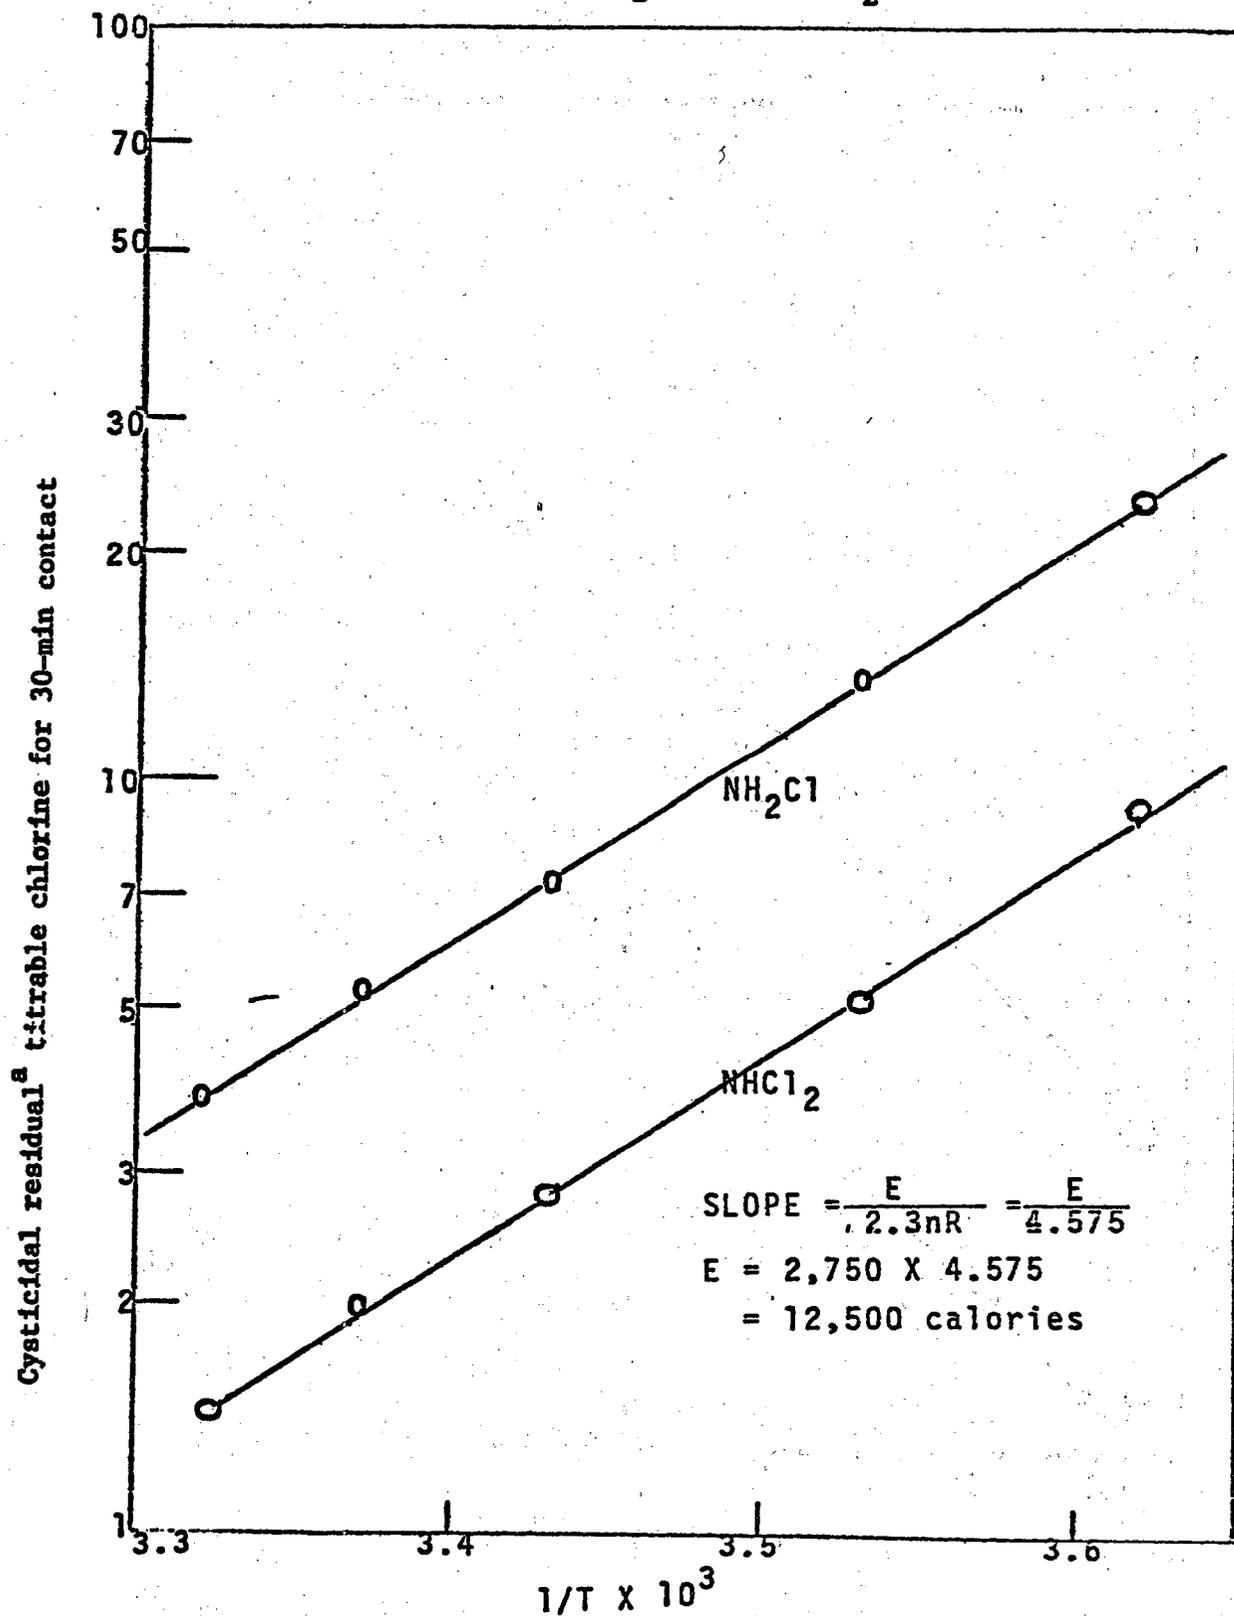

[a]Concentration required to kill 99.999 percent of cysts.

chlorination practiced in water treatment is inadequate to kill cysts (taking into account pH and temperature effects). Chlorine concentrations needed to kill E. histolytica cysts in clarified water in 20 to 30 min can exceed 9 ppm, depending on pH, temperature, and ammonia concentration. Likewise, Giardia lamblia cysts [See Section B.1.c(ii)] are not destroyed by chlorination at dosages and contact times commonly used in water treatment. Moreover, Acanthamoeba and Naegleria cysts [See Sections B.1.c (iii) and (iv)] are both highly resistant to chlorine (Dejonckheere and van de Voorde, 1976), which may account for their widespread presence in U.S. (and probably other) water supplies. Infective larvae of hookworms and threadworms [See Section B.1.c(v)] are more resistant to disinfection than enteric bacteria, viruses, or even protozoan cysts.

(v) The Action of Chlorine on Microorganisms. Chlorine acts on bacteria by changing membrane permeability, causing a loss of cellular material including potassium and UV-absorbing material (probably nucleic acids and protein). Also altered is the zeta potential of the membrane (Venkobachar, et al., 1977), whereby ozone acts upon those membrane-linked respiratory enzymes containing sulfhydryl groups (e.g., aldolase, triosephosphate-dihydrogenase, glutamate decarboxylase) (Green and Stumpf, 1946; Knox, et al., 1948). Finally, chlorine reacts with nucleic acids (Bocharov and Kulikovski, 1971; Fetner, 1962; Rosenkranz, 1978; Shih and Lederberg, 1976) of both bacteria and viruses.

Using coliphage f2, Dennis and coworkers (1979) demonstrated that chlorine reacted first with RNA (incorporation of chlorine being pH-dependent). In another study, chlorine was found to also react with the protein capsid of coliphage f2 (Olivieri, et al., 1975). In the case of enteric viruses, it probably is their lack of enzymes and other sensitive systems that accounts for their greater resistance to chlorine.

(vi) Summary. It is certainly true that chlorine alone cannot produce safe drinking water. However, the chemistry and microbiology of chlorine disinfection of water have been studied for many years and have resulted in a rich base of scientific literature. Used appropriately, chlorine is known to be effective against a wide variety of undesirable or pathogenic organisms in water. Other disinfectants may be superior in certain specific applications, but chlorine

remains the unchallenged standard for many purposes in drinking water treatment and distribution.

b. Ozone Treatment. Ozone (O_3), an allotropic form of oxygen, is a potent biocide used extensively throughout Europe in drinking water treatment. Schonbein coined the name ozone in 1839, from the Greek word ozein, to smell, which is appropriate because ozone was first recognized in 1783 by the Dutch physician Van Marum, on the basis of a peculiar odor given off by an electrical machine. However, it was not until 1865, that Soret demonstrated the existence of a triatomic molecule and in 1873, Fox described the bactericidal properties of ozone.

In 1976, 200 water treatment facilities in Europe disinfected with ozone, compared to 20 in Canada, and only three in the U.S. (International Ozone Institute, 1976). Ozone has received more attention in the U.S., though, as a disinfectant of urban wastewaters and is used for this purpose at ten U.S. facilities.

Ozone's disinfecting capability is at least equal to that of chlorine dioxide (Holluta and Unger, 1954) [See Section E.5.c] and is greater than that of chlorine (Fluegge, et al., 1978; Munger, et al., 1977; Traenhart and Kuwert, 1975) [See Section E.2], bromine, and iodine (Kruse, et al., 1970) [See Sections B.1.c(i) and E.5.d]. The powerful germicidal properties of this agent are due to its high oxidation-reduction (redox) potential that results from the different chemical forms of ozone formed in water, particularly the primary and secondary free radicals. It follows that, for all types of microorganisms, the specific coefficient of lethality, as defined by Morris (1967), is always higher for ozone than it is for free chlorine or chloramines.

(i) Factors Affecting the Disinfection Efficiency of Ozone. The efficiency with which ozone can be expected to disinfect water is influenced, as is true with other chemical oxidants, by: (1) the quality of the water to be treated; (2) the amount of disinfectant applied and the contact time; and (3) the types and densities of microorganisms in the water.

(i.1) Quality of the Water to be Treated. A discussion of water quality must address the parameters of pH,

temperature, suspended matter, and chemical composition. Ozone's bactericidal and virucidal capabilities are far less dependent on pH than are those of chlorine (Diaper, 1972; Kinman, 1975; Traenhart and Kuwert, 1975). Different authors have variously reported ozone to be effective as a disinfectant between pH 5.8 to 8 (Suchkov, 1964), pH 6 to 8 (Evison, 1977), and pH 5.6 to 9.8 (Farooq, et al., 1977a).

Part of the ozone decomposes into secondary oxidants in water at a rate that increases with higher pH's. At higher decomposition rates there is less ozone residual. This results in a reduced microbial inactivation rate for a given ozone dosage. The effect of pH seems to be entirely through its influence on the ozone residual, such that, if the ozone dose is adjusted to produce a standard residual, the microbial inactivation rate is the same at different pH's (Farooq, et al., 1977a).

Higher temperatures cause greater ozone inactivation of microorganisms, as predicted by the Van't Hoff-Arrhenius theory (Fair, et al., 1968), possibly due to the increased rate of disinfectant diffusion into microbial cells and greater reactivity with cellular substrates. However, the solubility of ozone in water decreases with increased temperatures and one might, therefore, expect the need for greater amounts of ozone with higher temperatures. Yet, between 6 and 30°C (Kinman, 1975), or 5 and 25°C (Evison, 1977), the inactivation rate of ozone remained nearly the same for colony counts and for phage 185. In fact, Farooq and co-workers (1977b) found that, for a given quantity of injected ozone and within a range of 9 to 37°C, an increase in temperature both enhanced inactivation and increased the residual ozone concentration.

Although some authors claim that turbidity has no effect on ozone disinfection (Cerkinsky and Trahtman, 1972; Gevaudan, et al., 1971), Block (1977) found that a population of poliovirus 1, 90 percent of which was adsorbed to kaolin, was more difficult to inactivate with ozone when the turbidity reached 9 Jackson turbidity units (JTU).

Ozone, upon injection into water, may follow any (or a sequential combination) of four pathways: (1) no diffusion in the water; (2) diffusion and autocatalytic oxidation; (3) diffusion and immediate reaction with organic matter; or (4) diffusion and temporary maintenance (a few minutes) of an active residual. The oxidizing action of ozone is dissipated rapidly in the presence of organic matter, but a weak

microbial inactivation is obtained with no measurable re-
sidual of ozone (Block, 1977; Block, et al., 1977; Burleson,
et al., 1975; Coin, et al., 1967; Farooq, 1976; Katzenelson,
et al., 1974; Majumdar, et al., 1974; Mercado-Burgos, et
al., 1975) [See Figure E.6-1, Zone 1]. According to Farooq
and coworkers (1976), inactivation of microorganisms in the
absence of residual ozone could be the result of collisions
between microbes and ozone bubbles that are covered with a
liquid film of high ozone content. The same authors found
that the presence of ozone bubbles alone increased disin-
fection by 90 percent. Block (1977) showed that in the
absence of residual ozone, inactivation was proportional to
the ozone concentration in the gas bubbles.

Beyond a critical ozone dose injected at the break-
point, a dissolved ozone residual is formed [See Figure
E.5.b-1, Zone 2] which can be measured by conventional
methods. Inactivation of microorganisms in Zone 2 is rapid
and considerable, and is a function of the concentration of
dissolved residual ozone and contact time (to be discussed
later). Disinfection, being almost instantaneous once the
ozone demand is satisfied, is reflected by a sharp drop in
the survival curve, referred to as the all-or-nothing effect
(Fetner and Ingols, 1956; Pavoni, et al., 1972; Tonelli
and Ho, 1977). This effect is probably due to a sudden
increase in the redox potential of the solution, causing
immediate catalysis induced by the residual ozone present.

A similar discontinuity is not evident in the curve for
organic matter [See Figure E.5.b-1], possibly because only
minor changes occur in it (Block, et al., 1976), or because
microorganisms comprise only a miniscule portion of the
total organic matter that is measured in the system (Block,
1977). At the breakpoint, low concentrations of organic
matter do not interfere with the inactivation of microor-
ganisms by ozone unless the organism actually is imbedded
within, and therefore physically protected by, the organic
matter (Evison, 1977; Gevaudan, et al., 1971).

(i.2) Ozone Dosages and Contact Time. Inactivation of
microorganisms occurs extremely rapidly once an ozone re-
sidual is present. Inactivation also relates directly to
the redox potential, wherein ozone, with a redox of 350 mv
(Fetner and Ingols, 1956) or 400 mv (Block, 1977; Hugues and
Plissier, 1977), applied for 2 to 4 min has been demon-
strated to inactivate > 99.9 percent of the microbial popu-
lation. This compares quite favorably to chlorine, which

FIGURE E.5.b-1

DIAGRAMMATIC REPRESENTATION OF COMPLETED BREAKPOINT REACTION
For OZONE
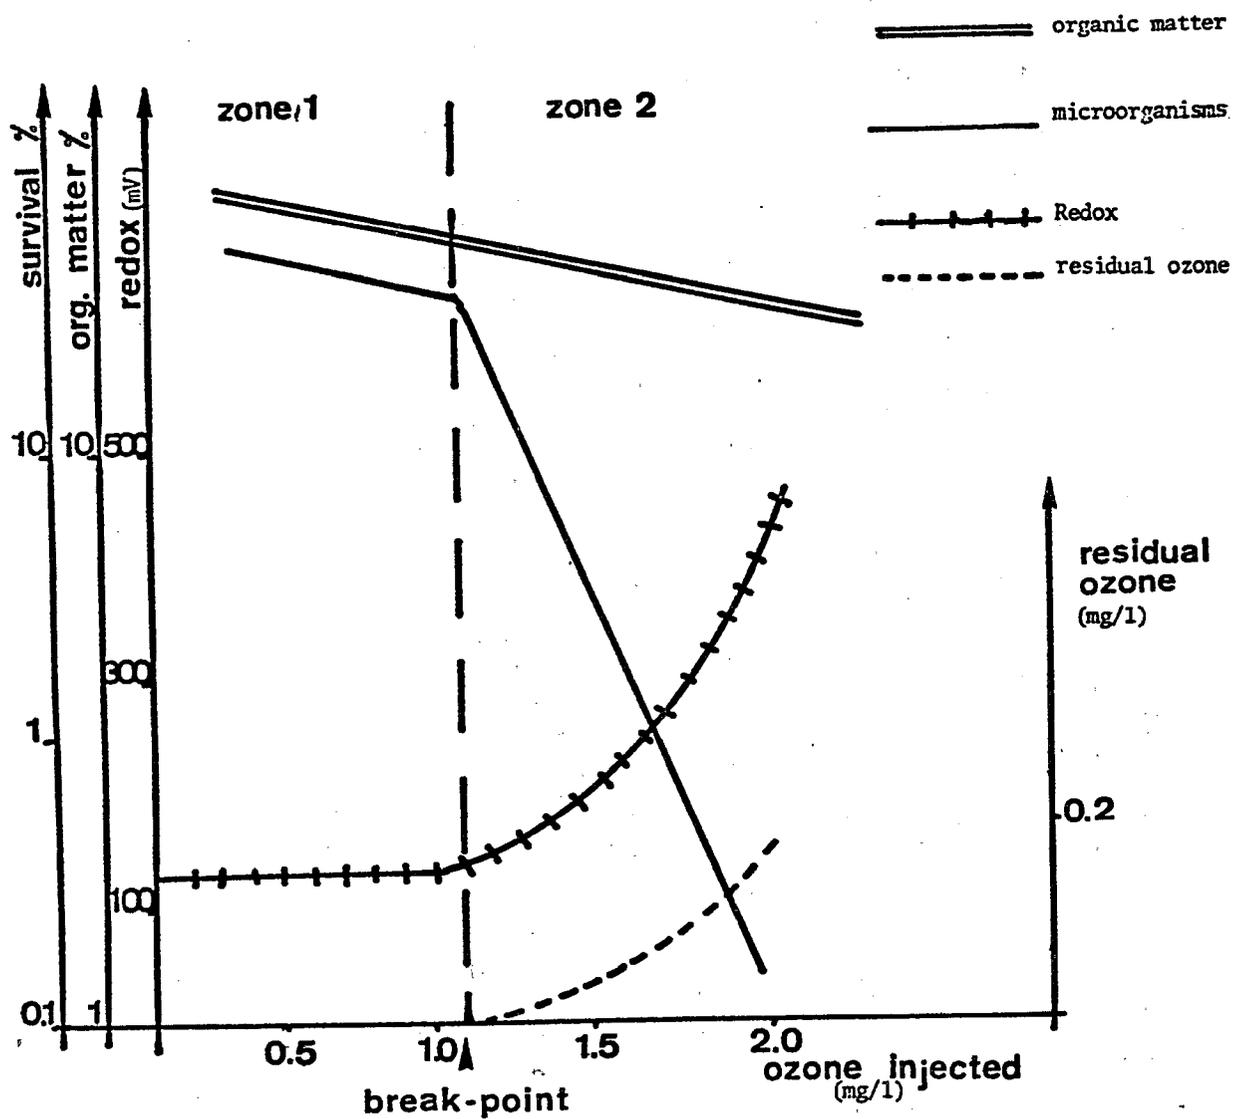

requires a redox of 500 mv and a contact time of 60 min for an equivalent inactivation (Lund, 1963).

Tables E.5.b-1 and 2 summarize data from various studies on inactivation of bacteria and viruses by ozone. There are a great many apparent discrepancies in these tables, which might at first glance be attributed to differences in experimental conditions. However, if one recalculates the results on the basis of the product of ozone concentration (in mg per 1) and time (in sec) required to cause 99.9 percent inactivation of a microbial agent in water that is free of organic matter, one finds that the discrepancies are small. For example, this product is either 3.0 (Block, 1977; Burleson, et al., 1973) or 2.5 (Farooq, et al., 1976) for E. coli and either 1.8 (Evison, 1977) or 1.9 (Block, 1977) for poliovirus 1.

In every case, the ozone residual dissolved in water remained the one critical parameter of disinfection efficiency. Knowing this, water treatment authorities can ensure the elimination of both micropollutants and aggregated or adsorbed microorganisms simply by applying ozone dosages higher than those applied in the laboratory.

(i.3) Sensitivity of Microorganisms to Ozone. Different organisms exhibit different sensitivities to ozone and many authors have tried to use this observation as a basis for classifying groups of organisms. Although some generalities can be drawn from such an exercise -- for example, that poliovirus 1 is more resistant than E. coli to ozone (Block, 1977; Evison, 1977; Farooq, 1976; Katzenelson, et al., 1974), or that bacterial spores are highly resistant to ozone treatment (Broadwater, et al., 1973; Burleson, et al., 1976; Haufele and Sprockoff, 1973; Leiguarda, et al., 1949), ambiguities emerge under closer scrutiny. Contradictory results have been obtained by several authors studying the relative sensitivities of three poliovirus types (Coin, et al., 1964, 1967; Evison, 1977; Snyder and Chang, 1974).

Other factors are likely involved in influencing the sensitivity of organisms to ozone. These might include: different techniques for preparation of stock cultures, age differences of the cultures (Wuhrmann and Meyrath, 1955), and aggregation phenomena (demonstrated experimentally using ultrasonication to change the inactivation kinetics: Burleson and Pollard, 1976; Dahi, 1977; Katzenelson, et al., 1974). Furthermore, relative sensitivity to ozone

TABLE E.5.b-1

[a]Data not reported by author.

varies with contact time and ozone concentration. That is, at disinfection levels necessary to obtain a 99 percent inactivation, poliovirus 1 was more sensitive than coliforms; yet, these two entities showed the same sensitivity when a 99.99 percent inactivation was sought (Ghan, et al., 1976).

The initial density of a microbial population does not appear to affect inactivation kinetics as long as increased numbers do not increase the ozone demand in the water (Block, 1977). On the other hand, the presence of organic matter does interfere with disinfection efficiency (Farooq, 1976).

(ii) Action of Ozone on Microorganisms. Ozone inactivation of bacteria can be described as an oxidation reaction (Bringmann, 1954), both the reaction and the inactivation being rapid. The ozone acts on at least three sites on the bacterium: the cell wall, the cytoplasmic membrane, and the nuclear apparatus.

Ozone acts on the cell wall, causing bacterial cell lysis and death which adds soluble COD to the water (Rosen, et al., 1974). Cell lysis, however, probably is not the primary means of inactivation, but a consequence of either high ozone levels (at the gas-liquid interface) or prolonged ozonation (Perrich, 1976). The cytoplasmic membrane probably is affected first (Christensen and Giese, 1954) by reactions of ozone with glycoproteins, glycolipids, (Scott and Lesher, 1963; Smith and Bodkin, 1944), or the amino acids tryptophan (Goldstein and McDonagh, 1975) or cysteine (Mudd and Freeman, 1977). Bacterial death also may result from changes in permeability of the cytoplasmic membrane. Ozone disrupts bacterial respiration by reacting with the sulfhydryl groups of certain enzymes. Bacteria exposed to ozone were shown to lose their ability to degrade sugars and produce gases (Vronchinskii, 1963). Ozone reacts with glucose-6-phosphate dehydrogenase as well as with other enzyme systems (Chang, 1971b).

In addition, ozone can act on the nuclear material and provoke mutations. Christensen and Giese (1954) and Scott and Lesher (1963) demonstrated that ozone affects both purines and pyrimidines. More recently, Prat and coworkers (1968) showed that pyrimidine bases of nucleic acids in E. coli undergo modifications when the bacteria are treated with ozone (thymine being more sensitive than cytosine or uracil). Sublethal exposure to ozone can cause nucleic acid mutations similar to those caused by x-rays, without impairing growth and division of the cell (Hamelin and Chung, 1974, 1975).

(iii) Summary. Ozone is effective against both bacteria and viruses in water. As a principal disinfectant (and disregarding cost), it appears to be faster and more effective than chlorine as well as less influenced by water quality; its only relative shortcoming is that active ozone residuals cannot be maintained in water for significant periods of time [See also Section F.2.a and Project Area IIA]. Ozone also has been used, with relative success, prior to slow sand filtration [See Section E.3] to render compounds more biodegradable.

c. Chlorine Dioxide. The history of chlorine dioxide, its physical and chemical properties and reactions, methods for generation and measurement, and its uses in water treatment have been reviewed in several recent publications (Gall, 1978; Miller, et al., 1978; Rosenblatt, 1975; Sussman and Rauh, 1978; White, 1972). Chlorine dioxide has been used primarily as an oxidant in industrial processes for bleaching of pulpwood, textiles, flour, fats, oils, and waxes. Its use in the treatment of drinking water has been extremely limited, however, especially in the U.S.; and when used at all, chlorine dioxide has been applied mainly to improve the organoleptic properties of the water rather than to disinfect. Recently, chlorine dioxide has been viewed with increased interest as a possible alternative to disinfection with chlorine, against which arguments have been raised concerning its capacity to generate toxic and carcinogenic compounds [See Section E.5.a].

(i) Bactericidal Efficiency. Of results reported in earlier studies on the bactericidal efficiency of chlorine dioxide, only some have been upheld by later work.

Ridenour and coworkers (1949) showed that chlorine dioxide was more effective than chlorine for inactivating endospores of Bacillus subtilis, B. megaterium, and B. mesentericus. Berndt and Linneweh (1969) also reported that chlorine dioxide was a more efficient sporicide than chlorine. In addition, Ridenour and Ingols (1947), and Ridenour and Armbruster (1949) found chlorine dioxide to be an effective bactericide against indicators (Escherichia coli, Enterobacter aerogenes), enteric pathogens (Salmonella typhi, S. paratyphi B, and Shigella dysenteriae) [See Sections B.1.a(i) and (ii)], and other pathogens (Staphylococcus aureus, Pseudomonas aeruginosa) [See Sections B.1.a(ix) and F.2 to 3]. Their results indicated that the disinfection

efficiency of chlorine dioxide increased at higher pH's and
that it was a more efficient bactericide at pH 9.5 than
chlorine. The work of Trakhtman (1946), and Bedulevich and
coworkers (1953) also indicated that the bactericidal ef-
fectiveness of chlorine dioxide was equal to or greater than
that of chlorine against E. coli, S. typhi, and S. para-
typhi. However, their results indicated that its effec-
tiveness decreased rather than increased under alkaline
conditions. Early studies by McCarthy (1944; 1945) indi-
cated that chlorine dioxide was an effective bactericide in
water low in organic matter content, but was less effective
when organic matter concentrations were higher.

White (1972) reviewed several of these early studies
and pointed out that the lack of methods for preparing pure
chlorine dioxide free of residual chlorine, and the lack of
analytical procedures for measuring it in the presence of
other oxychloro chemical species, would have tended to
produce errors in which analytic results showed mistakenly
high chlorine dioxide levels. Hence, the disinfection
efficiency of chlorine dioxide would, in fact, be higher
than had appeared in these earlier tests.

Later, Granstrom and Lee (1958) developed improved
methods for preparing and analyzing chlorine dioxide.
Benarde and colleagues (1965), using these improved tech-
niques, compared the bactericidal efficiency of chlorine and
chlorine dioxide at pH 6.5 and 8.5 in a disinfectant demand-
free buffered system. At pH 6.5, chlorine was slightly more
effective than chlorine dioxide when compared on the basis
of weight. However, at pH 8.5, chlorine dioxide was even
more effective than it was at pH 6.5, whereas chlorine
efficiency declined at the higher pH, reflecting a decrease
in HOCl (the more effective disinfecting species) and an
increase in OCl$^-$ (the weaker disinfecting species) at higher
pH's. Cronier and colleagues (1978) also showed that within
a pH range of 4.5 to 9.0, the bactericidal efficiency of
chlorine dioxide increased as pH increased.

In other studies, Benarde and coworkers (1965) used
sewage effluent to demonstrate that chlorine dioxide was a
more efficient disinfectant than chlorine in the presence of
high levels of organic material. An initial dose of 2 mg
per 1 of chlorine dioxide obtained > 99 percent reduction of
E. coli in sewage after 5 min of exposure, whereas 5 mg per
1 of chlorine destroyed only 90 percent of E. coli after the
same length of exposure. Moffa and coworkers (1975) re-
ported similar results when they compared the bactericidal

action of chlorine and chlorine dioxide applied as disinfectant to combined sewer overflows.

(ii) Virucidal Efficiency. Ridenour and Ingols (1946) reported that chlorine dioxide was as effective as chlorine against a mouse-adapted strain of poliovirus 1. Hettche and Schulz-Ehlbeck (1953) reported that 0.08 mg per 1 of chlorine dioxide was as virucidal for poliovirus as was 0.15 mg per 1 of ozone [See Section E.5.b] or 0.25 mg per 1 of free chlorine. An increase in pH from 5.7 to 8.5 enhanced inactivation of poliovirus 3 (Warriner, 1967); and chlorine dioxide inactivated poliovirus (Mahoney) 4.6 times faster at pH 9.0 than at pH 7.0 (Cronier, et al., 1978). Chlorine dioxide at pH 7.0 and free residual chlorine at pH 6.0 showed approximately equivalent virucidal efficiencies. As with chlorine [See Section E.2]; however, enteric viruses were found more resistant than E. coli to chlorine dioxide (reviewed by Allen, 1979) [See also Sections B.1.b and C.2.b].

(iii) Cysticidal Efficiency. No reports appear to be available on the efficiency of chlorine dioxide for disinfecting   protozoan cysts, notably those of Entamoeba histolytica and Giardia lamblia [See Section B.1.c].

(iv) Mechanism of Action. Ingols and Ridenour (1948) suggested that, following adsorption onto and penetration of the cell wall, chlorine dioxide exerted its bactericidal action by reacting with intracellular enzymes containing sulfhydryl groups. Benarde and coworkers (1967) showed that the incorporation of C^{14}-labelled amino acids [See also Section C.4.a] stopped within a few seconds after exposure of E. coli to chlorine dioxide, indicating interference with protein synthesis. Olivieri (1968) showed that the inhibition of protein synthesis in bacteria exposed to chlorine dioxide was dose-dependent. Examination of cell extracts showed the site of action to be localized in the portion of the cell containing enzymes. The ability of ribosomes to function in protein synthesis was not affected. Studies on the effects of chlorine dioxide on bacterial and viral nucleic acids apparently have not been performed.

(v) Use of Chlorine Dioxide in Water Treatment. Miller and coworkers (1978) reported that chlorine dioxide

is used for some purpose in at least 607 water treatment plants throughout the world. Of these, 495 are in Europe, 84 are in the U.S., and ten are in Canada. In the U.S., chlorine dioxide is used mainly for purposes other than disinfection (i.e., taste, odor, and color control; manganese and iron removal). It is used as the sole disinfectant at only one treatment plant in the U.S. In Europe, chlorine dioxide is used frequently for disinfection, but nearly always in combination with some other disinfectant, usually ozone or chlorine.

(vi) Conclusions. The available evidence indicates that chlorine dioxide is effective for disinfection against bacteria and viruses. When compared to chlorine on the basis of weight, in mg per 1, its disinfection capability is equivalent to free residual chlorine at pH 6 to 7 and is appreciably more efficient than free residual chlorine at higher pH's, which are encountered more commonly in actual water treatment plant operations. An additional advantage is that it does not react with ammonia, as does free residual chlorine, to form chloramines, which are less effective as germicides. Organic compounds normally present in water exhibit a high chlorine demand with free residual chlorine, but appear to be less reactive with chlorine dioxide. Thus, biocidal capability is maintained more effectively with chlorine dioxide than with chlorine.

The bactericidal and virucidal effectiveness of chlorine dioxide is well established; research is needed to determine its ability to inactivate the cysts of waterborne pathogenic protozoa, especially those of E. histolytica and G. lamblia. Additional information on the mode and site of its disinfectant activity also is needed. Other research needs not related directly to disinfection include: (1) developing improved methods for measurement, particularly in the presence of other disinfectants; and (2) evaluating health effects of its major end products, chlorite and chlorate, and of compounds formed by its reactions with other organic compounds in water.

d. Iodine. Historically, iodine has been used primarily in homes and hospitals as an antiseptic for skin surfaces, wounds, surgical instruments, etc. Iodine has been studied as a disinfectant for water for nearly 30 years.

The chemistry of iodine, methods for measurement, and use in water treatment were reviewed by White (1972). In

the pH range 5 to 8, iodine dissolved in water is present
predominantly as diatomic iodine (I_2) and hypoiodous acid
(HIO). Both of these chemical species are considered to be
effective biocides, although more recent evidence suggests
that the hydrated iodine cation (H_2OI^+) may be the active
species (Cramer, et al., 1976). At higher pH levels, the
ineffective biocidal species hypoiodite (IO^-) and iodate
(IO_3^-) are formed. White (1972) indicated that formation of
these inefficient disinfecting species would not be a prob-
lem below pH 8.4. The relative amounts of titrable iodine
existing as I_2 and HIO in aqueous solutions depends on the
pH, iodine concentration, and to a lesser extent, tempera-
ture. Although it is true that elemental iodine and hypoio-
dous acid are the two most powerful disinfecting species of
iodine, their relative efficiency varies considerably de-
pending on the microorganism exposed. Elemental iodine was
more effective than hypoiodous acid for inactivation of
Bacillus metrens spores and Entamoeba histolytica cysts [See
Section B.1.c], whereas hypoiodous acid was more effective
than elemental iodine for inactivation of enteroviruses and
Escherichia coli (White, 1972). Although there is a con-
siderable body of literature on the biocidal efficiency of
iodine, comparison of the results of different investiga-
tions is virtually impossible because of the lack of con-
sistency in experimental conditions such as temperature and
pH, methods for measuring and reporting free iodine, and
microorganisms used.

(i) Bactericidal Efficiency. Chambers and coworkers
(1952) studied the bactericidal efficiency of iodine under
closely controlled conditions of temperature, pH, free
iodine concentration, and exposure time. Bacterial species
studied were Aerobacter (now Enterobacter) aerogenes,
Salmonella paratyphi, S. schottmuelleri, S. typhimurium, S.
flexneri, Shigella dysenteriae, S. sonnei, and Streptococ-
cus faecalis, as well as two strains of E. coli and three
strains of S. typhosa. The results were reported as that
free iodine concentration required to kill all bacteria
exposed ($\sim 10^3$ per ml) in 1 min. Under the most favorable
conditions (pH 6.5, 20 to 26°C), 0.6 mg per l of free re-
sidual iodine killed all species tested. Under the most
adverse conditions (pH 9.15, 2 to 5°C), 4.3 mg per l of free
residual iodine was required.

Chang and Morris (1953) evaluated elemental iodine as
an emergency disinfectant for drinking water. Because they

were interested in practical applications, they used tap
water rather than well-defined, iodine-demand-free buffer
systems. They determined the effects of color, turbidity,
and nitrogenous material, as well as temperature and pH, on
the bactericidal efficiency of iodine. At 25°C and pH 8.1
to 8.5, iodine concentrations of 2 to 5 mg per 1 reduced E.
coli by approximately 6 logs in 10 min. They found in
further studies that S. typhosa, S. schottmuelleri, Shigella
dysenteriae, and mixed coliforms present in sewage were
about as iodine-sensitive as E. coli, whereas Vibrio cholerae
was more sensitive. The bactericidal efficiency of iodine
was approximately the same over a pH range of 4.5 to 8.1.
Low levels of ammonia and urea nitrogen (5 mg per 1), and
turbidity from clays (50 to 500 mg per 1) had no measurable
effect on disinfection efficiency, but high concentrations
of fine loess (165 to 245 mg per 1) interfered with bac-
tericidal action. Berg (1966) indicated that the bacteri-
cidal efficiency of I_2 was about one-fifth that of hypo-
chlorous acid, but about ten times that of the hypochlorite
ion.

    (ii) Virucidal Efficiency. Chang and Morris (1953)
studied the virucidal efficiency of aqueous iodine using
mouse-adapted poliovirus 1. Because of technical problems,
they were able to conclude only that iodine did have viru-
cidal properties and that it was effective against viruses
at the level needed for inactivation of amebic cysts.
Chang (1958) reported on the virucidal efficiency of several
chemical species of iodine for coxsackievirus B1: HOI was
somewhat more virucidal than I_2. At 25°C, approximately 60
min was required to reduce coxsackievirus B1 by 5 logs when
exposed to 1 mg per 1 of residual I_2. Triiodide and iodite
ions were non-virucidal.

    Clarke and coworkers (1964) found that 99 percent of an
E. coli strain was killed by 1 mg per 1 of I_2 in only 1 min
at 25°C, whereas 18 h were required to inactivate coxsackie-
virus A9 under similar conditions. Of five viruses tested,
coxsackievirus A9 was the most resistant to elemental iodine;
and the time required to produce equivalent inactivation of
two different enteroviruses was 200 times longer for elemental
iodine that for hypochlorous acid. Zoeteman (1972) interpreted these
data as indicating that, as a virucide, iodine was much less
efficient than free chlorine and slightly more effective
than combined chlorine. However, Mahnel (1977) tested
iodine and free residual chlorine against poliovirus 1,
enteric cytopathic bovine orphan virus, reovirus 1, canine
hepatitis virus, pseudorabies virus, vaccinia virus, New-
castle disease virus, and a bovine parvovirus. He found

that concentrations of iodine needed to inactivate all viruses at a pH between 5 and 8.5 were equal to or less than the concentrations of free residual chlorine needed for equivalent inactivation.

(iii) Cysticidal Efficiency. Much of the research on the cysticidal effects of iodine resulted from a military need for emergency disinfection of small water supplies. Amebic dysentery was endemic in many areas of military operation, and cysts of Entamoeba histolytica [See Section B.1.c] had been shown to be highly resistant to chlorine; disinfection studies directed at inactivation of this organism led to the development of the globaline tablet, presently used by the U.S. Armed Forces for disinfection of individual drinking water supplies (Chang, 1958; Chang and Morris, 1953; and Morris, et al., 1953). I_2 was two to three times as cysticidal as $\overline{HOI}$, so the globaline tablet was designed to release 8 mg per l of free iodine, which was sufficient to inactivate 5 logs of E. histolytica cysts in 10 min at pH $\leq$ 8.0.

Stringer and coworkers (1975) essentially confirmed the earlier results indicating that I_2 was the more active cysticidal species and that cyst inactivation rates were very slow at higher pH's. However, they found hypochlorous acid to be a more effective cysticide than I_2.

Information on Giardia lamblia cyst inactivation by iodine is not available.

(iv) Mechanism of Action. Historically, iodine has been considered to act like chlorine as a general cellular poison exerting its lethal effect by oxidation of sulfhydryl groups on enzymes or proteins (Dunn, 1952). Brandrick and coworkers (1967) showed that radioactive elemental iodine reacted with E. coli and Staphylococcus aureus by both oxidation-reduction and halogenation. Brammer (1963), Hsu (1964), and Hsu and coworkers (1966) showed that viral RNA from viruses and transforming DNA from bacteria inactivated by iodine remained active, indicating that the biocidal activity resulted from reactions with protein rather than nucleic acid components. Berg and coworkers (1964) reported that the kinetics of coxsackievirus A9 inactivation were consistent with a "single hit" hypothesis and inferred that inactivation resulted from reaction with a single iodine molecule. The failure of iodine to inactivate viral nucleic

acids has been cause for concern, although evidence of an actual hazard for man posed by these entities has not been provided.

(v) Use in Water Treatment. Although much of the research on the biocidal properties of iodine has been directed toward its potential use for drinking water disinfection, actual field studies have been very limited. Black and coworkers (1965) found iodine was an effective disinfectant in the water supplies at three Florida correctional institutions serving a population of about 700 persons. Although coliform bacteria were usually present in the untreated water, fewer than 1 percent or the samples treated with iodine were positive for coliforms. They concluded that 1 mg per 1 of iodine rendered the water supply safe under a variety of conditions including pH levels up to 7.5.

(vi) Conclusions. The available evidence indicates that iodine is an effective disinfectant for water. Iodine is probably somewhat less efficient than hypochlorous acid, but maintains peak disinfectant activity even in mildly alkaline water and is less subject to demand because it is less chemically reactive. The main deterrents to its use appear to be high cost and concern for yet-to-be-demonstrated adverse effects of long-term exposure to iodine on thyroid function (Kinman, et al., 1970). Although interest in iodine as a disinfectant has been restimulated as a result of the concern about chloroform and other trihalomethanes formed by water chlorination, studies on the formation of iodine-containing trihalomethanes apparently have not been published. Needed research on iodine as a disinfectant for drinking water principally concerns health effects and chemistry, rather than microbiology.

6. Summary

Pathogenic microorganisms are often present in waters that are contaminated with domestic sewage. It is essential to consumer safety that waterworks produce safe drinking water even from potentially contaminated raw water despite the demand for ever-increasing quantities. In this connection, the different treatment processes applied in the preparation of drinking water have been evaluated from the standpoint of their capacities to remove microorganisms. The most generally applied treatment processes, which have

been discussed in the previous sections, include: storage in reservoirs, coagulation, rapid and slow sand filtration, dune infiltration and underground storage, activated carbon treatment, chlorination, and ozonation.

These processes can be evaluated on the basis of their abilities to remove bacterial indicators of fecal contamination (viz., thermo-tolerant coliforms) and pathogenic agents that are more resistant than indicator bacteria (viz., polioviruses of the enterovirus group). A rough estimate of the removal percentage has been made for each treatment process, based on the data presented in Topic E and the cited literature [See Table E.6-1]; these must be considered only as guideline approximations.

The tabulations show that, depending on the quality of the raw water, a combination of different treatment processes can produce hygienically good finished water. A proper combination of treatments will result in a high capacity to remove bacteria and viruses. It should be noted that the removal or inactivation estimates for viruses are based on the polioviruses, which are only three of the more than 100 types of enteric viruses that may be present in water. However, in practice, no outbreak of enteric virus disease has ever been attributed to properly treated water.

Less information is available concerning parasitic cysts and metazoan parasites. Most of these organisms are supposed to be removed by sand filtration processes, but in some cases, sand filters did not effectively remove Schistosoma cercariae from the water. Thirty to 90 percent of the parasitic cysts can be removed by coagulation. Disinfection with chlorine can be accomplished only by doses much higher than those used in the preparation of drinking water. The evaluation of the treatment processes with respect to removal of these organisms is difficult because insufficient data are available. In practice, however, outbreaks of parasitic diseases have not been reported in connection with drinking water that has been adequately treated; coagulation and filtration steps are essential.

The data presented here and the experience of waterworks over many years lead to the conclusion that a proper choice of different combinations of treatment processes, depending on the raw water quality, will result in the production of finished drinking water that meets the microbiological standards. Further research is needed concerning the behavior or parasitic cysts, metazoan parasites, and

ESTIMATION OF THE PERCENTAGE OF MICROORGANISMS
REMOVED BY VARIOUS WATER TREATMENT PROCESSES

Treatment Process	Residual Disinfectant (mg/)	Contact Time (min)	Removal Percentage	
			Fecal Coliform Bacteria	Poliovirus
Open reservoir storage[1]			95 - 99.9	99 - 99.9
Coagulation			50 - 97	70 - 99.99
Sand filtration (a) Rapid			10 - 50	0 - 50
(b) Slow			70 - 99	96 - 99.99
Dune infiltration and underground storage			99.99	99.99
Activated carbon			10 - 50	-[2]
Chlorination (a) Breakpoint	2 - 3	1 - 2	99.99	99.9
(b) Post	0.1 - 0.5	15 - 30	99.9	99
Ozonization	0.3 - 0.4	2 - 4	99.999	99.99

[1] Average detention time 30-75 days.

[2] - not considered.

viruses, and to evaluate the threat to human health engendered by the presence of extremely low levels of pathogens in drinking water.

7. Recommendations

   1. The variety and degree of treatment used in preparing drinking water should be determined by the quality of the raw water.

   2. Where the source is variable in quantity or quality, reservoir storage may be used to buffer some of the fluctuations.

   3. Disinfection is essential in the production of safe drinking water.

   4. Physical (e.g., rapid sand filtration) and biological (e.g., slow sand filtration) processes should be employed more extensively prior to terminal disinfection so as to increase disinfection efficiency and reduce the risk of formation of toxic substances.

F. DISTRIBUTION SYSTEMS

With the application of standard water treatment techniques, water suppliers usually have no difficulty in producing potable water supplies of a quality that will meet the WHO European Standards for Drinking Water. During distribution through the supplier's network and within the consumer's plumbing system, this water is exposed to a variety of hazards.

A water supply distribution system is not a totally sealed entity, so the possibility of contamination from external sources must be considered. It is easy for consumers to make connections into the system and either accidentally or unknowingly introduce hazardous situations. Equipment and fittings of numerous types are necessary for the effective use of a water supply, and the design of these must be considered in relation to potential hazard.

The multitude of possible materials that could be used for the construction of pipelines and joints, all the water utilities' apparatus, and all the consumers' fittings is increasing at a rapid rate. The possible effects of all these materials on the quality of the water need consideration.

Some of the problems that have occurred from time to time in distribution systems have been public health problems; more commonly, they lead to complaints of taste, odor, color, or turbidity resulting from microbiological growth which have no public health significance, but which result in water quality that does not conform to national or international standards. This section examines some of these problems and ways of overcoming them.

1. Service Reservoirs

Service reservoirs are an essential part of any water supply distribution system, but they are frequently the weakest link in the system and are subject to several hazards. Reservoirs of this nature are known by different names in different countries, but the term is used here to include any treated water storage facility imposed between the water treatment works and the consumer. They may be underground concrete or brick structures, elevated tanks or towers, or possibly even open reservoirs suitably protected.

a. <u>Direct Contamination from Sewage</u>. The siting of sewers and service reservoirs in relation to each other is an essential feature of engineering design. Reservoirs should be on high ground so that surface water drains away from them and all sewers should be at a lower level. If a reservoir is on a slope, construction of buildings on higher land, with its attendant sewage and drainage hazards, should be avoided. Where there is any possible risk of leakage from local sewers, these should be laid with special precautions, such as in cast iron or encased in concrete. Risks from storm overflow should be avoided.

b. <u>Contamination of Open Service Reservoirs</u>. Once water has been treated, it should be fully protected and not see the light of day until it reaches the consumer's tap. This implies that all service reservoirs, tanks, and water towers should be covered, although there are known to be many open service reservoirs still in use in several developed countries.

The first and most obvious source of contamination of open reservoirs is from birds, including all kinds of water fowl, especially gulls. There have been several studies of pollution from gulls in different parts of the world, all of which have shown that a high proportion of these birds are carriers of salmonellae, especially in the more highly developed areas where they are in closer association with man (Jones, et al., 1978; Luttman, 1967; Metropolitan Water Board Report, 1966 and 1970a).

Elevated tanks and water towers with roofs also often provide attractive nesting sites for birds of all kinds, so that access to roof spaces must be adequately protected from small birds by netting which must always be kept in good

repair. Ventilating shafts of covered reservoirs must be similarly protected.

Flying insects can also be a nuisance and these can be excluded by covering the bird netting with fly screens. If only one ventilating shaft is installed, in a building at the side of a reservoir, the screening required will be small in area and more readily maintained.

Many waters exposed to daylight can also support algal growth of one sort or another; problems can occur where they have not been encountered before, due to the increasing need in many developed countries to utilize lowland, nutrient-rich rivers as sources of water supply. The algae can be controlled only by excluding daylight with adequate roofing.

c. Contamination from Leakage. A very common cause of bacterial contamination of service reservoirs is rain water penetrating through leaks in the roof. This is more common in older, brick-roofed reservoirs than in modern reinforced concrete structures. Leakage is enhanced by the penetration of plant roots and for this reason trees should not be planted on or alongside service reservoirs.

Contamination is frequently worse after heavy rain following a dry spell. A similar quantity of rain on an already saturated soil does not produce the same effect. This is probably due in the one case to penetration of polluted water through cracks in the dry soil and in the other case to the moist soil acting as a bacterial filter.

Contamination of this type frequently includes Escherichia coli or thermo-tolerant coliforms as well as other coliforms, presumably derived from birds, other wild animals, or domestic pets. The extent to which this type of contamination is detected will depend, considerably, on the method of sampling and the rate of water turnover in the reservoir. If sampling is carried out only once a week and the rate of turnover is high, the pollution resulting from one heavy thunderstorm can be gone before it is detected. Furthermore, as the contamination is from above, the highest concentration of polluting organisms is found near the surface and may be undetectable at the bottom drawoff point. Dip samples taken at the surface can, therefore, give results totally different from those of samples taken from the outlet main. Where this problem occurs, samples should be taken more frequently and at different points or depths in the reservoir.

Pollution of this nature can only be prevented by major repairs to the roof, either by complete reconstruction or by applying a waterproof coating, covering, or membrane which should extend down the walls below normal water level. In some cases, where minimal numbers of coliforms persist over a long period of time or occur relatively frequently during the year, long-term major repair or reconstruction programs may be necessary. The degree of risk involved must then be assessed in relation to priorities for capital expenditures.

d. **Growth in Bottom Deposits.** Because service reservoirs contain relatively still water, any suspended matter has an opportunity to settle as a sludge on the bottom. This suspended matter may be derived directly from inadequately treated water, due either to incomplete removal of silt, to filtration problems during algal blooms in the raw or stored water, or to post-precipitation of aluminum hydroxide. It may be generated in the trunk mains to the reservoir by the rusting or corrosion of the iron or steel mains or from wastes produced by small animals, such as Gammarus and Asellus, in the mains. It may also be produced by the precipitation of calcium carbonate, due to the loss of carbon dioxide, from high bicarbonate waters in the reservoir itself. Small animals may also live in this sludge and further modify its properties. Easily recognizable constituents of these sludges include calcite crystals, rust particles, amorphous siliceous material, Asellus fecal pellets, and organic debris.

Studies of these sludges have shown that they contain an abundant microbial flora which is quite different from that of the overlying water. Coliform organisms and E. coli are quite common in these sludges, even where they have never been found in routine examinations of the overlying water. Clostridium perfringens is also common, as are various fungi adapted to an aquatic environment. Some species of actinomycetes may be abundant, depending on the nature of the sludge, the water, and the water temperature. Protozoa usually are also abundant (Metropolitan Water Board Report, 1970b and 1973a).

Although these sludges seem to provide an environment for the development of particular ecological communities, the bacteria so produced do not seem to migrate in significant numbers to the overlying water. It is possible that certain by-products of microbial metabolism, notably

the odoriferous substances produced by fungi, could diffuse into the overlying water to cause a deterioration in quality, especially in taste.

The engineering design of reservoirs should be such that the water circulates along the floor and prevents static conditions that lead to accumulation of sludge, but this is not easy to arrange. Alternatively, the bottom layer should be left undisturbed, but cleaned out periodically when the reservoir is drained. This usually needs to be done at intervals of ten years or less.

2. Aftergrowth

Current methods of drinking water treatment in developed countries normally achieve a satisfactory bacterial quality in the water leaving the works and entering the distribution system. However, under some circumstances, growth of bacteria can occur in the distribution system after the water has left the works and this is usually referred to as aftergrowth.

a. Influence of Nature of Raw Water and Methods of Treatment on Aftergrowth. In order to grow, most common bacteria require the basic minerals that all living organisms require and a source of organic carbon, There are very few raw source waters used for public water supplies that do not contain adequate minerals in solution for the growth of a variety of bacteria, although different waters may favor different species according to their mineral composition. However, source waters differ widely in their content of organic carbon and, hence, in their ability to support microbial growth. Many underground waters are very low in organic matter and unable to support significant bacterial growth even though they may be quite rich in minerals [see Section A.1.].

Surface-derived waters, on the other hand, are relatively rich in organic matter and can support significant microbial growth; this microbial growth is an essential factor in the self-purification of rivers [see Section A.2]. If this organic matter is not removed during treatment, it remains available and can support microbial growth thereafter, provided that conditions are otherwise suitable for growth.

The major part of the organic matter in natural waters consists of humic compounds that are relatively resistant

to biodegradation and only slowly utilized for bacterial growth, mainly by specialized groups of bacteria. The by-products of the initial breakdown are then used by other bacteria.

The more readily biodegradable carbohydrates, proteins, and protein breakdown products are less abundant in water, but when present, can support growth of numerous bacteria. The various water treatment processes will remove a proportion of this organic matter. Alum coagulation [see Section E.2] processes bring about the inclusion of humic substances in the alum floc. Slow sand filtration provides suitable [see Section E.3] conditions for bacterial growth and biodegradation of organic matter; that which is not readily biodegradable will not easily support microbial after treatment.

These treatment processes are almost invariably followed by an oxidation process, usually chlorination [see Section E.5.a] and sometimes ozonation [see Section E.5.b.]. During this oxidation process, which is primarily for disinfection, any remaining organic compounds which may be relatively resistant to biodegradation are liable to become partially oxidized to intermediate products that are more readily usable as bacterial nutrients and may thus, be a potential stimulus to aftergrowth.

Ozone, in particular, has often been claimed to have this effect. One of the major advantages of ozone treatment is that it oxidizes the humic compounds, which are yellow-brown in color, and thus, produces a more attractive looking water. This effect, coupled with the instability of ozone and the inability to maintain a residual in the distribution system, enables aftergrowth to occur. It has been shown, however, that chlorination can give rise to a similar aftergrowth if no residual is maintained (Metropolitan Water Board Report, 1973b).

Whether the basic disinfection process is chlorination or ozonation, aftergrowth of this nature can be limited by maintaining a suitable chlorine residual in the distribution system. In some countries and some areas, however, consumers object to the taste of chlorine. Complete prevention of aftergrowth requires a substantial and often unacceptable chlorine residual unless, as a minimum, a rigid line flushing program and treatment to minimize pipe corrosion are also practiced. Attempts to resolve this problem with chlorination alone are totally inadequate to prevent growth on some materials which have a chlorine demand, or in deposits of organic substances, particularly in protected

situations such as pipe joints, where chlorine cannot pene-
trate effectively and where the organic material present may
bind the chlorine. Beulow and Walton (1971) reported that
an increase from 0.2 to 1.5 mg of chlorine per liter was necesary to
improve the coliform quality of water in a distribution
system. Reduction in colony counts could be expected to
require at least as great an increase in chlorine level.
Lee (1971) showed under experimental conditions that, in the
presence of nutrients, the same bacterial growth was ob-
tained with 0.5 mg per l of chlorine (80 percent as free
chlorine), as with no chlorine at all. Under the same condi-
tions, 1 mg per l suppressed the growth of bacteria.

It has also been suggested, however, that if ozonation
precedes a biological treatment process such as slow sand
filtration, the bacteria will utilize the partially oxidized
organic matter in the filter, producing a further improve-
ment in the water quality and preventing aftergrowth in the
distribution system. Chlorination before distribution would
still be necessary. This principle has been applied in the
Netherlands, where ozonation is followed by filtration to
enable the aftergrowth, and the biodegradation associated
with it, to occur in the filter instead of in the distri-
bution system.

The bacteria that cause aftergrowth are usually those
which prefer lower temperatures. This is reflected in the
difference between bacterial counts using the two standard
methods of bacterial colony counting employed in the water
industry, namely, with incubation at 20 to 22°C and at 35 to
37°C. Aftergrowth is much more evident with incubation at
20 to 22°C and extension of incubation to seven days pro-
duces even greater differences. In lowland river-derived
waters which receive treated sewage effluent, it is not
unusual for colony counts (at 20 to 22°C) that are less than
100 per ml in water leaving the treatment works, to increase
to over 10,000 per ml in a distribution system where only a
low chlorine residual is maintained. These increases are
directly related to temperature and time, being greater in
warm weather and where the water has remained for long
periods in service reservoirs. The draft EEC Directive
relating to the Quality of Water for Human Consumption
recommends some very low colony count guide levels that
appear to have been formulated without regard for the prob-
lems of aftergrowth in the distribution system. In certain
areas, some drastic changes would be needed to achieve
these levels.

The bacteria that predominate in aftergrowth are not easy to characterize, for they are difficult to maintain in pure culture. Furthermore, determination of their biochemical properties often results in a classification of bacteria into groups that are not taxonomically precise. However, a major part of the colony count is usually assignable to the rather ill-defined Flavobacterium group. Pseudomonas, Aeromonas, Arthrobacter, Caulobacter, Cytophaga, and actinomycetes also form a small part of the population (Van der Kooij and Zoeteman, 1978).

The bacteria from lowland, surface-derived water that form colonies at 37°C are usually survivors of treatment, consisting largely of the chlorine-resistant spores of the aerobic sporeforming bacilli.

A technique for determining the concentration of growth stimulating organic compounds in water, in order to be able to quantify the aftergrowth potential of drinking water and to measure the effect of different water treatment techniques on these compounds, has been developed in the Netherlands at Keuringsinstituut voor Waterleidingartikelen (KIWA). Maximum colony counts of pure bacterial cultures developing in water samples were expressed in terms of the concentration of assimilable organic carbon (Van der Kooij and Zoeteman, 1978).

By using a medium containing citrate as the sole carbon source, Van der Kooij (1977) also showed that treated water, before entering the distribution system, contained a small percentage (0.1 to 1 percent) of citrate-utilizing bacteria, mainly Pseudomonas and some Aeromonas, but that tap water contained a higher percentage (1 to 10 percent and sometimes more). It is suggested, therefore, that these organisms can be used to give information on the efficiency of substrate removal by water treatment.

b. Accumulation of Organic Debris in Dead Ends and Other Protected Areas. The causes and effects of accumulation of sludges in service reservoirs are described in Section 1.d. Similar accumulations of debris occur in the distribution system wherever there is little or no flow of water, such as in dead ends or in any disused apparatus that has not been disconnected. The bacteria and fungi that grow in these situations, and their by-products, are continually seeded into the water that flows past the dead end, causing a deterioration in bacteriological and other quality characteristics, especially taste and odor..

A similar effect occurs, even in the absence of dead ends, where a district is supplied from two sources that are fed into different ends of a system. At some intermediate points where the pressures balance, there will be little or no flow in the main, and a similar situation will develop. In addition to the "dead end" effect, this situation contains the added hazard that changes in the supply, caused either by repair work or the introduction of new treatment works or extensions to existing works or mains, may alter the pressure balance. The areas of little or no flow will then shift and the accumulations of debris will become stirred up, resulting in turbid or colored water.

These problems can be overcome by designing distribution systems to avoid dead ends and by determining the sections where little or no flow occurs, then ensuring that adequate flow does occur at sufficiently frequent intervals to keep them clean by means of valves that control the direction and rate of flow. Where dead ends already exist, these must be adequately flushed through hydrants situated at their extremities. Furthermore, adequate monitoring of the water quality in the distribution system should include regular sampling from such dead ends, for they are likely to contain the worst quality water. Most developed countries have regulations, codes of practice, or make recommendations about frequency of sampling in the distribution system, and sampling points are defined in a variety of ways. All of the matters discussed in Topic F should influence the choice of sites and the frequency of sampling.

c. <u>Interrelationships Between Organic Matter, Bacterial Growth, and Animals in the Distribution System</u>. The problems of animals in the distribution system are not relevant to a report of microbiology, except insofar as the two topics are interrelated. Animals will only become a nuisance in distribution systems when they can multiply to relatively large numbers. To do this, they require a source of food which must usually be organic particulate matter, either living or dead; unlike bacteria, they cannot live directly on organic matter in solution. However, if the organic matter in solution supports growth of bacteria and fungi, these organisms can be used as food by protozoa, and many animals can feed on bacteria, fungi, and protozoa. Therefore, conditions that discourage the aftergrowth of bacteria should discourage the growth of animals.

Animals are very rarely a nuisance in distribution systems supplied with slow sand filtered water. The paucity

of animals has been attributed to the greater efficiency of slow sand filters in removing the animals' ova from the water. However, the true explanation may be quite different. Nearly all distribution systems contain a small nucleus of animals, but they are generally unable to grow in slow sand filtered water, probably because the bacteria on which they feed have grown and remained in the filter bed, so that the food chain leading to growth of animals in the distribution system cannot get started.

    d.   <u>Chemical Changes in Distribution Systems</u>. Changes in the physical and chemical characteristics of water during distribution may be chemically induced, such as the leaching of heavy metals and other materials from pipes, pipe joints, or pipe linings. They may be, on the other hand, micro-biologically induced, such as the production of moldy, musty, or earthy tastes resulting from the by-products of the growth of fungi or actinomycetes on susceptible organic materials in the distribution system. More commonly, however, there may be a complete interaction between micro-bially induced changes and chemical reactions.

    (i) Leaching of Heavy Metals. The problems associated with leaching of lead from lead piping are well known. There is now some concern over the possibility of leaching of lead, and to a lesser extent of arsenic and cadmium, from copper alloys containing lead and from solders and galva-nizing. The copper alloys are used to overcome dezincifi-cation corrosion problems with brass. The leaching of lead from solder seems to be closely associated with the nature of the flux used. Arsenic is a common ingredient, at very low concentrations, in brass and cadmium and may be present as an impurity in the zinc used for galvanizing. Although these subjects are being investigated in various labora-tories, little published information is yet available. The use of lead and tin compounds as catalysts in production of some plastic pipes is controlled by national and inter-national standards. All these possibilities should be borne in mind when investigating trace heavy metal problems.

    (ii) Precipitation and Depositions. The information in this and the following paragraphs (iii), (iv), (v), and (vi) is derived mainly from two reviews by the Water Research

Association in the U.K. (Ainsworth, Ridgway, and Gwilliam, 1978). Deficiences in treatment are probably the major cause of dirty water. High levels of residual coagulant, together with the materials that it is intended to remove, namely, particulate matter, algae, and organic matter, will cause such problems; silica and manganese may also contribute. Gradual reductions in their concentrations through a supply indicate that these substances are settling out in the distribution system. Subsequent disturbance of these loose deposits is a common cause of objectionably dirty water.

Deposits formed by precipitation can also contain appreciable amounts of lead, nickel, and sometimes zinc and cadmium derived from waters with heavy metal concentrations well within the WHO recommended limits. These metals are probably being concentrated in the precipitates by chelation with organic matter and/or adsorption to hydrous iron and manganese oxides. Adsorption increases with pH and is reversible, so that pH changes could desorb heavy metals from precipitated organic complexes.

(iii) Changes in Source Water. Accumulated deposits of any kind are liable to undergo solution or disintegration if water from a supply with different chemical characteristics enters the distribution system. The growing tendency to obtain water from different catchments, and to alternate between different sources, has made this an increased possibility and probably the most important consideration when investigating the quality of alternative water sources for use in existing distribution systems. The most obvious result is a persistent dirty water problem, but the possible release of precipitated heavy metals must also be considered.

(iv) Total Organic Carbon. Even in a well-run treatment facility which relies on non-biological processes, soluble organic matter will remain in the treated water from a surface-derived supply at levels up to 5 mg per l of total organic carbon (TOC). A decrease in TOC, which will be greatest in lowland surface waters with initially high concentrations, may occur during distribution. Residual iron and aluminum, and iron produced by corrosion, will coagulate some organic material and some will interact with existing deposits and presumably be adsorbed. Further removal occurs by microbial metabolization. This leads to

decreases in dissolved oxygen, and more oxygen removal may result from corrosion.

(v) Microbially Induced Changes. These have been reviewed in detail by Hutchinson and Ridgway (1977). Some of these have been discussed in other sections of topic F. After some preliminary studies, these workers used a seven day, 22°C colony count in preference to a three day count, largely for the sake of convenience and greater flexibililty in sampling days. In a general survey of distribution systems, they found, overall, that 40 percent of the samples had a count exceeding 10^2 per ml and 20 percent exceeded 10^3 per ml. The higher counts were commonly associated with dirty water problems. In lowland, surface-derived waters there was a marked trend for an increased incidence of other microorganisms, including fluorescent pseudomonads, anaerobic bacteria, sulphate-reducers, and, sometimes, the organisms found in the 37°C colony count. Microbial activity produced water quality changes such as depletion of dissolved oxygen, increases in total organic carbon, objectionable tastes and odors, greater corrosiveness, and the incidence of animals.

Local accumulation of biomass, whether in dead ends, at the bottom of service reservoirs, in pipe joints, or on unsuitable materials used in fittings, may result in anaerobic conditions. In these circumstances nitrate or sulphate-reducing bacteria and anaerobic sporeforming bacilli may grow (O'Connor, et al., 1975; Willis, 1957).

Nitrate-reducing bacteria are common in tap water, but they are unable to reduce nitrate at the dissolved oxygen concentrations normally found in tap water. Ammonia-oxidizing bacteria that are capable of producing nitrites may also be present. The reaction seems to be time-dependent under fast flow conditions. a decrease in nitrite concentration was also shown to occur, presumably due to production of nitrate by nitrite-oxidizing bacteria also present in the water; however, techniques for detecting these organisms are difficult (Victorin and Stenstrom, 1975).

Substances derived from otherwise harmless bacteria may cause pyrogenic reactions in a patient when drinking water containing high numbers of bacteria, due to aftergrowth, is used for some highly specialized purpose, such as in artificial kidney machines.

(vi) Corrosion. Corrosion products in iron mains are usually in the form of tubercles composed of a thin shell of the very hard mineral, magnetite (Fe_3O_4). A mixture of hydrated ferrous oxides and iron sulfides is usually found under this shell, while the surface in contact with the water is a thin layer of goethite (-- Fe.O.OH) in conjunction with substances adsorbed from the water, such as organics, silica, and manganese. The presence of sulfides indicates the involvement of sulfate-reducing bacteria in the corrosion process, although the extent of this is still open to conjecture [See Section G.4.b]. High corrosion rates are best diagnosed by inspecting pipe interiors and eliminating all other possible causes of discoloration before assuming that bacteria are responsible.

3. Growth on Materials

a. Ability of Various Microorganisms to Grow on Some Materials Used in Distribution and Plumbing Systems. It has been stated in Section 2.a that most common bacteria and fungi require mineral salts and organic carbon for their growth and that most water supplies contain adequate mineral salts in solution. In the construction of distribution systems, and in consumers' plumbing and fittings, many organic carbon materials are used, and the number and variety of these is rapidly increasing with the growth of the plastics and synthetic chemicals industries. It is, therefore, necessary to consider whether any of these materials are capable of supplying organic carbon compounds, that support microbial growth, to a sufficient extent to cause water quality problems, either directly by increasing bacterial numbers or indirectly from their by-products, inducing objectionable taste, odor, or even toxicity (Burman and Colbourne, 1979).

(i) Nature of Materials that Can Support Growth. The range of materials containing organic carbon compounds that have been employed in water supply systems includes natural and synthetic rubbers, paints and coatings, pump and valve gland packings, lubricants, sealants, jointing compounds, and soldering fluxes. They also include a wide variety of plastics such as polyethylene, polypropylene, polyvinyl-chloride (PVC), polyamide (nylon), polytetrafluorethylene (PTFE), acrylonitrile - butadiene - styrene (ABS), glass fiber reinforced polyesters (GRP), acrylics, acetal copolymers, polycarbonates, silicones, polyurethanes, polysulfides,

and many others, all of which exist in a wide variety of modifications with different characteristics for different purposes; some traditional materials such as leather washers and jute or hemp yarn are also present.

Deterioration in bacteriological quality of tap water due to the growth of coliform organisms on vegetable tanned leather washers was first described by Houston (1916). The bacteriological problems caused by the use of jute yarn as a caulking material for lead run joints in water mains has been well documented (Windle Taylor, 1947). Any other natural, unmodified product of plant or animal origin in contact with water, including any cellulosic material, linseed oil and other vegetable or animal oils and greases, soaps, and shellac can be expected to support microbial growth. Many mineral oils, greases, and waxes can also support growth of a more limited range of microorganisms. Natural rubber is in a different category. Natural latex will support abundant growth of a variety of bacteria and fungi, but many compounded rubbers are much more resistant and do not support sufficient growth to have a significant effect on water quality. However, long-term resistance to biodeterioration is a different problem [See Section G.1].

With some notable exceptions, the basic high molecular weight polymers used in plastics manufacture do not support microbial growth. The exceptions are the soft polyurethanes and polysulfides both of which can support considerable microbial growth resulting in biodegradation of the product (Evans and Levisohn, 1968; Jones and Campion-Alsumard, 1970; Metropolitan Water Board Report, 1970c). However, nearly all plastics contain a variety of other low molecular weight carbon compounds essential for their manufacture or necessary to provide properties for particular uses. These include catalyzers, antioxidants, plasticizers, fillers, extenders, pigments, sizes, bonding agents, lubricants, mold release agents, etc. Excess monomer may still be present, due either to inadequate polymerization or to a deliberate excess. Overheating in molding a fitting can also result in partial degradation with formation of other low molecular weight compounds. In the production or use of some polymers, a volatile organic chemical may be formed that can support microbial growth and must evaporate by adequate curing if problems are to be avoided when in contact with water. The production of acetic anhydride in some silicone jointing compounds is a good example of this. The materials most likely to cause problems are the plasticizers, including phthalates and sebacates, oils and waxes, cellulosic fillers

such as wood-flour, or cotton fibers, excess monomer, especially styrene, and bonding agents incorporated with various fillers such as glass fiber or pigments.

Synthetic detergents that support microbial growth can also be present in some products, either as residues from precipitation of a polymer from an emulsion in a detergent, or from the washing of fibers used in packing materials.

(ii) Nature of Microorganisms that Can Grow. To maintain national and international standards for bacteriological quality of water at the consumer's tap, the water bacteriologist will be interested in any organisms which affect his standard quality tests. These will include coliform organisms and any of the bacteria which can produce colonies in the standard 37°C or 22°C colony counts. Many of the materials under discussion have been shown to support the growth of coliform organisms and mixtures of organisms capable of growth in the colony counts. Many of them can also support the growth of Pseudomonas aeruginosa and various fungi. Growth is often sufficiently abundant under test conditions to form slimes on the material or clumps or flakes of growth suspended in the water which are readily visible to the naked eye. These slimes, however, often consist of bacteria which do not grow readily in the standard colony counts. This is probably because the carbon compounds on which they are growing, and to which they have become adapted, are totally different from the carbon sources contained in the standard colony counting media. Numerous protozoa usually develop in these slimes, and nematodes may eventually grow there as well.

b. Problems that Can be Caused by Microbial Growth. Apart from failure to reach bacteriological standards, when tested by standard national or international methods, there are a number of additional problems that can arise. These problems are all accentuated at warm temperatures and under conditions of little or no flow. In modern buildings, for aesthetic and architectural reasons, hot and cold water pipes and central heating pipes are often installed in common ducts, with the result that the cold water has the opportunity to become warmed. In business premises unoccupied on weekends, there is no flow of water, thus, cold water temperatures can exceed 30°C and allow fungi and bacteria to grow much faster. However, warm water alone will not support the growth of organisms as described here.

Vending machines for drinks are often installed at the end of long lengths of narrow piping through warm factories separate from the rest of the supply system so that the only flow of water is that required for the cups of tea, coffee, or soft drinks. Drinking water fountains are often installed in similar situations and frequently give rise to complaints. Unused apparatus is often disconnected and the branch pipe left attached where there is no flow. These should always be removed at the junction with the main pipe.

(i) Taste and Odor. The growth of fungi and possibly of actinomycetes on materials, especially in consumers' plumbing systems, gives rise to musty, moldy, or earthy tastes in the water. In the Metropolitan Water Division, Thames Water Authority, London, it has been found that approximately 50 percent of all complaints referred to the Laboratories are of bad taste. In approximately half of these, there has been a significant increase in fungi, sometimes in conjunction with high bacterial colony counts or with the presence of P. aeruginosa (Burman and Colbourne, 1976).

(ii) Visible Growth. Under test conditions, visible growth is frequently observed on materials. This usually becomes very bad before a consumer notices it. Clumps of fungal growth on plasticized PVC tubing in drink vending machines sometimes detach and are discharged into the drinks. Accumulations of slimes have also been observed in tanks and cisterns constructed of unsuitable materials. Plasticized PVC capillary tubing used to supply water to dentists' drills has become blocked with visible growths of fungi. The aerator or antisplash devices, again usually of plasticized PVC, often fitted to kitchen taps, are a frequent cause of complaint in which slime growths can readily be observed.

(iii) Health Hazards. It has generally been assumed that although the by-products generated by bacteria and fungi growing in distribution and plumbing systems, can cause complaints of deterioration in quality, they do not constitute a health hazard. However, there are two possible health hazards which should be considered.

First, the significance of P. aeruginosa must be considered. This is an opportunist pathogen of eyes and ears and causes infection of wounds and burns. It is particularly undesirable in water supplies to hospital burn units

and to tonsillectomy wards (Lowbury, et al., 1970). P. aeruginosa contamination of ice served in drinks has been incriminated in serious post-operative infections in tonsillectomy patients (Newson, 1968). This organism may rapidly multiply at low temperature and is undesirable in cooling waters, particularly in dairies. By forming an enterotoxin, P. aeruginosa can give rise to severe diarrhea (Muller, 1974). There are currently no international standards for P. aeruginosa in drinking water, but they are under discussion in a number of countries. German drinking water legislation considers P. aeruginosa as a pathogen, and according to paragraph 1 of the German Drinking Water Ordinance (Aurand, et al., 1976), drinking water has to be free of pathogens. The absence of P. aeruginosa in swimming water will be regulated by a law, currently in preparation; a standard method for enumeration of P. aeruginosa is specified. Water leaving the treatment works is normally free from this organism, so its appearance at the consumer's tap is an indication of deterioration in water quality [See also Sections B.1.a(ix) and C.2.c].

Secondly, the significance of the growth of fungi must be considered with regard to the possible production of mycotoxins or of allergens. Active toxins (mycotoxins) have been associated with massive growths of fungi on food products and there is no evidence that growth of fungi in water cannot produce similar effects.

Exposure to fungal spores inhalation in various industries has given rise to respiratory allergies. A "bathing sickness" with fever and respiratory symptoms following the taking of hot baths, has been described in Sweden (Atterholm, et al., 1977). This has been shown to be produced merely by breathing the air above hot water, through volatile substances released from the water. It has been associated with water from two areas, one a filtered, surface-derived water and one an underground water. Although fungi produce volatile by-products readily detected by their odor, and released when water is heated, no abnormal counts of fungi or other microorganisms have been obtained from this water. However, similar reactions have resulted at sauna baths where abundant growth of fungi has occurred on the wood: precipitating antibodies against an antigen extracted from the fungal culture could be found in the patients' serum.

c. Methods of Testing Materials. The most reliable methods for testing the effects of materials on the quality

of the water with which they come into contact, are based on attempting to simulate the worst conditions under which the materials are likely to be used and to observe the effects on the test water. This is achieved by immersing the material in limited quantities of water kept at optimum temperature for microbial growth and changing the water at intervals of three or four days.

The overall methods used in the U.K. have been described by Burman and Colbourne (1979) and have been written as a British Standard draft which has been circulated for public comment. The microbiological methods have also been described by Burman and Colbourne (1977). The testing procedure involves consideration of three areas of study: (1) ability to support microbial growth; (2) effect on organoleptic and physical properties, especially taste, odor, color, and turbidity; and (3) toxicity, including toxic metals.

In the FRG, a test has been developed using a streptomycin-resistant mutant of P. fluorescens, P. cepacia, or P. putida in order to detect substances leached out of plastic materials that will be used in drinking water supply (Müller, et al., 1979). This is in preparation for a standard method and will be included in the FRG Standard Methods for water, sewage, and sludge examination (1979).

Although this section deals with testing of materials as it relates to microbiology, it would not be complete without references to the non-microbiological test procedures.

(i) Testing for Microbial Growth. As the test involves quantitative comparison with a control, it is necessary to standardize the test procedure as far as possible. Containers must be specially cleaned and the test carried out in premises free from atmospheric pollution by volatile organic solvents. A sample having a specified surface area is immersed in a standard volume of dechlorinated tap water and inoculated with a mixture of microorganisms by adding some polluted river water. This is incubated at 30°C and the water is changed twice weekly by replacement with dechlorinated tapwater only. This process continues for six to eight weeks. Negative controls containing glass samples, and positive controls containing paraffin wax, are similarly treated. Beginning the fourth week, the water is tested before it is discarded, for 37°C and 22°C colony counts, coliform organisms, P. aeruginosa, and fungi; the

sample and water are also observed for visible growth.

A material is considered to have passed the test if, in three consecutive water samples, coliforms and P. aeruginosa are not detected, the colony and fungal counts are less than ten times that of the glass control, and there is no readily visible growth on samples or in the surrounding water. This is a very brief summary of the procedure described by Burman and Colbourne (1977). It is claimed, after comparative trials in other laboratories, that the overall result of passing or failing the test is reproducible, although the group of organisms indicating failure may vary on different occasions and in different laboratories.

There are two obvious non-standard factors in this procedure: the mixture of organisms in the inoculum and the nature of the tap water. It has been shown that, provided the inoculum contains coliform organisms, P. aeruginosa, and a mixture of bacteria and fungi within fairly wide limits, its precise definition is not necessary. Soil extract, however, is not satisfactory. Distilled water is not an adequate replacement for tap water in the test, nor have satisfactory results been obtained with synthetic tap waters. Comparable results have been obtained with several surface-derived, underground, and soft upland waters.

A simple, quantitative alternative to this procedure has been developed; it replaces the 37° and 22°C colony counts, the fungal counts, and the assessment of visible growth by a more accurate and reproducible determination of total microbial activity based on the measurement of dissolved oxygen reduction (Colbourne and Brown, 1979). The test is carried out by a procedure similar to the growth test previously described, but in closed containers filled to the top with tap water saturated with air. This method still requires counting coliform organisms and P. aeruginosa, as these must be shown to be absent from 100 ml. Inequalities due to variability in the initial inoculum have been shown to disappear after the first three weeks of testing and no significant variation has been observed with several different types of tapwater (from surface-derived, underground, and soft upland sources); however, distilled water is unsuitable. This has become the recommended method of preference in the U.K.

(ii) Testing for Taste, Odor, Color, and Turbidity. These are usually determined by soaking the test material in chlorinated water and chlorine free water for 24 h at room temperature. If any change in taste, odor, color, or turbidity of the water is observed, the water is discarded and a further 24 h soaking is conducted and tested. This is continued up to a maximum of seven days as long as any change is observed. The tastes and odors observed in these relatively short-term tests are mainly those derived directly from the ingredients used in the materials and not secondary tastes resulting from bacterial or fungal growth. The ratio of sample size to volume of water must be standardized, and the intensity and nature of any persistent tastes or odors require interpretation, for many materials in common use will produce some persistent detectable change in taste or odor under these test conditions.

(iii) Toxicity. Determination of toxic hazards of new materials is much more difficult. There is no one standard test that can readily be used to assess even acute toxicity of leachates from materials. Carcinogenic and teratogenic properties are even more difficult, expensive, and time-consuming to determine.

Where all the ingredients of a material are known, useful information can be obtained from toxicology data banks, but this requires that manufacturers disclose the necessary details. Even where initial ingredients are known, all the subsequent reaction products may not be identified. The presence of toxic substances as impurities must also be considered.

Some acute toxicity test procedures, notably cyto-toxicity tests, have, however, been used as screening tests and yielded occasional positive results with some materials. The leaching of toxic metals is more easily determined by the use of standard chemical analytical methods on leachates. Here again, it is necessary to standardize the aggressivity of the test water and to decide whether WHO standards should be applied to the water under test conditions or whether a dilution factor should be applied.

d. Standards and Regulations Relating to Materials in Contact With Water. In the U.K., the National Water Council tests water fittings to determine whether they conform to the water bylaws and publishes lists of approved fittings. The non-metallic materials used in fittings are tested for

their effect on water quality by the methods described in Section C and a list of approved materials is published. The Regional Water Authorities normally require all fittings and materials used on consumers' premises to be on these lists in order to ensure conformity with the bylaws.

Many British Standards, and some international standards, contain clauses specifying that materials used for fittings in contact with potable water shall be non-toxic; shall not produce any taste, odor, color, or turbidity in the water; and shall not support microbial growth. However, there is no British Standard for testing these properties. In response to a strong demand, a draft standard has been prepared and is currently under consideration by a British Standards Institution Committee.

In Germany, materials used in contact with drinking water are subject to regulations in the German Food Act and have to be tested by prescribed chemical and bacteriological procedures (Anon., 1974).

In the Netherlands, KIWA (Keurings Instituut voor Waterleiding-Artikelen, 1974) publishes a brochure presenting guidelines for the installation of domestic water supply systems to prevent many of the problems described in Topic F. These guidelines are currently being revised. KIWA (1977) also publishes a brochure (in Dutch) on "Protection against the penetration of foreign compounds in water distribution systems."

In the U.S., greater emphasis is given to regulating the durability, mechanical performance, and toxicological properties of a material, rather than to the effects of microbial growth. Durability, however, does imply resistance to biodeterioration.

e. Growth on Atmospheric Volatile Organic Chemicals. A rather special case of microorganism growth on materials in contact with water is that involving water exposed to air contaminated with volatile organic chemicals, the commonest of which is ethanol. This is a common problem in some industries, but it has also been reported in retail shops, business premises (especially hairdressers), and even in homes (Poynter and Mead, 1964).

Ethanol is the most common substrate because it is most widely used; but any volatile organic chemical, such as

methanol, acetone, acetic acids, styrene, benzene, petro-
leum, and paraffins can cause a problem. The nature of the
mixture of organisms that will grow depends on the chemical
nature and characteristics of the water. Mixtures of fungi
and pseudomonads are common, including P. aeruginosa, and
sometimes aerobic sporeforming bacilli are present.

The growth usually appears as a gelatinous slime, espe-
cially around the edges of water tanks, around float valves
discharging into the water, or hanging from running or
dripping taps. This gives the impression that the slime is
in the water supply, whereas it does not form until the
water is exposed to the contaminated atmosphere. These
slimes often become quite massive and include numerous
protozoa that feed on the bacteria, and eventually nema-
todes.

The problem has occurred in the alcohol-distilling and
bottling industries, varnish and paint industries, in museums
using alcohol for preservatives, in buildings under con-
struction where adhesives containing volatile solvents are
used for laying floor tiles, in premises of hairdressers
using alcohol-based hair lacquers and in homes where hair
lacquers are used in unventilated bathrooms, in the printing
industry where solvents are used to clean type, in printing
and duplicating departments in offices, in roof spaces
following treatment of roof timbers with preservatives, in
buildings where petroleum products are stored in drums, in
rooms where glass reinforced polyester products containing
excess styrene are stored, and in numerous similar situ-
ations.

The fittings usually involved are open tanks and float
valves, dripping taps, tea boilers, vending machines for
drinks, or any other exposed water surface. The problem can
occur in rooms adjacent to where the offending chemical is
used or produced, or even in rooms separated by a corridor.
The problem is always worse with poor ventilation. It can
only be overcome by a total exclusion of all exposed water
surfaces from areas where volatile organic chemicals are
likely to pollute the atmosphere, or by thorough ventilation
after use where these chemicals are used only intermittently
for short periods. It is important that buildings in which
volatile organic chemicals are to be handled, be correctly
designed in the first place, for it is much more expensive
to correct this problem after it has occurred.

The phenomenon usually is only a nuisance, making the
water unattractive for use, producing a taste or odor, or

making it unsuitable for the purpose required; but in the printing industry it has given rise to health hazards which are now recognized by H.M. Factory Inspectorate in the U.K. Industrial alcohol is used to clean type. Humidity in printing rooms is maintained, to prevent paper curling, by spraying water into the atmosphere, often from tanks located in the printing room and supplied via float valves. Under these conditions typical slimes develop in the tanks and the resultant bacteria and/or fungi are sprayed into the atmosphere where the staff are working. This produces an allergic respiratory response that may occur after about 10 min or may be delayed for 2 to 4 h; due to progressive sensitization, the intensity of the response increases with subsequent exposure. This could be an allergy specific to fungal spores, but it may be a response to the general effect of any foreign protein sprayed into the atmosphere, for the effect has been observed with slimes composed mainly of a single bacterial species without any fungi.

4. Back-Siphonage and Cross-Connections

All water supply authorities in developed countries can quote examples of water supply contamination by back-siphonage due to inadequate plumbing, to equipment that pollutes the water during use, or from illegal cross-connections between different supplies. This type of pollution may introduce either chemical or microbiological hazards. In that water quality in distribution systems is not being considered elsewhere in this report, it is appropriate to consider pollution of this type under Topic F, Distribution Systems.

a. Types of Back-Siphonage and Cross-Connections and Risks Involved. Back-siphonage may be defined as siphonage of liquid back against the direction of normal flow or pressure. Reduction in pressure can occur for various reasons within public water supply mains and in individual plumbing systems, to the extent that pressure falls below atmospheric pressure. If outlets are submerged below the level of a contaminated liquid, or even just above it, the liquid can be drawn back and pollute the supply, either to other premises or to other outlets in the same premises. Therefore, there are three simultaneous requirements for back-siphonage to occur: the water outlet must be submerged or just above the water surface; the controlling valve must

be open; and the pressure at the outlet must be below that of the free water level at the fitting.

Submerged outlets occur for a variety of reasons such as faulty design or wrong positioning of float valves; inadequate overflows; hoses and other attachments fitted to taps and showers discharging below sink, bath, or shower tray level so that they can be submerged in contaminated water; garden, agricultural, or industrial hoses discharging into tanks, ponds, or even buckets; or leakage between primary and secondary heating circuits. It must be recognized that pressure changes will occur in the supply and cannot be prevented. Sewer flushing systems used in some countries also impose a special risk under some circumstances.

In multi-story buildings, negative pressures can occur at higher levels due to discharges at lower levels. The use of booster pumps on consumers' premises can create special problems because of the reduced pressure that can arise on the suction side of the pumps.

The risks to which consumers are exposed, in the event of back-siphonage, will depend on the nature of the contaminant that is introduced and the frequency with which it is likely to occur. In addition to threats to health, such contamination may make water unacceptable for a variety of other reasons. The seriousness of risk can, therefore, be classified and the degree of protection against back-siphonage can be chosen according to the class of risk. The Water Research Centre in the U.K. carried out a survey of back-siphonage risks in homes and reached the conclusion that, although 85 percent of properties surveyed were at risk in terms of the requirements laid down in Model Water Bylaws, the probability of back-siphonage occurring was really very low (Gilfillan, 1971).

Cross-connections may be defined as connections between a piped public water supply and any other pipe carrying any other water or liquid that is not obtained solely from the public supply. They occur most frequently in industrial premises, where various process waters are used in complex plumbing systems, and they are especially significant where high pressure hydraulic mains are concerned. However, cross-connections can also occur in mains in the street and even in homes. Most of them occur outside of the control of the water authorities and are very difficult to prevent. There are many recorded instances of illness among factory staff, and sometimes neighboring consumers, due to cross-connections.

b.   Regulations Concerning Back-Siphonage.   Most developed countries have water bylaws, or regulations of some description, that are designed to prevent contamination, waste, or undue consumption of the public water supply. Many of these regulations are specifically designed to prevent back-siphonage.   In order to make adequate regulations and to rationalize existing ones, it is necessary to have a thorough understanding of potential back-siphonage situations, the degree of risk involved, and methods of preventing their occurrence.   To this end, the Department of the Environment in the U.K. appointed a committee which produced its "Report of the Committee on Back-Siphonage in Water Installations" in 1974 (Committee on Back-Siphonage in Water Installations, 1974).

However, regulations or bylaws are useless without adequate means of enforcement, including inspection of installations and schemes for the approval of fittings and materials, as discussed in Section 3.d of this report. Surveys have shown that there are large numbers of premises in which fittings do not comply with the provisions of existing regulations, that requirements for inspection following alteration or extension to existing plumbing are largely ignored, and that present frequency of inspection is inadequate to identify all the risks.   It is recommended in the Report (1974), that an inspection force be staffed with one inspector per 25,000 people served.   The number of violations that would be discovered by routine regular inspections would subject consumers to considerable expense if immediate corrections were required.   It is, therefore, recommended that special attention be given to installations where large numbers of people congregate, to industrial premises, and to buildings with multiple occupancy.

c.   Mechanical Devices and Hydraulic Safeguards.   The prevention of back-siphonage is dependent on the incorporation of adequate hydraulic safeguards during installation and plumbing alterations and on the availability of reliable mechanical devices.

As a general principle, the degree of risk in each situation should be assessed and a mechanical device or hydraulic safeguard incorporated which is appropriate to the risk as well as to the reliability of the device.   The cheapest, most effective, and most reliable means of protection is some form of air gap.   Where the risk is greatest, such as where a pipe discharges into a container in which

the water becomes highly contaminated, an adequate air gap should be maintained between the pipe and the top of the container at which water overflows. Where the risk is less, the receiving container can be fitted with an overflow pipe; the effective air gap is the distance between the inlet pipe and the overflow pipe. This type of air gap works only if the overflow pipe does not become blocked. Stoppage of pumps downstream can also cause reverse flow.

The first type of air gap is used in certain industrial and research establishments; in baths, wash basins, and sinks; in drinking fountains; in tanks receiving water from other sources; on animal drinking troughs; and on overflow pipes discharging into a water closet or urinal. The second type of air gap is used for supplies to cold water cisterns and water closet flushing cisterns and is controlled by a float-operated valve.

A number of other devices are used in certain circum-stances including complete separation of systems; for example, at mixing taps for hot and cold water; non-return and air break valves; air inlet valves at the fixed ends of hand-held flexible hoses; lay-flat hoses that collapse when sub-atmospheric pressure occurs, as commonly used for fire hoses; air venting devices on hot water systems; and pipe interrupters. International standardized test procedures are needed for assessing the adequacy of devices to prevent back-siphonage.

5. Main Laying and Repair

a. Codes of Practice to Prevent Contamination. Codes of practice can be formulated to minimize contamination of mains during installation and repair, and many codes exist for this purpose, but the extent to which these are enforced seems to vary considerably, both between countries and between different water authorities in the same country.

Ideally, protection from contamination should start in the pipe store by blocking off the ends of all pipes to prevent access of small animals and birds. These end seals should remain in position until the pipe is in the trench and about to be joined. Pipe trenches should be deep enough to leave a clear space below the pipe joint, so that dirt from the trench is not incorporated into the joint. Pipes should not be lowered into the trench and left standing in the dirt and water at the bottom of the trench; they should

be lowered directly into the jointing position and joined immediately. Surplus water should be continuously pumped from the trench, and any open pipe ends should be blocked off at the end of a day's work.

b. <u>Problems with Jointing Materials</u>. There are a number of jointing systems available, but these are mainly variations of four basic types: (1) lead caulking; (2) push fit with rubber rings; (3) bolted flanges; and (4) solvent cement.

The traditional "socket and spigot" joint for iron mains used a melted lead caulking method with a packing material, usually jute yarn, to prevent lead flowing into the pipe. The problems associated with bacterial contamination of jute yarn have been well documented (Mackenzie, et al., 1948). This material usually contains large numbers of coliform organisms and supports their growth, which made it difficult to obtain water free of coliform organisms from new mains. Chlorination was unable to solve this problem because the chlorine deviated before it could penetrate the packed yarn; furthermore, once the initial high dose of chlorine had dispersed, the remaining yarn could support further growth.

This problem was greatly reduced by using yarn treated with a mercurial biocide that sterilized the yarn and prevented subsequent growth, although later leaching would ultimately nullify this effect, and bacterial degradation of the yarn could be expected. The use of mercury-based biocides would not now be approved and in situations where lead caulked joints are still needed, a biologically inert yarn packing such as nylon or polypropylene usually is used. Whatever yarn is used, however, it should be kept in a closed container and cut to appropriate lengths with a clean tool. It should not be laid on the ground or in the trench, but inserted direct from the container into the joint.

The jointing system has now been very largely replaced by various push fit type joints using specially molded rubber rings. These newer types of joints are needed because non-metallic pipes, which cannot be caulked with lead, are increasingly in use. To assist the jointing process, a lubricant is essential on the rubber rings. Excess lubricant tends to get pushed into the socket, where it is protected from chlorination and flushing water. The

original lubricants were usually based on soft soap, which is capable of supporting abundant microbial growth. Soft soap is completely soluble in soft water and is, therefore, readily flushed out when the main is charged with water, except in the protected areas behind the rubber rings. However, hard water produces precipitates of calcium salts with this soap; these can remain on the joints, relatively immune to flushing out with water, and can also support microbial growth. A detailed study of this phenomenon was made by the U.K. Water Research Association and resulted in the introduction of an antibacterial lubricant, based on cetrimide, that is now marketed and widely used under the name Medlube. It is miscible with hard or soft water and cannot support microbial growth. The bacteriological quality of water from mains laid using this lubricant has shown considerable improvement over that obtained with the soft soap lubricant. Other newer lubricants are based on synthetic detergents that are capable of supporting microbial growth, but that are completely soluble in hard or soft water and are, therefore, flushed out more readily.

The rubber rings themselves should be made of a material that is unable to support microbial growth, as described in Section F.3. Many rubber formulations, both natural and synthetic, are also subject to long-term biodegradation brought about by species of Nocardia. The phenomenon was first described by Leeflang (1963) and subsequently investigated further in the U.K. by the Water Research Centre, the rubber manufacturers, and their trade associations. Difficulty is being experienced in formulating materials that will not support microbial growth, that will not biodegrade, and that have the required mechanical and physical properties for joint rings [see Section G.1.a]

c. Cleaning, Disinfection, and Sampling Procedures. Even where proper codes of practice are followed and there is good supervision, further precautions, to ensure adequate cleanliness of new mains, are necessary. Foam swabbing is effective for this purpose. Cylindrical polyurethane foam swabs, slightly larger in diameter than the main, are inserted at the beginning of new work. When the work is completed and all valves are open and the water supply is turned on, the water pressure pushes the swab forward while allowing some water to pass through. The flexibility of the swab enables it to negotiate bends and valves and pushes before it any dirt or debris, eventually discharging from

the open end. It is surprising how much dirt is removed by this process even in situations of supposedly clean main installation. It is important to have a strictly controlled system of issue and recovery of swabs to ensure that none are left in the main when it is put into supply, for there is nothing more certain to result in irate complaints than fragments of polyurethane foam discharging from consumers' taps. It should also be borne in mind that fragments of foam left in the system can support microbial growth, for polyurethanes can be biodegraded by various fungi.

It is not usual practice to carry out foam swabbing after repairs to old mains; inner surfaces of old mains may not be smooth and may cause excessive breaking up of the foam or even stop the swab completely. Also, it is often difficult to arrange a suitable discharge point in an existing main.

Before putting a new or repaired main into supply, it must be disinfected; most countries or water authorities have their own recommended procedures for this. Hypochlorite solutions using an injector or chlorine gas from a mobile chlorination unit may be used for this purpose. The section of main to be treated must be isolated by closing all valves; a dose of 20 mg per l Cl, which must be achieved at all outlet points, is usually recommended. This should be left for 24 h in new mains, but in small repairs, 2 h is usually adequate. The main is then flushed with supply water until the chlorine residual at the discharge points is within acceptable limits, which may vary in different situations and in different countries, but may be as high as 2 mg per l.

After repair, disinfection, and flushing of small mains it is usual to put them straight back into supply. Samples are then taken to ensure that they meet the recommended bacteriological quality standards. With new mains, it is advisable to leave them full of water for 24 h after flushing before taking samples, to allow for possible aftergrowth in joints. They should not be put into service until satisfactory bacteriological results have been obtained. If this procedure is carried out a substantial amount of time in advance of their being required for supply, further bacteriological testing should be carried out before any consumers are connected.

d. Acceptable Standards. The WHO Standards for Drinking Water recommend that coliform organisms should be absent from 100 ml samples at all times and at all points in the distribution system. Various national standards recommend the action to be taken when this is not achieved. In new mains, this is sometimes very difficult to achieve, for the reasons given in Section F.3.b. Some water authorities, therefore, permit some relaxation under these circumstances. If the only detectable deterioration in bacterial quality is an increase in coliform organisms, without any thermo-tolerant coliforms, Escherichia coli, or fecal streptococci in a new main that is supplied with water free from any of these organisms, it must be concluded that the coliforms are multiplying on materials used in the construction of the main, either on the jointing materials, lubricants, or mains lining and as such would have no sanitary significance. Under these circumstances, some temporary relaxation of standards might be permitted, but the absence of fecal streptococci should be required.

The problems of aftergrowth, discussed in Section F.2, are liable to be accentuated in new mains and would make the application of the colony count guidelines in the draft EEC Directive relating to the Quality of Water for Human Consumption very difficult to achieve.

The significance of P. aeruginosa may also be considered in new mains. It is not a usual practice to look for this organism, but some studies have revealed its presence in a proportion of new mains. Its significance has been discussed in Section F.3.b(iii). It is desirable that international agreement should be reached regarding the status of this organism in water supplies, but its absence from 100 ml at all points in the distribution system would be much more difficult to achieve than the absence of coliform organisms.

6. Summary

a. Service Reservoirs. Service reservoirs, which are defined as any facilities for storage of treated water between the water treatment works and the consumer, are probably the weakest link in the distribution system, but are an essential part of it. Risks include direct contamination from sewage, which should be avoidable by careful

siting in relation to sewers. All such reservoirs should be completely covered to exclude daylight and all openings screened to prevent access by insects or birds, as the latter are a common cause of contamination. Rainwater penetrating through soil cover on roofs and through cracks in roofs is another common cause of contamination. This is worse after heavy rain following a dry spell, when cracks are present in the soil, and is accentuated by penetration of roots from trees planted too near the reservoir.

Any particulate matter present in the water is liable to settle in service reservoirs, and the accumulating sludge will support the growth of a variety of bacteria. The engineering design of reservoirs should be planned to avoid static conditions on the floor as much as possible, and periodic draining and cleaning is necessary at least once every ten years.

b. Aftergrowth. Untreated water sources contain variable amounts of organic matter which is removed or degraded to varying extents by different water treatment processes, including disinfection. This residual organic matter can support microbial growth that may appear as aftergrowth in the distribution system, especially when water temperatures are high. This can be limited, to some extent, by maintaining a high chlorine residual in the distribution system or by treating with ozone prior to a biological treatment process (e.g., slow sand filtration or carbon filter treatment).

Particulate matter may accumulate in dead ends and at any points where there is little or no flow between two or more interconnected sources of supply. The bacteria that grow, or tastes and odors derived from them, can be continually leaked into the water that flows past. Small animals, such as crustacea and oligochaetes, may also become a problem in areas where bacterial aftergrowth has occurred.

Changes in the chemical quality of water during distribution may be chemically induced, such as the leaching of metals from pipes or fittings or from the ingredients in some plastics. Deficiencies in treatment are a common cause of dirty water, for example when high levels of coagulant are in the system. Changes in source water, or mixing of water from sources with different chemical characteristics, can cause disintegration of accumulated deposits. Changes may also be microbioly induced, such as the production of moldy

tastes due to the growth of fungi on organic materials. There are, as well, a number of common interactions between microbial changes and chemical reactions, some of which may result in the internal corrosion of iron and steel mains. Local accumulations of biomass can produce anaerobic conditions, resulting in growth of nitrate or sulfate-reducing bacteria and their chemical by-products.

   c. **Growth on Materials**. Many bacteria and fungi can grow on a great variety of simple and complex organic compounds, either of natural or man-made origin. It is, therefore, important that materials used in distribution and plumbing systems should not contain enough of such organic compounds to cause either a direct microbial contamination or a deterioration in quality, such as moldy taste. In consequence, all new products intended for use in contact with treated water supplies should be tested, by a reliable method, for their ability to support microbial growth.

   A special example of growth on materials is that associated with water exposed to volatile organic solvents, the commonest being ethanol. This gives rise to the growth of massive bacterial and fungal slimes wherever a free water surface is exposed to an atmosphere containing such vapors. These situations can occur in domestic as well as business and industrial premises.

   d. **Back-Siphonage and Cross-Connections**. Reduction in pressure can occur in public water supply mains as well as in individual plumbing systems, and this is one of the conditions necessary for back-siphonage to occur, or for water to move against the normal direction of flow or pressure. Most water authorities have experienced problems from this cause, and many countries have bylaws or regulations designed to prevent its occurrence. Cross-connections, which may be defined as connections between a public water supply main and any other pipe, usually occur outside the control of water authorities. Recorded instances are not infrequent, sometimes with serious consequences.

   e. **Main Laying and Repair**. Most countries have codes of practice to minimize contamination during main installation and repair. Jointing systems have been a common cause of problems, such as bacterial growth on jute yarn or

on the soft soap used for lubricating rubber ring joints.
Nylon or polypropylene yarn should be used instead of jute
and lubricants which will not support microbial growth
should be used as well. Cleaning of new mains after con-
struction may be facilitated by using foam swabs. Disin-
fection procedures are critical and codes of practice should
be followed for satisfactory results. Sampling should be
conducted after the main has been flushed and has stood full
of water for 24 h, before being put into supply.

7. Recommendations

1. Service reservoirs, which are defined as any
treated water storage imposed between the water
treatment works and the consumer, should be
situated where risks from sewage contamination
are minimal. Service reservoirs should be
completely covered to exclude daylight and all
openings screened to prevent access by insects
or birds. They should be maintained in a good
state of repair and drained periodically for
cleaning.

2. Factors such as the presence of organic matter
and the accumulation of debris in dead ends and
at points where there is little or no water
flow may lead to aftergrowth and possibly the
presence of small animals in the distribution
system. Dead ends should, therefore, be avoided
in the design of a distribution system, and all
disused apparatus should be disconnected at the
junction with the main pipe. In areas where
balanced pressures between different supply
sources cause little or no flow, the mains
should be flushed at intervals.

3. Distribution and plumbing systems should be
constructed only of materials which will not
support microbial growth. New products should
be assessed by a reliable test procedure before
they are used in contact with potable water.

4. It is essential that regulations to prevent
back-siphonage and cross-connections be en-
forced.

5. Materials used in jointing systems and lubri-
cants in mains should be restricted to those
which have been tested by a reliable method and
found not to support microbial growth. Ade-
quate disinfection procedures after main
installation and repair are essential and codes
of practice should be strictly followed.
Sampling of the water should take place after
thorough flushing of the main.

G.   TECHNOLOGICAL ASPECTS

In highly industrialized countries, drinking water of good microbiological, chemical, and aesthetic qualities is routinely achieved with available treatment processes. Nevertheless, improved practices and equipment can exert their own influences by introducing man-made materials upon which microorganisms can become established.   Reduced efficiency of operation, increased costs, and overstressed equipment are oftentimes the consequence.   Such factors as degree of pipe bends and placement of joints, type and age of pipes, valves, and fittings, changes in pressure -- all combine with the constituents of a particular source water and occasionally give rise to complications within the system.   Therefore, the growth of organisms within a distribution system, however harmless to man at the outset, may ultimately threaten the quality of the finished water through these indirect means.

Filamentous iron bacteria are largely responsible for corrosion of metal pipes and the concomitant deposition of insoluble ferric hydroxide along pipe walls and well screens. Such bacteria may also initiate pitting and tuberculation of pipes.   The formation of pits and tubercles favors the survival of other organisms which can then attach to pipe walls and utilize dissolved substances present in the water. Furthermore, variations in hourly demand for water can bring about pressure changes sufficient to cause stripping of metabolic deposits and the delivery of dirty water.

Water mains are made of cast iron (both cement-lined and unlined), concrete, galvanized iron, polyvinyl chloride, and cement asbestos.   Whether enzymatic digestion of these and other materials occurs or not is dependent upon individual ingredients used in the manufacture of various component parts, plus whatever organisms inhabit a particular water source.

Many additional devices are employed as aids to household practices; for example, to soften water for dishwashers,

washing machines, coffee percolators, steam irons, etc. Such auxiliary equipment, installed beyond a household tap or the water meter, may include ion exchangers which apply phosphate, polystyrene filters (to remove small particles or bacteria), and active carbon filters (to remove taste and odor). These devices may give rise to bacteriological problems, since the resins or the filters adsorb organic matter which is a good nutrient source for bacteria.

Besides imparting to the water objectionable odor, taste, frothing, color, and turbidity [See Section F.3.b] certain slime-producing bacteria can significantly disturb the hydrodynamics of turbulent flow through a pipe. A very slight irregularity in the thickness of a pipe wall, caused by growth of slimes, can interrupt the laminar stream flow enough to increase the friction factor, encumbering the energetics of the system with a greater resistance to flow.

Industrialized nations share a responsibility to understand and protect against indirect and long-term effects from new machinery and techniques, as they apply to old, familiar microbes. The added expense, loss of efficiency, and possible health hazards triggered by a plugged well screen, a constricted pipe, or an obstructed filter are some of the considerations with which this section is concerned.

1. Biodeterioration of Materials

a. <u>Biodeterioration of Rubber Sealing Rings</u>. Although it is over half a century ago that microorganisms were first claimed to be capable of destroying natural rubber (Sohngen and Fol, 1914), the first evidence that this occurred in the water industry was found in the Netherlands around 1950. Rook (1955) isolated pink colonies of <u>Streptomyces</u> sp., from rings from a water main, on pure latex agar. In pure culture, these organisms could bring about deterioration of thin strips of vulcanized rubber.

These investigations were continued by Leeflang and others on behalf of the Institute for Testing Waterworks Materials, the Netherlands (Keurings Instituut voor Water-leiding-Artikelen, 1961). Of 651 rings examined, 59 percent were deteriorated on the surface in contact with the potable water and only 15 percent showed deterioration on the soil side. The majority of joint rings showed a loss of rubber of less than 5 percent of the cross-sectional area. The age of the rings varied from two to 23 years, but age was not

the sole determinant of the degree of deterioration. In all, five or six instances of hydraulic failure were observed. It was concluded that the problem occurred when natural rubber rings were exposed to a flow of unchlorinated potable water and, in the Netherlands, this was particularly prevalent with dune waters. These conclusions have been reported together with the results of exposure trials of rubbers (Leeflang, 1963).

In 1963, reports of deterioration of rings manufactured to BS 2494 (British Standards Institute, 1955) were emanating from Australia through the Standards Association of Australia. The problem was associated, in particular, with rubbers from sewer lines which, aften ten to twelve years of service showed losses of as much as 33 percent of the cross-sectional area. This was especially evident on the sewage side, above the liquid level.

Subsequently, Sphar (1966) sent questionnaires to manufacturers of pipe joint rings in the U.S. and he reported that before 1966, instances of microbiological deterioration were unknown. He cited a survey made by the American Concrete Pipe Association which reported no deterioration of rubber rings in concrete pressure pipelines carrying either chlorinated or unchlorinated water. Following laboratory trials of rubber rings manufactured in the U.S., Leeflang (1968) reported that all of the natural rubber and synthetic polyisoprene rubbers tested were attacked after two years' exposure in a test bath, whereas all the other synthetic rubbers were resistant.

Further studies in New Zealand by Kennet (1966) and Hills (1967) identified three types of "erosion": (1) attack spread around the ring which, it was claimed, occurs when the liquid levels are constantly varying from full to empty or when the pipe is fully charged with oxygenated water, as in a water main; (2) attack spread around an arc; this occurs when the liquid constantly varies between two levels (full and part full or empty and part full); and (3) attack at two points on opposite sides of the ring; this occurs when the liquid level is relatively static and little oxygen is present in the material passing through the pipe, as in a sewer. Many of the deteriorated pipe joint rings complied with the British Standards specification BS 2494 (British Standards Institute, 1955).

The New Zealand Department of Scientific and Industrial Research (1969) reported that 15 percent of the rings

examined showed serious deterioration and 40 percent slight
deterioration on the sewage, or water, side. Examination of
rubber rings after 25 years' service showed that, although
10 percent were free from excessive deterioration, others
were degraded by as much as 50 percent. The condition was
more evident in sewer pipes than in water lines.

Cundell and Mulcock (1973) continued this work and
found, in a survey of 583 natural rubber jointing rings
collected from domestic sewers in Christchurch, New Zealand,
that 36 percent showed deterioration about the mean water
line, 33 percent were deteriorated on the outside of the
ring in contact with the soil, and 6 percent were dete-
riorated on both sides. Furthermore, three of the rings
showed deterioration in excess of 50 percent of the cross-
sectional area, with a further three having 10 to 50 percent
deterioration. It was found to be difficult to predict the
extent or future progression of attack. Signs of attack
usually were not apparent until four years after instal-
lation, and after six years' exposure, more rings were
attacked than unattacked. In that the majority of rings
have only been used in Christchurch since about 1960, it is
not possible to predict their probable life. All rings
installed at this time in concrete sewers were found to be
in advanced state of decay, suggesting that the phenomenon
is progressive. However, it was claimed that no instances
of hydraulic failure of pipelines had been reported in
Christchurch to date. The authors remark that deterioration
of natural rubber rings is not readily appreciated by those
who lack first-hand experience with the problem. For this
reason, it was claimed that the occurrence of the phenomenon
may be more prevalent throughout the world than is generally
believed by rubber and pipe manufacturers or pipe users.

In the U.K., the Malaysian Rubber Producers Research
Association defended the use of natural rubber for pipe
joint rings (Dickenson, 1965). It was suggested that the
problem in the Netherlands might be related to the atypical
potable water, derived from dunes, rich in dissolved min-
erals (notably phosphate), and distributed without chlori-
nation. Furthermore, the conditions within the joint space
of asbestos cement mains would lead to a high pH of the
water in contact with the rings which, it was claimed, would
favor the growth of Streptomyces sp., the organisms impli-
cated in deterioration.

In 1969, Dickenson claimed that the oxidative attack on
the rubber molecule by microorganisms was probably terminal

and, in view of the low incidence of terminal sites in fully
vulcanized rubber, it was argued that low molecular weight
fragments were necessarily produced by primary, non-bio-
logical degradation. In view of the extreme slowness of
deterioration, it was suggested that the initial phase was
one of nonspecific chemical oxidation; in support of this,
it was claimed that chemical analysis of deteriorated rubbers
had revealed a notable absence of persistent antioxidant,
especially in the water environment. Other components of
natural rubber might be subject to microbiological attack
that could result in deterioration. These could include
plasticizers and antiozonants, especially paraffin wax.

Further work in the U.K., undertaken by the Water
Research Center (WRC), has concentrated on three aspects of
the problem: (1) the bacteria involved in biodeterioration;
(2) the incidence of deterioration in rubber rings recovered
after service in potable water pipelines; and (3) the effect
of rubber formulation on the rate of deterioration. WRC
studies have confirmed many previous findings. Natural
rubber is the most prone to attack, which is normally re-
stricted to the surface in contact with the water. In
sewage pipes, the attack may be concentrated in the area of
the mean sewage flow. High levels of rubber weight loss (up
to 33 percent) have been observed without apparent leakage,
but the possibility of mechanical failure cannot be ignored.

Deterioration can occur in pipelines carrying ground-
water, surface water, or sewage. Unchlorinated waters, or
waters in which the chlorine residual has disappeared, would
appear to support higher rates of attack than those in which
a residual may still be detected. In certain instances,
several rings showing deterioration have been recovered from
the same section of pipeline, suggesting that the phenom-
enon may be widespread.

Rings less than four years old do not show attack, but
there is an increasing tendency for rings older than this to
show deterioration. This is most marked in rubber rings
recovered from pipelines laid between 1950 - 1960. The
timing would indicate that this might be associated with
changes in rubber formulations which were necessary to
protect the health of workers in the rubber industry.

The incidence of attack does not seem to be specifi-
cally associated with ring diameter. However, there is a
distinct tendency for deterioration to be most marked in
asbestos-cement pipes and least in iron mains. Initially,

this was considered to reflect the preference of the actino-
mycetes, which may attack rubber, for the alkaline condi-
tions found in .the joint spaces of asbestos-cement pipes.
However, laboratory studies have shown that the formulation
of some rubber rings used for the assembly of asbestos-
cement pipes could make the rings more susceptible to deterio-
ration.

Examination of large numbers of rubber rings has indi-
cated that roughening and surface erosion are often symp-
tomatic of biological attack.   Two selective media, Kuster
and Williams agar (Kuster and Williams, 1964) and modified
DST (oOrchard and Goodfellow, 1974), were used for the
examination of both deteriorated and undeteriorated sections
of the same ring; it was shown that actinomycetes are a
significant factor in deterioration.   Irrespective of the
origin of the rubber ring, three morphological types were
predominant; these have been identified as Streptomyces
litmanii, Streptomyces fulvoviridis, and Nocardia asteroides
(Hutchinson, et al., 1975).   These were clearly the types
described as white and orange-pink streptomycetes by other
authors (Dickenson, 1969,; Leeflang, 1963; Rook, 1955).
Numbers as large as 10^5 to 10^6 per g·of deteriorated rubber
have been recorded.   The ability of these isolates to degrade
rubber has been confirmed by inoculation of a rubber latex
film supported on an aqueous agar base.   The organisms grow
and alter the physical properties of the rubber, confirming
their ability to degrade the polymer.   The ability of these
actinomycetes to use certain rubber ingredients as sole
carbon sources has also been demonstrated.

Other workers (Berridge, 1951; Thaysen, et al., 1945)
have commented on the involvement of sulfur-oxidizing bac-
teria, which are capable of producing significant levels of
sulfuric acid when growing on excess sulfur present in
sulfur-vulcanized rubbers.   This strong acid could cause a
chemical deterioration of the rubber.   Although these
organisms were found to be associated with deteriorated
rubber, it was considered that their presence was more
directly related to the sewage environment, in which reduced
sulfur compounds, namely hydrogen sulfide, were freely
formed (Hutchinson, et al., 1975).

The importance of rubber formulation in controlling the
rate at which a ring is attacked was clearly shown in a
series of accelerated aging tests performed at the WRC
using thin strips of rubber.   These showed that unprotected
natural rubber is rapidly degraded, but can be protected by

the use of antioxidants, especially those which are insoluble
in water as reported earlier by Derham (1975) and Dickenson
(1969). Chlorinated waxes and aromatic processing oils also
have a beneficial effect in improving the resistance of
natural rubber, but to a lesser extent than that afforded by
antioxidants. The presence of relatively high concentra-
tions of organic accelerators, such as thiocarbamates and
thiurams, has a beneficial effect on the resistance of
natural rubber to biodeterioration, as was found by
Cundell and Mulcock (1973). However, some ingredients,
especially plasticizers, may enhance the rate of deterio-
ration and in separate tests, some, especially sodium
octonoate, were found actively to support the growth of
rubber-degrading bacteria.

Although changes in the formulation of natural rubber may
delay the onset of microbial attack, they will not prevent
it from eventually happening. Whether careful selection of
ingredients (especially antioxidants) that are currently
acceptable to the rubber industry will protect rubber jointing
rings for the 50 years' service life normally expected by
water engineers is not clear from the short-term trials
that have been done. The demands of the water industry for
rubber formulations which are not toxic and do not permit
the growth of microorganisms is a further complication in
the selection of satisfactory rubber seals.

b. Biodeterioration of Sealants and Mastics. A sealant
is intended to maintain a seal between the sides of a joint
which may be subject to some degree of movement. In the
water industry, sealants are primarily to control the move-
ment of water, preventing both loss and contamination of
water held in various concrete and steel tanks. In addition
to good mechanical performance, sealants used in water
supply must show minimal toxicity for mammals and must not
support the growth of microorganisms. The National Water
Council approvals procedure [See Section F.3.d] will protect
the consumer from deterioration in water quality caused by
these two factors. Additionally, the service life of the
sealant must not be limited by microbial degradation.

WRC has assessed, for signs of microbial attack,
sealants which have lost their mechanical properties. The
following indices and microorganisms have been studied:
colony counts, fluorescent pseudomonads, actinomycetes
(including Nocardia sp.), sulfur-oxidizing bacteria, sul-
fate-reducing bacteria, and fungi. In strong contrast to
the findings with rubber sealing rings, no specific micro-
bial cause for deterioration could be found. Invariably,

the specific organisms likely to cause microbial deterio-
ration (pseudomonads, actinomycetes, and fungi) have been
found in no higher numbers than are present in neighboring
unattacked material, the surrounding water environment, or
in the case of filters, no more than is present in the
adjoining sand. However, the Metropolitan Water Board
(1970c) has shown that an ascomycete, possibly Herpotri-
chiella sp., was associated with disintegrated polysulfide
sealants.

It is possible that sealants, because their formu-
lations differ greatly (especially with respect to their
higher levels of plasticizer) from those of rubber sealing
rings, are more prone to a generalized attack by a variety
of microorganisms that are capable of exploiting a less
restrictive environment. At present, it is not possible to
say whether the service life of sealants is primarily con-
trolled by physical-chemical aging accentuated by chemical
leaching, or whether microbial activity can be considered a
limiting factor. However, it must be accepted that the
working life of a sealant will be considerably less than
that of a rubber ring and is unlikely to exceed ten to
fifteen years.

2. Microbial Growth On Resins and Filter Media

In a technologically developed country, the drinking
water is relatively free of bacteriological and aesthetic
problems. However, only a small proportion of this domestic
water is actually ingested by consumers as a beverage or in
food; the remainder, probably over a hundred times the
amount that is ingested, is used for hygienic, cleansing, or
technical purposes. Whereas this water may be of good
quality from the standpoint of health, it may have proper-
ties that make it unsuited to its alternative uses. There-
fore, it may be necessary to eliminate certain ions from the
water or to add special preparations so as to minimize
technical difficulties.

In a household, filtration or ion exchange devices may
be used to eliminate taste and odor-producing substances or
bacteria, or to soften hard water in order to improve the
performance of hot water equipment. Water can also be
softened by adding substances that contain phosphorus, such
as polyphosphates or ortho-phosphates, in order to prevent
corrosion or encrustation within the pipes. This equipment
may be installed behind the tap in an apartment or in the

basement of homes. Alternately, filters or small ion ex-
change boxes may not be connected to the distribution system,
but may instead, be used separately as adjuncts to a specific
household task. These small devices are often advertised
for use while traveling and camping, especially to areas
where sanitary conditions are suspected of being poor and
disease is endemic. On the whole, these apparati are un-
necessary in households of the developed countries and can
be ineffective and even dangerous when used in areas where
there is epidemic disease. Although useful in their spe-
cialized technical roles, they are apt to create bacterio-
logical problems in the process.

a. **Filters**. There is usually no need to use filters
for removal of bacteria in households of developed countries.
This is already accomplished by the municipal supplier.
However, filters (mainly of activated carbon or some plastic
compound) are advertized as a means of eliminating objec-
tionable tastes, odors, colors, and turbidity in the water.
It is well known that bacteria, along with organic matter,
can collect within filter pores providing a suitable en-
vironment for microbial growth. Periodic cleaning of the
filter becomes necessary to avoid large swells in bacterial
populations emanating from the filter. Since publically
supplied drinking water normally is free of pathogens, those
bacteria which multiply in the filter are more a nuisance
than a health hazard. Nevertheless, if there are legal
codes limiting the acceptable colony count levels, this can
create administrative problems.

b. **Ion Exchangers**. Ion exchange resins can produce
bacteriological problems not only from attachment of bac-
teria and organic matter to the resin, but also from com-
ponents of the resin itself that can serve as a nutrient
source. Frequently, newly purchased ion exchange resins may
already have defects in the individual resin granules. As a
rule, these defects will increase during the life of the
exchanger. Bacteria can very easily collect within these
surface irregularities and be protected from disinfection,
backwashing, or other cleaning attempts. Similar problems
may be seen with filters and can lead to high microbial
loads in the product [See Section E.4].

c. **Portable Filters**. As has already been mentioned,
portable filters are intended to produce good quality water
in areas where it is otherwise unobtainable. However,

portable filters are also advertised for use at camp sites or during times of emergency. Therefore, they should be designed so as to be capable of removing not only pathogenic bacteria, but also viruses, protozoa, and helminthic eggs that may be present in contaminated water. The small size of viruses dictates the need for extremely small pore diameters, which greatly reduces potential filtration speeds. Often, after a short period of use, the filter becomes clogged and will stop filtering altogether. Thus, effective portable filters are likely to be inconvenient, and convenient portable filters are likely to prove unsafe.

  d. <u>Water Softeners that Add Phosphorus</u>. Unlike ion exchangers and filtration units, phosphate-dosing equipment adds small amounts of phosphate to the drinking water. Legislation in some countries specifies an upper limit for phosphate that can be present in the drinking water. Dosing with phosphate is useful only if the water is not too hard and the temperature of the water is about 60°C. Phosphate should not be added to a cold water supply because at low temperatures it encourages the growth of bacteria and (if light is available) algae, especially if there is any degree of stagnation. There is also the danger that phosphate preparations will not be handled properly in transit from producer to consumer, this too can result in contamination of water with bacteria. Provision of nutrients to bacteria already present in the water, plus introduction of new bacterial species, possibly pathogens, are potential problems connected with the use of phosphate preparations. It is, therefore, recommended that such preparations be divided into small portions and durably packaged before sale.

  e. <u>Conclusion</u>. Small-scale water treatment apparatus for use in the field is frequently unnecessary or unreliable. Some devices fail to remove the microbes that they are supposed to take out of water, whereas others encourage microbial growth so that colony counts are increased in the treated water. The latter problem is also encountered when filter media, such as activated carbon [See Section E.5] or ion exchange resins, are used on a large scale; however, it is less of a nuisance when the treatment is being done by professionals and will be followed by disinfection.

3. Hydraulic Effects of Microbial Growth

Water from all public supplies must be delivered under pressure, whether its destination is a tap in the tallest skyscraper or the last tap at the end of a large distribution system. Pressure is necessary not only to supply people quickly with a desired volume of water, but also to maintain hygienic conditions. Flowing water seldom permits bacterial growth, and a properly functioning distribution system will maintain an adequate flow to ensure against microbiological problems.

a. __Types and Diameters of Pipes__. Often, the type of pipe used, or its diameter, will have an effect on bacterial growth, especially at locations in the home where a continuous flow of water is not guaranteed because of infrequent usage. Comparative studies with plastic, rubber, copper, and steel pipes showed that colony counts increased from one to 14,000 per ml in the rubber pipe; whereas steel and plastic pipes had colony counts of about 30, and the copper pipe showed a count of about zero after four days of use. Plastic material must be tested for use with drinking water because plastic paints and covers used in closed reservoirs very often lead to problems with bacterial growth.

In some buildings, especially in schools, the diameters of pipes in the distribution system are calculated for emergency cases (e.g., fire) and not for routine drinking water supply. This means that the amount of water being regularly used is small in comparison to the pipe diameters. The result can sometimes be stagnation and taste and odor problems, especially if drinking water pipes are installed near heating pipes where elevated temperatures will promote bacterial growth. __Streptomyces__ species are especially adapted to taking advantage of such situations, imparting an earthy taste and odor to the water.

b. __Microbial Oxidation of Manganese in Pipes__. Certain bacteria, including __Pseudomonas__ sp., __Hyphomicrobia__, and __Sphaerotilus discophorus__ can form oxides of manganese in water containing > 0.01 to 0.05 mg per l or more of manganese within a pH range of 6 to 7.5. These manganese oxides adhere to pipe walls forming ripples across the direction of flow, which invariably leads to losses in pressure. It has been shown (Schweisfurth and Mertes, 1962) that, at high

flow rates, the hydrodynamic effects in pipes become significant, leading to a substantial drop in pressure; whereas, at low flow rates, pressure changes are inconsequential. Pipes in which such a build-up has occurred, can be restored to good operating condition with mechanical cleaning, albeit the process is cumbersome and time-consuming. Alternatively, chlorination can be used to inhibit microbial activity; with chlorine, oxidation also takes place, but the end product , Mn (IV) does not adhere to pipes and can be removed by filtration.

c. **Microbial Growth from Improper Installation of Household Equipment.** The installation of dishwashers, washing machines, ion exchangers, or filtration units must take into account pressure differentials between the household water supply and equipment capacities. If some means of compensation is not also installed, back-siphonage and contamination can result. Rubber tubes are often added to the tap to extend use to the bottom of bathtubs or sinks. Turning water outlets in different locations of the house on or off can sometimes be sufficient to create hydraulic pressure changes and to flush contaminated bathing or washing water into the distribution system. Such events have been responsible for the occurrence of enteric disease in inhabitants of one household or several households along an entire street.

d. **Microbial Growth from Cross-Connections.** Industrial buildings and ships, in particular [See Section G.5], are known to have two or more distribution systems: one for drinking water supply and another to supply low quality water for other uses, such as cooling or fire protection. If these industries are situated near a large river or harbor, they very often use raw river or harbor water for these latter purposes. Normally, the two systems must be separated from each other by special instrumentation to ensure that no mixing occurs. In some cases, pressure in the water pipes used for fire protection is higher than that which is in the drinking water pipes and small amounts of contaminated water may continuously drip into the drinking water system. If this "inoculum" is derived from polluted river water, pathogens may be not only introduced, but may find conditions suitable for multiplying. If at any time, the slide valve is opened, the danger of contamination is greatly increased. Over the last 30 years, outbreaks of typhoid fever, paratyphoid-B fever, and salmonellosis have

resulted from such cross-connections and pressure differences in distribution systems of this kind. Therefore, two systems handling different quality water and operating side-by-side must be carefully controlled and supervised.

4. Microbially Mediated Chemical Cycles

a. Microbial Manganese Oxidation Affecting Wells and Water Distribution Systems. Manganese-oxidizing micro-organisms (bacteria, fungi, and very rarely protozoa) require a treatment separate from that for "iron bacteria" because only a few of the rare species of chlamydobacteria oxidize or precipitate both iron and manganese under natural conditions or in the laboratory. The references to reports of both iron and manganese oxidation by Siderocapsaceae are incorrectly quoted in most cases (Schweisfurth, 1973). Enzyme-mediated iron or manganese oxidation cannot be proved solely on the basis of microchemical detection of Fe (III) or Mn (IV) at the sheaths of the surfaces of these bacteria.

By contrast to Fe (II), Mn (II) is oxidized by O_2, at a rate that is of practical significance in the field of drinking water, only above a pH value of approximately 8 to 8.5. Correspondingly, reduction of Mn (IV) already occurs at Eh values near or below + 200 mV; this means that the microbiological oxidation of Mn (II) can only take place above this Eh value (Schweisfurth, 1972).

Depending on the geological and hydrological conditions in the aquifers or reservoirs, Mn (II) is formed from Mn (IV) by reduction or dissolved from manganese carbonate by reaction with CO_2 or HCO_3^-. In the case of waters with little or no dissolved oxygen, the Mn (II) penetrates into the wells and into the raw water, where, in the presence of O_2, micro-bial oxidation starts, as well as the formation of "MnO_2" (= MnO_{1+x}, x = 0.7) and the formation of deposits in the wells and water conduits. The problems caused by these deposits include clogging of slots in well pipes; increased turbulence and thus, a loss of flow velocity in conduits; damage to equipment for measuring water flows; black-colored water; stains in laundry; disturbances in food handling establishments; accumulation of heavy metals such as arsenic, lead, zinc, and copper (Basco and Szalay, 1978); and some-times an increase in the colony count of the water. Pre-vention is based on elimination of Mn (II) from raw water if limit values of 0.01 to 0.05 mg per l are exceeded. Based on the conditions under which Mn (II) and Mn (IV) are

stable (Hem, 1963-1965), Mn (II) can only be oxidized, within the Eh and pH ranges common for drinking water, by microbiological means. Various bacteria (Sphaerotilus discophorus, Pseudomonas, Arthrobacter, and Hyphomicrobium species), as well as fungi, induce manganese oxidation (Schweisfurth, 1978). Apparently only in the case of Hyphomicrobium manganoxidans is there an interdependence between the multiplication of microorganisms and manganese oxidation (Schweisfurth, et al., 1978).

The removal of manganese from raw water at a treatment plant can be accomplished either by chemical or microbiological means if conditions are adjusted. The chemical manganese oxidation is carried out by aeration, pH values, that is induced by the MnO_{1+x} already formed. During the microbiological removal of manganese, the medium of a filter serves as a support for the growth of microorganisms (mostly gram-negative, rod-shaped bacteria and in rare cases, sphaerotilus discophorus and manganese-oxidizing fungi). It is essential that the Eh value of the water be sufficiently high (more than + 200 mV); otherwise, manganese oxidation does not start, even after an inoculation with backwash sludge from another plant. If there is no removal of manganese in a microbial water treatment plant, no manganese-oxidizing microorganisms will be detectable by culture.

Formation of a high proportion of manganese-oxidizing growth on the inner surfaces of water pipes has not been shown to be directly related to corrosion.

b. Iron and Sulfur Bacteria Corroding Well Casings and Other Structures. Bacteria may take part in the corrosion of iron well pipes and drinking water conduits. In each case, corrosion may start from either the inside or the outside. Except for the coating of pipes against exterior corrosion, protective measures such as bituminizing or plastic coating afford only a partial protection.

In this discussion, the term "iron bacteria" will include: (1) bacteria suspected of being capable of drawing an energetic benefit from the oxidation of Fe^{++} to Fe^{+++} (Gallionella, possibly chlamydobacteria such as Leptothrix); and (2) bacteria utilizing the organic ligand from complex-bound Fe^{++}, following which Fe^{++} is subject to oxidation by O_2 at pH values above 5, such as are found in drinking

water. The latter bacteria, which are mostly rod-shaped, may also precipitate complex-bound Fe^{+++}.

The term "sulfur bacteria" will include: (1) sulfur-oxidizing bacteria that, being autotrophic, will generally oxidize reduced sulfur compounds to SO_4^{--}, mainly under aerobic conditions; and (2) sulfate-reducing bacteria that, at a locally or generally low Eh value and in the absence of O_2, form hydrogen sulfide using both organic hydrogen donors and molecular hydrogen.

Microbially mediated corrosion (i.e., a dissolution of elemental iron and other metals) will occur as a consequence of: (1) absorption of nutrients, as well as oxygen, by the colonies of microorganisms that have accumulated at the metal surface; (2) liberation of corrosive metabolites, such as organic acids and other complex-forming compounds; (3) production of sulfuric acid from S^{--} or elemental sulfur; and (4) inclusion of sulfate-reducing bacteria in the cathodic process under anaerobic conditions. Both natural and artificial anti-corrosive coatings are also subject to microbial attacks. Although the types of corrosion mentioned in (1) and (2) are assumed to occur only under conditions in which nutrients are plentiful (as is true in cooling systems), they may also play a role in interior corrosion within drinking water distribution systems.

The chemical and microbiologic processes involved have been summarized by Chantereau (1977). Subtle heterogeneity in the system can lead to the establishment of foci of anodic and cathodic depolarization, enabling electrolysis and metabolic activity of iron bacteria and, given a sulfur source, of sulfur bacteria as well [See Figure G.4.b-1]. As iron from the pipe is being eroded in the form of Fe^{++} ions, various derivative substances are being deposited on the inner surface of the pipe, sometimes to an extent that occludes the bore of the pipe substantially [See Figure G.4.b-2]. Maturation of the deposits leads to the presence of an anaerobic zone nearest the pipe surface and an aerobic zone in contact with the water, as well as an intermediate zone of low oxygen activity: this allows iron bacteria and both sulfur-reducing and sulfur-oxidizing bacteria to participate in the corrosion and deposition process [See Figure G.4.b-3].

In addition to their participation in corrosion processes, the iron bacteria have both favorable and unfavorable effects on the procurement and treatment of raw water

for the production of drinking water (Glathe and Ottow, 1972; Kullmann and Schweisfurth, 1978; Schulze and Schweisfurth, 1975). During procurement, they will accelerate Fe^{+++} precipitation when oxygen has entered the aquifer and the groundwater, and will thus, reduce the water-permeable cross-section of all structures (in the soil and in slotted well-pipes), thereby eventually resulting in failure of the well [See also Sections A.1.b to c and A.2.a(ii)]. On the other hand, the iron bacteria certainly take part in the breakdown of organic substances during the process of iron removal from waters, which opposes the precipitation of Fe^{+++}. These bacteria are also found where iron is precipitated within distribution networks [See Section F.2.d(vi)].

The problems caused by iron and sulfur bacteria have been described as briefly as possible in this discussion. In addition to the references cited above, valuable and much more extensive information will be found in Iverson (1975), Lovelock and Gilbert (1975), and Miller (1971).

5. Drinking Water Supply for Ships

Many countries have no regulations for ensuring good quality drinking water aboard ships (Müller, 1976; Goethe, et al., 1969) although a disproportionately high frequency of waterborne infections are known to occur on these vessels compared with incidences on land. A serious problem with shipboard water lies in the fact that many ports only have contaminated water (sometimes containing helminth eggs, protozoa, bacteria, and/or viruses) available to fill ships' tanks and because this water does not undergo any treatment or purification during storage.

Being confined on a ship means that both passengers and crew cannot avoid infection if water supplies are contaminated with pathogens; hence, outbreaks aboard ships tend to be epidemic. These not only include common waterborne diseases (e.g., typhoid fever, paratyphoid B fever, other salmonellosis, cholera, and dysentery), but also infections caused by large concentrations of opportunistic pathogens (e.g., P. aeruginosa, as well as Clostridium, Bacillus, and Staphylococcus species). This latter group, if incorporated into food through the addition of contaminated water, may become enriched in the process (Muller, 1974).

a. <u>Occurrence of Contamination Aboard Ships</u>. Investigators have found that the bacteriological quality of ships' drinking water is, on the average, inferior to that of land water. For example, from 1950 to 1960, 25 percent of the ships docking at the Hamburg harbor had water which tested positive for E. coli (Müller, 1961). In 1970, the Japanese found high total bacterial and coliform counts in drinking water from nearly 50 percent of their vessels (Hayashi, <u>et al.</u>, 1975). They later reduced the proportion to 27 percent in 1974 by adding sterilization and filtration equipment.

b. <u>Why Ships' Water Becomes Contaminated</u>. Observations made over a 20-year period have revealed several areas of neglect which are largely responsible for contamination of water supplies on ships. They are listed in order of their frequency of occurrence:

- Drinking water kept in open tanks during conveyance aboard lighters.

- Using the same bucket for drinking water as well as for river water.

- Tracking dirt from shoes into tanks during cleaning operations.

- Using river or sea water to clean tanks.

- River or sea water seeping into improperly closed tanks.

- Using the same hoses and pumps for both drinking water and river water.

c. <u>Water Distribution Systems on Ships</u>. Ships possess either a single, double, or triple distribution system. The single system, theoretically, provides potable water throughout the entire distribution network. Large, recently built ships are likely to have this arrangement, now that equipment for distilling salt water has provided an alternative to refilling tanks from water supplies of foreign harbors.

The double system conveys finished water for drinking and washing through one network, while river or sea water travels through a separate pipeline to water closets, ship cleaning, and fire protection facilities.

The triple system channels river water into showers and sinks for hand and dish washing; sea water into a network for fire protection, ship cleaning, and toilets; and drinking water into only a few taps, primarily for that purpose alone.

d. __Types of Disinfection Practiced on Ships__. Disinfection can be accomplished by physical or chemical means. These processes include boiling; filtration; or applying chlorine, silver, ozone, or ultraviolet irradiation.

The cost and bulky apparatus needed for boiling make this process impractical for use on ships. As for filters, they may become defective or clogged and they require careful maintenance, backwashing, and bacteriological monitoring of the filtrate (Müller, 1975) all of which require expertise not commonly available on board a ship.

The effectiveness of chlorine disinfection depends on maintaining an active residual in spite of possible high loads of organic matter; this can give rise to problems of taste and odor. Furthermore, automatic devices which utilize gaseous chlorine, and electrolytic processes for deriving chlorine from sodium chloride, can malfunction on a stormy sea.

Relatively small quantities of silver are bactericidal or bacteriostatic. If the dose is high enough and contact time long enough, adequate disinfection can result. Moreover, silver is easy to handle and maintains its potency for long periods of time.

Ozone has not, as yet, been employed on ships because of fire and explosion hazards associated with it, as well as the sensitivity of the production mechanism. Neither does it offer prolonged disinfection since, being toxic, it must be removed from the water.

Ultraviolet irradiation disinfects quite well, but only, when applied to relatively clear, colorless water already somewhat low in microorganisms (Müller, 1972). Unfortunately, a ship's movement during stormy weather can stir up sediment in the water tank and create problems of turbidity which prevent the ultraviolet light from adequately penetrating the water.

Distillation is the method of choice for providing drinking water on ships, although it too has its problems.

One great advantage of this technique is the availability of source water, once a ship is on the open seas. This limitless capacity obviates the need for strict conservation or priority uses, practices which may endanger the quality of the water.

Inasmuch as vacuum distillation may be done in the temperature range of 25 to 40°C, it will not protect against pathogens and should not be considered a substitute for boiling. A properly operated still will produce water with a chloride content below 6 mg/l, but the chloride test does not indicate microbiological purity. It is recommended (Muller, 1968) that distillation be used in conjunction with chlorine or silver, but that highly polluted waters (such as one may find in a harbor) not be used at all in this process.

e. **Bacterial Standards for Drinking Water on Ships.** All water used on ships for drinking, food preparation, and hand washing should conform to drinking water standards [See Section D]. This means that 100 ml of water sample should contain no E. coli or total coliforms. Because it is situated so close to polluted surface waters, ships' drinking water should, in addition, be monitored for total bacteria, in which no more than 1,000 per ml are an acceptable number. Pseudomonads (along with coliforms) are typical inhabitants of polluted surface waters. They can grow rapidly in low nutrient water and at low temperatures (e.g., in ice water). Because of these attributes and because P. aeruginosa is a potential pathogen, a test for these organisms should be included among microbiological analyses of ships' water. Culturing on gelatin pour plates will reveal any pseudomonads as green fluorescent colonies.

f. **Emergency Drinking Water Storage.** In case of shipwreck, consideration is first given to obtaining enough water. Water quality and safety, therefore, become issues of secondary importance.

Provision of sufficient amounts of potable water is one way of combating deficiencies during emergencies. The International Commission (International Ship Safety Treaty) specifies that quantities of 3 l per person be stored on lifeboats and 1.5 l per person on life rafts. These supplies are usually stored in plastic tanks (though formerly wooden or metal tanks were used) and fastened under the

thwarts. Water may also be contained in sterilized plastic bags or tins which, due to expense and number of processing steps, are usually reserved for life rafters. To avoid contamination after filling with good quality water, silver compounds are added, thereby permitting storage for three years or longer (Müller, et al., 1977). Also available are several small devices for converting sea water to drinking water, such as ion exchangers or distillers, which may be installed on life boats and life rafts.

6. Water in Containers

Microbiologically safe, piped water is available to most people in the industrialized nations a majority of the time. In these countries, water is put into containers and sealed for two principal reasons: (1) to have it available in the event of an emergency in which normal supply is interrupted; and (2) to allow water from a specific source to be distributed commercially over a wide area. The maintenance of water quality during prolonged storage in a container presents some special problems (Müller, 1969; Sepilli, et al., 1965).

a. **Water for Emergencies.** Water stored in containers for emergencies might be prepared in either of two ways: first, water of adequate bacteriologic quality might be sealed in containers just as it comes from the public supply. Second, water may be sealed in containers (tins, plastic bags, or glass vessels) and sterilized. Depending upon the level of organic matter present, water that has not been sterilized is likely to permit bacterial growth to reach colony counts of millions per milliliter unless some long-acting disinfectant such as silver salts is added. Sterilized water will remain bacteriologically acceptable for a virtually unlimited period of time, depending only on the integrity of the container.

The container is, therefore, the key to successful storage of water for emergencies. Tins sometimes oxidize, especially at the edges, so that metallic (tin or iron) ions or products become dissolved in the water. The resulting color, turbidity, and astringent or metallic taste impair the organoleptic quality of the water. Plastic bags appear to offer some comparative advantages, in that they are light in weight, and visible changes in water quality will be perceptible without opening the container. However, they

are more susceptible than tins to physical damage and occasionally impart off flavors (described as musty, foul, or not fresh) to the water if appropriate polymers are not chosen [See also Section F.3.b].

b. <u>Commercially Distributed Water</u>. For centuries, people have gone to certain wells and springs to drink or bathe in the waters as cures for, or to mitigate, symptoms of rheumatism and biliary or renal concretions, or to stimulate intestinal motility. More recently, water from such sources has been put into bottles (first of glass, but now more often of plastic) and sent all over the world. In addition to the renowned sources, commercially distributed water may simply derive from wells in which mineral content is known to be high (mineral water) or come from wells or public systems and then be supplemented with salts and carbon dioxide gas (bottled drinking water). Water bottled without carbon dioxide "still bottled water" may be preferred by those whose stomachs are upset by carbonation. Bottled water is favored in Europe because people are sensitive to the tastes and odors of chlorine and other substances present in tap water or because tap water is thought to be hazardous to health. Bottled water has become an item of great economic importance, partly because advertising has led people to believe it to be more healthful than tap water. Nevertheless, water cannot be assumed safe simply because it comes from a bottle. It must produce low bacterial colony counts and be free of fecal indicators, pathogens, and potential infectious agents as well as toxic chemicals. The bacteriologic quality of commercially distributed water should remain as good as that of tap water [See Section D] even through prolonged periods of storage at room temperature.

c. <u>Bacteriological Quality of Water in Containers</u>. Water in containers may contain bacteria which were present in the source water [See Section A] or may be contaminated in the process of bottling, through contact with contaminated containers or closures, or by contaminated air [See also Section F.3.d]. This means that the bacteriological quality of both the source water and the product in the final container must be continually monitored (Geldreich, et al., 1975). Water that has just been sealed into a container should be free of coliforms and E. coli and should have a colony count no higher than that of the source water. Sporeformers sometimes associated with food poisoning and

enteric diseases (e.g., *Clostridium* *perfringens* and *Bacillus subtilis*) should also be absent. *Pseudomonas* species have been a problem when certain plastic containers or caps with plastic inserts are used, and high counts of *P*. *aeruginosa* [See Section B.1.a(vii)] have been found in many samples of water bottled without carbonation (Müller, 1974; Soenke, 1974). Bacterial activity in the product may also give rise to toxicologic problems; given a high initial nitrate level, bacterial nitrosification may yield levels of nitrite which are hazardous to newborn and young children, for whom bottled water is especially recommended.

    d. <u>Storing Water in Containers</u>. Whether publically supplied or commercially packaged, drinking water will invariably harbor a few indigenous microbes whose numbers, under entirely normal circumstances, will increase as a function of time, temperature, and available nutrients. However, when water is stored in containers, initial counts of ten to twenty colonies per ml may soon grow to populations numbering in the millions per ml. Later, after three weeks to three months of storage, colony counts should decrease as a result of nutrient depletion. Such a swell in bacterial numbers can be prevented during bottling by the addition of disinfectants, such as silver salts, or by filter sterilization. Carbon dioxide in the water will help to inhibit growth of the indigenous flora, but will not kill pathogens or fecal indicators such as *E*. *coli*. Therefore, when analyzing samples it is important to look beyond total colony counts which, especially in the case of carbonated water, may prove misleading. Along with the standard fecal indicators [See Sections C.1.c to d], tests for pathogens (such as *P*. *aeruginosa*) [See Section C.2.c] and potential pathogens (such as aerobic and anaerobic sporeformers) [See Section C.1.e] should be routinely employed.

7. Summary

    Bacteria are classified, and subsequently identified, on the basis of the limited circumstances under which they can grow and the nutrients they can use. Although individual bacterial genera and species may be extremely limited in versatility, there always seems to be one or more species capable of growing in any given aqueous environment regardless of adverse conditions, extremes of temperature, or apparent absence of nutrients. Growth of such organisms in drinking water treatment, storage, and distribution facilities often proves detrimental to the facilities or to the quality of the water.

Facilities are structurally affected by deterioration of materials and by some of the chemical reactions that can lead to mobilization of iron in water mains. The functioning of facilities is affected when deposits of microorganisms and their products interfere with hydraulic conduction through water pipes or coat the active surfaces of filter media. Water quality may be degraded by inappropriate storage or by treatment in small-scale apparatus, the design of which is not microbiologically sound.

The importance of sanitation, in limiting the microbial inoculum that may give rise to these technological problems, must not be minimized. However, it must also be recognized that drinking water is almost never sterile, that organisms which may cause problems will eventually be encountered in every situation, and that only active measures against such organisms can be expected to succeed in the long term.

8. Recommendations

1. Construction materials used in treatment and distribution systems should be selected (among other factors) according to their resistance to biodeterioration. Those components that are prone to microbially-induced deterioration should receive appropriate servicing and be replaced as they near the end of their life expectancies.

2. Devices used in the home, primarily for the sake of convenience, as adjuncts to household tasks are apt to create bacteriological problems and should be avoided or professionally controlled.

3. Water, destined for public consumption, that is supplied in non-standard form (e.g., aboard transport conveyances or packaged commercially) should be subject to the same microbiological standards of quality enforced for publicly supplied water.

H. SUMMARY

The most potentially significant constraint upon the scope of the microbiology project is that it was to address the drinking water supply problems of <u>industrialized nations</u>. As was stated in the introduction to this report, industrialized nations usually have large quantities of water or industrialization would not have been possible. Even so, the quantities of water may not be adequate to meet anticipated needs and the quality of available water may be much degraded by prior use. It is well, at this point, to ask what distinctive features of water supply in industrialized nations are significant to microbiology.

>As major feature is high daily per capita water use. Daily consumption of beverage water is physiologically determined: the body's water losses must be replaced, so the total daily use of water, by ingestion, is determined by the climate and the size of the population in both industrialized and developing countries. Other uses of water in the home, which tend to be larger in industrialized nations than in developing countries, include flushing of water-carriage toilets and cleansing of food, clothing, the home, its contents, and its inhabitants. Outside-the-home uses that contribute to the high daily per capita demand in industrialized nations include a variety of applications in commerce and industry, as well as the occasional use of water for fighting fires.

Where the volume of water used exceeds the supply, a "reuse factor" (e.g., perhaps 25 percent of the water available at some point in a certain river has already been used somewhere upsteam) may be calculated. Some classes of water reuse are of far greater microbiologic concern than others. For example, human feces, and therefore, the water used to eliminate them from a household, are the most significant sources of infectious agents transmissible through water. By contrast, the direct disposal of human waste into waterways, that occurs in some parts of the world (either from ships and boats on the water or from unsewered communities along the banks), may decrease the calculated reuse factor,

but increase the risk of waterborne disease. Other micro-
biologically significant components of used water include
substances which may support the growth of organisms in the
water, and heat. Project Area V of this CCMS Pilot Study
addresses the broader aspects of water reuse, but reuse must
also be considered in the context of drinking water micro-
biology because the majority of the infectious agents that
might be transmitted by drinking water derive from the
human intestines and are carried by wastewater, in some
proportion, into waters that may serve as drinking water
sources. The problem of preventing waterborne infectious
diseases would be greatly mitigated if an appropriate, non-
polluting alternative to the water carriage toilet could be
developed; such a device would be accepted only if it met
the esthetic standards now prevalent in industrialized
nations. Otherwise, the protection of source waters demands
that wastewater discharges be carefully supervised and that
wastes be treated and disposed of in a manner that permits
water to be reclaimed as necessary. Many features of this
problem are considered in Project Area V and, in the speci-
fic context of groundwater protection, in Project Area VI.

Topic A of the microbiology report concerns Raw Water.
Every community or water supplier should, and ordinarily
will, select the purest available source for use in drinking
water production. Groundwater from a deep, protected aqui-
fer may contain only a few microorganisms, none of which is
of intestinal origin. Water of this kind may be used in
both private and public supplies with little or no treat-
ment. Even then, chlorination may have to be used in public
systems to avoid problems in distribution. However, really
well-protected aquifers in some areas may lie at such a
depth that they are not accessible to private users. The
depth of an aquifer may be less of a problem where public
water supplies are concerned, but the quantities of water
available must be adequate to the community's needs, or less
pure raw water will have to be used.

Groundwater is frequently discharged to surface water-
ways after use (and, one would hope, after treatment), but
increasing efforts are being made to dispose of wastewater
in such a way that the groundwater will be recharged. The
success and safety of this method of water reclamation
depend greatly upon the ability of soil to accomplish micro-
biologic purification of the water between the point of
application and the aquifer or, at least, the point of
abstraction of water from the aquifer. The efficiency of

purification will depend on the rate of application, on the character of the soil, and on whether recharge is undertaken by vertical infiltration under the influence of gravity or by pressure injection directly into the aquifer. This artificial recharge must be done with extreme caution, for the microbiologic purification of water by soil is not a well understood process and once contamination of a groundwater source has occurred, it is extremely difficult to correct. This is an area where a great deal of research is needed; until results are available, it will be prudent to treat wastewater, to be used for groundwater recharge, to a degree that does not demand too much of the purifying capacity of the soil. The introduction of viable organisms to an aquifer is not the only microbiologic concern in groundwater recharge. Some microbially-induced chemical transformations can lead to degradation of groundwater and toxins liberated upon the death of microbial contaminants may also prove significant.

Surface sources of raw water are more difficult to protect from microbial contamination and will frequently support the growth of some of the organisms that may be introduced. Airborne contamination and runoff from adjacent land surfaces, in addition to discharged wastewater, may contribute undesirable organisms or nutrients to surface waters. Surface water quality may also be directly affected by human activities such as recreational swimming and boating, residence in houseboats, or navigation on waterways for commercial transport of goods. Under optimal conditions, microbial counts in lakes, extremely rich in nutrients, may exceed 10^6 per ml. Many organisms in surface waters are capable of inducing undesirable chemical transformations. Photosynthetic bacteria and cyanobacteria (formerly called blue-green algae) can grow to high levels, given favorable conditions and adequate light. These bacteria, as well as the true algae, can induce off-flavors in water, bind large quantities of dissolved oxygen under certain circumstances, and physically interfere with water purification. Toxins produced by some cyanobacteria may also be significant to human health. It is clear that surface waters which serve as sources of drinking water need more rigorous protection than many of them get, but it is also clear that more research will be needed before the requisite protective measures are well understood.

Topic A also includes a survey of the microbiologic quality of at least some of the raw water in nine different countries. Not surprisingly, raw water quality is generally better where the source is groundwater and where it originates in less densely populated areas. Even in these situations, raw water quality is seldom so consistently excellent that one-step treatment can safely be trusted. Where raw water quality is poorer, more intensive treatment methods are generally employed. Finished water of adequate quality and safety can evidently be produced by a series of unit processes ending with disinfection; but the community served is, obviously, more vulnerable to any kind of event that might even temporarily interrupt treatment of the water before distribution.

Recommendations Concerning Raw Water

1. More research should be done on the microbial ecology of groundwater.

2. The microbiologic quality of source waters should routinely be tested, especially in those instances where the quality of the raw water is judged so good as to require only minimal treatment.

3. Laws to protect both groundwater and surface water sources should be more restrictive and specific, and should include adequate provision for enforcement.

4. Means of conveying good quality raw water to areas where source water quality is deficient should be investigated further.

Topic B surveys the specific Pathogens that may be transmitted through drinking water. Generally, these are infectious agents including bacteria, viruses, protozoa, and metazoa. The proximate source of these agents in water may vary, but most of them ultimately derive from the human intestines. Intestines of other warm-blooded animals are an alternate source of some waterborne agents infectious to humans and only a very few of these agents are apparently capable of living free in the environment for extended periods of time. Although the agents discussed are all of concern to human health, the majority of the infections caused by them are mild or asymptomatic. This fact tends

to complicate the investigation of waterborne disease outbreaks, in that the majority of infections may go unrecognized unless intensive and wide-ranging laboratory testing, frequently of fecal specimens, is undertaken.

Although quite long periods of persistence in water have been reported for some pathogens, the aqueous environment is not generally a favorable one for human infectious agents. Physical and chemical factors, as well as competition or predation by better-adapted indigenous microbial species, combine to kill or inactivate pathogens in water with the passing time. Other things being equal, higher temperatures and longer detention times favor the destruction of greater quantities of waterborne pathogens. However, it is important to note that most time-dependent death processes occur as logarithmic functions of time, so that the level of the dying agent, theoretically, never reaches absolute zero. This raises the dual questions of how sensitive a method must be for detecting a waterborne pathogen, and what significance to human health may be represented by some small residual level of a pathogen in water. These two questions may or may not be intimately interrelated. It is often argued that, as difficult as pathogens frequently are to detect in water, there is no need to develop methods to detect them at levels below which they represent a threat to health. However, there are those who believe that no level of an infectious agent is so low as to be insignificant to human health and that sample-to-sample variation offers the possibility that water sent to the laboratory for testing may contain less contaminant than water that someone drinks from the same source, so there is no limit to the desired level of sensitivity in testing for waterborne pathogens.

Further research is needed both to determine the relative threat to human health that is presented by different levels of a pathogen in water and to develop more sensitive methods for detecting waterborne pathogens. However, there is also a need for _simpler_ methods of detecting waterborne pathogens, in that more samples, tested by more laboratories, may eventually produce a more useful body of information, to aid in producing a safer supply of water, than would the testing of a few very large water samples by the few laboratories that are equipped to deal with them. Even if these were available, tests for pathogens could not afford a basis for routine quality control in drinking water supply. Given the problems inherent in detecting waterborne pathogens, it is not surprising that microbiologic testing of water is focused, instead, upon indicators.

Recommendations Concerning Pathogens

1. Even where water is protected, as is true of many groundwater sources, disinfection is recommended. This is especially important where finished water is to be stored rather than being used immediately.

2. Aftergrowth of opportunistic pathogens during distribution of finished water should be prevented by maintaining a chlorine residual throughout the distribution network, especially in large systems.

3. Testing for pathogens within the distribution water is appropriate: (a) after contamination is found to have occurred; (b) to trace the source of an outbreak; and (c) in analyzing disinfection efficiency.

4. Given the lack of correlation between viruses and the bacterial indicator systems, more research on the antiviral effectiveness of various water treatment processes is needed.

5. Mapping of waterborne outbreaks should be conducted in conjunction with epidemiological surveys of the population served by the water supply.

Topic C of this report deals with Indicator Systems, which are microbiologically-based quality control methods. Indicator systems already established in use are generally based upon enumeration of viable organisms on a selective basis. Some, but not all, of these indicators are supposed to correlate with the occurrence of fecal contamination and, implicitly, with the presence of enteric pathogens. The closeness of correlation between different established viable indicator systems and fecal contamination varies greatly. Where correlations are low, it is usually either because the organisms measured may include some that are not of fecal origin at all or some that are capable of proliferation in the environment outside of the body. Another potential liability, where disinfection is practiced, is that the indicator organisms may be more sensitive to the disinfectant than are some of the enteric pathogens which might be present. In addition to indicators of fecal contamination, there are indicator systems that gauge water quality

and others that serve to signal the presence of specific pathogens. Finally, there is always reason to wish for indicator systems that are more rapid or simpler to apply; such systems could permit more replication of tests.

These considerations led to the inclusion in Topic C of a survey of proposed alternate indicator systems based upon viable microbes, including coliphages and animal viruses, as well as a number of groups of bacteria. Some of these may eventually serve special purposes on a regular basis, but none is presently ready to supplant the "established" indicators for routine quality control in drinking water treatment and distribution. Other indicator systems surveyed are not based on determining numbers of viable organisms, or at least may not require incubation through many microbial generation times before results are obtained. Some of these alternate systems seem to offer significant potential for continuous monitoring of water quality in situations where rapidly obtained results will permit prompt remedial action. No system considered would obviate the need for proper sampling techniques or for adequately trained laboratory personnel.

Topic D surveys Testing and Standards for drinking water in various countries. For the time being, microbiologic quality control of drinking water, in most of the countries surveyed, is based upon the coliform group. However, in some countries, thermo-tolerant coliforms or Escherichia coli (based on a working definition of the species) are determined instead or in addition to the coliforms. Procedures for both sampling and testing are seen to vary from country to country, but the differences are not so great that the coliform test results cannot be compared. The general intention in every case seems to be that coliforms (or thermo-tolerant coliforms or E. coli, as the case may be) should be absent from samples of finished drinking water taken at the treatment plant or, in many instances, throughout the distribution system. Unfortunately, the survey that was done did not yield adequate bases for comparing methods of laboratory quality control; nor was it possible to determine how corrective action is taken in the event that indicators are found in finished drinking water. Efforts being made by several organizations to standardize analytic procedures in water microbiology are certainly to be commended. Whatever the analytic procedures used, it seems clear that the ability of laboratory microbiology to contribute to the safety of drinking water depends less on how standards are written than on the dedication with which they are applied or enforced.

Topic E deals with the _Treatment Methods_ used in producing finished drinking water. The emphasis in this case is on how various unit processes affect pathogens and indicator systems. However, much information on other aspects of some of the same treatments can be found in the reports of Project Area II: Advanced Treatment Technology. The variety and degree of treatment used in preparing drinking water should be, and usually are, determined by the quality of the raw water that is available. Where the source is variable in quantity or quality, reservoir storage may be used to buffer some of the fluctuations. The primary function of the reservoir may be storage, but considerable changes, for better or worse, can result from holding water in a reservoir. This depends on whether the reservoir is managed so as to minimize opportunities for contamination or growth of noxious organisms and to make use of the water's tendency for self-purification; at best, storage of water in a reservoir can serve as a treatment step, and is regarded as such in this report. Physical treatments, such as coagulation and flocculation or various versions of sand filtration, serve to remove suspended matter including many microbial cells. These treatments are especially important in removing protozoan cysts and metazoan eggs, as well as in eliminating suspended matter that might interfere with disinfection. Slow sand filtration, and often activated carbon treatment, have an important biological component. Activated carbon treatment is intended, primarily, to remove impurities that are dissolved, rather than suspended, in water. To the degree that the substances removed might have served as substrates for microbial growth, the growth becomes less likely to take place in the water, but more likely on the carbon surface. This will not necessarily produce a health hazard, but it can lead to disinfection problems and to a decrease in water palatability. The microflora in slow sand filters can effect important reductions in biodegradable dissolved substances, especially in water pre-treated with ozone.

The ultimate defense against carry-over of pathogenic bacteria and viruses into finished water is, ordinarily, disinfection. If pathogens were unlikely to have been present in the raw water, disinfection may be done solely to suppress opportunistic organisms and to avoid technical problems during distribution of the water. This requires use of a disinfectant such as chlorine, a residual of which can be maintained throughout the distribution network. On the other hand, disinfection may be needed to kill large numbers of microorganisms, possibly including pathogens.

Ozone is seen to be a major alternative to chlorine in this application; it is already well established as a primary drinking water disinfectant in many areas. Other disinfectants are also surveyed, and some of these may eventually capture a portion of the disinfection market. It is important to note that no disinfectant can make good water from bad, and that disinfection may fail if water has not first been treated in a manner appropriate to its original quality, so that the disinfectant has only to act upon reasonable numbers of microorganisms.

Topic F addresses the problem of maintaining finished water quality during Storage and Distribution. This represents a special challenge from both the standpoints of quality and safety. On the one hand, the quality of finished water at the treatment plant must be assumed to be the best that can be achieved with the means available, so that storage of finished water, for example, can maintain or degrade quality, but cannot improve it as in the case of raw water storage. On the other hand, the epidemiological record shows that cross-contamination and back-siphonage, by introducing raw sewage or otherwise polluted water into finished water in distribution, have been relatively important among causes of the rare outbreaks of disease associated with public water supplies. The most general problems are those of avoiding growth of organisms present in the finished water (for example, by maintaining an active level of chlorine in water throughout the distribution network) and preventing contamination of the finished water from external sources (for example, by covering service reservoirs in which finished water is stored). The materials and the manner of construction of the facilities are critical at every stage. Water contact surfaces in reservoirs and in mains all too frequently include materials which may support microbial growth. The joints that have been well designed to exclude contaminants from without are sometimes found to present favorable conditions for microbial growth within the system. Older materials used in constructing water distribution systems all have disadvantages, including increasingly high costs of production and installation and, in some instances, exceedingly short service lives when in contact with the water of some communities. Newer materials and joint designs appear to offer important advantages; but the testing of these cannot always include all of the conditions to which they will be subjected in use at various places. Thus, unforeseen difficulties are always possible, even under what may be described as routine conditions.

pipes may be degraded by microbial action, either because the organisms were able to use the material of the pipe as substrate or because microbial metabolism caused minerals to be eroded from or deposited on the inner surfaces. Microbial cells themselves, and the slimes associated with some of them, are able to coat resins and filter media or the interiors of pipes so as to exert a direct adverse physical effect upon the function of the facility. It is not surprising that resin function would be extremely susceptible to microbial growth, given the fact that normal function of the resin depends upon intimate interaction between the resin surface and the water; however, it is also true that a thin microbial slime coat can significantly interfere with the hydraulic conductivity of a water main, even though the deposit obstructs very little of the inside of the pipe.

Another set of technological problems involves the storage of water aboard ships, and in containers for commercial distribution or for use in emergencies. In a way, one might assert that drinking water in these contexts needs to be even purer than that in public supplies, for these classes of stored water will ordinarily be used in exactly the condition that the consumer receives them. Problems associated with ships' water supplies are discussed in detail; some of these problems are shared with supplies of drinking water aboard all classes of public conveyances, but they may be more extreme with ships because longer periods of storage and greater volumes of water are involved, and because many opportunities exist for cross-contamination from wastewater, water from the ship's bilge, and wash water derived from the often-polluted water in which the ship floats. Water sealed in containers also requires great care, as to the initial quality of the water, the use of preservatives (if any), and the selection of a container. Obviously, those who must use packaged water in times of disaster will have no opportunity at that point to reject that which, on the basis of off-flavor, odor, or appearance, might be suspected of being toxic. On the other hand, those who regularly drink bottled water in their daily lives place their trust in the safety of the commercial product and are therefore vulnerable to any lapse on the part of the bottler or distributor.

This report necessarily emphasizes water treatment and control measures for routine use. However, it must be recognized that emergencies do arise and that plans for dealing with them should be made beforehand, as much as possible. Causes of emergencies, in what may be descending order of likelihood, include undetected deterioration in the

physical apparatus, human error, power failures, adverse weather, willful mischief, earthquakes, and war. Both apparatus at the treatment plant and in the distribution network may be subject to deterioration or sudden malfunction. Human errors might include such events as construction machinery breaking water mains. Loss of electrical power could inactivate pumps, ozone generators, and vital control apparatus. Adverse weather can cause power failures; or extreme cold, floods, or windstorms may directly interfere with water treatment or distribution. Willful mischief would include any malicious act by which one or a few persons abused a water system in an effort to disrupt society. Earthquake prediction seems to be progressing, but is still not very useful for protecting water supplies. Finally, if war occurs, water systems may be disrupted incidentally to general bombardment, overtaxed through excessive water demand for firefighting, or directly targeted as a vehicle for biological warfare.

All communities are vulnerable to emergencies affecting their water distribution systems. However, there are potential differences, involving water sources and treatment, in susceptibility to emergencies. A community that has relatively low-quality water must use a complex treatment scheme and is vulnerable from that standpoint. On the other hand, a community that derives very pure source water from a deep aquifer will have no water at all if it loses its pumping capacity. Large water supply systems probably present more points of vulnerability than small systems, and communities that derive their water from distant sources are especially at risk.

If treatment is interrupted, but distribution is maintained, microbiologic safety can be achieved by drawing water from the tap and boiling it. Otherwise, any available water that does not contain acute toxicants may have to be boiled and used. Restoration of treatment and distribution services are likely to require extensive flushing and use of large quantities of chlorine to restore a system to normal; plans for such action should be made in advance, and key personnel should learn their tasks. Large communities, where great numbers of people might be unable to supply themselves with water in the event of a system stoppage, should consider storage of water for emergencies in moderate-sized containers at well-distributed and marked locations.

Industrialized nations in general share a relatively high level of public health, as measured by long life

expectancies and low child mortalities, which is at least
partly a tribute to the technical and institutional success
of drinking water supply in these countries. Even private
water supplies in these countries are often monitored on a
limited basis, so that relatively few inhabitants use water
that has not been safety tested in some manner. It is,
perhaps, noteworthy that the primary safety criteria ap-
plied, even to this day when many other aspects of drinking
water safety are under scrutiny, are based upon microbio-
logic indicator systems. This is reasonable, for a great
part of the public health gains that have been achieved in
industrialized nations have resulted from reduced incidence
of infectious diseases through sanitation. Hardly any
aspect of drinking water microbiology would not be likely to
benefit from further research, but it is important to note
that presently available treatment techniques, monitoring
methods, and other features of current drinking water supply
practice are serving their purposes remarkably well. In a
general sense, standards presently in effect must never be
relaxed because the populations of industrialized nations,
accustomed to a high level of sanitation, are likely to be
quite vulnerable to any abrupt lapse in established drinking
water practice.

Change is inevitable, however, and new classes of
chemical contaminants are being identified in wastewaters
and in some raw waters from which drinking water must be
produced. Aspects of these problems are discussed in Project
Areas I and IV. Research is needed both on effective and
feasible methods for protecting source waters and on modi-
fied disinfection methods that will produce fewer undesirable
disinfectant derivatives while serving the original purpose
of disinfection, which is to kill as many microorganisms as
possible in the water. The task of protecting source waters,
from a microbiologic standpoint, will be aided when more
research results are available regarding detection methods
for waterborne pathogens, as well as the probability of
infection as a function of ingesting different quantities of
waterborne pathogens. Indicator systems that are intended
to signal fecal or other microbiologic contamination of
water might be further refined and standardized, but it
seems likely that monitoring the adequacy of water treatment
and disinfection could better be based on the development
and application of a separate set of indicator systems.
These, and indicator systems designed to detect recontami-
nation of finished water in distribution, probably stand to
be most improved by automation or modification to afford
shorter readout times. In this age of dramatically improved
international communication, it seems clear that more standardi-
zation of criteria for water quality and safety will ensue.

If primary disinfection procedures must be modified out of concern for interactions between the disinfectants and chemical contaminants of water, further research will be needed on the adequacy of alternative disinfectants. At the same time, it will be very important to determine and attempt to utilize the antimicrobial effects inherent in all of the other unit processes employed in water treatment. Research to aid in protecting the quality of finished water during storage and distribution will, assuredly, focus on the development of low-cost, durable materials that are inert to the microflora in the water, but there are also many other research needs in this area. To the degree that microbial growth is capable of creating technologic problems, which have been enumerated previously, it is important that research contribute more to the understanding of these microbiologic processes, for it may be that the organisms cannot be entirely suppressed, but only minimized. Finally, further research on the evaluation and maintenance of water quality in closed containers is still needed.

Many new concerns about drinking water safety have been raised in recent years. Because these are generally chemical in nature and may be associated with such dire effects as cancer, they have tended to overshadow the microbiology of drinking water. Under the circumstances, it seems fitting to close by pointing out that: (1) the primary criteria of drinking water safety and quality are based upon microbiologic indicator systems; and (2) in any major lapse in drinking water treatment and distribution practices, the most immediate consequences to consumer health are more likely to be caused by pathogenic microorganisms than by chemicals.

GENERAL RECOMMENDATIONS

1. Every public water supply should begin with the highest quality raw water that is available in quantities sufficient to meet the community's needs. Efforts to protect and improve the quality of source waters are important; both waste discharges and non-point sources of pollution should be considered in attempts to prevent or alleviate contamination. Where possible, water to be used for irrigation or for industrial purposes other than food, drug, or cosmetic manufacture, should usually be drawn from less pure sources than those from which the public supply derives.

2. Disinfection is necessary, but not always sufficient, to ensure the safety of drinking water from virtually any source.

3. Complete treatment of drinking water, including at least coagulation and sedimentation with sand filtration or alternatively dual filtration including effective slow sand filtration, followed in all cases by disinfection, is essential in all cases where source waters are unprotected and is highly desirable even with protected sources.

4. Sound engineering practice is required to produce safe drinking water; microbiologic laboratory testing performed on a routine basis, according to standardized methods, and by properly trained and supervised staff is an important basis for assessment of drinking water quality. Indicator systems for use in these tests may be selected for any one of the following purposes: (i) to signal fecal contamination; (ii) to detect any abnormal and probably undesirable conditions that may occur; or (iii) to warn of the probable presence of specific pathogens. Larger waterworks, at least, should develop microbiologic quality control procedures and baseline data for all stages of treatment from raw water through distribution. Prompt corrective action

should be taken when norms are exceeded. At least one micro-
biology laboratory in each country should have the
ability to detect waterborne pathogens, either for spot-
checking or for investigating outbreaks, both from
water samples and from clinical specimens. Results of
tests for both indicators and pathogens should be re-
corded through a focal national center and shared on an
international basis.

5. Innovative indicator systems, capable of signaling
   fecal contamination, problems in treatment efficiency, loss of
   integrity of the distribution system, and perhaps the
   presence of pathogens, should continue to be sought.
   Rather than try to find a single indicator system that
   will serve all of these disparate functions at once,
   emphasis should be placed on individual systems offering
   convenience and economy that will allow more frequent
   testing.

6. In addition to the well-established research on water-
   borne bacterial pathogens, considerably more research
   is needed concerning viruses and protozoa transmissible
   by drinking water, in the areas of the dose-dependence
   of peroral infectivity and pathogenicity, the detection
   of these agents in water, and their removal or destruc-
   tion by water treatment and disinfection processes.

7. Monitoring of raw water quality on the basis of appro-
   priate indicator systems is desirable in all cases and
   essential in those instances where the usual purity of
   the raw water is such that less than complete treatment
   is used. At least one indicator system that is directly
   correlated with fecal contamination should be included;
   the choice of other indicator systems to signal other
   kinds of problems should be made on the basis of knowl-
   edge about local conditions.

8. Materials of which water treatment and distribution
   facilities are constructed should be pretested for
   chemical and biological stability. Testing methods, as
   well as results, should be shared internationally as
   much as possible; however, it is also best to test
   materials, before use in a given system, with the very
   water with which they will, in fact, be in contact.

9. Finished water in distribution, in both public and
   semipublic systems, should be sampled at representative
   locations and tested microbiologically with a frequency

that depends on the size of the population served. Private water supplies should be tested at least annually. In all instances, the presence of coliforms, thermo-tolerant coliforms, or E. coli in a 100-ml sample should be treated as unacceptable, or at the very least, undesirable.

10. To minimize aftergrowth or other technological problems and to provide a means of determining whether cross-contamination has occurred, water in public supply distribution should wherever possible contain a measur-able residual level of disinfectant (e.g., chlorine) at all points.

11. Inasmuch as distribution systems are a potential source of problems in all water supplies, every system should be under continuous surveillance. Where problems are identified, they should either be eliminated by modifi-cation of the system or be mitigated by routine main-tenance procedures.

12. Procedures for the installation and repair of water mains should be established beforehand and applied diligently when needed. Plans for dealing with emer-gencies should be made and communicated, in advance, to those responsible for implementing them.

13. Means are needed to control cross-connections, to ensure both that the consumer does not degrade publicly-supplied water to the detriment of his own health and that his use of the water does not cause contamination that threatens the health of others. To achieve these objectives, plumbing codes may need revisions and better enforcement with respect to water supply systems in buildings, to attachment devices that use water, and to point-of-use treatment units attached to the consumer's tap.

14. More intensive research and epidemiologic surveys are needed to determine the true health effects of microbes and their products in finished drinking water. For this purpose, closer cooperation and communication are needed among practicing physicians and veterinarians, public health authorities, and water microbiologists. Any proposed change in treatment, distribution, or quality control practice should be evaluated from the standpoint of probable impact on public health, as far as possible, before implementation.

Conditions in water distribution cannot always be counted on to remain routine. Perturbations of the system may occur through: (1) necessary expansion of the distribution network because of growth of the community; (2) use of large volumes of water to fight fires; (3) natural or manmade disasters that disrupt the integrity of the network; and (4) errors by users, beyond the direct control of a water authority, that result in back-contamination of the water in public distribution. If appropriate designs and materials have been used in constructing a distribution system, water quality can be protected, in most instances, by properly organized maintenance and surveillance. However, regulations of users connected to the system, as well as the development of effective plans for dealing with emergencies, are important further aspects of operation.

Recommendations Concerning Storage and Distribution

1. Careful consideration must be given to the siting of service reservoirs.

2. Dead ends in pipes must be avoided and disused apparati disconnected.

3. Distribution and plumbing systems should consist of materials that will not support microbial growth. New products should be tested for their ability to support microbial growth before they are accepted or rejected.

4. Regulations to prevent back-siphonage and cross-connections need enforcement.

5. Adequate disinfection procedures for the construction and repair of water mains are needed. Installers should be instructed to follow the installation codes, exactly.

Topic G discusses Technologic Problems in drinking water microbiology. A pervasive theme in drinking water microbiology is the avoidance, suppression, or destruction of microorganisms in water. As Topic G shows, some microorganisms have what might be regarded as a certain retaliatory capacity. Microorganisms have adapted to such a variety of aquatic environments outside of water systems that it is probably not surprising to find them so firmly entrenched in much of this manmade system as well. They may cause problems both in treatment and in distribution. Water
