DISCLAIMER

This report has been reviewed by the Office of Air Quality Planning and Standards, U.S. Environmental Protection Agency, and approved for publication. Approval does not signify that the contents necessarily reflect the views and policies of the U.S. Environmental Protection Agency, nor does mention of trade name or commercial products constitute endorsement or recommendation for use.

ABSTRACT

Ambient ozone concentrations in the New York Metropolitan area, encompassing portions of the States of New Jersey, New York and Connecticut, often exceeded the ozone National Ambient Air Quality Standard (NAAQS) of 0.12 ppm during the 1980 ozone season. To address this problem, a study entitled "Oxidant Modeling for the New York Metropolitan Area Project (OMNYMAP)" has been undertaken. The goals of this modeling study are to provide information on (a) the extent and magnitude of the ozone problem in the New York Metropolitan area during the 1980 ozone season; (b) the impact/benefit achieved with imposition of specific control strategies to which the three states committed themselves in their State Implementation Plans (SIPs); (c) the role of pollutant transport from the upwind regions into the modeling domain; and (d) meaningful and effective control strategies to meet and maintain ozone NAAQS in the New York Metropolitan area.

In this study, the urban AIRSHED model (UAM) has been used to simulate five high ozone days in the 1980 oxidant season. Typical characteristics of the five high ozone days were as follows: wind flow generally from the south to southwest at about 4 to 5 m/s, daily maximum surface temperature in the range of 30 to 35°C (86 to 95°F) and measured ozone concentrations exceeding 200 ppb within Connecticut. The emissions input data base consisted of major and minor point sources, area sources, and mobile sources. The inventory was compiled for the region on an hourly basis for NO_x, CO, and VOC emissions in terms of speciated components characterized by the Carbon Bond II (CBII) chemical mechanism.

The model results have been analyzed to assess the performance of the model in simulating the observed ozone concentrations. Various statistical measures were applied to the data for each of the five simulated days as well as for the ensemble data. A comparison of the observed and corresponding predicted concentrations as a pair indicates that the model performed reasonably well with correlation coefficients in the range of 0.47 to 0.75 for the five days. Examination of the model performance with the data base comprised of ozone concentrations greater than 100 ppb reveals that 60% of the predicted values were within $\pm 30\%$ of their corresponding observed concentrations with the remaining values distributed evenly between the under- and over-prediction

categories. However, the model has a tendency to underpredict the peak or the maximum concentrations over the modeling domain. These results are consistent with evaluations of the UAM performance at other urban areas by the U.S. Environmental Protection Agency.

The UAM was then applied to assess the impact of emissions controls implemented under the State Implementation Plans (SIPs) of the three states for 1988 together with appropriate reductions in the pollutant concentrations at the upwind boundary for two of the five days during which UAM performed the best. The modeling results indicate that although there is a decrease in the 1988 peak ozone levels, the predicted maximum concentrations are well above the NAAQS for ozone. Even with the imposition of all the extraordinary emissions control measures committed to under the SIPs, the results of a one day simulation reveal that the peak ozone level continues to be well above the NAAQS.

Analysis of the sensitivity of the model output to specific model input conditions discloses that pollutant transport into the modeling region is extremely important. Hence, serious consideration should be given to this feature in addition to other emissions reduction plans for developing meaningful and effective strategies to meet and maintain the ozone NAAQS in the New York Metropolitan area. Additional modeling analyses are necessary to quantify the level of reduction in the precursor emissions required to meet the ozone NAAQS in this area.

This is the final report for the study entitled "Oxidant Modeling for the New York Metropolitan Area Project (OMNYMAP)," which was partially funded by the Office of Air Quality Planning & Standards (OAQPS) of the U.S. Environmental Protection Agency (USEPA). This document could not have been prepared without the help of the New Jersey Department of Environmental Protection (NJDEP), Connecticut Department of Environmental Protection (CTDEP), U.S. EPA Regions I and II, Office of Research & Development (ORD) and OAQPS of USEPA.

In particular, the resourcefulness and assistance provided by Mr. Norman Possiel of OAQPS/USEPA, Mr. Kenneth L. Schere, and Dr. Robin L. Dennis of ORD/USEPA to this project deserve special recognition.

Technical work on this project was reviewed and approved by a Technical Committee, chaired by Mr. Edward Davis, with representation of technical staff from the three state agencies, OAQPS, ORD, and Regions I and II of USEPA. Management oversight was provided by a Policy Committee, chaired by Mr. Harry Hovey, consisting of senior staff from the three states, Regions I and II, and OAQPS of USEPA.

Special thanks are extended to Messrs. Johnnie Pearson and Richard Rhoads of OAQPS/USEPA who participated with considerable interest in this project and provided the support needed to complete this study.

INTRODUCTION

Pursuant to the 1970 Clean Air Act Amendments (CAA), the U.S. Environmental Protection Agency (USEPA) has promulgated the primary and secondary National Ambient Air Quality Standard (NAAQS) for ozone. As stated in the 36 Federal Register 8186 (April 1971), this standard was "0.08 ppm maximum one-hour concentration not to be exceeded more than once per year as measured by the reference test method for ozone. However, the measured concentrations often exceeded this value in both urban and rural locations. Subsequently, based upon information on the health effects of ozone in the atmosphere, the USEPA revised the NAAQS to 0.12 ppm in 1979 with the standard being attained when "the expected number of days per calendar year with maximum hourly average concentration above 0.12 parts per million is equal to or less than 1" (40 CFR 50.9). Under Section 110 of CAA, state and local air pollution control agencies are required to specify the methods that are to be implemented to reduce precursor emissions in urban areas to the extent necessary to comply with the NAAQS. These measures are to be identified in their State Implementation Plans (SIPs). To accomplish this in an equitable manner, the regulatory agencies must be able to relate the existing emission patterns from specific urban source areas to air quality at downwind receptor locations, expressed in terms of ground-level ozone concentrations.

Ozone is not usually emitted directly into the atmosphere, but is instead a secondary pollutant that is formed over a period of time from a variety of atmospheric reactants. The USEPA has specified a number of modeling techniques for estimating the required percentage reduction of precursor (hydrocarbon and oxides of nitrogen) emissions from an urban source area necessary to meet the air quality standards. Since implementation of an emission control strategy may require tremendous economic commitments and may cause severe social dislocation, reliable estimates of ozone concentrations due to the impact of precursor emissions from the specific urban area in question must be available prior to making a decision to adopt a particular control strategy for the area.

Downwind ozone levels are related to a specific area's precursor emissions, and transported ozone and precursor concentrations, by the mathematical models which predict these relationships in such a manner that various control

strategies can be evaluated. Confidence can be placed in the impact evaluation process only if reliable ozone prediction relationships are employed. Approaches for determining the level of emission reductions necessary to attain the NAAQS include, in the order of increasing complexity, linear rollback, the "Appendix J" method, empirical kinetics model, and numerical models for photochemical oxidants. The choice of approach not only affects the scientific credibility of results, but also the ease of implementation in areas having limited or none of the required input data, and/or the expertise required to utilize the approach.

Rollback models, which are now unacceptable, assume a direct proportionality between air quality and emissions. Thus, a reduction of a secondary pollutant concentration such as ozone, is assumed to be directly proportional to a reduction in source emissions for an entire region. This method may be used for regions only where very little detailed data are available, and then, too, only for screening purposes. Hence, this highly simplified approach to ozone modeling is largely outmoded.

The "Appendix J," or upper limit oxidant - hydrocarbon concentration approach, is a technique developed in the early 1970's which attempted to develop a simple relationship between afternoon oxidant levels and morning hydrocarbon concentrations. Since the model completely disregards the site-specific or local effects of nitrogen oxides, meteorology, and ozone transport, this approach also is no longer considered valid by USEPA.

Empirical kinetics models represent an attempt to develop the relationships between ambient ozone concentrations and precursor emissions, based on smog chamber simulations. Initial concentrations of various precursor mixtures are introduced into the smog chamber and are subjected to sunlight to induce photocnemical activity. Resulting ozone concentrations are observed as a function of time. The ozone concentrations for various simulations are plotted in an isopleth form as functions of initial concentrations of non-methane hydrocarbons (NMHC) and oxides of nitrogen (NO_x). This information was utilized to develop the USEPA Model, Empirical Kinetics Modeling Approach known as EKMA. The EKMA model is probably the most reasonable model currently available for

relatively widespread use. There are, however, some limitations to the model. For example, ambient precursor concentrations within the urban area are assumed to be directly proportional to emissions. Differences may exist between NMHC/NO_x ratios from measured concentrations and those deduced from emissions inventory data. Another problem is related to the treatment of background concentrations. Because of very rapid reactions between NO and O₃, the pre-existing ozone in an air mass moving into an urban locale is not necessarily additive to the ozone buildup resulting from locally emitted precursor pollutants. In addition, EKMA cannot predict spatial effects, does not allow horizontal pollutant exchange with air outside the parcel, and assumes instantaneous complete mixing in the vertical direction as the height of the air column (mixing height) increases. Furthermore, EKMA is unable to predict ozone concentrations at locations not represented by physical monitors. Finally, for a large urban area such as New York the trajectory approach is inadequate to describe the physical mechanisms of the large plume and the effects of a variety of meteorological conditions.

Numerical photochemical transport and dispersion models such as the Urban Airshed Model, UAM (Reynolds, 1979), and Livermore Regional Air Quality Model, LIRAQ (McCraken, et al., 1975) and the Cal Tech photochemical grid model (McRae, et al., 1982) are among the most sophisticated of the approaches, and are well-suited for predicting the spatial and temporal distributions of ozone concentrations downwind of urban areas. In theory, numerical modeling approach is the best choice. However, in practice, numerous problems arise. These include the following: the difficulty of numerically solving the complex conservation of mass equations accurately; the high computational costs and expertise required for model implementation and interpretation; the unknown effects of treatments of the transport, diffusion, and reaction processes in the model due to limitations of available data and knowledge; the large data requirements for testing critical features of the model and its validation; and perhaps most importantly, the need for a spatially and temporally accurate emissions inventory.

Thus, it is evident from the above discussion that advanced models are required to properly identify the relationship between emissions and ozone concentrations. Equitable and effective control strategies can only be developed based on the numerical models since the photochemistry, transport, and

diffusion of ozone are treated in detail by these state-of-the-science models. However, it is imperative that the emissions data base as well as the aerometric data used in the model are accurate to ensure that the modeling results are useful and credible. Further, the uncertainties associated with the model results must also be taken into account in the development of meaningful control strategies for ozone.

The goals of this project are to assess and quantify the ozone problem in the New York Metropolitan area, to evaluate the available control options and to develop effective and equitable strategies for reducing the ozone levels in the region through the application of the UAM photochemical oxidant model. The New York Metropolitan area includes portions of the states of New Jersey, New York, and Connecticut. As a part of this study, meteorological and ambient air quality data were analyzed to characterize those conditions that are conducive to the formation and production of peak ozone levels in the region. Based on this analysis, five typical high ozone days in the 1980 oxidant season were selected for detailed modeling analysis. The pertinent emissions and meteorological data were assembled to execute the UAM for these selected days for the base year, 1980. The model predictions were compared with the measurements to assess the model performance. These results indicate that the UAM performance in this study is similar to its performance in other urban areas such as Tulsa, St. Louis and Philadelphia.

Evaluation of the control options included emissions projections of the 1980 baseline to future scenarios (such as the 1982 SIP for 1988) in order to determine whether these measures will reduce the ozone concentrations to the level of the NAAQS in the region. These projections included changes in emissions arising from changes in population and activity levels, as well as specific changes in emissions associated with regulatory actions that are already mandated under the current laws and regulations and projected pollution reduction levels associated with existing emissions control plans. Using the meteorological features observed in 1980, model simulations were performed to assess the impact of selected emissions reduction scenarios for two of the five days. Although the predicted peak concentrations in 1988 in the New York Metropolitan area are reduced from the base year levels, the predicted peaks are still well above the ozone NAAQS. Simulation of the UAM for one day with the

imposition of all extraordinary emissions control measures included in the SIPs reveals that the peak ozone concentrations are still well above the ozone NAAQS. Finally, the sensitivity of the model to various input parameters was evaluated and the results suggest that transport of ozone and its precursors into the modeling domain significantly affects the ozone concentration field over the tri-state region. Additional modeling analyses are necessary to document clearly the dynamics associated with the oxidants and the level of reduction in the precursor emissions required to meet and maintain ozone NAAQS in the New York Metropolitan area.

CHAPTER 2

CHARACTERISTICS OF A HIGH OZONE DAY

Studies of ambient ozone concentrations in the Northeastern part of the United States have reported that the NAAQS value of 0.12 ppm is often exceeded. Air concentrations reaching as high as 300 ppb downwind of large urban regions. These exceedances are found region-wide, indicating that ozone is a pervasive air contaminant mainly occurring during the summer months of June, July and August, the so called "ozone season". In order to understand prevailing meteorological characteristics during the days of high ozone concentration, ambient air quality measurements from the states of New Jersey, New York, and Connecticut were examined for a six year period from 1978 to 1983. The criterion adopted to select a day as a high ozone day was that the maximum hourly concentration at a monitoring station be equal to or greater than 200 ppb. The days thus selected are listed in Table 2.1. The number of days range from a minimum of 5 days in 1982 to a maximum of 16 days in 1983 with a majority of them occurring over Connecticut. It should be noted that the number of monitoring stations and their locations often varied from year to year, and therefore a subset of high ozone days from Table 2.1 was selected such that there be at least two stations in Connecticut and at least one station in the New York-New Jersey area exceeding the 200 ppb concentration value. A general description of the meteorological features that are representative of this class of days is given below.

2.1 Synoptic-Scale Features

The daily weather maps published by the National Weather Service (NWS) were examined for the high ozone days both at the surface and upper levels. A fairly consistent weather pattern was observed along with a few outlying cases. Figure 2.1 shows a typical surface weather pattern for a high ozone day. A frontal zone stretched from the Northeastern U.S.-Canadian border westward and then southwestward through the eastern Great Lakes. High pressure prevailed over the Atlantic and westward through the southern States. The frontal position varied, in other cases, around this "average" position--latitudes from near James Bay to central New York and longitudes from western New York to the central Great Lakes. The "Bermuda High" varied in position from the Atlantic to the extreme

TABLE 2.1"
Days Classified as "High Ozone Days" During the 1978-83 Oxidant Seasons,
With Hourly Ozone Concentrations Greater Than or Equal to 200 ppb

Year	High Ozone Days (Julian Day)*
1978	78166, 78170, 78172, 78173, 78202, 78226, 78227
1979	79167, 79194, 79201, 79205, 79206, 79213
1980	80167, 80176, 80177, 80193, 80198, 80202, 80203, 80204, 80219, 80221, 80240, 80241
1981	81166, 81167, 81172, 81189, 81194, 81200
1982	82189, 82197, 82198, 82199, 82220
1983	83165, 83166, 83167, 83174, 83177, 83178, 83184, 83186, 83192, 83195, 83209, 83211, 83220, 83229, 83232, 83239.

*For example, Julian Day 78166 corresponds to June 16, 1978.

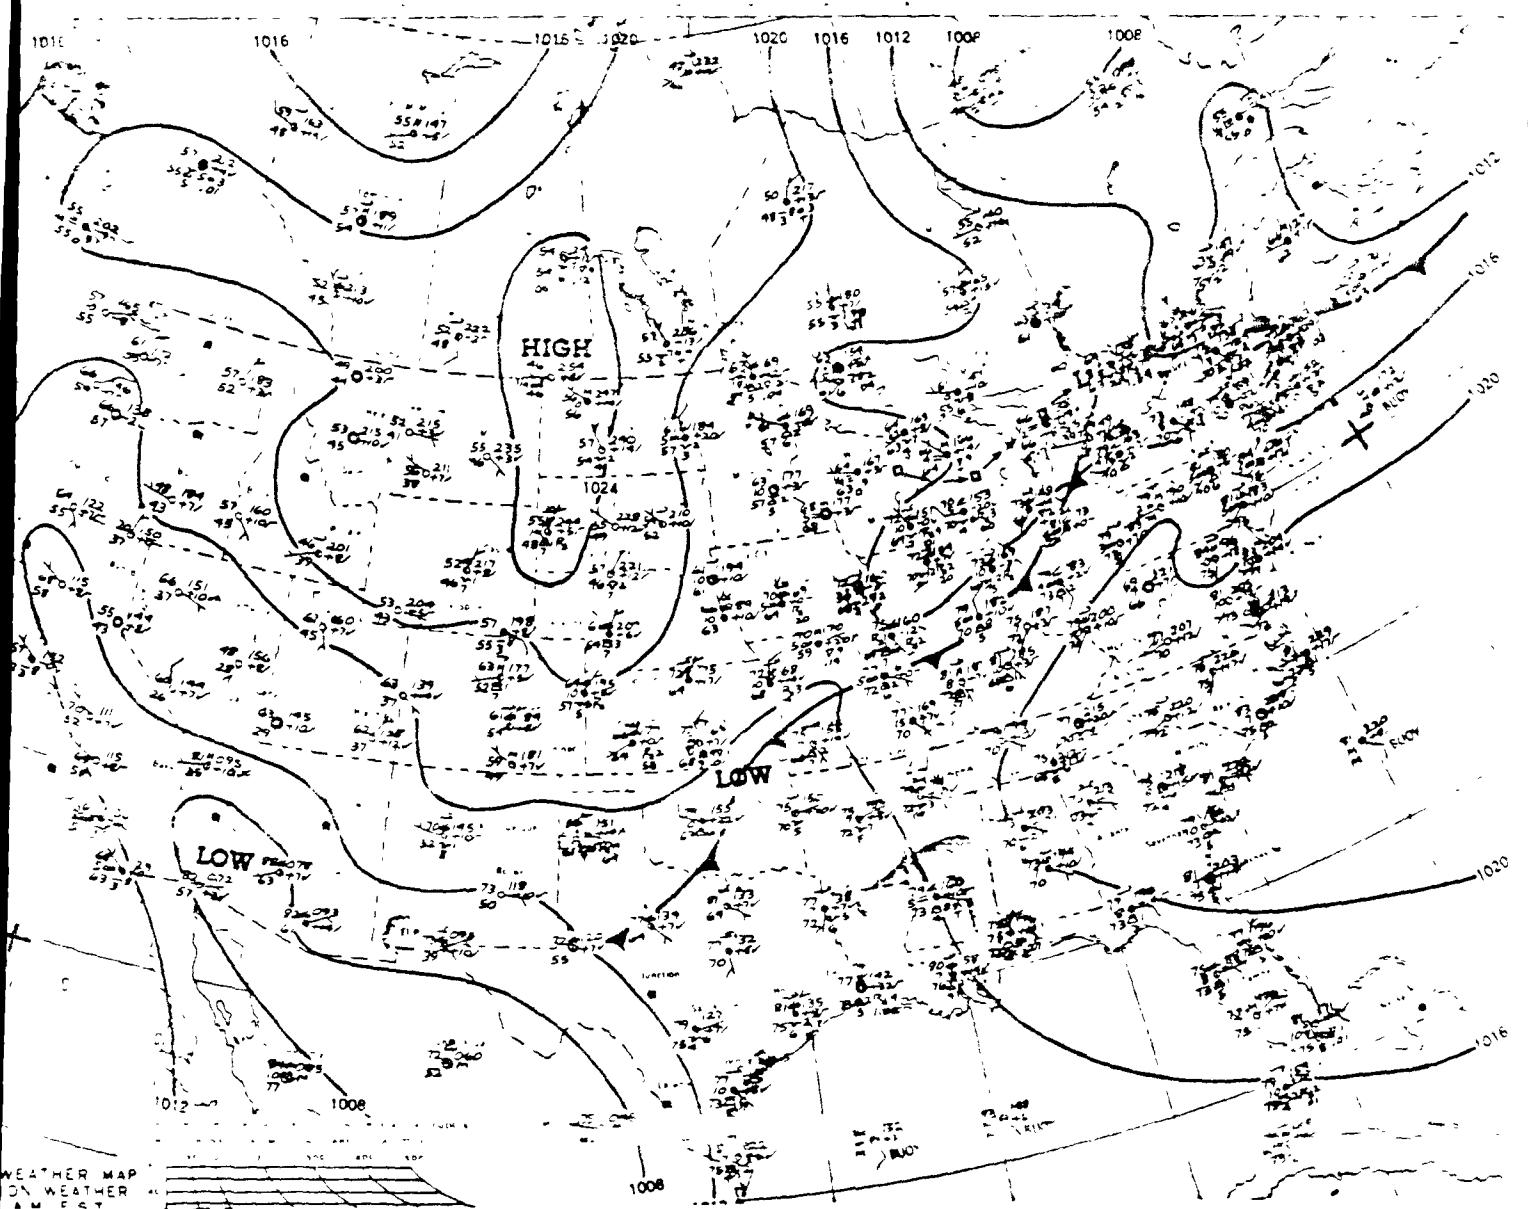

Figure 2.1 Typical Synoptic Scale Surface Weather Pattern for a High Ozone Day

southern Midwest. In addition, another characteristic feature that was observed on the smaller scale to the east of the Appalachian Mountains was a "lee-side trough", which extended with some variation, from southern New England southwestward to Virginia, the southern location being more pronounced and occurring more frequently (Pagnotti, 1987).

Near the region, cyclonic flow was found aloft in almost all cases with a short-wave trough approaching or passing through the region. Predominant upper level winds (500-700 MB level) varied from northwest through southwest, while surface winds were generally southwesterly. Precipitation over some part of the region was often observed while maximum temperatures over the region varied from the 80's to around 100°F.

In some instances, high ozone days were also observed under other meteorological conditions, usually with a surface cyclonic feature of some kind near or within the region. The latter included, for example, a frontal trough, or a low pressure area centered offshore or to the northeast. Also, a few cases had the surface and upper level winds from north or northeasterly directions.

2.2 Local Features

The local climatological data were scanned to describe a typical high ozone day. The meteorological variables averaged over 28 cases resulting from the subset classification for selected National Weather Service (NWS) stations over the tri-state region are listed in Table 2.2. Maximum temperatures in the region range from 85°F to 93°F, while the minima range from 66°F to 70°F. Precipitation occurs between 17% (Central Park) and 45% (Hartford) of the time, with a station mean of a hundredth of an inch at Central Park to a tenth of an inch at Bridgeport. The surface winds are generally south to southwesterly, with average hourly speeds for these days ranging from 3 m/sec (Hartford and, Atlantic City to 5 m/sec LaGuardia and Bridgeport). The average sky cover (sunrise to sunset) ranges from five to six tenths. Smoke and haze were the most common weather types reported, along with fog and occasional thunderstorms.

2.3 Selection of Modeling Days

By virtue of its design, the UAM requires the detailed input of various aerometric data sets for simulating the concentration field (Ames, et al., 1985a, 1985b). In a majority of the applications, the required input data are not available from routine measurements and have to be developed from special monitoring networks. One such network is the 1980 Northeast Corridor Regional Modeling Project (NECRMP, 1982a) conducted by USEPA, which provided a detailed and extensive aerometric data base for this region. An examination of the NECRMP data base for aircraft measurements (NECRMP, 1982b) and Table 2.1 reveals that of the 12 days only 5 days could be considered for the application of the UAM. The five days are JD80198(071680), JD80203(072180), JD80204(072280), JD80219(080680), and JD80221(080880).

A brief description of the synoptic weather pattern for these five days is given in Table 2.3. These days appear to fit the characteristic pattern discussed earlier for the high ozone day with a frontal array across the northeastern U.S. border, slightly disturbed west-southwesterly to west-northwesterly flow aloft, a weak surface trough east of the Appalachians, and a surface high pressure ridged from the Atlantic Ocean westward across the southern U.S. In Table 2.4 are listed the local climatological data for the five days. Most stations exhibit the typical conditions, namely, temperature maxima in the upper 80's and 90's °F, minima in the upper 60's and 70's °F, a prevalence of smoke, haze, some fog and occasional occurrence of thunderstorms. Average sky cover (sunrise to sunset) is generally five tenths or greater, and surface winds are generally south to southwesterly with wind speeds in the range 2-7 m/s.

TABLE 2.3

Synoptic Weather Pattern Summary for the Five Modeling Days Selected in 1980

- JD80198 Cold front lies from a position over Northern Indiana to
(071680) Northern Maine; high pressure from the Atlantic westward to
 Texas; weak trough east of the Appalachian Mountains; small
 upper-level trough over the Northeast, with northwesterly flow
 aloft, and short wave approaching from the west.
- JD80203 Frontal array (cold front-stationary front) midwest through
(072180) northern Maine; high pressure ridge from Atlantic westward to
 Alabama; trough east of the Appalachians; upper-level short-wave
 approaching from the west, with westsouthwesterly flow aloft.
- JD80204 Similar to JD80203(072180), except, southwesterly flow aloft.
(072280)
- JD80219 Cold front approaching from southern Canada-Great Lakes region;
(080680) high pressure from Atlantic westward to the southern Midwest;
 trough east of the Appalachians; upper-level disturbance to the
 northwest, with westerly flow aloft.
- JD80221 Stationary front - cold front Great Lakes to Northern
,080880, New England; high pressure from Atlantic westward to the southern
 Midwest and Texas; slightly cyclonic flow east of the
 Appalachians; upper-level short wave approaching from the
 northwest, with west to northwesterly flow aloft and a weak
 disturbance over New England.

CHAPTER 3

MODEL PREPARATION

The areal extent of the modeling region selected in this study was guided by the primary objective of capturing the peak ozone concentrations resulting from the emissions in New Jersey, New York, and Connecticut. Thus the modeling domain includes almost all of the State of Connecticut and the high emission density regions of New York and New Jersey. Trenton, NJ was selected as the approximate location of the southwest corner of the modeling domain. The areal extent of the modeling region as shown in Figure 3.1. is $49.6 \times 10^3 \text{ km}^2$ with east-west and north-south dimensions of 248 and 200 km, respectively.

3.1 Grid Cell Size

The UAM program utilizes the modeling region as a volume subdivided into an array of three-dimensional grid cells. The horizontal, i.e., the east-west, north-south plane is divided into cells of equal size. The vertical cell size is dependent upon the fixed number of layers into which the layer between the ground and the top of the simulation region is subdivided. In this study, an 8 km cell equal in east-west and north-south directions, was selected. This yielded 31 cells in the east-west direction and 25 cells in the north-south direction. The 8 km cell spacing was selected as a compromise between a 5 and a 10 km spacing, since the former would result in extensive data requirements and high computational costs, while the latter could be too coarse a cell size to provide the needed detail in the concentration field. The number of layers in the vertical direction was set to four, with three in the layer between the ground and the mixing height and one in between the mixing height and the top of the modeling region. The thickness of each of the four layers is dependent upon the hourly mixing height. A minimum height of 50 m was specified for the three layers below the mixing height, and 500 m for the layer "1" between the mixing height and the region top.

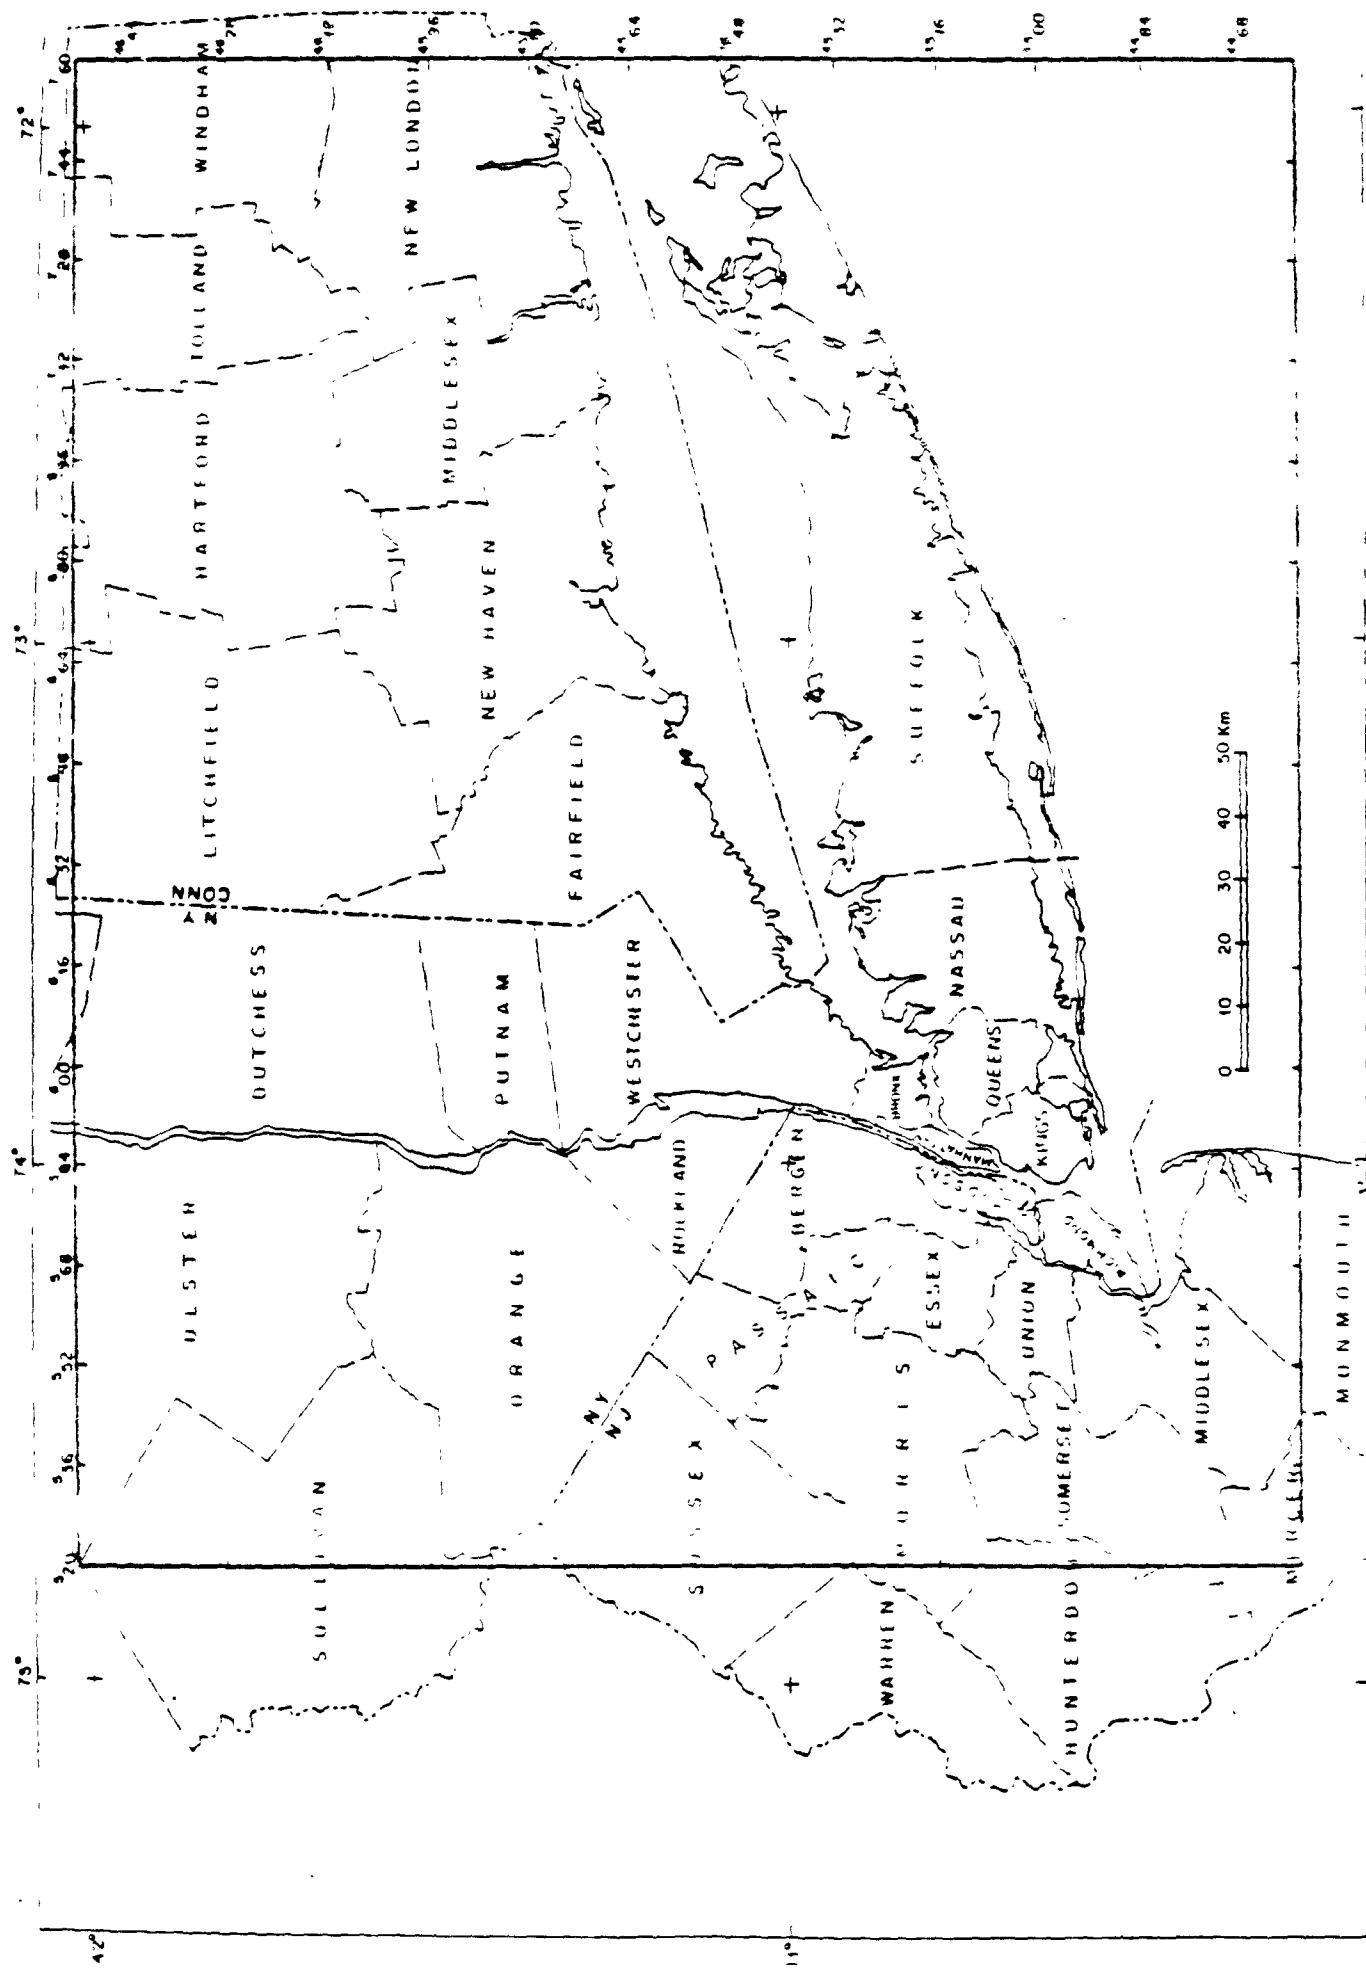

Figure 3.1 Areal Extent of the Modeling Region which includes Portions of the State

Thus, in summary, the modeling region consists of:

- 31 cells in the east-west (X) direction,
- 25 cells in the north-south (Y) direction, and
- 4 cells in the vertical (Z) direction

with the southwest corner, the origin, set at UTM 500,000.0 + E. 446,000.0 m² and a cell size of 8,000 m. The UTM zone 18, was extended for the easternmost parts of Long Island and portions of eastern Connecticut.

3.2 Ambient Air Quality and Meteorological Data

3.2.1 Ozone (O_3)

The geographic distribution of the ozone monitoring stations is shown in Figure 3.2. In general, monitoring data over the northwest quadrant are sparse, with the majority of the stations oriented along a southwest-northeast line. In addition to the routine monitoring stations, data are available at four other sites from NECRMP. These locations are also shown in Figure 3.2. On a state-by-state basis, the number of stations in Connecticut, New York and New Jersey were 10, 13 and 10, respectively with the majority of the New York and New Jersey stations located in the southwest quadrant of the model domain.

3.2.2 Non-Methane Hydrocarbons (NMHC)

The locations of the non-methane hydrocarbon monitoring stations are shown in Figure 3.3. It should be noted that no routine monitoring was performed for these pollutants and that the sites shown in Figure 3.3 represent the special sampling locations set up under the NECRMP. The stations were principally located in the southwest quadrant and were the only ones available for defining the initial NMHC distribution over the modeling domain.

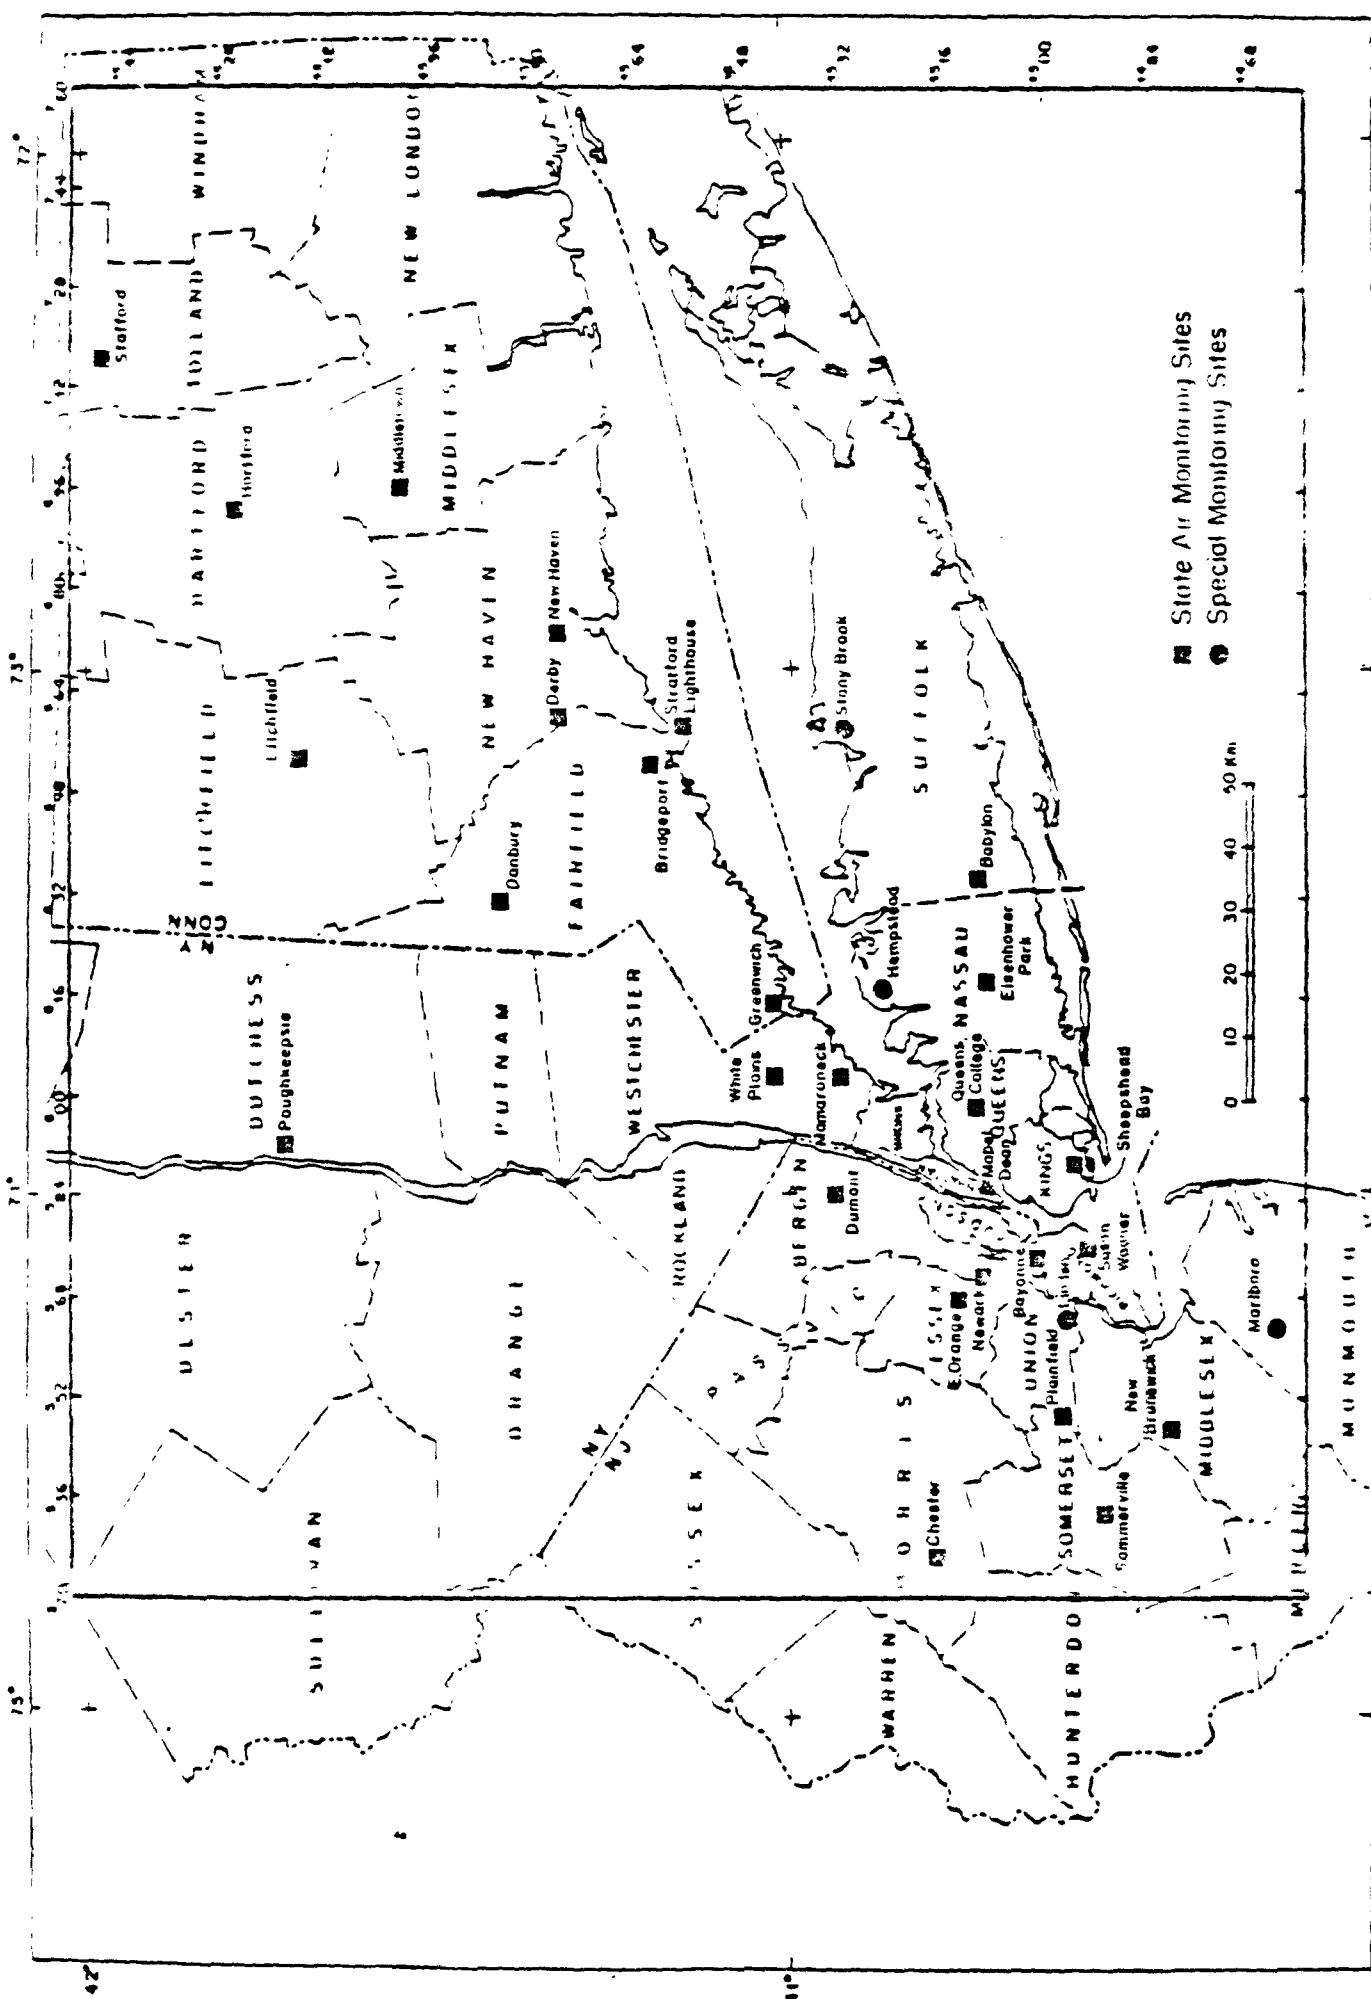

Figure 1.2 Geographic distribution of ozone monitor

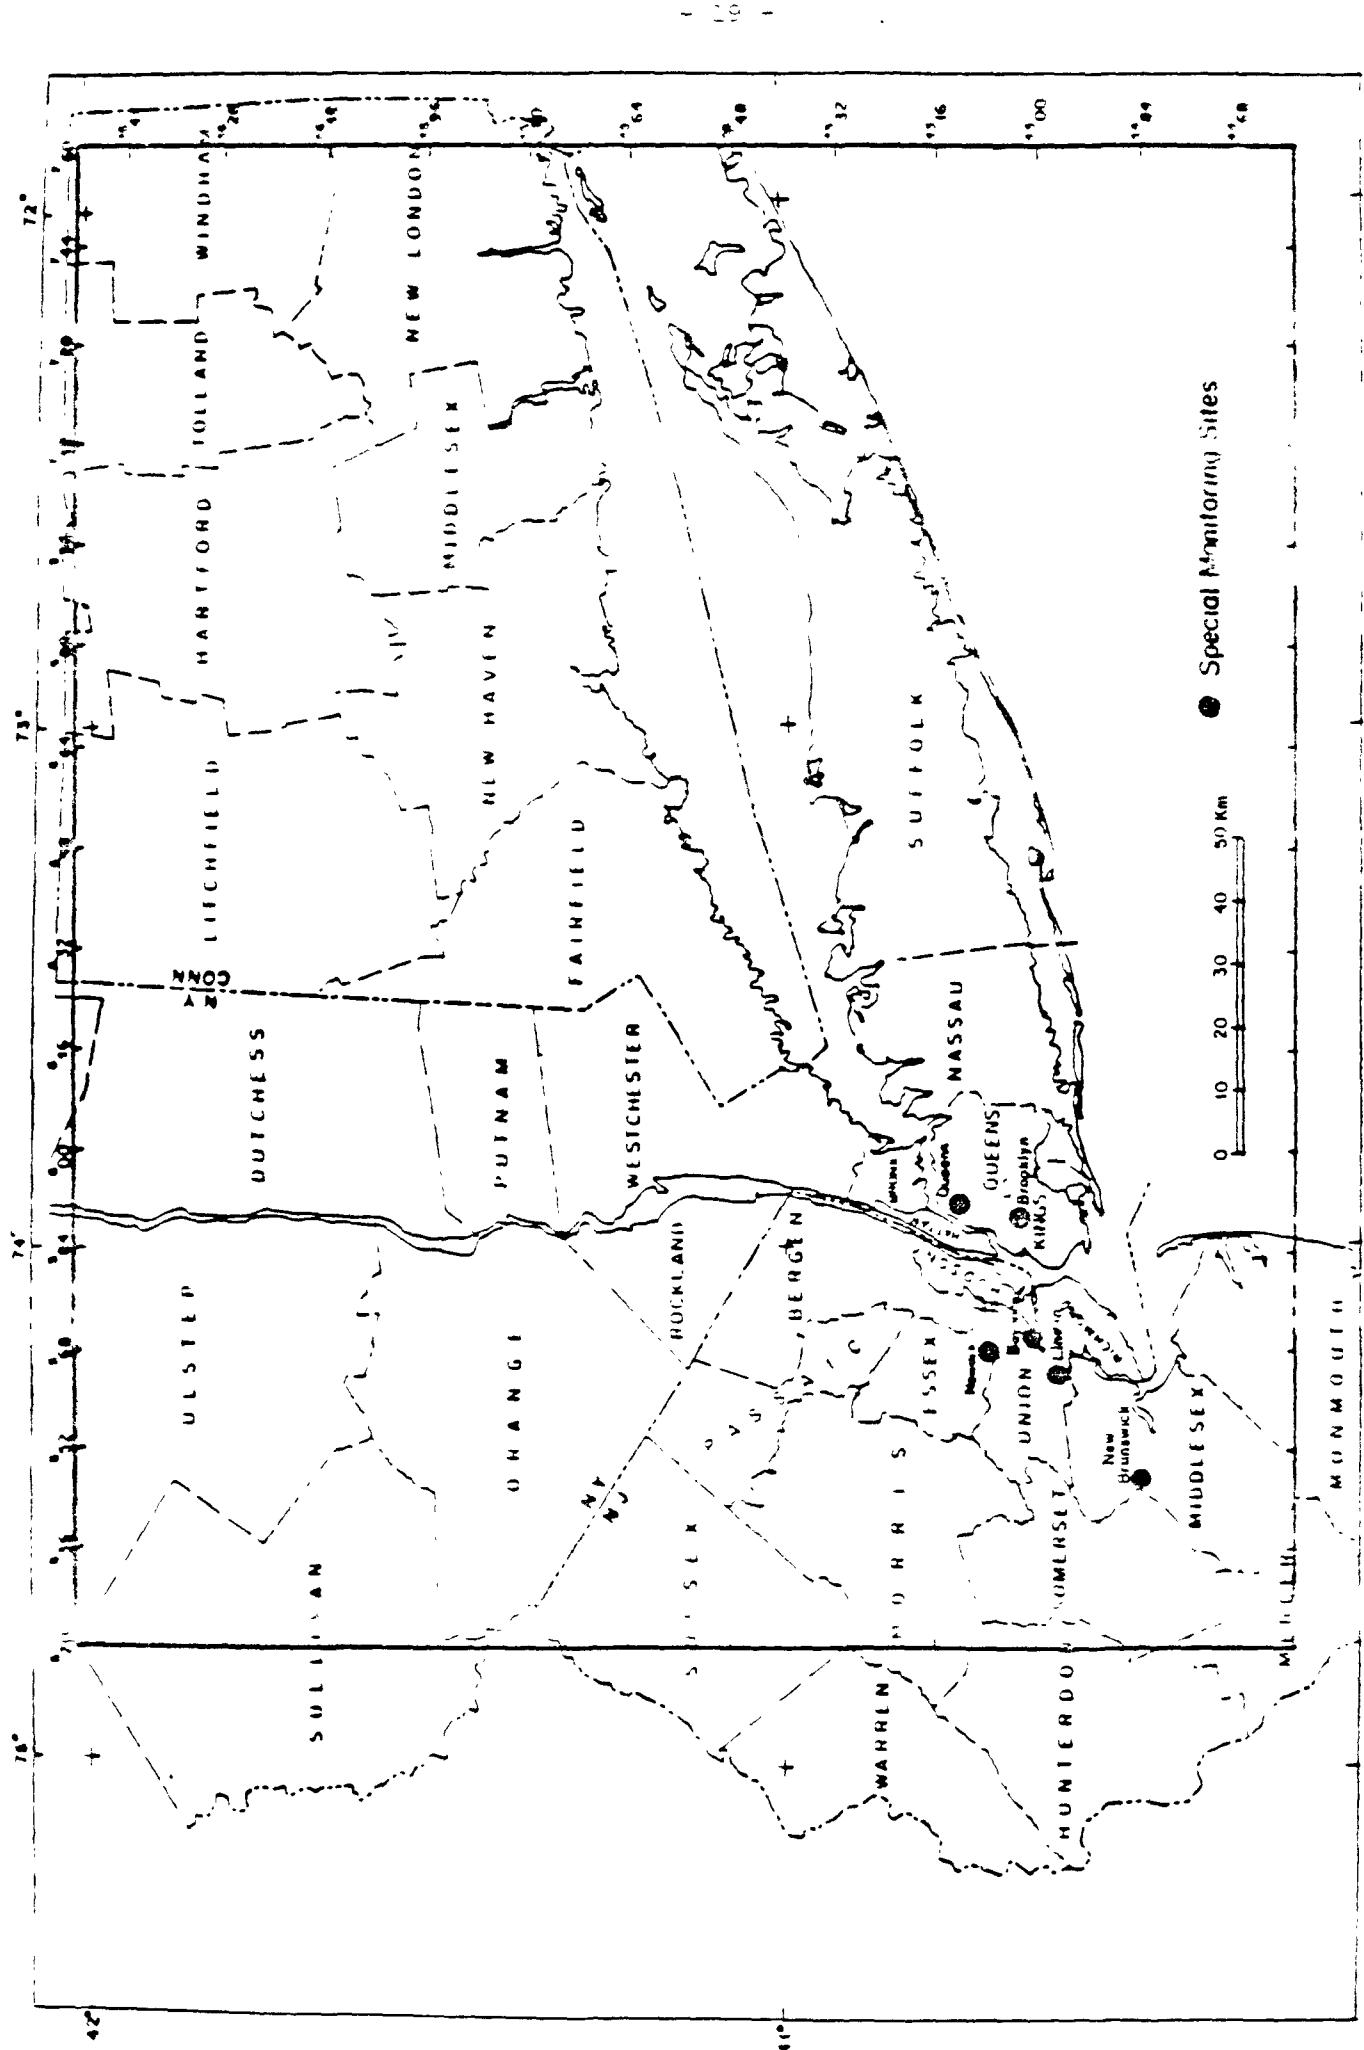

Figure 3.3 Geographic distribution of NMHC Monitoring Sites in the Middlebury region

3.2.3 Nitrogen Oxides (NO_x)

The monitoring stations reporting nitrogen oxides, shown in Figure 3.4, were all located in the southwestern portion of the modeling domain. In addition to the data from 15 to 20 routine monitoring stations, data from three other sites from the NECRMP study were used to estimate the distribution of the oxides of nitrogen in the modeling domain.

3.2.4 Carbon Monoxide ('CO')

The majority of the CO monitoring stations, shown in Figure 3.5, were located in the urban areas. The data from these stations were used to provide estimates of the distribution of the pollutant concentrations in the modeling domain.

3.2.5 Ancillary Ambient Air Quality Data

Ambient air quality data from stations located outside the domain, listed in Table 3.1, were assembled to provide the required input data at the boundaries of the modeling domain. Also, aircraft data collected under the NECRMP study were utilized to provide information on the pollutant distribution in the vertical plane. The flight paths over the domain consisted of horizontal traverses with spirals at the fixed locations shown in Figure 3.6.

3.2.6 Surface and Upper Air Meteorological Data

The routine NWS station network in the domain, shown in Figure 3.7, provided the surface wind speed and direction, relative humidity, atmospheric pressure and temperature measurements. The upper air data were obtained from the NWS station at JFK Airport, New York City and NECRMP stations shown in Figure 3.7, and the scatter data. Data were taken from Flemington and Fairborn in New Jersey.

3.3 Model Input Parameters - Meteorological

For each of the days selected, the UAM simulations were commenced at 0400 Hrs and terminated at 2000 Hrs. The meteorological parameters needed to execute the UAM program are listed in Table 3.2 and a brief description of the methodologies adopted for obtaining these parameters is given below.

Surface temperature	x, y	t
Atmospheric pressure		t
Concentration of water vapor		t
Exposure Index		t
NO ₂ Photolysis Rate constant		t
Temperature gradient above and below the diffusion break		t
Wind field in terms of u and v		t

3.3.1 Diffusion Break (Mixing Height)

The available data for the determination of the hourly mixing heights included rawinsonde temperature soundings and vertical profiles of temperature and pollutant concentration measured by aircraft obtained at the locations shown in Figures 3.6 and 3.7. The methods by which the hourly mixing heights were derived included those of Senkeley-Schulman (1979), Vieuwstadt (1981), and Garrett (1981). Also, the information on the vertical gradients in the ozone concentration and the extent of ozone scavenging were utilized in estimating the spatially invariant hourly mixing heights for each of the selected days.

3.3.2 Top of the Modeling Region

An hourly variable height for the region top was selected for this study. The region top was assumed to rise at a rate slower than that of the mixing height in the morning hours, and by midday both of them became equal. The region top was assumed to remain constant at that height, while the mixing height decreased in the late afternoon hours. The top of the modeling region was set at a minimum height of 1000 m with a minimum depth of 500 m for the layers between the top of the modeling region and the level below. Figure 3.8 shows schematically the diurnal profile of the top of the modeling region along with mixing heights for the modeling domain.

3.3.3 Surface Temperature

The distribution of the surface temperature within the domain was derived through an inverse-distance-squared weighting interpolation scheme utilizing the measurements available at the NWS stations shown in Figure 3.7 for each hour of the model simulation.

3.3.4 Atmospheric Pressure

Sea-level atmospheric pressure values, obtained from the NWS stations shown in Figure 3.7, for each hour are averaged to yield a value over the domain for that hour.

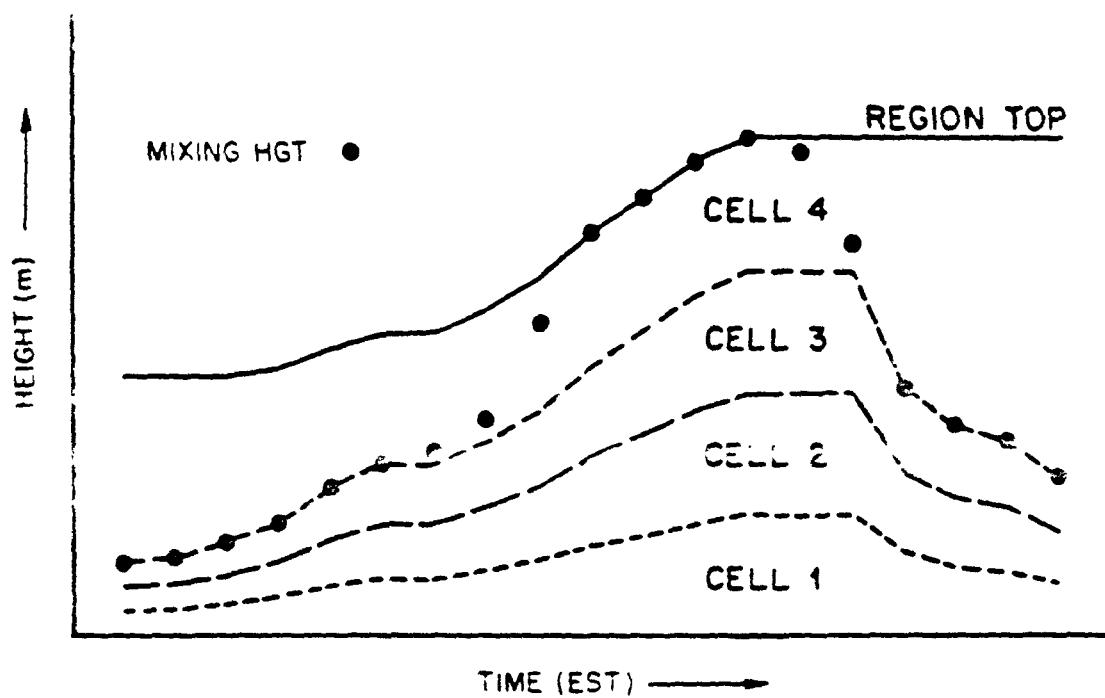

Figure 3.8 Schematic Representation of the Typical Diurnal Profile for the Region Top, Mixing Height and the Vertical Cell Height

3.3.5 Concentration of Water Vapor

Following Byers (1971) and Hull (1974) the specific humidity of saturation, q_s , was obtained as follows:

$$q_s \text{ (grams of water/grams of air)} = 0.622 e_s / (P - 0.37 e_s)$$

where e_s , the saturation vapor pressure (mb) is given by

$$e_s = E_s \exp \left(\frac{\lambda}{\rho} \left(\frac{1}{T} - \frac{1}{B} \right) \right)$$

where $\lambda = (T + 273.16 - B)$
 $\rho = 17.2693882$
 $B = 35.86$
 $E_s = 6.1078$
 $P = \text{atmospheric pressure (mb)}$
 $T = \text{dew point temperature } (^{\circ}\text{C})$

In this study, the specific humidity of saturation for each hour was calculated from the data collected at the NWS station located at JFK airport in New York City, which was then multiplied by 10^6 to yield the water vapor concentration in ppm as a representative value for the domain.

3.3.6 Exposure Index

This parameter is a measure of near ground level stability due to surface heating or cooling and is estimated from insolation as shown in Table 3.3. In this study, the data utilized to estimate the exposure index included the solar radiation data from the Flemington and Marlboro sites in the southwestern part of New Jersey and the hourly sky cover conditions reported from the NWS stations shown in Figure 3.7. An estimate of the exposure index for each hour was made using these data as well as synoptic weather information.

3.3.7 Diurnal Photolysis Rate Constant

A computer program that incorporates the data of Demerjian, et. al., (1980) was used to calculate layer-averaged NO_2 photolysis rate constants based upon the latitude, longitude, month, day and time of day, mixing height, and solar radiation data. Assuming clear sky conditions and using the mixing height information, the layer-averaged NO_2 photolysis rate constants were obtained for the modeling domain.

TABLE 3.3

Daytime Insolation and Nighttime Cloudiness Conditions
as a Function of Exposure Index

		<u>Exposure Index</u>
Insolation	Strong	3
	Moderate	2
	Slight	1
	Heavy overcast day or night	0
Night time	$\geq 4/8$	-1
Cloud cover	$\leq 3/8$	-2

3.3.8 Temperature Gradient

The temperature gradients above and below the diffusion break were calculated from the temperature soundings available at one or more locations shown in Figure 3.7. The gradients for each hour were estimated by averaging the measured profiles at increments of 100 m above and below the diffusion break. For those hours for which data were not available, the gradients were obtained through linear interpolation from adjacent hours.

3.3.9 Wind Field

UAM requires the specification of a gridded three-dimensional flow field. Attempts were made to generate a gridded wind field based upon the available surface and upper air data from the stations shown in Figure 3.7, using the Clark and Eskridge (1977) non-divergent algorithm. However, the spatial representativeness of the available upper air observations for the entire modeling domain was found to be questionable because of the influence of land-sea breeze circulations. Application of a bi-cubic splines interpolation technique to the surface level winds produced too much smoothing in the derived wind field. Thus, it was decided to use only the surface based observations and generate the three-dimensional non-divergent gridded wind field, assumed invariant in the vertical direction. However, examination of such a wind field and trajectory paths revealed an undue influence from the coastal NWS stations which appear to be affected significantly by the land-sea breeze interactions. Hence, a spatially constant but temporally varying vector-averaged wind speed and direction for each hour of the simulation were considered to be a reasonable compromise for capturing the transport characteristics prevailing in the modeling domain.

3.3.10 Initial Air Quality and Region Top Concentrations

The following procedures were adopted to obtain the gridded pollutant distribution at the surface and in the vertical. For each of the pollutants the concentrations measured at the ambient air quality monitoring stations shown in Figures 3.2 to 3.5 for the period 0300 and 0400 Hrs were averaged and formed the

basis for generating gridded surface concentrations. The methods consisted of an inverse-distance-squared weighting scheme or the population distribution as a surrogate parameter, particularly when there were very few or a limited number of surface stations from which data were available to make a meaningful interpolation over the modeling domain. For the grids over the Atlantic Ocean, the pollutant concentrations were assumed to be the same as those in layer 4 and assumed to be uniformly distributed in the vertical.

The pollutant measurements made with the aircraft over the domain were used to provide the concentration estimates at the top of the modeling domain for each of the pollutants as well as for the layer 4. For the intermediate levels between the surface and the base of the layer 4, the concentrations were determined as follows. If the grid cell was classified as urban, the concentrations were assumed to be uniform from the surface up to the base of layer 4; and if it was rural, the concentrations were obtained using the gradient determined from the aircraft spiral data. This is shown schematically in Figure 3.9.

Listed in Table 3.4 are the CBII chemical speciation factors which were developed from the ambient NECRMP data base and applied to the NMHC concentrations in this study. The NO₂-NO ambient concentrations were assumed to be in the ratio of 2 to 1.

3.3.11 Boundary Concentrations

The surface concentrations along the boundaries for each hour were estimated based upon measurements from the monitoring stations listed in Table 3.1. Attempts were made to take into account the wind direction for each hour in arriving at the surface boundary concentrations considering the location of the monitoring station and availability of data. The vertical gradients of the pollutants determined from the aircraft measurements were applied to all four sides and used to determine the concentrations in the vertical up to the 3rd layer. In those cases where the ozone concentrations in any one of the surface boundary grids was determined to exceed that of the region top value before the mixing height entrencheds into the layer 4, such grids were assumed to be uniformly mixed up to the layer 3. In the case of the 4th layer, it was assumed

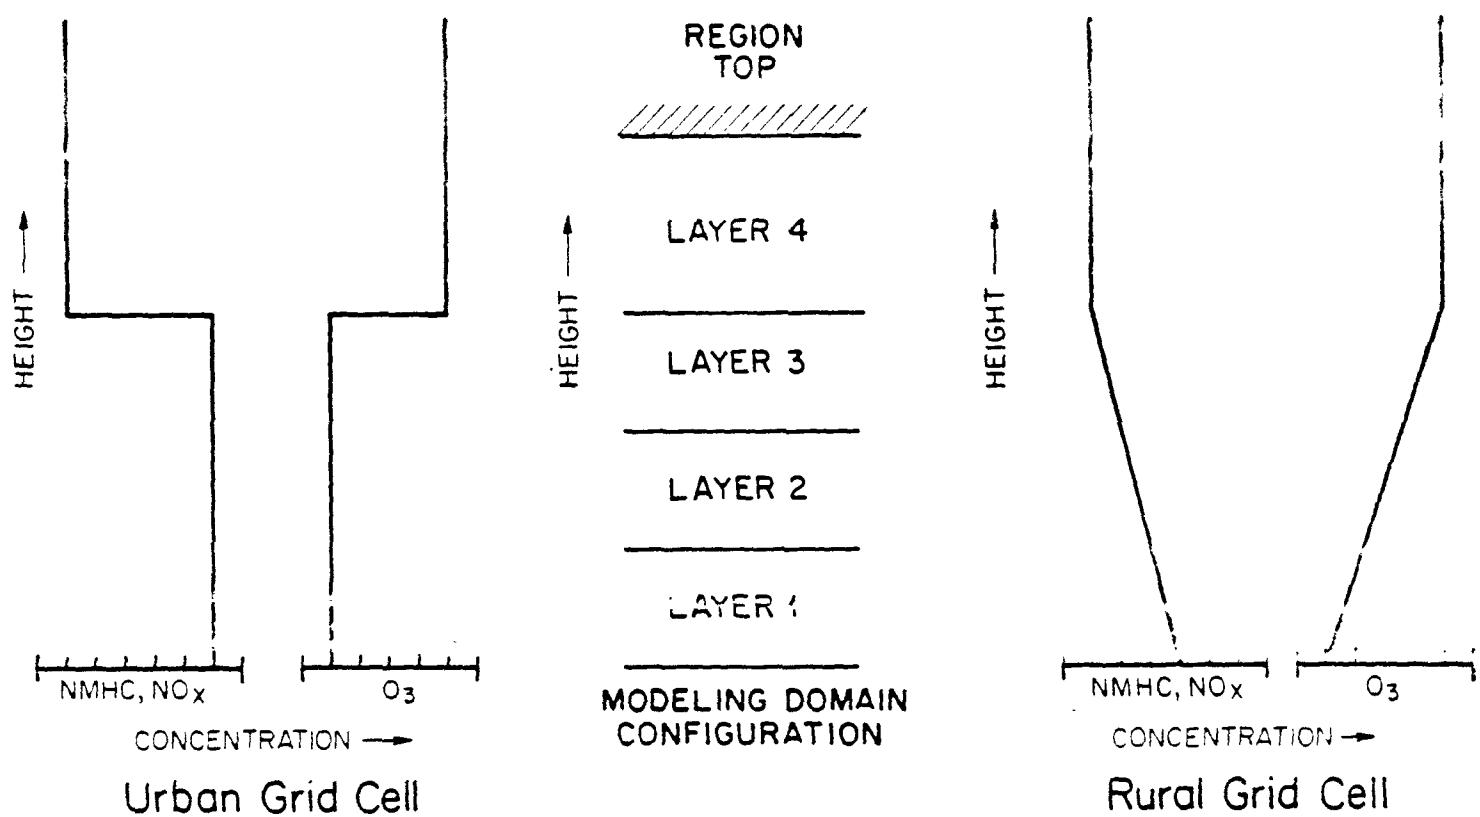

Figure 3.9 . Schematic of the Initial Pollutant Distribution in the Vertical Plane for Urban and Rural Grid Cells in the Modeling Region

that the pollutant concentrations are the same as those adopted for the top of the modeling region. This procedure was adopted for those hours for which the diffusion break (mixing height) was at or below the base of the layer 4. For all subsequent hours it was assumed that the pollutants are well-mixed throughout the layer from the surface up to the fourth layer. In the case of the grids over the Atlantic Ocean, it was again assumed that the concentrations were at the same levels as those of the layer 4 with no vertical gradient. The NO_x - VOC mix at the boundaries was also assumed to be in the ratio of 2 to 1 and the NMHC concentrations were speciated as follows - 6% carbonyls (CARB), 3% olefins (OLE), 24% aromatics (ARO), 58% paraffins (PAR), and 3% ethylenes (ETH).

CHAPTER 4

EMISSIONS

4.1 1980 Emissions Inventory Development

The UAM requires a gridded emissions inventory for each hour simulated, speciated into the hydrocarbon classes used in the Carbon Bond II Chemical mechanism. Since each state covered by the modeling domain has a different emissions inventory system, a new emissions data management system was required to merge these data into a form compatible with UAM. To assist in this task, NYSDEC contracted with Engineering Science (ES), Fairfax, VA for the installation of computer codes required for this purpose. ES had developed similar codes for the U.S. Environmental Protection Agency for the Philadelphia metropolitan area study (USEPA, 1982).

The system of programs accepts emissions data in the format used by the National Emission Data System (NEDS). It also makes use of modules from the Emissions Inventory System (EIS), which provides emissions calculation procedures. These procedures allow a user to estimate emissions using process rates or activity levels and emission factors. The emission factors are stored in a user-maintained table which is arranged by Source Classification Code (SCC) and pollutant identification number.

The installed system provides the means to disaggregate annual emission estimates to an hourly basis using specific or typical operating schedules, and to speciate total hydrocarbons into several classes depending on the composition of emissions from the source category (see Appendix A). After performing these calculations, the system formats the data to the specifications of UAM.

The system is designed for the processing of four types of emission sources: major and minor point sources, area sources, and mobile sources. Major and minor point sources are those sources which emit significant amounts from smokestacks or other readily identifiable emission points and for which detailed operating data are available. Area sources include residential emissions and others which are too small and too numerous to handle individually. Mobile sources are generally considered to be motor vehicles on established roadways.

In this study, major point sources were defined as those with annual emissions greater than 100 tons and a stack height greater than 65 meters and the remaining were classified as minor point sources and are individually formatted by the system. However, minor point sources falling within a grid were combined due to the computational limitations imposed by UAM model. Area source emissions were calculated and maintained separately for up to 54 source categories and combined within each grid cell. Mobile source emissions are generally tabulated by grid cell. The installed system handles all four source categories and performs the necessary combinations. In addition, other modules have been provided for the conversion of data from NEDS to EIS format, allocation of county-level area source data to the grid cell level and for calculation of area source emissions. Figure 4.1 illustrates schematically the flow of data through the system. Once the data are in the EIS format, tables are developed consisting of factors organized by SCC that indicate the seasonal, daily, and hourly variations in emission rates and proportion of the total hydrocarbons into the corresponding hydrocarbon category. The program performs a simple multiplication of the annual estimate of each pollutant and the appropriate factors to yield 24 hourly emission rates per source. A post-processing program takes the factored data and formats it to the specifications of UAM. Emissions from mobile sources, which are not stored in EIS format and which have been prepared on an hourly basis, require a separate factoring and formatting program.

Unfortunately, the available data are seldom in the EIS format that is required as input to the processing programs. For example, point source data may be obtained more readily in the NEDS format, while the area source activities are tabulated at the county level instead of at the grid-cell level. For this reason, some additional computer codes were used to distribute county-level activities to the grid cells, to calculate emission estimates based on activity levels and emission factors, and to re-arrange the data into EIS format.

Thus, the EIS programs convert point and area source data in NEDS format to EIS transactions, sort the transactions, insert emission factors into the transactions, calculate emission estimates if requested and create or modify an EIS master file, and create an emission factor table based on SCC.

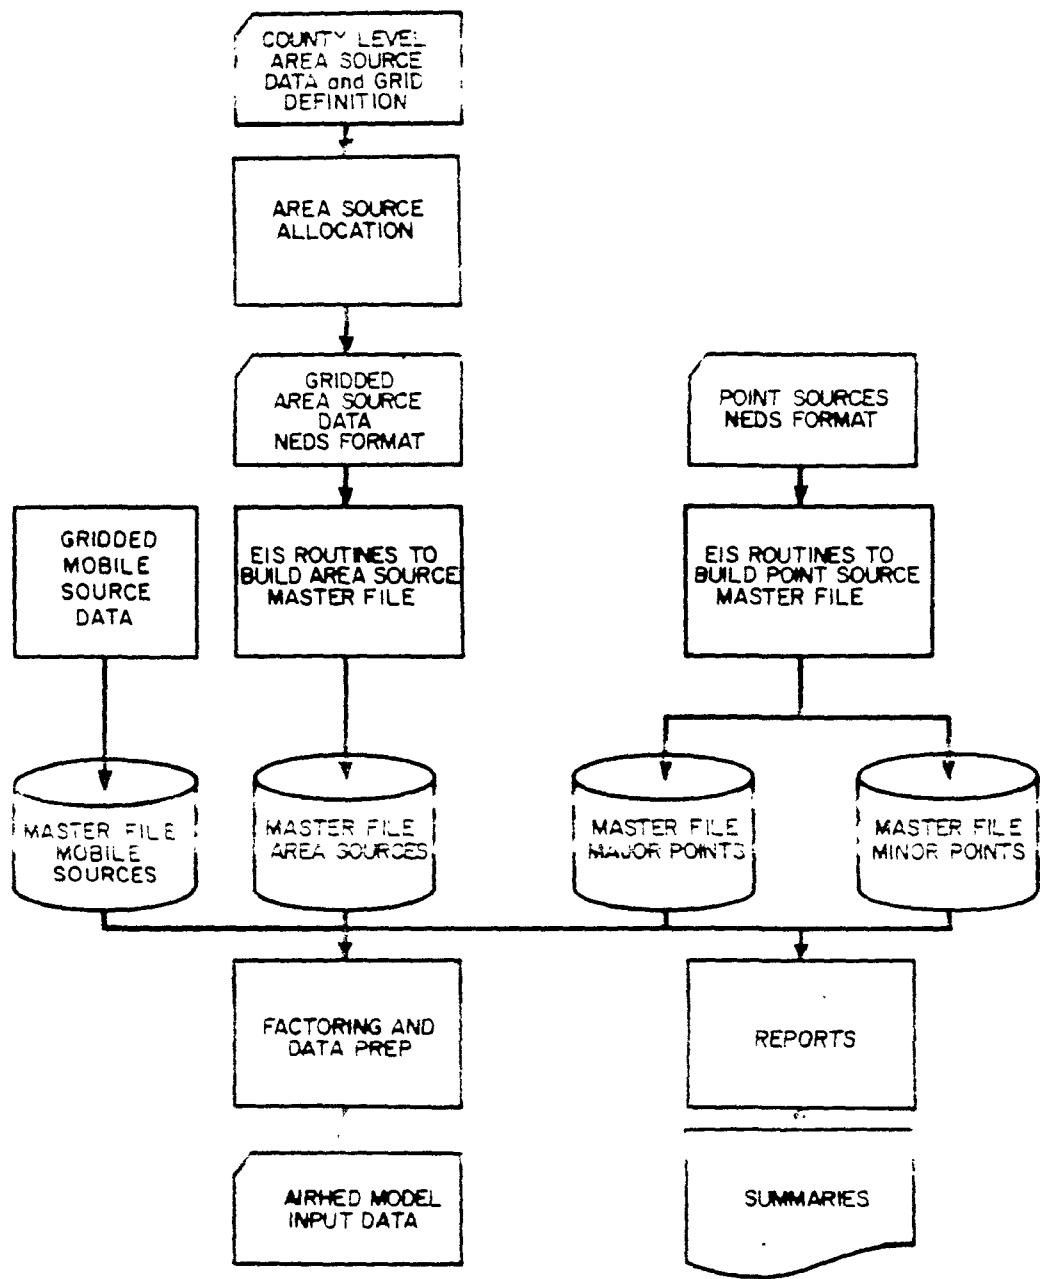

Figure 4.1 Overview of the Emissions Data Management System

Each State was responsible for collecting and preparing the necessary data for processing by the ES programs. A description of the procedures used for each generating State's inventory is provided below.

4.2 Connecticut 1980 Emissions Inventory

4.2.1 Area Sources

Connecticut's available emission inventory was in NEDS format on a state-designed grid system. NEDS activity levels were summed into the grids by Connecticut Department of Environmental Protection (CTDEP) and provided to New York State Department of Environmental Conservation (NYSDEC). Also provided were the appropriate emission factors based on AP-42 (USEPA, 1984) for each source category. ES programs are then used to process the data into UAM format, and in Table 4.1 emissions are listed by SCC category for 1980.

4.2.2 Point Sources

CTDEP provided their point source emission inventory in NEDS format. ES programs are applied to separate major and minor sources and process the data into proper format for UAM.

4.2.3 Mobile Sources

Connecticut mobile source emissions of VOC, CO, NO_x (kg/day), were calculated using MOBILE3 model. NYSDEC developed factors which are applied to daily values to convert these emissions to an hourly format. ES programs processed these data into the proper UAM format.

4.3 New Jersey 1980 Emissions Inventory

4.3.1 Area Sources

The New Jersey Department of Environmental Protection (NJDEP) provided the data necessary to create a UAM compatible area source emissions inventory. Activity levels for each source category were given for each NJ county in the

modeling domain. Appropriate emission factors were also provided. Since most area source emissions are based on population, the same basis was used for dividing these emissions into the modeling grid. NJDEP supplied 1980 U.S. Census population data for each municipality and the percentage of the municipality located in each grid. Factors were then developed to apportion total county emissions into each grid. If a grid contained emissions from one or more counties and/or states, the emissions were combined during a later processing operation. The ES programs were applied and in Table 4.2 are summarized the area source emissions for 1980 by SCC category.

4.3.2 Point Sources

New Jersey's point source data were in a format that could not readily be converted to the EIS format. Therefore, it was determined that an emission inventory prepared for the NECRMP was compatible with the ES programs. Using this NECRMP inventory, the ES programs were applied to separate major and minor sources and the data was processed into proper UAM format.

4.3.3 Mobile Sources

NJDEP provided mobile source VOC emissions (kg/day) using MOBILE3, for each county in the modeling region. Utilizing the population distribution, these county-wide emissions were allocated to the corresponding grids using the ES programs. Emissions of NC_x and CO were then obtained by scaling these VOC data using composite emission factors (g/mile) for each of these pollutants. NYSDEC developed factors which were applied to daily values to create hourly emission levels. Once on a gridded basis, ES programs processed the mobile emissions into the UAM format.

4.4 New York 1980 Emissions Inventory

4.4.1 Area Sources

NYSDEC developed the data necessary to use the ES programs for creating their area source emission inventory in UAM format. Activity levels for each source category were determined for each NY county in the modeling region. Appropriate emission factors were also assembled.

As with the New Jersey data, population was used as the basis to distribute most county level emissions to the modeling grids. Two source categories were deemed to have more appropriate methods of disaggregation - Vessels and Aircraft emissions. Vessel emissions are restricted to waterways in each county and aircraft emissions are limited to those grids which contained airports. Individual airport activity levels obtained from the New York Metropolitan Transportation Council (NYMTC) are used to proportion the county emission totals into the appropriate grids. Population for each grid was calculated from 1980 US Census data. NYMTC provided this data at 1 km grids for most New York counties which are then summed into the appropriate UAM grids. NYMTC had no data for Sullivan and Ulster counties so the procedure which New Jersey followed was used to apportion those counties' emissions to the modeling grids. The ES programs were applied and the 1980 area source emissions from New York are listed in Table 4.3 by SCC category.

4.4.2 Point Sources

New York's point source data were also in a format that could not be converted to the EIS format. Therefore, NY data had to be processed independently and subsequently combined with that from the other states. A search of the NYSDEC Source Management System (SMS) identified those sources meeting the major point source criteria. Only utility boilers and one correctional facility boiler were classified as major point sources. All others were deemed minor point sources for this study.

A survey was sent to each utility requesting actual hourly electricity generation values for the five modeling days. The five hourly values were averaged and emissions calculated using the average 1980 heat rate (Btu/kwhr) and appropriate emission factors based on AP-42, unless unit specific factors were available. Hourly emissions from the correctional facility's boiler are calculated based upon operational data obtained from the unit's Certificate to Operate permit. Those hourly emissions from the major point sources were then divided into the UAM species and processed into the correct format. Only NO_x emissions are used for this exercise. VOC emissions from these boilers were deemed negligible and not included in the model.

The minor point source data required additional evaluation. Since the data could not be processed (divided into model species by hour) by the ES programs, NYSDEC undertook the task. The SMS tracks pollutant emissions on a chemical basis, referenced to the Chemical Abstract Series (CAS) identification number. The 1980 emissions data were examined and it was determined that over 98% of the VOC emissions in the area were classified as one of 35 distinct pollutants. Factors were developed using the CBII chemical speciation for each of these 35 pollutants. The remaining 2% of VOC emissions were assigned a default speciation arrangement corresponding to that for the category Miscellaneous Organics (CAS No. NY990-00-0). The speciation breakdown for these 35 pollutants for the New York point source inventory is shown in Appendix A.

4.4.3 Mobile Sources

New York Metropolitan Transportation Council (NYMTC) provided 1980 daily mileage estimates for each of its 60 analysis areas in the New York City Metropolitan area. Mileage for each analysis area was given for five vehicle types - light duty gas vehicles (LDGV), taxis, light duty gas trucks (LDGT), heavy duty gas vehicles (HDGV), and heavy duty diesel vehicles (HDDV). For each vehicle type, mileage was given for three roadway types - freeway, arterial and local streets. Percentage hot/cold starts were also included for each roadway type by analysis area.

The assignment model that generated the above data computed the vehicle type distribution and percentage hot/cold starts on a county-wide basis. A review of these data, including comparisons of MOBILE3 emissions on the county level, revealed that each borough (county) of New York City should be modeled separately, while the suburban or surrounding counties had similar enough characteristics to use a single MOBILE3 emission simulation. Also, since taxi mileage was given for only Manhattan, Bronx, Queens and Brooklyn and taxi emissions are different from the other vehicle types, it was decided to model the taxis separately.

Table 4.4 shows the vehicle type distribution and percentage hot/cold starts used in the MOBILE3 program. The MOBILE3 version used by the NYSDEC included all USEPA suggested modifications to the model up to June 1985.

Typical speed scenarios were developed for rush hours, daytime, and nighttime for the three roadway categories. These are listed in Table 4.5. The data used in the analysis were obtained from the reports published by the NYS Department of Transportation which provided the hourly percentage of traffic for 15 locations within New York City as well as reports from other local agencies. The distribution of total VMT for the three roadway type categories are listed in Table 4.6.

Hourly emissions for each grid were then computed by summing for each roadway type the appropriate emission factor times the daily mileage of each analysis area within the grid, multiplied by the hourly percent of traffic and the percentage of the analysis area in the grid. The appropriate emission factor depended on the time of day (night, rush hours, in-between) and county (Manhattan, Rest of NYC) which in turn determined the speed, percentages of hot/cold start and the vehicle mix.

4.5 1980 Emissions for the Modeling Domain - Summary

The annual VOC and NO_x emissions from the three states are summarized in Table 4.7 for the four source categories. These emissions were further disaggregated as listed in Table 4.8, in g-moles on a daily basis (0400 to 2000 hours), and in terms of CBII species assuming the carbon ratios of 1,2,1,6 and 2 for Paraffins, Olefins, Carbonyls, Aromatics and Ethylenes, respectively. On a percentage basis the mobile sources contribute about 50% of the NO_x burden and approximately 45% of the VOC's for a typical day covering the hours of simulation for the base year 1980. The next important contribution to NO_x and VOC's are the area sources, with approximately 28% and 44%, respectively.

4.6 1988 Emissions Inventory

The 1988 emissions over the modeling domain were estimated based upon the control strategies proposed in the approved 1982 SIPs and projected changes in population levels. Utilizing the U.S. Census data, the area source projection

factors from 1980 to 1988 for each county were calculated and are listed in Table 4.9 for the three states. One exception to this method is the category of gasoline marketing. In the case of New York and Connecticut, the 1982 SIP regulations require the implementation of Stage II vapor recovery for 1988. Since such controls were already in place for New Jersey, they were accounted for in 1980 base year emissions for New Jersey.

4.6.1 Area Sources

Applying the factors listed in Table 4.9 to the 1980 area source inventory, projected VOC and NO_x emissions were calculated for 1988 and are listed in Tables 4.10a through 4.10d for Connecticut, New Jersey, New York, and the modeling region respectively.

4.6.2 Point Sources

The 1988 point source emissions were projected based upon control regulations expected to be in effect prior to 1988. Since the majority of the major point sources are mainly utility boilers, emission levels are not expected to change significantly from these sources. However, Connecticut expects the addition of several resource recovery facilities which will result in a slight increase in emissions under this category.

Substantial emission reductions are expected, however, from the minor point sources. Connecticut provided a 1985 inventory in the format required by the processing programs. It was considered by CTDEP to represent the emission levels expected to occur in 1988. Therefore, no projection factors were required for this data.

NJDEP utilized the 1980 emission inventory summary by SCC code and determined which source codes are subject to their control regulations and the degree of control expected. These factors were then used to project the 1980 inventory to 1988. A similar approach was adopted to project the New York minor source emissions.

4.6.3 Mobile Sources

New Jersey and Connecticut provided 1988 mobile emissions determined by using MOBILE3 with updated VMT (vehicle miles travelled) data and emission factors. New York's 1982 SIP assumed a 2% annual growth rate to project future years' mileage. The actual annual growth rate through 1985 by county, listed in Table 4.11, was 1.2% which was adopted to project the 1988 levels.

In summary, the projected 1988 annual emissions for VOC and NO_x by source type and region are listed in Table 4.12a and in Table 4.12b, along with the speciated emissions summary for the model application. The percentage change from the 1980 base year (see Table 4.12a) shows that there is an overall reduction of about 32% and 14% in the VOC's and NO_x emissions, respectively.

4.7 1988 Emissions Inventory Including Extraordinary Measures

The 1988 projection inventory included only those control strategies that are implemented to date. Other SIP mandated measures such as Stage II gasoline vapor recovery, controls on architectural surface coating, automobile refinishing and consumer/commercial solvent and small source RACT have not been fully implemented. Thus, each of these measures are assessed separately and collectively. In Table 4.13a are listed the emission summaries by state and source type with the imposition of Stage II controls which has effectively achieved another 2% reduction in the VOC emissions. Adoption of the other control measures noted earlier would result in a further reduction of about 6% in the VOC emissions (see Table 4.13b) or a total reduction of 40% from the 1980 base year.

CHAPTER 5

MODEL APPLICATION

For each of the five days selected, a simulation package conforming to the CAA input requirements (USEPA: 1985a, 1985b) was prepared for the 16 hour simulation period (0400 to 2000 Hrs) using the methodologies described in Chapter 3. The detailed descriptions of the input data for each day are given below.

5.1 Input Data for JD80198(071680) Simulation

On the synoptic scale weather map for this day, shown in Figure 5.1a, the "Bermuda" type high pressure area extended from the Atlantic Ocean westward through the southern states. A cold front lay from the Canadian Maritimes west-southwestward to western Lake Erie, where it became a warm front; the latter turned west-northwestward into western Wisconsin, where an occluded-cold frontal structure ran nearly north-south. Weak low pressure was located to the west of the Lakes, while weak high pressure was found to their east.

The hourly vector-averaged wind speeds and directions for this day are listed in Table 5.1. The winds were generally from the south-southwest around 4 to 5 m/s. The other meteorological parameters are listed in Tables 5.2 and 5.3. The mixing height reached a maximum of 1460 m. The pollutant gradients in the vertical and the concentrations at the top of the modeling region are listed in Table 5.4. The initial surface distributions of the pollutants are shown in Figure 5.2. The hourly highest and second highest measured ozone concentrations are listed in Table 5.5. A peak value of 291 ppb occurred over Connecticut. The diurnal variation of the pollutant concentrations in the southwest corner cell are displayed in Figure 5.6.

5.2 Input Data for JD80203(072180)

Examination of the daily surface weather map in terms of large-scale synoptic features, shown in Figure 5.1b, reveals that a "Bermuda high" extended westward to the southern Midwest. A warm front, with waves of low pressure on it, ran nearly east-west from Maine to well north of Lake Ontario, where a cold front ran southward then southwestward to mid-country. The surface winds during the day, listed in Table 5.6, were generally from the southwest to south-southwest with wind speeds ranging from 4 to 5 m/s. The other meteorological parameters for each hour of simulation are listed in Tables 5.7 and 5.8. The initial surface distribution of pollutants - ozone, nitrogen dioxide, non-methane hydrocarbons and carbon monoxide are shown in Figure 5.4, respectively. The vertical pollutant gradients determined from aircraft spiral data and the concentrations adopted for the top of the modeling region are provided in Table 5.9. The boundary concentrations at all four sides of the model domain varied both spatially and temporally. In Figure 5.5, the diurnal variations of the pollutant species at the surface level for the southwest corner cell are shown. On this day, the ozone concentrations measured over Connecticut often exceeded 200 ppb with a maximum measured hourly concentration of 303 ppb at Stratford, Connecticut. In Table 5.10 are listed the hourly highest and second highest measured concentrations along with their time of occurrence and their location.

5.3 Input Data for JD80204(072280)

On this day the synoptic-scale features, shown in Figure 5.1c, are as follows. The "Bermuda High" extended westward from the Atlantic. A broad area of low pressure was positioned over the northern New York-New England/Canadian border region, lying on a frontal system that stretched from Maine (warm-frontal) westward, then southward to Tennessee (cold-frontal) and on to Texas. The winds generally ranged from a south-southwest to southerly direction at speeds ranging from 3.5 to 5.5 m/s. The vector-averaged hourly wind speeds and directions are listed in Table 5.11. The other input meteorological parameters are listed in Tables 5.12 and 5.13. The initial surface distribution of pollutants are shown in Figure 5.6. The pollutant concentration gradients and the concentration at the top of the modeling region are provided in Table 5-14.

* Highest for the day

** Second highest for the day

The highest and second highest measured hourly ozone concentrations for this day, listed in Table 5.15, indicate a maximum of 240 ppb at Hartford, Connecticut with concentrations in excess of 200 ppb at other locations over Connecticut. The concentrations adopted for the pollutants at the southwest boundary cell are shown in Figure 5.7.

5.4 Input Data for JD80219(080680)

On this day the synoptic situation, shown in Figure 5.1d, is slightly different from the previous cases. A break-off extension of the "Bermuda" high was centered over West Virginia. A frontal zone was draped north of the border to a low pressure near James Bay.

The vector-averaged hourly winds are listed in Table 5.16, with speeds ranging from about 3 to 5 m/s from a south-southwest to southwesterly direction. The other input meteorological parameters are listed in Tables 5.17 and 5.18. The pollutant gradients and the concentration at the top of the modeling region are listed in Table 5.19. The initial surface distributions of the pollutants for the simulation day are shown in Figure 5.8. The highest and second highest measured hourly ozone concentrations are listed in Table 5.20 with the highest value of 249 ppb. The hourly boundary concentrations for the southwest corner grid are shown in Figure 5.9 to provide an example of the typical values used in this simulation.

5.5 Input Data for JD80221(080880)

The synoptic weather pattern for this day, shown in Figure 5.1e, consists of a double-structured "Bermuda" high with centers over the Atlantic and West Virginia. A frontal system arched across the northern part of the country. A high pressure center was found over James Bay, with a weak low pressure on the stationary portion of the front over Lake Superior.

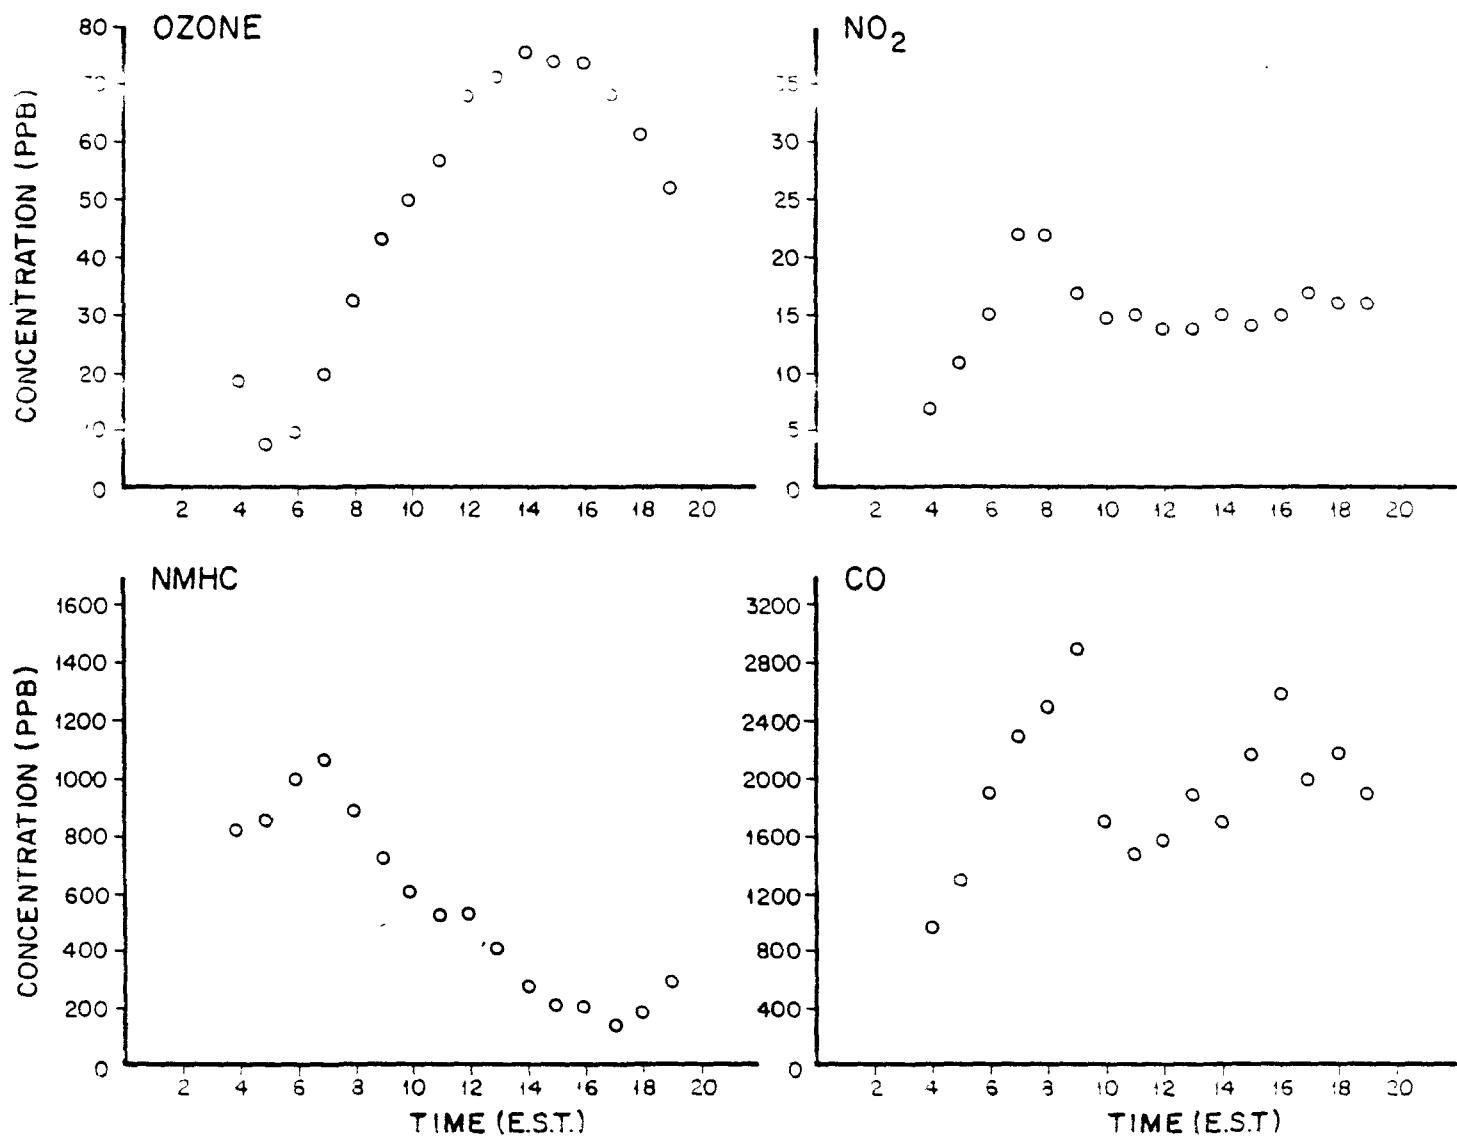

Figure 5.9 Diurnal Plot of Observed Pollutant Concentrations at the Southwest Corner Grid on JD80219(080680)

The hourly vector-averaged wind speeds and directions are listed in Table 5.21. The winds were from a south-southwesterly direction, with speeds ranging from 3.5 to 5 m/s. The other input meteorological parameters are listed in Tables 5.22 and 5.23. The mixing height reached a maximum of 1400 m. The pollutant gradients in the vertical are listed in Table 5.24 along with the concentrations at the top of the modeling region. The "initial" surface distributions of the pollutants for the simulation day are shown in Figure 5.10. The highest and second highest measured hourly ozone concentrations are listed in Table 5.25. The peak value was 246 ppb and exceedances of over 200 ppb are noted for other hours. Diurnal variation of the pollutant concentrations at the southwest corner grid are displayed in Figure 5.11.

CHAPTER 6

MODEL PERFORMANCE EVALUATION

The results of the UAM simulation for the five selected high ozone days are presented and discussed in this section. The model performance is evaluated on the basis of its overall predictive capability and its ability to capture the high concentration values through the application of various statistical measures recommended by the AMS workshop (Fox, 1981).

6.1 UAM Simulation of the Ozone Concentration Field for the Five Days

Using the model input data described in the previous chapter, the UAM was executed to provide hourly averaged ozone concentration fields for each of the five days. In Figures 6.1 to 6.5 are shown the isopleths of predicted ozone concentrations for selected hours when concentration maxima are expected to occur for each of the five days. One of the characteristic features of the five days simulated is the occurrence of a double peak over the modeling domain around the time of the occurrence of the ozone maximum with one peak over the northeastern portion of Connecticut and the other over the border areas of northeastern New Jersey-New York. Only in the case of JD80219 (080680) was there no clearly defined double peak. This may be due to the lower advection rate, and limited mixing in the vertical which could result in the merger of the two peaks. Also, in some instances, the peak concentration formed over the New Jersey-New York region is higher than the peak occurring over the Connecticut region suggesting a strong influence of pollutant transport through the southern and western boundaries.

6.2 Paired Comparisons - All Data

It should be noted that whereas the UAM predictions represent volume-averaged hourly concentration values (averaged over the cell volume specified in the program), the measured concentrations are at monitoring stations represented by points in space. Hence, perfect agreement between measured and predicted concentrations should be considered as fortuitous. To assess the model performance, the grid point nearest to the monitoring station is located and the predicted concentrations at this grid point are compared with the measurements

from the monitoring station. Diurnal plots of the observed and predicted concentrations at the monitoring stations are presented in Appendix B. Several standard statistical measures (Willmott, 1981; Fox, 1981; Rao, et al., 1985) are computed, and the results are listed in Table 6.1. The high correlation coefficients ($r_{\text{crit.}95} \geq 0.098$) indicate that the model predictions are reasonable either when the data are considered on an individual day-by-day basis or on an ensemble basis. However, on an overall basis, the model overpredicted the concentrations by about a factor of two as indicated by the mean of ratios of predicted to the observed concentrations. Of the five days, the two that show the highest correlation coefficient and index of agreement are JD80203(072180) and JD80221(080880).

A scatter plot of the observed and predicted concentrations for all data for each of the days considered is shown in Figure 6.6. In addition to the one-to-one line (perfect prediction), an envelope of $\pm 30\%$ of the observed concentrations is shown in the figure by dashed lines. The percentage number of points lying within $\pm 30\%$, greater than 30% , and less than 30% are provided in Table 6.2. The percentage of data within the $\pm 30\%$ envelope for each of the days is about 30% or better, while the percentage of underprediction is about 10%.

Figure 6.7 is a histogram of the difference between the measured and predicted concentrations for each of the simulation days. The percentage of data falling within ± 0.03 ppm ranges from 45 to 51% depending upon the simulation day, with the majority of the remaining data generally in the overprediction category ($\text{OBS-PRED} < -0.03$ ppm). The exception for this is the performance on JD80204(072280), (see Figure 6.7) for which about 27% of the data are in the overprediction category. However, examination of the model performance measures listed in Table 6.1 for this day indicates that its slope and correlation coefficient are slightly lower in comparison with other days.

For each of the simulation days, the diurnal variation of the mean difference between the observed and the predicted concentrations along with the standard deviation of the difference is shown in Figure 6.8. It is interesting to note that up to about 1300 Hrs the difference is confined to ± 0.03 ppm, and for the remaining hours of simulation the mean differences exceed 0.05 ppm, indicating an overprediction by the model. Also, the error spread in the afternoon hours is considerably larger than during the morning hours for each of the days.

6.2.1 Paired Comparison - Data from Connecticut

Since the measured ozone measurements for the five days indicate that the peak concentrations occur over the Connecticut region, assessment of the model performance in this region would be of particular interest. Figure 6.9 is a scatter plot of observed and predicted concentrations along with the ±30% envelope. In Table 6.3, the percentages of points within, below and above the ±30% envelope for each simulation day as well as the ensemble are listed. The percentage of underprediction is about 10%, with about 50% of the data lying in the ±30% envelope. In terms of the model performance, the day JD80203(072180) has 60% of its predictions within the ±30% envelope followed by JD80221(080880) with 50%, and in both cases about 9% or less of the data are in the underprediction category.

6.2.2 Paired Comparison - Concentrations Greater Than 100 ppb

It is important to analyze the model performance in simulating high ozone concentrations in order to provide an assessment of the model's ability to capture the peak concentration values. Toward this end, any hourly measured concentration greater than or equal to 100 ppb and its corresponding predicted value were examined as a set for (a) the domain as a whole, (b) the Connecticut region alone, and (c) New York and New Jersey. Scatter plots of the observed and predicted concentration for each of the five days are shown in Figures 6.10 and 6.11 for the latter two cases, respectively. The percentage of points lying within, above and below the ±30% envelope are listed in Tables 6.4a, 6.4b, and 6.4c for the entire domain, Connecticut, and New York and New Jersey, respectively. The model appears to perform quite well, with at least 60% of the predictions lying within the ±30% envelope in all the three cases and about 20% of the data on either side of the envelope. However, when measured concentrations greater than or equal to 200 ppb and the corresponding predictions are considered for the Connecticut region, the model underpredicts with an average predicted-to-measured ratio of 0.73. In Figure 6.12, the mean difference between the observed and predicted concentrations and the standard deviation of the differences are shown by the time of the day for each of the

five days over the domain when measured concentrations exceed 100 ppb. The systematic bias evident when all data are considered (see Figure 6.8) is absent in this case, and the mean differences between the observed and predicted are within ± 0.05 ppm.

6.3 Unpaired Comparison

Another way to assess the model performance is through an unpaired comparison of the daily maxima of the measured and predicted concentrations at each of the monitoring stations independent of their time of occurrence. The ratio between the predicted and measured peaks ranges from 1.29 to 1.72 for the ozone monitoring network over the tri-state region. The difference in the time of occurrence of the measured and predicted peaks ranges from ± 2 Hrs for the New Jersey stations to ± 5 Hrs for locations in Connecticut with the New York sites falling in between. A similar analysis of the second highest measured and second highest predicted concentrations at each of the monitoring stations yields a ratio in the range of 1.36 to 1.82 with a time difference of ± 2 to ± 5 Hrs. However, it should be recognized that, in general, the location of the model predicted ozone maximum may not necessarily be associated with those locations where ambient air quality measurements are available. Hence, for the purpose of comparison, the maximum measured and predicted ozone concentrations (independent of time and space) for all the five days are provided in Table 6.5. It should be noted that the measured ozone maxima for these five days are reported from the monitoring stations in Connecticut, as are the predicted values. The ratio of predicted to measured hourly maximum concentrations are in the range of 0.70 to 1.00 with a time lag of 0 to 3 Hrs. This indicates that the model under-predicts the peak value over the modeling domain as well as lags in terms of the time of occurrence of the maximum. This discrepancy may be due to numerous factors such as the uncertainty in the specification of the initial and boundary pollutant concentrations, space and time variation in the adopted mixing height, and the wind fields as well as the lack of day-to-day variations in the emissions data. It should also be noted that meteorological data summarized in Table 2.4 indicate the occurrence of precipitation over portions of the simulation region, presumably resulting in some scavenging of the pollutants in the real atmosphere, while the UAM does not include such processes.

6.4 Model Performance - Summary

The results from the above analysis suggest that the model has performed reasonably well with about 60% of the predictions in the $\pm 30\%$ envelope about the perfect prediction line when measured concentrations are greater than 100 ppb. Both temporal and spatial comparisons of the measured and predicted concentrations indicate that the UAM overpredicts on the average. However, the model is found to underpredict for the subset comprised of measured concentrations greater than or equal to 200 ppb. The model performance for the days JD80203(072180) and JD80221(080880) is, in general, better than the other three days with a tendency to underpredict the peak concentrations. Simulation studies conducted for Tulsa (Reynolds, et al., 1982), St. Louis (Cole, et al., 1983), and Philadelphia (Haney and Braverman, 1985) using the UAM have reported similar results. The fact that the model does not reproduce the measured maximum concentrations in the modeling domain should not deter its application in emissions control strategy evaluations, as long as the estimated ozone concentrations due to the imposition of specific controls are assessed in a relative sense.

6.5 Modeling Limitations

It is well known that several sources of uncertainty exist in air quality modeling that could affect the predicted concentrations of the pollutants. These uncertainties can be broadly categorized as "reducible" and "inherent" uncertainties. Errors in the input data to the model as well as inadequate formulation of the physical and chemical processes in the model lead to reducible uncertainty since uncertainties associated with these can be minimized through more accurate input data as well as improved model formulation. Inherent uncertainty stems from the stochastic nature of the atmosphere. No matter how perfect the model and the input data are, the imprecision cannot be reduced below a fundamental level because of the lack of predictability of the transport and diffusion processes in the atmosphere. Therefore, the model estimates will almost always differ from the measured concentrations. However, an understanding of the input uncertainty arising from errors in measurements, errors in estimation, non-representativeness of the data, etc., will enable proper interpretation of the modeling results.

As mentioned before, the numerical modeling approach adopted here is data-intensive. It should be recognized that errors stemming from sparsity of available data and the approximations used to generate information at each grid point for each variable will propagate through the model and affect the predicted concentrations. Quantification of the modeling uncertainty due to the uncertainty in the input data alone is an extremely difficult nonlinear problem. No attempts are made in this report to quantify the JAM limitations or uncertainties associated with the UAM application to the New York Metropolitan area because of the complexity of the problem. Evaluation of the modeling uncertainty is beyond the scope of this study.

CHAPTER 7

CONTROL STRATEGY SIMULATIONS

One of the primary objectives of this study was to evaluate whether selected control strategies on the precursor emissions would lead to the attainment of the NAAQS for ozone in the New York Metropolitan area. To this end, the UAM has been applied for five high ozone days occurring in the 1980 ozone season. Evaluation of the model performance in predicting the measured ozone levels revealed best performance of the model on two days - JD80203(072180) and JD80221(080880). Hence, these days were selected for assessing the impact of emissions control strategies on the ambient ozone concentrations. An emissions inventory based upon the 1982 State Implementation Plans (SIPs) for 1988 was prepared and the UAM simulation was performed for these two days with appropriate modifications to the initial and boundary air quality conditions, keeping the meteorological conditions the same as those for the 1980 base year cases. In this section, the results of the various control strategy scenarios are presented and are compared with the base case(s) to evaluate the effect of emissions reduction plans on the ambient ozone concentrations in the study region.

7.1 Initial and Boundary Conditions

The methodology adopted for defining the initial and boundary conditions for the control strategy simulations was as follows. For the initial conditions, a comparison was made between the projected 1988 NO_x and VOC emissions and those of the 1980 base case, and the percentage reductions for these two pollutants were calculated. These emissions reductions were then applied to scale the base year initial NO_x and VOC concentration fields from the surface up to the top of vertical layer 3 (through the mixed layer), under the assumption that the changes in the precursor emissions have a similar effect on the ambient concentration fields. The 1988 VOC and NO_x concentrations at the boundaries were obtained by reducing the base year boundary concentrations of VOC and NO_x by 40% and 20%, respectively, based upon the upwind region SIPs.

In the case of ozone, no direct methods are available to estimate the future year boundary and initial fields due to the changes in the precursor

emissions levels. Given that the ozone concentrations at the top of the modeling region for the five simulated days in the base year are in the range of 60 to 85 ppb, the proposed changes in the emissions both upwind and in the domain could result in a reduction of about 20 to 30% or in the 40 to 60 ppb range for ozone levels at the top of the modeling domain. These estimates are consistent with the suggested background levels (Wolff and Liou, 1978; Kelliher et. al., 1984). Another method is to apply the EKMA procedure (EPA, 1984) to estimate the expected changes in the ozone concentrations from changes in the VOC and NO_x levels. This procedure, results in a reduction of about 18% in ozone for an assumed change in the VOC and NO_x levels of 40% and 20%, respectively. In this study, as a first approximation, a 20% reduction from the ambient 1980 ozone levels was adopted for estimating the 1988 ozone concentrations for the region top and the initial and boundary fields. As an example of the 1988 boundary conditions, the changes in the NMHC and ozone concentrations for the southwest corner surface grid cell for the two days JD80203(072180) and JD80221(080880), are shown in Figure 7.1a and 7.1b, respectively.

7.2 Control Strategies

A set of six control strategy scenario simulations (CSSS), listed in Table 7.1, was performed to evaluate five control strategies proposed by the project (OMNYMAP) Policy and Technical Committees with three of the five strategies utilizing measures implemented and/or proposed in the current SIPs of the three states. The CSSS Runs 1 and 2 are based upon the projected 1988 emissions with the meteorological conditions prevailing on the days JD80203(072180) and JD80221(080880), respectively. The changes in the emissions resulting from the various control strategies are listed in Table 7.2. In the case of CSSS Runs 1 and 2, the reductions in VOC and NO_x emissions from the 1980 base year are 32% and 14%, respectively, while with implementation of the full SIP measures (CSSS Run 6), the reductions in the VOC's are estimated to be an additional 8% over the CSSS Run 1 case in the tri-state area. It should be noted that these changes in VOC and NO_x emissions are not uniform or across-the-board reductions but vary from grid cell to grid cell. The CSSS Runs 4,5, and 6 utilized the JD80203(072180) meteorological conditions but with the modified emissions while CSSS Run 3 was designed to investigate the effect on the ozone maximum due to the reduction of Connecticut VOC emissions from the base year 1980.

Summary of Control Strategy Scenario Simulations (CSSS)

- Run #1 Application of UAM using 1988 emissions inventory with JD80203(072180) meteorological conditions.
- Run #2 Application of UAM using 1988 emissions inventory with JD80221(080880) meteorological conditions.
- Run #3 Application of UAM with 1980 base year inventory excluding VOC emissions from Connecticut with JD80203(072180) meteorological conditions.
- Run #4 Application of UAM using 1988 emissions inventory with 50% reduction in NO_x from all sources in Connecticut only and JD80203(072180) meteorological conditions.
- Run #5 Application of UAM using 1988 emissions inventory with controls on gasoline vapors (marketing and motor vehicle) and JD80203(072180) meteorological conditions.
- Run #6 Application of UAM with full 1988 SIP (extraordinary measures) and JD80203(072180) meteorological conditions.

7.3 Results and Discussion

The spatial distributions of ozone for CSSS Runs 1 and 2 for the hours when peak concentrations are expected to occur are shown in Figure 7.2. For both days, the isopleths show the occurrence of a double peak similar to the base case although the peak value over the modeling domain has decreased from 229 ppb to 183 ppb for the JD80203(072180) case and from 145 ppb to 130 ppb for the JD80221(080880) case. The relative reduction in the peak concentration is approximately 19% in both cases for an emissions reduction of 32% in the VOC's and 14% in the NO_x over the modeling domain from the base year. The areal extent of the decrease in the level of ozone exceedances was examined by counting the number of cells equal to or exceeding the concentration of 125 ppb for each hour starting at 0900. This is shown as a histogram plot in Figure 7.3 both for the entire modeling domain (667 cells) as well as for the Connecticut region alone (208 cells). On a percentage basis for the peak ozone hour of 1500, the decrease in the number of cells (areal extent) is about 50% for JD80203(072180) compared with about 20% for the JD80221(080880) case for the entire domain as well as for the Connecticut region for the peak ozone hour of 1500. This may be due to the differences in the prevailing meteorological and initial/boundary conditions on these two days.

The runs, CSSS Run 5 and Run 6, are an extension of the control strategies to further reduce the 1988 emissions with the imposition of additional controls on gasoline vapors in New York and Connecticut (marketing and motor vehicles - CSSS Run 5) and the implementation of controls on (a)architecture coatings, (b)auto body refinishing, (c)consumer/commercial solvents, and (d) small source RACT (CSSS Run 6). Under the CSSS Run 5 scenario, the estimated reduction in the 1988 VOC emissions was an additional 2%, while for CSSS Run 6, the reduction was about 6% from the base 1988 emissions level (CSSS Run 1). To compare the effects of emissions reductions on ozone levels, the predicted concentration fields for CSSS Run 5 were subtracted from those of CSSS Run 1 for the hours of highest concentrations (1400 and 1500 Hrs) and are shown in Figure 7.4. The differences are of the order of 1 ppb over the Connecticut region which is essentially within the noise range and, therefore, the additional controls in New York and Connecticut arising from CSSS Run 5 have very little impact on the reduction of the ozone levels in the domain on this day.

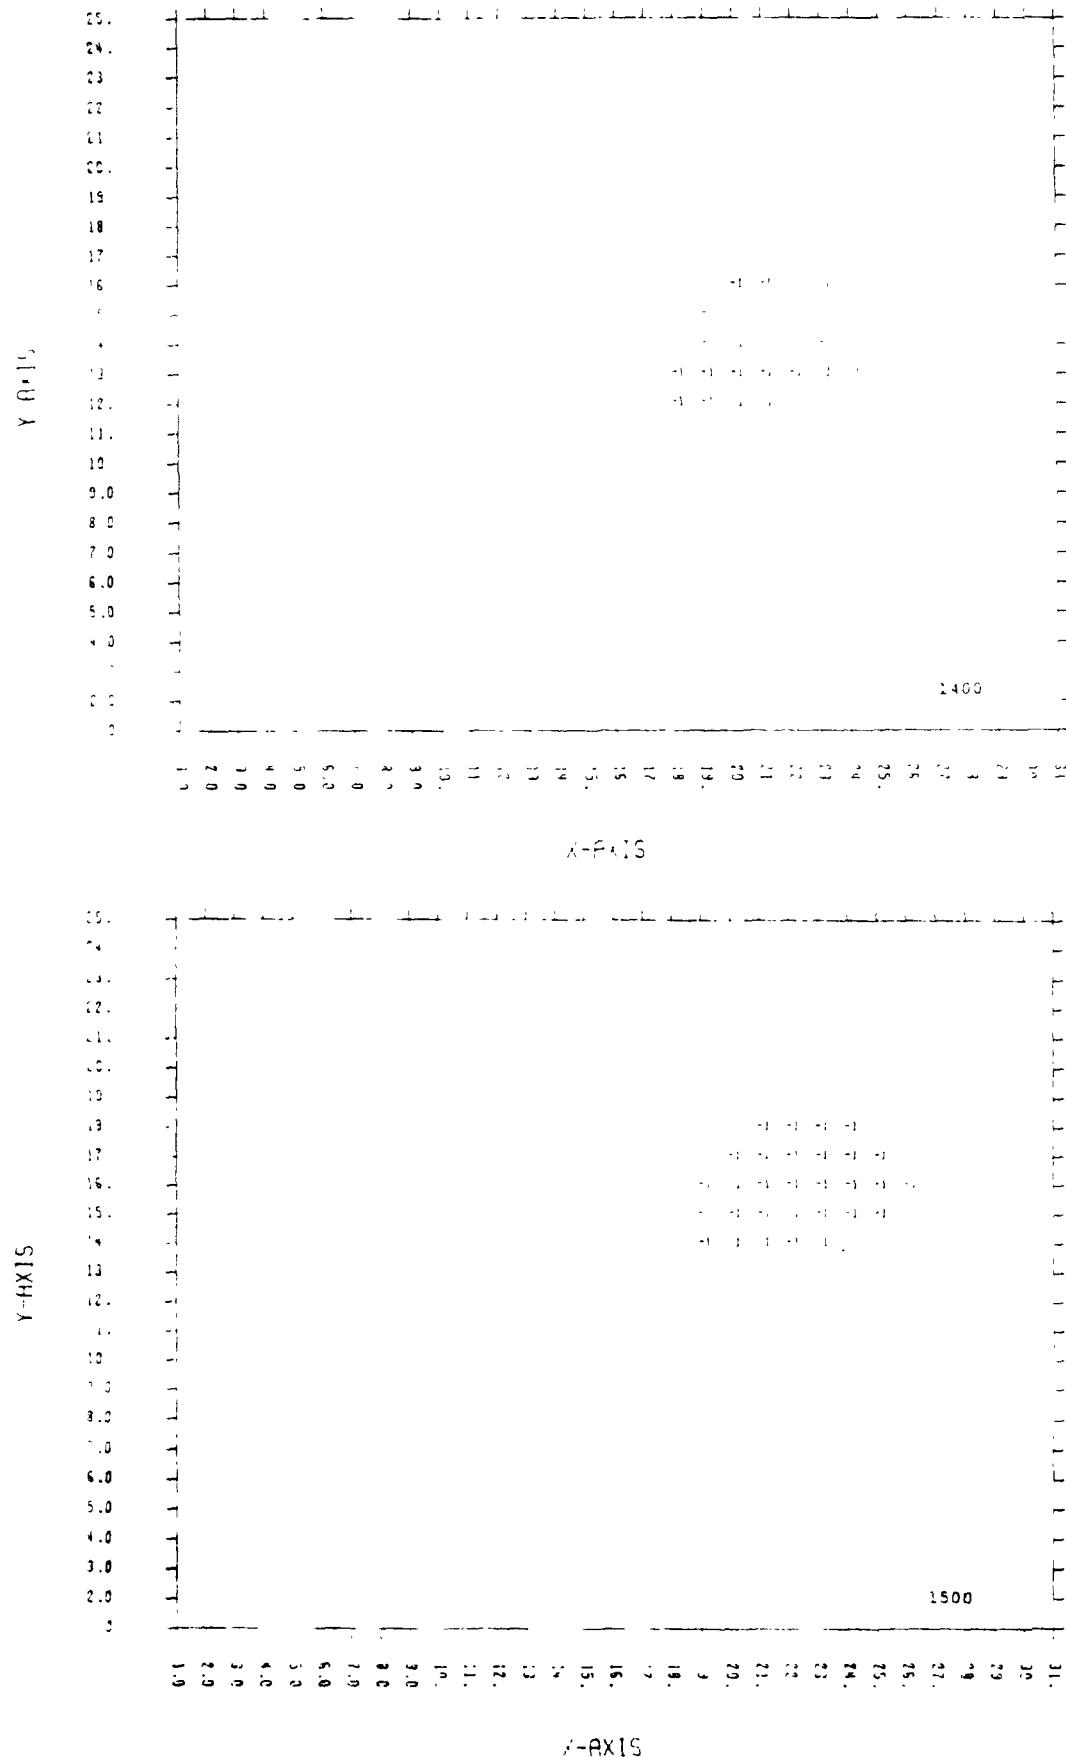

Figure 7.4 Difference Map of Ozone Concentrations (ppm) Between
CSSS Run 5 and CSSS Run 1 at 1400 and 1500 Hours

In Figure 7.5 are shown the ozone isopleths for CSSS Run 6. The peak ozone concentration is 175 ppb compared with 185 ppb in the case of CSSS Run 1. The areal extent or the number of cells equal to or exceeding 125 ppb for CSSS Run 6 is shown in Figures 7.3a and 7.3b for the entire domain and for the Connecticut region only. Comparisons between the results of CSSS Run 1 and CSSS Run 6 reveal that the percentage changes in the areal extent is in the range of 0 to 10% for the entire domain, as well as for the Connecticut region alone. Although the controls identified under CSSS Run 6 are not explicitly evaluated with the meteorological conditions prevailing on JD80221(080880), from a comparison of the results of CSSS Run 2 with the corresponding base case it should become evident that these emissions reductions cannot result in ozone concentrations below the level of the ozone NAAQS. Thus, while the reduction in emissions under CSSS Run 6 has resulted in a further reduction in the areal extent of the ozone exceedances, these strategies cannot reduce the peak ozone concentration in the New York Metropolitan area to the level of the ozone NAAQS.

Two other runs, CSSS Run 3 and CSSS Run 4, were performed to evaluate the effects of emissions controls imposed over the Connecticut region only. In CSSS Run 3 the 1980 base year inventory was utilized to exclude all VOC emissions from the Connecticut region, and CSSS Run 4 was based upon a 50% reduction in the 1988 NO_x emissions from Connecticut. The results of these two simulations are presented in terms of the difference maps in Figures 7.6a and 7.6b. In the case of CSSS Run 3, the decrease in the ozone levels is on the order of 6 to 8 ppb over the northeast portion of the domain, while in the case of CSSS Run 4, the change is ± 3 ppb. Thus, these reductions of VOC and NO_x emissions in the Connecticut area alone have minimal or no effect on the predicted ozone levels over the modeling domain.

In summary, the UAM simulations for the two days with the control measures identified in the SIPs for the New York Metropolitan area demonstrate that (a) there is an overall improvement in the ozone concentration levels from the 1980 base year, and (b) the peak ozone concentrations would not likely be reduced to levels at or below that of the ozone NAAQS in the 1988 ozone season.

CHAPTER 8

SENSITIVITY ANALYSIS

Analysis of the control strategy options considered in this study indicates that significant portions of the modeling domain will continue to exceed the NAAQS for ozone during the 1988 ozone season. To understand how some of the input variables affect the predicted ozone concentrations, six sensitivity runs were performed with this data base. For each of these runs, meteorological conditions prevailing on JD80203(072180) were considered, since model evaluation results indicate "best" model performance on this day, with variations in the UAM input data bases of initial and boundary concentrations and emissions. In this section the methodology adopted to perform the sensitivity runs is presented along with the results and their implications.

8.1 Initial and Boundary Concentrations

A set of initial concentrations for the pollutants NMHC, NO_x, O₃, and CO was selected to be representative of "clean" background conditions and is reflective of "minimum" ambient concentration levels. The pollutant concentrations for the "clean" conditions, listed in Table 8.1, are assumed to be uniform across the domain. Similarly, when a "clean" boundary condition was desired, the concentrations in Table 8.1 were used for the boundaries as well as for the region top.

The sensitivity tests were designed to evaluate the influence of initial and boundary concentrations and emissions on the predicted ozone concentrations in the modeling domain. A total of six sensitivity runs, listed in Table 8.2, were performed and the results are discussed below.

8.1.1 Sensitivity Run 1

This simulation was designed to evaluate the effects of initial conditions with "clean" air influx into the modeling domain; the emissions in the domain were "turned off". The initial conditions at the beginning of the simulation reflect the interaction of the base year emissions in the domain up to the start

se case corresponds to 1980 emissions with realistic initial, boundary and region top concentration and predicted peak ozone concentration of 229 ppb over Connecticut (see figure 6.2).

* CSSS Run 1 corresponds to 1988 emissions with realistic initial, boundary, and region top concentrations (Table 7.1), and predicted peak ozone concentration of 185 ppb over Connecticut (Figure 7.2).

of the simulation as well as pollutant transport from upwind regions. A peak ozone value of 107 ppb was predicted in the Connecticut region with lower concentrations over the rest of the modeling domain. This run demonstrates that even with the exclusion of emissions and pollutant transport into the modeling domain, reasonable initial conditions alone could produce ozone levels of the order of 100 ppb.

8.1.2 Sensitivity Run 2

In this simulation, the effect of 1988 emissions alone was evaluated by imposing "clean" pollutant levels both for the initial concentration fields and for the boundary (transport) conditions. The peak value of ozone formed under these conditions was 43 ppb over the Connecticut region, far below the levels projected from CSSS Run 1, indicating the importance of the role of the initial as well as pollutant influx through the lateral boundaries and region top.

8.1.3 Sensitivity Run 3

In contrast to the previous run where "clean" conditions were considered for the initial and transported pollutant fields, this run incorporates "realistic" initial and transported pollutant concentrations from CSSS Run 1 with the emissions "turned off". The effect of these "realistic" conditions is that over the Connecticut region an ozone peak value of 158 ppb was predicted with concentrations exceeding 125 ppb for parts of New York and New Jersey. The areal distribution of ozone for 1400 Hrs., shown in Figure 8.1, has the characteristic double peak formation, revealing the importance of the "realistic" initial and boundary fields.

8.1.4 Sensitivity Run 4

In this run, the influence of the peak ozone levels formed from the lateral transport of pollutants into the domain is examined by setting the concentrations at the top of the region to the "clean" level while retaining the boundary conditions to reflect those of CSSS Run 1. Also, the initial pollutant fields were set to the "clean" conditions with no emissions in the domain. This

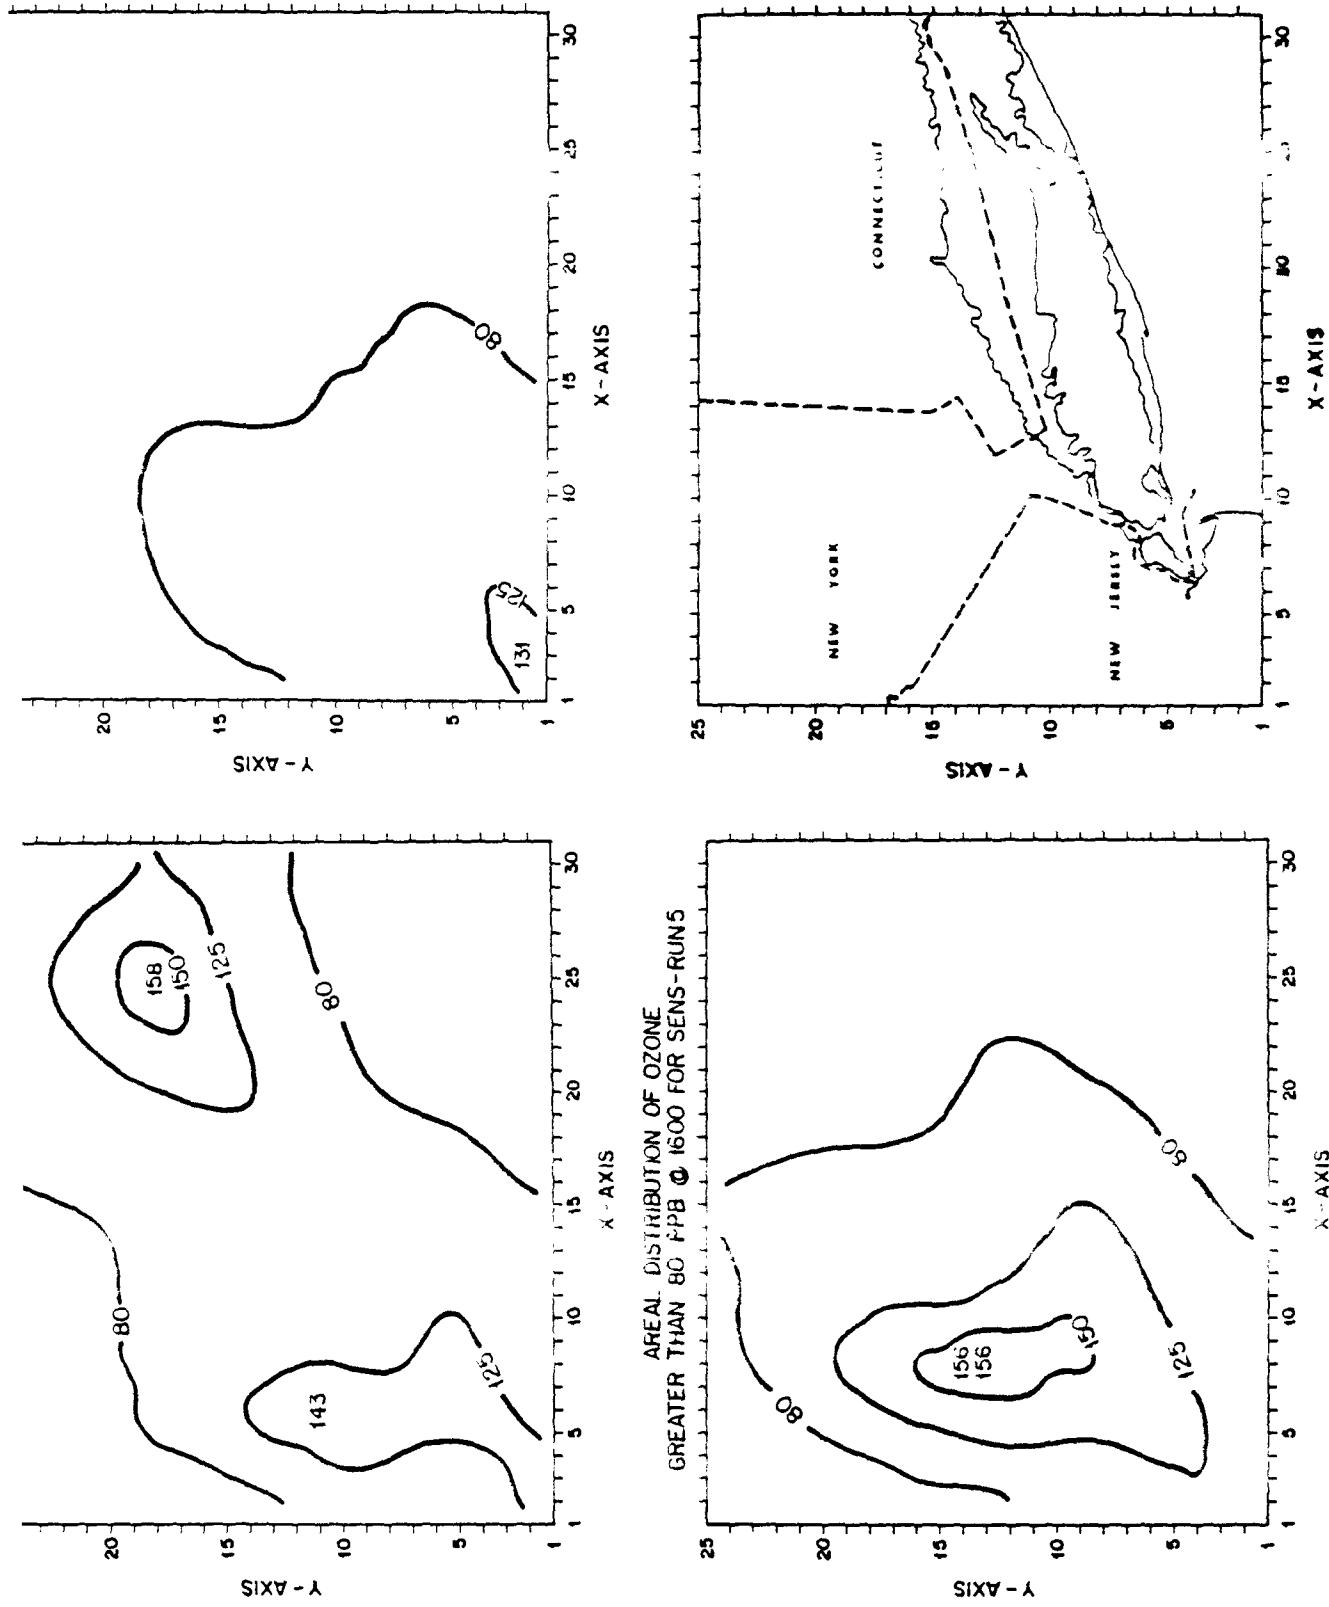

Figure 8.1 Ozone Isopleths (ppb) for Sensitivity runs 3, 4 and 5

simulation, shown in Figure 8.1, indicates ozone concentrations exceeding 125 ppb over New Jersey, and levels reaching 100 and 50 ppb over New York and Connecticut, respectively. This suggests that the boundary fields play a role in the generation of the peak over the New Jersey - New York area in addition to contributing to the peak over the Connecticut region.

8.1.5 Sensitivity Run 5

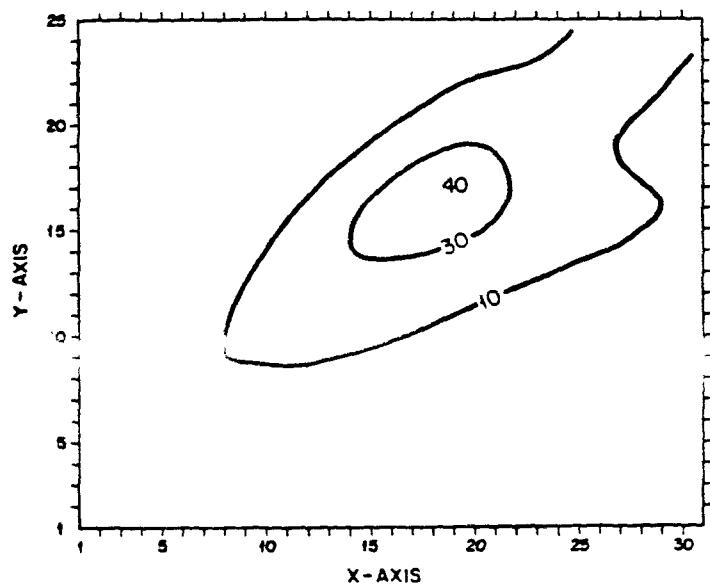

This run complements the previous run such that the pollutant concentrations at the top of the region were set to those of CSSS Run 1, or to the "realistic" levels. There were no emissions within the domain and the initial pollutant fields were set to the "clean" conditions. The areal distribution of ozone for this simulation, shown in Figure 8.1, has wide areas exceeding 125 ppb over much of New Jersey, New York and portions of southwestern Connecticut. This simulation, in contrast to sensitivity Run 3, demonstrates the role of the initial conditions on the prediction of peak ozone levels over Connecticut.

8.1.6 Sensitivity Run 6

In this run, the effect of inclusion of emissions with realistic initial conditions and "clean" concentrations for the region top and boundaries was examined. This run can be compared with Sensitivity Run 2 in which the initial conditions and transported pollutants were set to the "clean" level. This simulation yields no exceedances of the ozone NAAQS over New Jersey or New York but predicts a peak ozone value of 158 ppb over the Connecticut region. In Figure 8.2 are shown the areal distributions for selected hours for Sensitivity Runs 1 and 6. In both cases no second ozone peak was formed over the New Jersey-New York region indicating the effect of "clean" boundary concentrations. The peak arising from the realistic initial pollutant concentrations in this run shows areas of exceedances of the NAAQS, while with the "clean" conditions it is well below the standard, indicating the influence and importance of the initial pollutant fields.

8.2 Discussion

Six sensitivity runs were performed to examine the effects of transport of pollutants into the New York Metropolitan area coupled with the emissions from the region. In all these runs, the adopted boundary conditions refer either to those included in Table 8.1 as the "clean" influx or to those adopted from CSSS Run 1, as discussed in Chapter 7. It would be prudent to assess whether the ozone concentrations exceeding 125 ppb during 1400 to 1600 Hrs. at the southwest boundary will affect the predicted concentration fields in the New Jersey area. Examination of the isopleths for Sensitivity Run 5 (see Figure 8.1) shows that the peak value of 156 ppb occurs approximately 120 km from the southwest boundary. During this period the winds were from a south-southwesterly direction at 4 to 5 m/s suggesting a travel time of 6 to 8 Hrs. for the airmass from the southwest boundary to reach the location of the peak concentration. Thus, these high ozone levels at this boundary should have little effect on the predicted peak ozone concentration in the New Jersey area. However, the cells near the southwest boundary could be affected by the transport of ozone exceeding 125 ppb (Sensitivity Run 4), and perhaps the peak ozone concentration of 131 ppb in Figure 8.1 could be attributed solely to this high ozone influx. Sensitivity Run 3, in which the emissions have been "turned off" predicts concentrations in excess of NAAQS over the modeling domain just from the initial concentrations and pollutant transport, while Sensitivity Run 6 reveals that "turning off" the influx of concentrations into the domain but including emissions will also result in similar exceedances of the NAAQS over the region. Furthermore, emissions alone within the domain, without the influence of the initial and boundary concentrations (Sensitivity Run 2), result in a peak ozone of 43 ppb over Connecticut. Thus, it is evident that controls or reductions in the emissions levels within the modeling domain should be coupled with reductions in ozone and its precursors transport from the upwind regions in developing meaningful strategies to meet and maintain the NAAQS for ozone in the New York Metropolitan area.

CHAPTER 9

SUMMARY AND CONCLUSIONS

In this study, the Urban Airshed Model (UAM) was used to simulate five high ozone days in the 1980 ozone season. These five days were characterized by exceedances of the ozone NAAQS over wide areas of the New York Metropolitan region consisting of portions of the States of New Jersey, New York, and Connecticut. Typical meteorological conditions associated with high ozone days are as follows: (a) winds from the south to southwest at 4 to 5 m/s, (b) surface temperatures in excess of 80's°F, and (c) a high pressure system over the Atlantic, ridged westward through the southern states.

The New York Metropolitan area lies within the emissions-rich Northeast urban corridor with significant inter-urban transport of ozone and its precursors. All five days simulated show the occurrence of two peaks, one over central Connecticut attributable primarily to emissions from the NY/NJ area, and the other over the northeastern New Jersey and New York border areas attributable to the influx of ozone and its precursors into the modeling domain from the upwind boundary.

The first part of the study was designed to adopt the UAM to the New York Metropolitan area, and to assess the model's performance in simulating observed ozone concentrations. Analysis of modeling results revealed that although the model underpredicts the peak concentrations over the modeling domain, the performance of the model in predicting within the $\pm 30\%$ envelope of the measured concentration levels is reasonable both on an individual day basis as well as on an ensemble basis. The performance statistics of concentrations greater than 100 ppb over the entire modeling domain or over the New Jersey-New York region or over the Connecticut region revealed that at least 60% of the model predictions were within the $\pm 30\%$ of their corresponding observed concentrations.

Of the five days that were simulated, two days, JD80203(072180) and JD80221(080880), were used in the detailed evaluation of the control measures identified in the State Implementation Plans of the three states for attaining the NAAQS for ozone. The reductions in the VOC and NO_x emissions in the modeling region in 1988 were estimated to be 32% and 14%, respectively, from the

1980 base year emissions. Assuming that the SIP and motor vehicle reductions in the upwind emissions will occur in 1988, concentration levels at the boundaries were reduced by 40% in VOC, 20% in NO_x, and 20% in ozone from their 1980 levels. The UAM simulations for the two selected days with the projected 1988 emissions indicate that the peak ozone level over the Connecticut region decreases by about 20% from the 1980 level but is still well above the NAAQS for ozone. The decrease in the areal extent of exceedances of the NAAQS ranged from 10% to 50% depending upon the simulation day.

Adoption of additional extraordinary emissions controls, as envisioned under the SIPs, upon such source categories as architectural coatings, auto refinishing, consumer/commercial solvents and adoption of small source RACT for the 1988 emissions resulted in a 40% reduction in VOC from the 1980 base year. The UAM simulation using this 1988 emissions inventory revealed that these extraordinary control measures result in only a marginal improvement in the peak ozone level and in the areal extent of the ozone exceedances. Thus, it is evident that even with these proposed control measures of VOC and NO_x emissions in the New York Metropolitan area, the peak ozone levels can be expected to be well above the ozone NAAQS during the 1988 ozone season.

In an attempt to assess the influence of the initial and boundary conditions, and emissions on the predicted ozone levels, several model sensitivity simulations were performed using the JD80203(072180) meteorological conditions. The results indicate that even when the emissions in the New York Metropolitan area are "turned off", transport into the modeling domain alone could lead to exceedances of the NAAQS over the region. Peak ozone levels in this scenario are comparable to those predicted by a 40% VOC emissions reduction strategy (CSSS Run 6). Further, hypothetically "clean" air influx through the boundaries and "realistic" initial conditions and emissions also result in exceedance of the NAAQS. However, neither of these extreme cases, "turning off" the emissions in the modeling domain or having the modeling domain surrounded by "clean" boundaries, are realistic assumptions.

The results presented here strongly suggest that both emissions reductions within the New York Metropolitan area and further reductions in ozone and its precursors transport from the upwind areas are necessary to meet and maintain the ozone NAAQS in the region. Clearly, additional modeling analyses are needed to document the level of control required to achieve the NAAQS for ozone in the New York Metropolitan area.

APPENDIX A

Temporal and Speciation Factors for Area and Point Source Emissions

The total VOC and NO_x emission inputs were divided into the UAM required hydrocarbon species and/or NO-NO₂ splits using the data developed by Engineering Sciences for USEPA (EPA, 1982). Temporal factors for area source emissions detailed in the ES study were adopted in this application.

In the case of point source categories not included in the ES study, appropriate factors were determined based upon similarities in fuels burned and/or process description. For example, emissions from bituminous coal fired utility boilers were assumed to have the same component splits regardless of the manner in which the fuel was burned, and in the following Tables are listed the factors used in the OMNYMAP study:

APPENDIX B

Diurnal Plots of Predicted and Measured Ozone Concentrations

The diurnal variation of the measured and predicted ozone concentrations at the monitoring stations in the OMNYMAP domain, see Figure B-1, are presented for each of the five days. These diurnal plots presented in this manner are helpful in providing a qualitative assessment of the UAM performance.

SUPPLEMENTARY NOTES

ABSTRACT
The goals of the "Oxidant Modeling for the New York Metropolitan Area Project (NYMAP)" are to examine (a) the extent and magnitude of the ozone problem in the New York area; (b) the impact of specific control strategies committed to by New Jersey, New York and Connecticut in the 1982 State Implementation Plans (SIPs); (c) the role of pollutant transport from upwind regions; and (d) strategies to meet and maintain ozone AQS in the New York area. In this study, the urban AIRSHED model was used to simulate five high ozone days in the 1980 oxidant season. The model results were analyzed to assess the performance of the model in simulating the observed ozone concentrations. Examining the data set of ozone concentrations greater than 100 ppb reveals that 60% of the predicted values were within $\pm 30\%$ of their corresponding observed concentrations. However, the model has a tendency to underpredict the peak concentrations over the modeling domain. The results of simulating the emissions controls to be implemented by 1988 indicate that although there is a decrease in the peak ozone levels, predicted concentrations are well above the NAAQS for ozone. Even with the imposition of extraordinary emissions control measures, the results of a one day simulation reveal that the peak ozone level continues to be well above the NAAQS. Analysis of the sensitivity of the ozone predictions to specific model inputs indicates that pollutant transport is important and that additional modeling is necessary to quantify the level of controls required to meet the ozone NAAQS in this area.
