LIST OF ACRONYMS

AHA	American Hospital Association
AISI	American Iron and Steel Institute
$AlCl_3$	Aluminum Chloride
AMSA	Association of Metropolitan Sewerage Agencies
APC	Air Pollution Control
APCD	Air Pollution Control Device
atm	Atmosphere
ATSDR	Agency for Toxic Substances and Disease Registry
BAAQMD	Bay Area Air Quality Management District
BCF	Bioconcentration Factor
BDDs	Polybrominated Dibenzo-p-dioxins or PBDDS
BDFs	Polybrominated Dibenzofurans or PBDFs
BHF	Bag House Filter
Btu	British Thermal Unit
CAA	Clean Air Act
$CaCl_2$	Calcium Chloride
CARB	California Air Resources Board
CBI	Confidential Business Information
°C	Degree Celsius
CD	Compact Disk
CDDs	Polychlorinated Dibenzo-p-dioxins or PCDDs
CDFs	Polychlorinated Dibenzofurans or PCDFs
CEQ	Council on Environmental Quality
CERCLA	Comprehensive Environmental Response, Compensation and Liability Act (also know as Superfund)
C-ESP	Cold-side Electrostatic Precipitator
CETRED	Combustion Emissions Technical Resource Document
CFR	Code of Federal Regulations
CSF	Confidential Statement of Formula
CKD	Cement Kiln Dust
Cl^-	Chloride
Cl_2	Dichloride
cm	Centimeters
CO	Carbon Monoxide
CO_2	Carbon Dioxide
CRWQCB	California Regional Water Quality Control Board
CR	Confidence Rating
CuCl	Copper (Cupric) Chloride
$CuCl_2$	Copper (Cupric) Dichloride
D	Symbol for Congener Class: Dibenzo-p-dioxin
D	Symbol for di (i.e., Two Halogen Substitution)
DBF	Dibenzofuran
DCBz	Dichlorobenzene
DCI	Data Call-In

LIST OF ACRONYMS (continued)

DCP	Dichlorophenols
DHHS	U.S. Department of Health and Human Services
DL	Detection Limit
DOC	U.S. Department of Commerce
DOE	U.S. Department of Energy
d_p	Physical Diameter
dscm	Dry Standard Cubic Meter
DSI	Dry Sorbent Injection
EAF	Electric Arc Furnaces
EDC	Ethylene Dichloride
EEI	Edison Electric Institute
EF	Emission Factor
e.g.	For example
EGB	Electro Granular Bed
EIA	Energy Information Administration
EPA	U.S. Environmental Protection Agency
EPRI	Electric Power Research Institute
ESP	Electrostatic Precipitator
F	Symbol for Congener Class: Dibenzofuran
FF	Fabric Filter
^oF	Degree Fahrenheit
FB-RDF	Fluidized Bed Refuse-Derived Fuel
FCEM	Field Chemical Emissions Measurement
$FeCl_2$	Ferric (Iron) Dichloride
$FeCl_3$	Ferric (Iron) Trichloride
FGD	Flue Gas Desulfurization
FIFRA	Federal Insecticide, Fungicide, and Rodenticide Act
ft	Feet
ft^3	Cubic Feet
g	Gram
GAC	Granular Activated Carbon
GC-ECD	Gas Chromatography/Electron Capture Detector
GC-MS	Gas Chromatography/Mass Spectrometry
gplg	Grams Per Leaded Gallon
gpg	Gram Per Gallon
gr/dscf	Grains Per Dry Standard Cubic Foot
HAPs	Hazardous Air Pollutants
HCl	Hydrogen Chloride
HCBz	Hexachlorobenzene
HD	Heavy Duty
HDD	Polyhalogenated Dibenzo-p-Dioxins
HDF	Pollyhalogenated Dibenzofurans
H-ESP	Hot-side Electrostatic Precipitator
Hp	Symbol for Hepta (i.e., Seven Halogen Substitution)

hr	Hour
HWI	Hazardous Waste Incineration
Hx	Symbol for Hexa (i.e., Six Halogen Substitution)
HxCB	Hexachlorobiphenyl
i.e.	That Is
ITC	U.S. International Trade Commission
IUPAC	International Union of Pure and Applied Chemistry
J	Joules
KCl	Potassium Chloride
kg	Kilogram
km	Kilometer
kW	Kilowatt
L	Liter
lb	Pound
LII	Liquid Injection Incinerator
LOQ	Limits of Quantitation
M	Symbol for Mono (i.e., One Halogen Substitution)
MACT	Maximum Achievable Control Technologies
MB	Mass Burn
MB-RC	Mass Burn Rotary Kiln
MB-REF	Mass Burn Refractory-Walled
MB-WW	Mass Burn Waterwall
MCBz	Monochlorobenzene
MCP	Monochlorophenol
$MgCl_2$	Magnesium Chloride
MgO	Magnesium Oxide
μg	Microgram
mg	Milligram
mm	Millimeter
mol	Mole (Unit of Substance)
MOD/EA	Modular Excess Air
MOD/SA	Modular Starved Air
MSW	Municipal Solid Waste
MSWI	Municipal Solid Waste Incinerator
MWI	Medical Waste Incineration
m^2	Square Meter
m^3	Cubic Meter
Na	Sodium

LIST OF ACRONYMS (continued)

ND	Not Detected
NCEA	National Center for Environmental Assessment
NEG	Expected To Be Negligible or Non-existent
NESHAP	National Emission Standards for Hazardous Air Pollutants
$NiCl_2$	Nickel Chloride
NiO	Nickel Oxide
Nm^3	Standard Cubic Meter
NMOC	Nonmethane Organic Compounds
NR	Not Reported
NYSDEC	New York State Department of Environmental Conservation
NYSDOH	New York State Department of Health
O	Symbol for Octa (i.e., Eight Halogen Substitution)
OAQPS	Office of Air Quality Planning and Standards
O_2	Molecular Oxygen
OH	Hydroxide ion
OMS	Office of Mobile Sources
OPP	Office of Pesticide Programs
OPPT	Office of Pollution Prevention and Toxics
ORD	Office of Research and Development
OSW	Office of Solid Waste
Pa	Pascals (i.e., Unit of Pressure)
PAH	Polycyclic Aromatic Hydrocarbons
Pb	Lead
PBDDs	Polybrominated Dibenzo-p-dioxins or BDDs
PBDFs	Polybrominated Dibenzofurans or BDFs
PBS	Packed Bed Scrubber
PCA	Portland Cement Association
PCBs	Polychlorinated Biphenyls
PCDDs	Polychlorinated Dibenzo-p-dioxins or CDDs
PCDFs	Polychlorinated Dibenzofurans or CDFs
PCP	Pentachlorophenol
PCP-Na	Pentachlorophenate
PCT	Polychlorinated Terphenyl
Pe	Symbol for Penta (i.e., Five Halogen Substitution)
PeCB	Pentachlorobiphenyl
PeCBz	Pentachlorobenzene
pg	Picogram
PL	Public Law
PM	Particulate Matter
POM	Polycyclic Organic Matter
POTW	Publicly Owned Treatment Works
ppb	Parts Per Billion
ppm	Parts Per Million
ppmv	Parts Per Million (Volume Basis)

LIST OF ACRONYMS (continued)

ppq	Parts Per Quadrillion
ppt	Parts Per Trillion

1.0. BACKGROUND AND SUMMARY

1.1. BACKGROUND

This reassessment is comprised of three reports:

Part 1. *Estimating Exposure to Dioxin-Like Compounds* (U.S. EPA, 2000b) (which expanded upon a 1988 draft exposure report titled, *Estimating Exposure to 2,3,7,8-TCDD* [U.S. EPA, 1988d]);
Part 2. *Health Assessment of 2,3,7,8-Tetrachlorodibenzo-p-Dioxin (TCDD) and Related Compounds* (U.S. EPA, 1994a; U.S. EPA, 2000c); and
Part 3. *Dioxin: Integrated Summary and Risk Characterization for 2,3,7,8-Tetrachlorodibenzo-p-Dioxin (TCDD) and Related Compounds* (U.S. EPA, 2000d).

Throughout the remainder of this document, these three parts as a whole will be abbreviated as the Reassessment Documents, and the individual parts will be referred to as the Exposure Reassessment Document, the Health Reassessment Document, and the Risk Characterization. The Exposure Reassessment Document has expanded to three volumes, as discussed below. Volumes 1 and 2 of the Exposure Reassessment Document are summarized in Section 4 of the Risk Characterization.

The process for developing the Reassessment Documents has been open and participatory. Each of the documents has been developed in collaboration with scientists from inside and outside the Federal Government. Each document has undergone extensive internal and external review, including review by EPA's Science Advisory Board (SAB). In September 1994, drafts of each document were made available for public review and comment. This included a 150-day comment period and 11 public meetings around the country to receive oral and written comments. These comments, along with those of the SAB (U.S. EPA, 1995a), have been considered in the drafting of this final document. The Dose-Response Chapter of the Health Document underwent peer review in 1997 (U.S. EPA, 1997a); an earlier version of the Integrated Summary and Risk Characterization underwent development and review in 1997 and 1998, and comments have been incorporated. In 1998, EPA released a workshop review version of the sources inventory (U.S. EPA, 1998a), one of the three volumes of the Exposure Reassessment Document. In

addition, as requested by the SAB, a chapter on Toxic Equivalency has been developed and underwent external peer review in parallel with the Integrated Summary and Risk Characterization in July 2000. The November 2000, review by the SAB of the Dose-Response Chapter, the Toxic Equivalency Chapter and the Integrated Summary and Risk Characterization was the final step in this open and participatory process of reassessment. The full set of background documents and the integrative summary and risk characterization replace the previous dioxin assessments as the scientific basis for EPA decision-making.

The final Exposure Reassessment Document reflects changes made as a result of both review comments and analyses of a variety of other types of information that has come available. These include relevant information obtained from published peer-reviewed literature, EPA program offices, and other Federal agencies. This version of the Exposure Reassessment Document is current in this regard through 2000.

The purpose of the Exposure Reassessment Document is threefold: 1) to inventory the known sources of release of dioxins into the environment, 2) to develop an understanding of dioxins in the environment, including fate and transport properties, environmental and exposure media concentrations, background as well as elevated exposures, and temporal trends in exposure, and 3) provide site-specific procedures for evaluating the incremental exposures due to specific sources of dioxin-like compounds. Following this structure, the Exposure Reassessment Document is presented in three volumes:

Volume 1 - Sources of Dioxin-Like Compounds in the United States

This volume presents a comprehensive review of known sources of environmental releases of dioxin-like compounds in the United States. It includes an inventory of known source activity in terms of estimates of annual releases of dioxin-like compounds into the U.S. environment (i.e., air, water and land). This inventory is specific for two reference years, 1987 and 1995. From these data, it is possible to compare and contrast releases of dioxin-like compounds among the sources and between the reference years.

Volume 2 - Properties, Environmental Levels, and Background Exposures

This volume presents and evaluates information on the physical-chemical properties, environmental fate, environmental and exposure media levels, background and elevated human exposures, and temporal trends of dioxin-like compounds in the U.S. environment during the 20th century.

Volume 3 - Site-Specific Assessment Procedures

This volume presents procedures for evaluating the incremental impact from sources of dioxin release into the environment. The sources covered include contaminated soils, stack emissions, and point discharges into surface water. This volume includes sections on: exposure parameters and exposure scenario development; stack emissions and atmospheric transport modeling; aquatic and terrestrial fate, and food chain modeling; demonstration of methodologies; and uncertainty evaluations including exercises on sensitivity analysis and model validation, review of Monte Carlo assessments conducted for dioxin-like compounds, and other discussions.

The primary technical resource supporting the development of the inventory of sources of dioxin-like compounds discussed in Volume I (above) is the Database of Sources of Environmental Releases of Dioxin-Like Compounds in the United States (EPA/600/C-01/012. March, 2001). This database includes congener-specific CDD and CDF emissions data extracted from original engineering test reports. It has been published independently from the Reassessment and is available on Compact Disk-Read only Memory (CD-ROM), without cost, from EPA's National Service Center for Environmental Publications (NSCEP) in Cincinnati, Ohio (telephone: 1-800-490-9198, or 513-489-8190; fax: 513-489-8695). Summary files from the database will be available for downloading from the Web page of the National Center for Environmental Assessment, www.epa.gov/ncea/dioxin.htm. Instructions on how to order and obtain the CD-ROM will also be available on the Web page.

1.2. DEFINITION OF DIOXIN-LIKE COMPOUNDS

This assessment addresses specific compounds in the following chemical classes: polychlorinated dibenzo-*p*-dioxins (PCDDs or CDDs), polychlorinated dibenzofurans (PCDFs

or CDFs), polybrominated dibenzo-*p*-dioxins (PBDDs or BDDs), polybrominated dibenzofurans (PBDFs or BDFs), and polychlorinated biphenyls (PCBs), and describes this subset of chemicals as "dioxin-like." Dioxin-like refers to the fact that these compounds have similar chemical structure, similar physical-chemical properties, and invoke a common battery of toxic responses. Because of their hydrophobic nature and resistance towards metabolism, these chemicals persist and bioaccumulate in fatty tissues of animals and humans. The CDDs include 75 individual compounds; CDFs include 135 different compounds. These individual compounds are referred to technically as congeners. Likewise, the BDDs include 75 different congeners and the BDFs include an additional 135 congeners. Only 7 of the 75 congeners of CDDs, or of BDDs, are thought to have dioxin-like toxicity; these are ones with chlorine/bromine substitutions in, at a minimum, the 2, 3, 7, and 8 positions. Only 10 of the 135 possible congeners of CDFs or of BDFs are thought to have dioxin-like toxicity; these also are ones with substitutions in the 2, 3, 7, and 8 positions. This suggests that 17 individual CDDs/CDFs, and an additional 17 BDDs/BDFs, exhibit dioxin-like toxicity. The database on many of the brominated compounds regarding dioxin-like activity has been less extensively evaluated, and these compounds have not been explicitly considered in this assessment.

There are 209 PCB congeners. Only 13 of the 209 congeners are thought to have dioxin-like toxicity; these are PCBs with 4 or more lateral chlorines with 1 or no substitution in the ortho position. These compounds are sometimes referred to as coplanar, meaning that they can assume a flat configuration with rings in the same plane. Similarly configured polybrominated biphenyls (PBBs) are likely to have similar properties. However, the database on these compounds with regard to dioxin-like activity has been less extensively evaluated, and these compounds have not been explicitly considered in this assessment. Mixed chlorinated and brominated congeners of dioxins, furans, and biphenyls also exist, increasing the number of compounds potentially considered dioxin-like within the definitions of this assessment. The physical/chemical properties of each congener vary according to the degree and position of chlorine and/or bromine substitution. Very little is known about occurrence and toxicity of the mixed (chlorinated and brominated) dioxin, furan, and biphenyl congeners. Again, these compounds have not been explicitly considered in this assessment. Generally speaking, this assessment focuses on the 17 CDDs/CDFs and a few of the coplanar PCBs that are frequently encountered in

source characterization or environmental samples. While recognizing that other "dioxin-like" compounds exist in the chemical classes discussed above (e.g., brominated or chlorinated/brominated congeners) or in other chemical classes (e.g., halogenated naphthalenes or benzenes, azo- or azoxybenzenes), the evaluation of less than two dozen chlorinated congeners is generally considered sufficient to characterize environmental "dioxin."

The chlorinated dibenzodioxins and dibenzofurans are tricyclic aromatic compounds with similar physical and chemical properties. Certain of the PCBs (the so-called coplanar or mono-ortho coplanar congeners) are also structurally and conformationally similar. The most widely studied of this general class of compounds is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). This compound, often called simply "dioxin," represents the reference compound for this class of compounds. The structure of TCDD and several related compounds is shown in Figure 1-1. Although sometimes confusing, the term "dioxin" is often also used to refer to the complex mixtures of TCDD and related compounds emitted from sources, or found in the environment or in biological samples. It can also be used to refer to the total TCDD "equivalents" found in a sample. This concept of toxic equivalency is discussed below.

1.3. TOXIC EQUIVALENCY FACTORS

CDDs, CDFs, and PCBs are commonly found as complex mixtures when detected in environmental media and biological tissues, or when measured as environmental releases from specific sources. Humans are likely to be exposed to variable distributions of CDDs, CDFs, and dioxin-like PCB congeners that vary by source and pathway of exposures. This complicates the human health risk assessment that may be associated with exposures to variable mixtures of dioxin-like compounds. In order to address this problem, the concept of toxic equivalency has been considered and discussed by the scientific community, and TEFs have been developed and introduced to facilitate risk assessment of exposure to these chemical mixtures.

On the most basic level, TEFs compare the potential toxicity of each dioxin-like compound comprising the mixture to the well-studied and understood toxicity of TCDD, the most toxic member of the group. The background and historical perspective regarding this procedure is described in detail in Part II, Chapter 9, Section 9.1, 9.2, and in Agency

documents (U.S. EPA, 1987e; 1989a,b; 1991i). This procedure involves assigning individual TEFs to the 2,3,7,8-substituted CDD/CDF congeners and "dioxin-like" PCBs. To accomplish this, scientists have reviewed the toxicological databases along with considerations of chemical structure, persistence, and resistance to metabolism, and have agreed to ascribe specific, "order of magnitude" TEFs for each dioxin-like congener relative to TCDD, which is assigned a TEF of 1.0. The other congeners have TEF values ranging from 1.0 to 0.00001. Thus, these TEFs are the result of scientific judgment of a panel of experts using all of the available data and are selected to account for uncertainties in the available data and to avoid underestimating risk. In this sense, they can be described as "public health conservative" values. To apply this TEF concept, the TEF of each congener present in a mixture is multiplied by the respective mass concentration and the products are summed to represent the 2,3,7,8-TCDD Toxic Equivalence (TEQ) of the mixture, as determined by Equation (1-1):

$$TEQ \cong \sum_{i-n}\left(Congener_i \times TEF_i\right) + \left(Congener_j \times TEF_j\right) + ...\left(Congener_n \times TEF_n\right) \quad (1\text{-}1)$$

The TEF values for PCDDs and PCDFs were originally adopted by international convention (U.S. EPA, 1989a). Subsequent to the development of the first international TEFs for CDD/CDFs, these values were further reviewed and/or revised and TEFs were also developed for PCBs (Ahlborg et al., 1994; van den Berg et al., 1998). A problem arises in that past and present quantitative exposure and risk assessments may not have clearly identified which of three TEF schemes was used to estimate the TEQ. This reassessment introduces a new uniform TEQ nomenclature that clearly distinguishes between the different TEF schemes and identifies the congener groups included in specific TEQ calculations. The nomenclature uses the following abbreviations to designate which TEF scheme was used in the TEQ calculation:

1. I-TEQ refers to the International TEF scheme adopted by EPA in 1989 (U.S. EPA, 1989a). See Table 1-1.
2. TEQ-WHO_{94} refers to the 1994 WHO extension of the I-TEF scheme to include 13 dioxin-like PCBs (Ahlborg et al., 1994). See Table 1-2.

3. TEQ-WHO_{98} refers to the 1998 WHO update to the previously established TEFs for dioxins, furans, and dioxin-like PCBs (van den Berg et al., 1998). See Table 1-3.

The nomenclature also uses subscripts to indicate which family of compounds is included in any specific TEQ calculation. Under this convention, the subscript D is used to designate dioxins, the subscript F to designate furans and the subscript P to designate PCBs. As an example, "TEQ_{DF}-WHO_{98}" would be used to describe a mixture for which only dioxin and furan congeners were determined and where the TEQ was calculated using the WHO_{98} scheme. If PCBs had also been determined, the nomenclature would be "TEQ_{DFP}-WHO_{98}." Note that the designations TEQ_{DF}-WHO_{94} and I-TEQ_{DF} are interchangeable, as the TEFs for dioxins and furans are the same in each scheme. Note also that in this document, I-TEQ sometimes appears without the D and F subscripts. This indicates that the TEQ calculation includes both dioxins and furans.

This reassessment recommends that the WHO_{98} TEF scheme be used to assign toxic equivalency to complex environmental mixtures for assessment and regulatory purposes. Sections in the Health Reassessment Document, and summarized in the Risk Characterization, describe the mode(s) of action by which dioxin-like chemicals mediate biochemical and toxicological actions. These data provide the scientific basis for the TEF/TEQ methodology. In its 20-year history, the approach has evolved, and decision criteria supporting the scientific judgment and expert opinion used in assigning TEFs has become more transparent. Numerous states, countries, and several international organizations have evaluated and adopted this approach to evaluating complex mixtures of dioxin and related compounds. It has become the accepted methodology, although the need for research to explore alternative approaches is widely endorsed. Clearly, basing risk on TCDD alone or assuming all chemicals are equally potent to TCDD is inappropriate on the basis of available data. Although uncertainties in the use of the TEF methodology have been identified (which are described in detail in the Health Reassessment Document, Chapter 9, Section 9.5), one must examine the use of this method in the broader context of the need to evaluate the potential public health impact of complex mixtures of persistent, bioaccumulative chemicals. It can be generally concluded that the use of TEF methodology for evaluating complex mixtures of dioxin-like compounds decreases the overall uncertainties in the risk assessment process as compared to alternative approaches.

Use of the latest consensus values for TEFs assures that the most recent scientific information informs this "useful, interim approach" (U.S. EPA, 1989a; Kutz et al., 1990) to dealing with complex environmental mixtures of dioxin-like compounds. As stated by the U.S. EPA Science Advisory Board (U.S. EPA, 1995a), "The use of the TEFs as a basis for developing an overall index of public health risk is clearly justifiable, but its practical application depends on the reliability of the TEFs and the availability of representative and reliable exposure data." EPA will continue to work with the international scientific community to update these TEF values to assure that the most up-to-date and reliable data are used in their derivation and to evaluate their use on a periodic basis.

A chemical is assigned a TEF value based on all the available data comparing the chemical to either TCDD or PCB 126. In addition, there are weighting criteria that place more emphasis on chronic and subchronic studies examining toxic endpoints (van den Berg et al., 1998). There is a broad range in the quantity and quality of the data available for individual congeners. For example, the TEF for PCB 126 is based on over 60 in vivo endpoints examining responses as diverse as enzyme induction, developmental toxicity, immunotoxicity, hepatic toxicity, alterations in hormones and tumor promotion, while the TEF for 3,4,4',5-tetrachlorobiphenyl (PCB 81) is based on in vitro CYP1A induction and QSAR calculations. Fortunately, PCB 81 does not significantly contribute to human TEQ exposures. There are 5 congeners that contribute approximately 80% of the total TEQ in humans: 2,3,7,8-TCDD, 1,2,3,7,8-PCDD, 1,2,3,6,7,8-HxCDD, 2,3,4,7,8-PCDF, and PCB 126 (See Part I, Volume 2 and Section 4.4.3 of this document). With the exception of 1,2,3,6,7,8-HxCDD, the TEFs for these chemicals are based on a number of different endpoints from multiple studies performed in different laboratories. The TEF for 1,2,3,6,7,8-HxCDD is based on a two-year bioassay in which rats were exposed to a mixture of 1,2,3,6,7,8-HxCDD and 1,2,3,7,8,9-HxCDD. The TEFs for 2,3,4,7,8-PCDF and PCB 126 are similar to the mean REP value for all in vivo endpoints and are similar to their REPs for tumor promotion. The TEF for 12378-PCDD is based largely on its REP for tumor promotion in rats. From these data, it is clear that the chemicals that contribute approximately 80% to the total human TEQ are well studied and the assigned TEFs provide reasonable estimates of the relative potency of these chemicals. In contrast, while there are some chemicals in the TEF methodology which have minimal data sets to reliably

assess their relative potency, these chemicals do not contribute substantially to the human blood TEQ.

The ability of the TEF methodology to predict the biological effects of mixtures containing dioxin-like chemicals has been evaluated in a number of experimental systems. These studies generally demonstrate that the assumption of additivity provides a reasonable estimate of the dioxin-like potential of a mixture (described in the Health Reassessment Document, Chapter 9, Section 9.4). In addition, there are examples of non-additive interactions between dioxins and non-dioxins. Both greater than additive and less than additive interactions have been observed in these studies. In general the non-additive interactions between the dioxins and non-dioxins have been observed at doses that are considerably higher than present background human exposures.

There are a number of natural chemicals that bind and activate the aryl hydrocarbon receptor (AhR) and induce some dioxin-like effects. It has been proposed by some scientists that these chemicals contribute significantly to the total TEQ exposures and that these exposures far out weigh those from PCDDs, PCDFs and PCBs (Safe, 1995). While this hypothesis is intriguing, there are several limitations to these analyses. The in vivo data on the natural aromatic hydrocarbon receptor (AhR) ligands is limited to enzyme induction and a single developmental study. Few, if any, toxicology studies demonstrating clear dioxin-like toxicities have been published. The natural AhR ligands are rapidly metabolized and result in both transient tissue concentrations and transient effects. The natural ligands also have significant biological effects that are independent of the AhR and it is not clear as to the role of the AhR in the biological effects of these chemicals. Clearly this issue requires further research in order to better understand the relative potential health effect of dioxin and related chemicals as compared to natural AhR ligands.

One of the limitations of the use of the TEF methodology in risk assessment of complex environmental mixtures is that the risk from non-dioxin-like chemicals is not evaluated in concert with that of dioxin-like chemicals. Another limition of the TEF methodology is their application to non-biological samples. The fate and distribution of PCDDs, PCDFs and PCBs are not necessarily related to their TEF. Thus, the use of the TEF for non-biological media must be done cautiously. Future approaches to the assessment of environmental mixtures should focus on the development of methods that will allow risks to be predicted when multiple mechanisms are present from a variety of contaminants.

1.4. OVERVIEW OF SOURCES AND EMISSIONS INVENTORY METHODOLOGY

In the United States, the major identified sources of environmental release have been grouped into five broad categories for the purposes of this report:

- Combustion Sources: CDD/CDFs are formed in most combustion systems. These can include waste incineration (such as municipal solid waste, sewage sludge, medical waste, and hazardous wastes), burning of various fuels (such as coal, wood, and petroleum products), other high temperature sources (such as cement kilns), and poorly or uncontrolled combustion sources (such as forest fires, building fires, and open burning of wastes).

- Metals Smelting, Refining and Processing Sources: CDD/CDFs can be formed during various types of primary and secondary metals operations including iron ore sintering, steel production, and scrap metal recovery.

- Chemical Manufacturing: CDD/CDFs can be formed as by-products from the manufacture of chlorine bleached wood pulp, chlorinated phenols (e.g., pentachlorophenol - PCP), PCBs, phenoxy herbicides (e.g., 2,4,5-T), and chlorinated aliphatic compounds (e.g., ethylene dichloride).

- Biological and Photochemical Processes: Recent studies suggest that CDD/CDFs can be formed under certain environmental conditions (e.g., composting) from the action of microorganisms on chlorinated phenolic compounds. Similarly, CDD/CDFs have been reported to be formed during photolysis of highly chlorinated phenols.

- Reservoir Sources: Reservoirs are materials or places that contain previously formed CDD/CDFs or dioxin-like PCBs and have the potential for redistribution and circulation of these compounds into the environment. Potential reservoirs include soils, sediments, biota, water and some anthropogenic materials. Reservoirs become sources when they have releases to the circulating environment.

1.4.1. Overview and Organization of Source Analysis

Only sources judged to have a reasonable likelihood for releases to the "circulating environment" were addressed in ths document. Examples of the circulating environment system boundary are as follows:

- CDD/CDFs and dioxin-like PCBs in air emissions and wastewater discharges were included; whereas, CDD/CDFs and dioxin-like PCBs in intermediate products or internal wastestreams were excluded. For example, the CDD/CDFs in a wastestream going to an on-site incinerator would not be addressed in this

document, but any CDD/CDFs in the stack emissions from the incinerator would be included.

- CDD/CDFs and dioxin-like PCBs in wastestreams applied to land in the form of "land farming" are included; whereas, those disposed in permitted landfills were excluded. Properly designed and operated landfills are considered to achieve long-term isolation from the circulating environment. Land farming, however, involves the application of wastes directly to land, clearly allowing for releases to the circulating environment.

The sources addressed in this document (as defined above) can be divided into two subclasses: 1) contemporary formation sources (sources which have essentially simultaneous formation and release) and 2) reservoir sources (materials or places that contain previously formed CDD/CDFs or dioxin-like PCBs that are re-released to environment). The contemporary formation sources are discussed in Chapters 2 through 11 and the reservoir sources are discussed in Chapter 12. The presence of CDD/CDFs in ball clay is discussed in Chapter 13. Table 1-5 provides a comprehensive list of all known or suspected sources of CDDs/CDFs in the United States. The checkmarks indicate how each source was classified in terms of the following six categories:

- Contemporary formation sources with reasonably well quantified releases (referred to in this document as the Quantitative Inventory of Sources). These sources are listed in Table 1-5 and release estimates are shown in Tables 1-7 and 1-8.
- Contemporary formation sources with preliminary release estimates. These sources are listed in Table 1-5 and release estimates are shown in Tables 1-7 and 1-8.
- Contemporary formation sources without quantified release estimates. These sources are listed in Table 1-5.
- Reservoir sources with reasonably well quantified releases. These sources are listed in Table 1-5.
- Reservoir sources with preliminary release estimates. These sources are listed in Table 1-5 and release estimates are shown in Tables 1-7 and 1-8.
- Reservoir sources without quantified releases. These sources are listed in Table 1-5.

This document includes discussions on products which contain dioxin-like compounds. Some of these, such as 2,4-D, are considered to be sources since they are clearly used in ways that result in environmental releases. These products have been

classified into one of the above six groups. Other products containing dioxin-like compounds, such as vinyl chloride products, do not appear to have environmental releases and are not considered sources. For all CDD/CDF containing products, this document summarizes the available information about the contamination levels and, where possible, makes estimates of the total amount of CDD/CDF produced annually in these products. Estimates of the CDD/CDF TEQ amounts in products are summarized in Tables 1-11 and 1-12.

Throughout this document, environmental release estimates are presented in terms of TEQs. This is done for convenience in presenting summary information and to facilitate comparisons across sources. For purposes of environmental fate modeling, however, it is important to use the individual CDD/CDF and PCB congener values, rather than TEQs. This is because the physical/chemical properties of individual CDD/CDF congeners vary and, consequently, the congeners will behave differently in the environment. For example, the relative mix of congeners released from a stack cannot be assumed to remain constant during transport through the atmosphere and deposition to various media. The full congener-specific release rates for most sources are given in an electronic database which is available as a companion to this document (Database of Sources of Environmental Releases of Dioxin-Like Compounds in the United States, EPA/600/R-01/012). In Part I-Volume 3, site-specific procedures are provided for estimating the impact of emissions on local populations and emphasizes that congener-specific emission values should be used in modeling environmental fate. Finally, it is important to understand that this series of documents does not use source release estimates to generate background population intake/risk estimates (rather these estimates are derived in Volume 2 primarily from food levels and consumption rates).

1.4.2 Quantitative Inventory of Sources

EPA's Science Advisory Board (SAB) reviewed an earlier draft of the national dioxin source emissions inventory and commented that the effort was comprehensive and inclusive of most known sources (U.S. EPA, 1995f). However, the SAB emphasized that source emissions are time-dependant, and recommended that emissions be associated with a specific time reference. In consideration of this recommendation, EPA developed in this report emission estimates for two reference years: 1987 and 1995.

EPA selected 1987 primarily because, prior to this time, little empirical data existed for making source specific emission estimates. The first study providing the type of data needed for a national inventory was EPA's National Dioxin Study (U.S. EPA, 1987a). The year 1987 also corresponds roughly with the time when significant advances occurred in emissions measurement techniques and in the development of high resolution mass spectrometry and gas chromatography necessary for analytical laboratories to achieve low level detection of CDD and CDF congeners in environmental samples. Soon after this time, a number of facilities began upgrades specifically intended to reduce CDD/CDF emissions. Consequently, 1987 is also the latest time representative of the emissions occurring before widespread installation of dioxin-specific emission controls.

EPA selected 1995 as the latest time period that could practically be addressed consistent with the time table for producing the rest of the document. The data collected in the companion document to this document on CDD/CDF and dioxin-like PCB levels in environmental media and food were used to characterize conditions in the mid-1990s. So the emissions data and media/food data in these two volumes are presented on a roughly consistent basis. Since 1995, EPA has promulgated regulations limiting CDD/CDF emissions for a number of the source categories that contribute to the inventory including municipal waste combustors, medical waste incinerators, hazardous waste incinerators, cement kilns burning hazardous waste, and pulp and paper facilities using chlorine bleached processes. Consequently, the estimate of releases in the1995 inventory should not be assumed to accurately represent post-1995 releases. EPA intends to periodically revise this inventory.

A key element of the inventory is the method of extrapolation from tested facilities to national estimates of environmental releases. Because not every U.S. facility in each of the source categories have been tested for CDD/CDF emissions and releases, an extrapolation procedure was developed to estimate national emissions for most source categories. Many of the national emission estimates were, therefore, developed using a "top down" approach. The first step in this approach is to derive from the available emission monitoring data an emission factor (or series of emission factors) deemed to be representative of the source category (or segments of a source category that differ in configuration, fuel type, air pollution control equipment, etc.). The emission factor relates mass of CDD/CDFs or dioxin-like PCBs released into the environment per some measure of

activity (e.g., kilograms of material processed per year, vehicle miles traveled per year, etc.). The emission factor is then multiplied by a national value for the activity level basis of the emission factor (e.g., total kilogram [kg] of material processed in the United States annually).

With the exception of certain releases from the bleached chemical wood pulp/paper industry, no source category has estimates developed from a true "bottom up" approach (i.e., estimates developed using site-specific emissions and activity data for all individual sources in a category and then summed to obtain a national total). Existing facility-specific emissions testing and activity level data for some source categories (e.g., municipal solid waste incinerators) supported a semi- "bottom up" approach. In this approach, facility-specific annual emissions were calculated for those facilities with adequate data. For the untested facilities in the class, a subcategory (or class) emission factor was developed by averaging the emission factors for the tested facilities in the class. This average emission factor was then multiplied by the measure of activity for the non-tested facilities in the class. Emissions were summed for the tested facilities and non-tested facilities. In summary, this procedure can be represented by the following equations:

$$E_{total} = \Sigma E_{tested,i} + \Sigma E_{untested,i}$$
$$E_{total} = \Sigma E_{tested,i} + \Sigma (EF_i * A_i)_{untested}$$

Where: E_{total} = annual emissions from all facilities (g TEQ/yr)

$E_{tested,i}$ = annual emissions from all tested facilities in class I (g TEQ/yr)

$E_{untested,i}$ = annual emissions from all untested facilities class I (g TEQ/yr)

Ef_i = mean emission factor for tested facilities in class I (g TEQ/kg)

A_i = activity measure for untested facilities class I (kg/yr)

Some source categories are made up of facilities that vary widely in terms of design and operating conditions. For these sources, as explained above, an attempt was made to create subcategories that grouped facilities with common features and then to develop separate emission factors for each subcategory. Implicit in this procedure is the assumption that facilities with similar design and operating conditions should have similar

CDD/CDF release potential. For most source categories, however, the specific combination of features that contributes most to CDD/CDF or dioxin-like PCB release is not well understood. Therefore, how to best subcategorize a source category was often problematic. For each subcategorized source category in this report, a discussion is presented about the variability in design and operating conditions, what is known about how these features contribute to CDD/CDF or dioxin-like PCB release, and the rationale for subcategorizing the category.

As discussed above, each source emission calculation required estimates of an "emission factor" and the "activity level." For each emission source, the quantity and quality of the available information for both terms vary considerably. Consequently, it is important that emission estimates be accompanied by some indicator of the uncertainties associated with their development. For this reason, a qualitative confidence rating scheme was developed as an integral part of the emission estimate in consideration of the following factors:

- *Emission Factor* - The uncertainty in the emission factor estimate depends primarily on how well the tested facilities represent the untested facilities. In general, confidence in the emission factor increases with increases in the number of tested facilities relative to the total number of facilities. Variability in terms of physical design and operating conditions within a class or subclass must also be considered. The more variability among facilities, the less confidence that a test of any single facility is representative of that class or subclass. The quality of the supporting documentation also affects uncertainty. Whenever possible, original engineering test reports were used. Peer reviewed reports from the open literature were also used for developing some emission factors. In some cases, however, draft reports that had undergone more limited review were used. In a few cases, unpublished references were used (such as personal communication with experts) and are clearly noted in the text.

- *Activity Level* - The uncertainty in the activity level estimate was judged primarily on the basis of the extent of the underlying data. Estimates derived from comprehensive surveys (including most facilities in a source category) were assigned high confidence. As the number of facilities in the survey relative to the total decreased, confidence also decreased. The quality of the supporting documentation also affects uncertainty. Peer reviewed reports from the open literature (including government and trade association survey data) were considered most reliable. In some cases, however, draft reports that had undergone more limited review were used. In a few cases, unpublished references were used (such as personal communication with experts) and are clearly noted in the text.

The confidence rating scheme, presented in Table 1-6, presents the qualitative criteria used to assign a high, medium, or low confidence rating to the emission factor and activity level terms for those source categories for which emission estimates can be reliably quantified. The overall "confidence rating" assigned to an emission estimate was determined by the confidence ratings assigned to the corresponding "activity level" term and "emission factor" term. If the lowest rating assigned to either the activity level or emission factor terms is “high,” then the category rating assigned to the emission estimate is high (also referred to as “A”). If the lowest rating assigned to either the activity level or emission factor terms is “medium,” then the category rating assigned to the emission estimate is medium (also referred to as “B”). If the lowest rating assigned to either the activity level or emission factor terms is “low,” then the category rating assigned to the emission estimate is low (also referred to as “C”). It is emphasized that this confidence rating scheme should be interpreted as subjective judgements of the relative uncertainty among sources, not statistical measures.

For many source categories, either emission factor information or activity level information were inadequate to support development of reliable quantitative release estimates for one or more media. For some of these source categories, sufficient information was available to make preliminary estimates of emissions of CDD/CDFs or dioxin-like PCBs; however, the confidence in the activity level estimates or emission factor estimates was so low that the estimates cannot be included in the sum of quantified emissions from sources with confidence ratings of A, B and C. These preliminary estimates were given an overall confidence class rating of D (see Tables 1-7 and 1-8). As preliminary estimates of source magnitude, they can be used, however, to help prioritize future research and data collection. The actual magnitude of emissions from these sources could be significantly lower or higher than these preliminary estimates. Although EPA has chosen not to include them in the more thoroughly characterized emissions of the national inventory, some of these poorly characterized sources have the potential of being major contributors of releases to the environment. As the uncertainty around these sources is reduced, they will be included in future inventory calculations. For other sources, some information exists which suggests that they may release dioxin-like compounds; however, the available data were judged to be insufficient for developing any quantitative emission estimate. These source categories were assigned a confidence category rating of “E” and

also were not included in the national inventory (See listings in Table 1-5 under the "Not Quantifiable" column).

The emission factors developed for the emissions inventory are intended to be used for estimating the total emissions for a source category rather than for individual facilities. EPA has made uncertainty determinations for each of these emission factors based, in part, on the assumption that by applying them to a group of facilities, the potential for overestimating or underestimating individual facilities will to some extent be self compensating. This means that in using these emission factors one can place significantly greater confidence in an emission estimate for a class than can be placed on an emission estimate for any individual facility. Given the limited amount of data available for deriving emission factors, and the limitations of our understanding about facility-specific conditions that determine formation and control of dioxin-like compounds, the current state of knowledge cannot support the development of emission factors that can be used to accurately estimate emissions on an individual facility-specific basis.

1.5. GENERAL FINDINGS OF THE EMISSIONS INVENTORY

Nationwide emission estimates of I-TEQ_{DF} and TEQ_{DF}-WHO_{98} for the United States inventory are presented in Tables 1-7 and 1-8, respectively, for those source categories for which emission estimates can be reliably quantified. Nationwide emission estimates for dioxin-like PCBs are presented in Chapter 11. Figures 1-2 and 1-3 are charts that visually display the range of I-TEQ_{DF} emission estimates to air that are reported in Table 1-7 with confidence ratings of A, B, or C. Figure 1-4 compares the I-TEQ_{DF} emission estimates to air for the two reference years (i.e., 1987 and 1995). Figures 1-5 and 1-6 are charts that visually display the range of TEQ_{DF}-WHO_{98} emission estimates to air that are reported in Table 1-8 with confidence ratings of A, B, or C. Figure 1-7 compares the TEQ_{DF}-WHO_{98} emission estimates to air for the two reference years.

Table 1-9 lists the I-TEQ_{DF} emission factors used to derive the emission estimates presented in Table 1-7 with confidence ratings of A, B, or C. Table 1-10 lists the TEQ_{DF}-WHO_{98} emission factors used to derive the emission estimates presented in Table 1-8 with confidence ratings of A, B, or C. The emission factors used to calculate these emission estimates were derived by setting "not detected" (ND) values in test reports as zeros. Because detection limits were not always reported in test reports, it was not possible to

consistently develop emission factors on any other basis (e.g., values set at one-half the detection limit) for all source categories. When detection limits were reported for all test reports for a given source category, emission factors were calculated and are presented in this report for both ND equals zero and ND equals one-half the detection limit.

Tables 1-7 and 1-8 also present preliminary indications of the potential magnitude of I-TEQ_{DF} and TEQ_{DF}-WHO_{98} emissions, respectively, from category D sources in reference year 1995. These estimates are based on very limited data whose representativeness is unknown. The estimates were developed primarily as a tool to direct future investigations and studies.

EPA's best estimates of releases of CDD/CDFs to air, water, and land from reasonably quantifiable sources were approximately 3,000 gram (g) I-TEQ_{DF} (3,300 g TEQ_{DF}-WHO_{98}) in 1995 and 12,800-g I-TEQ_{DF} (14,000 g TEQ_{DF}-WHO_{98}) in 1987.

The environmental releases of CDD/CDFs in the United States occur from a wide variety of sources, but are dominated by releases to the air from combustion sources. The current (i.e., 1995) inventory indicates that quantifiable emissions from combustion sources are more than an order of magnitude greater than quantifiable emissions from all other categories combined. Approximately 71% of all quantifiable environmental releases were dominated by air emissions from just three source categories in 1995: municipal waste incinerators (representing 38% of total environmental releases); backyard burning of refuse in barrels (representing 19% of total releases); and medical waste incinerators (representing 14% of total releases).

The decrease in estimated emissions of CDD/CDFs between 1987 and 1995 (approximately 77 percent) was due primarily to reductions in air emissions from municipal and medical waste incinerators, and further reductions are anticipated. For both categories, these emission reductions have occurred from a combination of improved combustion and emission controls and from the closing of a number of facilities. EPA's regulatory programs estimate that full compliance with recently promulgated regulations should result in further reductions in emissions from the 1995 levels (i.e., a reduction of more than 1,800 grams I-TEQ_{DF} by the year 2005). Specifically, the Office of Air and Radiation estimates that full compliance with Maximum Achievable Control Technology (MACT) standards under the Clean Air Act (CAA) will result in annual emissions of 12 g I-TEQ_{DF} from municipal solid waste incinerators and 6 g I-TEQ_{DF} from medical waste

incinerators by the year 2005. The Office of Solid Waste anticipates that full compliance with regulations promulgated under the combined authorities of the CAA and the Resource Conservation and Recovery Act (RCRA) will result in annual emissions from hazardous waste incinerators and cement kilns burning hazardous waste of about 4 and 8 g I-TEQ_{DF}, respectively, by 2002. The Office of Water estimates that full compliance with effluent guidelines promulgated under the Clean Water Act for the pulp and paper industry will result in annual releases to water of 5 g I-TEQ_{DF}. However, no Federal regulations are in place or currently under development for limiting CDD/CDF emissions from backyard burning of refuse in barrels. A number of states have general restrictions on the practice of backyard trash burning.

Insufficient data are available to comprehensively estimate point source releases of dioxin-like compounds to water. Sound estimates of releases to water are only available for chlorine bleached pulp and paper mills (356 g I-TEQ_{DF} or TEQ_{DF}-WHO_{98} for 1987 and 28 g I-TEQ_{DF} or TEQ_{DF}-WHO_{98} for 1995) and manufacture of ethylene dichloride (EDC)/vinyl chloride monomer (VCM) (<1 g I-TEQ_{DF} or TEQ_{DF}-WHO_{98} in 1995). Other releases to water bodies that cannot be quantified on the basis of existing data include effluents from POTWs and most industrial/commercial sources.

Based on the available information, the quantitative inventory of sources includes only a limited set of activities that result in direct environmental releases to land. The only releases to land quantified in the national inventory are land application of sewage sludge or commercial sludge products (106.5 g I-TEQ_{DF} or 79 g TEQ_{DF}-WHO_{98} in 1995), land application of pulp and paper mill wastewater sludges (2.0 g I-TEQ_{DF} or TEQ_{DF}-WHO_{98} in 1995), use of 2,4-D pesticides (18.4 g I-TEQ_{DF} or 28.9 g TEQ_{DF}-WHO_{98}), and manufacturing wastes from EDC/VCM (<1 g I-TEQ_{DF} or TEQ_{DF}-WHO_{98}). Not included in the Inventory's definition of an environmental release is the disposal of sludges and ashes into approved and regulated landfills.

Significant amounts of dioxin-like compounds produced annually are not considered environmental releases and, therefore, are not included in the national inventory. Examples include dioxin-like compounds generated internal to a process, but destroyed before release, waste streams which are disposed of in approved landfills and are therefore outside the definition of annual environmental releases, and products which contain dioxin-like compounds but for which environmental releases, if any, cannot be estimated.

The procedures and results of the U.S. inventory may have underestimated releases from contemporary sources. A number of investigators have suggested that national inventories may underestimate emissions because of the possibility of unknown sources. This claim has been supported with mass balance analyses suggesting that deposition exceeds emissions (Rappe et al., 1991; Harrad et al. 1992b; Bruzy and Hites, 1995). The uncertainty, however, in both the emissions and deposition estimates for the United States prevents the use of this approach for reliably evaluating the issue (U.S. EPA, 1995a). As explained below, this document has instead evaluated this issue by making preliminary estimates of poorly characterized sources and listing other sources that have been reported to emit dioxin-like compounds but cannot be characterized on even a preliminary basis.

- A number of sources were not included in the inventory even though limited evidence exists indicating that these sources can emit CDD/CDFs. These sources include various components of the metals industries such as electric arc furnaces and foundries and uncontrolled or minimally controlled combustion practices (e.g., backyard trash burning and accidental fires at landfills). Tables 1-11 and 1-12 present preliminary estimates of U.S. national emissions using the emission factors reported in these other studies as though they were representative of emission factors for U.S. facilities.

- The possibility remains that truly unknown sources exist. Many of the sources that are well accepted today were only discovered in the past 10 years. For example, CDD/CDFs were found unexpectedly in the wastewater effluent from bleached pulp and paper mills in the mid 1980s. Ore sintering is now listed as one of the leading sources of CDD/CDF emissions in Germany, but was not recognized as a source until the early 1990s.

1.6. GENERAL SOURCE OBSERVATIONS

For any given time period, releases from both contemporary formation sources and reservoir sources determine the overall amount of the dioxin-like compounds that are being released to the open and circulating environment. Because existing information is incomplete with regard to quantifying contributions from contemporary and reservoir sources, it is not currently possible to estimate total magnitude of release for dioxin-like compounds into the U.S. environment from all sources. For example, in terms of 1995 releases from reasonably quantifiable sources, this document estimates releases of 3,000 g T-TEQ_{DF} (3,300 g TEQ_{DF}-WHO_{98}) for contemporary formation sources and 2,900 g I-TEQ_{DF} or TEQ_{DF}-WHO_{98} for reservoir sources. In addition, there remains a number of

unquantifiable and poorly quantified sources. No quantitative release estimates can be made for agricultural burning or for most CDD/CDF reservoirs or for any dioxin-like PCB reservoirs. The preliminary estimate of 1995 poorly characterized contemporary formation sources is 1,500 g I-TEQ_{DF} or TEQ_{DF}-WHO_{98}.

The contribution of dioxin-like compounds to waterways from nonpoint source reservoirs is likely to be greater than the contributions from point sources. Current data are only sufficient to support preliminary estimates of nonpoint source contributions of dioxin-like compounds to water (i.e., urban storm water runoff and rural soil erosion). These estimates suggest that, on a nationwide basis, total nonpoint releases are significantly larger than point source releases.

Current releases of CDD/CDFs to the U.S. environment result principally from anthropogenic activities. This finding applies to both sources of newly formed dioxin-like compounds and reservoir sources. Four lines of evidence support this finding:

- As discussed in Volume 2, the companion document to this report, studies of sediment corings in lakes in the United States show a consistent pattern of change in CDD/CDF concentration in the sediments over time. The time period when increases are observed in CDD/CDF levels in sediments coincides with the time period when general industrial activity began increasing rapidly. CDD/CDF concentrations in sediments began to increase around the 1930s, and continued to increase until the 1960s and 1970s. Decreases appear to have occurred only during the most recent time periods (i.e., 1970s and 1980s). These trend observations are consistent among the dated sediment cores collected from over 20 freshwater and marine water bodies in various locations throughout the United States and Europe. Levels of CDD/CDF in sediments from these lakes are considered to be a reasonable indicator of the rate of environmental deposition. The period of increase generally matches the time when a variety of industrial activities began rising and the period of decline appears to correspond with growth in pollution abatement. Some of these pollution abatement actions are likely to have resulted in decreased CDD/CDF emissions (i.e., elimination of much open burning of solid waste, installation of particulate controls on combustors, phase out of leaded gasoline, and bans or restrictions on PCBs, 2,4,5-T, and PCP).
- In at least one case, soil erosion to surface waters, reservoir sources are thought to be a significant contributor to the environment. However, the principal source of CDD/CDFs in surface soils is air deposition. As discussed in the first bullet, it appears that CDD/CDFs associated with air deposition are primarily of anthropogenic origin.

- No large natural sources of CDD/CDF have been identified. EPA's current estimate of emissions from all sources of CDD/CDFs suggests that forest fires are a minor source of emissions compared to anthropogenic combustion activity. Recently

CDD/CDFs have been discovered in ball clay deposits in western Mississippi, Kentucky, and Tennessee. Although the origin of the CDD/CDFs in these clays may be natural, it has not been confirmed.

- As discussed in Volume 2, the companion document to this report, CDD/CDF levels in human tissues from the general population in industrialized countries are higher than levels observed in less-industrialized countries. Human populations in Europe and North America have significantly higher mean tissue levels (e.g., blood, adipose tissues, and breast milk) than human populations in developing countries of Asia.

Although chlorine is an essential component for the formation of CDD/CDFs in combustion systems, the empirical evidence indicates that for commercial scale incinerators, chlorine levels in feed are not the dominant controlling factor for rates of CDD/CDF stack emissions. Important factors which can affect the rate of CDD/CDF formation include the overall combustion efficiency, post-combustion flue gas temperatures and residence times, and the availability of surface catalytic sites to support CDD/CDF synthesis. Data from bench, pilot and commercial scale combustors indicate that CDD/CDF formation can occur by a number of mechanisms. Some of these data, primarily from laboratory and pilot scale combustors, have shown direct correlation between chlorine content in fuels and rates of CDD/CDF formation. Other data, primarily from commercial scale combustors, show little relation between availability of chlorine in feeds and rates of CDD/CDF formation. These studies are summarized below:

- Evidence from laboratory studies - A number of laboratory studies indicate that changes in the chlorine content of feed materials may result in changes in the amount of CDD/CDFs formed in the post-combustion region of a bench scale combustion system (Kanters and Louw, 1994; Kanters et al., 1996; De Fre and Rymen 1989; Wagner and Green, 1993).

- Evidence from pilot-scale studies - Recent evidence from a pilot-scale combustion study suggests that the amount of CDD/CDFs formed is not strongly correlated with chlorine content of the feed material when the feed material contains less than one percent chlorine; when chlorine in the feed is above one percent, the chlorine feed content appears to be directly proportional to the amount of CDD/CDFs formed (Wikstrom et al., 1996). Other pilot-scale studies indicate a strong relationship between the amount of HCl formed (from organically-bound chlorine in feeds) and the amount of CDD/CDFs formed (Bruce et al., 1991; Wagner and Green, 1993). Wagner and Green (1993) concluded that a decrease in the levels of organically-bound chlorine in the feed leads to a decrease in chlorinated organic emissions.

- Evidence from studies of full-scale systems - Combustors having poor combustion characteristics and hot-sided particulate control devices show a positive correlation between chlorine in feeds/fuels and CDD/CDF stack emissions (Thomas and Spiro 1995; U.S. EPA, 1987a). Combustors with high combustion efficiency, cool-sided particulate control devices, and advanced dioxin-specific air pollution control systems, however, do not show a strong correlation between chlorine amounts in feeds/fuels and the amount of CDDs/CDFs emitted from the stack (Rigo et al., 1995). This conclusion has been questioned in a paper by Costner (1998) who claims that many of the facilities assessed by Rigo et al. (1996) show a positive (though small) correlation between chlorine in feed and CDD/CDF emissions. Conversely, Costner (1998) also found that about half the facilities showed a weak inverse relationship. The American Society of Mechanical Engineers (ASME) has concluded that, "Whatever effect chlorine has on PCDD/CDF emissions in commercial scale systems is masked by the effect of APCS (air pollution control systems), temperature, ash chemistry, combustion conditions, measurement imprecision, and localized flow stratification (ASME, 1995)."

The conclusion that chlorine in feed is not a strong determinant of CDD/CDF emissions applies to the overall population of commercial scale combustors. For any individual commercial scale combustor, circumstances may exist in which changes in chlorine content of feed could affect CDD/CDF emissions. For uncontrolled combustion, such as open burning of household waste, the chlorine content of the waste may play a more significant role in rates of CDD/CDF formation and release than is observed at commercial scale combustors.

Dioxins are present in some ball clays, but insufficient data are available to estimate whether environmental releases occur during the mining and use. Recent studies in the U.S. and Europe have measured dioxins (principally CDDs) in some ball clays and other related clays. As discussed in Chapter 13, it is likely that the CDDs present in ball clay are of a natural origin. Ball clay is principally used in the manufacture of ceramics which involves firing the clay in high temperature kilns. This activity may cause some portion of the CDDs contained in the clay to be released into the air, but emission tests have not yet been conducted which would allow characterizing these releases.

Data are available to estimate the amounts of CDD/CDFs contained in only a limited number of commercial products. No systematic survey has been conducted to determine levels of dioxin-like compounds in commercial products. The available data does, however, allow estimates to be made of the amounts of dioxin-like compounds in bleached pulp (40 g I-TEQ_{DF} or TEQ_{DF}-WHO_{98} in 1995), POTW sludge used in fertilizers (3.5 g I-TEQ_{DF} or 2.6 g

TEQ_{DF}-WHO_{98} in 1995), pentachlorophenol-treated wood (8,400 g I-TEQ_{DF} or 4,800 g TEQ_{DF}-WHO_{98} in 1995), dioxazine dyes and pigments (<1 g I-TEQ_{DF} or TEQ_{DF}-WHO_{98} in 1995) and 2,4-D (18.4 g I-TEQ_{DF} or 28.9 g TEQ_{DF}-WHO_{98} in 1995).

No significant release of newly formed dioxin-like PCBs is occurring in the United States. Unlike CDD/CDFs, PCBs were intentionally manufactured in the United States in large quantities from 1929 until production was banned in 1977. Although it has been demonstrated that small quantities of dioxin-like PCBs can be produced during waste combustion, no strong evidence exists that the dioxin-like PCBs make a significant contribution to TEQ releases during combustion. The occurrences of dioxin-like PCBs in the U.S. environment most likely reflect past releases associated with PCB production, use, and disposal. Further support for this finding is based on observations of reductions since the 1980s in PCB concentrations in Great Lakes sediment and other areas.

It is unlikely that the emission rates of CDD/CDFs from known sources correlate proportionally with general population exposures. Although the Inventory shows the relative contribution of various sources to total emissions, it cannot be assumed that these sources make the same relative contributions to human exposure. It is quite possible that the major sources affecting CDD/CDF concentrations in food (see discussion in Section 2.6 of Volume 2) may not be those sources that represent the largest fractions of current total emissions in the United States. The geographic locations of sources relative to the areas from which much of the beef, pork, milk, and fish are produced are important to consider. That is, many of the agricultural areas that produce dietary animal fats are not located near or directly down wind of the major sources of dioxin-like compounds.

The contribution of reservoir sources to human exposure may be significant. Several factors support this finding:

- Because the magnitude of releases from current sources of newly formed PCBs are most likely negligible, human exposure to the dioxin-like PCBs is thought to be derived almost completely from reservoir sources. Key pathways involve releases from both soils and sediments to both aquatic and terrestrial food chains. As discussed in Volume 2, one third of general population TEQ_{DFP} exposure is due to PCBs. Thus, at least one third of the overall risk from dioxin-like compounds comes from reservoir sources.

- CDD/CDF releases from soil via soil erosion and runoff to waterways may be significant. These releases appear to be greater than releases to water from the primary sources included in the inventory. CDD/CDFs in waterways can

bioaccumulate in fish leading to human exposure via consumption of fish. As discussed in Volume 2, fish consumption makes up about one third of the total general population CDD/CDF TEQ exposure. This suggests that a significant portion of the CDD/CDF TEQ exposure could be due to releases from the soil reservoir. It is not known, however, how much of the soil erosion and runoff represents recently deposited CDD/CDFs from primary sources or longer term accumulation. Much of the eroded soil comes from tilled agricultural lands which would include a mix of CDD/CDFs from various deposition times. The age of CDD/CDFs in urban runoff is less clear.

- Potentially, soil reservoirs could have vapor and particulate releases which deposit on plants and enter the terrestrial food chain. The magnitude of this contribution, however, is unknown. EPA plans future studies in agricultural areas which will compare modeled air concentrations from primary sources to measured levels as a way to get further insight to this issue.

1.7. CONGENER PROFILES OF CDD/CDF SOURCES

This section summarizes congener profiles of known sources of dioxin-like compounds in the United States (Cleverly et. al, 1998). Congener profiles are the fractional distribution of CDD/CDF congeners in an environmental release, in an environmental sample, or in a biological sample. Under some circumstances, these congener profiles may assist researchers in: (1) identification of specific combustion source contributions to near field air measurements of CDD/CDFs; (2) comparing sources in terms of discerning differences in the types and amplitude of CDD/CDF congeners emitted; and (3) providing insights on formation of CDDs and CDFs in various sources and chemicals. There are numerous procedures one could elect to use to derive a congener profile, and there is no single agreed-upon convention (Cleverly et al., 1998; Lorber et al., 1996; Hagenmaier et al., 1994). In this report, congener profiles were developed primarily by calculating the ratio of specific 2,3,7,8-substituted CDDs and CDFs in the emission or product to the total (Cl_4 - Cl_8) CDDs/CDFs. With respect to combustion sources, the profiles were derived by: (a) dividing the congener-specific emission factors by the total (Cl_4 - Cl_8) CDD/CDF emission factor for each tested facility; and (b) then averaging the congener profiles developed for all tested facilities within the combustor type. For chemical processes and commercial chemicals, CDD/CDF profiles were typically generated by dividing average congener concentrations (ppt) in the chemical by the total CDD/CDF present. Profiles for selected source categories are presented in Figure 1-8.

On the basis of inspection and comparisons of the average CDD/CDF congener profiles across combustion and non-combustion sources, the following observations are made (Cleverly et al., 1998): (These generalizations are derived from this data set, and their application beyond these data is uncertain).

i. It appears that combustion sources emit all 2,3,7,8-substituted CDDs and CDFs, although in varying percentages of total CDD/CDF.

ii. In combustion source emissions, 2,3,7,8-TCDD is usually 0.1 to 1.0 percent of total CDD/CDF. The exception to this are stack emissions from industrial oil-fired boilers where the available, but limited data, indicate that 2,3,7,8-TCDD constitutes an average of 7 percent of total CDD/CDF emissions.

iii. It cannot be concluded that OCDD is the dominant congener for all combustion generated emissions of CDD/CDFs. OCDD dominates total emissions from: mass burn municipal solid waste incinerators (MSWI) that have dry scrubbers and fabric filters (DS/FF) for dioxin controls; industrial oil-fired boilers; industrial wood-fired boilers; unleaded gasoline combustion; diesel fuel combustion in trucks; and sewage sludge incinerators. The dominant congeners for other combustion sources are: 1,2,3,4,6,7,8-HpCDF in emissions from mass burn MSWIs equipped with hot-sided electrostatic precipitators (ESPs); OCDF in emissions from medical waste incineration; 1,2,3,4,6,7,8-HpCDF in hazardous waste incinerators; 2,3,4,7,8-PeCDF in cement kilns burning hazardous waste; 2,3,7,8-TCDF in cement kilns not burning hazardous waste; OCDF in industrial/utility coal-fired boilers; 1,2,3,4,6,7,8-HpCDF in secondary aluminum smelters; and 2,3,7,8-TCDF in secondary lead smelters.

iv. The 1,2,3,4,6,7,8-HpCDF appears to be the dominant congener in the following sources: secondary aluminum smelters; MSWIs equipped with hot-sided ESPs; hazardous waste incinerators; and 2,4-D salts and esters.

v. Evidence for a shift in the congener patterns potentially caused by the application of different air pollution control systems within a combustion source-type can be seen in the case of mass burn MSWIs. For mass burn MSWIs equipped with hot-sided ESPs, the most prevalent CDD/CDF congeners are: 1,2,3,4,6,7,8-HpCDF; OCDD; 1,2,3,4,6,7,8-HpCDD/1,2,3,4,7,8-HxCDF; 2,3,4,6,7,8-HxCDF/OCDF; 1,2,3,6,7,8-HxCDF. The most prevalent congeners emitted from MSWIs equipped with DS/FF are: OCDD; 1,2,3,4,6,7,8-HpCDD; 1,2,3,4,6,7,8-HpCDF; OCDF; 2,3,7,8-TCDF/1,2,3,4,7,8-HxCDD; 2,3,4,6,7,8-HxCDF.

vi. There is evidence of marked differences in the distribution of CDD/CDF congeners between cement kilns burning and not burning hazardous waste. When not burning hazardous waste as supplemental fuel, the dominant congeners appear to be 2,3,7,8-TCDF; OCDD; 1,2,3,4,6,7,8-HpCDD, and OCDF. When burning hazardous waste, the dominant congeners are: 2,3,7,8-PeCDF; 2,3,7,8-TCDF; 1,2,3,4,7,8-

HxCDF; and 1,2,3,4,6,7,8-HpCDD. When burning hazardous waste, OCDD and OCDF are minor constituents of stack emissions.

vii. The congener profile of 2,4-D salts and esters seems to mimic a combustion source profile in the number of congeners represented, and in the minimal amount of 2,3,7,8-TCDD relative to all 2,3,7,8-substituted congeners. A major difference is the prevalence of 1,2,3,7,8-PeCDD in 2,4-D (i.e., 14 percent), which is not seen in any other combustion or non-combustion sources presented here.

viii. There are similarities in the congener profiles of pentachlorophenol (PCP), diesel truck emissions, unleaded gasoline vehicle emissions, and industrial wood combustors. In these sources, OCDD dominates total emissions, but the relative ratio of 1,2,3,4,6,7,8-HpCDD to OCDD is also quite similar.

ix. The congener profiles for diesel truck exhaust and air measurements from a tunnel study of diesel traffic are quite similar.

Table 1-1. The TEF Scheme for I-TEQ_{DF}

Dioxin (D) Congener	TEF	Furan (F) Congener	TEF

Table 1-4. Nomenclature for Dioxin-Like Compounds

Term/Symbol	Definition
Congener	Any one particular member of the same chemical family (e.g., there are 75 congeners of chlorinated dibenzo-p-dioxins).
Congener Group	Group of structurally related chemicals that have the same degree of chlorination (e.g., there are eight congener groups of CDDs, monochlorinated through octochlorinated).
Isomer	Substances that belong to the same congener group (e.g., 22 isomers constitute the congener group of TCDDs).
Specific Isomer	Denoted by unique chemical notation (e.g., 2,4,8,9-tetrachlorodibenzofuran is referred to as 2,4,8,9-TCDF).
D	Symbol for congener class: dibenzo-p-dioxin
F	Symbol for congener class: dibenzofuran
M	Symbol for mono (i.e., one halogen substitution)
D	Symbol for di (i.e., two halogen substitution)
Tr	Symbol for tri (i.e., three halogen substitution)
T	Symbol for tetra (i.e., four halogen substitution)
Pe	Symbol for penta (i.e., five halogen substitution)
Hx	Symbol for hexa (i.e., six halogen substitution)
Hp	Symbol for hepta (i.e., seven halogen substitution)
O	Symbol for octa (i.e., eight halogen substitution)
CDD	Chlorinated dibenzo-p-dioxins, halogens substituted in any position
CDF	Chlorinated dibenzofurans, halogens substituted in any position
PCB	Polychlorinated biphenyls
2378	Halogen substitutions in the 2,3,7,8 positions

Table 1-6. Confidence Rating Scheme for U.S. Emission Estimates

Confidence Rating	Activity Level Estimate	Emission Factor Estimate
Categories/Media for Which Releases Can Be Reasonably Quantified		
High	Derived from comprehensive survey	Derived from comprehensive survey
Medium	Based on estimates of average plant activity level and number of plants or limited survey	Derived from testing at a limited but reasonable number of facilities believed to be representative of source category
Low	Based on data judged possibly nonrepresentative	Derived from testing at only a few, possibly nonrepresentative facilities or from similar source categories
Categories/Media for Which Releases Cannot Be Reasonably Quantified		
Preliminary Estimate	Based on extremely limited data, judged to be clearly nonrepresentative	Based on extremely limited data, judged to be clearly nonrepresentative
Not Quantified	No data available	1) Argument based on theory but no data, or 2) Data available indicating formation, but not in a form that allows developing an emission factor

[1]/ The most reliable estimates of environmental releases are those sources within Categories A, B and C (see footnote 'a' for definitions).

[a] A = Characterization of the Source Category judged to be **Adequate for Quantitative Estimation** with **High Confidence** in the **Emission Factor** and **High Confidence** in **Activity Level**.
B = Characterization of the Source Category judged to be **Adequate for Quantitative Estimation** with **Medium Confidence** in the **Emission Factor** and at least **Medium Confidence** in **Activity Level**.
C = Characterization of the Source Category judged to be **Adequate for Quantitative Estimation** with **Low Confidence** in either the **Emission Factor** and/or the **Activity Level**.
D = **Preliminary Indication** of the Potential Magnitude of I-TEQ_{DF} Emissions from "Unquantified" (i.e., Category D) Sources in Reference Year 1995. **Based on extremely limited data, judged to be clearly nonrepresentative**.

[b] Leaded fuel production and the manufacture of motor vehicle engines requiring leaded fuel for highway use have been prohibited in the United States. (See Section 4.1 for details.)

[c] TOTAL reflects only the total of the estimates made in this report.

[d] This refers to conventional pollutant control, not dioxin emissions control. Very few of the sources listed in this inventory control specifically for CDD/CDF emissions.

[e] Included within estimate for Wood Combustion - industrial.

[f] This term refers to the burning of residential waste in barrels.

[1]/ The most reliable estimates of environmental releases are those sources within Categories A, B and C (see footnote 'a' for definitions).

[a] A = Characterization of the Source Category judged to be **Adequate for Quantitative Estimation** with **High Confidence** in the **Emission Factor** and **High Confidence** in **Activity Level**.
B = Characterization of the Source Category judged to be **Adequate for Quantitative Estimation** with **Medium Confidence** in the **Emission Factor** and at least **Medium Confidence** in **Activity Level**.
C = Characterization of the Source Category judged to be **Adequate for Quantitative Estimation** with **Low Confidence** in either the **Emission Factor** and/or the **Activity Level**.
D = **Preliminary Indication** of the Potential Magnitude of I-TEQ_{DF} Emissions from "Unquantified" (i.e., Category D) Sources in Reference Year 1995. **Based on extremely limited data, judged to be clearly nonrepresentative**.

[b] Leaded fuel production and the manufacture of motor vehicle engines requiring leaded fuel for highway use have been prohibited in the United States. (See Section 4.1 for details.)

[c] TOTAL reflects only the total of the estimates made in this report.

[d] This refers to conventional pollutant control, not dioxin emissions control. Very few of the sources listed in this inventory control specifically for CDD/CDF emissions.

[e] Congener-specific emissions data were not available; the I-TEQ_{DF} emission estimate was used as a surrogate for the TEQ_{DF}-WHO_{98} emission estimate.

[f] Included within estimate for Wood Combustion - industrial.

[g] This term refers to the burning of residential waste in barrels.

Table 1-9. I-TEQ$_{DF}$ Emission Factors Used to Develop National Emission Inventory Estimates of Releases to Air

Emission Source	I-TEQ$_{DF}$ Emission Factor		Emission Factor Units
	1995	1987	
Waste Incineration			
Municipal waste incineration	38.2[a]	573[a]	ng TEQ/kg waste combusted

2.0. MECHANISMS OF FORMATION OF DIOXIN-LIKE COMPOUNDS DURING COMBUSTION OF ORGANIC MATERIALS

More than a decade of combustion research has contributed to a general understanding of the central molecular mechanisms that form CDDs and CDFs emitted from combustion sources. Current understanding of the conditions necessary to form CDDs and CDFs were primarily derived from studying full-scale municipal solid waste incinerators (MSWIs), augmented with observations involving the experimental combustion of synthetic fuels and feeds within the laboratory. However, the formation mechanisms elucidated from these studies are generally relevant to most combustion systems in which organic material is burned with chlorine. Intensive studies have examined MSWIs from the perspective of identifying the specific formation mechanism(s) that occur within the system. This knowledge may lead to methods that prevent the formation of CDDs and CDFs and their release into the environment. Although much has been learned from such studies, how to completely prevent CDDs/CDFs from forming during the combustion of certain organic materials in the presence of a source of chlorine and oxygen is still unknown. The wide variability of organic materials incinerated and thermally processed by a wide range of combustion technologies that have variable temperatures, residence times, and oxygen requirements adds to this complex problem. However, central chemical events that participate in forming CDDs and CDFs can be identified by evaluating emission test results from MSWIs in combination with laboratory experiments.

CDD/CDF emissions from combustion sources can potentially be explained by three principal mechanisms, which should not be regarded as being mutually exclusive. The first is that CDDs and CDFs are present as contaminants in the combusted organic material, and pass through the furnace and are emitted unaltered. This mechanism is discussed in Section 2.1. The second is that CDD/CDFs ultimately form from the thermal breakdown and molecular rearrangement of precursor ring compounds, which are defined as chlorinated aromatic hydrocarbons with a structural resemblance to the CDD and CDF molecules. Ringed precursors emanated from the combustion zone are a result of the incomplete oxidation of the constituents of the feed (i.e., products of incomplete combustion). The precursor mechanism is discussed in Section 2.2. The third mechanism, similar to the second and described in Section 2.3, is that CDD/CDFs are synthesized *de novo*. *De novo* synthesis describes a pathway of forming CDD/CDFs from

heterogeneous reactions on fly ash involving carbon, oxygen, hydrogen, chorine, and a transition metal catalyst. With these reactions, intermediate compounds having an aromatic ring structure are formed. Studies in this area suggest that aliphatic compounds, which arise as products of incomplete combustion, may play a critical role in initially forming simple ring molecules, which later evolve into complex aromatic precursors. CDD/CDFs are then formed from the intermediate compounds. In both mechanisms (2) and (3), formation occurs outside the furnace, in the so-called post-combustion zone. Particulate bound carbon is suggested as the primary reagent in the *de novo* syntheses pathway.

Section 2.4 gives an overview of studies that investigate the role that chlorine plays in forming CDDs and CDFs. Although chlorine is an essential component for the formation of CDD/CDFs in combustion systems, the empirical evidence indicates that for commercial scale incinerators, chlorine levels in feed are not the dominant controlling factor for rates of CDD/CDF stack emissions. There are complexities related to the combustion process itself, and types of air pollution control equipment that tend to mask any direct association. Therefore, the chlorine content of fuel and feeds to a combustion source is not a good indicator of levels of CDDs and CDFs emitted from the stack of the same source.

Section 2.5 discusses the generation and formation of coplanar PCBs. The presence of coplanar PCBs in stack emissions to combustors is an area in need of further research. Evidence to date suggests that PCB emissions are mostly attributed to PCB contamination in waste feeds, and that emissions are related to mechanism (1). However, newly published research has also indicated that it is possible to form PCBs in much the same way as described in mechanisms (2) and (3) identified in the formation of CDD/CDFs within the post-combustion zone.

Section 2.7 provides a closing summary of the three principal formation mechanisms and the role of chlorine. From the discussion in this chapter, it should be evident that no clear distinction exists between the precursor and de novo synthesis mechanisms for forming CDDs and CDFs. Both formation pathways depend on the evolution of precursors within combustion gases, the interaction of reactive fly ashes, a generally oxidative environment, the presence of a transition metal catalyst, the presence of gaseous chlorine, and a favorable range of temperature. Temperature of the

combustion gases (i.e., flue gases) is perhaps the single most important factor in forming dioxin-like compounds. Temperatures between 200° and 450° Celsius (C) are most conducive to forming CDD/CDFs, with maximum formation occurring at around 350°C. If temperature falls outside this range in temperature, the amount of CDD/CDFs formed is minimized.

2.1. MECHANISM 1: CDD/CDF CONTAMINATION IN FUEL AS A SOURCE OF COMBUSTION STACK EMISSIONS

The first mechanism involved in the stack emission of CDDs and CDFs is the incomplete destruction of CDD/CDF contaminants present in the fuel or feeds delivered to the combustion chamber. Not all of these molecules are destroyed by the combustion system, thus allowing trace amounts to be emitted from the stack. Most work in this area has involved the study of municipal solid waste incineration (MSWI), where CDDs and CDFs were analytically measured in the raw refuse fed into the incinerator.

As discussed in Volume 2 to this report, CDD/CDFs are ubiquitous in the environment (air, water, soil) and in foods and paper. Therefore, CDD/CDFs are clearly present in municipal waste. Tosine et al. (1983) first reported detecting trace amounts of HpCDD and OCDD in the MSW fed into an MSWI in Canada. HpCDD ranged in concentration from 100 ppt to 1 ppb, and OCDD ranged from 400 to 600 ppt. Wilken et al. (1992) separated the various solid waste fractions of MSW collected from municipalities in Germany and analyzed them for the presence of CDD/CDFs and other organochlorine compounds. Total CDD/CDFs were detected in all MSW fractions in the following range of concentrations: paper and cardboard = 3.1 to 45.5 ppb; plastics, wood, leather, and textiles combined = 9.5 to 109.2 ppb; vegetable matter = 0.9 to 16.9 ppb; and "fine debris" (defined as particles < 8 mm) = 0.8 to 83.8 ppb. Ozvacic (1985) measured CDD/CDFs in the raw MSW fed into two MSWIs operating in Canada. In one MSWI, CDDs were detected in the refuse; concentration ranged from 10 to 30 ppb, but no CDFs were detected (detection limit: 1 pg/g). In the MSW fed to the second MSWI, CDDs were detected in a range of 75 to 439 ppb, and CDFs were detected only in one of three samples at a total concentration of 11 ppb. EPA has reported detecting CDD/CDFs in refuse derived fuel (RDF) burned in a large urban MSWI (Federal Register, 1991a). CDDs were detected in 13 MSW samples taken prior to incineration at

concentrations ranging from 1 to 13 ppb; CDFs ranged from not detected to 0.6 ppb. In these samples, OCDD predominated; the lower chlorinated congeners were not detected. Clement et al. (1988) performed a mass balance involving an input versus output of CDD/CDFs at two operational MSWIs in Canada. The mass balance showed that the mass of CDDs and CDFs emitted at the stack point was much greater than the mass of CDD/CDFs in the raw MSW fed into the incinerator, and that the profiles of the distributions of CDD/CDF congeners were strikingly different. Primarily, higher chlorinated congeners were detected as contaminants in the waste; whereas, the total array of tetra - octa CDD/CDFs could be detected in the stack gases.

CDDs/CDFs present in the waste feeds may account for some fraction of the CDD/CDFs released from the stack. However, mass balance studies have clearly shown that more CDD/CDF can be detected downstream of the furnace than what is detected in the feed, indicating that CDD/CDFs are being synthesized after the feed has been combusted (Commoner et al., 1984, 1985, 1987; Clement et al., 1988; Hay et al., 1986; Environment Canada, 1985). Moreover, it is expected that the conditions of thermal stress imposed by high temperatures reached in typical combustion would destroy and reduce the CDDs and CDFs present as contaminants in the waste feed to levels that are 0.0001 to 10 percent of the initial concentration, depending on the performance of the combustion source and the level of combustion efficiency. Stehl et al. (1973) demonstrated that the moderate temperature of 800°C enhances the decomposition of CDDs at a rate of about 99.95 percent, but that lower temperatures result in a higher survival rate. Theoretical modeling has shown that unimolecular destruction of CDDs/CDFs at 99.99 percent can occur at the following temperatures and retention times within the combustion zone: 977°C with a retention time of 1 second; 1,000°C at a retention time of ½ second; 1,227°C at a retention time of 4 milliseconds; and 1,727°C at a retention time of 5 microseconds (Schaub and Tsang, 1983). Thus, CDDs and CDFs would have to be in parts per million concentration in the feed to the combustor to be found in the part per billion or part per trillion level in the stack gas emission (Shaub and Tsang, 1983). However, it cannot be ruled out is that CDDs/CDFs in the waste or fuel may contribute (up to some percentage) to the overall concentration leaving the stack. This leaves the only other possible explanation for CDD/CDF emissions from high temperature combustion of organic material, formation outside and downstream of the

furnace. These studies point to formation mechanisms other than simple pass through of non-combusted feed contamination. These formation mechanisms are discussed and reviewed in the sections which follow.

2.2. MECHANISM 2: FORMATION OF CDD/CDFs FROM PRECURSOR COMPOUNDS

The second mechanism involves the formation of CDDs and CDFs from aromatic precursor compounds in the presence of a chlorine donor. This mechanism has been elucidated from laboratory experiments involving the combustion of known precursors in quartz ampules under starved-air conditions, and in experiments that investigate the role of combustion fly ash in promoting the formation of CDD/CDFs from precursor compounds. The general reaction in this formation pathway is an interaction between an aromatic precursor compound and chlorine promoted by a transition metal catalyst on a reactive fly ash surface (Dickson and Karasek, 1987; Liberti and Brocco, 1982). Examples of well studied precursor compounds include chorobenzenes, chlorophenols, phenol, and benzene (Esposito et al., 1980). Examples of diverse chlorine donor compounds are polyvinyl chloride (PVC), and gaseous hydrogen chloride (HCl). CDD and CDF formation results from heterogeneous gas-phase reactions involving chlorinated precursor compounds and a source of chlorine. Chlorophenol and chlorobenzene compounds are measured in flue gases from MSWIs (Dickson and Karasek, 1987). Precursors are carried from the furnace to the flue duct as products of incomplete combustion. These compounds can adsorb on the surface of combustion fly ash, or entrain in the gas phase within the flue gases. In the post-combustion region outside the furnace, heterogeneous reactions ensue to form CDD/CDFs. Laboratory experiments involving the controlled combustion of precursor compounds have caused the breakdown of the precursor reagent and the subsequent appearance of CDD/CDFs as products of the reaction. For example, Jansson et al. (1977) produced CDDs through the pyrolysis of wood chips treated with tri-, tetra-, and pentachlorophenol in a bench-scale furnace operated at 500-600°C. Stehl and Lamparski (1977) combusted grass and paper treated with the herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T) in a bench-scale furnace at 600-800°C and generated ppm_v levels of TCDD. Ahling and Lindskog (1982) reported CDD formation during the combustion of tri- and tetrachlorophenol formulations at temperatures of 500-600°C. Decreases in oxygen during combustion generally increased the CDD yield.

Ahling and Lindskog (1982) noted that adding copper salts to the tetrachlorophenol formulation significantly enhanced the yield of CDDs. This may have been an early indication of copper's role in catalyzing the condensation of chlorophenol to dioxin. Combustion of pentachlorophenol (PCP) resulted in low yields of CDDs. However, when PCP was burned with an insufficient supply of oxygen, investigators noted the formation of tetra- through octa-chlorinated congeners. Buser (1979) generated CDD/CDFs on the order of 0.001-0.08 percent (by weight) by heating tri-, tetra-, and pentachlorobenzenes at 620°C in quartz ampules in the presence of oxygen. It was noted that chlorophenols formed as combustion byproducts; Buser (1979) speculated that these were acting as reaction intermediates in the formation of CDD/CDFs.

Temperature of the combustion gases is, perhaps, the most dominant factor in the formation of CDDs and CDFs from aromatic precursor compounds (Fangmark et al., 1994; Vogg et al., 1987, 1992; Oberg et al.,1989; Weber and Hagenmaier, 1999). Vogg et al. (1987) found that formation probably occurs outside and downstream from the combustion zone of a furnace to a combustion source in regions where the temperature of the combustion offgases has cooled within a range of 200° to 450°C.

After carefully removing organic contaminants from MSWI fly ash, Vogg et al. (1987) added known concentrations of isotopically labeled CDD/CDFs to the matrix. The MSWI fly ash was then heated for 2 hours in a laboratory furnace at varying temperatures. The treated fly ash was exposed to increasing temperatures in 50°C increments in a temperature range of 150^0 to 500°C. Table 2-1 summarizes these data. Because the relative concentration of CDD/CDFs increased while exposed to varying temperature, it was concluded that the temperature of the combustion gas is crucial to promoting the formation of CDD/CDFs on the surface of fly ash. Within a temperature range of 200° to 450°C, the concentration of CDD/CDFs increases to some maxima; outside this range, the concentration diminishes.

The region of cooler gas temperature is often referred to as the "post-combustion zone." The heat loss may be inherent to the conduction and transfer through the combustion gas metal ducting system, or related to adsorbing/exchanging heat to water in boiler tubes. This region extends from near the exit of the furnace to the point of release of the combustion gases at stack tip.

Fangmark et al. (1994) found that CDD/CDFs exhibit a similar dependence on temperature and residence times between 260° and 430°C, with maximum formation occurring around 340°C. Using a pilot-scale combustor, Behrooz and Altwicker (1996) found the formation of CDD/CDFs from the precursor 1,2-dichlorobenzene rapidly occurred within the post-combustion region in a temperature range of 390° to 400°C, with residence times of only 4-5 seconds. On the other hand, CDD/CDF formation from 1,2-dichlorophenol seemed to require higher temperatures; still outside the furnace, but likely in the exit to the furnace where gas temperatures are >400°C.

Oberg et al. (1989) investigated the role that temperature plays in the formation kinetics using a full-scale hazardous waste incinerator operating in Sweden. Oberg et al. (1989) observed that maximum CDD/CDF formation transpired in the boiler used to extract heat for co-generation of energy. In this investigation, significant increases in total concentration of I-TEQ_{DF} occurred between temperatures of 280° to 400°C, and concentrations declined at temperatures above 400°C. Weber and Hagenmaier (1999) showed that in gas phase reactions chlorophenols react in the presence of oxygen at above 340°C to form CDDs and CDFs. Phenoxyradicals were formed which, in turn, caused the formation of CDDs. Polychlorinated dihydroxybiphenyls were identified as reaction intermediates in the gas phase dimerization of chlorophenols, and these intermediates could form PCDFs.

Other conditions postulated to regulate the synthesis of CDDs and CDFs from the aromatic precursor compound are adsorption and interaction with the reactive surface of combustion generated fly ash (particulate matter) entrained in the combustion plasma, and the presence of a transition metal catalyst (Vogg et al., 1987; Bruce et al., 1991; Cleverly et al., 1991; Gullet et al., 1990a; Commoner et al., 1987; Dickson and Karasek, 1987; Dickson et al., 1992). The molecular precursor leaves the gas-phase and condenses to the fly ash particle. This places greater emphasis on heterogeneous surface reactions and less emphasis on homogeneous gas-phase reactions. This condition was first postulated by Shaub and Tsang (1983) using thermal-kinetic models based on heats of formation, adsorption, and desorption. Shaub and Tsang (1983) modeled CDD production from chlorophenols and concluded that gas-phase formation within an incineration system is likely to be of low probability and importance given the short (i.e., seconds) residence time of the combustion gases. Konduri and Altwicker (1994) proposed that rate limiting

factors were the nature and the concentrations of the precursors, the reactivity and availability of the fly ash surface, and the residence time in the post-combustion zone. Dickson and Karasek (1987) investigated fly ash reactivity with $^{13}C_6$-chlorophenol compounds. Several fly ashes from a variety of combustion fuels were heated at 300°C in quartz tubes under conditions known to catalyze the conversion of chlorophenols to CDD/CDFs (i.e., MSWI, and copper smelter fly ashes). The MSW ashes included a sample from a poorly-operated mass burn refractory incinerator and a sample from a well-operated fluidized bed combustor. The MSWI fly ashes proved to be the most active catalytic medium, despite similarities with respect to specific surface area and average pore diameters. The ash from the refractory MSWI generated about seven times more mass of dioxin-like compounds than the fluidized-bed MSW incinerator. In the MSW ashes, all CDD/CDF congener groups were formed from labeled chlorophenols; however, only trace amounts of heptachloro- and octachlorodioxin were formed with the copper smelter/refiner. X-ray photoelectron spectroscopy revealed the presence of chlorine adsorbed to the surface of the MSWI fly ashes, but an absence of chlorine sorbed to the copper smelter fly ash.

CDD congener groups were postulated to form from the labeled pentachlorophenol precursors by: (1) first forming octachlorodioxin by the condensation of two pentachlorophenol molecules, and (2) forming other lower chlorinated dioxins through dechlorination of the more highly chlorinated isomers. These steps seemed to proceed by an increased reactivity of the chemisorbed precursor molecule caused by the removal of one or more hydrogen or chlorine atoms along the ring structure (Dickson and Karasek, 1987), an observation consistent with the kinetic model of Shaub and Tsang (1983). In related experiments, Dickson and Karasek (1987) more specifically reported on forming CDD/CDFs from condensation reactions of chlorophenols on the surface of MSWI fly ash heated in a bench-scale furnace. Their experiment was designed to mimic conditions of MSW incineration, to identify the step-wise chemical reactions involved in converting a precursor compound into dioxin, and to determine if MSWI fly ash could promote these reactions. MSWI fly ash was obtained from facilities in Canada and Japan. The MSWI fly ash was rinsed with solvent to remove any organic constituents prior to initiating the experiment. Twenty grams of fly ash were introduced into a bench-scale oven (consisting of a simple flow-tube combustion apparatus) and heated at 340°C overnight to desorb

any remaining organic compounds from the matrix. $^{13}C_{12}$ -labeled pentachlorophenol (PCP) and two trichlorophenol isotopes ($^{13}C_{12}$- 2,3,5-Trichlorophenol and 3,4,5-Trichlorophenol) were added to the surface of the clean fly ash matrix and placed into the oven for 1 hour at 300°C. Pure inert nitrogen gas (flow rate of 10 mL/min) was passed through the flow tube to maintain constant temperatures. Tetra- through octa- CDDs were formed from the labeled pentachlorophenol experiment; over 100 μg/g of total CDDs were produced. The congener pattern was similar to that found in MSWI emissions. The 2,3,5-Trichlorophenol experiment primarily produced HxCDDs and very small amounts of tetra- and octa-CDD. The 3,4,5-Trichlorophenol experiment mainly produced OCDD and 1,2,3,4,6,7,8-HpCDD. Dickson and Karasek (1987) proposed that CDDs on the fly ash surface may result from chlorophenol undergoing molecular rearrangement or isomerization as a result of dechlorination, dehydrogenation, and trans-chlorination before condensation occurs. These reactions were proposed as controlling the types and amounts of CDDs that are ultimately formed. Born et al. (1993) conducted experiments on the oxidation of chlorophenols with fly ash in a quartz tube reactor heated to about 300°C. The MSWI fly ash mediated the oxidation of chlorophenols to produce carbon dioxide and carbon monoxide as major products, and polychlorinated benzenes, monobenzofurans, and nonhalogenated dibenzo-p-dioxins as trace species. Formation of these trace aromatic species occurred after residence times of only 7 - 8 seconds which was consistent with the later experimental result of Behrooz and Altwicker (1995) which showed the potential for rapid formation from a precursor. Milligan and Altwicker (1996) fitted experimental flow-tube reactor data to classical catalytic reaction models to empirically explain the interaction of 2,3,4,6-tetrachlorophenol (as a model precursor) with reactive MSWI fly ash during MSW incineration. The precursor was found to be highly adsorptive on fly ash, with a first-order dependence on gas-phase precursor concentration to CDD formation. Milligan and Altwicker (1996) concluded that chlorophenol's dependence on gas-phase concentration to form CDD on fly ash reflects the highly heterogeneous nature of the fly ash surface. Moreover the estimated 6 x 10^{18} adsorption sites per gram of fly ash suggest the presence of highly energetic sites, which may be important in the surface-catalyzed reactions forming CDDs. An interesting observation of Milligan and Altwicker (1996) was that precursor molecules appeared to compete with oxygen molecules for the reactive sites; therefore, chlorophenols are expected to adsorb less readily to the fly ash

surface in the presence of oxygen. Experimental evidence suggests that condensation to CDD of chlorophenol compounds via isomerization and the Smiles rearrangement on reactive MSWI fly ash surfaces is a proven pathway for forming dioxins from a precursor compound (Addink and Olie, 1995). However, no detailed mechanisms have been presented for CDD/CDF formation from other precursors, such as chlorobenzenes under conditions simulating incineration.

A condition to the synthesis of CDD/CDFs from aromatic precursor compounds is that the presence of a transition metal catalyst promotes the chemical reaction on the surface of fly ash. Copper chloride is a strong catalyst for promoting surface reactions on particulate matter to convert aromatic precursor compounds to chlorinated dioxins and dibenzofurans (Vogg et al., 1987). Copper chloride promotes ring condensation reactions (e.g., chorophenols) on fly ash to form CDD/CDFs (Addink and Olie, 1995) via the Ullman reaction (Born et al., 1993). In the Ullman reaction, copper catalyzes the formation of diphenyl ethers by the reaction of halogenated benzenes with alkali metal phenolates (Born et al., 1993), with copper participating in a nucleophilic aromatic substitution reaction. Thus, Born et al. (1993) proposes a similar mechanism in catalyzing the formation of dioxin-like compounds. Using the Ullman reaction as a model, Born et al. (1993) proposed that the copper-catalyzed condensation of two ortho-substituted chlorophenol molecules form chlorine-free dibenzo-p-dioxins. Vogg et al. (1987) proposed an oxidation reaction pathway, giving rise to the formation of CDDs and CDFs in the post-furnace regions of the incinerator in the following order: (1) hydrogen chloride gas (HCl) is thermolytically derived as a product of the combustion of heterogeneous fuels containing abundant chlorinated organic chemicals and chlorides; (2) oxidation of HCl, with copper chloride ($CuCl_2$) as a catalyst, yields free gaseous chlorine via the Deacon reaction; (3) phenolic compounds (present from combustion of lignin in the waste or other sources) entrained in the combustion plasma are substituted on the ring structure by contact with the free chlorine; and (4) the chlorinated precursor to dioxin (e.g., chlorophenol) is further oxidized (with copper chloride as a catalyst) to yield CDDs and CDFs and chlorine.

Gullett et al. (1990a; 1990b; 1991a; 1991b; 1992) studied the formation mechanisms through extensive combustion research at EPA, and verified the observations of Vogg et al. (1987). It was proven that CDDs and CDFs could be ultimately produced from low temperature reactions (i.e., 350°C) between Cl_2 and a phenolic precursor,

combining to form a chlorinated precursor, followed by oxidation of the chlorinated precursors (catalyzed by a copper catalyst such as copper chloride) as in examples (1) and (2), below.

(1) The initial step in forming dioxin is the formation of chlorine from HCl in the presence of oxygen (the Deacon process), as follows (Vogg et al., 1987; Bruce et al., 1991):

$$2HCl + \tfrac{1}{2} O_2 \xrightarrow{\Delta} H_2O + Cl_2$$

(2) Phenolic compounds adsorbed on the fly ash surface are chlorinated to form the dioxin precursor, and the dioxin is formed as a product from the breakdown and molecular rearrangement of the precursor. The reaction is promoted by copper chloride acting as a catalyst (Vogg et al., 1987; Dickson and Karasek, 1987; Gullett et al., 1992):

(a) phenol + Cl_2 ———> chlorophenol (dioxin precursor)

(b) 2-chlorophenol + $\tfrac{1}{2} O_2 \xrightarrow{CuCl_2}$ dioxin + Cl_2

On the other hand, Eklund et al. (1986) observed the high temperature formation of a large variety of chlorinated toxic compounds, including CDDs and CDFs, from precursors during a simple experiment in which phenol was oxidized with HCl at 550°C. One milligram of phenol was placed in a quartz tube reactor with an aqueous solution (10μL) of HCl and heated at 550°C for 5 minutes. Trichlorobenzene, dichlorophenol, dichlorobenzofuran, tetrachlorobenzene, trichlorophenol, and tetrachlorophenol were identified as major products formed. Monochlorobenzene, chlorophenol, dichlorobenzene, tetrachloropropene, pentachloropropene, trichlorobenzofuran, tetrachlorodibenzofuran, trichlorodibenzodioxin, tetrachlorodibenzodioxin, hexachlorodibenzodioxin, hexachlorodibenzofuran, pentachlorobenzene, pentachlorobiphenyl, and pentachlorodihydroxycylohexane were seen as minor products. Trace species formed included: monochlorodibenzofuran, pentachlorodibenzofuran, pentachlorodibenzodioxin, octachlorodibenzofuran, and octachlorodibenzodioxin. Eklund et al. (1986) hypothesized

that chlorinated organic compounds can be produced from phenols, acids, and any chlorine source in the hot post-combustion region (e.g., just exit to the furnace). The reaction was seen as very sensitive to HCl concentration. At HCl $< 10^{-3}$ moles, no chlorinated compounds could be detected. Nestrick et al. (1987) reported that the thermolytic reaction between benzene (an unsubstituted precursor) and iron (III) chloride on a silicate surface yielded CDD/CDFs at temperatures $\geq$150°C. The experimental protocol introduced 100 - 700 mg of native and $^{13}C_6$-benzene into a macro-reactor system, consisting of a benzene volatilization chamber connected to a glass tube furnace. The investigators noted the relevance of this experiment to generalizations about combustion processes because benzene is the usual combustion byproduct of organic fuels. Inert nitrogen gas carried the benzene vapor to the furnace area. The exit from the glass tubing to the furnace was plugged with glass wool, and silica gel was introduced from the entrance end to give a bed depth of 7 cm to which the $FeCl_3$ was added to form a $FeCl_3$/silica reagent. The thermolytic reaction took place in a temperature ranging from 150-400°C, at a residence time of 20 minutes. Although di- through octa-CDD/CDF were formed by this reaction at all the temperatures studied, the percent yields were extremely small. Table 2-2 summarizes these data.

2.3. MECHANISM 3: THE *DE NOVO* SYNTHESIS OF CDDS/CDFS DURING COMBUSTION OF ORGANIC MATERIALS

The third and last mechanism, *de novo* synthesis, promotes CDD/CDF formation in combustion processes from the oxidation of carbon particulate catalyzed by a transition metal in the presence of chlorine. As in mechanism 2, synthesis is believed to occur in regions outside of the furnace zone of the combustion process, where the combustion gases have cooled to a range of temperatures considered favorable to formation chemistry. A key component to *de novo* synthesis is the production of intermediate compounds (either halogenated or nonhalogenated) that are precursors to CDD/CDF formation. Research in this area has produced CDD/CDFs directly by heating carbonaceous fly ash in the presence of a transition metal catalyst, without the apparent generation of reactive intermediates. Thus, the specific steps involved in the *de novo* process have not been fully and succinctly delineated. However, laboratory experimentation has proven that MSWI fly ash, itself, is a reactive substrate, and the

matrix can actually catalyze the *de novo* formation chemistry. Typically, fly ash is composed of an alumina-silicate construct, with 5-10 percent concentrations of silicon, chlorine (as inorganic chlorides), sulfur, and potassium (NATO, 1988). Twenty percent of the weight of fly ash particles are carbon, and the particles have specific surface areas in the range of 2-4 m^2 (NATO, 1988). The *de novo* synthesis essentially is the oxidative breakdown of macromolecular carbon structures, and CDD/CDFs are formed partially from the aromatic carbon-oxygen functional groups embedded in the carbon skeleton (Huang et al., 1999). The distinguishing feature of the *de novo* synthesis over the precursor synthesis is the oxidation of carbon in particulate at the start of the process to yield precursor compounds. In mechanism 2, the precursor compound is the starting molecule to the condensation reactions forming CDD/CDFs (Dickson et al., 1992). By this distinction, however, one could argue that mechanism 3 is really an augmentation to mechanism 2, because the production of CDD/CDFs may still require the formation of a CDD/CDF precursor as an intermediate species. Nevertheless, a distinction is presented here to describe additional pathways suggested for the thermal formation of these compounds.

To delineate the *de novo* synthesis of CDD/CDFs, Stieglitz et al. (1989a) conducted experiments that involved heating particulate carbon containing adsorbed mixtures of Mg-Al silicate in the presence of copper chloride (as a catalyst to the reaction). The authors described heating mixtures of Mg-Al silicate with activated charcoal (4 percent by weight), chloride as potassium chloride (7 percent by weight), and 1 percent copper chloride ($CuCl_2$) (in water) in a quartz flow tube reactor at 300°C. The retention time was varied at 15 minutes, 30 minutes, and 1, 2, and 4 hours to obtain differences in the amounts of CDD/CDFs that could be formed. The results are summarized in Table 2-3. In addition to the CDD/CDFs formed as primary products of the *de novo* synthesis, the investigators observed precursors formed at the varying retention times during the experiment. In particular, similar yields of tri- though hexa-chlorobenzenes, tri- through hepta-chloronaphthalenes, and tetra- through hepta-chlorobiphenyls were quantified; this was seen as highly suggestive of the role these compounds may play as intermediates in the continued formation of CDD/CDFs. Stieglitz et al. (1989a) made the following observations:

- The *de novo* synthesis of CDD/CDFs via the oxidation of carbonaceous particulate matter occurred at a temperature of 300°C. Additionally, the experiment yielded

ppb to ppm concentrations of chlorinated benzenes, chlorinated biphenyls, and chlorinated naphthalenes through a similar mechanism. When potassium bromide was substituted for potassium chloride as a source of halogen for the organic compounds in the reaction, polybrominated dibenzo-p-dioxins and dibenzofurans formed as reaction products.

- The transition metal compound copper chloride catalyzed the *de novo* synthesis of CDD/CDFs on the surface of particulate carbon in the presence of oxygen, yielding carbon dioxide and chlorinated/brominated aromatic compounds.

- Particulate carbon, which is characteristic of combustion processes, may act as the source for the direct formation of CDD/CDFs, as well as other chlorinated organics. More recently, Stieglitz et al. (1991) investigated the role that particulate carbon plays in the *de novo* formation of CDD/CDFs from fly ash containing appreciable quantities of organic chlorine. Stieglitz et al. (1991) found that the fly ash contained 900 μg/g of bound organic chlorine. Only 1 percent of the organic chlorine was extractable. Heating the fly ash at 300-400°C for several hours caused the carbon to oxidize, leading to a reduction in the total organic chlorine in the matrix and a corresponding increase in the total extractable organic chlorine (TOX) (e.g., 5 percent extractable TOX at 300°C and 25-30 percent extractable total organic chlorine at 400°C). From this, Stieglitz et al. (1991) concluded that the oxidation and degradation of carbon in the fly ash are the source for the formation of CDD/CDFs; therefore, they are essential in the *de novo* synthesis of these compounds.

Addink et al. (1991) conducted a series of experiments to observe the *de novo* synthesis of CDD/CDFs in a carbon-fly ash system. In this experiment, 4 grams of carbon-free MSWI fly ash were combined with 0.1 gram of activated carbon and placed into a glass tube between two glass wool plugs. The glass tube was then placed into a furnace at a specific temperature, ranging from 200 to 400°C. This was repeated for a series of retention times and temperatures. The investigators observed that CDD/CDF formation was optimized at 300°C and at the furnace retention times of 4-6 hours. Figure 2-1 displays the relationship between retention time, temperature, and CDD/CDF production from the heating of carbon particulate. Addink et al. (1991) also investigated the relationship between furnace temperature and CDD/CDF production from the heating of carbonaceous fly ash. Figure 2-2 displays this relationship. In general, the concentration began to increase at 250°C and crested at 350°C, with a sharp decrease in concentration above 350°C. The authors also noted a relationship between temperature

and the CDD/CDF congener profile; at 300°C to 350°C, the lower chlorinated tetra- and penta-CDD/CDF congeners increased in concentration, while hexa-, hepta-, and octa-CDD/CDF congeners either remained the same or decreased in concentration. The congener profile of the original MSWI fly ash (not subject to *de novo* experimentation) was investigated with respect to changes caused by either temperature or residence time in the furnace. No significant changes occurred, leading the authors to propose an interesting hypothesis for further testing: after formation of CDD/CDFs occurs on the surface of fly ash, the congener profile remains fixed and insensitive to changes in temperature or residence time, indicating some form of equilibrium is reached in the formation kinetics.

Gullett et al. (1994) used a pilot-scale combustor to study the effect of varying the combustion gas composition, temperature, residence time, quench rate, and sorbent ($Ca[OH]_2$) injection on CDD/CDF formation. The fly ash loading was simulated by injecting on fly ash collected from a full-scale MSWI. Sampling and analysis indicated CDD/CDF formed on the injected fly ash at levels representative of those observed at full-scale MSWIs. A statistical analysis of the results showed that, although the effect of combustor operating parameters of CDD/CDF formation is interactive and very complicated, substantial reduction in CDD/CDF formation can be realized with high temperature sorbent injection to reduce HCl or Cl_2 concentrations, control of excess air (also affects ratio of CDDs to CDFs formed), and increased quench rate.

Several steps may be involved in the copper-catalyzed formation of CDDs and CDFs, with residual carbon on fly ash at 300°C (Addink and Olie, 1995). Copper initially reacts with chlorine to form $CuCl_2$, and then the ligand transfers the halide to a carbon atom of an organic macromolecule. The chlorinated macromolecular structure oxidizes into small compounds. Milligan and Altwicker (1995) found that increases in the carbon gasification rate caused increases in the amounts of CDDs and CDFs formed, and gave further evidence linking the oxidation of carbon to the formation of CDD/CDFs. Neither the gas-phase CO_2 nor CO (products of carbon oxidation) act as precursors to chlorobenzenes or CDD/CDF from reactions with carbon particulate (Milligan and Altwicker, 1995). Activated carbon, with a high surface area and excellent adsorptive characteristics, also has the highest gasification rate of all residual carbon (Addink and Olie, 1995). Experimental evidence suggest that the conditions for the *de novo* synthesis of CDDs and CDFs from carbon are: (a) the carbon consists of imperfect and degenerated

layers of graphite; (b) oxygen must be present; (c) chlorine must be present; (d) the reactions are catalyzed by copper chloride or some other transition metal; and (e) temperatures in the range of 200°C to 350°C (Huang and Buekens, 1995). The oxidation of carbon in fly ash is apparently inhibited at temperatures below 200°C, thus indicating the lower temperature limit for the thermal inertization of *de novo* synthesis (Lasagni et al., 2000). Lasagni et al. (2000) determined that at a temperature of 250^0 C, the primary product of the gasification of carbon in fly ash is CO_2 , but in a temperature range of 250-325°C, organic compounds are formed as products of the oxidation of the carbon. Addink and Olie (1995) raised the possibility that the molecular backbone of CDDs and CDFs may be present in carbon. If this is the case, the generation of dioxins and furans from the oxidation of carbon would not require the formation of intermediate aromatic ring structures. More work is needed to identify these possibilities.

The *de novo* synthesis of CDD/CDFs also involves the possibility that aromatic precursors could be formed within the post-combustion zone as in the following manner: (1) fuel molecules are broken into smaller molecular species (e.g., C_1, C_2 molecules) during primary combustion; and (2) these simple molecules recombine in the post-combustion zone to form larger molecular aromatic species (i.e., chlorobenzenes and chlorophenols) (Altwicker et al., 1993). Thus, small molecular products that evolve in the hot-zone of the furnace as a consequence of the incomplete fuel or feed material combustion may be important foundation molecules to the subsequent formation of precursor compounds in the cooler, post-combustion region. Eklund et al. (1988) reported formation of a wide range of chlorinated organic compounds, including CDDs, CDFs, and PCBs, from the oxidation of methane with HCl at temperatures of 400° to 950°C in a quartz flow tube reactor. No active catalysts nor reactive fly ashes were added to the combustion system. From these experimental results, Eklund et al. (1988) hypothesized that chlorocarbons, including CDDs and CDFs, are formed at high temperatures via a series of reversible reactions starting with chloromethyl radicals. The chloromethyl radicals can be formed from the reaction of methyl radicals and hydrogen chloride in a sooting flame. Methane is chlorinated by HCl in the presence of oxygen at high temperatures, forming chlorinated methanes, which react with methyl radicals at higher temperature (e.g., 800°C) to form aromatic compounds. In an oxidative atmosphere, chlorinated phenols are formed, but

alkanes and alkenes are the primary products. The chlorinated phenols then act as precursors for the subsequent formation of CDD/CDFs.

Aliphatic compounds are common products of incomplete combustion, and may be critical to the formation of simple ring structures in the post-combustion zone (Weber et al., 1999; Sidhu, 1999; Froese and Hutzinger, 1996a; Froese and Hutzinger, 1996b; Jarmohamed and Mulder, 1994). The aromatic precursor compounds may be formed in a potentially rich reaction environment of aliphatic compounds, reactive fly ash particles, HCl, and oxygen. Sidhu (1999) noted that combustion of acetylene on carbon (a common combustion effluent) in the presence of gaseous HCl and copper chloride (as a catalyst) at 300°C formed intermediate precursors, and subsequently, CDDs and CDFs. Propene oxidized at 350° to 550°C in contact with reactive MSWI fly ash in a flow tube reactor forms a wide range of chlorinated aromatic compounds, when the resulting combustion gases are mixed with hydrogen chloride gas (Jarmohamed and Mulder, 1994). Although the conversion was low (i.e., 1-3 percent), the oxidation of propene on fly ash in the presence of HCl can yield chlorinated benzenes and monobenzofurans. Incorporating an oxygen atom into the monobenzofuran structure leads then to the formation of monodibenzofuran. The HCl contributes chlorine to the aromatic ring through the Deacon reaction, and cyclization on the fly ash surface can yield cyclohexadienyl-substituted benzenes, which, in turn, can be further oxidized into CDFs (Jarmohamed and Mulder, 1994). Froese and Hutzinger (1996a) investigated the heterogeneous combustion reactions of the nonchlorinated C_2 aliphatics. Acetylene, as a model aliphatic compound, was allowed to react with pre-cleaned MSWI fly ash in a tube flow reactor at ca. 600°C. Metal oxides (e.g., SiO_2, Fe_2O_3, and CuO) were added separately as catalysts, instead of the metal chlorides used in other precursor experiments. The reactants were put into contact with HCl vapor, introduced at a constant flow rate. The acetylene flow was set at 1.1 mL/min and constantly fell to near 0.9 mL/min over 30 minutes. Regulated air flow maintained homeostatic oxidation conditions. Chorobenzenes and chlorophenols were formed, with isomer patterns generally resembling isomer patterns of chlorobenzene and chlorophenol emissions from MSWIs. CuO was seen as catalyzing condensation and chlorination reactions under heterogeneous conditions to form the chlorinated CDD/CDF precursor compounds. Additional more volatile compounds formed were short-chain aliphatic products, such as chloromethane, dichloromethane, and chloro-and

dichloroacetylene. Chlorobenzene congeners were not the major products formed; perchlorinated aliphatic compounds dominated as gas-phase reaction products. Froese and Hutzinger (1997) noted that perchlorinated aliphatic compounds (e.g., hexachloropropene, hexachloro-1,3-butadiene, and hexachlorocyclopentadiene) are important intermediates in aromatic ring formation; they concluded that the catalytic reaction of C_2 aliphatic compounds at 600°C dramatically contributes to formation of chlorinated and nonchlorinated aromatic compounds during combustion. Thus, aliphatic compounds can form CDD/CDF precursor compounds. Variable temperature effects were observed in the formation of CDD/CDF in the same reactions. Maximal OCDD formation occurred at 400°C, and the tetra-hepta homologue groups were maximally formed at 600°C. For CDFs, production of higher chlorinated homologues occurred at 400°C, and 500°C favored the formation of tetrachlorodibenzofurans. Froese and Hutzinger (1996a) noted a 100-fold increase in TCDF formation at 500°C, when compared to formation at 400°C. An explanation for this is that the higher temperature of 500°C maximized the formation CDD/CDF precursor (chlorophenol) from the aliphatic starting compound; whereas, at the lower temperature of 300°C, practically no ring structures were observed. Froese and Hutzinger (1996b) have produced polychlorinated benzene and phenol compounds from the high temperature (i.e., 300° to 600°C) heterogeneous combustion reactions of ethylene and ethane over fly ash in the presence of HCl, oxygen, and a metal catalyst in a combustion flow tube. No chlorobenzene congener precursors were formed from ethylene and ethane at 300°C; however, the formation rate increased with temperature, until a maximum production was achieved at 600°C. No definitive temperature dependence was observed for the formation of chlorophenols from the aliphatic starting compounds. However, at 500°C, 2,4,6-trichlorophenol dominated the reaction products; at 300°C, pentachlorophenol was initially produced. Froese and Hutzinger (1996b) also investigated the effects of elemental catalysts on potentiating the heterogeneous combustion reactions by measuring the amount of chlorobenzene and chlorophenol product formed from the reactions of ethylene/HCl over each catalyst at 600°C. The reaction with SiO_2 did not have a catalytic effect. Al_2O_3 catalytic action showed high intensity for the dichlorobenzene isomers, and decreasing intensity for the higher chlorinated isomers. Comparison of the amount of dichlorobenzene product formed indicated that an equal quantity was produced with either Al_2O_3 or fly ash; however, Al_2O_3

formed four to five times more product than the CuO catalyst. For tri- to hexa-chlorobenzene congeners, MSWI fly ash reactions produced 5 to 10 times more product that the metal catalysts. However, the presence of the CuO catalyst in these reactions produced a chlorobenzene congener pattern comparable to the fly ash reactions. With regard to chlorophenol production, Al_2O_3 also produced a unique dichlorophenol pattern, suggesting that Al_2O_3 has a unique catalytic effect in the high-temperature reactions of C_2 aliphatic compounds. Reactions over CuO produced additional products, including chlorinated methyl compounds, chlorinated C_2 aliphatics, and perchlorinated C_3 - C_5 alkyl compounds. Froese and Hutzinger (1996b) noted that these perchlorinated alkyl groups, formed by reacting ethylene and ethane over fly ash in the presence of the CuO catalyst, are key intermediate compounds to the formation of first aromatic rings in typical combustion systems. This emphasizes the importance of copper's catalytic effects in a combustion fly ash system. Al_2O_3 catalyzed reactions produced nonchlorinated naphthalene and akyalbiphenyl compounds. Furthermore, the organic chlorine in aliphatic compounds may also act as a direct source of chlorine for the formation of CDDs, CDFs in a carbon fly ash system (Weber et al., 1999).

In an earlier experiment using a similar flow-tube apparatus, Froese and Hutzinger (1994) formed chlorinated benzenes and phenols in fly ash catalyzed reactions with trichloroethylene at temperatures of 400° to 500°C. In this case, metal oxides (CuO, FeO_3, Al_2O_3) were used as catalysts, but no HCl was added for oxychlorination of product compounds. Under combustion conditions, a temperature dependent formation of chlorinated aromatics occurred from the trichloroethylene starting compound. Reaction with fly ash at 600°C formed hexachlorobenzene in concentrations that were about 1,000 times greater than at 400° and 500°C, with similar results for chlorophenols. Froese and Hutzinger (1994) hypothesized that key aromatic precursors for CDD/CDFs are formed in the higher temperature region of a post-combustion zone (ca. 600°C), which are then carried to the cooler post-combustion region (ca. 300°C), where the precursors form CDDs and CDFs.

2.4. THE ROLE OF CHLORINE IN THE FORMATION OF CDDS AND CDFS IN COMBUSTION SYSTEMS

The formation of CDDs and CDFs in the post-combustion region of combustion systems via either the precursor or *de novo* synthesis pathways requires the availability of gaseous chlorine (Luijk et al., 1994; Addink et al., 1995). Chlorine concentration in this region is related somehow to the chlorine content of combustion fuels and feed materials in incineration/combustion systems, because there can be no other source. The central question of the role of chlorine in forming CDDs and CDFs is whether or not their exists a positive and direct correlation between the amount of chlorine in feeds and the amount of CDDs and CDFs formed and emitted from the stack. If a direct relationship appears, then reductions in the chlorine content of fuels/feeds prior to combustion should result in a corresponding reduction in the concentrations of CDDs and CDFs formed after combustion. If the oxychlorination reactions require a number of steps, then the relationship between chlorine in uncombusted fuels and CDD/CDFs formed after combustion may not be linear, although still dependent in some nonlinear association. The central question can best be addressed by examining both formation mechanisms revealed in laboratory scale combustion experiments and correlations between Cl inputs with CDD/CDF outputs in commercial scale combustors.

2.4.1. Review of Laboratory-Scale Studies

A wide body of experimental evidence has elucidated the direct and indirect associations between chlorine in feeds and fuels and the potential formation of CDDs and CDFs during combustion. The *de novo* synthesis of CDDs and CDFs requires two basic reactions: the transfer of chlorine to residual carbon particulate with subsequent formation of carbon-chlorine bonds, and the oxidation of this macromolecular complex to yield carbon dioxide and volatile and semivolatile organic compounds as side products (Weber et al., 1999). Transition metal compounds, such as copper chloride, catalyze these reactions. Hydrogen chloride gas is the major direct source of chlorine available for participating in the formation of CDD/CDFs, which is initially formed as a combustion by-product from the inorganic and organic chlorine contained in the fuel (Vogg et al., 1987; Bruce et al., 1991; Gullet et al., 1990; Commoner et al., 1987; Addink et al., 1995; Luijk et al., 1994; Dickson et al., 1992; Wagner and Green, 1993; Halonen et al., 1994; Rigo

et al., 1995; Rigo, 1998; Altwicker et al.,1993). MSW contains approximately 0.45-0.90 percent (by weight) chlorine (Domalski et al., 1986). If left uncontrolled, MSW incinerators are a major stationary combustion source of HCl air emissions, which average between 400 to 600 ppm in the combustion gas (U.S. EPA, 1987a). In the presence of oxygen, HCl may oxidize to yield free chlorine gas by the Deacon process, and the free chlorine directly chlorinates a CDD/CDF precursor along the aromatic ring structure. Further oxidation of the chlorinated precursor in the presence of a transition metal catalyst (of which copper chloride was found to be the most active) yields CDDs and CDFs (Altwicker et al.,1993). Increasing the yield of chlorine in vapor phase from HCl oxidation generally increases the rate of CDD/CDF formation. Formation kinetics are most favored at temperatures between 200°C to 450°C. Chlorine production can be reduced either by limiting initial HCl concentration or by shortening the residence time in the Deacon process temperature (Bruce et al., 1991; Gullett et al., 1990b; Commoner et al., 1987). Bruce et al. (1991) observed a general increase in CDD and CDF formation, with increases in the vapor phase concentration of chlorine. Figure 2-3 shows the apparent dependence of the extent of formation of CDDs and CDFs upon chlorine concentration in the vapor phase. Bruce et al. (1991) verified a dependence on the concentration and availability of gaseous chlorine in the formation of CDD/CDFs in the post-combustion zone. This is in agreement with a simple experiment of Eklund et al. (1986) in which unsubstituted phenol was mixed with HCl at 550°C in a quartz tube reactor and formed a wide range of toxic chlorinated hydrocarbons, including CDDs and CDFs as reaction products. Eklund et al. (1988) also found a dependence of the amounts of chlorinated phenol product formed from the nonchlorinated starting material with the increased amount of HCl introduced into the reaction. Under the conditions of this experiment, no chlorinated compounds were formed at an HCl concentration of less than 10^{-3} moles, and maximum chlorophenol concentration occurred at ca. 10^{+8} M. Born et al. (1993) also observed that increasing levels of HCl give rise to increasing rates of oxychlorination of precursors, with increasing chances for the post-combustion formation of CDDs and CDFs. However, recently Addink et al. (1995) observed that an HCl atmosphere and/or chlorine produced approximately equal quantities of CDD/CDFs during the *de novo* synthesis from oxidation of particulate carbon. These experimental results suggest that chlorine production via the Deacon process reaction in the *de novo* synthesis may not be the only chlorination pathway, and may

indicate that the HCl molecule can be a direct chlorinating agent. In addition, some chlorine is expected to be formed from the oxidation of metal chlorides (e.g., $CuCl_2$), but Cl_2 formation from the Deacon process is greater because of the continuous supply of HCl delivered from the combustion chamber (Bruce et al., 1991). In this case, a first order dependence of HCl to Cl_2 is observed.

Wagner and Green (1993) investigated the correlation of chlorine content in feed to stack emissions of chlorinated organic compounds in a pilot-scale incinerator, using HCl flue gas measurements as a surrogate for fuel-bound organic chlorine. In addition to MSW as a fuel, variable amounts of PVC resin were added during 6 of 18 stack test runs. The resulting data were regressed to determine the coefficient of correlation between HCl measurements and total chlorobenzene compound emission measurements. In nearly all of the different regression analyses performed, the relationship between HCl emission and emissions of chlorinated organic compounds was positive and well-defined. In addition, Wagner and Green (1993) found a direct dependence of HCl emission levels to the level of PVC in the waste, with generally increasing amounts of HCl formed as increasing amounts of PVC were added. From these experiments, Wagner and Green (1993) concluded that decreases in the levels of organically bound chlorine in the input to an incinerator led to decreases in chlorinated organic compound stack emissions. Kanters and Louw (1994) investigated a possible relationship of chlorine content in waste feed to chlorophenol emissions in a bench-scale thermal reactor. MSWI, with a higher content of chlorine, caused a higher emission of chlorophenols via the *de novo* synthesis pathway. Kanters and Louw (1994) lowered the chlorine content of the prototype MSWI by replacing Cl-containing fractions with cellulose. They observed appreciable decreases in the amounts of chlorophenol formed from combustion. Kanters and Louw (1994) concluded that reductions in the chlorine content of waste feeds or elimination of PVC prior to MSWI combustion should result in a corresponding reduction in chlorophenol and CDD/CDF emissions.

In a similar experiment, Wikstrom et al. (1996) investigated the influence of chlorine in feed materials to the formation of CDDs, CDFs, and benzenes in a laboratory-scale fluidized bed reactor. An artificial fuel (composed of 34 percent paper, 30 percent wheat flour, 14 percent saw dust, 7 percent polyethylene, and 2 percent metals) to which varying amounts of organic chlorine (PVC) and inorganic chlorine ($CaCl_2 \cdot 6H_2O$) were

added, was combusted. Seven fuels were studied, and the chlorine content was varied from 0.12 to 2 percent. Flue gases were sampled for CDDs, CDFs, and chlorobenzenes. All combustion was performed with a high degree of combustion efficiency (e.g., 99.999 percent) to avoid forming polyvinylidene chloride and naphthalenes as products of incomplete combustion of pure PVC. With the combustion conditions held constant, only the chlorine content of the fuel was varied. From these experiments, about 1,000-fold higher concentrations of PCB isomers were produced, as compared to CDD/CDF (expressed as concentration of I-TEQ_{DF}). Moreover, a correlation was found between I-TEQ_{DF} and PCB levels in the flue gases and the chlorine content of the fuel. A 5-fold increase in both I-TEQ_{DF} and PCB concentration was observed in the flue gases from combustion of fuels containing 0.5 and 1.7 percent total chlorine. Moreover, no differences were observed in the amount of chlorinated product produced or whether the source of chlorine in the fuel was organic or inorganic. No correlation was observed between total CDD/CDF and PCB formation and total chlorine in the feed when chlorine levels in feed were 0.5 percent or lower. Highest amounts of CDD/CDFs and PCBs were formed from the fuel having the highest total chlorine content (1.7 percent). Under the conditions of this experiment, Wikstrom et al. (1996) observed that a chlorine fuel content of 1.0 percent was a threshold for forming excess CDDs, CDFs, and PCBs during combustion. The authors noted that Swedish MSW contains about 0.7 percent chlorine, of which approximately 40 percent are organic chlorine. They concluded that Swedish MSW is below the observed threshold value of 1.0 percent chlorine associated with a general increase in CDD, CDF, and PCB formation in the post-combustion region. Wikstrom et al. (1996) stated that their study does not support the thesis that elimination of only PVC from the waste prior to combustion will cause a significant reduction of CDD/CDF emissions if the combustion process is well controlled (high combustion efficiency).

A primary byproduct of combusting PVC is the generation of HCl. Paciorek et al. (1974) thermally degraded pure PVC resin at 400°C and produced 550 mg/g HCl vapor as a primary thermolysis product, which was observed as being 94 percent of the theoretical amount based on the percent weight chlorine on the molecule. Ahling et al. (1978) concluded that HCl can act as a chlorine donor to ultimately yield chlorinated aromatic hydrocarbons from the thermolytic degradation of pure PVC, and that these yields are a

function of transit time, percent oxygen, and temperature. They observed data from 11 separate experiments, conducted with a range of temperatures from 570 to 1,130°C. These data indicated that significant quantities of various isomers of dichloro-, trichloro-, tetrachloro-, and hexachlorobenzenes could be produced. Choudhry and Hutzinger (1983) proposed that the radical species $Cl\cdot$ and $H\cdot$ generated in the incineration process may attack the chlorinated benzenes thus formed, and abstract hydrogen atoms to produce ortho-chlorine substituted chlorophenol radicals. These intermediate radical species then react with molecular oxygen to yield ortho-substituted chlorophenols. As a final step, the ortho-substituted chlorophenols act as ideal precursors to yield CDD/CDFs with heat and oxygen. The chlorine in aliphatic compounds has been observed as both yielding high amounts of HCL during combustion, and also acting as a direct chlorine source for the *de novo* synthesis of CDDs/CDFs (Weber et al., 1999).

Recently Addink and Altwicker (1999) have reported on the role of the inorganic chloride ion in the formation of CDD/CDFs using the labeled compound, $Na^{37}Cl$. The inorganic chloride ion forms carbon-chlorine bonds on soot particles during combustion. The chlorine in the soot can both be directly inserted into a CDD/CDF molecule during formation, or can exchange with the chloride ions in the transitional metal catalyst which promotes CDD/CDF formation. Thus, the inorganic chlorine ion participates as a chlorine donor to CDD/CDF formation.

De Fre and Rymen (1989) reported on forming CDDs and CDFs from hydrocarbon combustion in a domestic gas/oil heating burner in the presence of 15 and 300 ppm concentrations of HCl. Over 100 chlorinated organic compounds were detected in the flue gases whenever HCl was injected into the system. De Fre and Rymen (1989) observed formation of CDDs and CDFs in all experiments where HCl was injected in a hydrocarbon flame. In this case, CDFs were always more abundant that CDDs. De Fre and Rymen (1989) concluded that the relationship between the HCl concentration and the emitted concentration of CDD/CDF under fixed combustion conditions appeared to be exponential for a wide range in temperature (e.g., 240° to 900°C).

2.4.2. Review of Full Scale Combustion Systems

The review of experimental data clearly indicates an association between chlorine content of feed/fuels and the potential synthesis of CDDs and CDFs. Paradoxically, the

review of full-scale operating incineration processes does not yield such unequivocal results indicating that complex kinetic events make strong associations difficult in full-scale systems. The following is a review of studies of the association between chlorine in feeds and stack releases of CDD/CDFs in full-scale incineration systems. In the stack testing of a variety of industrial stationary combustion sources during the National Dioxin Study in 1987, EPA made a series of qualitative observations on the relationship between total chlorine present in the fuel/waste and the magnitude of emissions of CDDs and CDFs from the stack of the tested facilities (U.S. EPA, 1987a). In general, combustion units with the highest CDD emission concentrations had greater quantities of chlorine in the fuel; conversely, sites with the lowest CDD emission concentrations contained only trace quantities of chlorine in the feed. The typical chlorine content of various combustion fuels was reported by Lustenhouwer et al. (1980) as: coal: 1,300 μg/g; MSW: 2,500 μg/g; leaded gasoline: 300-1,600 μg/g; and unleaded gasoline: 1-6 μg/g.

Thomas and Spiro (1995) also analyzed the relationship of CDD/CDF emissions from combustion to the chlorine content of feed materials. Thomas and Spiro (1996) plotted average CDD/CDF emission factors for a variety of combustion processes (black liquor boilers, unleaded gasoline combustion, leaded gasoline combustion, wire incineration, cigarette combustion, sewage sludge incineration, MSWI, PCP-treated wood combustion, hazardous waste incineration, and hospital waste incineration) against the average chlorine concentration of the combusted material. The plot showed that average CDD/CDF emissions of combustion source categories tend to increase with the average chlorine content of the combusted fuel. The analysis clearly indicated that combustion sources with relatively high combustion efficiency and adequate air pollution controls tended to have two order of magnitude lower emissions than poorly operated sources. This suggested a strong dependence on chlorine concentration in fuels and the magnitude of CDD/CDF emissions in the more poorly controlled combustion sources. The slope of the log-log plot was between 1 and 2, indicating that the relationship of chlorine content to CDD/CDF emissions was more than proportional.

Recently Costner (1998) reported finding a positive correlation between chlorine content of feed material and CDD/CDF emissions at a full-scale hazardous waste incinerator. Costner concluded that emissions at this facility were dependent on chlorine

input at a chlorine concentration as low as 0.031 percent, and that there was no evidence of a threshold in the relationship between chlorine in feed and CDD/CDF emissions.

Rigo et al. (1995) summarized the results of a study commissioned by the American Society of Mechanical Engineers (ASME, 1995). The study was a statistical evaluation of the relationship of HCl concentration in flue gases to various combustion systems (i.e., MSWI, hospital waste incineration, hazardous waste incineration, biomass combustors, laboratory and bench-scale combustors) to the stack emission of total CDDs and CDFs. HCl was a surrogate for total chlorine feed content in this study. The data analysis was sufficient for 92 facilities in the data base that showed both HCl and CDD/CDF emissions. From the 92 facilities, 72 did not show statistically significant relationship between chlorine input and CDD/CDF output in emissions streams; 2 facilities showed increasing CDD/CDF concentrations with increasing chlorine; and 8 facilities showed decreasing CDD/CDF concentrations with increasing chlorine. AMSE (1995) concluded that:

> "The failure to find simultaneous increases in most cases and finding inverse relationships in a few indicates that any effect chlorine has on PCDD/F emissions is smaller than the variability of other causative factors. Whatever effect chlorine has on PCDD/F emissions in commercial scale systems is masked by the effect of APCS (air pollution control systems) temperature, ash chemistry, combustion conditions, measurement imprecision, and localized flow stratification."

Liberson and Belanger (1995) reported the results of an analysis of the formation and emission of CDDs and CDFs as a function of total chlorine in combustion feed materials at a rotary kiln hazardous waste incinerator (HWI). The data were generated from multiple test series conducted over a 13-month period at the HWI, while operating a carbon injection system specifically designed to control and reduce CDD and CDF stack emissions. The chlorine feed rates ranged from 0 to 3,300 pounds per hour, while the CDD/CDF emission rates ranged between 0.7 and 39 ng/DSCM. The authors noted that multiple series of CDD/CDF control systems were employed on this HWI (e.g., a high temperature secondary combustion chamber, a spray dryer-evaporative quench that

further cools the combustion gases, activated carbon injection to adsorb semi-volatile organics, and a cool-side electrostatic precipitator followed by an acid gas scrubber to collect HCl and Cl_2). From the analyses of data, Liberson and Belanger (1995) concluded no correlation exists between CDD/CDF emissions and chlorine feed in a modern MWI, using carbon injection for CDD/CDF control.

2.5. POTENTIAL PREVENTION OF CDD/CDF FORMATION IN COMBUSTION SYSTEMS

Given what is currently understood about oxychlorination reactions in the synthesis of CDDs and CDFs, researchers have identified certain interventions that could be taken to reduce or impede formation in combustion systems. Recently, Haghunathan and Gullett (1996) demonstrated in a pilot-scale incinerator that sulfur compounds can combine with the metal catalyst necessary to stimulate the Deacon reaction of HCl and O_2 to yield Cl_2, thereby, neutralizing the catalyzing agent and reducing the formation of CDDs and CDFs. The Deacon reaction, which forms free chlorine in the combustion plasma, is seen as only occurring in the presence of a catalyst. Thus, the SO_2 molecule (formed when sulfur in the fuel combines with oxygen) can either inhibit the catalytic activity of the fly ash by combining with a metal-based Deacon catalyst in the fly ash, or by depleting the Cl_2 formed. Haghunathan and Gullett (1996) observed that the principal action of sulfur for inhibiting the formation of CDDs and CDFs in combustion systems is through SO_2 depletion of Cl_2, as follows:

$$Cl_2 + SO_2 + H_2O \leftrightarrow 2HCl + SO_2$$

The relevance of this finding is that the co-combustion of municipal solid waste with coal (that contains sulfur) should lead to dramatic reductions in the amount of CDDs and CDFs formed and emitted, and may explain why, in the United States, coal combustion at power plants results in over a magnitude lower CDD/CDF emission rate than MSWIs.

Naikwadi and Karasek (1989) investigated the addition of calcium oxide (CaO) and triethylamine (TEA) to the flue gases of a combustion system as an inhibitor of the catalytic activity of fly ash. They placed 500 μg C-13-labeled pentachlorophenol (a dioxin precursor) in a combustion flow tube and allowed it to react with organic-extracted MSWI fly ash at 300°C under an air stream. Under these condition, CDD/CDFs were formed at

concentrations ranging from 1,660 ng to 2,200 ng per 100 μg ^{13}C-PCP. The experimental method was then modified by mixing reactive MSWI fly ash with either CaO or TEA. The results showed that the amount of CDD/CDF formed could be reduced by an order of magnitude from the reaction of PCP with fly ash and the addition of TEA as an inhibitor. When CaO was mixed with fly ash, the amount of CDD/CDFs formed decreased by over 20 times.

2.6. THEORY ON THE EMISSION OF POLYCHLORINATED BIPHENYLS

The air emission of PCBs from MSW incineration is less well studied. Probably the formation mechanisms that apply to CDDs/CDFs would also apply to PCBs. Mechanism 1 (pass through) is implicit in the TSCA rule which requires 99.9999 percent destruction in hazardous waste incinerators. When this occurs, 0.0001 percent of the initial amount of PCBs fed into the hazardous waste incinerator may be emitted out the stack. This may indicate that some small fraction of the PCBs present in the fuel fed into an incineration process may result in PCB emissions from the stack of the process.

PCBs have been measured as contaminants in the raw refuse prior to incineration in an MSWI (Choudhry and Hutzinger, 1983; Federal Register, 1991a). Using this information, it is possible to test Theory mechanism 1 involved in CDD/CDF emissions: that the PCB contamination present in the fuel is responsible for emissions from the stack. The mass balance of total PCB, beginning with measurement in the raw refuse and ending with measurement at the stack to an RDF MSW incinerator (Federal Register, 1991a), can be used to calculate the destruction rated efficiency (DRE) of incineration of the PCB contaminated MSW. Using results from test number 11 at the RDF facility (Federal Register, 1991a), a computation of DRE can be made with the following equation (Brunner, 1984):

$$\text{DRE} = \frac{W_I - W_o}{W_I} \times 100\%$$

Where:

W_I = mass rate of contaminant fed into the incinerator system

W_o = mass rate of contaminant exiting the incinerator system

In test 11, 811 nanograms of total PCBs/gram of refuse (ng/g) were measured in the MSW fed into the incineration system, and 9.52 ng/g of total PCB were measured at the inlet to the pollution control device (i.e., outside the furnace region, but preceding emission control). From these measurements, a DRE of 98.8 percent can be calculated. Therefore, it appears that PCB contamination in the raw MSW, which was fed into this particular incinerator, may have accounted for the PCB emissions from the stack of the MSW incinerator.

PCBs can be thermolytically converted into CDFs (Choudhry and Hutzinger, 1983; U.S. EPA, 1984). This process occurs at temperatures somewhat lower than typically measured inside the firebox of an MSWI. Laboratory experiments conducted by EPA (U.S. EPA, 1984) indicate that the optimum conditions for CDF formation from PCBs are near a temperature of 675°C in the presence of 8 percent oxygen and a residence time of 0.8 seconds. This resulted in a 3 to 4 percent efficiency of conversion of PCBs into CDFs. Because 1 to 2 percent of the PCBs present in the raw refuse may survive the thermal stress imposed in the combustion zone to the incinerator (Federal Register, 1991a), then it is reasonable to presume that PCBs in the MSW may contribute to the total mass of CDF emissions released from the stack of the incinerator.

Although it appears that contamination of waste feeds with PCBs may be an important factor to detecting PCBs in stack emissions from combustion processes, recent research has indicated the possibility that these compounds may also be formed in the post-combustion zone either from *de novo* synthesis or from precursor compounds. Zheng et al. (1999) observed the formation of PCBs in the post-combustion zone from the pyrolysis of chlorobenzenes using a laboratory scale furnace. Zheng and coworkers (1999) observed that PCBs were optimally formed from lower chlorinated chlorobenzenes (i.e., 1,3-dichlorobenzene) catalyzed by copper chloride. In this experiment, maximum PCB production occurred at a temperature of 350°C. Wikstrom et al. (1998) reported secondary formation of PCB in the post-combustion zone similar to the *de novo* synthesis of CDDs and CDFs, albeit, PCBs were formed in only small amounts relative to CDD/CDFs. Fangmark and coworkers (1994) have postulated that formation of PCBs, CDDs, and CDFs in the post-combustion zone may occur either from a common precursor, or by side reactions affected in a similar way by temperature and residence time. On the other hand, Blumenstock et al. (1998) produced results in a pilot-scale furnace that were inconsistent

with the *de novo* formation of CDDs and CDFs in the post-combustion zone (i.e., PCBs seemed to be optimally formed at high temperatures in oxygen deficient atmospheres). Shin and Chang (1999) have noted a positive correlation between PCB concentrations on MSW incineration fly ash and fly ash concentrations of CDDs and CDFs, suggesting that high PCBs levels in fly ash may be a contributory cause to the post-combustion formation of CDDs and CDFs (i.e., PCBs are precursors to CDD/CDFs). Nito et al. (1997) noted the formation of CDFs and CDDs from the pyrolysis of PCBs in a fluidized bed system indicating that PCBs in feeds may account for CDFs formed in municipal solid waste incineration. More combustion related research needs to be conducted to firmly establish whether or not PCB contamination in feeds or post-combustion formation (or both) may explain the presence of PCBs in combustion flue gases.

2.7. SUMMARY AND CONCLUSIONS

2.7.1. Mechanisms of Formation of Dioxin-Like Compounds

There are three primary mechanisms for CDD/CDF emissions from combustion sources:

Mechanism 1: This refers to CDD/CDFs contained in the feed which pass through the combustor intact and are subsequently released to the environment. For most systems, this is not thought to be a major contributor to CDD/CDF emissions for two reasons. First, for commercial systems with good combustion controls, the temperatures and residence times should result in the destruction of most CDD/CDFs in the feed. Second, mass balance studies of a number of combustion systems show that more CDD/CDFs can be detected downstream of the furnace than in the feed. Consequently synthesis appears to be a more important mechanism than pass through.

Mechanism 2: This is the formation of CDD/CDFs from the thermal breakdown and molecular rearrangement of aromatic precursors either originating in the feed or forming as a product of incomplete combustion. Actual synthesis of CDD/CDF occurs in the post-combustor environment. The CDD/CDFs form when the precursors sorb onto binding sites on the surface of fly ash particles. This reaction has been observed to be catalyzed by the presence of a transition metal sorbed to the particulate. The most potent catalyst is copper chloride. Heat in a range of 200 to 450°C has been identified as a necessary condition for these reactions to occur, with either lower or higher temperatures inhibiting

the process. Since these reactions involve heterogenous chemistry, the rate of emissions is less dependent on reactant concentration than conditions that promote formation such as temperature, retention time and availability of catalytic surfaces. For this mechanism to be significant, two broad conditions are needed.

Mechanism 3: This is the formation of CDD/CDFs in the post-combustion environment in the absence of aromatic precursors. This *de novo* synthesis involves the oxidative breakdown of macromolecular carbon structures (e.g., graphite) leading to the formation of aromatic CDD/CDF precursors. These precursors then undergo the transformations associated with mechanism 2 to form CDD/CDFs. As with mechanism 2, since this mechanism involves heterogenous chemistry, the rate of emissions is dominated by the same physical conditions as discussed in mechanism 2. Mechanisms 2 and 3 can occur simultaneously, share a number of common reaction pathways, occur in the same physical environment and are controlled by many of the same physical conditions. In well designed and operated combustion systems, the precursor species needed for mechanism 2 are not in abundant supply; consequently *de novo* synthesis can become the dominant pathway for formation. In systems with incomplete combustion, it is difficult to sort out the relative contribution of these two mechanisms to total emissions. Both mechanisms, however, can be curtailed if steps are taken to minimize the physical conditions needed to support formation (i.e., time, temperature and reactive surface).

The combustion formation chemistry of PCBs is less well-studied than for CDD/CDFs, but it is reasonable to assume that these same three mechanisms would apply. For waste incineration, PCBs can exist in significantly higher concentrations in the feed than CDD/CDFs. Consequently, mechanism 1 may play a more prominent role in PCB emissions from some forms of waste combustion.

2.7.2. Role of Chlorine

From the various analyses on the role and relationship of chlorine in feeds to CDD/CDF formation and emissions, the following observations and conclusions are made:

1. Although chlorine is an essential component for the formation of CDD/CDFs in combustion systems, the empirical evidence indicates that, for commercial scale incinerators, chlorine levels in feed are not the dominant controlling factor for rates of

CDD/CDF stack emissions. Important factors which can affect the rate of CDD/CDF formation include the overall combustion efficiency, post-combustion flue gas temperatures and residence times, and the availability of surface catalytic sites to support CDD/CDF synthesis. Data from bench, pilot and commercial scale combustors indicate that CDD/CDF formation can occur by a number of mechanisms. Some of these data, primarily from laboratory and pilot scale combustors, have shown direct correlation between chlorine content in fuels and rates of CDD/CDF formation. Other data, primarily from commercial scale combustors, show little relation with availability of chlorine and rates of CDD/CDF formation. The conclusion that chlorine in feed is not a strong determinant of CDD/CDF emissions applies to the overall population of commercial scale combustors. For any individual commercial scale combustor, circumstances may exist in which changes in chlorine content of feed could affect CDD/CDF emissions. For uncontrolled combustion, such as open burning of household waste, chlorine content of wastes may play a more significant role in affecting levels of CDD/CDF emissions than observed in commercial scale combustors.

2. Both organic and inorganic chlorine in combustion fuels yield HCl in the post-combustion region. HCl vapor is the dominant source of chlorine leading to the formation of CDD/CDFs. The reaction proceeds via the oxidation of HCl in the presence of an inorganic chloride catalyst (the Deacon reaction). Although the preponderance of scientific evidence suggest that this is a dominant pathway for producing chlorinated compounds in emissions, it is still unclear if HCl can also directly chlorinate aromatics, or must first be oxidized to yield free chlorine.

3. Laboratory scale experiments have examined correlations between chlorine content of feeds with total CDD/CDF formation. These experiments have suggested that for feeds containing less than 1% Cl, the rate of CDD/CDF formation is independent of Cl. For feeds with Cl content greater than 1%, a positive correlation is seen. Although this relationship is observed at the laboratory scale, it has been shown not to apply to commercial scale combustors (see 1 above). It has not been determined, however, if these relationships are relevant to other types of combustion such as backyard barrel burning, landfill fires and agricultural burning.

2.7.3. General Conclusion

The trace chemistry of combustion appears to involve a wide variety of formation pathways indicating that the chemistry of CDD/CDF formation is more complicated than the relatively simple constructs described in this review. Despite this complexity, the current weight of evidence would suggest that the role of chlorine and the formation mechanisms outlined above will account for most of the CDD/CDF emissions associated with combustion.

Table 2-1. Concentration of CDD/CDFs on Municipal Incinerator Fly Ash at Varying Temperatures

Congener	CDD/CDF Concentration on Fly Ash (ng/g)				
	Temperature (°C)				
	200°	250°	300°	350°	400°
CDD					
Tetra	15	26	188	220	50
Penta	40	110	517	590	135
Hexa	65	217	1029	550	110

3. COMBUSTION SOURCES OF CDD/CDF: WASTE INCINERATION

Incineration is the destruction of solid, liquid, or gaseous wastes through the application of heat within a controlled combustion system. The purposes of incineration are to reduce the volume of waste that needs land disposal and to reduce the toxicity of the waste, making it more sterile. In keeping with this definition, incinerator systems can be classified by the types of wastes incinerated: municipal solid waste incineration; medical and pathological waste incineration; hazardous waste incineration; sewage sludge incineration; tire incineration; and biogas flaring. Each of these types of incinerators are discussed in this chapter. The purposes of this chapter are to: characterize and describe waste incineration technologies in the United States and to derive estimates of annual releases of CDDs and CDFs into the atmosphere from these facilities for reference years 1987 and 1995.

Combustion research has developed three theories on the mechanisms involved in the emission of CDDs and CDFs from combustion systems: (1) CDD/CDFs can be introduced into the combustor with the feed and pass through the system unchanged, (2) CDD/CDFs can be formed during combustion, or (3) CDD/CDFs can be formed via chemical reactions in the post-combustion portion of the system. The total CDD/CDF emissions are likely to be the net result of all three mechanisms; however, their relative importance is often uncertain. To the extent practical with the available data, the combustors in each source category were divided into classes judged to have similar emission factors. This classification effort attempted to reflect the emission mechanisms described above. The emission mechanisms suggest that the aspects of combustor design and operation that could affect CDD/CDF emissions are furnace design, composition of the waste feed, temperature in the post-combustion zone of the system, and type of air pollution control device (APCD) used to remove contaminants from the flue gases. Therefore, incineration systems that are similar in terms of these factors should have similar CDD/CDF emissions. Accordingly, this chapter proposes classification schemes that divide combustors into a variety of design classes based on these factors. Design class, as used here, refers to the combination of furnace type and accompanying APCD.

3.1. MUNICIPAL SOLID WASTE INCINERATION

As discussed previously, CDD/CDF emission theory suggests that CDD/CDF emissions can be related to several factors, including furnace design, composition of the waste feed, temperature in the post-combustion zone of the system, and type of APCD used to remove contaminants from the flue gases. Accordingly, this chapter proposes a classification scheme that divides municipal solid waste incinerators (MSWIs) into a variety of design classes based on those factors. Some APCDs are operated at different temperatures; therefore, operating temperature is used to define some design classes. Because the theory also suggests that feed can influence CDD/CDF emissions, the proposed furnace classification system distinguishes refused-derived fuel from normal municipal solid waste (MSW). This section begins with a description of the MSWI technology and then proposes the design classification scheme. Using this scheme, the MSWI industry is characterized for the reference years 1987 and 1995. Finally, the procedures for estimating emissions are explained, and results summarized.

3.1.1. Description of Municipal Solid Waste Incineration Technologies

For purposes of this report, MSWI furnace types are divided into three major categories: mass burn, modular, and refuse-derived fuel. Each of these furnace types is described below, followed with a description of the APCDs used with these systems.

Furnace Types

Mass Burn: Historically, this furnace type derived its name because it burned MSW as received (i.e., no preprocessing of the waste was conducted other than removal of items too large to go through the feed system). Today, a number of other furnace types also burn unprocessed waste (as described below). Mass burn furnaces are distinguished from these others because they burn the waste in a single stationary chamber. In a typical mass burn facility, MSW is placed on a grate that moves through the combustor. The 1995 inventory indicates that the combustion capacity of facilities ranges from 90 to 2,700 metric tons of MSW per day. Three subcategories of mass burn (MB) technologies are described below:

- Mass burn refractory-walled (MB-REF) systems represent an older class of MSWIs (generally built in the late 1970s to early 1980s) that were designed only to reduce

the volume of waste in need of disposal by 70 to 90 percent. These facilities usually lacked boilers to recover the combustion heat for energy purposes. In the MB-REF design, the MSW is delivered to the combustion chamber by a traveling grate and/or a ram feeding system. Combustion air in excess of stoichiometric amounts (i.e., more oxygen is supplied than needed for complete combustion) is supplied both below and above the grate.

- Mass burn waterwall (MB-WW) facilities represent enhanced combustion efficiency, as compared with MB-REF incinerators. Although it achieves similar volume reductions, the MB-WW incinerator design provides a more efficient delivery of combustion air, resulting in sustained higher temperatures. Figure 3-1 is a schematic of a typical MB-WW MSWI. The term 'waterwall ' refers to a series of steel tubes, running vertically along the walls of the furnace. The tubes contain water, which when heated by combustion, transfer energy from the heat of combustion to the water. The water reaches boiling temperature, and steam is produced. The steam is then used to drive an electrical turbine generator or for other industrial needs. This transfer of energy is termed 'energy recovery.'

- Mass burn rotary kiln combustors (MB-RC) use a water-cooled rotary combustor, which consists of a rotating combustion barrel configuration mounted at a 15-20^{o} angle of decline. The refuse is charged at the top of the rotating kiln by a hydraulic ram (Donnelly, 1992). Preheated combustion air is delivered to the kiln through various portals. The slow rotation of the kiln (i.e., 10 to 20 rotations/hour) causes the MSW to tumble, thereby exposing more surface area for complete burnout of the MSW. These systems are also equipped with boilers for energy recovery. Figure 3-2 is a schematic of a typical MB-RC MSWI.

Modular Incinerator: This is the second general type of MSWI furnace used in the United States. As with the mass burn type, modular incinerators burn waste without preprocessing. Modular MSWIs consist of two vertically mounted combustion chambers (i.e., a primary and secondary chamber). In the 1995 inventory, modular combustors' combustion capacity ranged from 4 to 270 metric tons/day. The two major types of modular systems, "excess air" and "starved air," are described below.

- The modular excess-air system consists of a primary and secondary combustion chamber, both of which operate with air levels in excess of stoichiometric requirements (i.e., 100 to 250 percent excess air). Figure 3-3 illustrates a typical modular excess air MSWI.

- Starved (or controlled) air is another type of modular system in which air is supplied to the primary chamber at sub-stoichiometric levels. The products of incomplete combustion entrain in the combustion gases that are formed in the primary combustion chamber, then pass into a secondary combustion chamber. Excess air is added to the secondary chamber, and combustion is completed by elevated

temperatures sustained with auxiliary fuel (usually natural gas). The high and uniform temperature of the secondary chamber, combined with the turbulent mixing of the combustion gases, results in low-levels of particulate matter and organic contaminants being formed and emitted. Therefore, many existing modular units lack post-combustion air pollution control devices. Figure 3-4 is a schematic view of a modular starved air MSWI.

Refuse-Derived Fuel (RDF): The third major type of MSWI furnace technology is designed to combust refuse-derived fuel (RDF). RDF is a general term that describes MSW from which relatively noncombustible items are removed, thereby enhancing the combustibility of the MSW. RDF is commonly prepared by shredding, sorting, and separating out metals to create a dense MSW fuel in a pelletized form having a uniform size. Three types of RDF systems are described below.

- The dedicated RDF system burns RDF exclusively. Figure 3-5 shows a typical dedicated RDF using a spreader-stoker boiler. Pelletized RDF is fed into the combustor through a feed chute, using air-swept distributors; this allows a portion of the feed to burn in suspension and the remainder to burn out after falling on a horizontal traveling grate. The traveling grate moves from the rear to the front of the furnace, and distributor settings are adjusted so that most of the waste lands on the rear two-thirds of the grate. This allows more time to complete combustion on the grate. Underfire and overfire air are introduced to enhance combustion, and these incinerators typically operate at 80 to 100 percent excess air. Waterwall tubes, a superheater, and an economizer are used to recover heat for production of steam and/or electricity. The 1995 inventory indicates that dedicated RDF facilities range in total combustion capacity from 227 to 2,720 metric tons/day.

- Cofired RDFs burn both RDF and normal MSW.

- The fluidized-bed RDF (FB-RDF) burns the waste in a turbulent and semi-suspended bed of sand. The MSW may be fed into the incinerator either as unprocessed waste or as a form of RDF. The RDF may be injected into or above the bed through ports in the combustor wall. The sand bed is suspended during combustion by introducing underfire air at a high velocity, hence the term "fluidized." Overfire air at 100 percent stoichiometric requirements is injected above the sand suspension. Waste-fired FB-RDFs typically operate at 30 to 100 percent excess air levels and at bed temperatures around 815°C (1,500°F). A typical FB-RDF is presented as Figure 3-6. Technology has two basic design concepts: (1) a bubbling-bed incineration unit and (2) a circulating-bed incineration unit. The 1995 inventory indicates that fluidized-bed MSWIs have capacities ranging from 184 to 920 metric tons/day. These systems are usually equipped with boilers to produce steam.

Air Pollution Control Devices (APCDs)

MSWIs are commonly equipped with one or more post-combustion APCDs to remove various pollutants prior to release from the stack (e.g., particulate matter, heavy metals, acid gases, and/or organic contaminants) (U.S. EPA, 1992d). These APCDs include:

- Electrostatic precipitator (ESP),
- Fabric filter (FF),
- Dry scrubber (DS),
- Dry sorbent injection (DSI), and
- Wet scrubber (WS)

Electrostatic Precipitator: The ESP is generally used to collect and control particulate matter that evolves during MSW combustion, by introducing a strong electrical field in the flue gas stream; this, in turn, charges the particles entrained in the combustion gases (Donnelly, 1992). Large collection plates receive an opposite charge to attract and collect the particles. CDD/CDF formation can occur within the ESP at temperatures in the range of 150 to about 350°C. As temperatures at the inlet to the ESP increase from 150 to 300°C, CDD/CDF concentrations have been observed to increase by approximately a factor of two for each 30°C increase in temperature (U.S. EPA, 1994f). As temperature increases beyond 300°C, formation rates decline. Although ESPs in this temperature range efficiently remove most particulates and the associated CDD/CDFs, the formation that occurs can result in a net increase in CDD/CDF emissions. This temperature related formation of CDD/CDF within the ESP can be applied to distinguish hot-side ESPs from cold-side ESPs. For purposes of this report, ESPs are classified as follows:

- A cold-side ESP operates at or below 230°C.
- A hot-side ESP operates at an inlet temperature greater than 230°C.

Fabric Filters (FF): FFs are also particulate matter control devices, which remove dioxins associated with particles and any vapors that adsorb to the particles. Six- to 8-inch diameter bags, made from woven fiberglass material, are usually arranged in series. An induction fan forces the combustion gases through the tightly woven fabric. The porosity of the fabric allows the bags to act as filter media and retain a broad range of particles sizes (i.e., down to less than 1 micrometer in diameter). The FF is sensitive to

acid gas; therefore, it is usually operated in combination with spray dryer adsorption of acid gases.

Dry Scrubbers (DS): DSs, also called spray dryer adsorption, involve both the removal of acid gas and particulate matter from the post-combustion gases. By themselves, these units probably have little effect on dioxin emissions. In a typical DS system, hot combustion gases enter a scrubber reactor vessel. An atomized hydrated lime slurry (water plus lime) is injected into the reactor at a controlled velocity (Donnelly, 1992). The hydrated lime slurry rapidly mixes with the combustion gases within the reactor. The water in the hydrated lime slurry quickly evaporates, and the heat of evaporation causes the combustion gas temperature to rapidly decrease. The neutralizing capacity of hydrated lime reduces the combustion gas content of acid gas constituents (e.g., hydrogen chloride gas, and sulfur dioxide gas) by greater than 70 percent. A dry product, consisting of particulate matter and hydrated lime, settles to the bottom of the reactor vessel. DS technology is used in combination with ESPs. The DS reduces ESP inlet temperatures to make a cold-side ESP. DS/FFs have achieved greater than 95 percent reduction and control of CDD/CDFs in MSWI emissions (U.S. EPA, 1992d).

Dry Sorbent Injection (DSI): DSI is used to reduce acid gas emissions. By themselves, these units probably have little effect on dioxin emissions. DSI involves the injection of dry hydrated lime or soda ash either directly into the combustion chamber or into the flue duct of the hot post-combustion gases. In either case, the reagent reacts with and neutralizes the acid gas constituents (Donnelly, 1992).

Wet Scrubber (WS): WS devices are designed for acid gas removal, and are more common to MSWIs in Europe than in the United States. They should help reduce emissions of dioxin in both vapor and particle forms. WS devices consist of two-stage scrubbers. The first stage removes hydrogen chloride (HCl), and the second stage removes sulfur dioxide (SO_2) (Donnelly, 1992). Water is used to remove the HCl, and caustic or hydrated lime is added to remove SO_2 from the combustion gases.

In addition to the APCDs described above, some less common types are also used in some MSWIs. An example is the Electro Granular Bed (EGB), which consists of a packed bed of activated carbon. An electric field is passed through the packed bed; particles entrained in the flue gases are given a negative charge, and the packed bed is given a positive charge. EGB systems function much like an ESP. Particulate matter is

collected within the bed; therefore, they will remove dioxins associated with collected particles and any vapors that adsorb to the particles. Only one facility in the United States currently employs the EGB system, a fluidized bed-RDF MSWI.

Classification Scheme

Based on the array of MSWI technologies described above, a classification system for deriving CDD/CDF emission estimates was developed. As discussed earlier, it is assumed that facilities with common design and operating characteristics have a similar potential for CDD/CDF emissions. The MSWIs operating in 1987 and 1995 were divided according to the eight furnace types and seven APCDs described above. This resulted in 17 design classes in 1987 and 40 design classes in 1995. Because fewer types of APCDs were used in 1987 than in 1995, fewer design classes are needed for estimating emissions. This taxonomy is summarized in Figures 3-7 and 3-8.

3.1.2. Characterization of MSWI Facilities in Reference Years 1995 and 1987

Table 3-1 lists by design/APCD type, the number of facilities and activity level (kg MSW incinerated per year) for MSWIs in the reference year 1995. A similar inventory is provided for reference year 1987 in Table 3-2. This information was derived from four reports: U.S. EPA (1987b), Systems Applications International (1995), Taylor and Zannes (1996), and Solid Waste Technologies (1994). In general, these studies collected the information via telephone interviews with the plant operators.

Using Tables 3-1 and 3-2, a number of comparisons can be made between the two reference years:

- The number of facilities stayed about the same (113 in 1987 and 130 in 1995), but the amount of MSW incinerated more than doubled (13.8 billion kg in 1987 and 28.8 billion kg in 1995).
- The dominant furnace technology shifted from modular in 1987 (57 units and 1.4 billion kg) to mass burn waterwall facilities in 1995 (57 units and 17 billion kg).
- The dominant APCD technology shifted from hot-sided ESPs in 1987 (54 units and 11 billion kg) to fabric filters in 1995 (55 units and 16 billion kg).
- The use of hot-sided ESPs dropped from 54 facilities in 1987 (11 billion kg) to 16 facilities in 1995 (2.2 billion kg).
- The number of uncontrolled facilities dropped from 38 in 1987 (0.6-billion kg) to 10 facilities in 1995 (0.2 billion kg).

3.1.3. Estimation of CDD/CDF Emissions from MSWIs

Compared to other CDD/CDF source categories, MSWIs have been more extensively evaluated for CDD/CDF emissions. Within the context of this report, adequate emission testing for CDD/CDFs were available for 11 of the 113 facilities in the 1987 inventory and 27 of the 130 facilities in the 1995 inventory. Nationwide CDD/CDF air emissions from MSWIs were estimated using a three-step process as described below.

Step 1. Estimation of emissions from all stack tested facilities. The EPA stack testing method (EPA Method 23) produces a measurement of CDD/CDF in units of mass concentration of CDD/CDF (i.e., nanograms per dry standard cubic meter of combustion gas [ng/dscm]) at standard temperature and pressure (20°C and 1 atmosphere), and adjusted to a measurement of 7 percent oxygen in the flue gas (U.S. EPA, 1995b). This concentration is assumed to represent conditions at the point of release from the stack into the air. Equation 3-1 below was used to derive annual emission estimates for each tested facility:

$$E_{TEQ} = \frac{C \times V \times CF \times H}{10^9 \text{ ng/g}} \qquad \text{(Eqn. 3-1)}$$

Where:

E_{TEQ}	=	Annual TEQ emission (g/yr)
C	=	Combustion flue gas TEQ concentration (ng/dscm) (20°C, 1 atm; adjusted to 7% O_2)
V	=	Volumetric flow rate of combustion flue gas (dscm/hour) (20°C, 1 atm; adjusted to 7% O_2)
CF	=	Capacity factor, fraction of time that the MSWI operates (i.e., 0.85)
H	=	Total hours in a year (8,760 hr/yr)

After calculating annual emissions for each tested facility, the emissions were summed across all tested facilities for each reference year. [Note: Many of the emission tests do not correspond exactly to these 2 years. In these cases, the equipment conditions present at the time of the test were compared to those during the reference year to determine their applicability.]

Step 2. Estimation of emissions from all non-tested facilities. This step involves multiplying the emission factor and annual activity level for each MSWI design class and then summing across classes. The activity levels for reference years 1995 and 1987 are summarized in Tables 3-1 and 3-2, respectively. The emission factors were derived by averaging the emission factors across each tested facility in a design class. The emission factor for each facility was calculated using the following equation:

$$EF_{mswi} = \frac{C \times F_v}{I_w} \qquad \text{(Eqn. 3-2)}$$

Where:

EF_{mswi} = Emission factor, average ng TEQ per kg of waste burned
C = TEQ or CDD/CDF concentration in flue gases (ng TEQ/dscm) (20°C, 1 atm; adjusted to 7% O_2)
F_v = Volumetric flue gas flow rate (dscm/hr) (20°C, 1 atm; adjusted to 7% O_2)
I_w = Average waste incineration rate (kg/hr)

Example: A mass burn waterwall MSWI equipped with cold-sided ESP.

Given:

C = 10 ng TEQ/dscm (20°C, 1 atm; adjusted to 7% O_2)
F_v = 40,000 dscm/hr (20°C, 1 atm; adjusted to 7% O_2)
I_w = 10,000 kg MSW/hr

$$EF_{MBWW} = \frac{10 \text{ ng}}{\text{dscm}} \times \frac{40{,}000 \text{ dscm}}{\text{hr}} \times \frac{\text{hr}}{10{,}000 \text{ kg}}$$

$$EF_{MBWW} = \frac{40 \text{ ng TEQ}}{\text{kg MSW burned}}$$

EPA was not able to obtain engineering test reports of CDD/CDF emissions for a number of design classes. In these cases, the above procedure could not be used to derive emission factors. Instead, the emission factors of the tested design class that was judged most similar in terms of dioxin control was assumed to apply to the untested class. The following logic was used to make this decision:

1. The tested APCDs for the furnace type of the untested class were reviewed to see if any operated at a similar temperature.
2. If any operated at similar temperatures, the one with most similar technology was assumed to apply.
3. If none operated at a similar temperature, then the most similar furnace type with same control device was assumed to apply.

Table 3-3 lists all design categories with no tested facilities and shows the class with tested facilities that was judged most similar.

It should be understood that the emission factors for each design class are the same for both reference years. This is because the emission factor is determined only by the design and operating conditions and is independent of the year of the test.

Step 3. Sum emissions from tested and untested facilities. This step simply involves summing emissions from all tested and untested facilities. This process is shown in Tables 3-4 and 3-5 for the reference years 1995 and 1987, respectively. The tables are organized by design class and show separately the emission estimates for the tested and untested facilities. The calculation of emissions from untested facilities is broken out to show the activity level and emission factor for each design class.

3.1.4. Summary of CDD/CDF (TEQ) Emissions from MSWIs for 1995 and 1987

The activity level estimates (i.e., the amount of MSW that is annually combusted by the various MSWI technologies) are given a high confidence rating for both 1987 (i.e., 13.8 billion kg of waste) and 1995 (i.e., 28.8 billion kg of waste). For both years, comprehensive surveys of activity levels were conducted by independent sources on virtually all facilities (U.S. EPA, 1987b; Systems Application International, 1995; Taylor and Zannes, 1996; Solid Waste Technologies, 1994).

The emission factor estimates are given a medium confidence rating for both 1987 and 1995. A moderate fraction of the facilities were tested in both years: 11 of 113 facilities in 1987 (10 percent), and 27 of 130 facilities (21 percent) in 1995. Moreover, the tested facilities represent 21 and 27 percent of the total activity level of operating MSWIs in 1987 and 1995, respectively. These tests represent most of the design

categories identified in this report. The emission factors were developed from emission tests that followed standard EPA protocols, used strict QA/QC procedures, and were well documented in engineering reports. Because all tests were conducted under normal operating conditions, some uncertainty exists about the magnitude of emissions that may occur during other conditions (i.e., upset conditions, start-up and shut-down).

These confidence ratings produce an overall medium confidence rating in the annual emission estimates of 7,915 g I-TEQ_{DF} (8,877 g TEQ_{DF}-WHO_{98}) in 1987 and 1,100 g I-TEQ_{DF} (1,250 g TEQ_{DF}-WHO_{98}) in 1995.

3.1.5 Congener Profiles of MSWI Facilities

The air emissions from MSWIs contain a mixture of CDD and CDF congeners. These mixtures can be translated into what are termed 'congener profiles,' which represent the distribution of total CDDs and CDFs present in the mixture. A congener profile may serve as a signature of the types of CDDs and CDFs associated with particular MSWI technology and APCD. Figure 3-9 is a congener profile of a mass-burn waterwall MSWI equipped with a dry scrubber and fabric filter (i.e., the most common type of MSWI and APCD design in use today). This congener profile indicates that OCDD dominates CDD/CDF emissions and that every toxic CDD/CDF congener is detected in the emissions.

3.1.6 Estimated CDD/CDFs in MSWI Ash

Ash from MSWIs is required to be disposed of in permitted landfills from which releases to the general environment are controlled. For background purposes, however, some information is presented below about the quantities of CDD/CDFs in ash from MSWIs.

An estimated 7 million metric tons of total ash (bottom ash plus fly ash) were generated by MSWIs in 1992 (telephone conversation between J. Loundsberry, U.S. EPA Office of Solid Waste, and L. Brown, Versar, Inc., on February 24, 1993). U.S. EPA (1991b) indicated that 2 to 5 million metric tons of total ash were produced annually in the late 1980s from MSWIs, with fly ash comprising 5 to 15 percent of the total. U.S. EPA (1990c) reported the results of analyses of MSWI ash samples for CDDs and CDFs. Ashes from five state-of-the-art facilities located in different regions of the United States were analyzed for all 2,3,7,8-substituted CDDs and CDFs. The TEQ levels in the ash (fly

ash mixed with bottom ash) ranged from 106 to 466 ng I-TEQ_{DF}/kg, with a mean value of 258 ng I-TEQ_{DF}/kg. CDD/CDF levels in fly ash are generally much higher than in bottom ash. For example, Fiedler and Hutzinger (1992) reported levels of 13,000 ng I-TEQ_{DF}/kg in fly ash.

In another study (Washington, 1998), CDD/CDF congener data were reported for ash and other solid residuals from three municipal incinerators (Fort Lewis, Bellingham [municipal plus medical wastes], and Spokane). The data were compiled and evaluated to determine a total I-TEQ concentration and loading. Non-detect values were included as either zero, ½ DL, or at the DL. The results were as follows, assuming that non-detect values were at zero concentration:

Location	Type of Residual	T-TEQ (μg/kg)	I-TEQ (mg/day)
Ft. Lewis	Bottom Ash Fly Ash	0.00 4.98	0.00 0.76
Bellingham	Mixed Ash (avg. of 3 tests)	0.038	1.14
Spokane	Mixed Ash Fly Ash Bottom Ash	0.163 0.51 0.0001	38.0 24.3 0.02

In Shane (1990), five municipal incinerator ashes were analyzed for a number of constituents including CDDs (not CDFs) and PCBs. For dioxins, three of the incinerators were at non-detectable levels (detection limit of 1 μg/kg). The other two incinerators had detectable levels of five CDD congener groups. (No analyses were reported for individual congeners.) The average for those two units were:

TCDD	26 μg/kg
PeCDDs	59 μg/kg
HxCDDs	53 μg/kg
HpCDDs	25 μg/kg
OCDDs	12 μg/kg

These levels were much higher that those reported in U.S. EPA (1990c).

For PCBs, the five sets of ashes were analyzed for 10 congener groups. All groups were detected for one of the incinerators. However, the other four incinerators contained little or no octa-, nona-, or deca- congeners. The average PCB concentration (all congener groups) for the five incinerators was 216 μg/kg, with a range of 99-322 μg/kg.

No generation rates of the ashes were given in Shane (1990). Therefore, the measured concentrations cannot be readily converted to quantities of CDDs or PCBs. The ashes from each of the five incinerators were disposed of in multiple fashions. For two of the incinerators, the ash was sent to metal recovery and also landfilled. For a third, the fly ash was sold. For a fourth, the ashes were only landfilled. For the fifth, the ashes were used in road building and also landfilled. For those incinerators with more than one ash disposition, no breakdown was given of how much went to each location. There were 15 other incinerators discussed in Shane (1990). Thirteen of them disposed of their ash exclusively in landfills, and the other two partially disposed of their ash in landfills.

Table 7 of Clement (1988) presented 13 data sets for CDD/CDF congener groups for a municipal incinerator ash. The average data for each congener group and the ranges of each group are given in Table 3-6. No data were presented in Clement (1988) for individual congeners, nor were there data for ash quantities.

In Table 3-3 of U.S. EPA (1987a), there were data stating that ashes from three incinerators (one in North America, one in Europe, and one in Japan) had mean CDD concentrations of 363, 588, and 2.6 μg/kg, respectively. The ranges of those data were from <0.5 to 3.537 μg/kg. Similarly, for CDFs, the respective mean concentrations for the first two incinerators were 923 and 288 μg/kg. The third incinerator was not reported. The CDF range for the two incinerator ashes was <0.5 to 1,770 μg/kg. No data were given for individual congeners, nor were there any data for quantities of the ashes.

In Table 1 of Lahl (1991), data were presented for the concentrations of total CDDs and for total CDFs for the ash from an electrostatic precipitator from a municipal incinerator. Data were reported for summer sampling and for winter sampling. The total CDDs in the summer were 140.46 μg/kg, and for the winter were 86.00 μg/kg. The total CDFs in the summer were 54.97 μg/kg, and for the winter were 73.85 μg/kg. No data

were given for individual congeners, nor was there information about the quantity of precipitator ash generated. It was assumed that the data were not for TEQs.

In Table 3-11 of U.S. EPA (1987a), a wire reclamation incinerator was reported to have 0.41 μg/kg of CDDs and 11.6 μg/kg of CDFs in fly ash from its "stack" emissions. For the same incinerator, the "furnace" ash concentrations were reported as 0.58 μg/kg CDDs and 0.73 μg/kg CDFs. Again, no data were given for individual congeners, nor were there any data for quantities of the ashes.

Data from the aforementioned sources have been compiled in Table 3-7 for comparison purposes. Annual TEQ amounts were estimated by multiplying the mean TEQ total ash concentration by the estimated amount of MSWI ash generated annually (approximately 7 million metric tons in 1995 and 5 million metric tons in 1987). Where possible, ash quantities were broken down into fly ash and/or bottom ash categories. Fly ash is assumed to be 10% of the total ash and bottom ash is assumed to be 90% of the total ash.

Each of the five facilities sampled in U.S. EPA (1990c) had companion ash disposal facilities equipped with leachate collection systems or some means of collecting leachate samples. Leachate samples were collected and analyzed for each of these systems. Detectable levels were only found in the leachate at one facility (3 ng I-TEQ_{DF}/L); the only detectable congeners were HpCDDs, OCDD, and HpCDFs.

3.1.7 Recent EPA Regulatory Activities

On December 19, 1995, EPA promulgated CDD/CDF emission standards for all existing and new MSWI units at facilities with aggregate combustion capacities greater than 35 metric tons per day (Federal Register, 1995e). In response to a court remand, the regulations were subsequently amended to remove small MWC units (i.e., units with capacities ranging from 35 to 225 kkg/day) (Federal Register, 1997c). The specific emission standards (expressed as ng/dscm of total CDD/CDF - based on standard dry gas corrected to 7 percent oxygen) are a function of the size, APCD configuration, and age of the facility as listed below:

1995 Emission standard (ng total CDD/CDF/dscm)	Facility age, size, and APCD
60	• Existing; >225 metric tons/day; ESP-based APCD
30	• Existing; >225 metric tons/day; non-ESP-based APCD
13	• New; >225 metric tons/day

EPA reproposed emission standards for small MWCs (defined as units with capacities of between 32 and 224 kkg/day) on August 30, 1999 (Federal Register, 1999c). The proposed emission standard is 125 ng total CDD/CDF per dscm at 7 percent oxygen.

States have up to 3 years from promulgation of the Federal standards to submit revised State Implementation Plans to EPA for approval. Once approved, States have the primary responsibility to implement the new standards. EPA's Office of Air Quality Planning and Standards (OAQPS) estimates that the full compliance by all MSWIs with the 1995 standards and 1999 proposed standards will result in an annual emission of about 12 g I-TEQ_{DF}/yr (U.S. EPA, 2000a).

3.2. HAZARDOUS WASTE INCINERATION

Hazardous waste incineration (HWI) is the controlled pyrolysis and/or oxidation of potentially dangerous liquid, gaseous and solid waste. HWI is one technology used to manage hazardous waste under the Resource Conservation and Recovery Act (RCRA) and Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) (Superfund) programs. As described below, hazardous wastes are burned in a variety of situations and are covered in a number of different sections in this report.

- Much of the hazardous waste is burned in facilities dedicated to burning hazardous waste. Most of these dedicated facilities are located on-site at chemical manufacturing facilities and only burn waste associated with their on-site industrial operations. Hazardous waste is also burned at dedicated facilities located off-site from manufacturing facilities and accept waste from multiple sources. These fixed location facilities dedicated to burning hazardous waste at both on- and off-site locations are addressed in Sections 3.2.1 to 3.2.4.

- Hazardous waste is also burned in industrial boilers and furnaces that are permitted to burn the waste as supplemental fuel. These facilities have significantly different

furnace designs and operations than dedicated HWIs; therefore, they are discussed in Section 3.2.5.

- A number of cement kilns and lightweight aggregate kilns are also permitted to burn hazardous waste as auxiliary fuel; these are discussed separately in Section 5.1.

- Mobile HWIs are typically used for site cleanup at Superfund sites and operate for a limited duration at any given location. These units are mobile in the sense that they can be transported from one location to another. Due to the transitory nature of these facilities, they are not included in this inventory at this time.

The following subsections review the types of HWI technologies commonly in use in the United States, and present the derivation of emissions estimates of CDD/CDFs from all facilities operating in 1995 and 1987.

3.2.1. Furnace Designs for Hazardous Waste Incinerators

The four principal furnace designs employed for the combustion of hazardous waste in the United States are: rotary kiln, liquid injection, fixed hearth, and fluidized-bed incinerators (Dempsey and Oppelt, 1993). The majority of commercial operations are of the rotary kiln incinerator type. On-site (noncommercial) HWI technologies are an equal mix of rotary kiln and liquid injection facilities, with a few additional fixed hearths and fluidized bed operations (U.S. EPA, 1996h). Each of these HWI technologies is discussed below:

Rotary Kiln HWI: Rotary kiln incinerators consist of a rotary kiln, coupled with a high temperature afterburner. Because these are excess air units designed to combust hazardous waste in any physical form (i.e., liquid, semi-solid, or solid), rotary kilns are the most common type of hazardous waste incinerator used by commercial off-site operators. The rotary kiln is a horizontal cylinder lined with refractory material. Rotation of the cylinder on a slight slope provides for gravitational transport of the hazardous waste through the kiln (Buonicore, 1992a). The tumbling action of the rotating kiln causes mixing and exposure of the waste to the heat of combustion, thereby enhancing burnout. Solid and semi-solid wastes are loaded into the top of the kiln by an auger or rotating screw. Fluid and pumpable sludges and wastes are typically introduced into the kiln through a water-cooled tube. Liquid hazardous waste is fed directly into the kiln through a burner nozzle. Auxiliary fuel (natural gas or oil) is burned in the kiln chamber at start-up

to reach elevated temperatures. The typical heating value of hazardous waste (i.e., 8,000 Btu/kg) is sufficient to sustain combustion without auxiliary fuel (U.S. EPA, 1996h). The combustion gases emanating from the kiln are passed through a high temperature afterburner chamber to more completely destroy organic pollutants entrained in the flue gases. Rotary kilns can be designed to operate at temperatures as high as 2,580°C, but more commonly operate at about 1,100°C.

Liquid Injection HWI: Liquid injection incinerators (LIIs) are designed to burn liquid hazardous waste. These wastes must be sufficiently fluid to pass through an atomizer for injection as droplets into the combustion chamber. The LIIs consist of a refractory-lined steel cylinder mounted either in a horizontal or vertical alignment. The combustion chamber is equipped with one or more waste burners. Because of the rather large surface area of the atomized droplets of liquid hazardous waste, the droplets quickly vaporize. The moisture evaporates, leaving a highly combustible mix of waste fumes and combustion air (U.S. EPA, 1996h). Secondary air is added to the combustion chamber to complete the oxidation of the fume/air mixture.

Fixed Hearth HWI: Fixed hearths are starved air or pyrolytic incinerators. Waste is ram-fed into the primary chamber and incinerated below stoichiometric requirements (i.e., at about 50 to 80 percent of stoichiometric air requirements). The resulting smoke and pyrolytic combustion products are then passed though a secondary combustion chamber where relatively high temperatures are maintained by the combustion of auxiliary fuel. Oxygen is introduced into the secondary chamber to promote complete thermal oxidation of the organic molecules entrained in the gases.

Fluidized-bed HWI: The fourth hazardous waste incineration technology is the fluidized-bed incinerator, which is similar in design to that used in municipal solid waste incineration. (See Section 3.1.) In this configuration, a layer of sand is placed on the bottom of the combustion chamber. The bed is preheated by underfire auxiliary fuel at startup. During combustion of auxiliary fuel at start-up, the hot gases are channeled through the sand at relatively high velocity, and the turbulent mixing of combustion gases and combustion air causes the sand to become suspended (Buonicore, 1992a). This takes on the appearance of a fluid medium, hence the incinerator is termed a 'fluidized bed' combustor The incinerator is operated below the melting point temperature of the bed material. Typical temperatures of the fluid medium are within the range of 650 to 940°C.

A constraint on the types of waste burned is that the solid waste particles must be capable of being suspended within the furnace. When the liquid or solid waste is combusted in the fluid medium, the exothermic reaction causes heat to be released into the upper portion of the combustion chamber. The upper portion is typically much larger in volume than the lower portion, and temperatures can reach 1,000°C (Buonicore, 1992a). This high temperature is sufficient to combust volatilized pollutants emanating from the combustion bed.

3.2.2. APCDs for Hazardous Waste Incinerators

Most HWIs use APCDs to remove undesirable components from the flue gases that evolved during the combustion of the hazardous waste. These unwanted pollutants include suspended ash particles (particulate matter or PM), acid gases, metal, and organic pollutants. The APCD controls or collects these pollutants and reduces their discharge from the incinerator stack to the atmosphere. Levels and kinds of these combustion byproducts are highly site-specific, depending on factors such as waste composition and incinerator system design and operating parameters (e.g., temperature and exhaust gas velocity). The APCD is typically comprised of a series of different devices that work together to clean the exhaust combustion flue gas. Unit operations usually include exhaust gas cooling, followed by particulate matter and acid gas control.

Exhaust gas cooling may be achieved using a waste heat boiler or heat exchanger, mixing with cool ambient air, or injection of a water spray into the exhaust gas. A variety of different types of APCDs are employed for the removal of particulate matter and acid gases. Such devices include: wet scrubbers (such as venturi, packed bed, and ionizing systems), electrostatic precipitators, and fabric filters (sometimes used in combination with dry acid gas scrubbing). In general, the control systems can be grouped into the following three categories: wet, dry, and hybrid wet/dry systems. The controls for acid gases (either dry or wet systems) cause temperatures to be reduced preceding the control device. This impedes the extent of formation of CDDs and CDFs in the post-combustion area of the typical HWI. It is not unusual for stack concentrations of CDD/CDFs at a particular HWI to be in the range of 1 to 100 ng CDD/CDF/dscm (Helble, 1993), which is low in comparison to other waste incineration systems. The range of total CDD/CDF flue gas concentrations measured in the stack emissions of HWIs during trial burns across the

class of HWI facilities, however, has spanned four orders of magnitude (ranging from 0.1 to 1,600 ng/dscm) (Helble, 1993). The APCD systems are described below:

- **Wet Systems:** A wet scrubber is used for both particulate and acid gas control. Typically, a venturi scrubber and packed-bed scrubber are used in a back-to-back arrangement. Ionizing wet scrubbers, wet electrostatic precipitators, and innovative venturi-type scrubbers may be used for more efficient particulate control. Wet scrubbers generate a wet effluent liquid wastestream (scrubber blowdown), are relatively inefficient at fine particulate control compared to dry control techniques, and have equipment corrosion concerns. However, wet scrubbers do provide efficient control of acid gases and have lower operating temperatures (compared with dry systems), which may help control the emissions of volatile metals and organic pollutants.
- **Dry Systems:** In dry systems, a fabric filter or electrostatic precipitator (ESP) is used for particulate control. A fabric filter or ESP is frequently used in combination with dry scrubbing for acid gas control. Dry scrubbing systems, in comparison with wet scrubbing systems, are inefficient in controlling acid gases.
- **Hybrid Systems:** In hybrid systems, a dry technique (ESP or fabric filter) is used for particulate control, followed by a wet technique (wet scrubber) for acid gas control. Hybrid systems have the advantages of both wet and dry systems (lower operating temperature for capture of volatile metals, efficient collection of fine particulate, efficient capture of acid gases), while avoiding many of the individual disadvantages. In some hybrid systems, known as "zero discharge systems," the wet scrubber liquid is used in the dry scrubbing operation, thus minimizing the amount of liquid byproduct waste.
- **Uncontrolled HWIs:** Facilities that do not use any air pollution control devices fall under a separate and unique category. These are primarily liquid waste injection facilities, which burn low ash and chlorine content wastes; therefore, they are low emitters of PM and acid gases.

3.2.3. Estimation of CDD/CDF Emission Factors for Hazardous Waste Incinerators

For purposes of estimating emission factors, this document considers subdividing the combustors in each source category into design classes judged to have similar potential for CDD/CDF emissions. As explained below, it was decided not to subdivide dedicated HWIs.

Combustion research has identified three mechanisms involved in the emission of CDD/CDFs from combustion systems: (1) CDD/CDFs can be introduced into the combustor with the feed and pass through the system not completely burned/destroyed; (2) CDD/CDFs can be formed by chemical reactions inside the combustion chamber; and (3) CDD/CDFs can be formed by chemical reactions outside the combustion chamber. The total CDD/CDF emissions are likely to be the net result of all three mechanisms; however, the relative importance of the mechanisms can vary among source categories. In the case of HWIs, the third mechanism (i.e., post-combustion formation) is likely to dominate, because HWIs are typically operated at high temperatures and long residence times, and most have sophsiticated real-time monitoring and controls to manage the combustion process. Therefore, any CDD/CDFs present in the feed or formed during combustion are likely to be destroyed before exiting the combustion chamber. Consequently, for purposes of generating emission factors, it was decided not to subdivide this class on the basis of furnace type.

Emissions resulting from the post-combustion formation in HWIs can be minimized through a variety of technologies:

- **Rapid Flue Gas Quenching**: The use of wet and dry scrubbing devices to remove acid gases usually results in the rapid reduction of flue gas temperatures at the inlet to the PM APCD. If temperature is reduced below 200˚C, the low-temperature catalytic formation of CDD/CDFs is substantially retarded.
- **Use of Particulate Matter (PM) Air Pollution Control Devices**: PM control devices can effectively capture condensed and adsorbed CDD/CDFs that are associated with the entrained particulate matter (in particular, that which is adsorbed on unburned carbon containing particulates).

- **Use of Activated Carbon**: Activated carbon injection is used at some HWIs to collect (sorb) CDD/CDFs from the flue gas. This may be achieved using carbon beds or by injecting carbon and collecting it in a downstream PM APCD.

All of these approaches appear very effective in controlling dioxin emissions at dedicated HWIs, and insufficient emissions data are available to generalize about any minor differences. Consequently, for purposes of generating emission factors, it was decided not to subdivide this class on the basis of APCD type.

EPA compiled a data base summarizing the results of stack testing for CDDs and CDFs at 17 HWIs (U.S. EPA, 1996c). Most facilities were tested between 1993 and 1996. For purposes of this report, CDD/CDF emission factors were estimated based on the results of the emission tests contained in this data base. The breakdown of furnace types of tested HWI facilities is as follows: 10 rotary kiln incinerators, 4 liquid injection incinerators, 1 fluidized-bed incinerator, and 2 fixed-bed.

As stated earlier, EPA/ORD decided not to subclassify the dedicated HWI designs for purposes of deriving an emission factor (EF). Instead, the emission factor was derived as an average across all 17 tested facilties. First, an average emission factor was calculated for each of 17 HWIs with Equation 3-3.

$$EF_{hwi} = \frac{C \times F_v}{I_w} \qquad \text{(Eqn. 3-3)}$$

Where:

EF_{hwi} = Emission factor (average ng TEQ per kg of waste burned)
C = TEQ or CDD/CDF concentration in flue gases (ng TEQ/dscm) (20°C, 1 atm; adjusted to 7% O_2)
F_v = Volumetric flue gas flow rate (dscm/hr) (20°C, 1 atm; adjusted to 7% O_2)
I_w = Average waste incineration rate (kg/hr)

After developing average emission factors for each HWI, the overall average congener-specific emission factor was derived for all 17 tested HWIs using Equation 3-4.

$$EF_{avgHWI_{n=1-17}} = (EF_{HWI_1} + EF_{HWI_2} + EF_{HWI_3} + \ldots\ldots\ldots + EF_{HWI_{17}}) / N \qquad \text{(Eqn. 3-4)}$$

Where:

EF_{HWI} = Average emission factor for the 17 tested HWIs, (ng/kg)
N = Number of tested facilities (i.e., 17)

Table 3-8 presents the average emission factors developed for specific congeners, total CDDs/CDFs, and TEQs for the tested HWIs. The average congener emission profile for the 17 tested HWIs are presented in Figure 3-10. The average I-TEQ_{DF} and TEQ_{DF}-WHO_{98} emission factors for the 17 tested HWIs are 3.83 ng I-TEQ_{DF}/kg of waste feed and 3.88 ng TEQ_{DF}-WHO_{98}/kg of waste feed (assuming not detected values are zero). The available data did not support development of different emission factors for the two reference years, 1987 and 1995.

3.2.4. Emission Estimates for Hazardous Waste Incinerators

Although emissions data were available for 10 percent of the HWIs (i.e., 17 of 162 have been tested), the emission factor estimates are assigned a medium confidence rating due to uncertainties resulting from:

- *Variability of the waste feeds*. The physical and chemical composition of the waste can vary from facility to facility and even within a facility. Consequently, CDD/CDF emissions measured for one feed may not be representative of other feeds.

- *Trial burns*. Much of the CDD/CDF emissions data were collected during trial burns, which are required as part of the RCRA permitting process and are used to establish Destruction Rated Efficiency (DRE) of principal hazardous organic constituents in the waste. During trial burns, a prototype waste is burned, which is intended to maximize the difficulty in achieving good combustion. For example, chlorine, metals, and organics may be added to the waste. The HWI may also be operated outside normal operating conditions. The temperature of both the furnace and the APCD may vary by a wide margin (high and low temperatures), and the waste feed system may be increased to maximum design load. Accordingly, it is uncertain how representative the CDD/CDF emissions measured during the trial burn will be of emissions during normal operating conditions.

Dempsey and Oppelt (1993) estimated that up to 1.3 million metric tons of hazardous waste were combusted in HWIs during 1987. EPA estimated that 1.5 million metric tons of hazardous waste were combusted each year in the early 1990s in HWIs (Federal Register, 1996b). This activity level estimate for 1995 is assigned a high confidence rating, because it is based on a review by EPA of the various studies and surveys conducted in the 1990s to assess the quantity and types of hazardous wastes

being managed by various treatment, storage, and disposal facilities. A confidence rating of medium is assigned to the activity level estimate for 1987.

The annual TEQ emissions for the reference years 1995 and 1987 were estimated using Equation 3-5.

$$E_{HWI} = EF_{HWI} \times A_{HWI} \qquad \text{(Eqn. 3-5)}$$

Where:

E_{HWI} = Annual emissions from all HWIs, tested and non-tested (g TEQ/yr)
EF_{HWI} = Mean emission factor for HWIs (ng TEQ/kg of waste burned)
A_{HWI} = Annual activity level of all operating HWIs (million metric tons/yr)

Applying the average TEQ emission factors for dedicated HWIs (3.83 ng I-TEQ_{DF}/kg and 3.88 ng TEQ_{DF}-WHO_{98}/kg waste) to these production estimates yields estimated emissions of 5.7 g I-TEQ_{DF} (or 5.8 g TEQ_{DF}-WHO_{98}) in 1995 and 5.0 g TEQ (I-TEQ_{DF} or TEQ_{DF}-WHO_{98}) in 1987 for HWIs. The medium confidence rating assigned to the emission factor, combined with the medium confidence rating for the 1995 activity level and medium confidence rating for the 1987 activity level, yields an overall medium confidence rating for both years.

3.2.5. Recent EPA Regulatory Activities

EPA/OSW has also developed estimates of the CDD/CDF emissions from HWIs as part of the development of the Hazardous Waste Combustors Rule (Federal Register, 1999b). Like ORD, OSW also decided not to subdivide the HWIs on the basis of design. Instead of an emission factor approach, OSW used an imputation method to estimate emissions at untested facilities. This procedure involved randomly selecting measured CDD/CDF flue gas concentrations (ng/dscm) from the pool of tested HWI facilities and assigning them to the untested facilities. With this procedure, all non-tested HWIs have an equal chance of being assigned any flue gas concentration from the pool of measured values. The flue gas concentrations were combined with flue gas flow rates for each facility to estimate the emission rate. Using this approach, EPA/OSW estimated that I-TEQ_{DF} emissions in 1997 were 24.8 grams and that the emissions would be reduced to

3.5 g after full implementation of the rule. A key difference in these approaches is that ORD uses waste feed rate directly in the calculation of emissions and the OSW approach is independent of waste feed rate. Both procedures are reasonable ways to deal with the broad range of uncertainties and both yield similar emission estimates. ORD has not identified any inherent advantage of one approach over the other and elected to use the emission factor approach primarily because it is consistent with the methods used in this document to characterize CDD/CDF emissions from all other source categories.

3.2.6. Industrial Boilers and Furnaces Burning Hazardous Waste

In 1991, EPA established rules that allow the combustion of some liquid hazardous waste in industrial boilers and furnaces (Federal Register, 1991c). These facilities typically burn oil or coal for the primary purpose of generating electricity. Liquid hazardous waste can only be burned as supplemental (auxiliary) fuel, and usage is limited by the rule to no more than 5 percent of the primary fuels. These facilities typically use an atomizer to inject the waste as droplets into the combustion chamber and are equipped with particulate and acid gas emission controls. In general, they are sophisticated, well controlled facilities, which achieve good combustion.

The national data base contains congener-specific emission concentrations for two tested boilers burning liquid hazardous waste as supplemental fuel. The average congener and congener group emission profiles for the industrial boiler data set are presented in Figure 3-11. The average congener and TEQ emission factors are presented in Table 3-8. The limited set of emissions data prevented subdividing this class for the purpose of deriving an emission factor. The equation used to derive the emission factor is the same as Equation 3-4 above. The average TEQ emission factor for the two industrial boilers is 0.64 ng I-TEQ_{DF}/kg of waste feed (or 0.65 ng TEQ_{DF}-WHO_{98}/kg of waste feed). These emission factors are assigned a low confidence rating, because they reflect testing at only 2 of the 136 hazardous waste boilers/furnaces.

Dempsey and Oppelt (1993) estimated that approximately 1.2 billion kg of hazardous waste were combusted in industrial boilers/furnaces in 1987. EPA estimates that each year in the early 1990s approximately 0.6 billion kg of hazardous waste were combusted in industrial boilers/furnaces (Federal Register, 1996b). It is possible that cement kilns and lightweight aggregate kilns burning hazardous waste were included in

this estimate by Dempsey and Oppelt for 1987; the estimate for 1995 does not appear to include these hazardous waste burning kilns. This activity level estimate for 1995 is assigned a medium confidence rating, because it was based on a review by EPA of the various studies and surveys conducted in the 1990s to assess the quantity and types of hazardous wastes being managed by various treatment, storage, and disposal facilities. A confidence rating of low is assigned to the estimated activity level for 1987. The 1987 estimate was largely based on a review of State permits (Dempsey and Oppelt,1993).

Equation 3-5, used to calculate annual TEQ emissions for dedicated HWIs, was also used to calculate annual TEQ emissions for industrial boilers/furnaces. Multiplying the average TEQ emission factors by the total estimated kg of liquid hazardous waste burned in 1995 and 1987 yields annual emissions in g-TEQ/yr. From this procedure, the emissions from all industrial boilers/furnaces burning hazardous waste as supplemental fuel are estimated as 0.38 g I-TEQ_{DF} (or 0.39 g TEQ_{DF}-WHO_{98}) in 1995 and 0.77 g I-TEQ_{DF} (or 0.78 g TEQ_{DF}-WHO_{98}) in 1987. Because of the low confidence rating for the emission factor, the overall confidence rating is low for both the 1987 and 1995 emission estimates.

3.2.7. Solid Waste from Hazardous Waste Combustion

U.S. EPA (1987a) contains limited data on ash generated from hazardous waste incineration. Table 3-8 of U.S. EPA (1987a) indicates that 538 μg/kg and 2,853 μg/kg were the mean concentrations of CDDs and CDFs, respectively, from a hazardous waste incinerator with an afterburner. Specific data for congeners and for ash quantities were not given.

3.3. MEDICAL WASTE INCINERATION

Medical waste incineration (MWI) is the controlled burning of solid wastes generated primarily by hospitals, veterinary, and medical research facilities. The U.S. EPA defines medical waste as any solid waste generated in the treatment, diagnosis, or immunization of humans or animals, or research pertaining thereto, or in the production or testing of biologicals (Federal Register, 1997b). The primary purposes of MWI are to reduce the volume and mass of waste in need of land disposal, and to sterilize the infectious materials. The following subsections review the basic types of MWI designs

used to incinerate medical waste, review the distribution of APCDs used on MWIs, summarize the derivation of dioxin TEQ emission factors for MWIs, and summarize the national dioxin TEQ emission estimates for reference years 1995 and 1987.

3.3.1. Design Types of MWIs Operating in the United States

For purposes of this document, EPA has classified MWIs into three broad technology categories: modular furnaces using controlled-air, modular furnaces using excess-air, and rotary kilns. Of the MWIs in use today, the vast majority are believed to be modular furnaces using controlled-air. EPA has estimated that 97 percent are modular furnaces using controlled-air, 2 percent are modular furnaces using excess air, and 1 percent are rotary kiln combustors (U.S. EPA, 1997b).

Modular Furnaces Using Controlled-air: Modular furnaces have two separate combustion chambers mounted in series (one on top of the other). The lower chamber is where the primary combustion of the medical waste occurs. Medical waste is ram-fed into the primary chamber, and underfire air is delivered beneath the incinerator hearth to sustain good burning of the waste. The primary combustion chamber is operated at below stoichiometric levels, hence the terms "controlled" or "starved-air." With sub-stoichiometric conditions, combustion occurs at relatively low temperatures (i.e., 760 to 985°C). Under the conditions of low oxygen and low temperatures, partial pyrolysis of the waste occurs, and volatile compounds are released. The combustion gases pass into a second chamber. Auxiliary fuel (such as natural gas) is burned to sustain elevated temperatures (i.e., 985 to 1,095°C) in this secondary chamber. The net effect of exposing the combustion gases to an elevated temperature is more complete destruction the organic contaminants entrained in the combustion gases emanating from the primary combustion chamber. Combustion air at 100 to 300 percent in excess of stoichiometric requirement is usually added to the secondary chamber. Gases exiting the secondary chamber are directed to an incinerator stack (U.S. EPA, 1997b; U.S. EPA, 1991d; Buonicore, 1992b). Figure 3-12 displays a schematic of a typical modular furnace using controlled-air. Because of it's low cost and good combustion performance, this design has been the most popular choice for MWIs and has accounted for more than 95 percent of systems installed over the past two decades (U.S. EPA, 1990d; U.S. EPA, 1991d; Buonicore, 1992b).

Modular Furnaces Using Excess-air: These systems use the same modular furnace configuration as described above for the controlled air systems. The difference is that the primary combustion chamber is operated at air levels of 100 percent to 300 percent in excess of stoichiometric requirements. Hence the name "excess-air." A secondary chamber is located on top of the primary unit. Auxiliary fuel is added to sustain high temperatures in an excess-air environment. Excess-air MWIs are typically smaller in capacity than controlled-air units and are usually batch-fed operations. This means that the medical waste is ram-fed into the unit and allowed to burn completely before another batch of medical waste is added to the primary combustion chamber.

Rotary Kiln MWI: This technology is similar in terms of design and operational features to the rotary kiln technology employed in both municipal and hazardous waste incineration. (See description in Section 3.1.) Because of their relatively high capital and operating costs, few rotary kiln incinerators are in operation for medical waste treatment (U.S. EPA, 1990d; U.S. EPA, 1991d; Buonicore, 1992b).

MWIs can be operated in three modes: batch, intermittent, and continuous. Batch incinerators burn a single load of waste, typically only once per day. Waste is loaded, and ashes are removed manually. Intermittent incinerators, loaded continuously and frequently with small waste batches, operate less than 24 hours per day, usually on a shift-type basis. Either manual or automated charging systems can be used, but the incinerator must be shut down for ash removal. Continuous incinerators are operated 24 hours per day and use automatic charging systems to charge waste into the unit in small, frequent batches. All continuous incinerators operate using a mechanism to automatically remove the ash from the incinerator (U.S. EPA, 1990d; U.S. EPA, 1991d).

3.3.2. Characterization of MWIs for Reference Years 1995 and 1987

MWI remains a poorly characterized industry in the United States in terms of knowing the exact number of facilities operational over time, the types of APCDs installed on these units, and the aggregate volume and weight of medical waste that is combusted in any given year (U.S. EPA, 1997b). The primary reason for this is that permits were not generally required for the control of pollutant stack emissions from MWIs until the early 1990s when State regulatory agencies began setting limits on emissions of particulate

matter and other contaminants (Federal Register, 1997b). Prior to that timeframe, only opacity was controlled.

The information available to characterize MWIs comes from national telephone surveys, stack emission permits, and data gathered by EPA during public hearings (Federal Register, 1997b). This information suggests the following:

- The number of MWIs in operation was approximately 5,000 in 1987 (U.S. EPA, 1987d) and 2,375 in 1995 (Federal Register, 1997b).
- The amount of medical waste combusted annually in the United States was approximately 1.43 billion kg in 1987 (U.S. EPA, 1987d) and 0.77 billion kg in 1995 (Federal Register, 1997b).

These estimates indicate that, between 1987 and 1995, the total number of operating MWIs and the total amount of waste combusted decreased by more than 50 percent. Certain activities caused this to occur, including more stringent air pollution control requirements by State regulatory agencies and the development of less expensive medical waste treatment technologies, such as autoclaving (Federal Register, 1997b). Because many MWIs have small waste charging capacity (i.e., about 50 metric tons per day), the installation of even elementary APCDs proved not to be cost effective. Thus, a large number of facilities elected to close rather than retrofit.

The actual controls used on MWIs on a facility-by-facility basis in 1987 are unknown, and EPA generally assumes that MWIs were mostly uncontrolled (U.S. EPA,1987d). However, the modular design does cause some destruction of organic pollutants within the secondary combustion chamber. Residence time within the secondary chamber is key to inducing the thermal destruction of the organic compounds. Residence time is the time that the organic compounds entrained within the flue gases are exposed to elevated temperatures in the secondary chamber. EPA has demonstrated with full-scale MWIs that increasing residence time from 1/4 second to 2 seconds in the secondary chamber can reduce organic pollutant emissions, including CDD/CDFs, by up to 90 percent (Federal Register, 1997b). In this regard, residence time can be viewed as a method of air pollution control.

EPA estimates that about two-thirds of medical waste burned in MWIs in 1995 went to facilities equipped with some method of air pollution control (Federal Register, 1997b). The types of APCDs installed and the methods used on MWIs include: dry

sorbent injection, fabric filters, electrostatic precipitators (ESPs), wet scrubbers, and fabric filters combined with packed-bed scrubbers (composed of granular activated carbon). Some organic constituents in the flue gases can be adsorbed by the packed bed. Within the uncontrolled class of MWIs, about 12 percent of the waste were combusted in facilities with design capacities of $<$200 lbs/hr, with the majority of waste burned facilities $>$200 lbs/hr. The estimated breakdown of controlled facilities is: 70 percent of the aggregate activity level are associated with facilities equipped with either wet scrubbers, fabric filters, or ESPs; 29.9 percent are associated with facilities utilizing dry sorbent injection, combined with fabric filters, and less than 1 percent is associated with facilities having the fabric filter/packed-bed APCD (AHA, 1995; Federal Register, 1997b).

3.3.3. Estimation of CDD/CDF Emissions from MWIs

Emission tests reported for 24 MWIs (i.e., about 1 percent of existing facilities) were collected for use in this report. Consequently, most facilities have unmeasured emission levels of dioxin-like compounds. Because so few have been evaluated, the estimation of annual air emissions of CDD/CDFs from MWIs is quite dependent on extrapolations, engineering judgement, and the use of assumptions. In addition, the information about the activity levels of these facilities is also quite limited. With these data limitations, two approaches have been used in the past to estimate CDD/CDF emissions from MWIs, and a third is proposed here. These three approaches are as follows:

1. **EPA/OAQPS Approach**: EPA's Office of Air Quality Planning and Standards (OAQPS) used this approach in support of the promulgation of final air emission standards for hospital/medical/infectious waste incinerators (Federal Register, 1997b).

2. **AHA Approach**: The American Hospital Association proposed an approach in its comments on drafts of this document and on the proposed MWI emissions regulations (AHA, 1995).

3. **EPA/ORD Approach**: In preparation of this document, EPA's Office of Research and Development (ORD) has developed a third approach.

Given the limitations with existing information, both the EPA/OAQPS and AHA approaches are reasonable methods for calculating annual releases of CDD/CDFs from MWIs. Both

methods relied heavily on a series of assumptions to account for missing information. In developing a third approach, EPA/ORD built upon the other two approaches by utilizing the most logical features of each. Because of the uncertainties with existing data, it is currently not known which approach gives the most accurate estimate of CDD/CDF air emissions from all MWIs, nationwide. The three approaches yield different air emission estimates, but the estimates all agree within a factor of four. As discussed below, the EPA/ORD approach used the strengths of the other two approaches, and represents some improvement in estimating CDD/CDF emissions.

3.3.4. EPA/OAQPS Approach for Estimating CDD/CDF Emissions from MWIs

On September 15, 1997, EPA promulgated final standards of performance for new and existing MWIs under the Clean Air Act Amendments (Federal Register, 1997b). CDD/CDF stack emission limits for existing MWIs were established as follows: 125 ng/dscm of total CDD/CDF (at 7 percent O_2, 1 atm), equivalent to 2.3 ng/dscm TEQ. In order to evaluate emissions reductions that will be achieved by the standard, OAQPS estimated, as a baseline for comparison, nationwide annual CDD/CDF emissions from all MWIs operating in 1995.

3.3.4.1. *EPA/OAQPS Approach for Estimating Activity Level*

As a starting point for deriving the national estimates, OAQPS constructed an inventory of the numbers and types of MWIs believed to be operating in 1995. The inventory was based on an inventory of 2,233 MWIs prepared by the American Hospital Association (AHA, 1995), supplemented with additional information compiled by EPA. This created a listing of 2,375 MWIs in the United States. Next a series of assumptions were used to derive activity level estimates, as follows:

1. The analysis divided MWIs into three design types based on the mode of daily operation: batch, intermittent, and continuous. This was done using the information from the inventory on design-rated annual incineration capacity of each facility. The smaller capacity units were assumed to be batch operations, and the others were classified as either intermittent or continuous, assuming a ratio of three to one.

2. The activity level of each facility was estimated by multiplying the design-rated annual incineration capacity of the MWI (kg/hr) by the hours of

operation (hr/yr). The annual hours of operation were determined by assuming a capacity factor (defined as the fraction of time that a unit operates over the year) for each design type of MWI (Randall, 1995). Table 3-9 is a summary of the OAQPS estimated annual operating hours per MWI design type.

3.3.4.2. *EPA/OAQPS Approach for Estimating CDD/CDF Emission Factors*

Based on information obtained from AHA and State regulatory agencies, one-third of the population of MWIs operating in 1995 was etimated to have had no APCDs (i.e., were uncontrolled), and two-thirds had some type of APCD. CDD/CDF TEQ emission factors were then developed for uncontrolled and controlled MWIs. The procedure was as follows:

Estimating TEQ Emission Factors for Uncontrolled Facilities: The uncontrolled category of facilities was subdivided by residence time of the secondary combustion chamber. Based on tests at three MWIs, OAQPS concluded that stack emissions of CDD/CDFs from uncontrolled facilities were dependent on the residence time (i.e., the duration of time the compounds are exposed to elevated temperatures within the secondary combustion chamber) (Strong, 1996). The tests demonstrated that when the residence time in the secondary chamber was short (i.e., <1 sec), the stack emissions of CDDC/CDFs would increase; conversely, the longer the residence time (i.e., >1 sec), the CDD/CDF emissions decrease. The emissions testing at these MWIs provided the basis for the derivation of I-TEQ_{DF} emission factors for residence times of 1/4-sec, 1-sec and 2-sec. Table 3-10 is a summary of the emission factors developed for each MWI type as a function of residence time.

The OAQPS inventory of MWIs in 1995 did not provide residence times for each facility. OAQPS overcame this data gap by assuming that residence time in the secondary combustion chamber approximately corresponds with the particulate matter (PM) stack emission limits established in State air permits. This approach assumed that the more stringent PM emission limits would require longer residence times in the secondary chamber in order to further oxidize carbonaceous soot particles and reduce PM emissions. Table 3-10 lists the assumed residence times in the secondary chamber corresponding to various State PM emission limits. State Implementation Plans (SIPs) were reviewed to determine the PM emission limits for incinerators, and from this review, both a residence

time and an I-TEQ_{DF} emission factor were assigned to each uncontrolled MWI on the inventory.

Estimating TEQ Emission Factors for Controlled MWIs: Two-thirds of the MWI population were assumed to have some form of APCD. As previously discussed, APCDs typically used by MWIs consist of one or more of the following: wet scrubber, dry scrubber, and fabric filter combined with a packed bed. The EPA/OAQPS approach also included the addition of activated carbon to the flue gases as a means of emissions control (i.e., dry scrubbers combined with carbon injection). TEQ emission factors were developed for these control systems based on incinerator emissions testing data gathered in support of the regulations (U.S. EPA, 1997b). Because the inventory did not list the APCDs for all MWIs, State requirements for PM control were used to make assumptions about the type of APCD installed on each facility in the inventory. These assumptions are summarized in Table 3-11.

3.3.4.3. *EPA/OAQPS Approach for Estimating Nationwide CDD/CDF TEQ Air Emissions*

Annual TEQ emissions for each MWI facility were calculated as a function of the design capacity of the incinerator, the annual waste charging hours, the capacity factor, and the TEQ emission factor as shown in Equation 3-6.

$$E_{mwi} = (C \times H \times C_1) \times F_{TEQ} \qquad \text{(Eqn. 3-6)}$$

Where:

E_{mwi}	=	Annual MWI CDD/F TEQ stack emissions (g/yr)
C	=	MWI design capacity (kg/hr)
H	=	Annual medical waste charging hours (hr/yr)
C_1	=	Capacity factor (unitless)
F_{TEQ}	=	CDD/CDF TEQ emission factor (g TEQ/kg)

The annual TEQ air emission of all MWIs operating in 1995 is the sum of the annual emissions of each individual MWI. The following equation is applied to estimate annual TEQ emissions from all MWIs.

$$E_{mwi}(\text{nationwide}) = (Em_{mwi_1} + Em_{mwi_2} + + \ldots\ldots + Em_{mwi_{2375}}) \quad \text{(Eqn. 3-7)}$$

Where:

E_{mwi}(nationwide) = Nationwide MWI TEQ emissions (g/yr)

Table 3-11 is a summary of I-TEQ_{DF} emissions for 1995 estimated using the EPA/OAQPS Approach.

3.3.5. AHA Approach for Estimating CDD/CDF Emissions from MWIs

In 1995, the American Hospital Association (AHA) submitted written comments to EPA in response to EPA's request for public comment of the 1994 draft public release of this document (AHA, 1995). As part of these comments, the AHA attached an analysis of CDD/CDF emissions from MWIs prepared by Doucet (1995) for the AHA. Doucet (1995) estimated the total number of MWIs operating in 1995, the distribution of APCDs, CDD/CDF TEQ emission factors, and the nationwide TEQ emissions. The following is a brief discussion of the AHA inventory and the Doucet (1995) analysis.

From a national telephone survey of member hospitals conducted between September and November 1994, the AHA developed what is generally considered as the first attempt to systematically inventory MWIs in the United States. Approximately 6 percent of the hospitals with MWIs were contacted (AHA,1997). The AHA survey showed that, as of December 1994, 2,233 facilities were in operation. Doucet (1995) subdivided the AHA MWI inventory into two uncontrolled categories based on combustor design-rated capacity and two controlled categories based on APCD equipment. Doucet (1995) then developed CDD/CDF emission factors for each MWI category. Test reports of 19 MWIs were collected and evaluated. Average CDD/CDF TEQ flue gas concentrations (i.e., ng/dscm @7 percent O_2) were derived by combining tests from several MWIs in each capacity range category and APCD. The average TEQ flue gas concentrations were then converted to average TEQ emission factors, which were in units of lb TEQ/10^6 lbs of medical waste incinerated (equation for conversion not given). Table 3-12 lists the I-TEQ_{DF} emission factors calculated by Doucet (1995) for each level of assumed APCDs on MWIs.

Similar to the EPA/OAQPS Approach (Section 3.3.4), the distribution of the APCD categories was derived by assuming that State particulate emission (PM) limits would indicate the APCD on any individual MWI (Doucet, 1995). Table 3-13 displays the AHA assumptions of air pollution control (APC) utilized on MWIs based upon PM emission limits.

With the activity levels, the percent distribution of levels of controls, and the CDD/CDF TEQ emission factors having been calculated with existing data, the final step of the AHA Approach was the estimation of annual I-TEQ_{DF} emissions (g/yr) from MWIs, nationwide. Although no equation is given, it is presumed that the emissions were estimated by multiplying the activity level for each MWI size and APCD category by the associated I-TEQ_{DF} emission factor. The sum of these calculations for each designated class yields the estimated annual I-TEQ_{DF} emissions for all MWIs, nationwide. Doucet (1995) indicates that these computations are appropriate for I-TEQ_{DF} emissions in 1995. Table 3-14 summarizes the nationwide annual I-TEQ_{DF} emissions from MWIs using the AHA Approach.

3.3.6. EPA/ORD Approach for Estimating CDD/CDF Emissions from MWIs

Because of limitations in emissions data and on activity levels, the EPA/ORD approach used many of the logical assumptions developed in the EPA/OAQPS and AHA approaches. The discussion below describes the rationale for how these decisions were made, and presents the resulting emission estimates.

3.3.6.1. *EPA/ORD Approach for Classifying MWIs and Estimating Activity Levels*

As with the EPA/OAQPS and AHA approaches, the EPA/ORD approach divided the MWIs into controlled and uncontrolled classes. The decisions about further dividing these two classes are described below:

Uncontrolled MWIs: For purposes of assigning CDD/CDF emission factors and activity levels to the uncontrolled class of MWIs, the EPA/OAQPS approach divided this class on the basis of residence time within the secondary combustion chamber. This approach has theoretical appeal, because it is logical to expect more complete combustion of CDD/CDFs with longer residence times at high temperatures. Unfortunately, the residence times on a facility-by-facility basis are not known, making it difficult to assign

emission factors and activity levels on this basis. As discussed earlier, the EPA/OAQPS approach assumed that residence time would strongly correlate with State PM stack emission requirements (i.e., the more stringent the PM requirements, the longer the residence time required to meet the standard). This PM method for estimating residence time resulted in the following distribution of residence times: 6 percent of the waste incinerated at MWIs with 1/4-sec residence time; 26 percent of the waste incinerated at MWIs with 1-sec residence time; and 68 percent of the waste incinerated at MWIs with 2-sec residence time. Thus, about two-thirds of the activity level within the uncontrolled class were assumed in the EPA/OAQPS approach to be associated with facilities with the longest residence time and the lowest CDD/CDF emission factor.

The AHA approach subcategorized the uncontrolled class on the basis of design-rated capacity. There is also theoretical support for this approach. Smaller capacity operations (i.e., $<$200 lb/hr) are likely to have higher emissions, because they are more likely to be operating in a batch mode. The batch mode results in infrequent operation with more start-up and shut-down cycles. Thus, the batch-operated MWI usually spends more time outside of the ideal range of operating conditions. In support of this approach, the AHA presented limited empirical evidence indicating that CDD/CDF emission factors calculated from emission test reports for the low capacity units were about a factor of two higher than the emission factors for the high capacity units (Doucet, 1995).

Thus, both the EPA/OAQPS and AHA approaches have a sound theoretical basis but lack strong supporting data. In order to decide which of the two approaches to use, ORD first tested the assumption that there is a strong relationship between State PM requirements and residence time. ORD conducted a limited telephone survey of regulatory agencies in four States where a large number of MWI facilities were in operation: Michigan, Massachusetts, New Jersey, and Virginia (O'Rourke, 1996). The results of the limited survey, summarized in Table 3-15, did not verify the existence of a strong dependent relationship between PM emission limits and residence time in the secondary chamber at MWIs.

Next, the available emission testing data for small and high capacity units (i.e., less than and greater than 200 lb/hr) were evaluated to determine if, as posited in the AHA approach, smaller capacity units have greater emission factors than large capacity units. This evaluation indicated a distinct difference in the emission factors between the two

capacity categories, although the difference in the set of data evaluated was not as great as the difference observed in the data set evaluated in the AHA approach. The EPA/ORD approach, therefore, adopted the subcategorization scheme used in the AHA approach.

Controlled MWIs: Both the EPA/OAQPS approach and the AHA approach subcategorized the controlled MWIs on the basis of APCD equipment. However, the two approaches differed in the subcategories developed. The AHA approach divided the controlled class into two groups: facilities equipped with wet scrubbers (alone, with an ESP, or with a fabric filter), and facilities equipped with dry sorbent injector and a fabric filter (Doucet, 1995). The EPA/OAQPS approach divided the controlled class into three groups: facilities equipped with wet scrubbers, facilities equipped with dry scrubbers (with or without carbon injection), and facilities equipped with fabric filters and packed bed scrubbers. This third category is comprised of a few facilities primarily located in the Northeast United States (O'Rourke, 1996). The EPA/ORD approach adopted the two subcategories of the AHA approach and the third subcategory of the EPA/OAQPS approach. For 1995, EPA/ORD used the activity levels for each facility as reported in the EPA/OAQPS inventory; the activity levels were then summed across facilities for each APCD subclass.

For 1987, the EPA/ORD approach assumed that every MWI was uncontrolled. An EPA study of MWI incineration conducted at that time indicates that MWIs operating in 1987 did not need controls, because they were not subject to State or Federal limits on either PM or organic pollutant emissions (U.S. EPA, 1987d). The activity level estimates were derived from data presented in U.S. EPA (1987d). This approach resulted in the following activity level assumptions for 1987: (a) 15 percent of the activity level (i.e., 0.22 billion kg medical waste) were incinerated/yr by MWIs with capacities less than or equal to 200 lb/hr, and (b) 85 percent of the activity level (i.e., 1.21 billion kg/yr) were incinerated by facilities with capacities greater than 200 lb/hr.

3.3.6.2. *EPA/ORD Approach for Estimating CDD/CDF Emission Factors*

EPA/ORD collected the engineering reports of 24 tested MWIs. After reviewing these test reports, 20 met the criteria for acceptability. (See Section 3.1.3 for further details on the criteria.) In some cases, CDD/CDF congener-specific data were not reported, or values were missing. In other cases, the protocols used in the laboratory

analysis were not described; therefore, no determination of the adequacy of the laboratory methods could be made.

The EPA stack testing method (EPA Method 23) produces a measurement of CDD/CDFs in units of mass concentration (i.e., nanograms per dry standard cubic meter of combustion gas (ng/dscm)) at standard temperature and pressure and one atmosphere and adjusted to a measurement of 7 percent oxygen in the flue gas (U.S. EPA, 1995b). This concentration is assumed to represent conditions at the point of release from the stack into the air, and to be representative of routine emissions. The emission factors were derived by averaging the emission factors across each tested facility in a design class. The emission factor for each tested MWIs was calculated using the following equation:

$$EF_{mwi} = \frac{C \times F_v}{I_w} \qquad \text{(Eqn. 3-8)}$$

Where:

EF_{mwi}	=	Emission Factor per MWI (average ng TEQ per kg of medical waste burned)
C	=	Average TEQ concentration in flue gases of tested MWIs (ng TEQ/dscm) (20°C, 1 atm; adjusted to 7% O_2)
F_v	=	Average volumetric flue gas flow rate (dscm/hr) (20°C, 1 atm; adjusted to 7% O_2)
I_w	=	Average medical waste incineration rate of the tested MWI (kg/hr)

The emission factor estimate for each design class and the number of stack tests used to derive it are shown in Table 3-16. Figures 3-12 and 3-13 present congener and congener group profiles for air emissions from MWIs lacking APCDs and for MWIs equipped with a wet scrubber/baghouse/fabric filter APCD system, respectively.

3.3.7. Summary of CDD/CDF Emissions from MWIs

Because the stack emissions from so few facilities have been tested (i.e., 20 test reports) relative to the number of facilities in this industry (i.e., 2,375 facilities in 1995 and 5,000 facilities in 1987) and because several tested facilities are no longer in operation or have installed new APCD after testing, the EPA/ORD approach did not calculate nationwide CDD/CDF emissions by calculating emissions from the tested

facilities and adding those to calculated emissions for the non-tested facilities. Rather, the EPA/ORD approach (as well as the EPA/OAQPS and AHA approaches) calculated nationwide CDD/CDF emissions by multiplying the emission factor and activity level developed for each design class and then summing the calculated emissions for all classes. Tables 3-16 and 3-17 summarize the resulting national TEQ air emissions for the reference years 1995 and 1987, respectively. Tables 3-16 and 3-17 also indicate the activity level and the TEQ emission factor used in estimating annual TEQ emissions.

In estimating annual TEQ emissions in both reference years, a low confidence rating was assigned to the estimate of the activity level. The primary reason for the low confidence rating is that very limited information is available on a facility level basis for characterizing MWIs in terms of the frequency and duration of operation, the actual waste volume handled, and the level of pollution control. The 1987 inventory of facilities was based on very limited information. Although the 1995 EPA/OAQPS inventory was more comprehensive than the 1987 inventory, it was still based on a fairly limited survey of operating facilities (i.e., approximately 6 percent).

The emission factor estimates were given a low confidence rating, because only the reports of 20 tested MWI facilities could be used to derive emissions factors representing the 2,375 facilities operating in 1995 (i.e., less than 1 percent of estimated number of operating facilities). Even fewer tested facilities could be used to represent the larger number of facilities operating in 1987 (i.e., 8 tested facilities were used to represent 5,000 facilities). The limited emission tests available do cover all design categories used here to develop emission factors. However, because of the large number of facilities in each of these classes, it is very uncertain whether the few tested facilities in each class capture the true variability in emissions. As shown in Table 3-16, the TEQ emissions in 1995 are estimated to have been 461 g I-TEQ_{DF} or 488 g TEQ_{DF}-WHO_{98}. As shown in Table 3-17, the TEQ emissions in 1987 are estimated to have been 2,440 g I-TEQ_{DF} or 2,590 g TEQ_{DF}-WHO_{98}.

As explained above, the EPA/ORD approach to estimating national CDD/CDF TEQ emissions is a 'hybridization' of the EPA/OAQPS and AHA approaches. Table 3-18 compares the main features of each of the three approaches. The 1995 TEQ emissions estimated here (461 g I-TEQ_{DF}/yr) are about 3.5 times higher than those of OAQPS and AHA (141 and 138 g I-TEQ_{DF}/yr, respectively). Most of this difference is due to

differences in the emission estimates for the uncontrolled facilities (ORD - 432 g I-TEQ_{DF}/yr, OAQPS - 136 g I-TEQ_{DF}/yr, AHA - 120 g I-TEQ_{DF}/yr). An analysis of the differences in how these groups estimated emissions from the uncontrolled facilities are presented below:

- **Differences between the EPA/ORD and AHA Approaches:** The ORD approach adopted the classification scheme of the AHA approach for the uncontrolled class and assumed similar activity levels. Thus, the difference in emission estimates is primarily due to differences in the emission factors used. Both groups use similar emission factors for facilities with design capacities less than or equal to 200 lbs/h, but the emission factor for MWIs >200 lbs/hr used in the EPA/ORD approach was higher than that used in the AHA approach by a factor of three. This results from the fact that the two approaches used different sets of emission tests to derive their emission factors.

- **Differences between the EPA/ORD and EPA/OAQPS Approaches**: Because the two approaches subcategorized the uncontrolled facilities into different classes, the activity levels and emission factors cannot be directly compared. Considering the class as a whole, however, both approaches used essentially identical activity levels. The EPA/OAQPS approach assigned 68 percent of the total activity to the class with the lowest emission factor (i.e., those with >2-sec residence time). The emission factor for this class, 74 ng I-TEQ_{DF}/kg, is considerably lower than either emission factor used in the EPA/ORD approach (1,680 and 1,860 ng I-TEQ_{DF}/kg).

Given the uncertain data base available for making these estimates, it is difficult to know which of these three estimation approaches yields the most accurate annual TEQ estimate. However, despite the differences in methodologies and assumptions used, the three approaches yield annual TEQ estimates that are not fundamentally different; the estimates differ from each other by a factor of four or less. Because the EPA/ORD approach was the last of the three to be developed, it has the benefit of being able to utilize the most logical and supportable features of the previously developed EPA/OAQPS and AHA approaches.

3.3.8. Recent EPA Regulatory Activities

Regardless of the approach taken to estimate what the CDD/CDF emissions from 2,375 MWIs were in 1995, the National Emission Standards promulgated by EPA in September 1997 (Federal Register, 1997b) require substantial reductions of CDD/CDF air emissions from MWIs. As a result of these standards, MWI emissions will be thoroughly assessed for purposes of compliance with the CDD/CDF standard. Compliance testing will allow the development of a more comprehensive emissions data base and more accurate characterization of this industry. EPA projects that, following full compliance with these standards, annual emissions will be 5 to 7g I-TEQ_{DF}year.

3.4. CREMATORIA

Bremmer et al. (1994) measured CDD/CDF emissions at two crematoria in The Netherlands. The first, a "cold" type furnace with direct uncooled emissions, was calculated to yield 2.4 μg I-TEQ_{DF} per body. In the cold type furnaces, the coffin is placed inside at a temperature of about 300°C. Using a burner, the temperature of the chamber is increased to 800 to 900°C and kept at that temperature for 2 to 2.5 hours. The second furnace, a "warm" type with cooling of flue gases to 220°C prior to discharge, was calculated to yield 4.9 μg I-TEQ_{DF} per body. In the warm type furnace, the coffin is placed in a chamber preheated to 800°C or higher for 1.2 to 1.5 hours. The chamber exhausts from both furnace types were incinerated in an after burner at a temperature of about 850°C. The higher emission rate for the warm-type furnace was attributed by Bremmer et al. (1994) to the formation of CDD/CDF during the intentional cooling of the flue gases to 220°C.

Jager et al. (1992) (as reported in Bremmer et al., 1994) measured an emission rate of 28 μg I-TEQ_{DF} per body for a crematorium in Berlin, Germany. No operating process information was provided by Bremmer et al. (1994) for the facility.

Mitchell and Loader (1993) reported even higher emission factors for two crematoria in the United Kingdom. The first facility tested was manually-operated, had primary and secondary combustion chambers preheated to 650°C, and had a residence time of 1 second in the secondary combustion chambers. The second tested facility was computer-controlled, had primary and secondary combustion chambers heated to 850°C, and had a residence time of 2 seconds in the secondary combustion chamber. The

measured stack gas concentrations of I-TEQ_{DF} ranged from 42.0 to 71.3 ng I-TEQ_{DF}/m^3 (at 11% O_2) at the first facility and from 25.4 to 45.5 ng I-TEQ_{DF}/m^3 (at 11% O_2) at the second facility. Emission factors based on these test results and gas generation rates reported by Bremmer et al. (1994) were calculated to range from 70 to 80 μg I-TEQ_{DF}/body (HMIP, 1995).

Takeda et al. (1998) measured CDD/CDF emissions at 10 crematoria in Japan. Although there are more than 1,600 crematoria in Japan, the 10 tested facilities handle four percent of the cremations carried out in Japan annually. A wide range in emission factors was observed. When not-detected values are treated as zero, the range was 0.042 to 62 μg I-TEQ_{DF}/body (mean of 9.2 μg I-TEQ_{DF}/body). When not-detected values are treated as one-half the detection limit, the range was 0.45 to 63 μg I-TEQ_{DF}/body (mean of 11 μg I-TEQ_{DF}/body).

In the United States, CDD/CDF emissions have been measured at one crematorium (CARB, 1990c) classified as a warm type facility using the criteria of Bremmer et al. (1994). The combusted material at this facility was comprised of the body, as well as 4 pounds of cardboard, up to 6 pounds of wood, and an unquantified amount of unspecified plastic wrapping. The three emission tests conducted at this facility yielded an average emission factor of 0.50 μg I-TEQ_{DF}/body (or 0.54 μg TEQ_{DF}-WHO_{98}/body). Table 3-19 presents the congener-specific emission factors for this facility. Figure 3-14 presents CDD/CDF congener and congener group emission profiles based on these emission factors.

The emission factor measured at the one tested U.S. facility is at the lower end of the range reported for 10 Japanese facilities by Takeda et al. (1998) and is also lower than the results reported by Bremmer et al. (1994) for two Dutch facilities, by Jager et al. (1992) for one German facility, and by Mitchell and Loader (1993) for two British facilities. The average emission factor for these 16 tested facilities is 17 μg I-TEQ_{DF}/body (assuming not-detected values are zero). Because congener-specific results were not provided in the non-U.S. reports, it was not possible to calculate the average emission factor in units of TEQ_{DF}-WHO_{98}. This average emission factor is assigned a low confidence rating because it is based primarily on tests conducted at non-U.S. facilities.

In 1995, there were 1,155 crematories reported in the United States. However, there are no readily available data on the number of cold versus warm crematoria furnaces. In 1995, 21.1 percent of the deceased bodies were cremated (i.e., 488,224

cremations), and 15.2 percent of the deceased were cremated in 1987 (i.e., 323,371 cremations). Cremations are projected to increase to 25 percent in the year 2000 and 37 percent in the year 2010. A high confidence rating is assigned to these activity level estimates, because they are based on recent data provided by the Crematoria Association of North America (Springer, 1997).

Combining this average emission rate of 17 μg I-TEQ$_{DF}$/body with the number of cremations in 1995 (488,224) yields an estimated annual release of 9.1 g I-TEQ$_{DF}$. Combining the emission rate of 17 μg I-TEQ$_{DF}$/body with the number of cremations in 1987 (323,371) yields an estimated release of 5.5 g.

3.5. SEWAGE SLUDGE INCINERATION

The three principal combustion technologies used to incinerate sewage sludge in the United States are the multiple-hearth incinerator, fluidized-bed incinerator, and the electric furnace (Brunner, 1992; U.S. EPA, 1995b). All of these technologies are "excess-air" processes (i.e., they combust sewage sludge with oxygen in excess of theoretical requirements). Approximately 80 percent of operating sludge incinerators are multiple-hearth design. About 20 percent are fluidized-bed incinerators, and less than 1 percent are electric incinerators. Other types of technologies not widely used in the United States are single-hearth cyclones, rotary kilns, and high-pressure wet-air oxidation (U.S. EPA, 1997b; Maw, 1998).

Multiple-hearth Incinerator: This consists of refractory hearths arranged vertically in series, one on top of the other. Dried sludge cake is fed to the top hearth of the furnace. The sludge is mechanically moved from one hearth to another through the length of the furnace. Moisture is evaporated from the sludge cake in the upper hearths of the furnace. The center hearths are the burning zone, where gas temperatures reach 871°C. The bottom hearths are the burn-out zone, where the sludge solids become ash. A waste-heat boiler is usually included in the burning zone, where steam is produced to provide supplemental energy at the sewage treatment plant. Air pollution control measures typically include a venturi scrubber, an impingement tray scrubber, or a combination of both. Wet cyclones and dry cyclones are also used (U.S. EPA, 1995b).

Fluidized-bed Incinerator: This is a cylindrical refractory-lined shell with a steel plate structure that supports a sand bed near the bottom of the furnace (Brunner, 1992).

Air is introduced through openings in the bed plate supporting the sand. This causes the sand bed to undulate in a turbulent air flow; hence, the sand appears to have a fluid motion when observed through furnace portals. Sludge cake is added to the furnace at a position just above this fluid motion of the sand bed. The fluid motion promotes mixing in the combustion zone. Sludge ash exits the furnace with the combustion gases; therefore, air pollution control systems typically consist of high-energy venturi scrubbers. Air pollution control measures typically include a venturi scrubber or venturi/impingement tray combinations (U.S. EPA, 1995b).

Electric Furnaces: Also called infrared furnaces, these consist of a long rectangular refractory-lined chamber. A belt conveyer system moves the sludge cake through the length of the furnace. To promote combustion of the sludge, supplemental heat is added by electric infrared heating elements within the furnace that are located just above the traveling belt. Electric power is required to initiate and sustain combustion. Emissions are usually controlled with a venturi scrubber or some other wet scrubber (Brunner, 1992; U.S. EPA, 1995b).

3.5.1. Emission Estimates from Sewage Sludge Incinerators

EPA measured CDD/CDF emissions at three multiple-hearth incinerators as part of Tier 4 of the National Dioxin Survey (U.S. EPA, 1987a). During the pre-test surveys, two of the facilities were judged to have "average" potential and one facility was judged to have "high" potential for CDD/CDF emissions with respect to other sewage sludge incinerators. The results of these tests include congener group concentrations in stack gas, but lack measurement results for specific congeners other than 2,3,7,8-TCDD and 2,3,7,8-TCDF. EPA measured CDD/CDF emissions (including all 17 toxic congeners) at a fluidized-bed incinerator and a multiple hearth incinerator in 1990 (U.S. EPA, 1990f). In 1995, the Association of Metropolitan Sewerage Agencies (AMSA) submitted to EPA the results of stack tests conducted at an additional 13 sewage sludge incinerators (Green et al., 1995). Two of these data sets were considered not useable by EPA, because either detection limits or feed rates and stack flow rates were not provided. The average congener and congener group emission factors are presented in Table 3-20 for the three facilities from U.S. EPA (1987a) and the 11 AMSA facilities from Green et al. (1995). A wide variability was observed in the emission factors for the tested facilities. The total

CDD/CDF emission factors for the three U.S. EPA (1987a) facilities ranged from 90 to 3,400 ng/kg. The total CDD/CDF emission factors for the two facilities reported in U.S. EPA (1990f) were 79 to 846 ng/kg. For the 11 facilities reported in Green et al. (1995), a similarly large variability in emission factors was observed. Figure 3-15 presents the average congener and congener group profiles based on these data.

The average TEQ emission factor based on the data for the 11 AMSA facilities and the two facilities reported in U.S. EPA (1990f) is 6.94 ng I-TEQ_{DF}/kg of dry sludge combusted (or 7.04 ng TEQ_{DF}-WHO_{98}/kg of dry sludge), assuming nondetected values are zero. Other countries have reported similar results. Bremmer et al. (1994) reported an emission rate of 5 ng I-TEQ_{DF}/kg for a fluidized-bed sewage sludge incinerator, equipped with a cyclone and wet scrubber, in The Netherlands. Cains and Dyke (1994) measured CDD/CDF emissions at two sewage sludge incinerators in the United Kingdom. The emission rate at an incinerator equipped with an electrostatic precipitator and wet scrubber ranged from 2.75 ng I-TEQ_{DF}/kg to 28.0 ng I-TEQ_{DF}/kg. The emission rate measured at a facility equipped with only an electrostatic precipitator was 43.0 ng I-TEQ_{DF}/kg.

In 1988, approximately 199 sewage sludge incineration facilities combusted about 0.865 million metric tons of dry sewage sludge (Federal Register, 1993b). In 1995, approximately 257 sewage sludge incinerators (some of which were backup or alternate incinerators) combusted about 2.11 million dry metric tons of sewage sludge (Maw, 1998). Given these estimated amounts of sewage sludge incinerated/yr, the estimate of TEQ emissions to air is 6.0 g I-TEQ_{DF} (or 6.1 g TEQ_{DF}-WHO_{98}) in 1987 and 14.6 g I-TEQ_{DF} (or 14.8 g TEQ_{DF}-WHO_{98}) in 1995, using the average TEQ emission factor of 6.94 ng I-TEQ_{DF}/kg (7.04 ng TEQ_{DF}-WHO_{98}/kg).

A medium confidence rating is assigned to the average TEQ emission factor because it was derived from stack testing at 13 U.S. sewage sludge incinerators. The 1988 activity level estimate (used as a surrogate for the 1987 activity level) is assigned a high confidence rating, because it is based on an extensive EPA survey to support rulemaking activities. The 1995 activity level estimate is assigned a medium confidence rating because assumptions concerning hours of operation, operating capacity, and design capacity were made for numerous facilities.

3.5.2. Solid Waste from Sewage Sludge Incinerators

In Table 5-16 of U.S. EPA (1987a), data are presented indicating that 2,3,7,8-TCDD was not detected in the bottom ash or scrubber water filtrate from three sewage sludge incinerators. However, total CDDs for the three incinerators and the filtrate were: non-detect, 20 ng/kg, 10 ng/kg, and 0.3 ng/kg, respectively. For total CDFs, the respective values were: non-detect, 70 ngk/kg, 50 ng/kg, and 4.0 ng/kg. No data were given for any congeners (other than 2,3,7,8-TCDD), nor were there any data on the quantities of ash or filtrate.

3.6. TIRE COMBUSTION

Emissions of CDD/CDFs from the incineration of automobile tires were measured from a dedicated tire incinerator tested by the California Air Resources Board (CARB, 1991a). The facility consists of two excess air furnaces equipped with steam boilers to recovery the energy from the heat of combustion. Discarded whole tires were fed to the incineration units at rates ranging from 2,800 to 5,700 kg/hr during the 3 test days. The facility was equipped with a dry acid gas scrubber and fabric filter for the control of emissions prior to exiting the stack. Table 3-21 presents the congener-specific emission factors for this facility. Figure 3-16 presents CDD/CDF congener and congener group profiles based on these TEQ emission factors. From these data, the average emission factor is estimated to be 0.282 ng I-TEQ_{DF}/kg of tires incinerated (or 0.281 ng TEQ_{DF}-WHO_{98}) when all not detected values are treated as zero.

Cains and Dyke (1994) reported much higher emission rates for two tire incinerators equipped only with simple grit arrestors in the United Kingdom, 188 and 228 ng I-TEQ_{DF}/kg of combusted tire.

EPA estimated that approximately 0.50-million metric tons of tires were incinerated in 1990 in the United States (U.S. EPA, 1992a). This activity level estimate is given a medium confidence rating, because it is based on both published data and professional judgement. The use of scrap tires as a fuel was reported to have increased significantly during the late 1980s; however, no quantitative estimates were provided in U.S. EPA (1992a) for this period. In 1990, 10.7 percent of the 242 million scrap tires generated were burned for fuel. This percentage is expected to continue to increase (U.S. EPA, 1992a). Of the tires burned for energy recovery purposes, approximately 46 percent were

utilized by pulp and paper facilities, 23 percent were utilized by cement kilns, and 19 percent were utilized by one tire-to-energy facility (U.S. EPA, 1995c). Estimates of CDD/CDF emissions from cement kilns (inclusive of emissions from combustion of tires) are addressed in Section 5.1 of this report.

If it is assumed that 385 million kilograms of discarded tires were incinerated in the United States in 1987 and 1995 by facilities other than cement kilns (i.e., 500 million kg less approximately 115 million kg burned by cement kilns), then, using the TEQ emission factor derived from stack data from the one tested facility, an average of 0.11 grams of I-TEQ_{DF} (or 0.11 g TEQ_{DF}-WHO_{98}) per year are estimated to have been emitted to the air in both of these reference years. It must be noted that this may be an underestimate of emissions from this source category, because the one facility tested is a dedicated tire combustion facility and is equipped with a dry scrubber combined with a fabric filter for air pollution control. These devices are capable of greater than 95 percent reduction and control of dioxin-like compounds prior to discharge from the stack. It is not known to what extent other facilities combusting tires are similarly controlled. If such facilities are not so equipped, then the emission of CDD/CDF TEQ could be much greater than the estimates developed above. Therefore, the estimated emission factor for tire incineration is given a low confidence rating.

3.7. COMBUSTION OF WASTEWATER SLUDGE AT BLEACHED CHEMICAL PULP MILLS

Approximately 20.5 percent of the wastewater sludges generated at bleached chemical pulp mills are dewatered and burned in bark boilers at the pulp mills. These sludges can contain CDD/CDFs and elevated levels of chloride. However, the level of heat input from sludge in the mixed feed to bark boilers rarely exceeds 10 percent (NCASI, 1995).

NCASI (1995) provided congener-specific test results for four wood residue/sludge boilers tested between 1987 to 1993. Sludge comprised 6 to 10 percent of the solids in the feed. The average congener-specific emission factors derived from the stack test results obtained from these facilities are presented in Table 3-22. The average TEQ emission factors derived from the test results are 0.061 ng I-TEQ_{DF}/kg of feed (i.e., sludge and wood residue) (or 0.062 ng I-TEQ_{DF}-WHO_{98}), assuming nondetected values are zero. The range in facility-specific emission factors was wide (0.0004 to 0.118 ng I-TEQ_{DF}/kg

assuming nondetected values are zero). NCASI (1995) also presented stack emission test results for five other bark boilers. These boilers combusted only bark during the tests even though the boilers normally fire bark in combination with sludge and coal. These are discussed in Section 4.2.2 for industrial facilities burning wood scrap/residues. The average TEQ emission factor for these facilities was 0.4 ng I-TEQ_{DF}/kg of feed. The emissions test data presented in NCASI (1995), and discussed above, indicate that the CDD/CDF emission factors for bark/sludge combustors are similar to the emission factor developed in Section 4.2.2 for industrial facilities burning only wood residues/scrap. Based on the fact that wood residues comprise a far greater fraction of the feed to these bark/sludge burners than does sludge, the national TEQ emission estimates derived in Section 4.2.2 of this report for industrial wood burning facilities are assumed to include emissions from these bark/sludge combustion units.

3.8. BIOGAS COMBUSTION

Using a specially developed sampling apparatus, Schreiner et al. (1992) measured the CDD/CDF content of a flare combusting exhaust gases from an anaerobic sewage sludge digestor in Germany. The nozzle of the apparatus was moved through three cross-sections of the flame and cooling zone. The CDD/CDF content at the bottom of the flare was 1.4 pg I-TEQ_{DF}/Nm^3, 3.3. pg I-TEQ_{DF}/Nm^3 at the top of the flare, and 13.1 pg I-TEQ_{DF}/Nm^3 in the middle of the flare. Congener-specific results were not reported. Using the theoretical ratio of flare gas volume to digestor gas volume combusted, 78.6:1, and the average CDD/CDF content of the three measurements, 5.9 pg I-TEQ_{DF}/Nm^3, an emission rate of 0.46 ng I-TEQ_{DF}/Nm^3 of digestor gas combusted is yielded.

During 1996, POTWs in the United States treated approximately 122 billion liters of wastewater daily (U.S. EPA, 1997c). Although reliable data are not readily available on the amount of sewage sludge generated by POTWs that is subjected to stabilization by anaerobic digestion, a reasonable approximation is 25 percent of the total sludge generated (i.e., the sludge generated from treatment of about 30 trillion liters per day of wastewater). An estimated 196 kg of sludge solids are generated for every million liters of wastewater subjected to primary and secondary treatment (Water Pollution Control Federation, 1990). Thus, multiplying 30 billion liters per day (i.e., 25 percent of 122

billion liters) by 196 kg/million liters and 365 days/yr yields an annual estimate of 2 million metric tons of sludge solids that may be anaerobically digested in POTWs annually.

The volume of sludge digestor gas combusted in flares annually can be estimated using operation parameters for a "typical" anaerobic digestor system as described in Water Pollution Control Federation (1990). Multiplying the annual amount of sludge solids of 2 million metric tons by the following parameters and appropriate conversion factors yields an annual flared digestor gas volume of 467-million Nm^3:

- Fraction of total solids that are volatile solids = 75 percent;
- Reduction of volatile solids during digestion = 50 percent;
- Specific gas production = 0.94 m^3/kg volatile solids reduced; and
- Fraction of produced gas that is flared = 66 percent.

Because there are no direct measurements of CDD/CDF emissions from U.S. anerobic sludge digestor flares and because of uncertainties about the activity level for biogas combustion, no national emission estimate has been developed for inclusion in the national inventory. However, a preliminary estimate of the potential annual TEQ emissions from this source can be obtained by multiplying the emission factor of 0.46 ng I-TEQ_{DF}/Nm^3 of digestor gas flared by the estimated volume of gas flared annually in the United States, 467 million Nm^3. This calculation yields an annual potential release of 0.22 grams. This estimate should be regarded as a preliminary indication of possible emissions from this source category; further testing is needed to confirm the true magnitude of these emissions.

	H-ESP	79.0	85.7	Based on direct tests
	UNC	0.025	0.024	Based on Mod-SA; DSI/FF, same furnace and most similar expected emissions
	WS	16.2	17.0	Based on Mod-EA; C-ESP, similar furnace (modular design) and similar APCD temperature
	WS/FF	16.2	17.0	Based on Mod-EA; C-ESP, similar furnace (modular design) and similar APCD temperature
Modular Excess-air	C-ESP	16.2	17.0	Based on direct tests
	DS/FF	16.2	17.0	Based on Mod-EA; C-ESP, same furnace and similar temperature in APCD - may over-estimate emissions
	DSI/FF	0.025	0.024	Based on Mod-SA; DSI/FF, similar (modular design) furnace and same APCD
	DSI/H-ESP	118	119	Based on Mod-EA; H-ESP, same furnace and similar emissions
	EGB	0.025	0.024	Based on Mod-SA; DSI/FF, same furnace and most similar expected emissions
	H-ESP	118	119	Based on direct tests
	UNC	0.025	0.024	Based on Mod-SA; DSI/FF, same furnace and most similar expected emissions
	WS	16.2	17.0	Based on Mod-EA; C-ESP, same furnace and similar APCD temperature
	WS/C-ESP	16.2	17.0	Based on Mod-EA; C-ESP, same furnace and similar APCD
Fluidized-bed RDF	DS/FF	0.63	0.72	Based on MB-WW; DS/FF, similar furnace and same APCD
	DSI/EGB	0.63	0.72	Based on MB-WW; DS/FF, similar furnace - may under-estimate emissions
	DSI/FF	0.63	0.72	Based on MB-WW; DS/FF, similar furnace - may under-estimate emissions

Key:
- ng/kg = Nanograms TEQ per kilograms waste
- DS/FF = Dry scrubber combined with a fabric filter
- DSI/FF = Dry sorbent injection coupled with a fabric filter
- DS/CI/FF = Dry scrubber coupled with carbon injection and a fabric filter
- C-ESP = Cold-sided electrostatic precipitator (temperature at control device is below $\leq$ 230°C
- H-ESP = Hot-sided electrostatic precipitator (temperature at control device is above $\geq$ 230°C
- WS = Wet scrubber
- UNC = Uncontrolled (no APCD)

NA = Not applicable
ng/kg = nanograms per kilogram
kg/yr = kilograms per year
g/yr = grams per year

Table 3-12. AHA Approach: I-TEQ$_{DF}$ Emission Factors Calculated for Air Pollution Control

APC Category	I-TEQ$_{DF}$ Emission Factor (lb/10^6 lbs waste)	Number of MWI Test Reports Used[a]
Uncontrolled		
MWIs up to 200 lb/hr	1.53e-03	4
MWIs > 200 lb/hr	5.51e-04	13
Wet scrubber/BHF/ESP[b]	4.49e-05	11
Dry sorbent injection/Fabric Filter	6.95e-05	8

[a] The same MWI may have been used more than once in deriving emission factors.

[b] Wet scrubbers-bag house filters-electrostatic precipitators. Bag house is also called Fabric Filter.

Source: Doucet (1995).

Table 3-13. AHA Assumptions of the Percent Distribution of Air Pollution Control on MWIs Based on PM Emission Limits

PM Emission Limits[a] (gr/dscf)	Percent MWIs Uncontrolled[b]	Percent MWIs with Scrubbers/ BHFs/ESPs[c]	Percent MWIs DI/FF[d]
≥ 0.10	50%	50%	0%
0.08 to < 0.10	25%	75%	0%
0.03 to < 0.08	0%	98%	2%
< 0.03	0%	30%	70%

[a] Particulate matter (PM) emission limits at the stack, grains per dry standard cubic foot (gr/dscf).

[b] Uncontrolled means there is no air pollution control device installed on the MWI.

[c] Scrubbers/BHFs/ESPs means wet scrubbers/bag house filters/electrostatic precipitators.

[d] DI/FF means dry sorbent injection combined with fabric filters.

Table 3-14. AHA Approach: Estimated Annual Nationwide I-TEQ$_{DF}$ Emissions

APCD[a]	MWI Capacity[b] (lb/hr)	I-TEQ$_{DF}$ Emission Factor[c] (g/kg waste)	MWI Activity Level[d] (kg/yr)	Annual I-TEQ$_{DF}$ Emissions (g/yr)
Uncontrolled	≤ 200 > 200	1.54 e-06 5.51 e-07	2.28 e+07 1.54 e+08	3.51e+01 8.48e+01
Subtotal: Uncontrolled			1.77 e+08	1.20e+02
WS/BHF/ESP	>200	4.49 e-08	3.51 e+08	1.58e+01
DI/FF	>200	6.95 e-08	2.60 e+07	1.81
Subtotal: Controlled			3.77 e+08	1.76e+01
Total			5.54 e+08	1.38e+02

[a] APCD = Air Pollution Control Device assumed by AHA. Uncontrolled means there is no air pollution control device installed on the MWI. WS/BHF/ESP = Wet scrubber-bag house filter-electrostatic precipitator. DI/FF = Dry sorbent injection-fabric filter.

[b] MWI capacity is the design capacity of the primary combustion chamber.

[c] I-TEQ$_{DF}$ Emission Factor derived from tested facilities.

[d] Activity Level is the annual amount of medical waste incinerated by each APCD class.

lb/hr = pounds per hour
g/kg = grams per kilogram
kg/yr = kilograms per year
g/yr = grams per year

Table 3-15. Comparison Between Predicted Residence Times and Residence Times Confirmed by State Agencies in EPA/ORD Telephone Survey

State	Residence Time Categories	Percentage of Uncontrolled MWIs Predicted by PM Method	Percentage of Uncontrolled MWIs Confirmed by State Agency
Michigan	1/4 second 1.0 second 2.0 seconds	2% (6/280 MWIs) 2% (5/280) 96% (269/280)	96% (269/280 MWIs) 3% (9/280) 1% (1/280)
Massachusetts	1/4 second 1.0 second 2.0 seconds	6% (6/94 MWIs) 0% (0/94) 94% (88/94)	Unknown Unknown 4% (2/50)

APCD = Air Pollution Control Devices
ng/kg = nanograms per kilogram
kg/yr = kilograms per year
g/yr = grams per year
lb/hr = pounds per hour

Table 3-17. Summary of Annual TEQ Emissions from Medical Waste Incineration (MWI) for Reference Year 1987

MWI Class[a]	No. of Tested Facilities	Total CDD/CDF Emission Factor[b] (g/kg)	I-TEQ_{DF} Emission Factor (g/kg)	TEQ_{DF}-WHO_{98} Emission Factor (g/kg)	Activity Level (kg/yr)	Annual CDD/CDF Emissions (g/yr)	Annual I-TEQ_{DF} Emissions (g/yr)	Annual TEQ_{DF}-WHO_{98} Emissions (g/yr)
≤ 200 lb/hr	3	9.25e-05	1.86e-06	1.98e-06	2.19e+08	2.02e+04	4.08e+02	4.34e+02
> 200 lb/hr	5	6.05e-05	1.68e-06	1.78e-06	1.21e+09	7.32e+04	2.03e+03	2.15e+03
Total	8				1.43e+09	9.34e+04	2.44e+03	2.59e+03

[a] This uses the categorization scheme of the AHA Approach (Doucet, 1995).

kg/yr = kilograms per year
g/kg = grams per kilogram
g/yr = grams per year
lb/hr = pounds per hour

Table 3-18. Comparison of Basic Assumptions Used in the EPA/ORD, the EPA/OAQPS, and the AHA Approaches to Estimating Nationwide CDD/CDF TEQ Emissions from MWIs in 1995

Assumptions	EPA/ORD Approach	EPA/OAQPS Approach	AHA Approach
Reference Year	1995	1995	1995
Number of MWIs	2,375	2,375	2,233
Estimated Activity Level	7.71 e+08 kg/yr	7.71 e+08 kg/yr	5.54 e+08 kg/yr
Percent of Activity Level at Uncontrolled MWIs	33%	33%	32%
Percent of Activity Level at Controlled MWIs	67%	67%	68%
Subclassification of Uncontrolled Class	Same as AHA assumption	By residence times (RT) in secondary chamber	By design capacity
Assumed Distribution of Uncontrolled Class	Same as AHA assumption	By RT of 0.25, 1.0 and 2.0 sec by State PM emission limits	By estimated annual hrs of operation of <200 lb/hr and >200 lb/hr design capacity
APCDs Assumed for Controlled Class	WS/FF/ESP DI/FF FF/Packed Bed Scrub	WS DS-no Carbon DS-Carbon FF/Packed Bed Scrub	WS/FF/ESP DI/FF
Assumed Distribution of Controls	Yes/ Analogous to AHA method.	Yes/ Analogous to AHA method	Yes/ Based on survey and State PM emission limits
Emission Factor Approach Used	Yes	Yes	Yes
No. of Tested MWIs Used to Develop Emission Factors	Uncontrolled: 8 Controlled: 11	Uncontrolled: 10 Controlled: 23	Uncontrolled: 13 Controlled: 12
Uncontrolled I-TEQ_{DF} Emission Factors (ng/kg)	1,865 = ≤200 lb/hr 1,680 = >200 lb/hr	a/ 3,960 = 0.25 s RT b/ 909 = 1.0 s RT c/ 74 =2.0 s RT	d/ 1,540 =≤200 lb/hr e/ 551= > 200 lb/hr
Controlled I-TEQ_{DF} Emission Factors (ng/kg)[f]	WS/FF/ESP: 72.2 DSI/FF: 6.8 FF/PBS: 1,350	WS: 10 DS no carbon: 7 DS with carbon: 2 FF/PBS: 681	WS/FF/ESP: 44.9 DSI/FF: 69.5

WS = Wet Scrubber; FF = Fabric Filter; ESP = Electrostatic Precipitator; DSI = Dry Sorbent Injection; DS = Dry Scrubber; no carbon = without the addition of activated carbon; with carbon = with the addition of activated carbon; PBS = Packed Bed Scrubber.

a 0.25 seconds (s) residence time (RT) in the secondary chamber.

b 1.0 seconds (s) residence time (RT) in the secondary chamber.

c 2.0 seconds (s) residence time (RT) in the secondary chamber.

d design capacities less than or equal to 200 lbs/hr.

e design capacities greater than 200 lbs/hr.

f emission factors as reported in Tables 3-9, 3-12, and 3-14.

lb/hr = pounds per hour

kg/yr = kilograms per year

4. COMBUSTION SOURCES OF CDD/CDF: POWER/ENERGY GENERATION

4.1. MOTOR VEHICLE FUEL COMBUSTION

Ballschmiter et al. (1986) reported detecting CDD/CDFs in used motor oil and thus provided some of the first evidence that CDD/CDFs might be emitted by the combustion processes in gasoline- and diesel-fueled engines. Incomplete combustion and the presence of a chlorine source in the form of additives in the oil or the fuel (such as dichloroethane or pentachlorophenate) were speculated to lead to the formation of CDDs and CDFs. The congener patterns found in the used oil samples were characterized by Ballschmiter et al. (1986) as similar to the patterns found in fly ash and stack emissions from municipal waste incinerators.

Since 1986, several studies have been conducted to measure or estimate CDD/CDF concentrations in emissions from vehicles. Although there is no standard approved protocol for measuring CDD/CDFs in vehicle exhausts, researchers have developed and implemented several measurement approaches for collecting and analyzing vehicle exhausts. Other researchers have estimated vehicle exhaust emissions of CDD/CDFs indirectly from studies of tunnel air. The results of these two types of studies are summarized in chronological order in the following Section 4.1.1 and Section 4.1.2. Estimates of national annual CDD/CDF TEQ emissions from on-road motor vehicles fueled with leaded gasoline, unleaded gasoline, and diesel fuel are presented in Section 4.1.3 based on the results of these studies. It should be noted, however, that relatively few tests on emissions from diesel and unleaded gasoline fueled vehicles are available considering the variety and numbers of such vehicles currently in operation, and the range of operational, technical, and environmental conditions in which they are operated. As a result, the emission factors developed in this report for on-road motor vehicles are quite uncertain.

National emission estimates have not been generated in this report for off-road vehicles (i.e., construction and farm vehicles) or stationary sources using these fuel types because of lack of emission factor data; activity level information, however, is presented in this report for these potential source categories.

4.1.1. Tailpipe Emission Studies

Marklund et al. (1987) provided the first direct evidence of the presence of CDDs and CDFs in car emissions based on tailpipe measurements on Swedish cars. Approximately 20 to 220 pg of I-TEQ_{DF} from tetra- and penta-CDD/CDFs were reported per kilometer driven for four cars running on leaded gasoline. For this study, an unleaded gasoline was used to which was added tetramethyl lead (0.15 g/L or 0.57 grams per gallon) and dichloroethane (0.1 g/L as a scavenger). The fuel used may not have accurately represented commercial fuels at that time, which typically contained a mixture of chlorinated and brominated scavengers (Marklund et al., 1990). Also, the lead content of the fuel used (0.15 g lead/L), although the normal lead content for Swedish fuels at the time (Marklund et al., 1990), was higher than the lead content of leaded gasoline in the United States during the late 1980s (lowered to 0.10 g lead/gallon or 0.026 g lead/L effective January 1, 1986). Marklund et al. (1987) reported a striking similarity in the TCDF and PeCDF congener profiles in the car exhausts and those found in emissions from municipal waste incinerators. For two cars running on unleaded gasoline, CDD/CDF emissions were below the detection limit, which corresponded to approximately 13 pg of I-TEQ_{DF} per kilometer driven.

Table 4-1 presents a summary description of the results of the Marklund et al. (1987) study and subsequent studies (presented in chronological order) discussed below. Tables 4-2 and 4-3 present the results of tailpipe emission studies reported for diesel-fueled cars and trucks, respectively. Table 4-4 presents the results of studies using leaded gasoline-fueled cars, and Tables 4-5 and 4-6 present results of studies with cars fueled by unleaded gasoline. Figures 4-1, 4-2, and 4-3 present congener and congener group profiles for emissions from diesel-fueled vehicles, leaded gasoline-fueled vehicles, and unleaded gasoline-fueled vehicles, respectively.

Virtually no testing of vehicle emissions in the United States for CDD/CDFs has been reported. In 1987, the California Air Resources Board (CARB) produced a draft report on the testing of the exhausts of four gasoline-powered cars and three diesel fuel-powered vehicles (one truck, one bus, and one car) (CARB, 1987a). However, CARB indicated to EPA that the draft report should not be cited or quoted to support general conclusions about CDD/CDFs in motor vehicle exhausts because of the small sample size of the study and because the use of low rather than high resolution mass spectrometry in

the study resulted in high detection limits and inadequate selectivity in the presence of interferences (Lew, 1993). CARB did state that the results of a single sample from the heavy-duty diesel truck could be reported, because congeners from most of the homologue groups were present in the sample at levels that could be detected by the analytical method and there were no identified interferences in this sample. This test was conducted under steady state conditions (50 km/hr) for 6 hours with an engine with a fuel economy of 5.5 km/L. The TEQ emission factor of this one sample was equivalent to 7,290 pg I-TEQ_{DF}/L of fuel burned (7,190 pg TEQ_{DF}-WHO_{98}/L). Assuming a fuel economy of 5.5 km/L yields an emission factor of 1,325 pg I-TEQ_{DF}/km (1,307 pg TEQ_{DF}-WHO_{98}/km). Treating nondetected values as zeros yields TEQ emission factors of 3,720 pg I-TEQ_{DF}/L of fuel burned (or 676 pg I-TEQ_{DF}/km driven) and 3,280 pg TEQ_{DF}-WHO_{98}/L (or 596 pg TEQ_{DF}-WHO_{98}/km driven) (Lew, 1996).

Haglund et al. (1988) sampled exhaust gases from three different vehicles (two cars fueled with leaded and unleaded gasoline, respectively, and a heavy-duty diesel truck) for the presence of brominated dibenzo-p-dioxins (BDD) and brominated dibenzofurans (BDF). The authors concluded that the dibromoethane scavenger added to the tested gasoline probably acted as a halogen source. TBDF emissions measured 23,000 pg/km in the car with leaded gasoline and 240 pg/km in the car with unleaded gasoline. TBDD and PeBDF emissions measured 3,200 and 980 pg/km, respectively, in the car with leaded gasoline. All BDD/Fs were below detection limits in the diesel truck emissions.

Bingham et al. (1989) analyzed the exhausts of four cars using leaded gasoline (0.45 g/L tetramethyllead, 0.22 g/L dichloroethane, and 0.2 g/L dibromoethane), and the exhaust from one car using unleaded gasoline. Analytical results and detection limits were reported for only five of the 17 toxic CDD/CDF congeners. TEQ emission rates for the cars using leaded fuel, based on detected congeners only, ranged from 1 to 39 pg I-TEQ_{DF}/km. CDD/CDFs were not detected in the exhaust from the vehicle using unleaded fuel. The total I-TEQ_{DF} emission rate for this car using unleaded fuel, based on one-half the detection limits for the five reported congeners, was 20 pg I-TEQ_{DF}/km.

Marklund et al. (1990) tested Swedish cars fueled with commercial fuels, measuring CDD/CDF emissions before and/or after the muffler. Both new and old vehicles were tested. Three cars were tested using unleaded gasoline, and two cars were tested with leaded gasoline (0.15 g Pb/L and dichloroethane and dibromoethane scavengers).

CDD/CDFs were not detected in the fuels at a detection limit of 2 pg I-TEQ_{DF}/L, but were detected at a level of 1,200 pg I-TEQ_{DF}/L in the new semi-synthetic engine lube oil used in the engines. The test driving cycle employed (i.e., 31.7 km/hr as a mean speed; 91.2 km/hr as a maximum speed; and 17.9 percent of time spent idling) yielded fuel economies ranging from approximately 9 to 10 km/L or 22 to 24 miles/gallon in the various cars. The reported ranges of emission factors were:

- Leaded gas/before muffler: 2.4 to 6.3 pg I-TEQ_{DF}/km (or 21 to 60 pg I-TEQ_{DF}/L of fuel consumed);
- Leaded gas/in tailpipe: 1.1 to 2.6 pg I-TEQ_{DF}/km (or 10 to 23 pg I-TEQ_{DF}/L);
- Unleaded gas/catalyst-equipped/in tailpipe: 0.36 pg I-TEQ_{DF}/km (or 3.5 pg I-TEQ_{DF}/L); and
- Unleaded gas/before muffler: 0.36 to 0.39 pg I-TEQ_{DF}/km (or 3.5 pg I-TEQ_{DF}/L).

The TEQ levels in exhaust gases from older cars using leaded gasoline were up to six times greater when measured before the muffler than after the muffler. No muffler-related difference in new cars running on leaded gasoline or in old or new cars running on unleaded gasoline was observed.

Marklund et al. (1990) also analyzed the emissions from a heavy-duty diesel-fueled truck for CDD/CDFs. None were detected; however, the authors pointed out that the test fuel was a reference fuel and may not have been representative of commercial diesel fuel. Also, due to analytical problems, a much higher detection limit (about 100 pg I-TEQ_{DF}/L) was realized in this diesel fuel test than in the gasoline tests (5 pg I-TEQ_{DF}/L) conducted. Further uncertainty was introduced because the diesel emission samples were only collected prior to the muffler.

Hagenmaier et al. (1990) ran a set of tests using conditions comparable to the FTP-73 test cycle on gasoline- and diesel-fueled engines for light duty vehicles in Germany. The following average TEQ emission rates per liter of fuel consumed were reported:

- Leaded fuel: 1,080 pg I-TEQ_{DF}/L (1,287 pg TEQ_{DF}-WHO_{98}/L);
- Unleaded fuel (catalyst-equipped): 7.2 pg I-TEQ_{DF}/L (7.9 pg TEQ_{DF}-WHO_{98}/L);

- Unleaded fuel (not catalyst-equipped): 50.9 pg I-TEQ_{DF}/L (60.2 pg TEQ_{DF}-WHO_{98}/L); and
- Diesel fuel: 20.8 pg I-TEQ_{DF}/L (24.8 pg TEQ_{DF}-WHO_{98}/L).

The major findings of a German study of emissions of halogenated dibenzodioxins and dibenzofurans from internal combustion engines running on commercial fuels were published in 1991 (Schwind et al., 1991), and the full detailed report was published in 1992 (Hutzinger et al., 1992). The study was conducted by the Universities of Stuttgart, Tübingen, and Bayreuth for the Federal Ministry for Research and Technology, the Research Association for Internal Combustion Engines, and the German Association for the Petroleum Industry and Coal Chemistry. Tests were conducted using engine test benches and rolling test benches under representative operating conditions. Tests were performed on leaded gasoline engines, unleaded gasoline engines, diesel car engines, and diesel truck engines. The reported range of CDD/CDF emission rates across the test conditions in units of pg TEQ per liter of fuel consumed are presented below. The results from those tests conducted under normal operating conditions with commercial fuels and for which congener-specific emission results were presented in Hutzinger et al. (1992) are listed in Tables 4-2 through 4-6.

- Leaded fuel: 52 to 1,184 pg I-TEQ_{DF}/L (72 to 1,417 pg TEQ_{DF}-WHO_{98}/L);
- Unleaded fuel (not catalyst-equipped): 96 to 177 pg I-TEQ_{DF}/L (102 to 181 pg TEQ_{DF}-WHO_{98}/L);
- Unleaded fuel (catalyst-equipped): 10 to 26 pg I-TEQ_{DF}/L (9.6 to 28.0 pg TEQ_{DF}-WHO_{98}/L);
- Diesel fuel (cars): 10 to 130 pg I-TEQ_{DF}/L (12 to 140 pg TEQ_{DF}-WHO_{98}/L); and
- Diesel fuel (trucks): 70 to 81 pg I-TEQ_{DF}/L (79 to 82 pg TEQ_{DF}-WHO_{98}/L).

Although no specific details on the methodology used were provided, Hagenmaier (1994) reported that analyses of emissions of a diesel-fueled bus run either on steady state or on the "Berlin cycle" showed no CDD/CDF present at a detection limit of 1 pg/L of fuel consumed for individual congeners.

Gullett and Ryan (1997) recently reported the results of the first program to sample diesel engine emissions for CDD/CDFs during actual highway and city driving. The exhaust emissions from a 1991 Freightliner diesel tractor with a 10.3 L, 6-cylinder Caterpillar engine, representative of the first generation of computerized fuel controlled vehicles manufactured in the United States, were sampled during both highway and city driving routes. The average emission factor for the three highway tests conducted (15.1 pg I-TEQ_{DF}/km; range 11.7-18.7 pg I-TEQ_{DF}/km; standard deviation of 3.5 pg I-TEQ_{DF}/km) was a factor of three below the average of the two city driving tests (49.9 pg I-TEQ_{DF}/kg; range 3.0-96.8 pg I-TEQ_{DF}/km). Detection limits were considered as zeros in the calculation of these emission factors. The average of all five tests was 29.0 pg I-TEQ_{DF}/km with a standard deviation of 38.3 pg I-TEQ_{DF}/km; this standard deviation reflects the 30-fold variation in the two city driving route tests.

4.1.2. Tunnel Emission Studies

Several European studies and one recent U.S. study evaluated CDD/CDF emissions from vehicles by measuring the presence of CDD/CDFs in tunnel air. This approach has the advantage that it allows random sampling of large numbers of cars, including a range of ages and maintenance levels. The disadvantage of this approach is that it relies on indirect measurements (rather than tailpipe measurements), which may introduce unknown uncertainties and make interpretation of the findings difficult. Concerns have been raised that the tunnel monitors are detecting resuspended particulates that have accumulated over time, leading to overestimates of emissions. Also, the driving patterns encountered in these tunnel studies are more or less steady state driving conditions rather than the transient driving cycle and cold engine starts that are typical of urban driving conditions and that may affect emission levels. Each of these studies is summarized below in chronological order.

Rappe et al. (1988) reported the CDD/CDF content of two air samples (60 m^3 per sample) collected from a tunnel in Hamburg, Germany, during January of 1986 to be 0.42 and 0.58 pg I-TEQ_{DF}/m^3 (0.44 and 0.59 pg TEQ_{DF}-WHO_{98}/m^3. Each sample was collected over a period of about 60 hours. The tunnel handled 65,000 vehicles per day of which 17 percent were classified as "heavy traffic." The congener-specific results of the two samples are presented in Table 4-7. Measurement of ambient air conducted in September

of 1986 at a nearby highway in Hamburg was reported to contain CDD/CDF levels two to six times lower than those measured in the tunnel.

Larssen et al. (1990) and Oehme et al. (1991) reported the results of a tunnel study in Olso, Norway, performed during April/May of 1988. Oehme et al. (1991) estimated total vehicle emissions by measuring CDD/CDF concentrations in tunnel inlet and outlet air of both the uphill and downhill lanes. Emission rates for light-duty and heavy-duty vehicle classes in the uphill and downhill lanes were estimated by counting the number of light-duty vs. heavy-duty vehicles passing through the tunnel on workdays and a weekend and assuming a linear relationship between the percentage of the light- or heavy-duty traffic and the overall emission rate. Thus, the linear relationship for each emission rate was based on only two points (i.e., the weekday and weekend measurements). The emission rates, in units of Nordic TEQ, estimated in this study are:

- Light-duty vehicles using gasoline (approximately 70-75 percent using leaded gas): uphill = 520 pg TEQ/km; downhill = 38 pg TEQ/km; mean = 280 pg TEQ/km; and
- Heavy-duty diesel trucks: uphill = 9,500 pg TEQ/km; downhill = 720 pg TEQ/km; mean = 5,100 pg TEQ/km.

The mean values are the averages of the emission rates corresponding to the two operating modes: vehicles moving uphill on a 3.5 percent incline at an average speed of 37 miles per hour and vehicles moving downhill on a 3.5 percent decline at an average speed of 42 miles per hour. Although Oehme et al. (1991) reported results in units of Nordic TEQ, the results in I-TEQ_{DF} should be nearly identical (i.e., about 3 to 6 percent higher), because the only difference between the two TEQ schemes is the toxic equivalency factor assigned to 1,2,3,7,8-PeCDF (0.1 in Nordic and 0.05 in I-TEQ_{DF}), a minor component of the toxic CDD/CDFs measured in the tunnel air. Table 4-7 presents the congener-specific differences in concentrations between the tunnel inlet and outlet concentrations.

Wevers et al. (1992) measured the CDD/CDF content of air samples taken during the winter of 1991 inside a tunnel in Antwerp, Belgium. During the same period, background concentrations were determined outside the tunnel. Two to four samples were collected from each location with two devices: a standard high volume sampler with a glass fiber filter and a modified two-phase high volume sampler equipped with a glass

fiber filter and a polyurethane foam plug (PUF). The I-TEQ_{DF} concentration in the air sampled with the filter/PUF device was 74 to 78 percent of the value obtained with the high volume sampler. However, the results obtained from both sets of devices indicated that the tunnel air had a CDD/CDF TEQ concentration about twice as high as the outside air (filter and PUF: 80.3 fg I-TEQ_{DF}/m^3 for tunnel air vs. 35 fg I-TEQ_{DF}/m^3 for outside air; filter only: 100 fg I-TEQ_{DF}/m^3 for tunnel air vs. 58 fg I-TEQ_{DF}/m^3 for outside air). The authors presented the congener-specific results for only one tunnel air measurement; these results are presented in Table 4-7.

During October/November 1995, Gertler et al. (1996, 1998) conducted a study at the Fort McHenry Tunnel in Baltimore, Maryland, with the stated objective of measuring CDD/CDF emission factors from in-use vehicles operating in the United States, with particular emphasis on heavy-duty vehicles. The air volume entering and leaving the tunnel bore that services most of the heavy-duty vehicles (i.e., approximately 25 percent of the vehicles using the bore are heavy-duty) was measured, and the air was sampled for CDD/CDFs during 7 sampling periods of 12-hour duration. Three of the samples were collected during daytime (i.e., 6 am to 6 pm) and four samples were collected during the night (i.e., 6 pm to 6 am). The air volume and concentration measurements were combined with information on vehicle counts (obtained from videotapes) and tunnel length to determine average emission factors. A total of 33,000 heavy-duty vehicles passed through the tunnel during the seven sample runs. Heavy-duty vehicles accounted for 21.2 to 28.8 percent of all vehicles passing through the tunnel for the seven sample runs. The emission factors calculated, assuming that all CDD/CDF emitted in the tunnel were from heavy-duty vehicles, are presented in Table 4-8. The average I-TEQ_{DF} emission factor was reported to be 172 pg I-TEQ_{DF}/km (182 pg TEQ_{DF}-WHO_{98}/km). The major uncertainties identified by the authors in the study were tunnel air volume measurement, sampler flow volume control, and analytical measurement of CDD/CDF.

EPA's Office of Mobile Sources (OMS) reviewed the Gertler et al. (1996) study (Lorang, 1996) and found the study to be technologically well done, with no major criticisms or comments on the test methodology or protocol. OMS found no reason to doubt the validity of the emission factor determined by the study. OMS did note that the particulate emission rate for heavy-duty vehicles measured in the study (0.32 g/mile) is lower than the general particulate emission rate used by EPA (i.e., about 1 g/mile) and,

thus, may underestimate CDD/CDF emissions under different driving conditions. OMS cautioned that the reported emission factor should be regarded only as a conservative estimate of the mean emission factor for the interstate trucking fleet under the driving conditions of the tunnel (i.e., speeds on the order of 50 miles/hour with the entering traffic slightly higher and the exiting traffic slightly lower.

Figure 4-4 graphically presents the results of the studies by Rappe et al. (1988), Oehme et al. (1991), Wevers et al. (1992), and Gertler et al. (1996, 1998). The figure compares the congener profiles (i.e., congener concentrations or emission factors normalized to total concentration or emission factor of 2,3,7,8-substituted CDDs and CDFs) reported in the four studies. The dominant congeners in the Rappe et al. (1988), Wevers et al. (1992), and Gertler et al. (1996, 1998) studies are OCDD, 1,2,3,4,6,7,8-HpCDD, OCDF, and 1,2,3,4,6,7,8-HpCDF. With the exception of OCDD, these congeners are also major congeners reported by Oehme et al. (1991). The Oehme et al. (1991) study also differs from the other two studies in that the total of 2,3,7,8-substituted CDFs dominates total 2,3,7,8-substituted CDDs (by a factor of 2), whereas just the opposite is observed in Rappe et al. (1988), Wevers et al. (1992), and Gertler et al. (1996, 1998).

4.1.3. National Emission Estimates

Estimates of national CDD/CDF TEQ emissions are presented in this section only for on-road vehicles utilizing gasoline or diesel fuel. Because emission factors are lacking for off-road uses (i.e., construction vehicles, farm vehicles, and stationary industrial equipment), no emission estimates could be developed at this time; however, activity level information for off-road uses is presented below.

Activity Information for On-Road Vehicles: The U.S. Federal Highway Administration, as reported in U.S. Department of Commerce (DOC) (1997), reports that 1,586-billion total vehicle miles (2,552 billion km) were driven in the United States during 1994 by automobiles and motorcycles. Because 1994 is the last year for which data are available, these data are used as a surrogate for 1995 activity levels. Trucks accounted for 840-billion vehicle miles (1,351 billion km), and buses accounted for 6.4 billion vehicle miles (10 billion km) (U.S. DOC, 1997). In 1992, diesel-fueled trucks accounted for 14.4 percent of total truck vehicle km driven; gasoline-fueled trucks accounted for the

remaining 85.6 percent (U.S. DOC, 1995b). Applying this factor (i.e., 14.4 percent) to the 1994 truck km estimate (i.e., 1,351 billion km) indicates that an estimated 195 billion km were driven by diesel-fueled trucks in 1994. It is assumed that all other vehicle km driven (3,718 billion km) (i.e., non-diesel trucks, all automobiles, all buses, and all motorcycles) were those of gasoline-powered vehicles; although it is recognized that a fraction of the buses and automobiles use diesel fuel, the exact numbers are not known. It is further assumed that all of these km were driven by unleaded gasoline-powered vehicles because in 1992, only 1.4 percent of the gasoline supply were leaded fuel (EIA, 1993); usage should have further declined by 1995, because use of leaded fuel in motor vehicles for highway use in the United States was prohibited as of December 31, 1995 (Federal Register, 1985a).

Similar information for 1987 is as follows. An estimated 3,092 billion km were driven in the United States of which trucks accounted for 887 billion km (U.S. DOC, 1995a). In 1987, diesel-fueled trucks accounted for 17.2 percent of total truck km driven (U.S. DOC, 1995b). Applying this factor (i.e., 17.2 percent) to the 1987 truck km estimate (i.e., 887 billion km) indicates that an estimated 153 billion km were driven by diesel-fueled trucks. It is assumed that all other vehicle km driven (2,939 billion km) were those of gasoline-powered vehicles. Leaded gasoline accounted for 24.1 percent of the gasoline supply in 1987 (EIA, 1993). Thus, it can be estimated that 708 billion km (i.e., 24.1 percent of 2,939 billion km) were driven by leaded gasoline-fueled vehicles. The remaining 2,231 billion km are estimated to have been driven by unleaded gasoline-fueled vehicles. These mileage estimates are given a high confidence rating because they are based on recent U.S. Bureau of the Census transportation studies.

Activity Information for Off-Road Uses: Although on-road vehicles are the largest consumers of diesel fuel (accounting for about 50 percent of U.S. sales), other sectors of the economy use significant volumes: farm use, railroad use, vessel bunkering, and other off-highway uses. The following paragraphs define each of these uses and present volumes of distillate fuel sales in each sector for reference years 1987 and 1995. For these sectors, the majority of "distillate fuel" sales are diesel fuels; a small fraction are fuel oils.

Farm use includes sales for use in tractors, irrigation pumps and other agricultural machinery, as well as that used for crops drying, smudge pot fuel and space heating of buildings. Sales in 1987 and 1995 were 2,999 and 3,476 million gallons, respectively (EIA, 1992; EIA, 1997a).

Railroad use includes sales to railroads, for any use, including diesel fuel for railroad locomotive engines and fuel used for heating buildings operated by railroads. Sales in 1987 and 1995 were 2,850 and 3,429 million gallons, respectively (EIA, 1992; EIA, 1997a).

Vessel bunkering includes sales for the fueling of commercial or private boats, such as pleasure craft, fishing boats, tug boats, and ocean-going vessels, including vessels operated by oil companies. Excluded are volumes sold to the U.S. Armed Forces. Sales in 1987 and 1995 were 1,865 and 2,339 million gallons, respectively (EIA, 1992; EIA, 1997a).

Off-highway use includes sales for use in: (1) construction equipment including earthmoving equipment, cranes, stationary generators, air compressors, etc.; and (2) sales for non-construction other off-highway uses such as logging. Sales in 1987 and 1995 were 1,560 and 2,173 million gallons, respectively (EIA, 1992; EIA, 1997a).

Emission Estimates: Using the results of the studies discussed in Section 4.1.1, separate annual national emission estimates are developed below for vehicles burning leaded gasoline, unleaded gasoline, and diesel fuel. Estimates are provided for the years 1987 and 1995. The emission estimates for reference year 1995 are based on activity data (i.e., kilometers driven) for calendar year 1994.

Leaded Gasoline: Literature indicates that CDD/CDF emissions do occur from vehicles using leaded gasoline and that considerable variation occurs depending, at least in part, on the types of scavengers used. Marklund et al. (1987) reported emissions ranging from 20 to 220 pg I-TEQ_{DF}/km from four cars fueled with a reference unleaded fuel to which lead (0.5 gplg) and a chlorinated scavenger were added. Marklund et al. (1990)

reported much lower emissions in the exhaust of cars (1.1 to 6.3 pg I-TEQ_{DF}/km) using a commercial leaded fuel (0.5 g/L) containing both dichloroethane and dibromoethane as scavengers. Marklund et al. (1990) attributed the difference in the emission measurements of the 1987 and 1990 studies to the different mix of scavengers used in the two studies, which may have resulted in preferential formation of mixed chlorinated and brominated dioxins and furans. Hagenmaier et al. (1990) reported TEQ emissions of 1,080 pg I-TEQ_{DF}/L of fuel (approximately 108 pg I-TEQ_{DF}/km or 129 pg TEQ_{DF}-WHO_{98}/km) from a car fueled with a commercial leaded fuel (lead content not reported). Bingham et al. (1989) reported emissions from four cars using gasoline with a lead content of 1.7 g/L in New Zealand to range from 1 to 39 pg I-TEQ_{DF}/km. The German study reported by Schwind et al. (1991) and Hutzinger et al. (1992) measured emissions of 52 to 1,184 pg I-TEQ_{DF}/L (approximately 5.2 to 118 pg I-TEQ_{DF}/km or 7.2 to 142 pg TEQ_{DF}-WHO_{98}/km) for cars under various simulated driving conditions. The tunnel study by Oehme et al. (1991) estimated that emissions from cars running primarily on leaded gasoline (i.e., 70 to 75 percent of the cars) ranged from 38 to 520 pg Nordic TEQ/km.

As shown in Table 4-4, the average emission factor reported for the tailpipe emission studies performed using commercial leaded fuel which reported analytical results for all 17 toxic CDD/CDF congeners (i.e., Marklund et al., 1990; Hagenmaier et al., 1990; and Schwind et al., 1991) is 450 pg I-TEQ_{DF}/L or 532 pg TEQ_{DF}-WHO_{98}/L. Assuming an average fuel economy of 10 km/L, these emission factors are approximately 45 pg I-TEQ_{DF}/km and 53 pg TEQ_{DF}-WHO_{98}/km. A low confidence rating is assigned to this emission factor because it is based on European fuels and emission control technologies, which may have differed from U.S. leaded-fuels and engine technology, and also because the factor is based is based on tests with only nine cars.

Combining the average emission factor developed above (45 pg I-TEQ_{DF}/km or 53 pg TEQ_{DF}-WHO_{98}/km, assuming not detected values are zero) with the estimate for km driven by leaded fuel-powered vehicles in 1987 (708 billion km) suggests that 31.9 g I-TEQ_{DF} (or 37.5 pg TEQ_{DF}-WHO_{98}) were emitted from vehicles using leaded fuels in 1987. Although there likely was minor use of unleaded fuel in 1995 in on-road vehicles, further use of leaded fuel in motor vehicles for highway use in the United States was prohibited as of December 31, 1995 (Federal Register, 1985a). In 1992, the last year for which data are available on consumption of leaded gasoline by on-road vehicles, only 1.4 percent

of the gasoline supply was leaded gasoline (EIA, 1993). If it is conservatively assumed that 1 percent of the total vehicle km driven in 1995 (i.e., 37.2 billion km of a total of 3,718 billion km) were driven by leaded fuel-powered vehicles, then combining the emission factor of 45 pg I-TEQ_{DF}/km (or 53 pg TEQ_{DF}-WHO_{98}/km) with this activity level estimate yields an annual emission of 1.7 g I-TEQ_{DF} (or 2.0 g TEQ_{DF}-WHO_{98}) in 1995.

Unleaded Gasoline: The literature documenting results of European studies indicates that CDD/CDF emissions from vehicles burning unleaded fuels are less than the emissions from vehicles burning leaded gas with chlorinated scavengers. It also appears, based on the limited data available, that catalyst-equipped cars have lower emission factors than noncatalyst-equipped cars. Marklund et al. (1987) did not detect CDD/CDF in emissions from two catalyst-equipped cars running on unleaded gasoline at a detection limit of 13 pg I-TEQ_{DF}/km. Marklund et al. (1990) reported emission factors of 0.36 and 0.39 pg I-TEQ_{DF}/km for two noncatalyst-equipped cars and an emission factor of 0.36 pg I-TEQ_{DF}/km for one catalyst-equipped car. Hagenmaier et al. (1990) reported an emission factor of 5.1 pg I-TEQ_{DF}/km for one noncatalyst-equipped car and 0.7 pg I-TEQ_{DF}/km for one catalyst-equipped car. Schwind et al. (1991) and Hutzinger et al. (1992) reported emission factors of 9.6 to 17.7 pg I-TEQ_{DF}/km for several noncatalyst-equipped cars tested under various conditions; the reported emission factor range for catalyst-equipped cars was 1.0 to 2.6 pg I-TEQ_{DF}/km.

All automobiles running on unleaded gasoline in the United States are equipped with catalysts. As shown in Table 4-6, the average emission factor reported for the tailpipe emission studies performed on catalyst-equipped cars (i.e., Hagenmaier et al. 1990; Schwind et al., 1991; and Hutzinger et al., 1992) is 14.9 pg I-TEQ_{DF}/L or 15.6 pg TEQ_{DF}-WHO_{98}/L. Assuming an average fuel economy of 10 km/L yields emission factors of 1.5 pg I-TEQ_{DF}/km and 1.6 pg TEQ_{DF}-WHO_{98}/km. A low confidence rating is assigned to this emission factor because the European fuels and emission control technology used may have differed from U.S. fuels and technology and also because the emission factor range is based on tests with only three catalyst-equipped cars.

Combining the calculated mean emission factor of 1.5 pg I-TEQ_{DF}/km (or 1.6 pg TEQ_{DF}-WHO_{98}/km) with the estimate derived above for vehicle km driven in 1995 by all gasoline-powered vehicles (3,718 billion km) suggests that 5.6 g of I-TEQ_{DF} (or 5.9 g

TEQ_{DF}-WHO_{98}) were emitted from vehicles using unleaded fuels in 1995. Applying the same emission factors to the estimate derived above for vehicle km driven in 1987 by unleaded gasoline-powered vehicles (2,231 billion km), suggests that 3.3 g of I-TEQ_{DF} (or 3.6 g TEQ_{DF}-WHO_{98}) may have been emitted in 1987.

Diesel Fuel: Few data are available upon which to base an evaluation of the extent of CDD/CDF emissions resulting from diesel fuel combustion. The limited data available address emissions only from on-road vehicles; no emissions data are available for off-road diesel uses (i.e., construction vehicles, farm vehicles, and stationary equipment). Two U.S. tailpipe studies are available: CARB (1987a) and Gullett and Ryan (1997). CARB (1987a) reported a relatively high emission factor of 676 pg I-TEQ_{DF}/km (not detected values assumed to be zero) for one tested heavy-duty truck with a fuel economy at 50 km/hr of 5.5 km/L. Gullett and Ryan (1997) reported a range of emission factors for one diesel truck tested on six highway or city driving routes, 3.0 to 96.8 pg I-TEQ_{DF}/km (mean of 29.0 pg I-TEQ_{DF}/km).

The results of several tailpipe studies conducted in Europe have also been published. Marklund et al. (1990) reported no emissions at a detection limit of 100 pg I-TEQ_{DF}/L (or 18 pg I-TEQ_{DF}/km assuming a fuel economy of 5.5 km/L) for one tested truck. Schwind et al. (1991) and Hutzinger et al. (1992) reported emission factors of 32 to 81 pg I-TEQ_{DF}/L (or 6 to 15 pg I-TEQ_{DF}/km assuming a fuel economy of 5.5 km/L) for a truck engine run under various simulated driving conditions. Hagenmaier (1994) reported no emissions from a bus at a detection limit of 1 pg/L of fuel consumed for individual congeners. For diesel-fueled cars, Hagenmaier et al. (1990) reported an emission factor of 24 pg I-TEQ_{DF}/L (or approximately 2.4 pg I-TEQ_{DF}/km) for one tested car. Schwind et al. (1991) and Hutzinger et al. (1992) reported emission factors of 5 to 13 pg I-TEQ_{DF}/km for a car engine run under various simulated driving conditions.

The tunnel study by Oehme et al. (1991) generated an estimated mean emission factor of 5,100 pg TEQ/km and a range of 720 to 9,500 pg TEQ/km (in units of Nordic TEQ) for diesel-fueled trucks. Insufficient information was provided in Oehme et al. (1991) to enable an exact calculation of emission in units of I-TEQ_{DF} or TEQ_{DF}-WHO_{98}. However, based on the information that was provided, the mean emission factor in units of I-TEQ is approximately 5,250 to 5,400 pg I-TEQ_{DF}/km. These indirectly estimated

emission factors are considerably larger than those reported from engine studies by Marklund et al. (1990), Schwind et al. (1991), and Hutzinger et al. (1992); the CARB (1987a) diesel truck emission factor falls at the low end of the range. Although aggregate samples were collected in this study representing several thousand heavy duty diesel vehicles, several characteristics of this study introduce considerable uncertainty with regard to using the study's results as a basis for estimating emissions in the United States. These factors include: (1) heavy-duty vehicles comprised only 3 to 19 percent of total vehicle traffic in the tunnel; (2) the majority of the light-duty vehicles were fueled with leaded gasoline the combustion of which, as noted above in Table 4-4, can release considerable amounts of CDD/CDFs; and (3) technology differences likely existed between the 1988 Norwegian and the 1987 and 1995 U.S. vehicle fleets.

The recent tunnel study conducted in Baltimore, Maryland, by Gertler et al. (1996, 1998) has the same disadvantages shared by all tunnel studies relative to tailpipe studies. Specifically, tunnel studies rely on indirect measurements (rather than tailpipe measurements), which may introduce unknown uncertainties, and the emission factors calculated from these studies reflect driving conditions by the vehicle fleet using the tunnel and not necessarily the overall vehicle fleet under other driving conditions. However, the Gertler et al. (1996, 1998) study does have strengths lacking in the Oehme et al. (1991) tunnel study. Also, the Gertler et al. (1996, 1998) study has benefits over the two U.S. diesel truck tailpipe studies. These include (1) the study is a recent study conducted in the United States and thus reflects current U.S. fuels and technology, (2) virtually no vehicle using the tunnel used leaded gasoline, (3) the tunnel walls and streets were cleaned 1 week prior to the start of sampling and, in addition, the study analyzed road dust and determined that resuspended road dust contributed only about 4 percent of the estimated emission factors, (4) heavy-duty vehicles comprised, on average, a relatively large percentage (25.7 percent) of vehicles using the tunnel, and (5) a large number of heavy-duty vehicles, approximately 33,000, passed through the tunnel during the sampling period, which generates confidence that the emission factor is representative of interstate trucks.

In consideration of the strengths and weaknesses of the available emission factor data from the tailpipe and tunnel studies, the mean TEQ emission factor reported by Gertler et al. (1996, 1998), 172 pg I-TEQ_{DF}/km (or 182 pg TEQ_{DF}-WHO_{98}/km), is assumed

to represent the best current estimate of the average emission factor for on-road diesel-fueled trucks. Because it may not be representative of emission rates for the entire fleet of diesel-fueled trucks under the wide array of driving conditions encountered on the road, this emission factor is assigned a low confidence rating.

Combining the calculated mean emission factors from Gertler et al. (1996, 1998) with the above estimate for vehicle kms driven in 1995 in the United States by diesel-fueled trucks (195 billion km) suggests that 33.5 g of I-TEQ_{DF} (or 35.5 g TEQ_{DF}-WHO_{98}) were emitted from trucks using diesel fuel in 1995. Combining the same emission factors to the estimate derived above for vehicle km driven in 1987 by diesel-fueled trucks (153 billion km) suggests that 26.3 g of I-TEQ_{DF} (or 27.8 g TEQ_{DF}-WHO_{98}) were emitted from diesel-fueled trucks in 1987.

4.2. WOOD COMBUSTION

In 1995, wood fuel (including black liquor solids) provided about 2.6 percent (or 2,350-trillion Btu) of the total primary energy consumed in the United States (EIA, 1997b). During 1987, wood energy consumption is estimated to have been 2,437 trillion Btu, or 3.2 percent of total primary energy consumed (EIA, 1997b). The industrial sector is the largest consumer of wood fuel, accounting for almost 72 percent of total wood fuel consumption in 1995 and 65 percent in 1987. The residential sector accounted for 25 percent of consumption in 1995 and 35 percent in 1987. The electric utility sector accounted for less than 1 percent of total consumption in both years. There are no accurate sources to provide reliable estimates of commercial wood energy use; consumption is thought to be between 20 and 40 trillion Btu, or 2 to 4 percent of total wood consumption (EIA, 1994, 1997b).

These energy consumption estimates, however, appear to include the energy value of black liquor solids, which are combusted in recovery boilers by wood pulp mills. In 1987 and 1995, the energy value of combusted black liquor solids were 950 trillion Btu and 1,078 trillion Btu, respectively (American Paper Institute, 1992; American Forest & Paper Association, 1997). Subtracting these black liquor energy value estimates from the national totals for wood fuel yields 1,487 trillion Btu in 1987 and 1,272 trillion Btu in 1995. Assuming that 1 kg of oven-dried wood (i.e., 2.15 kg of green wood) provides approximately 19,000 Btu (EIA, 1994), then an estimated 66.9 million and 78.3 million

metric tons of oven-dried wood equivalents were burned for energy purposes in 1995 and 1987, respectively. Of these totals, an estimated 31.4 million metric tons and 44.8 million metric tons were consumed by the residential sector in 1995 and 1987, respectively. An estimated 35.5 million metric tons and 33.5 million metric tons were consumed by the industrial sector in 1995 and 1987, respectively.

The following two subsections discuss the results of relevant emission studies for the residential and industrial sectors, respectively, and present annual TEQ emission estimates for the reference years 1987 and 1995.

4.2.1. Residential Wood Combustion

Four studies have provided direct measurement of CDD/CDFs in flue gas emissions from wood stoves and/or fireplaces (Schatowitz et al., 1993; Vikelsoe et al., 1993; Bremmer et al., 1994; Broker et al., 1992). The findings of each of these studies are summarized in the following paragraphs.

Schatowitz et al. (1993) measured the CDD/CDF content of flue gas emissions from several types of wood burners used in Switzerland: a household stove (6 kW), automatic chip furnaces (110 to 1,800 kW), and a wood stick boiler (35 kW). The emissions from combustion of a variety of wood fuels were measured (natural beech wood, natural wood chips, uncoated chipboard chips, waste wood chips from building demolition, and household paper and plastic waste). The results from the testing of the household stove are most relevant for assessing releases from residential combustion. The household stove was tested with the stove door both open and closed. The open door stove can be assumed to be representative of fireplaces because both have an uncontrolled draft. Although the congener/congener group analytical results were not reported, the following emission factors (dry weight for wood; wet weight for household waste) and emission rates (corrected to 13 volume% oxygen) for the household stoves and furnaces were reported.

Stoves

- Open door burn of beech wood sticks: 0.77 ng I-TEQ_{DF}/kg (0.064 ng I-TEQ_{DF}/Nm^3);

- Closed door burn of beech wood sticks: 1.25 ng I-TEQ$_{DF}$/kg (0.104 ng I-TEQ$_{DF}$/Nm^3); and
- Closed door burn of household waste: 3,230 ng I-TEQ$_{DF}$/kg (114.4 ng I-TEQ$_{DF}$/Nm^3).

Furnaces

- Natural wood chips: 0.79 to 2.57 ng I-TEQ$_{DF}$/kg
- Chipboard chips (uncoated): 0.29 to 0.91 ng I-TEQ$_{DF}$/kg
- Waste wood chips from building demolition: 26.0 to 173.3 ng I-TEQ$_{DF}$/kg

Vikelsoe et al. (1993) studied emissions of CDD/CDF congener groups from residential wood stoves in Denmark. The wood fuels used in the experiments were seasoned birch, beech, and spruce, equilibrated to 18 percent absolute moisture. Four different types of stoves (including one experimental stove) were evaluated under both normal and optimal (i.e., well controlled with CO emission as low as possible) operating conditions. Widely varying total CDD/CDF emissions were found for the 24 different fuel/stove type/operating condition combinations. The emissions from spruce were about twice as high as the emissions from birch and beech. Surprisingly, the optimal operating condition led to significantly higher CDD/CDF emissions for two stove types, but not for the other stoves. The predominant congener group for all experiments was TCDF. The weighted average (considering wood and stove types) emission factor and flue gas concentration for wood stoves were reported to be 1.9 ng Nordic-TEQ/kg and 0.18 ng Nordic-TEQ/Nm^3, respectively. Because Vickelsoe et al. (1993) did not measure congener levels, the reported emission factor and emission rate were estimated by assuming the same congener distribution in each congener group that had been found for municipal waste incinerators.

Bremmer et al. (1994) reported results of testing performed with a cast-iron, wood burning stove with a combustion chamber lined with fire refractory clay. Measurements were conducted at three loads (maximum, average, and minimum) using clean wood as fuel. The emission factors ranged from 1.0 to 3.3 ng I-TEQ$_{DF}$/kg (average of about 2.2 ng I-TEQ$_{DF}$/kg). Bremmer et al. (1994) also reported results of testing conducted at a

fireplace of a type that is common in The Netherlands. The measured emission factors from burning of clean wood ranged from 13.0 to 28.5 ng I-TEQ_{DF}/kg (average of about 20 ng I-TEQ_{DF}/kg). Bremmer et al. (1994) noted that the measured emission factors for fireplaces were considerably higher than those reported by others (see Broker et al., 1992, below) and they, therefore, assigned "great uncertainty" to the emission factors.

Broker et al. (1992) reported results of a series of three tests with a wood stove and a fireplace. The average of the minimum and maximum emission factors measured for the woodstove tests ranged from 0.53 to 0.94 ng I-TEQ_{DF}/kg, respectively. The geometric mean of these two average values is 0.71 ng I-TEQ_{DF}/kg. The average of the minimum and maximum emission factors measured for the fireplace tests ranged from 0.20 to 1.06 ng I-TEQ_{DF}/kg, respectively. The geometric mean of these two average values is 0.46 ng I-TEQ_{DF}/kg.

Based on the results reported by Schatowitz et al. (1993), Vikelsoe et al. (1993), Bremmer et al. (1994), and Broker et al. (1992), 2 ng I-TEQ_{DF}/kg appear to be a reasonable average emission factor for residential burning of clean wood in fireplaces and stoves. Although the cited studies were conducted in Europe, residential wood burning practices are probably sufficiently similar to apply to the United States. Nevertheless, a low confidence rating was assigned to this estimate on the basis that it is derived from only four direct measurement studies. With the exception of the Broker et al. (1992) study, none of the cited studies presented results for the individual 2,3,7,8-substituted congeners. The Broker et al. (1992) study reported congener-specific results for only one of the test runs. Consequently, the data are not available from which to derive a corresponding emission factor for TEQ_{DF}-WHO_{98}. For purposes of this inventory, an emission factor of 2 ng TEQ_{DF}-WHO_{98}/kg is assumed.

Several studies have reported that combustion of non-clean wood in stoves and fireplaces can result in significantly higher CDD/CDF emission factors. The results of Schatowitz et al. (1993) for combustion of household waste in stoves and demolition waste in wood furnaces are presented above. A few researchers (e.g., Vikelsoe et al, 1993) have reported high CDD/CDF emission rates when PCP-contaminated wood is combusted in residential wood stoves and furnaces. The European Inventory (Quab and Fermann, 1997) used the results of these studies to derive best estimates of CDD/CDF emission factors for combustion of "slightly contaminated wood (excluding PCP)" and

"PCP-contaminated wood" to be 50 and 500 ng I-TEQ_{DF}/kg, respectively. Although it is likely that there is some residential combustion of these types of wood in the United States, there are no corresponding activity level data upon which to base a national annual estimate of emissions.

In 1987, 22.5 million households in the United States burned wood (EIA, 1991). Of these households, wood was used in 1987 as the primary heating fuel in 5 million households and as a secondary source for aesthetic purposes (i.e., fireplaces) in 17.4 million households (EIA, 1991; EIA, 1997b). Lower numbers were reported for 1995; wood was reported to be used as the primary fuel in 3.53 million households (EIA, 1997b). More rural low-income households consume wood as a primary heating fuel than do other sectors of the population. The majority of these households use wood-burning stoves as the primary heating appliance. Although fireplaces are the most common type of wood-burning equipment in the residential sector, only 7 percent of fireplace users report use of fireplaces for heating an entire home (EIA, 1991; EIA, 1994).

Residential wood consumption in 1995 was 596 trillion Btu (31.4 million metric tons), or 25 percent of total U.S. wood energy consumption (EIA, 1997b). In 1987, residential wood consumption was 852 trillion Btu (44.8 million metric tons), or 35 percent of total U.S. consumption (EIA, 1997b). These production estimates are given high confidence ratings because they are based on recent government survey data.

Combining the best estimate of the emission factor (2 ng I-TEQ_{DF}/kg wood) with the mass of wood consumed by residences in the years 1995 and 1987 indicates that the annual I-TEQ_{DF} air emissions from this source were approximately 62.8 grams in 1995 and 89.6 grams in 1987.

4.2.2. Industrial Wood Combustion

Emissions Data - Congener-specific measurements of CDD/CDFs in stack emissions from industrial wood-burning furnaces were measured by the California Air Resources Board at four facilities in 1988 (CARB, 1990b; CARB, 1990e; CARB, 1990f; CARB, 1990g). Measurements of CDD/CDF congener groups and 2,3,7,8-TCDD and 2,3,7,8-TCDF were reported for one facility by EPA (U.S. EPA, 1987a). The National Council of the Paper Industry for Air and Stream Improvement (NCASI) (1995) presented congener-specific emission factors for five boilers tested during burns of bark/wood residue. The

average congener emission factors derived from the four CARB and five NCASI studies are presented in Table 4-9. Average congener and congener group profiles are presented in Figure 4-5a for the four CARB studies and in Figure 4-5b for the five NCASI studies.

In CARB (1990b), CDD/CDFs were measured in the emissions from a quad-cell wood-fired boiler used to generate electricity. The fuel consisted of coarse wood waste and sawdust from nonindustrial logging operations. The exhaust gas passed through a multicyclone before entering the stack. From this study, average emission factors for total CDD/CDF and I-TEQ_{DF} are calculated to be 48.1 and 0.64 ng/kg of wood burned, respectively.

In CARB (1990e), CDD/CDFs were measured in the emissions from two spreader stoker wood-fired boilers operated in parallel by an electric utility for generating electricity. The exhaust gas stream from each boiler is passed through a dedicated ESP after which the gas streams are combined and emitted to the atmosphere through a common stack. Stack tests were conducted both when the facility burned fuels allowed by existing permits and when the facility burned a mixture of permitted fuel supplemented by urban wood waste at a ratio of 70:30. From this study, average emission factors for total CDD/CDF and I-TEQ_{DF} are calculated to be 29.2 and 0.82 ng/kg of wood burned, respectively.

In CARB (1990f), CDD/CDFs were measured in the emissions from a twin fluidized bed combustors designed to burn wood chips for the generation of electricity. The air pollution control device (APCD) system consisted of ammonia injection for controlling nitrogen oxides, and a multiclone and electrostatic precipitator for controlling particulate matter. During testing, the facility burned wood wastes and agricultural wastes allowed by existing permits. From this study, average emission factors for total CDD/CDF and I-TEQ_{DF} are calculated to be 47.9 and 1.32 ng/kg of wood burned, respectively.

In CARB (1990g), CDD/CDFs were measured in the emissions from a quad-cell wood-fired boiler. During testing, the fuel consisted of wood chips and bark. The flue gases passed through a multicyclone and an ESP before entering the stack. From this study, average emission factors for total CDD/CDF and I-TEQ_{DF} are calculated to be 27.4 and 0.50 ng/kg of wood burned, respectively.

NCASI (1995) presented stack emission test results for five boilers burning bark or wood residues. One of these facilities, equipped with a multicyclone, normally burns bark

in combination with sludge and coal. One other facility, equipped with an ESP, normally fires pulverized coal. The other three facilities were spreader stokers equipped with multicyclones or ESPs. Although stack gas flow rates were obtained during these tests, accurate measurements of the amounts of bark/wood fired were not made and had to be estimated by NCASI (1995) from steam production rates. The average TEQ emission factor for these facilities was 0.40 ng I-TEQ_{DF}/kg of feed (or 0.46 ng TEQ_{DF}-WHO_{98}/kg).

The mean of the emission factors derived from the four CARB studies and five NCASI studies, 0.56 ng I-TEQ_{DF}/kg wood (assuming nondetected values are zero) (or 0.60 ng TEQ_{DF}-WHO_{98}/kg wood), is used in this report as most representative of industrial wood combustion. This emission factor was assigned a medium confidence rating.

It should be noted, however, that these mean emission factors may not be appropriate emission factors to apply to the combustion of waste wood containing elevated chlorine content. NCASI (1995) concluded that CDD/CDF emissions from facilities burning salt-laden wood residue may be considerably higher than from those burning salt-free wood. Similarly, Umweltbundesamt (1996) reported the results of stack gas testing at approximately 30 facilities of varying design type as well as type of wood fuel combusted and noted that elevated CDD/CDF emissions were observed when the combustion conditions were poor, as evidenced by elevated carbon monoxide emissions, and/or when the fuel contained elevated chlorine levels. Umweltbundesamt (1996) attributed the correlation between elevated CDD/CDF emissions and elevated chlorine content of the fuel to the fire retardant effects of chlorine, which may have inhibited complete combustion. The chlorine content of untreated wood and bark were reported to range from 0.001 to 0.01 percent by weight and 0.01 to 0.02 percent by weight, respectively. Chipboard can contain up to 0.2 percent chlorine by weight because of binding agents used to manufacture the chipboard. Preservative-treated wood and PVC-coated wood were reported to contain chlorine contents as high as 1.2 and 0.3 percent by weight, respectively.

The facility tested by EPA in 1987 was located at a lumber products plant that manufactures overlay panels and other lumber wood products. Nearly all the wood fed to the lumber plant had been stored in sea water adjacent to the facility and, therefore, had a significant concentration of inorganic chloride. The wood-fired boiler tested was a three-cell dutch oven equipped with a waste heat boiler. The feed wood was a mixture of bark,

hogged wood, and green and dry planar shavings. The exhausted gases from the boiler passed through a cyclone and fabric filter prior to discharge from the stack. From this study, an average emission factor for total CDD/CDF of 1,020 ng/kg of wood burned (range: 552 to 1,410 ng/kg) was reported for the three collected samples. An average emission factor for I-TEQ_{DF} of 17.1 ng/kg of wood burned (range: 7.34 to 22.8 ng/kg) was estimated by EPA using measured congener group concentrations and concentrations of 2,3,7,8-TCDD and 2,3,7,8-TCDF. Similar emission factors were reported by Lutke et al. (1998) for testing conducted during the 1990s at four Canadian coastal, salt-laden wood power boilers: 1.4, 2.6, 17.4, and 27.6 ng I-TEQ_{DF}/kg wood combusted. The overall average of the five tested Canadian and U.S. facilities is 13.2 ng I-TEQ_{DF}/kg of wood combusted. The confidence rating assigned to this emission factor is low because it is based on reporting of limited congener data at one U.S. facility and testing at four non-U.S. sources and because the fraction of salt-laden wood combusted across facilities is likely to be highly variable.

Activity Level Information - As discussed in Section 4.2, industrial wood consumption in 1995 totaled 35.5 million metric tons. A similar amount, 33.5 million metric tons, was burned for fuel in industrial furnaces in 1987. The majority of wood fuel consumed in the industrial sector consists of wood waste (i.e., chips, bark, sawdust, and hogged fuel). Consumption in the industrial sector is dominated by two industries: the Paper and Allied Products industry and the Lumber and Wood Products industry (EIA, 1994). These activity level estimates are assigned a high confidence rating because they are based on recent government survey data.

As noted above, the emission factor associated with combustion of salt-laden wood appears to be greater than that associated with combustion of non-salt-laden wood. However, activity level data on combustion of salt-laden wood are not normally collected. Nonetheless, attempts have been made to estimate this activity level. NCASI combined the results from a 1995 survey of combustion units in the pulp and paper industry with an ad hoc telephone survey of mills in the Pacific Northwest (i.e., Oregon and Washington) to produce a conservative (i.e., high end) estimate of the amount of salt-laden wood combusted at U.S. pulp and paper mills in 1995: 254,000 metric tons (or 0.7 percent of the estimated 35.5 million metric tons of industrial wood consumed that year). NCASI

suspects that a similar fraction of industrial wood combustion in 1987 by pulp and paper mills was salt-laden (Gillespie, 1998).

For purposes of the NCASI survey, salt-laden wood was defined as wood that had been transported, stored, or otherwise exposed to saltwater prior to being processed as fuel. None of the three responding mills in Oregon reported use of salt-laden wood. Eight of the 13 responding mills in Washington reported some combustion of salt-laden wood. The estimated percentage of salt-laden wood to total wood consumption in the Washington mills was 17 percent.

As noted above, the majority of industrial wood combustion (i.e., 97 percent) occurs in two industries: the Paper and Allied Products industry and the Lumber and Wood Products industry. The relative amounts of wood combusted by each of these two industries were the same in 1990 and 1992, the only years for which these statistics are readily available (EIA, 1991, 1994). Therefore, it can be assumed that the percentage of total wood combusted nationally by the Lumber and Wood Products industry that is salt-laden is the same percentage as that reported by the Paper and Allied Products industry, 0.7 percent. Therefore, the total percentage of wood combusted by industry that is salt-laden is 1.4 percent. On a mass basis, this equates to 0.5 million metric tons in 1995 and 0.5 million metric tons in 1987. These activity level estimates are assigned a low confidence rating.

Emission Estimates - Applying the average TEQ emission factor from the four CARB and five NCASI studies (0.56 ng I-TEQ_{DF}/kg wood or 0.60 ng TEQ_{DF}-WHO_{98}/kg wood) to the estimated quantities of non-salt-laden wood burned by industrial facilities in 1995 (35 million metric tons) and 1987 (33 million metric tons) yields estimated TEQ emissions to air of 19.6 g I-TEQ_{DF} (or 21.0 g TEQ_{DF}-WHO_{98}) in 1995 and 18.5 g I-TEQ_{DF} (or 19.8 g TEQ_{DF}-WHO_{98}) in 1987.

Applying the average TEQ emission factor from the five studies on boilers combusting salt-laden wood (13.2 ng I-TEQ_{DF}/kg wood) to the estimated quantities of salt-laden wood burned by industrial facilities in 1995 (0.5 million metric tons) and 1987 (0.5 million metric tons) yields estimated TEQ emissions to air of 6.6 g TEQ in both 1995 and 1987.

Total emissions are estimated to have been 26.2 and 25.1 g I-TEQ_{DF} in 1995 and 1987, respectively. Total emissions of TEQ_{DF}-WHO_{98} are estimated to have been 27.6

and 26.4 g in 1995 and 1987, respectively. As noted above, these emissions are based on tests conducted at nine facilities in two industries. These two industries account for 97 percent of total industrial wood fuel combustion. The remaining 3 percent of industrial combustion and the combustion of wood by the commercial sector (for which no reliable activity level estimates are available) may not be well represented by the emission factors used above, particularly if poorly controlled combustors or treated wood (e.g., treated with PCP or plastics) are combusted.

4.2.3. Solid Waste from Wood Combustion

The measurement of CDDs and CDFs in chimney soot and bottom ash from wood-burning stoves and fireplaces has been reported by several researchers (Bumb et al., 1980; Nestrick and Lamparski, 1982 and 1983; Clement et al., 1985b; Bacher et al., 1992; Van Oostam and Ward, 1995; and Dumler-Gradl et al., 1995a).

Bumb et al. (1980) detected TCDDs (ND to 0.4 μg/kg), HxCDDs (0.2 to 3 μg/kg), HpCDDs (0.7 to 16 μg/kg), and OCDD (0.9 to 25 μg/kg) in residues from the wall of a home fireplace and from the firebrick of another home fireplace; for lack of a suitable analytical method, analysis was not performed for PeCDDs. Neither of the fireplaces sampled by Bumb et al. (1980) had burned preservative-treated wood.

Nestrick and Lamparski (1982, 1983) expanded the research of Bumb et al. (1980) by conducting a survey of CDD concentrations in chimney soot from residential wood-burning units in three different rural areas of the United States. Samples were collected from the base of six chimneys in each of the three study areas. Samples were not collected from units where any type of treated or manufactured wood had been burned. For lack of a suitable analytical method, analysis was not performed for PeCDDs. The results of this survey are summarized in Table 4-10. There was wide variation in the results across soot samples with standard deviations for congeners and congener groups often equal to or exceeding the mean value; however, CDDs in each congener group were detected in the soot from almost all sampled units. Nestrick and Lamparski (1982, 1983) concluded that the results do not appear to present any easily discernible patterns with respect to geographic region, furnace operational parameters, or wood fuel type. Nestrick and Lamparski (1982, 1983) attribute the wide variability observed to differences in

design of the different units, which affected the sampling point and/or the conditions at the sampling point, and/or possible contamination of the fuel wood.

Clement et al. (1985b) analyzed chimney soot and bottom ash from residential woodstoves and fireplaces in Canada. The CDD/CDF congener concentrations are presented in Table 4-10 (soot) and Table 4-11 (bottom ash). CDD/CDF congeners were detected in all samples analyzed, although the relative amounts of the different congener groups varied considerably and inconsistently within the type of wood burning unit and between ash and soot samples from the same unit. Clement et al. (1985b) also presents total CDD/CDF concentration data for bottom ashes from outside open-air burning of wood. No analyses were reported for individual congeners. The results for the congener groups are presented below. Clement et al. (1985b) did not present the quantities of ashes produced by the outside open-air burning test, hence it is not possible to readily determine the quantities of CDD/CDF disposed.

Congener group	Concentration (μg/kg)	Congener group	Concentration (μg/kg)
TCDDs	0.8	TCDFs	2.2
PeCDDs	4.2	PeCDFs	7.6
HxCDDs	7.2	HxCDFs	8.2
HpCDDs	11	HpCDFs	11
OCCDs	10	OCDFs	1.7

Bacher et al. (1992) characterized the full spectrum (i.e., mono- through octa-substitution) of chlorinated and brominated dibenzo-p-dioxin and dibenzofuran congeners in the soot from an old farmhouse in southern Germany. The chimney carried smoke from an oven that had used untreated wood at the rate of about 5 m^3 per year for more than 10 years. The sample was taken during the annual cleaning by a chimney sweep. The only BDF detected was mono-BDF (230 ng/kg). No BDDs, BCDDs, or BCDFs were detected at a detection limit of 20 ng/kg. The results for the tetra- through octa- CDDs and CDFs are presented in Table 4-10. The results indicate that CDFs dominate the CDDs in each congener group except octa. Also, the lower chlorinated congener groups dominate the higher chlorinated congener groups for both the CDDs and CDFs. The TEQ

content of the chimney soot was 720 ng I-TEQ_{DF}/kg (755 ng TEQ_{DF}-WHO_{98}/kg) of which less than 30 percent was due to CDDs.

Van Oostdam and Ward (1995) analyzed soot from two wood stoves in British Columbia, Canada. The average TEQ concentrations were 211 ng I-TEQ_{DF}/kg and 246 ng TEQ_{DF}-WHO_{98}/kg. The congener-specific results are presented in Table 4-10. The soot from a wood stove burning salt-laden wood in a coastal area was found to have an I-TEQ_{DF} content of 7,706 ng I-TEQ_{DF}/kg or 20 to 90 times greater than the concentrations found in the soot from the other two tested stoves.

Dumler-Gradl et al. (1995a) analyzed chimney soot samples collected by chimney sweeps from 188 residences in Bavaria. The summary results of the survey, the largest published survey of its kind to date, are presented in Table 4-12. As was observed by Nestrick and Lamparski (1982, 1983) and Clement et al. (1985b), CDD/CDFs were detected in all samples; however, there was wide variability in total TEQ concentrations within and across unit type/fuel type combinations.

Washington (1998) reports CDD/CDF congener data for ash from hog fuel boilers at three paper mills. The data are compiled and evaluated to determine a total I-TEQ concentrations and loading. Non-detect values were included as either zero, ½ DL or at the DL. The results are as follows, assuming that non-detect values are at zero concentration:

Location	Type of Residual	I-TEQ_{DF} (ng/kg)	I-TEQ_{DF} (mg/day)
Daishowa America, Port Angeles	Mixed Ash	0.31	0.012
Ft. James	Fly Ash	35.4	0.544
Rayonier	Filter Ash Vacuum Filter & Grate Filter Ash Fly Ash	12,640 1,150 2,299 225	68.9 6.27 12.5 1.23

Pohlandt (1994) presents CDD/CDF concentration data for various ashes ("bottom", "furnace", "boiler", "fly") from 12 wood burning boilers. The "fly ash" samples from two wood working industry boilers appear to have the greatest concentrations of CDD/CDF. Table 4-13 list the average congener concentration for those two boilers.

Three boiler bottom ash samples contain detectable amounts of only total HpCDD/HpCDF and OCDD/OCDF. All the other boiler samples were from boilers that burned copper/chrome/boron impregnated woods. These samples had total TEQs (assumed to be I-TEQs) ranging from 0.07 - 89 ppt, the highest being the fly ash samples (52 and 89). Pohlandt (1994) did not report the quantities produced by the boilers that were tested, hence it is not possible to readily determine the quantities of CDD/CDF disposed.

Carpenter (2001) reported the results of analyses of two ash samples from wood burning facilities in New Hampshire. Both samples are from the burning of clean (i.e., untreated) wood chips, sawdust and bark. The first sample is a combination of fly ash and bottom ash. The second sample is only fly ash, but it is a combination of fly ash from two wood burning boilers. For the first sample, none of the 2,3,7,8-substituted congeners were detected at detection limits that ranged from 0.98 ng/kg for 2,3,7,8-TCDD and 2,3,7,8-TCDF to 9.80 ng/kg for OCDD and OCDF. (All other congeners had a detection limit of 4.90 ng/kg.) For the second sample, except for two congeners, all congeners were below detection limits (which ranged from 0.379 to 0.831 ng/kg). The two congeners that exceeded detection limits were OCDD at 1.261 ng/kg, and 1,2,3,4,6,7,8-HpCDF at 1.022 ng/kg. For this sample, assuming that the non-detect congeners are not present, I-TEQ_{DF} concentration is 0.011 ng/kg. The quantities of the ash produced were not reported.

In a CARB report of emissions from a wood waste fired incinerator (CARB, 1990b) data are given for CDDs and CDFs for four ash samples. The concentrations of 2,3,7,8-substituted CDD/CDF congeners for each of those four tests were *all* below the method detection limits (MDLs) except for OCDD, which was detected in three samples at concentrations of 14,18, and 32 ng/kg, and 2,3,7,8-TCDF, which was detected in one sample at a concentration of 2.2 ng/kg. The method detection limits for each CDD and CDF congener ranged from 0.63 ppt (for 2,3,7,8-TCDD) to 9.5 ppt (for HpCDF congeners). Total CDD and total CDF values are given for each of the four samples. However, those values assume that non-detected congeners are at the MDL level. Consequently, the total CDD and total CDF values are biased high. The average of the four total CDD values is 28.8 ng/kg (with a range of 20.3 - 44.0). The average of the four total CDF values is 21.9 ng/kg (with a range of 16.0 - 26.9).

In another CARB report (CARB, 1990e), data are presented for CDDs and CDFs for several samples of Electrostatic Precipitator (ESP) waste ash from a wood-fired boiler. The report provides sample results for two weeks of sampling conducted at the facility. During the first week, the boiler burned fuels that were allowed by the facility permit; during the second week, the boiler burned a mixture containing 70 percent permitted fuel and 30 percent urban wood wastes. For the six samples collected over the three days of the first week, many of the concentrations of CDD/CDF congeners in the ESP ash were below the detection limits. CARB reports the CDD concentrations in ESP waste ash ranged from 24 to 264 ng/kg, and the CDF concentrations ranged from 12 to 151 ng/kg. However, those values assume that non-detected congeners are present at the detection level. One sample does not have any non-detect values for CDDs. The total CDD concentration for this sample is 264 ng/kg, or about 8.3 ng/kg I-TEQ_{DF} and 11.4 ng/kg WHO-TEQs. The I-TEQ_{DF} and TEQ_{DF}-WHO_{98} CDF concentrations for this sample are both less than 1.5 ng/kg. These values are less than 1 ng/kg for the other five samples. All of the samples have some non-detects for the CDF analysis.

Six samples were also collected over three days during the second week of sampling, when the 70/30 permitted/urban wood waste mix was burned. For the samples from the second week, the CDD concentrations in ESP waste ash ranged from 1,365 to 3,190 ng/kg, and the CDF concentrations ranged from 2,866 to 11,282 ng/kg. CARB (1990e) assumes that non-detected congeners are present at the detection level. However, this is a reasonable estimate for this data set because there is only one non-detect value. Table 4-14 presents the average congener concentrations for these samples.

CARB (1990e) did not present quantities of ESP ashes produced by the boiler, therefore, it is not possible to readily determine the quantities of CDD/CDF disposed.

Appendix II of Luthe (1998) reports TEQ concentrations (assumed to be I-TEQ_{DF}) in ashes collected from air pollution control devices from "salt-laden" wood steam boilers. The I-TEQ_{DF} content of ashes from three for primary multiclone hoppers varied significantly, 0.0978, 0.186, and 9.375 μg/kg. For the secondary multiclone hoppers, two samples of ash were taken. The secondary multiclone removes dust from the primary multiclone emissions; and therefore, the ash is finer than primary dust). The I-TEQ_{DF} for the ash were 1.073 and 20.879 μg/kg. The I-TEQ_{DF} for two samples taken from the

electrostatic precipitator, which collects dust from the secondary multiclone emissions, and is, therefore, finer than multiclone dust, are 3.926 and 8.044 μg/kg. No data are given for individual congeners. In fact, because the reference discusses only "dioxins", it is unclear whether the TEQ data are for CDDs, or CDDs plus CDFs. Quantities of collected ash are not given.

Also for the burning of salt-laden wood in paper mill boilers, Table II of Luthe (1996) presents data for the "TEQs [assumed to be I-TEQs] on particulates from secondary collection device" for four different paper mills. Eight data points are given (two for each mill), the average of which is 3.6 μg/kg. The range of values is 1.3 to 8.0 μg/kg. As with Luthe (1998), no data are given for individual congeners. It is also unclear whether the TEQ data are for CDDs, or CDDs plus CDFs. Quantities of collected ash are not given.

Table 5-16 of U.S.EPA (1987a) contains data indicating that the bottom ash from wood combustion (it is not indicated whether the combustion source was a boiler) from one source contained 140 ng/kg of 2,3,7,8-TCDD, 138,200 ng/kg of CDDs, and 7,400 ng/kg of CDFs. For a second wood combustion source, the ash contained no detectable 2,3,7,8-TCDD, but did contain about 125 ng/kg of CDDs and non detectable levels of CDFs. The baghouse dust from the second source contained 100 ng/kg of 2,3,7,8-TCDD, 1,143,600 ng/kg of CDDs, and 315,600 ng/kg of CDFs. Specific data for congeners and for ash/dust quantities were not given.

4.3. OIL COMBUSTION

Two major categories of fuel oil are burned by combustion sources: distillate oils and residual oils. These oils are further distinguished by grade numbers, with Nos. 1 and 2 being distillate oils; Nos. 5 and 6 being residual oils; and No. 4 either distillate oil or a mixture of distillate and residual oils. No. 6 fuel oil is sometimes referred to as Bunker C. Distillate oils are more volatile and less viscous than residual oils. They have negligible nitrogen and ash contents and usually contain less than 0.3 percent sulfur (by weight). Distillate oils are used mainly in domestic and small commercial applications. Being more viscous and less volatile than distillate oils, the heavier residual oils (Nos. 5 and 6) must be heated for ease of handling and to facilitate proper atomization. Because residual oils are produced from the residue remaining after the lighter fractions (gasoline, kerosene, and

distillate oils) are removed from the crude oil, they contain significant quantities of ash, nitrogen, and sulfur. Residual oils are used mainly in utility, industrial, and large commercial application (U.S. EPA, 1995b).

4.3.1. Residential/Commercial Oil Combustion

No testing of the CDD/CDF content of air emissions from residential/commercial oil-fired combustion units in the United States could be located. However, U.S. EPA (1997b) has estimated CDD/CDF congener group and I-TEQ$_{DF}$ emission factors based on average CDD/CDF concentrations reported for soot samples from 21 distillate fuel oil-fired furnaces used for central heating in Canada, and a particulate emission factor for distillate fuel oil combustors (300 mg/L of oil) obtained from AP-42 (U.S. EPA, 1995b). The I-TEQ$_{DF}$ emission factor estimate in U.S. EPA (1997b) was derived using the calculated emission factors for 2,3,7,8-TCDD, 2,3,7,8-TCDF, and the 10 congener groups. These emission factors are presented in Table 4-15, and the congener group profile is presented in Figure 4-6.

Because there are no direct measurements of CDD/CDF emissions in stack gases from U.S. residential oil-fired combustors and because of uncertainties associated with using chimney soot data to estimate stack emissions, no national emission estimates for this category are proposed at this time. However, a preliminary estimate of potential national TEQ emissions from this source category can be made using the emission factor presented in Table 4-13 (150 pg I-TEQ$_{DF}$/L of oil combusted). Distillate fuel oil sales to the residential/commercial sector totaled 39.7 billion liters in 1995 (EIA, 1997a). Application of the emission factor of 150 pg I-TEQ$_{DF}$/L to this fuel oil sales estimate results in estimated emissions of 6.0 g I-TEQ$_{DF}$ in 1995. This estimate should be regarded as a preliminary indication of possible emissions from this source category; further testing is needed to confirm the true magnitude of the emissions.

4.3.2. Utility Sector and Industrial Oil Combustion

Preliminary CDD/CDF emission factors for oil-fired utility boilers developed from boiler tests conducted over the past several years are reported in U.S. EPA (1997b). The data are a composite of various furnace configurations and APCD systems. Table 4-16 lists the median emission factors presented in U.S. EPA (1997b). The congener and

congener group profiles based on these data are presented in Figure 4-7. The median I-TEQ_{DF} emission factor was reported to be 314 pg/L of oil burned (or 366 pg TEQ_{DF}-WHO_{98}/L).

In 1993, the Electric Power Research Institute (EPRI) sponsored a project to gather information of consistent quality on power plant emissions. This project, the Field Chemical Emissions Measurement (FCEM) project, included testing of two cold side ESP-equipped oil-fired power plants for CDD/CDF emissions (EPRI, 1994). The averages of the congener and congener group emission factors reported for these two facilities are presented in Table 4-16. The average TEQ emission factors are 83.1 pg I-TEQ_{DF}/L and 93.6 pg TEQ_{DF}-WHO_{98}/L of oil burned (when nondetected values are treated as zero).

The TEQ emission factors reported in EPRI (1994) are a factor of three to four less than the median TEQ emission factor reported in U.S. EPA (1997b). For purposes of this assessment, emission factors of 200 pg I-TEQ_{DF}/L and 230 pg TEQ_{DF}-WHO_{98}/L (i.e., the average of the EPA median and EPRI mean emission factors) are assumed to be current best estimates of the average TEQ emission factors for utility/industrial oil burning. These estimated emission factors are assigned a low confidence rating.

The emission factors derived above were based on combustion of virgin oil by utility boilers. Significantly greater emission factors have been reported by Bremmer et al. (1994) for combustion of used oil by smaller combustion units in The Netherlands. Flue gases from a garage stove consisting of an atomizer fueled by spent lubricating oil from diesel engines (35 mg Cl^-/kg) were reported to contain 0.1 ng I-TEQ_{DF}/Nm^3 (or 2,000 pg I-TEQ_{DF}/kg of oil burned). The flue gases from a hot water boiler consisting of a rotary cup burner fueled with the organic phase of rinse water from oil tanks (340 mg Cl^-/kg) contained 0.2 ng I-TEQ_{DF}/Nm^3 (or 4,800 pg I-TEQ_{DF}/kg of oil burned). The flue gases from a steam boiler consisting of a rotary cup burner fueled by processed spent oil (240 mg Cl^-/kg) contained 0.3 ng I-TEQ_{DF}/Nm^3 (or 6,000 pg I-TEQ_{DF}/kg of oil burned). The emission factor for a ferry burning heavy fuel oil containing 11 ng/kg organic chlorine was 3,200 to 6,500 pg I-TEQ_{DF}/kg of oil burned. From these data, Bremmer et al. (1994) derived an average emission factor for combustion of used oil of 4,000 pg I-TEQ_{DF}/kg of oil burned. Bremmer et al. (1994) also reported measuring CDD/CDF emissions from a river barge and a container ship fueled with gas oil (less than 2 ng/kg of organic chlorine). The exhaust gases contained from 0.002 to 0.2 ng I-TEQ_{DF}/Nm^3. From these data, Bremmer et al.

(1994) derived an average emission factor for inland oil-fueled vessels of 1,000 pg I-TEQ_{DF}/kg oil burned. The applicability of these emission factors to used oil combustors in the United States is uncertain. Therefore, estimates of potential emissions from used oil combustion in the United States are not being developed at this time.

Residual fuel oil sales totaled 46.6 billion liters in 1995 and 77.3 billion liters in 1987 (EIA, 1992, 1997a). Vessel bunkering was the largest consumer (48 percent of sales) followed by electric utilities and the industrial sector. A high confidence rating is assigned to these production estimates. Application of the TEQ emission factor of 200 pg I-TEQ_{DF}/L (230 pg TEQ_{DF}-WHO_{98}/L) to these residual fuel oil sales results in estimated TEQ emissions of 9.3 g I-TEQ_{DF} (10.7 g TEQ_{DF}-WHO_{98}) in 1995 and 15.5 g I-TEQ_{DF} 1987 (17.8 g TEQ_{DF}-WHO_{98}) in 1987.

4.4. COAL COMBUSTION

During 1995, coal consumption accounted for approximately 22 percent of the energy consumed from all sources in the United States (U.S. DOC, 1997). In 1995, 872 million metric tons of coal were consumed in the United States. Of this total, 88.4 percent (or 771 million metric tons) were consumed by electric utilities, 11.0 percent (or 96 million metric tons) were consumed by the industrial sector (including consumption of 30 million metric tons by coke plants), and 0.6 percent (or 5.3 million metric tons) were consumed by residential and commercial sources (EIA, 1997b). Comparable figures for 1987 are: total consumption, 759 million metric tons; consumption by electric utilities, 651 million metric tons; consumption by coke plants, 33.5 million metric tons; consumption by other industries, 68.2 million metric tons; and consumption by the residential and commercial sectors, 6.3 million metric tons (EIA, 1995c). These production estimates are assigned a high confidence rating because they are based on detailed studies specific to the United States.

The following two subsections discuss the results of relevant emission studies for the utility/industrial and residential sectors, respectively, and present annual TEQ emission estimates for the reference years 1987 and 1995.

4.4.1. Utilities and Industrial Boilers

Until fairly recently, few studies had been performed to measure CDD/CDF concentrations in emissions from coal-fired plants, and several of these studies did not have the congener specificity and/or detection limits necessary to fully characterize this potential source (U.S. EPA, 1987a; NATO, 1988; Wienecke et al., 1992). The results of more recent testing of coal-fired utility and industrial boilers in The Netherlands (Bremmer et al., 1994), the United Kingdom (Cains and Dyke, 1994; CRE, 1994), Germany (Umweltbundesamt, 1996), and the United States (Riggs et al., 1995; EPRI, 1994) have achieved lower detection limits.

Bremmer et al. (1994) reported the results of emission measurements at two coal-fired facilities in The Netherlands. The emission factor reported for a pulverized coal electric power plant equipped with an ESP and a wet scrubber for sulfur removal was 0.35 ng I-TEQ_{DF}/kg of coal fired (or 0.02 ng I-TEQ_{DF}/Nm^3 at 11 percent O_2). The emission factor reported for a grass drying chain grate stoker equipped with a cyclone APCD was 1.6 ng I-TEQ_{DF}/kg of coal fired (or 0.16 ng I-TEQ_{DF}/Nm^3 at 11 percent O_2).

Cains and Dyke (1994) reported an emission factor of 102 to 109 ng I-TEQ_{DF}/kg of coal at a small-scale facility in the United Kingdom that was equipped with an APCD consisting only of a grit arrestor. CRE (1994) reported results of testing at 13 commercial/ industrial coal-fired boilers in the United Kingdom. The I-TEQ_{DF} emission factors ranged from 0.04 to 4.8 ng I-TEQ_{DF}/kg coal combusted (mean value of 0.6 ng I-TEQ_{DF}/kg). CRE (1994) also reported testing results for one coal-fired power plant, 0.06 ng I-TEQ_{DF}/kg coal combusted.

Umweltbundesamt (1996) reported that the I-TEQ_{DF} content of stack gases from 16 coal-burning facilities in Germany ranged from 0.0001 to 0.04 ng I-TEQ_{DF}/m^3; the data provided in that report did not enable emission factors to be calculated.

The U.S. Department of Energy sponsored a project in 1993 to assess emissions of hazardous air pollutants at coal-fired power plants. As part of this project, CDD/CDF stack emissions were measured at seven U.S. coal-fired power plants. The preliminary results of this project (i.e., concentrations in stack emissions) were reported by Riggs et al. (1995) and are summarized in Table 4-17. The levels reported for individual 2,3,7,8-substituted congeners were typically very low (i.e., $\leq$0.033 ng/Nm^3) or not detected. In general, CDF levels were higher than CDD levels. OCDF and 2,3,7,8-TCDF were the most

frequently detected congeners (i.e., at four of the seven plants). Table 4-18 presents characteristics of the fuel used and APCD employed at each plant. Variation in emissions between plants could not be attributed by Riggs et al. (1995) to any specific fuel or operational characteristic.

During the early 1990s, EPRI also sponsored a project to gather information of consistent quality on power plant emissions. This project, the Field Chemical Emissions Measurement (FCEM) project, included testing of four cold-side ESP-equipped coal-fired power plants for CDD/CDF emissions. Two plants burned bituminous coal and two burned subbituminous coal. The final results of the DOE project discussed above (Riggs et al., 1995) were integrated with the results of the EPRI testing and published in 1994 (EPRI, 1994). The average congener and congener group emission factors derived from this 11 facility data set, as reported in EPRI (1994), are presented in Table 4-19. Congener and congener group profiles for the data set are presented in Figure 4-8. The average I-TEQ_{DF} and TEQ_{DF}-WHO_{98} emission factors, assuming nondetected values are zero, are 0.079 ng I-TEQ_{DF}/kg of coal combusted and 0.078 ng TEQ_{DF}-WHO_{98}/kg. A medium confidence rating is assigned to these emission factors derived from the DOE and EPRI studies because they are based on recent testing at U.S. utilities.

Because the EPRI and DOE data only characterized emissions from units with cold-side ESPs, there has been uncertainty regarding the applicability of the emission factors derived from these data to units with hot-side ESPs. In July 1999, EPA conducted testing of stack emissions at a coal-fired utility equipped with a hot-side ESP. The preliminary results of this testing indicate that the TEQ emission factor for hot-sided ESPs is of the same order of magnitude as the average TEQ emission factors derived above.

As stated above, consumption of coal by the U.S. utility sectors was 771 million metric tons in 1995 and 651 million metric tons in 1987. Applying the TEQ emission factors of 0.079 ng I-TEQ_{DF}/kg of coal combusted and 0.078 ng TEQ_{DF}-WHO_{98}/kg to these production factors yields estimated annual emissions of 60.9 g I-TEQ_{DF} and 60.1 g TEQ_{DF}-WHO_{98} in 1995 and 51.4 g I-TEQ_{DF} and 50.8 TEQ_{DF}-WHO_{98} in 1987 by the utility sector.

No testing of the CDD/CDF content of air emissions from commercial/industrial coal-fired combustion units in the United States could be located. However, as noted above, several studies have been performed in European countries (Bremmer et al., 1994; CRE, 1994). It is uncertain whether the data collected in these European studies

accurately represent U.S. sources, but the data suggest that emission factors for commercial/industrial sources can be higher than those reported above for U.S. coal-fired utilities. Therefore, no national emission estimate for this category is being derived at this time. However, a preliminary estimate of potential national TEQ emissions from this source category can be derived using the average emission factor reported in CRE (1994), 0.6 ng I-TEQ_{DF}/kg coal combusted. As noted above, 66 million metric tons of coal were consumed by the industrial sector (excluding 30 million metric tons consumed by coke plants). Applying the emission factor of CRE (1994) to this activity level estimate yields an estimated national emission of 39.6 g I-TEQ_{DF} in 1995. This estimate should be regarded as a preliminary indication of possible emissions from commercial/industrial coal-fired boilers; further testing is needed to confirm the true magnitude of these emission.

4.4.2. Residential/Commercial Coal Combustion

Coal is usually combusted in underfeed or hand-stoked furnaces in the residential sector. Other coal-fired heating units include hand-fed room heaters, metal stoves, and metal and masonry fireplaces. Stoker-fed units are the most common design for warm-air furnaces and for boilers used for steam or hot water production. Most coal combusted in these units are either bituminous or anthracite. These units operate at relatively low temperatures and do not efficiently combust the coal. Coal generally contains small quantities of chlorine and CDD/CDF; therefore, the potential for CDD/CDF formation exists. Typically, coal-fired residential furnaces are not equipped with particulate matter or gaseous pollutant control devices that may limit emissions of any CDD/CDFs formed (U.S. EPA, 1997b). No testing of the CDD/CDF content of air emissions from residential/commercial coal-fired combustion units in the United States could be located. However, several relevant studies have been performed in European countries.

Thub et al. (1995) measured flue gas concentrations of CDD/CDF from a household heating system in Germany, fired either with salt lignite coal (i.e., total chlorine content of 2,000 ppm) or normal lignite coal (i.e., total chlorine content of 300 ppm). CDD/CDFs were detected in the flue gases generated by combustion of both fuel types. (See Table 4-20.) The congener profiles and patterns were similar for both fuel types, with OCDD the dominant congener and TCDF the dominant congener group. However, the emissions were higher for the "salt" coal (0.109 ng I-TEQ_{DF}/m^3 or 2.74 ng I-TEQ_{DF}/kg of

coal) by a factor of eight than for the "normal" coal (0.015 ng I-TEQ_{DF}/m^3 or 0.34 ng I-TEQ_{DF}/kg of coal).

Eduljee and Dyke (1996) used the results of testing performed by the Coal Research Establishment in the United Kingdom to estimate emission factors for residential coal combustion units as follows:

- Anthracite coal: 2.1 ng I-TEQ_{DF}/kg of coal; and
- Bituminous coal: 5.7 to 9.3 ng I-TEQ_{DF}/kg of coal (midpoint of 7.5 ng I-TEQ_{DF}/kg).

CDD/CDF emission factors for coal-fired residential furnaces were estimated in U.S. EPA (1997b) based on average particulate CDD/CDF concentrations from chimney soot samples collected from seven coal ovens, and particulate matter emission factors specific to anthracite and bituminous coal combustion obtained from AP-42 (U.S. EPA, 1995b). The I-TEQ_{DF} emission factors estimated in U.S. EPA (1997b) (i.e., 60.0 and 98.5 ng I-TEQ_{DF}/kg of anthracite and bituminous coal, respectively) were derived using the calculated emission factors for 2,3,7,8-TCDD 2,3,7,8-TCDF, and the 10 congener groups. U.S. EPA (1997b) stated that the estimated factors should be considered to represent maximum emission factors, because soot may not be representative of the particulate matter actually emitted to the atmosphere. These emission factors are presented in Table 4-20, and congener group profiles are presented in Figure 4-9.

Although the congener group profiles of the Thub et al. (1995) measurements and the U.S. EPA (1997b) estimates are similar, the I-TEQ_{DF} emission factors differ by factors of 175 to 289 between the two studies. The emission factors used by Eduljee and Dyke (1996) to estimate national annual emissions of I-TEQ_{DF} from residential coal combustion in the United Kingdom fall in between those other two sets of estimates but are still about one to two orders of magnitude greater than the estimated emission factor for industrial/ utility coal combustors. (See Section 4.4.1.)

Because there are no direct measurements of CDD/CDF emissions from U.S. residential coal-fired combustors and because of uncertainties regarding the comparability of U.S. and German and British coal combustion units, no national emission estimate for this category is being derived at this time. However, a preliminary estimate of potential

national TEQ emissions from this source category can be derived using the emission factors of Eduljee and Dyke (1996). As noted above, 5.3 million metric tons of coal were consumed by the residential/commercial sector in 1995 (U.S. DOC, 1997). U.S. EPA (1997b) reports that 72.5 percent of the coal consumed by the residential sector in 1990 were bituminous and 27.5 percent were anthracite. Assuming that these relative proportions reflect the actual usage in 1995, then application of the emission factors from Eduljee and Dyke (1996) (i.e., 2.1 ng I-TEQ_{DF}/kg of anthracite coal and 7.5 ng I-TEQ_{DF}/kg of bituminous coal) to the consumption value of 5.3 million metric tons results in an estimated I-TEQ_{DF} emission of 32.0 g TEQ in 1995. This estimate should be regarded as a preliminary indication of possible emissions from this source category; further testing is needed to confirm the true magnitude of these emissions.

4.4.3. Solid Wastes from Coal Combustion

A limited amount of CDD/CDF concentration data have been developed for utility industry solid wastes (U.S.EPA, 1999b). These data are for utility industry solid wastes that are comanaged (i.e., combinations of fly ash, bottom ash, boiler slag, and flue gas desulfurization [FGD] wastes). Samples were taken from 11 disposal sites. A total of 15 samples were taken from the 11 sites. The average concentrations for each of the CDD and CDF congeners are presented in the second column of Table 4-21. It should be noted that most of the concentration values shown in Table 4-21 represent limits of detection. Consequently, the values overestimate the actual concentration.

Section 3.3 of U.S.EPA (1999c) indicates that there were approximately 63 million tons (assumed to be short tons, i.e., 2,000 pounds) of large-volume utility coal combustion solid wastes produced in 1995. Of this amount, about 67 percent was landfilled, and the balance was disposed of in surface impoundments. The concentration data presented in Table 4-21 is only for the 53 million tons that were comanaged (or about 84 percent of the total wastes). For purposes of this analysis it will be assumed that the CDD/CDF concentrations in the comanaged wastes are the same as for the entire waste quantity. Combining the concentration data with the 63 million tons of total waste yields the total quantities of each congener disposed of in 1995. These data are presented in the fourth column of Table 4-21. Section 4.4 of this document indicates that total consumption of coal for electric utility boilers in 1987 was 98.4 percent of 1995

consumption. Consequently, the quantities of CDD/CDF disposed of in 1987 is assumed to be 98.4 percent of the 1995 values. These values are presented in column 3 of Table 4-21.

The 1995 congener quantities are converted into I-TEQ_{DF} and TEQ_{DF}-WHO_{98} values in columns 5 and 6 of Table 4-21 respectively. The values for 1987 are assumed to be 98.4 percent of the 1995 values based on the assumptions stated in the above paragraph.

[a] Dichloroethane and dibromoethane, except for Marklund et al. (1987), used as scavengers.

[b] Results reported were in units of pg TEQ/liter of fuel. For purposes of this table, the fuel economy factor used by Marklund et al. (1990), 10 km/L or 24 miles/gal, was used to convert the emission rates into units of pg TEQ/km driven for the cars. For the diesel-fueled truck, the fuel economy factor reported in CARB (1987a) for a 1984 heavy-duty diesel truck, 5.5 km/L (or 13.2 miles/gal), was used.

[c] Tests were conducted over portions of 4 days, with traffic rates of 8,000-14,000 vehicles/day. Heavy duty vehicles (defined as vehicles over 7 meters in length) ranged from 4-15% of total.

[d] Emission factors are reported in units of pg Nordic TEQ/km driven; the values in units of I-TEQ_{DF}/km are expected to be about 3 to 6 percent higher.

[e] Table reflects the range of summary results reported in Marklund et al. (1990); however, the congener-specific results for the single run reported indicate an emission rate of about 7.3 pg I-TEQ_{DF}/km.

[f] Tests were conducted over 5 days with heavy-duty vehicle rates of 1,800-8,700 vehicles per 12-hour sampling event. Heavy-duty vehicles accounted for 21-28 percent of all vehicles.

[G] Values listed are in units of I-TEQ_{DF}. Values in brackets are in units of TEQ_{DF}-WHO_{98}.

NR = Not Reported

Source: Gertler et al. (1996, 1998)

Notes:
1) Listed values are based on the difference between the calculated chemical mass entering the tunnel and the mass exiting the tunnel.
2) All calculated negative emission factors were set equal to zero.
3) All CDD/CDF emissions were assumed to result from heavy-duty diesel fueled vehicles. The table presents in the last row the percent of total traffic that was heavy-duty vehicles.

5. COMBUSTION SOURCES OF CDD/CDF: OTHER HIGH TEMPERATURE SOURCES

5.1. CEMENT KILNS AND LIGHTWEIGHT AGGREGATE KILNS

This section addresses CDD/CDF emissions from portland cement kilns. These facilities use high temperatures to convert mineral feedstocks into portland cement and other types of construction materials. For purposes of this analysis, cement kilns have been subdivided into two categories, those that burn hazardous waste and those that do not, and these two subcategories are further divided into kilns with inlet APCD temperatures above and below 450°F. The following subsections describe cement kiln technology, the derivation of TEQ emission factors for cement kilns that burn hazardous waste as supplemental fuel and those that do not, and the derivation of annual TEQ air emissions (g/yr) for 1995 and 1987.

Lightweight aggregate kilns that combust liquid hazardous wastes are not addressed in detail in this report. Only 5 of the more than 36 lightweight aggregate kilns in the United States combust hazardous waste. Those facilities are estimated to have emitted 3.3 g I-TEQ$_{DF}$ to air in 1990 (Federal Register, 1998b) and 2.4 g I-TEQ$_{DF}$ in 1997 (Federal Register, 1999b). These estimates are used in this report as the estimates for reference years 1987 and 1995, respectively. Regulations issued by EPA under the Clean Air Act (CAA) and Resource Conservation and Recovery Act (RCRA) in 1999 (Federal Register, 1999b) are expected to reduce those emissions to 0.4 g I-TEQ$_{DF}$ within the next 3 to 4 years.

5.1.1. Process Description of Portland Cement Kilns

In the United States, the primary cement product is portland cement. Portland cement is a fine, grayish powder consisting of a mixture of four basic materials: lime, silica, alumina, and iron compounds. Cement production involves heating (pyroprocessing) the raw materials to a very high temperature in a rotary (rotating) kiln to induce chemical reactions that produce a fused material called clinker. The cement clinker is then ground into a fine powder and mixed with gypsum to form the portland cement. The cement kiln is a large, steel, rotating cylindrical furnace lined with refractory material. The kiln is aligned on a slight angle, usually a slope of 3 to 6°. This allows the materials to pass through the kiln by gravity. The upper end of the kiln, known as the "cold" end, is where

the raw materials, or meal, are generally fed into the kiln. Midpoint injection is practiced at some facilities. The lower end of the kiln is known as the hot end. The hot end is where the combustion of primary fuels (usually coal and petroleum coke) transpires to produce a high temperature. The cement kiln is operated in a counter-current configuration, in which the hot combustion gases are convected up through the kiln while the raw materials pass down toward the lower end. The kiln rotates about 50 to 70 revolutions per hour, and the rotation induces mixing and the forward progress of mixed materials. As the meal moves through the cement kiln and is heated by the hot combustion gases, water is vaporized and pyroprocessing of materials occurs.

When operating, the cement kiln can be viewed as consisting of three temperature zones necessary to produce cement clinker. Zone 1 is at the upper end of the kiln where the raw meal is added. Temperatures in this zone typically range from ambient up to 600°C. In this area of the kiln, moisture is evaporated from the raw meal. The second thermal zone is known as the calcining zone. Calcining occurs when the hot combustion gases from the combustion of primary fuels dissociates calcium carbonate from the limestone to form calcium oxide. In this region of the kiln, temperatures range from 600°C to 900°C. Zone 3 is known as the burning or sintering zone. The burning zone, the lowest region of the kiln, is the hottest. Here temperatures in excess of 1,500°C induce the calcium oxide to react with silicates, iron, and aluminum in the raw materials to form cement clinker. The formation of clinker actually occurs close to the combustion of primary fuel. The chemical reactions that occur in Zone 3 are referred to as pyroprocessing.

The cement clinker, which leaves the kiln at the hot end, is a gray, glass-hard material consisting of dicalcium silicate, tricalcium silicate, calcium aluminate, and tetracalcium aluminoferrite. At this point, the clinker is about 1,100°C. The hot clinker is then dumped onto a moving grate, where it cools as it passes under a series of cool air blowers. Once cooled to ambient temperature, the clinker is ground into a fine powder and mixed with gypsum to produce the portland cement product.

Cement kilns can be either wet or dry processes. In the wet process, the raw materials are ground and mixed with water to form a slurry, which is fed into the kiln through a pump. This is an older process. A greater amount of heat energy is needed in

the wet process than in other types of kilns. These kilns consume about 5 to 7 trillion BTUs per ton of clinker product to evaporate the additional water.

In the dry process, a preheater is used to dry the raw meal before it enters the kiln. A typical preheater consists of a vertical tower containing a series of cyclone-type vessels. Raw meal is added at the top of the tower, and hot exhaust gases from the kiln operation preheat the meal, thus lowering the fuel consumption of the kiln. Dry kilns are now the most popular cement kiln type. Portland cement clinker production in the United States is estimated to have been 67.6 billion kg in 1995 and 52 billion kg in 1987 (U.S. Department of Commerce, 1996).

5.1.2. Cement Kilns That Burn Hazardous Waste

The high temperatures achieved in cement kilns make the kilns an attractive technology for combusting hazardous waste as supplemental fuel. Sustaining the relatively high combustion temperatures (1,100°C to 1,500°C) that are needed to form cement clinker requires the burning of a fuel with a high energy output. Therefore, coal or petroleum coke is typically used as the primary fuel source. Because much of the cost of operating the cement kiln at high temperatures is associated with the consumption of fossil fuels, some cement kiln operators have elected to burn hazardous liquid and solid waste as supplemental fuel. Currently about 75 percent of the primary fuel is coal. Organic hazardous waste may have a similar energy output as coal (9,000 to 12,000 Btu/lb for coal). The strategy of combusting the waste as supplemental fuel is to offset the amount of coal/coke that is purchased and burned by the kiln. The operator may charge a disposal fee to the waste generator for the right to combust the hazardous waste at the kiln, which also offsets the cost of kiln operation. Much of the high-energy and ignitable wastes primarily comprise such diverse substances as waste oils, spent organic solvents, sludges from the paint and coatings industry, waste paints and coatings from auto and truck assembly plants, and sludges from the petroleum refining industry (Greer et al., 1992).

The conditions inherent in the cement kiln mimic conditions of hazardous waste incineration. For example, the gas residence time in the burning zone is typically three seconds while at temperatures in excess of 1,500°C (Greer et al., 1992). The method of introducing liquid and solid hazardous waste into the kiln is a key factor to the complete

consumption of the waste during the combustion of the primary fuel. Liquid hazardous waste is either injected separately or blended with the primary fuel (coal). Solid waste is mixed and burned along with the primary fuel. Trial burns have consistently shown that 99.99 to 99.9999 percent destruction and removal efficiencies for the very stable organic wastes can be achieved in cement kilns (Greer et al., 1992). However, although the combustion of hazardous waste as supplemental or substitute fuel does have apparent advantages, only 16 percent of the portland cement kilns (34 of 212 kilns) in the United States combusted hazardous waste in 1995 (Federal Register, 1996b). Other types of supplemental fuel used by these facilities include automobile tires, used motor oil, sawdust, and scrap wood chips.

5.1.3. Air Pollution Control Devices Used on Cement Kilns

The pyroprocessing of raw meal in a cement kiln produces fine particulates, referred to as cement kiln dust. Cement kiln dust is collected and controlled with fabric filters or electrostatic precipitators, or both. Acid gases such as SO_2 can be formed during pyroprocessing of the sulfur-laden minerals, but the minerals have high alkalinity, which neutralizes SO_2 gases. Most particulate matter (PM) control devices used at cement kilns in 1995 and 1987 were considered to be hot-side control devices. A hot-sided control device is one that operates at flue gas temperatures above 450°F (some EPA rules use different definitions for hot-sided control devices for different industries).

Reducing the flue gas temperature in the PM control device is one factor shown to have a significant impact on limiting dioxin formation and emissions at cement kilns (U.S. EPA, 1997d). Recent emissions testing at a portland cement kiln showed that CDD/CDFs were almost entirely absent at the inlet to a hot-sided ESP, but CDDs and CDFs were measured at the exit (U.S. EPA, 1997d), showing conclusively that dioxins were formed within the hot-sided ESP. Reducing the flue gas temperature in the PM control device to below 450°F has been shown to substantially limit CDD/CDF formation at cement kilns. Lower temperatures are believed to prevent the post-combustion catalytic formation of CDD/CDFs. Consequently a number of cement kilns have added flue gas quenching units upstream of the APCD to reduce the inlet APCD temperature, thereby reducing CDD/CDF stack concentrations. A quenching unit usually consists of a water spray system within the flue duct. Thus, current CDD/CDF emissions from cement kilns are believed to be

substantially lower than CDD/CDF emissions in 1987 and 1995; EPA/OAQPS estimated emissions to be 13.1 g I-TEQ_{DF} in 1997 (Federal Register, 1999b).

5.1.4. CDD/CDF Emission Factors for Cement Kilns

For purposes of deriving emission factors, the general strategy used in this document is to consider subdividing each source category on the basis of design and operation. However, cement kilns are relatively uniform in terms of kiln design, raw feed material, temperatures of operation, and APCDs. Therefore, no subdivisions were made on these bases. An important potential difference among kilns, however, is whether or not hazardous waste is burned as a supplementary fuel. The source emissions database used in this report contains CDD/CDF emissions data for 16 cement kilns burning hazardous waste and 15 cement kilns not burning hazardous waste as reported in U.S. EPA (1996c). The majority of stack emissions data from cement kilns burning hazardous waste were derived during trial burns and may overestimate the CDD/CDF emissions that most kilns achieve during normal operations. Stack emissions data from kilns not burning hazardous waste were derived from testing during normal operations. The average TEQ emission factors are 20.91 ng I-TEQ_{DF}/kg clinker produced (22.48 ng TEQ_{DF}-WHO_{98}/kg clinker) and 0.27 ng I-TEQ_{DF}/kg clinker produced (0.29 ng TEQ_{DF}-WHO_{98}/kg clinker) for cement kilns burning and not burning hazardous waste, respectively. Accordingly, the average emission factor for kilns burning hazardous waste is about 90 times greater than that for kilns not burning hazardous waste. As discussed in Section 5.1.6 (Cement Kiln Dust), a comparison of CDD/CDF concentrations in cement kiln dust samples from cement kilns burning and not burning hazardous waste shows a similar relationship (i.e., the cement kiln dust from kilns burning hazardous waste had about 100 times higher CDD/CDF TEQ concentration than dust from kilns not burning hazardous waste).

Although the average emission factors for the two groups of kilns differ substantially, the emission factors for individual kilns in the two groups overlap. Therefore, other aspects of the design and operation of the kilns are likely to be affecting CDD/CDF emissions, particularly the temperature of the APCD equipment as discussed in Section 5.1.3.

Previous attempts to understand this issue through parametric testing of cement kilns have yielded mixed results. EPA conducted a limited comparison of CDD/CDF TEQ

stack gas concentrations (ng TEQ/dscm) between cement kilns burning hazardous wastes and not burning hazardous wastes (U.S. EPA, 1997d). Those comparisons were made at 14 cement kilns. Operating conditions (e.g., APCD temperature), with the exception of the fuel being burned, were the same or similar for each set of comparisons. Baseline conditions used coal as the only primary fuel. The results of these comparisons showed the following:

- Seven kilns in which the baseline (i.e., no combustion of hazardous waste) CDD/CDF TEQ stack gas concentrations were about the same as that for the burning of hazardous wastes.
- Two kilns in which the baseline CDD/CDF I-TEQ_{DF} stack gas concentrations were about double that for the burning of hazardous wastes.
- Five kilns in which the hazardous waste CDD/CDF I-TEQ_{DF} stack gas concentrations were substantially greater (from 3 to 29 times greater) than that for the baseline operating conditions.

Subsequently, EPA/ORD conducted analyses of the available emissions data to evaluate, on a congener-specific basis, whether there were significant differences in emission factors between (a) kilns burning hazardous waste and those not burning hazardous waste; (b) kilns with APCD inlet temperatures greater than 450°F and those with temperature less than 450°F; (c) hazardous waste burning and non–hazardous waste burning facilities with APCD inlet temperatures greater than 450°F; (d) hazardous waste burning and non–hazardous waste burning facilities with APCD inlet temperatures less than 450°F; (e) hazardous waste burning facilities with APCD inlet temperatures less than or greater than 450°F; and (f) non–hazardous waste burning facilities with APCD inlet temperatures less than or greater than 450°F. The results of all analyses showed significant differences in the sample mean values ($p < 0.05$).

Currently no satisfactory explanation exists for the apparent differences in the emission factors. Given the strong empirical evidence that real differences may exist, EPA/ORD has decided to treat the kilns burning hazardous waste separately from those not burning hazardous waste for the purposes of developing a CDD/CDF emissions inventory, and to subdivide the hazardous waste burning category into subcategories by APCD inlet temperature (i.e., less than 450°F or greater than 450°F). APCD inlet

temperature data were available for 88 test runs at 14 cement kilns. The number of test runs conducted at individual kilns ranged from 1 to 26. Each test run was treated as an individual facility and each was classified according to APCD inlet temperature and whether or not hazardous waste was burned. The emission factor (EF) for each cement kiln test run was calculated using Equation 5-1.

$$EF_{ck} = \frac{C \times F_v}{I_{cl}} \qquad \text{(Eq. 5-1)}$$

Where:

EF_{ck} = Cement kiln emission factor (burning or not burning hazardous waste), (ng TEQ/kg of clinker produced)

C = TEQ or CDD/CDF concentration in flue gases (ng TEQ/dscm) (20°C, 1 atm; adjusted to 7% O_2)

F_v = Volumetric flue gas flow rate (dscm/hr) (20°C, 1 atm; adjusted to 7% O_2)

I_{cl} = Average cement kiln clinker production rate (kg/hr)

After developing the emission factor for each cement kiln test run, the overall average congener-specific emission factor was derived for all test runs in each subcategory using Equation 5-2 below.

$$EF_{avgCK} = \frac{EF_{CK_1} + EF_{CK_2} + EF_{CK_3} + \ldots\ldots + EF_{CKN}}{N} \qquad \text{(Eq. 5-2)}$$

Where:

EF_{avgCK} = Average emission factor of tested cement kilns burning hazardous waste as supplemental fuel and with APCD inlet temperatures either greater than or less than 450°F (ng TEQ/kg clinker)

N = Number of cement kiln test runs

The average emission factors representing these categories of cement kilns are summarized in Table 5-1. Because the same test reports were used, the emission factors are the same for both the 1995 and 1987 reference years. Average congener and congener group profiles for cement kilns burning hazardous waste are presented in Figure 5-1 and for cement kilns not burning hazardous wastes in Figure 5-2.

5.1.5. National Estimates of CDD/CDF Emissions from Cement Kilns

Non–hazardous waste burning cement kilns produced 61.3 billion kg of cement clinker in 1995 (Heath, 1995). Since a total of 67.6 billion kg of cement clinker were produced in the United States in 1995 (U.S. DOC, 1996), it follows that cement kilns burning hazardous waste produced 6.3 billion kg of clinker, or 9.3 percent of the clinker produced. In 1987, approximately 52 billion kg of cement clinker were produced (U.S. DOC, 1996). If it is assumed that 9.3 percent of this total clinker production was from kilns burning hazardous waste, then about 4.8 billion kg of clinker were produced in hazardous waste burning kilns in 1987. These activity level estimates are given a high confidence rating for 1995 because they are based on recent survey data, but a medium rating for 1987 because of uncertainty concerning the proportion produced by hazardous waste burning kilns (U.S. EPA, 1996c).

The TEQ emission factors are given a low confidence rating for all subcategories. The emission factor for non–hazardous waste burning kilns was given a low rating because test data were available for only 15 of 178 facilities. The tested facilities may not be representative of routine CDD/CDF emissions from all kilns not burning hazardous waste. Although a higher percentage of the kilns burning hazardous waste (with reported APCD temperature data) had been tested (10 out of 34; eight with APCD inlet temperatures greater than 450°F and two with temperatures less than 450°F), greater uncertainty exists about whether the emissions are representative of normal operations because trial burn procedures were used. Accordingly, a low confidence rating was also assigned to the estimated emissions factors for kilns burning hazardous waste.

National estimates of CDD/CDF air emissions (grams TEQ per year) from all portland cement kilns operating in 1995 and 1987 were made by multiplying the average

TEQ emission factors by an estimate of the annual activity level (cement clinker produced) for each of the three subcategories (hazardous waste burning kilns with APCD inlet temperatures greater than 450°F, hazardous waste burning kilns with APCD inlet temperatures less than 450°F, and kilns not burning hazardous waste).

Of the 10 hazardous waste burning kilns with APCD temperature data, 8 facilities (80 percent) had APCD inlet temperatures greater than 450°F; 2 (20 percent) had APCD inlet temperatures less than 450°F. If it is assumed that the percentages of hazardous waste burning kilns less than and greater than 450°F represent the actual distribution of activity level in the industry, then one can use these percentages, coupled with the TEQ emission factors presented in Table 5-1 and the activity levels established at the beginning of this section, to calculate the annual national TEQ emission estimates shown below.

Reference Year 1995

Category	TEQ Emission Factor (ng/kg clinker)		Activity Level (billion kg clinker/yr)	Annual TEQ Emission (g/yr)	
	I-TEQ_{DF}	TEQ_{DF}-WHO_{98}		I-TEQ_{DF}	TEQ_{DF}-WHO_{98}
HW >450°F	28.58	30.70	5.04	144.0	154.7
HW <450°F	1.04	1.11	1.26	1.3	1.4
NHW	0.27	0.29	61.3	16.6	17.8
TOTAL			67.6	162	174

Reference Year 1987

Category	TEQ Emission Factor (ng/kg clinker)		Activity Level (billion kg clinker/yr)	Annual TEQ Emission (g/yr)	
	I-TEQ_{DF}	TEQ_{DF}-WHO_{98}		I-TEQ_{DF}	TEQ_{DF}-WHO_{98}
HW >450°F	28.58	30.70	3.8	108.6	116.7
HW <450°F	1.04	1.11	1.0	1.0	1.1
NHW	0.27	0.29	47.2	12.7	13.7
TOTAL			52.0	122	132

5.1.6. Recent EPA Regulatory Activities

In May 1999, EPA promulgated national emission standards under the authority of the Clean Air Act for hazardous air pollutants (including CDD/CDFs) for new and existing cement kilns not burning hazardous waste (Federal Register, 1999a). EPA/OAQPS expects this rule to reduce emissions of I-TEQ_{DF} by existing and new facilities by 36 percent over the next 5 years (i.e., from an estimated 44 g I-TEQ_{DF} in 1997 to 29 g I-TEQ_{DF} per year).

In July 1999, EPA promulgated national emission standards under the joint authority of the Clean Air Act and the Resource Conservation and Recovery Act for hazardous air pollutants (including CDD/CDFs) for hazardous waste combustion facilities (including cement kilns burning hazardous waste). Within the next 3 to 4 years under the final emissions limits, emissions of I-TEQ_{DF} by hazardous waste burning facilities are projected by EPA/OAQPS to be reduced by 40 percent (i.e., from an estimated 13.1 g I-TEQ_{DF} in 1997 to 7.7 g I-TEQ_{DF} per year) (Federal Register, 1999b).

5.1.7. Solid Waste from Cement Manufacturing

The solid residual generated during the manufacturing of cement is known as Cement Kiln Dust (CKD). EPA characterized CKD in a Report to Congress (U.S. EPA, 1993g). The report was based in part on a 1991 survey of cement manufacturers conducted by the Portland Cement Association (PCA). Survey responses were received from 64 percent of the active cement kilns in the United States. On the basis of the survey responses, EPA estimated that in 1990 the U.S. cement industry generated about 12.9 million metric tons of gross CKD and 4.6 million metric tons of "net CKD," of which 4.2 million metric tons were land disposed. The material collected by the APCD system is called "gross CKD" (or "as generated" CKD). The gross CKD is either recycled back into the kiln system or is removed from the system for disposal (i.e., "net CKD" or "as managed" CKD) (U.S. EPA, 1993g).

In support of the Report to Congress, EPA also conducted sampling and analysis during 1992 and 1993 of CKD and clinker. The purposes of the sampling and analysis efforts were to: (1) characterize the CDD/CDF content of clinker and CKD; (2) determine the relationship, if any, between the CDD/CDF content of CKD and the use of hazardous

waste as fuel; and (3) determine the relationship, if any, between the CDD/CDF content of CKD and the use of wet process versus dry process cement kilns (U.S. EPA, 1993g).

Clinker samples were collected from five kilns not burning hazardous waste and six kilns burning hazardous waste (U.S. EPA, 1993g). CDD/CDFs were not detected in any cement kiln clinker samples. Tetra- through octa-chlorinated CDDs and CDFs were detected in the gross CKD samples obtained from 10 of the 11 kilns and in the net CKD samples obtained from 8 of the 11 kilns. The CDD/CDF content of gross CKD ranged from 0.008 to 247 ng I-TEQ_{DF}/kg and from 0.045 to 195 ng I-TEQ_{DF}/kg for net CKD. Analyses for seven PCB congeners were also conducted, but no congeners were detected in any clinker or CKD sample. The mean CDD/CDF concentrations in net CKD generated by the kilns burning hazardous waste are higher (35 ng I-TEQ_{DF}/kg) than in net CKD generated by the facilities not burning hazardous waste (3.0E-02 ng I-TEQ_{DF}/kg). These calculations of mean values treated nondetected values ("nondetects") as zero. If the nondetected values had been excluded from the calculation of the means, the mean value for net CKD from kilns burning hazardous waste would increase by a factor of 1.2, and the mean value for net CKD from kilns not burning hazardous waste would increase by a factor of 1.7. One sampled kiln had a net CKD TEQ concentration more than two orders of magnitude greater than the TEQ levels found in samples from any other kiln. If this kiln was considered atypical of the industry (U.S. EPA, 1993g) and was not included in the calculation, then the mean net CKD concentration for hazardous waste burning kilns decreases to 2.9 ng I-TEQ_{DF}/kg.

In a recent report (Washington, 1998), CDD/CDF congener data for CKD from Holnam, Inc., Seattle, Washington, were presented. The data were compiled and evaluated to determine total I-TEQ concentrations and loadings. Non-detect values were included as either zero, ½ DL, or at the DL. The results of three separate tests were as follows, assuming that non-detect values were at zero concentration:

Date	Location	I-TEQ (ng/kg)	I-TEQ (mg/day)
5/15/96	not stated	0.038	0.0038
10/21/97	HLMN Bin	0.67	0.0674
10/21/97	HLMN Final	0.95	0.0948

In a recently compiled database, EPA (1999d) provided data for ashes from an electric static precipitator connected to a cement kiln and a fabric filter connected to a light weight aggregate (LWA) kiln. The average congener concentrations for the ash samples are listed in Table 5-8.

The average concentrations for the cement kiln were determined from two different waste streams, each with five sample burns. The average concentrations for the LWA kiln were determined using one waste stream with three sample burns.

All CKD is normally disposed of in engineered landfills and is consequently not categorized as an environmental release as defined in this emission inventory. The amount of CDD/CDF associated with these materials is calculated for informational purposes. The estimate of land-disposed CKD from the 1991 PCA survey (4.2 million metric tons per year; basis year is 1990) was divided among kilns that burn hazardous waste (34 kilns) and those that do not (178 kilns) on the basis of the number of kilns in each category. The average TEQ concentration in the net CKD from kilns burning hazardous waste (including the high value discussed above) was 35 ng I-TEQ_{DF}/kg. For kilns that do not burn hazardous waste, the average concentration in the net CKD was 3.0E-02 ng I-TEQ_{DF}/kg. Multiplying these average concentrations by the estimated annual net CKD production yields 24 g I-TEQ_{DF}/yr for kilns burning hazardous waste and 0.1 g I-TEQ_{DF}/yr for kilns not burning hazardous waste, a total of 24.1 g I-TEQ_{DF}/yr for all kilns in 1990.

EPA is currently developing cement kiln dust storage and disposal requirements (Federal Register, 1999b).

5.2. ASPHALT MIXING PLANTS

Asphalt consists of an aggregate of gravel, sand, and filler mixed with liquid asphalt cement or bitumen. Filler typically consists of limestone, mineral stone powder, and sometimes ash from power plants and municipal waste combustors. The exact composition of an asphalt formulation depends on how it will be used. The aggregate typically constitutes over 92 percent by weight of the total asphalt mixture. The components of the aggregate are dried, heated to a temperature ranging from 275 to 325°F, and then mixed and coated with the bitumen at an asphalt mixing installation. "Old" asphalt (i.e., asphalt from dismantled bridges and roads) can be heated and

disaggregated to its original components and reused in the manufacture of new asphalt (U.S. EPA, 1996i).

No data are available on levels of CDD/CDF emissions, if any, from U.S. asphalt mixing operations. However, limited data are available for facilities in The Netherlands and Germany.

Bremmer et al. (1994) reported the CDD/CDF emissions factor for an asphalt mixing plant in The Netherlands at 47 ng I-TEQ_{DF} per metric ton of produced asphalt. No congener-specific emission factors were reported. The facility they tested heated old asphalt to about 150°C in an individual recycling drum with flue gases that were mixed with ambient air and heated to a temperature of 300–400°C. Parallel to this recycling drum, the main drum dried and heated the aggregate (sand and gravel/granite chippings) to a temperature of about 220°C. The flue gases leaving the recycling drum were led along the main burner of the main drum for incineration. The old asphalt, the minerals from the main drum, and new bitumen from a hot storage tank (about 180°C) were mixed in a mixer to form new asphalt. Natural gas fueled the tested facility during the sample collection period and used old asphalt as 46 percent of the feed. The facility's APCD system consisted of cyclones and a fabric filter.

Umweltbundesamt (1996) reported lower emission factors for three tested facilities in Germany that were also equipped with fabric filters. These three facilities were fueled by oil or butane gas and used old asphalt at rates ranging from 30 to 60 percent of the feed. The emission factors calculated from the stack gas concentrations, gas flow rates, and hourly throughputs for these three facilities were 0.2, 3.5, and 3.8 ng I-TEQ_{DF}/metric ton of asphalt produced.

Approximately 25 million metric tons of asphalt bitumen were produced in the United States in 1992. An identical quantity was produced in 1990 (U.S. DOC, 1995a). Bitumen constitutes approximately 5 percent by weight of finished paving asphalt (Bremmer et al., 1994). Thus, an estimated 500 million metric tons of paving asphalt are produced in the United States annually.

Because there are no direct measurements of CDD/CDF emissions from U.S. asphalt plants and because of uncertainties regarding the comparability of U.S. and Dutch asphalt plant technologies and feed materials, no national emission estimate for this category is proposed at this time. However, a preliminary estimate of the potential

magnitude of annual TEQ emissions for U.S. production of asphalt can be obtained by averaging the emission factors for the four facilities reported by Bremmer et al. (1994) and Umweltbundesamt (1996). Applying this average emission factor (i.e., 14 ng I-TEQ_{DF}/metric ton of asphalt produced) to the activity level of 500 million metric tons of paving asphalt produced annually yields an annual emission of 7 g I-TEQ_{DF}/yr. This estimate should be regarded as a preliminary indication of possible emissions from this source category; further testing is needed to confirm the true magnitude of these emissions. Congener-specific results were not reported in either report. Therefore, TEQ_{DF}-WHO_{98} estimates could not be calculated.

5.3. PETROLEUM REFINING CATALYST REGENERATION

Regeneration of spent catalyst from the reforming process at petroleum refineries is a potential source of CDDs and CDFs according to limited testing conducted in the United States (Amendola and Barna, 1989; Kirby, 1994), Canada (Maniff and Lewis, 1988; Thompson et al., 1990), and The Netherlands (Bremmer et al., 1994). This section summarizes the catalyst regeneration process, relevant studies performed to date, and the status of EPA regulatory investigations of this source.

Catalytic reforming is the process used to produce high-octane reformates from lower octane reformates for blending of high-octane gasolines and aviation fuels. The reforming process occurs at high temperature and pressure and requires the use of a platinum or platinum/rhenium catalyst. During the reforming process, a complex mixture of aromatic compounds, known as coke, is formed and deposited onto the catalyst. As coke deposits onto the catalyst, its activity is decreased. The high cost of the catalyst necessitates its regeneration. Catalyst regeneration is achieved by removing the coke deposits via burning at temperatures of 750 to 850°F and then reactivating the catalyst at elevated temperatures (850 to 1,000°F) using chlorine or chlorinated compounds (e.g., methylene chloride, 1,1,1-trichloroethane, and ethylene dichloride). Burning of the coke produces flue gases that can contain CDDs and CDFs along with other combustion products. Because flue gases, if not vented directly to the atmosphere, may be scrubbed with caustic or water, internal effluents may become contaminated with CDD/CDFs (Kirby, 1994; SAIC, 1994).

There are three basic catalyst regeneration processes used: semi-regenerative, cyclic, and continuous. During the semi-regenerative process, the entire catalytic reformer is taken off-line. In the cyclic process, one of two (or more) reforming reactors is taken off-line for catalyst regeneration; the remaining reactor(s) remains on-line so that reforming operations continue. In the continuous process, aged catalyst is continuously removed from one or more on-line stacked or side-by-side reactors, regenerated in an external regenerator, and then returned to the system; the reforming system, consequently, never shuts down (SAIC, 1994).

In 1988, the Canadian Ministry of the Environment detected concentrations of CDDs in an internal waste stream of spent caustic in a petroleum refinery that ranged from 1.8 to 22.2 μgL, and CDFs ranging from 4.4 to 27.6 μg/L (Maniff and Lewis, 1988). The highest concentration of 2,3,7,8-TCDD was 0.0054 μg/L. CDDs were also observed in the refinery's biological sludge at a maximum concentration of 74.5 μg/kg, and CDFs were observed at a maximum concentration of 125 μg/kg. The concentration of CDD/CDFs in the final combined refinery plant effluent was below the detection limits.

Amendola and Barna (1989) reported detecting trace levels of hexa- to octa-CDDs and CDFs in untreated wastewaters (up to 2.9 pg I-TEQ_{DF}/L) and wastewater sludges (0.26 to 2.4 ng I-TEQ_{DF}/kg) at a refinery in Ohio. The levels of detected total CDD/CDFs in the wastewater and sludge were much lower ($<$3 ng/L and $<$1 μg/kg, respectively) than the levels reported by Maniff and Lewis (1988). No CDD/CDFs were detected in the final treated effluent (i.e., less than 0.2 ng I-TEQ_{DF}/L). The data collected in the study were acknowledged to be too limited to enable identifying the source(s) of the CDD/CDFs within the refinery. Amendola and Barna (1989) also present in an appendix to their report the results of analyses of wastewater from the catalyst regeneration processes at two other U.S. refineries. In both cases, untreated wastewaters contained CDDs and CDFs at levels ranging from high pg/L to low ng/L (results were reported for congener group totals, not specific congeners). However, CDD/CDFs were not detected in the only treated effluent sample collected at one refinery.

Thompson et al. (1990) reported total CDD and CDF concentrations of 8.9 ng/m^3 and 210 ng/m^3, respectively, in stack gas samples from a Canadian petroleum refinery's reforming operation. They also observed CDDs and CDFs in the internal wash water from a scrubber of a periodic/cyclic regenerator in the pg/L to ng/L range.

Beard et al. (1993) conducted a series of benchtop experiments to investigate the mechanism(s) of CDD/CDF formation in the catalytic reforming process. A possible pathway for the formation of CDFs was found, but the results could not explain the formation of CDDs. Analyses of the flue gas from burning coked catalysts revealed the presence of unchlorinated dibenzofuran (DBF) in quantities up to 220 μg/kg of catalyst. Chlorination experiments indicated that DBF and possibly biphenyl and similar hydrocarbons act as CDF precursors and can become chlorinated in the catalyst regeneration process. Corrosion products on the steel piping of the process plant seem to be the most likely chlorinating agent.

In May 1994, EPA's Office of Water conducted a sampling and analytical study of catalyst regeneration wastewater for CDD/CDFs at three petroleum refining plants (Kirby, 1994). The study objectives were to determine the analytical method best suited for determining CDD/CDFs in refinery wastewater and to screen and characterize wastewater discharges from several types of reforming operations for CDD/CDFs. The report for this study (Kirby, 1994) also presented results submitted voluntarily to EPA by two other facilities. The sampled internal untreated wastewaters and spent caustics were found to contain a wide range of CDD/CDF concentrations, 0.1 pg I-TEQ_{DF}/L to 57.2 ng I-TEQ_{DF}/L. The study results also showed that 90 percent of the TEQ was contained in the wastewater treatment sludges generated during the treatment of wastewater and caustic from the regeneration process.

In 1995, EPA issued a notice of its proposed intent not to designate spent reformer catalysts as a listed hazardous waste under RCRA (Federal Register, 1995b). The final rule was issued in August 1998 (Federal Register, 1998a). The Agency's assessment of current management practices associated with recycling of reforming catalyst found no significant risks to human health or the environment. The Agency estimated that 94 percent of the approximately 3,600 metric tons of spent reformer catalyst sent off-site by refineries are currently recycled for their precious-metal content. However, EPA made no determination of the "listability" of spent caustic residuals formed during regeneration of spent reforming catalyst. The Agency did identify as being possibly of concern potential air releases from the combustion of the reforming catalyst prior to reclamation. The Agency requested comments on (a) opportunities for removing dioxin prior to discharge of scrubber water into the wastewater treatment system; (b) opportunities to segregate this

wastestream; and (c) potential health risks associated with insertion of dioxin-contaminated media back into the refinery process (such as the coker). In this proposed rulemaking, EPA also noted the possibility of dioxin releases to air during regeneration operations.

As part of its regulatory investigation under RCRA, EPA's OSW commissioned a study to analyze and discuss existing data and information concerning CDD/CDF formation in the treatment of catalytic reformer wastes. This report (SAIC, 1994) also identified potential process modifications that may prevent the formation of CDD/CDFs. SAIC (1994) concluded that, although the available data indicate that CDD/CDFs can be generated during the catalyst regeneration process, the available data indicate that CDD/CDF concentrations in treated wastewater and in solid waste are minimal. Releases to air could result from vented flue gases at some facilities. In addition, the CDD/CDFs formed could possibly be reintroduced into other refining operations (e.g., the coker) and resulting products.

In 1998, emissions from the caustic scrubber used to treat gases from the external regeneration unit of a refinery in California were tested (CARB, 1999). This facility uses a continuous regeneration process. The reactor is not taken off-line during regeneration; rather, small amounts of catalyst are continuously withdrawn from the reactor and are regenerated. The emissions from the regeneration unit are neutralized by a caustic scrubber before being vented to the atmosphere. The catalyst recirculation rate during the three tests ranged from 733 to 1,000 lbs/hr.

All 2,3,7,8-substituted CDD/CDFs were detected in each of the three samples collected. The average emission factors in units of ng/barrel of reformer feed are presented in Table 5-2. The congener profile is presented in Figure 5-3. The samples showed a wide range in concentrations of the CDD/CDF congeners (up to fivefold difference); however, the congener profile was consistent in all samples. The concentrations of the individual furan congener groups were always higher than the concentrations of the corresponding dioxin congener group. The average I-TEQ_{DF} emission factor for these three tests is 3.04 ng TEQ/barrel and the average TEQ_{DF}-WHO_{98} is 3.18 ng TEQ/barrel.

In 1991, stack testing was performed on the exhaust from one of three semi-regenerative catalytic reforming units of a refinery in California (Radian, 1991b). A caustic

solution is introduced to the exhaust to neutralize hydrochloric acid emissions from the catalyst beds prior to release to the atmosphere. The tested unit was considered to be representative of the other units. Each unit is periodically (approximately once per year) taken off-line so the catalyst beds can be regenerated. The tested unit has a feed capacity of 7,000 barrels per day. Approximately 59,500 pounds of catalyst were regenerated during the tested regeneration cycle, which tested for 62 hours.

The average emission factors for this facility (in units of ng/barrel of reformer feed) are presented in Table 5-2 and the congener profile is presented in Figure 5-3. The majority of the 2,3,7,8-substituted CDD congeners were not detected during testing. In contrast, the majority of the 2,3,7,8-substituted CDF congeners were detected. The average I-TEQ_{DF} emission factor (assuming not detected values are zero) is 1.01E-03 ng TEQ/barrel and the average TEQ_{DF}-WHO_{98} emission factor is 1.04E-03 ng TEQ/barrel. These values are three orders of magnitude less than the emission factor reported in CARB (1999). The calculation of these emission factors involved several assumptions: the unit is regenerated once per year; the unit operates at capacity (i.e., 7,000 barrels/day); and the facility operates 362 days per year.

The average of the two facility emission factors, 1.52 ng I-TEQ_{DF}/barrel of reformer feed (1.59 ng TEQ_{DF}-WHO_{98}/barrel), is assigned a low confidence rating. Only one continuous and only one semi-regenerative unit in the United States have been tested. Combined, these two facilities represent less than 1 percent of the catalytic reforming capacity in U.S. petroleum refineries in 1987 (3.805 million barrels per day) and in 1995 (3.867 million barrels per day) (EIA, 1997c). The average emission factor developed above assumes that emissions are proportional to reforming capacity; however, emission factors may be more related to the amount of coke burned, the APCD equipment present, or other process parameters.

The 1987 and 1995 national daily average catalytic reforming capacities in the United States were 3.805 and 3.867 million barrels per day (EIA, 1997c). If it is conservatively assumed that all units operated at full capacity in 1987 and 1995, then applying the average emission factors of TEQ/barrel yields annual emissions of 2.11 g I-TEQ_{DF} in 1987 (2.21 g TEQ_{DF}-WHO_{98}) and 2.14 g I-TEQ_{DF} in 1995 (2.24 g TEQ_{DF}-WHO_{98}).

5.4. CIGARETTE SMOKING

Bumb et al. (1980) were the first to report that cigarette smoking is a source of CDD emissions. Subsequent studies by Muto and Takizawa (1989), Ball et al. (1990), and Löfroth and Zebühr (1992) also reported the presence of CDDs as well as CDFs in cigarette smoke. A recent study by Matsueda et al. (1994) reported the CDD/CDF content of the tobacco from 20 brands of cigarettes from seven countries. Although a wide range in the concentrations of total CDD/CDFs and total TEQs were reported in these studies, similar congener profiles and patterns were reported. The findings of each of these studies are described in this section.

No studies published to date have demonstrated a mass balance, and it is not known whether the CDD/CDFs measured in cigarette smoke are the result of formation during tobacco combustion, volatilization of CDD/CDFs present in the unburned tobacco, or a combination of these two source mechanisms. The combustion processes operating during cigarette smoking are complex and could be used to justify both source mechanisms. As reported by Guerin et al. (1992), during a puff, gas phase temperatures reach 850°C at the core of the firecone, and solid phase temperatures reach 800°C at the core and 900°C or greater at the char line. Thus, temperatures are sufficient to cause at least some destruction of CDD/CDFs initially present in the tobacco. Both solid and gas phase temperatures rapidly decline to 200 to 400°C within 2 mm of the char line. Formation of CDD/CDFs has been reported in combustion studies with other media in this temperature range of 200 to 900°C. However, it is known that a process likened by Guerin et al. (1992) to steam distillation takes place in the region behind the char line because of high, localized concentrations of water and temperatures of 200 to 400°C. At least 1,200 tobacco constituents (e.g., nicotine, n-paraffin, some terpenes) are transferred intact from the tobacco into the smoke stream by distillation in this region, and it is plausible that CDD/CDFs present in the unburned tobacco would be subject to similar distillation.

Bumb et al. (1980), using low-resolution mass spectrometry, analyzed the CDD content of mainstream smoke from the burning of a U.S. brand of unfiltered cigarette. A package of 20 cigarettes was combusted in each of two experiments. Approximately 20 to 30 puffs of 2 to 3 seconds duration were collected from each cigarette on a silica

column. Hexa-, hepta-, and octa-CDD were detected at levels of 0.004–0.008, 0.009, and 0.02–0.05 ng/g, respectively.

Muto and Takizawa (1989) employed a continuous smoking apparatus to measure CDD congener concentrations in the mainstream smoke generated from the combustion of one kind of filtered cigarette (brand not reported). The apparatus pulled air at a constant continuous rate (rather than a pulsed rate) through a burning cigarette and collected the smoke on a series of traps (glass fiber filter, polyurethane foam, and XAD-II resin). The CDD content of the smoke, as well as the CDD content of the unburned cigarette and the ash from the burned cigarettes, were also analyzed using low-resolution mass spectrometry. The results are presented in Table 5-3, and the congener group profiles are presented in Figure 5-4. Table 5-3 and Figure 5-4 present the mainstream smoke results on a mass per cigarette basis to enable comparison with the results of other studies. The major CDD congener group that was found was HpCDD, which accounted for 84 percent of total CDDs found in the cigarette, 94 percent of total CDDs found in smoke, and 99 percent of total CDDs found in the ash. The 2,3,7,8-HpCDDs also accounted for the majority of the measured TEQ in the cigarettes and smoke; however, none were measured in the ash. Although no PeCDDs were detected in the cigarette, PeCDDs were detected at low levels in the smoke, indicating probable formation during combustion. On the basis of the similarities in the congener group profiles for the three media, Muto and Takizawa (1989) concluded that most of the CDDs found in the cigarette smoke are the result of volatilization of CDD/CDFs present in the unburned cigarette rather than formation during combustion.

Ball et al. (1990) measured the CDD/CDF content of mainstream smoke for the 10 best-selling German cigarette brands. The international test approach (i.e., 1 puff/min; puff flow rate of 35 mL/2 sec) was employed with an apparatus that smoked 20 cigarettes at a time in three successive batches with a large collection device. The average TEQ content (on both an I-TEQ_{DF} and TEQ_{DF}-WHO_{98} basis) in mainstream smoke for the 10 brands tested, normalized to a mass per cigarette basis, was 0.09 pg/cigarette (i.e., 16.5 times less than the value reported by Muto and Takizawa (1989) for a Japanese cigarette brand). However, the congener group profiles were similar to those reported by Muto and Takizawa (1989) with HpCDD and OCDD the dominant congener groups found.

Löfroth and Zebühr (1992) measured the CDD/CDF content of mainstream and sidestream smoke from one common Swedish cigarette brand. The cigarette brand was labeled as giving 17 mg carbon monoxide, 21 mg tar, and 1.6 mg nicotine. The international test approach (i.e., 1 puff/min; puff flow rate of 35 mL/2 sec) was used, and the smoke was collected on glass fiber filters followed by two polyurethane plugs. The analytical results for mainstream and sidestream smoke are presented in Table 5-4. The TEQ content in mainstream smoke, normalized to a mass per cigarette basis, was 0.90 pg I-TEQ_{DF}/cigarette or 0.96 pg TEQ_{DF}-WHO_{98}/cigarette (i.e., about 2 times less than the value reported by Muto and Takizawa (1989) and 10 times greater than the average value reported by Ball et al. 1990). As was reported by Muto and Takizawa (1989) and Ball et al. (1990), the dominant congener groups were HpCDDs and OCDD; however, HpCDFs were also relatively high compared to the other congener group totals. The sidestream smoke contained 1.96 pg I-TEQ_{DF} per cigarette (2.08 pg TEQ_{DF}-WHO_{98} per cigarette), or twice that of mainstream smoke.

Using high-resolution mass spectrometry, Matsueda et al. (1994) analyzed the CDD/CDF content of tobacco from 20 brands of commercially available cigarettes collected in 1992 from Japan, the United States, Taiwan, China, the United Kingdom, Germany, and Denmark. Table 5-5 presents the study results. The total CDD/CDF content and total I-TEQ_{DF} content ranged from 109 to 1,136 pg/pack and from 1.4 to 12.6 pg/pack (1.9 to 14.0 pg/pack on a TEQ_{DF}-WHO_{98} basis), respectively. The Chinese cigarette brand contained significantly lower CDD/CDFs and TEQs than any other brand of cigarette. Figure 5-6 depicts the congener group profiles for the average results for each country. A high degree of similarity is shown in the CDF congener group profiles between the tested cigarette brands. The Japanese and Taiwanese cigarettes show CDD congener group profiles different from the other countries' cigarettes.

In 1995, approximately 487 billion cigarettes were consumed in the United States and by U.S. overseas armed forces personnel. In 1987, approximately 575 billion cigarettes were consumed. Per capita U.S. cigarette consumption, based on total U.S. population aged 16 and over, declined to 2,415 in 1995; the record high was 4,345 in 1963 (The Tobacco Institute, 1995; USDA, 1997). These activity level estimates are assigned a high confidence rating.

The available emission factor data presented above provide the basis for two methods of estimating the amount of TEQs that may have been released to the air in the United States in 1995 and in 1987 from the combustion of cigarettes. The confidence rating assigned to the emission factor is low because of the very limited amount of testing performed to date. First, an annual emission estimate for 1995 of 0.21 g TEQ (on an I-TEQ_{DF} or TEQ_{DF}-WHO_{98} basis) is obtained if it is assumed that (a) the average TEQ content of seven brands of U.S. cigarettes reported by Matsueda et al. (1994), 8.6 pg I-TEQ_{DF}/pack or 8.8 pg TEQ_{DF}-WHO_{98}/pack, are representative of cigarettes smoked in the United States; (b) CDD/CDFs are not formed, and the congener profile reported by Matsueda et al. (1994) is not altered during combustion of cigarettes; and (c) all CDD/CDFs contributing to the TEQ are released from the tobacco during smoking. The second method of estimating is based on the assumption that the TEQ emission rates for a common Swedish brand of cigarette reported by Löfroth and Zebühr (1992) for mainstream smoke (0.90 pg I-TEQ_{DF}/cigarette or 0.96 pg TEQ_{DF}-WHO_{98}/cigarette) and sidestream smoke (1.96 pg I-TEQ_{DF}/cigarette or 2.08 pg TEQ_{DF}-WHO_{98}/cigarette) are representative of the emission rates for U.S. cigarettes. This second method yields an annual emission estimate of 1.41 g I-TEQ_{DF} or 1.48 g TEQ_{DF}-WHO_{98}. For 1987, the two methods yield estimates of 0.25 g TEQ (I-TEQ_{DF} or TEQ_{DF}-WHO_{98} basis) and 1.67 g I-TEQ_{DF} (or 1.75 g TEQ_{DF}-WHO_{98}).

For purposes of this report, the best estimates of annual emissions are assumed to be the average of the annual emissions estimated by the two methods for 1995 and 1987 (0.8 g TEQ and 1.0 g TEQ), respectively (I-TEQ_{DF} or TEQ_{DF}-WHO_{98} basis). Although these emission quantities are relatively small when compared to the emission quantities estimated for various industrial combustion source categories, the emissions are significant because humans are directly exposed to cigarette smoke.

5.5. PYROLYSIS OF BROMINATED FLAME RETARDANTS

The pyrolysis and photolysis of brominated phenolic derivatives and polybrominated biphenyl ethers used as flame retardants in plastics (especially those used in electronic devices), textiles, and paints can generate considerable amounts of polybrominated dibenzo-p-dioxins (BDDs) and dibenzofurans (BDFs) (Watanabe and Tatsukawa, 1987; Thoma and Hutzinger, 1989; Luijk et al., 1992). Watanabe and Tatsukawa (1987)

observed the formation of BDFs from the photolysis of decabromobiphenyl ether. Approximately 20 percent of the decabromobiphenyl ether was converted to BDFs in samples that were irradiated with ultraviolet light for 16 hours.

Thoma and Hutzinger (1989) observed the formation of BDFs during combustion experiments with polybutylene-terephthalate polymers containing 9 to 11 percent decabromodiphenyl ether. Maximum formation of BDFs occurred at 400 to 600°C, with a BDF yield of 16 percent. Although Thoma and Hutzinger (1989) did not provide specific quantitative results for similar experiments conducted with octabromodiphenyl ether and 1,2-bis(tri-bromophenoxy)ethane, they did report that BDDs and BDFs were formed.

Luijk et al. (1992) studied the formation of BDD/BDFs during the compounding and extrusion of decabromodiphenyl ether into high-impact polystyrene polymer at 275°C. HpBDF and OBDF were formed during repeated extrusion cycles, and the yield of BDFs increased as a function of the number of extrusion cycles. HpBDF increased from 1.5 to 9 ppm (in the polymer matrix), and OBDF increased from 4.5 to 45 ppm after four extrusion cycles.

Insufficient data are available at this time from which to derive annual BDD/BDF emission estimates for this source.

5.6. CARBON REACTIVATION FURNACES

Granular activated carbon (GAC) is an adsorbent that is widely used to remove organic pollutants from wastewater and to treat finished drinking water at water treatment plants. Activated carbon is manufactured from the pyrolytic treatment of nut shells and coal (Buonicore, 1992a). The properties of GAC make it ideal for adsorbing and controlling vaporous organic and inorganic chemicals entrained in combustion plasmas, as well as soluble organic contaminants in industrial effluents and drinking water. The high ratio of surface area to particle weight (600 to 1,600 m^2/g), combined with the extremely small pore diameter of the particles (15–25 angstroms), increases the adsorption characteristics (Buonicore, 1992a). GAC eventually becomes saturated, and the adsorption properties significantly degrade. When saturation occurs, GAC usually must be replaced and discarded, which significantly increases the costs of pollution control. The introduction of carbon reactivation furnace technology in the mid-1980s created a method involving the thermal treatment of used GAC to thermolytically desorb the synthetic

compounds and restore the adsorption properties for reuse (Lykins et al., 1987). Large-scale regeneration operations, such as those used in industrial water treatment operations, typically use multiple-hearth furnaces. For smaller-scale operations, such as those used in municipal water treatment operations, fluidized-bed and infrared furnaces are used. Emissions are typically controlled by afterburners followed by water scrubbers (U.S. EPA, 1997b).

The used GAC can contain compounds that are precursors to the formation of CDD/CDFs during the thermal treatment process. EPA measured precursor compounds in spent GAC that was used as a feed material to a carbon reactivation furnace tested during the National Dioxin Study (U.S. EPA, 1987a). The total chlorobenzene content of the GAC ranged from 150 to 6,630 ppb. Trichlorobenzene was the most prevalent species present, with smaller quantities of di- and tetra-chlorobenzenes detected. Total halogenated organics were measured to be about 150 ppm.

EPA has stack-tested two GAC reactivation furnaces for the emission of dioxin (U.S. EPA, 1987a; Lykins et al., 1987). One facility was an industrial carbon reactivation plant, and the second facility was used to restore GAC at a municipal drinking water plant. EPA (1997b) also reported results of other testing performed at a county water facility in California during 1990.

The industrial carbon reactivation plant processed 36,000 kg/day of spent GAC used in the treatment of industrial wastewater effluents. This facility was chosen for testing because it was considered to be representative of other facilities in the source category (U.S. EPA, 1987a). Spent carbon was reactivated in a multiple-hearth furnace, cooled in a water quench, and shipped back to primary chemical manufacturing facilities for reuse. The furnace was fired by natural gas and consisted of seven hearths arranged vertically in series. The hearth temperatures ranged from 480 to 1,000°C. Air pollutant emissions were controlled by an afterburner, a sodium spray cooler, and a fabric filter. Temperatures in the afterburner were about 930°C. The estimated I-TEQ_{DF} emission factor (treating not-detected values as zero) was 0.64 ng I-TEQ_{DF}/kg carbon processed (0.76 ng TEQ_{DF}-WHO_{98}). The emission factor for total CDD/CDF was 58.6 ng/kg. Because analyses were performed only for 2,3,7,8-TCDD, 2,3,7,8-TCDF, OCDD, and OCDF and the congener groups, equivalent concentrations were assumed for all toxic and nontoxic congeners in each of the penta-, hexa-, and hepta-congener groups.

The second GAC reactivation facility tested by EPA consisted of a fluidized-bed furnace located at a municipal drinking water treatment plant (Lykins et al., 1987). The furnace was divided into three sections: a combustion chamber, a reactivation section, and a dryer section. The combustion section was fired by natural gas and consisted of a stoichiometrically balanced stream of fuel and oxygen. Combustion temperatures were about 1,038°C. Gases from the reactivation and combustion section were directed through an acid gas scrubber and high-temperature afterburner prior to discharge from a stack. Although measurable concentrations of dioxin-like compounds were detected in the stack emissions, measurements of the individual CDD/CDF congeners were not performed; therefore, it was not possible to derive TEQ emission factors for this facility. With the afterburner operating, no CDD congeners below HpCDD were detected in the stack emissions. Concentrations of HpCDDs and OCDD ranged from 0.001 to 0.05 ppt/v and 0.006 to 0.28 ppt/v, respectively. All CDF congener groups were detected in the stack emissions even with the afterburner operating. Total CDFs emitted from the stack averaged 0.023 ppt/v.

From the results of a test of the reactivation unit at a county water facility in California in 1990, EPA reported a TEQ emission factor of 1.73 ng I-TEQ_{DF}/kg of carbon processed (U.S. EPA, 1997b). The emission factor for total CDD/CDF was reported to be 47 ng/kg (i.e., similar to the total CDD/CDF emission factor of 58.6 ng/kg at the industrial GAC facility). Because congener-specific results were not reported, it was not possible to calculate the TEQ_{DF}-WHO_{98} emission factor. The report also did not provide the configuration and type of furnace tested; however, it did state that the emissions from the furnace were controlled by an afterburner and a scrubber.

The industrial GAC reaction furnace test data indicate that an average of 0.64 ng I-TEQ_{DF}/kg of GAC may be released. The I-TEQ_{DF} emission rate for the reactivation unit at the county water treatment facility was 1.73 ng I-TEQ_{DF}/kg carbon. Low confidence ratings are given to these emission factors because only two GAC reactivation furnaces were stack-tested and not all congeners were analyzed at the industrial GAC facility.

The mass of GAC that is reactivated annually in carbon reactivation furnaces is not known. However, a rough estimate, to which a low confidence rating is assigned, is the mass of virgin GAC shipped each year by GAC manufacturers. According to the Department of Commerce (1990c), 48,000 metric tons of GAC were shipped in 1987.

EPA (1995c; 1997b) reported that in 1990, water and wastewater treatment operations consumed 65,000 metric tons of GAC. The 1990 activity level is used in this document as a surrogate for the 1995 activity level.

Applying the average TEQ emission factor of 1.2 ng I-TEQ_{DF} (or TEQ_{DF}-WHO_{98}) per kg of reactivated carbon for the two tested facilities to the estimates of potential GAC reactivation volumes, yields annual release estimates of 0.06 g I-TEQ_{DF} (or TEQ_{DF}-WHO_{98}) in 1987 and 0.08 g I-TEQ_{DF} (or TEQ_{DF}-WHO_{98}) in 1995 (assuming that the activity level for 1990 is representative of the 1995 activity level).

5.7. KRAFT BLACK LIQUOR RECOVERY BOILERS

Kraft black liquor recovery boilers are associated with the production of pulp in the making of paper using the Kraft process. In this process, wood chips are cooked in large vertical vessels called digesters at elevated temperatures and pressures in an aqueous solution of sodium hydroxide and sodium sulfide. Wood is broken down into two phases: a soluble phase containing primarily lignin, and an insoluble phase containing the pulp. The spent liquor (called black liquor) from the digester contains sodium sulfate and sodium sulfide, which the industry recovers for reuse in the Kraft process. In the recovery of black liquor chemicals, weak black liquor is first concentrated in multiple-effect evaporators to about 65 percent solids. The concentrated black liquor also contains 0.5 to 4 percent chlorides by weight, which are recovered through combustion. The concentrated black liquor is sprayed into a Kraft black liquor recovery furnace equipped with a heat recovery boiler. The bulk of the inorganic molten smelt that forms in the bottom of the furnace contains sodium carbonate and sodium sulfide in a ratio of about 3:1. The combustion gas is usually passed through an electrostatic precipitator (ESP) that collects particulate matter prior to being vented out the stack. The particulate matter can be processed to further recover and recycle sodium sulfate (Someshwar and Pinkerton, 1992).

In 1987, EPA stack-tested three Kraft black liquor recovery boilers for the emission of dioxin in conjunction with the National Dioxin Study (U.S. EPA, 1987a). The three sites tested by EPA were judged to be typical of Kraft black liquor recovery boilers at that time. During pretest surveys, two facilities were judged to have average potential and one was judged to have high potential for CDD/CDF emissions based on the amount of

chlorine found in the feed to these units. Dry-bottom ESPs controlled emissions from two of the boilers; a wet-bottom ESP controlled emissions from the third. The results of these tests include congener group concentrations but lack measurement results for specific congeners other than 2,3,7,8-TCDD and 2,3,7,8-TCDF. NCASI (1995) provided congener-specific emission test results for six additional boilers tested during 1990 to 1993. Three boilers were of the direct contact type, and three were noncontact type. All were equipped with ESPs. The average congener and congener group emission factors are presented in Table 5-6 for the three facilities from U.S. EPA (1987a) and the six facilities from NCASI (1995). Figure 5-7 presents the average congener and congener group profiles based on the test results presented in NCASI (1995).

The average TEQ emission factor based on the data for the six NCASI facilities with complete congener data is 0.029 ng I-TEQ_{DF}/kg of black liquor solids, assuming nondetected values are zero (0.028 ng TEQ_{DF}-WHO_{98}/kg), and 0.068 ng I-TEQ_{DF}/kg assuming nondetected values are present at one-half the detection limit (0.078 ng TEQ_{DF}-WHO_{98}/kg). The results for the three facilities reported in U.S. EPA (1987a) were not used in the derivation of the TEQ emission factor because congener-specific measurements for most 2,3,7,8-substituted congeners were not made in the study. A medium confidence rating is assigned to those emission factors because the emission factors were derived from the stack-testing of six Kraft black liquor recovery boilers that were judged to be fairly representative of technologies used at Kraft pulp mills in the United States. A 1995 survey of the industry indicated that 215 black liquor recovery boilers were in operation at U.S. pulp and paper mills. All but one of these boilers used ESPs for control of particulate emissions; the one unique facility used dual scrubbers. In addition, ESPs were reported to have been the predominant means of particulate control at recovery boilers for the past 20 years (Gillespie, 1998).

The amounts of black liquor solids burned in Kraft black liquor recovery boilers in the United States during 1987 and 1995 were 69.8 million metric tons and 80.8 million metric tons, respectively (American Paper Institute, 1992; American Forest & Paper Association, 1997). These activity level estimates are assigned a high confidence rating because they are based on recent industry survey data. Combining the emission factors derived above with the activity level estimates of 69.8 and 80.8 million metric tons in 1987 and 1995, respectively, yields estimated annual emissions from this source of

approximately 2.0 g I-TEQ_{DF} (2.0 g TEQ_{DF}-WHO_{98}) in 1987 and 2.3 g I-TEQ_{DF} (2.3 g TEQ_{DF}-WHO_{98}) in 1995.

5.8. OTHER IDENTIFIED SOURCES

Several manufacturing processes are identified as potential sources of CDD/CDF formation because the processes use chlorine-containing components or involve application of high temperatures. However, no testing of emissions from these processes has been performed in the United States, and only minimal emission rate information has been reported for these processes in other countries.

Burning of Candles. Schwind et al. (1995) analyzed the wicks and waxes of uncolored candles, as well as the fumes of burning candles, for CDD/CDF, total chlorophenol, and total chlorobenzene content. The results presented in Table 5-7 show that beeswax contained the highest levels of CDD/CDF and total chlorophenols. In contrast, the concentration of total chlorobenzenes in stearin wax was higher by a factor of 2 to 3 times than that in paraffin or beeswax. The concentrations of the three analyte groups were significantly lower in the wicks than in the waxes. Emissions of CDD/CDF from all three types of candles were very low during burning. In fact, comparison of the emission factor to the original CDD/CDF concentration in the wax indicates a net destruction of the CDD/CDF originally present in the wax.

Information is not readily available on the volume of candles consumed annually in the United States. However, in 1992, the value of wholesale shipments of candles in the United States was nearly $360 million (U.S. DOC, 1996). Assuming that the average wholesale cost per kg of candle is $1, then the volume of candles shipped was 360 million kg. If it is further assumed that 75 percent of the candle volume is actually burned and that the CDD/CDF emissions rate is 0.015 ng/kg, then a rough preliminary estimate of the potential annual emission from combustion of candles is 4 mg I-TEQ_{DF}/yr.

Glass Manufacturing. Bremmer et al. (1994) and Douben et al. (1995) estimated annual emissions of less than 1 g I-TEQ_{DF}/yr from glass manufacturing facilities in The Netherlands and the United Kingdom, respectively. Glass is manufactured by heating a mixture of sand and, depending on the type of glass, lime, sodium carbonate, dolomite, clay, or feldspar to a temperature of 1,400 to 1,650°C. In addition, various coloring and clarifying agents may be added. Chlorine enters the process as a contaminant (i.e., NaCl)

in sodium carbonate (Bremmer et al. 1994). However, the emission factors used by Bremmer et al. (1994) and Douben et al. (1995) were not reported. Umweltbundesamt (1996) reported relatively low emission factors (approximately 0.002 and 0.007 ng I-TEQ_{DF}/kg) for two glass manufacturing facilities in Germany.

Lime Kilns. Annual emissions from lime kilns in Belgium and the United Kingdom have been reported by Wevers and De Fre (1995) and Douben et al. (1995), respectively. However, the emission factors used to generate those estimates were not provided. Umweltbundesamt (1996) reported low emissions (0.016 to 0.028 ng I-TEQ_{DF}/kg) during tests at two lime kilns in Germany.

Ceramics and Rubber Manufacturers. Douben et al. (1995) estimated annual emissions from ceramic manufacturers and rubber manufacturers in the United Kingdom. Lexen et al. (1993) had previously detected high concentrations of CDD/CDF in emissions from a ceramic manufacturer in Sweden, which occasionally glazed ceramics by volatilization of sodium chloride in a coal-fired oven. Lexen et al. (1993) also detected high pg/L levels of I-TEQ_{DF} in the scrubber water from the vulcanization process at a Swedish rubber manufacturer.

6. COMBUSTION SOURCES OF CDD/CDF: MINIMALLY CONTROLLED AND UNCONTROLLED COMBUSTION SOURCES*

6.1. COMBUSTION OF LANDFILL GAS

The U.S. EPA promulgated emission standards and guidelines in 1996 to control emissions of landfill gas from existing and future landfills under the Clean Air Act (Federal Register, 1996a). Those regulations require the largest landfills in the United States (approximately 312) (i.e., largest on the basis of design capacity) to periodically measure and determine their annual emissions of landfill gas. Landfills that emit annually more than 50 metric tons of nonmethane organic compounds (NMOC) must collect landfill gas and reduce its NMOC content by 98 percent weight through use of a control device. EPA estimates that, when implemented, these controls will reduce NMOC annual emissions from existing landfills by 77,600 metric tons. The cost analysis supporting this rulemaking based control device costs on open flares, because flares are applicable to all the regulated facilities. Assuming that this mass reduction is achieved by use of flares, the corresponding volume of landfill gas that will be burned is approximately 14 billion m^3/yr. The calculation is based on an assumed default NMOC concentration in landfill gas of 1,532 ppmv and a conversion factor of 3.545 mg/m^3 of NMOC per 1 ppmv of NMOC (Federal Register, 1993d). EPA estimated that more than 100 of the approximately 312 landfills had some form of collection or control system, or both, in place in 1991 (Federal Register, 1991b). Thus, a rough approximation of the volume of landfill gas that is currently combusted is 4.7 billion m^3/yr (or 33 percent of the future expected 14 billion m^3/yr reduction). This estimate is similar to the 2.0 to 4.0 billion m^3 of landfill gas that were estimated in EIA (1994) as collected and consumed for energy recovery purposes in 1992. The Energy Information Administration (EIA, 1992) estimated that between 0.9 and 1.8 billion m^3 of landfill gas were collected and burned in 1990 for energy recovery purposes.

Although no data could be located on the levels of CDD/CDFs in untreated landfill gas, several studies have reported detecting CDD/CDFs in the emissions resulting from the

---

* This chapter discusses combustion sources of CDD/CDF that have some (in the case of combustion of landfill gas) or no post-combustion pollution control equipment for conventional pollutant emissions. Note that very few of the CDD/CDF sources listed in this report control specifically for CDD/CDF emissions.

combustion of landfill gas. Only one study of CDD/CDF emissions from a landfill flare has been reported for a U.S. landfill (CARB, 1990d). The I-TEQ_{DF} and TEQ_{DF}-WHO_{98} emission factor calculated from the results of this study is approximately 2.4 ng TEQ/m^3 of landfill gas combusted. The congener-specific results of this study are presented in Table 6-1. Figure 6-1 presents the CDD/CDF congener emission profile based on these emission factors. Bremmer et al. (1994) reported a lower emission factor, 0.4 ng I-TEQ_{DF}/m^3, from the incineration of untreated landfill gas in a flare at a facility located in The Netherlands. No congener-specific emission factors were provided in Bremmer et al. (1994). The average TEQ emission factor for the CARB (1990d) and Bremmer et al. (1994) studies is 1.4 ng I-TEQ_{DF}/m^3 of landfill gas combusted. Umweltbundesamt (1996) reported even lower TEQ emission factors for landfill gas burned in engines or boiler mufflers rather than in a flare. The reported results for 30 engines and mufflers tested in Germany ranged from 0.001 to 0.28 ng I-TEQ_{DF}/m^3 with most values below 0.1 ng I-TEQ_{DF}/m^3. However, Bremmer et al. (1994) also reported an emission factor of 0.5 ng I-TEQ_{DF}/m^3 from a landfill gas–fired engine in The Netherlands.

The limited emission factor data that are available were judged inadequate for developing national emission estimates that could be included in the national inventory. However, a preliminary estimate of the potential annual TEQ release from landfills can be obtained using the estimated volume of combusted gas and the available emission factors. Combining the estimate of current landfill gas volume that is combusted (4.7 billion m^3/yr) with the emission factor of 1.4 ng I-TEQ_{DF}/m^3 of flare-combusted gas yields an annual emission estimate of 6.6 g I-TEQ_{DF}. This estimate should be regarded as a preliminary indication of possible emissions from this source; further testing is needed to confirm the true magnitude of those emissions.

6.2. ACCIDENTAL FIRES

Accidental fires in buildings and vehicles are uncontrolled combustion processes that, because of poor combustion conditions, typically result in relatively high emissions of incomplete combustion products (Bremmer et al., 1994). The incomplete combustion products can include CDDs and CDFs. Polyvinyl chloride (PVC) building materials and furnishings, chloroparaffin-containing textiles and paints, and other chlorinated organic compound–containing materials appear to be the primary sources of the chlorine (Rotard,

1993). Although the results of several studies demonstrate the presence of CDD/CDF concentrations in soot deposits and residual ash from such fires, few direct measurements of CDD/CDFs in the fumes or smoke of fires have been reported. The results of some of those studies are described below, followed by an evaluation of the available data.

6.2.1. Soot and Ash Studies

Christmann et al. (1989b) analyzed the soot formed during combustion and pyrolysis of pure PVC and PVC cable sheathings in simple laboratory experiments designed to mimic the conditions of fires. For the combustion experiments, 2 grams of a PVC sample were incinerated with a laboratory gas burner. The combustion products were collected on the inner walls of a cooled gas funnel placed above the sample. For the pyrolysis experiments, about 50 mg of the sample were placed in a quartz tube and heated to about 950°C for 10 minutes in either an air atmosphere or a nitrogen atmosphere. The combustion experiments yielded CDD/CDF concentrations in soot of 110 μg I-TEQ$_{DF}$/kg for a low-molecular-weight PVC, 450 μg I-TEQ$_{DF}$/kg for a high molecular weight PVC, and 270 μg I-TEQ$_{DF}$/kg for PVC cable. The pyrolysis experiments in the air atmosphere yielded lower CDD/CDF concentrations in soot: 24.4 μg I-TEQ$_{DF}$/kg for a low-molecular-weight PVC, 18.7 μg I-TEQ$_{DF}$/kg for a high-molecular-weight PVC, and up to 41 μg I-TEQ$_{DF}$/kg for PVC cable. In general, CDFs were predominantly formed over CDDs. The lower chlorinated CDF congeners were dominant in the combustion experiments; however, the HpCDF and OCDF congeners were dominant in the pyrolysis experiments. No CDD/CDFs were detected in pyrolysis experiments under a nitrogen atmosphere. Also, no CDD/CDFs were detected when chlorine-free polyethylene samples were subjected to the same combustion and pyrolysis conditions.

Deutsch and Goldfarb (1988) reported finding CDD/CDF concentrations ranging from 0.04 to 6.6 μg/kg in soot samples collected after a 1986 fire in a State University of New York lecture hall. The fire consumed or melted plastic furnishings, cleaning products containing chlorine, wood, and paper.

Funcke et al. (1988; as reported in Bremmer et al., 1994, and Rotard, 1993) analyzed 200 ash and soot samples from sites of accidental fires in which PVC was involved. CDD/CDFs were detected in more than 90 percent of the samples at concentrations in the ng I-TEQ$_{DF}$/kg to μg I-TEQ$_{DF}$/kg range. Fires involving the

combustion of materials containing relatively large amounts of PVC and other chlorinated organic substances resulted in the highest levels of CDD/CDFs, with CDD/CDF concentrations ranging from 0.2 to 110 μg I-TEQ$_{DF}$/kg of residue.

Thiesen et al. (1989) analyzed residues from surfaces of PVC-containing materials that were partially burned during accidental fires at sites in Germany that manufactured or stored plastics. CDD/CDF concentrations in residues were reported as 0.5 μg I-TEQ$_{DF}$/kg for soft PVC, 4.6 μg I-TEQ$_{DF}$/kg for PVC fibers, and 28.3 μg I-TEQ$_{DF}$/kg for a hard PVC. The ratio of total CDFs to total CDDs in the three samples ranged from 4:1 to 7:1. The dominant 2,3,7,8-substituted CDF and CDD congeners in all three samples were 1,2,3,4,6,7,8-HpCDF and 1,2,3,4,6,7,8-HpCDD.

Following an accidental fire at a Swedish carpet factory in 1987, 200 metric tons of PVC and 500 metric tons of PVC-containing carpet burned. Marklund et al. (1989) analyzed snow samples within 1,500 meters downwind from the fire site and found CDD/CDF concentrations in the top 2 cm ranging from 0.32 μg I-TEQ$_{DF}$/m^2 at 10 meters of the site to 0.01 μg I-TEQ$_{DF}$/m^2 at 1,500 meters downwind of the site. Because of an atmospheric inversion and very light wind at the time of the fire, the smoke from the fire remained close to the ground. The soot deposited onto the snow was thus assumed to be representative of the soot generated and released from the fire. Wipe samples of soot from interior posts of the plant (5 and 20 meters from the fire) contained EADON TEQ concentrations of 0.18 and 0.05 μg/m^2, respectively. On the basis of these deposition measurements, Marklund et al. (1989) estimated the total CDD/CDF emission from the fire to be less than 3 mg I-TEQ$_{DF}$.

Carroll (1996) estimated a soot-associated CDD/CDF emission factor (i.e., not including volatile emissions) of 28 to 138 ng I-TEQ$_{DF}$/kg of PVC burned for the Swedish carpet factory fire using the following assumptions: (1) the PVC carpet backing was one-half the weight of the carpet, (2) the carpet backing contained 30 percent by weight PVC resin, and (3) 20 to 100 percent of the PVC and PVC carpet backing present in the warehouse actually burned. Carroll (1996) also estimated a similar soot-associated emission factor (48 to 240 ng I-TEQ$_{DF}$/kg of PVC burned) for a fire at a plastics recycling facility in Lengerich, Germany. Carroll (1996) used the results of wipe samples collected at downwind distances of up to 6,300 meters from the fire to estimate the emission factor.

Fiedler et al. (1993) presented a case study of CDD/CDF contamination and associated remedial actions taken at a kindergarten in Germany following a fire, that destroyed parts of the roof, windows, and furnishings. Soot collected from the building contained CDD/CDFs at a concentration of 45 μg I-TEQ$_{DF}$/kg (or 15 μg I-TEQ$_{DF}$/m^2). Fiedler et al. (1993) attributed the CDD/CDFs detected to the combustion of plastic and wooden toys, floors, and furnishings; however, no information was provided on the quantities of those materials.

Fiedler and Lindert (1998) presented results of soot sampling following a serious fire at Düsseldorf Airport in Germany. Polystyrene sheets and PVC-coated cables were involved in the fire, together with PCB-containing condensers (bulbs). Surface wipe samples contained up to 0.33 μg I-TEQ$_{DF}$/m^2. Concentrations in soot ranged from 7 to 130 μg I-TEQ$_{DF}$/kg. Concentrations of BDD/BDFs were detected in soot at concentrations as high as 0.9 mg/kg soot.

Wichmann et al. (1993, 1995) measured the CDD/CDF content of ash and debris and deposited surface residues that resulted from experimental test burns of two cars (a 1974 Ford Taurus and a 1988 Renault Espace), one subway car, and one railway coach in a tunnel in Germany. On the basis of measurements obtained from sampled ash and debris and from soot collectors placed at regular intervals up to 420 meters downwind of the burn site, the total amounts of CDD/CDF in the ash/debris and tunnel surface residues from each vehicle burn experiment were estimated as follows: 1974 model car—0.044 mg I-TEQ$_{DF}$; 1988 model car—0.052 mg I-TEQ$_{DF}$; subway car—2.6 mg I-TEQ$_{DF}$; and railway coach—10.3 mg I-TEQ$_{DF}$. For each vehicle burn experiment, the mass of TEQ in tunnel surface residue exceeded the mass in ash and debris; 73 to 89 percent were accounted for by the tunnel surface residues and 11 to 27 percent by ash and debris. The average CDD/CDF content of the ash and debris from each experimental burn was as follows: new car—0.14 μg I-TEQ$_{DF}$/kg; old car—0.30 μg I-TEQ$_{DF}$/kg; subway car—3.1 μg I-TEQ$_{DF}$/kg; and railway coach—5.1 μg I-TEQ$_{DF}$/kg.

6.2.2. Fume and Smoke Studies

Merk et al. (1995) collected fume and smoke generated during the burning of 400 kg of wood and 40 kg of PVC in a building (4,500 m^3 volume) over a 45-minute period. The sampling device consisted of dual glass fiber filters to collect particles greater than

0.5 μm, followed by a polyurethane foam filter to collect vapor phase CDD/CDFs. The particulate phase and gas phase showed the same congener pattern, decreasing concentration with increasing degree of chlorination, thus indicating no preferential sorption of higher chlorinated congeners to smoke particulates. However, the CDD/CDF found in the gas phase (about 5 ng I-TEQ_{DF}/m^3) accounted for more than 90 percent of the detected CDD/CDFs. Merk et al. (1995) also reported that the soot deposited from this fire onto a 1 m^2 aluminum sheet resulted in surface contamination of 0.050 μg I-TEQ_{DF}/m^2. Although it was stated in Merk et al. (1995) that the building was 'closed,' subsequent communication with one of the coauthors (Schramm, 1998) clarified that a 'gas cleaning' system was in operation during the testing. Because a ventilation system was in operation during the testing, there was likely some loss of vapor phase CDD/CDFs from the hall. Therefore, the deposits (from particulate deposition and vapor phase condensation) on the test aluminum plate may not reflect total CDD/CDF formation during the fire.

Dyke and Coleman (1995) reported a fourfold increase in CDD/CDF TEQ concentrations in the ambient air during "bonfire" night in Oxford, England. Bonfire night (November 5) is an annual event in England during which it is customary to set off fireworks and have bonfires to commemorate a failed plot to overthrow the king in 1605. Air concentrations before and after bonfire night ranged from 0.15 to 0.17 pg I-TEQ_{DF}/m^3. The air concentration during the bonfire night was 0.65 pg I-TEQ_{DF}/m^3. The dominant congeners in all samples were the hepta- and octa-CDDs. The study was not designed to collect data that would enable calculation of an emission rate nor to differentiate the relative importance of the various materials combusted. However, the results do indicate that open burning of materials likely to be combusted in accidental fires (with the exception of fireworks) results in the release of CDDs and CDFs.

6.2.3. Data Evaluation

Structural Fires — The limited data available on structural fires were judged inadequate for developing national emission estimates that could be included in the national inventory. This conclusion was also reached in national emission inventories developed for The Netherlands (Bremmer et al., 1994) and the United Kingdom (UK Department of the Environment, 1995). Most cited studies involved situations (i.e., field

and laboratory) where relatively high loadings of PVC or plastics were combusted. The effects of different mixes of combusted materials, oxygen supplies, building configurations, durations of burn, and so forth, likely to be found in accidental fires cannot be accounted for by the factors that can be derived from these studies. Also, most of the studies addressed only soot or ash residues and did not address potential volatile emissions of CDD/CDFs which, according to Merk et al. (1995), may represent 90 percent of the CDD/CDFs generated during burning of PVC.

Two recent reports (Carroll, 1996; Thomas and Spiro, 1995) attempted to quantify CDD/CDF emissions from U.S. structural fires, and Lorenz et al. (1996) estimated emissions from structural fires in the Federal Republic of Germany. The estimates derived in these three studies are presented below, following a brief summary of the number and types of accidental fires reported annually in the United States.

In 1995, approximately 574,000 structural fires were reported in the United States. Of these, 426,000 were reported for residential structures, including 320,000 fires in 1–2 family units, 94,000 fires in apartments, and 12,000 fires in other residential settings. The remaining 148,000 structural fires were broken down as follows: 15,000—public assembly; 9,000—educational; 9,000—institutional; 29,000—stores and offices; 29,000—special structures; 39,000—storage; and 18,000—industry, utility, and defense. The latter two categories may be underreported as some incidents were handled by private fire brigades or fixed suppression systems, which do not report (U.S. DOC, 1997).

Carroll (1996) estimated the total CDD/CDF content of soot and ash generated from the 358,000 fires reported in U.S. DOC (1995a) for 1993 in 1–2 family unit residential structural fires. Carroll (1996) developed detailed estimates of the PVC content of typical homes, including plumbing, wiring, siding and windows, wallpaper, blinds and shades, and upholstery. Using statistical data on fire loss (i.e., dollar value) provided the typical loss per recorded fire (9.5 percent of value) which Carroll assumed also represented the typical percentage of PVC burned. Extrapolating to all 358,000 1–2 family unit fires yielded an annual mass of 2,470 metric tons of PVC burned. Carroll (1996) then developed TEQ emission factors from the results of Thiesen et al. (1989) and Marklund et al. (1989). The estimated CDD/CDF content ranged from 0.47 to 22.8 g I-TEQ_{DF} with 0.07 to 8.6 g I-TEQ_{DF} in soot and 0.4 to 14.2 g I-TEQ_{DF} in ash. Carroll derived

a soot emission factor (i.e., grams of soot produced per gram of PVC combusted) from his assumptions regarding the surface area of the soot collection funnel used by Christmann et al. (1989a) and the soot deposition rate on that funnel. Carroll then applied these I-TEQ_{DF} emission factors to the estimated 2,470 metric tons of PVC burned annually in 1–2 family unit residential fires to obtain estimates of the annual mass of TEQ that would be found in the soot and ash of residential fires (i.e., 0.48 to 22.8 g I-TEQ_{DF}/yr). The average emission per fire is thus 1.3 to 64 μg I-TEQ_{DF}.

Thomas and Spiro (1995) estimated that 20 g of I-TEQ_{DF} may be released annually to air from structural fires. This estimate assumed an emission factor of 4 ng I-TEQ_{DF}/kg of material combusted (i.e., the emission rate for "poorly controlled" wood combustion), an assumed material combustion factor of 6,800 kg/fire, and 688,000 structural fires per year. The average emission per fire is thus 29 μg I-TEQ_{DF}.

Lorenz et al. (1996) estimated annual generation of CDD/CDF TEQs in the Federal Republic of Germany using data on the number of residential and industrial/commercial structural fires coupled with data on CDD/CDF content in soot and ash residues remaining after fires. The potential annual I-TEQ_{DF} generation was estimated to be 78 to 212 grams.

Although, as stated above, the available data were judged to be inadequate to support development of an emission estimate for the national inventory, a preliminary estimate of the potential magnitude of TEQ emissions can be obtained using the estimates of Carroll (1996) and Thomas and Spiro (1995), that annual releases are about 20 g I-TEQ_{DF}.

There is very low confidence in these estimated emissions because of the numerous assumptions employed in their derivation. If the conclusion of Merk et al. (1995) is assumed to be correct, that 90 percent of the CDD/CDFs formed in fires are in the gaseous phase rather than particulate phase (i.e., greater than 0.5 μm diameter), and it is also assumed that the estimates of Carroll (1996) and of Thomas and Spiro (1995) do not totally account for volatile emissions, then the total CDD/CDF emissions estimated by Carroll (1996) and by Thomas and Spiro (1995) may be underestimates. Further testing is needed to confirm the true magnitude of these releases.

Vehicle Fires—The limited data available on vehicle fires were judged inadequate for developing national emission estimates that could be included in the national inventory. However, a preliminary estimate of the range of potential CDD/CDF emissions that may

result from vehicle fires can be calculated using the results reported by Wichmann et al. (1993, 1995) for controlled vehicle fires in a tunnel (0.044 mg I-TEQ_{DF} for an old car to 2.6 mg I-TEQ_{DF} for a subway car). Although Wichmann et al. (1993; 1995) did not measure volatile CDD/CDFs (which were reported by Merk et al. (1995) to account for the majority of CDD/CDFs formed during a fire), the study was conducted in a tunnel, and it is likely that a significant fraction of the volatile CDD/CDFs sorbed to tunnel and collector surfaces and were thus measured as surface residues. In 1995, approximately 406,000 vehicle fires were reported in the United States (U.S. DOC, 1997). If it is assumed that 99 percent of those involved cars and trucks (i.e., the approximate percentage of all U.S. motor vehicles that are in-service cars and trucks; U.S. DOC, 1995a), and that the applicable emission rate is 0.044 mg I-TEQ_{DF} per incident, then the annual TEQ formation is 17.7 g I-TEQ_{DF}. The emission factor of 2.6 mg I-TEQ_{DF}/fire is assumed to be applicable to the remaining 1 percent of vehicle fires, thus yielding an emission of 10.6 g I-TEQ_{DF}/yr. The total TEQ annual emission is roughly estimated to be 28.3 g I-TEQ_{DF}/yr. This estimate should be regarded as a preliminary indication of possible emissions from this source category; further testing is needed to confirm the true magnitude of these emissions.

6.3. LANDFILL FIRES

In the late 1980s, two serious fires occurred in landfills near Stockholm, Sweden. The first involved a fire in a large pile of refuse-derived fuel. Using measurements of chlorobenzenes in the air emissions, it was estimated that 50 to 100 kg of chlorobenzenes were released. CDD/CDF emissions were estimated to be several tens of grams, on the assumption that the ratio of CDD/CDFs to chlorobenzenes in landfill fire emissions is similar to the ratio observed in stack gases of municipal waste incinerators. In connection with the second fire, which occurred at a large conventional landfill, birch leaves were collected from trees close to the fire and at distances up to 2 km downwind of the fire, as well as from nearby areas not affected by smoke from the fire. The discharge of CDD/CDF necessary to cause the CDD/CDF concentrations measured on the leaves was estimated to be several tens of grams (Persson and Bergström, 1991).

In response to these incidents, Persson and Bergström (1991) measured CDD/CDF emissions from experimental fires designed to simulate surface landfill fires and deep landfill fires. The experiments used 9-month-old domestic waste. The tests showed no

significant difference in CDD/CDF content of the fire gas produced by the simulated surface and deep fires. The average CDD/CDF emission rate was reported to be 1 μg Nordic TEQ/kg of waste burned. Persson and Bergström (1991) and Bergström and Björner (1992) estimated annual CDD/CDF Nordic TEQ emissions in Sweden from landfill fires to be 35 grams. The estimate was based on the emission rate of 1 μg Nordic TEQ/kg waste burned, an assumed average density of landfill waste of 700 kg/m^3, an assumed waste burn of 150 m^3 for each surface landfill fire (167 fires in Sweden per year), and an assumed waste burn of 500 m^3 for each deep landfill fire (50 fires in Sweden per year). The estimates of waste burn mass for each type of fire were the average values obtained from a survey of 62 surface fires and 25 deep fires. The estimated number of fires per year was based on the results of a survey of all Swedish municipalities for fires reported during the years 1988 and 1989. In 1991, Sweden had an estimated 400 municipal landfills (Persson and Bergström, 1991).

Ruokojärvi et al. (1995) measured the ambient air concentrations of CDD/CDF in the vicinity of real and experimental landfill fires in Finland. The most abundant toxic congeners were the hepta- and octa-CDDs and the penta-, hepta-, and octa-CDFs. The highest contributions to the measured TEQ were made by 1,2,3,7,8-PeCDD and 2,3,4,7,8-PeCDF. In Finland, annual CDD/CDF emissions from landfill fires are estimated to be 50–70 g Nordic TEQ (Aittola, 1993, as reported by Ruokojärvi et al., 1995).

Although no U.S. monitoring studies are available, an emission factor similar to the Swedish emission factor would be expected in the United States, because the contents of the municipal waste are expected to be similar between the United States and Sweden. However, because no data could be located on characterization of landfill fires in the United States (i.e., number, type, mass of waste involved), the limited data available were judged inadequate for developing national emission estimates that could be included in the national inventory. However, a preliminary estimate of the potential magnitude of TEQ emissions associated with landfill fires in the United States can be obtained by assuming a direct correlation of emissions to population size for the United States and Sweden or by assuming a direct correlation between emissions and the number of landfills in each country. Both countries are Western, industrialized countries. Although the per capita waste generation rate in the United States is nearly 1.5 times that of Sweden, the composition of municipal waste and the fraction of municipal waste disposed of in landfills

in the two countries are nearly identical (U.S. EPA, 1996b). The 1995 population of Sweden is 8,822,000 (U.S. DOC, 1995a). Thus, the per capita landfill fire–associated Nordic TEQ emission factor is 4.0 μg TEQ/person/year (i.e., 35 grams/8,822,000 people). Because congener-specific results were not provided in Persson and Bergström (1991) and Bergström and Björner (1992), it was not possible to derive emission factors in units of I-TEQ_{DF} or TEQ_{DF}-WHO_{98}. Applying this factor to the U.S. population (263,814,000) (U.S. DOC, 1995a) results in an estimated annual emission of 1,050 g of TEQ. This estimate should be regarded as a preliminary indication of possible emissions from this source category; further testing is needed to confirm the true magnitude of these emissions. An annual emission of similar size is obtained if it is assumed that the ratio of annual TEQ emissions to number of landfills in Sweden, 87.5 mg TEQ/landfill (i.e., 35 grams/400 landfills), is applicable to the United States, which has 3,558 landfills (U.S. EPA, 1996b). The resulting annual emission estimate is 311 g TEQ/yr.

6.4. FOREST AND BRUSH FIRES

Because CDD/CDFs have been detected both in the soot from residential wood burning (Bumb et al., 1980; Nestrick and Lamparski, 1982, 1983; Bacher et al., 1992), and in the flue gases from residential wood burning (Schatowitz et al., 1993; Vickelsoe et al., 1993), it is reasonable to presume that wood burned in forest and brush fires may also be a source of CDD/CDFs (Section 4.2 contains details on these studies).

Only one study could be found that reported direct measurements of CDD/CDFs in the emissions from forest fires. This study, by Tashiro et al. (1990), reported detection of total CDD/CDFs in air at levels ranging from about 15 to 400 pg/m^3. The samples were collected from fixed collectors located 10 meters above the ground and from aircraft flying through the smoke. Background samples collected before and after the tests indicated negligible levels in the atmosphere. These results were presented in a preliminary report; however, no firm conclusions were drawn about whether forest fires are a CDD/CDF source. The final report on this study, Clement and Tashiro (1991), reported total CDD/CDF levels in the smoke of about 20 pg/m^3. The authors concluded that CDD/CDFs are emitted during forest fires but recognized that some portion of these emissions could represent resuspension from residues deposited on leaves rather than newly formed CDD/CDFs.

Although not designed to directly assess whether CDD/CDFs are formed during brush fires, Buckland et al. (1994) measured the CDD/CDF levels in soil samples from both burnt and unburnt areas in national parks in New Zealand 6 weeks after large-scale brush fires. Four surface soil cores (2 cm depth) were collected and composited from each of three burnt and three unburnt areas. Survey results indicated that brush fires did not have a major impact on the CDD/CDF levels in soil. The I-TEQ_{DF} contents in soil sample composites of the three unburnt areas were 3.0 ng/kg, 8.7 ng/kg, and 10.0 ng/kg. The I-TEQ_{DF} contents in the soil sample composites of three burnt areas were 2.2 ng/kg, 3.1 ng/kg, and 36.8 ng/kg. Total CDD/CDF contents ranged from 1,050 to 7,700 ng/kg in the unburnt area soil samples and from 1,310 to 27,800 ng/kg in the burnt area soil samples. OCDD accounted for 94 to 97 percent of the total CDD/CDF content in all samples.

Similarly, a survey of controlled straw-field burning in the United Kingdom (Walsh et al., 1994) indicated that the straw burning did not increase CDD/CDF burden in the soil; however, a change in congener distribution was observed. Soils from three fields were sampled immediately before and after burning, along with ash from the fire. The mean I-TEQ_{DF} concentrations in the preburn soil, postburn soil, and ash were 1.79 ng/kg, 1.72 ng/kg, and 1.81 ng/kg, respectively. Concentrations of 2,3,7,8-TCDF were lower in the postburn soils than in the preburn soils. Conversely, the concentrations of OCDD were higher in the postburn soils indicating possible formation of OCDD during the combustion process.

Van Oostdam and Ward (1995) reported finding no detectable levels of 2,3,7,8-substituted CDD/CDFs in three soil samples and four ash samples following a forest fire in British Columbia. The detection limits on a congener-specific basis (unweighted for TEQ) ranged from 1 to 2 ng/kg. Nondetected values were also reported by Van Oostdam and Ward (1995) for ashes at a slash and burn site; the soil contained about 0.05 ng I-TEQ_{DF}/kg, whereas background soil contained about 0.02 ng I-TEQ_{DF}/kg.

The concentrations presented by Clement and Tashiro (1991) cannot accurately be converted to an emission factor, because the corresponding rates of combustion gas production and wood consumption are not known. As a result, three alternative approaches were considered to develop an emission factor.

Soot-Based Approach—This approach assumes that the levels of CDD/CDFs in chimney soot are representative of the CDD/CDFs in emissions. The CDD/CDF emission factor is calculated as the product of the CDD/CDF concentration in soot and the total particulate emission factor. This calculation involves first assuming that the CDD/CDF levels measured in chimney soot (720 ng I-TEQ_{DF}/kg) by Bacher et al. (1992) are representative of the CDD/CDF concentrations of particles emitted during forest fires. Second, the total particulate generation factor must be estimated. Ward et al. (1976) estimated the national average particulate emission factor for wildfires as 150 lb/ton biomass dry weight using primarily data for head fires. Ward et al. (1993) estimated the national average particulate emission factor for prescribed burning as 50 lb/ton biomass dry weight. Combining the total particulate generation rates with the I-TEQ_{DF} level in soot results in emission factor estimates of 54 ng of I-TEQ_{DF} and 18 ng of I-TEQ_{DF}/kg of biomass burned in wildfires and prescribed burns, respectively. These estimated factors are likely to be overestimates, because the levels of CDD/CDF measured in chimney soot by Bacher et al. (1992) may represent the accumulation and enrichment of CDD/CDFs measured in chimney soot over time, leading to much higher assumed levels than what is actually on emitted particles.

Carbon Monoxide (CO) Approach—Carbon monoxide is a general indicator of the efficiency of combustion, and the emission factors of many emission products can be correlated to the CO emission factor. The Schatowitz et al. (1993) data for emissions during natural wood burning in open stoves suggest an emission factor of 10 μg I-TEQ_{DF}/kg of CO. Combining this factor with the CO emission factor during forest fires (roughly 0.1 kg CO/kg of biomass, Ward et al., 1993) yields an emission factor of 1,000 ng I-TEQ_{DF}/kg biomass. This factor is higher than the soot-based factor discussed above, which is itself considered to be an overestimate. In addition, although the formation kinetics of CDD/CDF during combustion are not well understood, CDD/CDF emissions have not been shown to correlate well with CO emissions from other combustion sources. (See Chapter 2.)

Wood Stove Approach—This approach assumes that the emission factor for residential wood burning (using natural wood and open door, i.e., uncontrolled draft)

applies to forest fires. As discussed in Section 4.2.1, this approach suggests an emission factor of about 2 ng I-TEQ_{DF}/kg of wood burned. This value appears more reasonable than the factors suggested by the soot and CO approaches because it is based on direct measurement of CDD/CDFs from combustion of wood rather than indirect techniques. However, forest fire conditions differ significantly from combustion conditions in wood stoves. For example, forest fire combustion does not occur in an enclosed chamber, and the biomass consumed in forest fires is usually green and includes underbrush, leaves, and grass. Given these differences and the uncertainties about the formation kinetics of CDD/CDF during combustion, it is difficult to determine whether CDD/CDF emissions would be higher or lower from forest fires than from wood stoves. Thus, although an emission factor of 2 ng I-TEQ_{DF}/kg appears to be the best estimate that can be made currently, it must be considered highly uncertain.

The limited emission factor data available and the degree of confidence in the three approaches evaluated to derive an emission factor were judged inadequate for developing national emission estimates that could be included in the national inventory. However, a preliminary estimate of the potential annual TEQ release associated with forest and brush fires can be obtained using estimates of the biomass burned annually in wildfire and prescribed burns and the emission factor used for wood stoves (2 ng I-TEQ_{DF}/kg of biomass). According to the Council on Environmental Quality's 25th Annual Report (CEQ, 1997), 5 million acres of forest were lost to wildfires in 1987 and 7 million acres were lost in 1995. Estimates of the acreage consumed annually during prescribed burns are not readily available for the reference years 1995 and 1997. An estimated 5.1 million acres of biomass were burned in 1989 during prescribed burns (Ward et al., 1993). Prescribed burning, also known as managed or controlled burning, is used as a forest, range, and wetland management tool conducted under prescribed weather and fuel conditions. This value of 5.1 million acres is assumed to be an appropriate value to use for reference years 1987 and 1995.

Combining these acreage estimates with biomass consumption rates of 9.43 metric tons/acre in areas consumed by wildfires (Ward et al., 1976) and 7.44 metric tons/acre in areas consumed in prescribed burns (Ward et al., 1993) indicates that 47 million metric tons of biomass were consumed by wildfires in 1987, 66 million metric tons were

consumed by wildfires in 1995, and 38 million metric tons were consumed by prescribed burns in 1987 and 1995.

Combining the emission factor developed using the wood stove approach (2 ng I-TEQ_{DF}/kg biomass) with the amount of biomass consumed annually in wildfires and prescribed fires (total of 85 million metric tons in 1987 and 104 million metric tons in 1995) yields I-TEQ_{DF} annual emission estimates of 170 g in 1987 and 208 g in 1995. These estimates should be regarded as preliminary indications of possible emissions from this source; further testing is needed to confirm the true magnitude of emissions.

6.5 BACKYARD BARREL BURNING

In many rural areas of the United States, disposal of residential solid waste may take place via open backyard burning in barrels or similar homemade devices. Although no national statistics on the prevalence of this practice have been reported, the results of a telephone survey conducted in the early 1990s of residents in five central Illinois counties indicate that about 40 percent of the residents in a typical rural Illinois county burn household waste. The survey also found that, on average, those households that burn waste dispose of approximately 63 percent of their household waste by burning it in barrels (Two Rivers Region Council of Public Officials and Patrick Engineering, 1994).

Similar results were recently obtained in a survey conducted by Zenith Research Group, Inc. for the Western Lake Superior Sanitary District of Minnesota (Zenith, 2000). This survey of 760 residents of selected portions of Northwest Wisconsin and Northeast Minnesota addressed, in part, use of burn barrels or other devices to burn household garbage or other materials. The survey found that 71 percent of the respondents indicated their residence currently had garbage hauling service. Of those respondents lacking a garbage hauling service, 92 percent said they currently used a nearby garbage disposal site. However, among all respondents, 27.5 percent admitted they currently use a burn barrel or other device to burn household garbage or other materials. Of these respondents who admitted burning, 39 percent indicated they burn at least weekly and 30 percent indicated they burned once or twice monthly.

6.5.1. Emission Estimates from Backyard Barrel Burning

The low combustion temperatures and oxygen-starved conditions associated with barrel burning may result in incomplete combustion and increased pollutant emissions. In 1997, EPA's Control Technology Center, in cooperation with the New York State Departments of Health (NYSDOH) and Environmental Conservation (NYSDEC), conducted an initial study to examine, characterize, and quantify emissions from the simulated open burning of household waste materials in barrels (Lemieux, 1997). A representative waste to be burned was prepared based on the typical percentages of various waste materials disposed of by New York State residents (i.e., nonavid recyclers); hazardous wastes (i.e., chemicals, paints, oils, etc.) were not included in the test waste. A variety of compounds, including CDD/CDFs, were measured in the emissions from two simulated open burnings of this "baseline" waste.

Combustion studies were subsequently performed by EPA to provide additional "baseline" waste tests and to provide an initial indication of the impact of limited variation in waste composition and combustion conditions on CDD/CDF emissions from a simulated domestic backyard barrel burn of 6.8 kg of unshredded household waste (Gullet et al., 1999; 2000a; 2000b; Lemieux et al., 2000; Lemieux, 2000).

The results of seven "baseline" waste tests were reported in these EPA studies. These tests exhibited variation in the emissions of CDD/CDFs with a 1-2 order of magnitude spread between the lowest and highest values for individual congeners, congener groups, total CDD/CDFs, and TEQ values. The average TEQ emission factor for the seven wastes was 72.8 ng I-TEQ_{DF}/kg of waste burned (setting not detected values equal to zero) and 73.7 ng I-TEQ_{DF}/kg (setting not detected values equal to one-half the detection limit). The corresponding TEQ_{DF}-WHO_{98} values were 76.8 and 77.7 ng TEQ_{DF}-WHO_{98}/kg. Table 6-2 presents the average congener and congener group results for these tests.

Variation from the baseline waste chlorine content (0.2 percent by weight PVC) included testing at three different PVC levels (0, 1.0, and 7.5 percent by weight PVC). The average emissions from the 0, 1.0, and 7.5 percent PVC were, respectively, 14, 201, and 4,916 ng I-TEQ_{DF}/kg. Two tests using waste impregnated with inorganic chloride (i.e., $CaCl_2$) at a 7.5 percent by weight level (and no PVC) averaged 734 ng I-TEQ_{DF}/kg.

Qualitative comparisons suggest that the tests with higher Cl, via PVC or $CaCl_2$, resulted in substantial increase in TEQ emissions.

Other variations in baseline waste composition included conducting one test with compressed waste, one test with a double load of waste, and one test in which some of the waste paper was wetted to simulate high moisture burns. These tests resulted in a higher mean TEQ emission factor (534 ng I-TEQ_{DF}) than that of the baseline runs.

Several waste combustion variables were studied such as average temperatures at prescribed barrel heights, duration that temperatures were within the favorable temperature range for CDD/CDF formation, and measurement of CO, CO_2, O_2, PM, and HCl. Statistical analyses of the results indicated that an interactive term, the product of the CO emissions and the temperature in the uppermost portion of the barrel, and CO emissions were the best predictors of TEQ variation. However, the wide variability in test results (i.e., from less than 10 to more than 6,000 ng I-TEQ_{DF}/kg) also indicates that a high degree of CDD/CDF emission variation can be expected due to factors, such as waste orientation, that are not wholly related to waste composition or burning practice.

The limited emission factor and activity level data available for developing national emission estimates that could be included in the national inventory were assigned low confidence ratings. The number of households nationwide burning waste in barrels and the total amount and variability of burned waste can only be roughly estimated, and the representativeness of the trash and burning conditions used in the baseline experiments to conditions nationwide is uncertain. Combining the emission factors of 72.8 ng I-TEQ_{DF}/kg of waste burned and 76.8 ng TEQ_{DF}-WHO_{98}/kg with the following information and assumptions allows estimates to be made of the potential magnitude of national CDD/CDF TEQ emissions from backyard household trash burning.

- Of the rural population in the United States, 40 percent are assumed to burn their household waste in a barrel (Two Rivers Region Council of Public Officials and Patrick Engineering, 1994).

- On average, each U.S. citizen generates 3.72 pounds of solid waste (excluding yard waste) per day (or 616 kg/person-yr) (U.S. EPA, 1996b).

- On average, in households that dispose of household waste by burning, approximately 63 percent of waste generated is burned (i.e., 63 percent of 616 kg/person-yr = 388 kg/person-year) (Two Rivers Region Council of Public Officials and Patrick Engineering, 1994).

- In 1994 (used for 1995 reference year), 52.7 million people lived in nonmetropolitan areas. In 1990 (used for 1987 reference year), 50.7 million people lived in nonmetropolitan areas (U.S. DOC, 1997).

Annual nationwide TEQ emissions were calculated using Equation 6-1.

$$E_{TEQ} = EF_{TEQ} \times P \times F \times W \qquad \text{(Eqn. 6-1)}$$

where:

E_{TEQ}	=	Annual TEQ_{DF} emissions (g/yr)
EF_{TEQ}	=	TEQ_{DF} emission factor (g TEQ_{DF}/kg of waste)
P	=	Nonmetropolitan population of U.S. in reference year
F	=	Fraction of nonmetropolitan population assumedto burn household waste (0.4)
W	=	Mass of household waste burned per year on a per capita basis (388 kg/person-year)

Therefore, estimated nationwide emissions in 1995 and 1987 were 595 g I-TEQ_{DF} (628 g TEQ_{DF}-WHO_{98}) and 573 g I-TEQ_{DF} (604 g TEQ_{DF}-WHO_{98}), respectively.

6.5.2. Barrel Burning Ash Composition

Ash samples were also collected from the open barrel burning (Lemieux, 1997) and analyzed for PCDD/PCDFs and PCBs. Ash samples from the experiments were combined resulting in two composite samples, one for "avid" recyclers and one for non-recyclers. The results for PCBs depict only the data for specific PCB congeners. Remaining PCB data reported in Lemieux (1997) could not be related to a particular congener. The results are depicted in Tables 6-3 and 6-4.

6.6. UNCONTROLLED COMBUSTION OF POLYCHLORINATED BIPHENYLS (PCBs)

The accidental combustion of PCB-containing electrical equipment or intentional combustion of PCBs in incinerators and boilers not approved for PCB burning (40 CFR 761) may produce CDDs and CDFs. At elevated temperatures, such as in transformer fires, PCBs can undergo reactions to form CDF and other by-products. More than 30 accidental fires and explosions involving PCB transformers and capacitors in the United States and Scandinavia, which involved the combustion of PCBs and the generation of CDDs and CDFs, have been documented (Hutzinger and Fiedler, 1991b; O'Keefe and Smith, 1989; Williams et al., 1985). For example, analyses of soot samples from a

Binghamton, New York, office building fire detected 20 μg/g of total CDDs (0.6 to 2.8 μg/g of 2,3,7,8-TCDD) and 765 to 2,160 μg/g of total CDFs with 12 to 270 μg/g of 2,3,7,8-TCDF. At that site, the fire involved the combustion of a mixture containing PCBs (65 percent) and chlorobenzene (35 percent). Laboratory analyses of soot samples from a PCB transformer fire, which occurred in Reims, France, indicated total CDD and CDF levels in the range of 4 to 58,000 ng/g and 45 to 81,000 ng/g, respectively.

Using a bench-scale thermal destruction system, Erickson et al. (1984) determined the optimum conditions for CDF formation to be 675°C, an excess oxygen concentration of 8 percent, and a residence time of 0.8 seconds or longer. Combusting mineral oil and silicone oil containing 5, 50, and 500 ppm of Aroclor 1254 at these conditions for 0.8 seconds yielded PCB to CDF conversion efficiencies as high as 4 percent. Up to 3 percent conversion efficiency was observed when an askarel (70 percent Aroclor 1260) was combusted under the same conditions.

The use of PCBs in new transformers in the United States is banned, and their use in existing transformers and capacitors is being phased out under regulations promulgated under the Toxic Substances Control Act (TSCA).

Because of the accidental nature of these incidents, the variation in duration and intensity of elevated temperatures, the variation in CDD/CDF content of residues, and uncertainty regarding the amount of PCBs still in service in electrical equipment, EPA judged the available data inadequate for developing national emission estimates that could be included in the national inventory. However, Thomas and Spiro (1995) conservatively estimated that about 15 g of TEQ may be generated annually from fires in commercial and residential buildings each year. This estimate is based on the following assumptions: (1) the I-TEQ_{DF} emission rate is 20 μg/kg of PCB burned; (2) 74,000 metric tons of PCB are still in use in various electrical equipment; and (3) 1 percent of the in-use PCBs is burned during the course of structural fires annually.

6.7. VOLCANOES

To date, no studies demonstrating formation of CDD/CDFs by volcanoes have been published. Given the available information from the studies discussed below, volcanoes do not appear to be sources of CDD/CDF release to the environment.

Gribble (1994) summarized some of the existing information on the formation of chlorinated compounds by natural sources, including volcanoes. Gribble (1994) reported that several studies had demonstrated the presence of chlorofluorocarbons and simple halogenated aliphatic compounds (one and two carbon chain length) in volcanic gases. In addition, several chlorinated monoaromatic compounds as well as three PeCB congeners were reported as having been detected in the ash from the 1980 eruption of Mount St. Helens. Gribble hypothesized that the formation of these PCB compounds was the result of rapid, incomplete high-temperature combustion of chloride-containing plant material in the eruption zone. However, he presented no information indicating formation of CDD/CDFs by volcanoes.

Lamparski et al. (1990) analyzed groundfall ash samples collected at various distances and locations from Mount St. Helens following the eruption in 1980. The findings of this study indicate that volcanic particulate emissions were free of detectable PCBs and nearly free of detectable CDDs (0.8 ng/kg HpCDD detected) upon exiting the volcano and remained so throughout their period of deposition in the blast zone. However, upon transport through the atmosphere, measurable and increasing levels of CDDs and PCBs were detected in deposited ash as the ash passed from rural to urban environments. The authors hypothesized that CDDs and PCBs in the atmosphere became associated with the volcanic ash particulates through gas-phase sorption or particulate agglomeration.

Takizawa et al. (1994) sampled the dust fall from the active volcano, Fugendake, as well as the volcanic ash from the active volcano, Sakurajima, for CDD and CDF congener group concentrations. The study was not designed to determine whether the CDD/CDFs observed were formed by the volcanoes or were scavenged from the atmosphere by the falling dust and ash. The dust fall was collected for 1-month periods during July and October 1992; two samples of the volcanic ash were collected in 1992. The results of the sample analyses for 2,3,7,8-substituted CDDs and CDFs, presented in Table 6-5, show that no 2,3,7,8-substituted congeners with less than 7 chlorines were detected; however, Takizawa et al. (1994) reported that non-2,3,7,8-substituted congeners in the lower chlorinated congener groups were detected.

Figure 6-1. Congener Profile for Landfill Flare Air Emissions

7. METAL SMELTING AND REFINING SOURCES OF CDD/CDF

7.1. PRIMARY NONFERROUS METAL SMELTING/REFINING

Little information has been published on the potential for the formation and environmental release of CDD/CDFs from primary nonferrous metal manufacturing facilities. Norwegian investigators (Oehme et al., 1989) have reported the presence of CDD/CDFs in the wastewater of a magnesium refining facility and in the receiving water sediments downstream of a nickel refining facility in Norway. Insufficient information is available from this study for evaluating CDD/CDF emissions, if any, from the smelting/refining of magnesium and nickel in the United States. The potential for formation and release of CDD/CDFs by primary copper smelters in the United States has been reported by Environmental Risk Sciences (1995) to be negligible. Lexen et al. (1993) reported finding few or no CDD/CDFs in solid wastes from a primary aluminum smelter. Bramley (1998) indicated that the smelting/refining of titanium may be a source of CDD/CDFs. The findings of these studies are discussed in the following subsections.

7.1.1. Primary Copper Smelting and Refining

Environmental Risk Sciences (1995) prepared an analysis for the National Mining Association on the potential for CDD/CDF emissions from the primary copper smelting industry. The analysis included reviewing the process chemistry and technology of primary copper smelting, identifying operating conditions, and comparing process stream compositions from seven of the eight U.S. primary copper smelters that are members of the National Mining Association. The analysis also included stack testing for CDD/CDFs at two facilities. The stack testing (Secor International Inc., 1995a and 1995b) involved the principal off-gas streams for copper smelters: main stack, plant tail gas stack, and the vent fume exhaust. The two facilities that were tested (Phelps Dodge Mining Co. in Playas, New Mexico, and Cyprus Miami Mining Co. in Claypool, Arizona) were selected as representative of the other facilities in the industry because of their similarity to the other facilities in terms of process chemistry, process stream composition, and process stream temperatures.

The results of the assessment of the process chemistry and technology and the operating conditions and process stream compositions indicate that although there is some

potential for CDD/CDF formation in this industry, several factors lessen the probability of CDD/CDF formation. These factors include (a) most of the energy used to melt copper is derived from oxidation of copper sulfide ore minerals (i.e., $CuFeS_2$) rather than carbon (i.e., fossil fuels); (b) low concentrations of organic carbon and chloride are present in raw materials and reagents; (c) high concentrations of sulfur dioxide are present in process gases (6 to 40 percent SO_2 by volume); (d) high temperatures are maintained in the furnaces and converters (1,100 to 1,500°C); and (e) copper (II) chloride is apparently absent in process emissions.

The results of this assessment were supported by the stack test data from the two tested facilities. CDD/CDFs were not detected in the air emissions from either facility. In 1995, eight primary smelters were in operation in the United States, one of which closed at the end of the year (Edelstein, 1995). Total refinery production was 1.60 million metric tons in 1995, including 0.36 million metric tons from scrap material (Edelstein, 1995) and 1.13 million metric tons in 1987 (USGS, 1997c). Conservatively assuming that all nondetected values were present at one-half the detection limits, Environmental Risk Sciences (1995) calculated the annual TEQ emission to air to be less than 0.5 g I-TEQ_{DF} in 1995 for the seven facilities (out of a total of eight) belonging to the National Mining Association. Assuming that feed and processing materials were similar in 1987, 1987 releases can be estimated at less than 0.5 g I-TEQ_{DF} as well. The activity level estimates are assigned a high confidence rating and the emission factor estimate a medium rating.

7.1.2. Primary Magnesium Smelting and Refining

Oehme et al. (1989) reported that the production of magnesium can lead to the formation of CDDs and CDFs. Oehme et al. (1989) estimated that 500 g of I-TEQ_{DF} were released in wastewater to the environment and 6 g I-TEQ_{DF} were released to air annually from a magnesium production facility studied in Norway; CDFs predominated with a CDF to CDD concentration ratio of 10:1. At the time of sampling, the magnesium production process involved formation of MgO (magnesium oxide) from calcinated dolomite followed by a step in which $MgCl_2$ was produced by heating MgO/coke pellets in a shaft furnace in a pure chlorine atmosphere to about 700 to 800°C. The $MgCl_2$ was then electrolyzed to form metallic magnesium and Cl_2. The Cl_2 excess from the $MgCl_2$ process and the Cl_2 formed during electrolysis were collected by water scrubbers and directly discharged to

the environment. The discharged wastewater contained 200–500 ppm of suspended particulate matter. All but trace quantities of the hexa- through octa- congeners were associated with the particulates; up to 10 percent of the tetra- and penta- congeners were present in the water phase.

A recent study by the firm operating the facility (Musdalslien et al., 1998) indicates that installation of a water treatment system has reduced annual emissions to water to less than 1 g Nordic TEQ and emissions to air have been reduced to less than 2 g Nordic TEQ. This study also presented results demonstrating that the carbon reducing agent used in the $MgCl_2$ production step and the operating conditions of the shaft furnace greatly affect the formation of CDD/CDFs. Gases from the furnace were measured nine times over sampling periods of 6 to 8 hours. The calculated emission factor to air (i.e., before any APCD controls) ranged from 468 to 3,860 ng Nordic TEQ per kg of $MgCl_2$ produced. The APCD controls consist of three water scrubbers, a wet ESP, and an incinerator.

U.S. production of primary magnesium was 142,000 metric tons in 1995. This production was about 98 percent of the rated capacity of the three U.S. magnesium production facilities. The United States has been the world's largest producer of metallic magnesium for the past five decades (Kramer, 1996). Similar to the Norwegian plant, an electrolytic process (i.e., electrolysis of magnesium chloride) is used at the plants in Texas (capacity of 65,000 kkg/yr) and Utah (capacity of 40,000 kkg/yr) to recover metallic magnesium from $MgCl_2$. However, these two facilities reportedly use seawater and lake brines as the source of magnesium, and the procedures to obtain and purify $MgCl_2$ do not involve chlorinating furnaces and carbonized pellets (Lockwood et al., 1981). A thermic process is used to recover magnesium from dolomite at the facility in Washington (capacity of 40,000 kkg/yr) (Kramer, 1995). In thermic processes, magnesium oxide (MgO), a component of calcinated dolomite, is reacted with a metal such as silicon (usually alloyed with iron) to produce metallic magnesium.

Monitoring of wastewater discharges for CDD/CDF content from U.S. magnesium production facilities has not been reported. Wastewater discharge of CDD/CDF reported for the Norwegian facility, discussed in the previous paragraphs, are not adequate to support development of wastewater emission factors for U.S. facilities because of

possible differences in the processes used to manufacture $MgCl_2$ and pollution control equipment.

Monitoring of air emissions for CDD/CDF content has recently been reported for one of the three U.S. primary magnesium production facilities, the Magnesium Corporation of America facility near Rowley, Utah. The average emission rates (for three tests) reported for the melt reactor stack and the cathode stack were 0.31 mg I-TEQ_{DF}/hr and 0.16 mg I-TEQ_{DF}/hr, respectively (Western Environmental Services and Testing, Inc., 2000). The confidence in the degree to which the one tested facility represents the emissions from the other two U.S. facilities is currently very low. Therefore, the emissions data were judged inadequate for developing at this time national emission estimates that could be included in the national inventory. However, a preliminary estimate of potential TEQ annual emissions from U.S. primary magnesium production facilities can be made by assuming that the average total emission factor for the Utah facility (i.e., 0.47 mg I-TEQ_{DF}/hr) measured in May of 2000 is representative of the other two facilities on a magnesium production basis. Specifically, if it is assumed that this facility operated for 24 hours per day and 365 days in 1995, then the annual release in 1995 would have been 4.1 g I-TEQ_{DF}. If it is further assumed that this facility operated at 98 percent of it's rated capacity of 40,000 kkg/yr, then the production-based emission factor is 105 ng I-TEQ_{DF}/kg of magnesium produced. Applying this emission factor to 98 percent of the industry's production capacity in 1995 (i.e., 142,000 kkg) yields an annual emission estimate of 14.6 g I-TEQ_{DF} in 1995. This estimate should be regarded as a preliminary indication of possible emissions from this source category; further testing is needed to confirm the magnitude of these emissions.

7.1.3. Primary Nickel Smelting and Refining

Oehme et al. (1989) reported that certain primary nickel refining processes generate CDDs and CDFs, primarily CDFs. Although the current low-temperature process used at the Norwegian facility is estimated to result in releases to water of only 1 g I-TEQ_{DF} per year, a high temperature (i.e., 800°C) $NiCl_2$ to NiO conversion process that had been used for 17 years at the facility is believed to have resulted in significant releases in earlier years based on the ppb levels of CDFs detected in aquatic sediments downstream of the facility (Oehme et al., 1989).

The only nickel mining and smelting complex in the United States is located in Oregon. This facility restarted operations in April 1995 and produced 8,290 metric tons of nickel that year. The facility had been on standby since August 1993 and had no production in 1994. The smelter has a capacity of 16,000 metric tons per year (Kuck, 1995).

Monitoring of discharges for CDD/CDF content at this one U.S. facility has not been reported. Emissions of CDD/CDF were reported for a Norwegian facility in the late 1980s, as discussed in Section 7.1.4. The emissions information contained in the Norwegian study, Oehme et al. (1989), is not adequate to support development of emission factors for the U.S. facility.

7.1.4. Primary Aluminum Smelting and Refining

No sampling of air emissions from this industry for the presence of CDD/CDFs has been reported. Lexen et al. (1993) reported that samples of filter powder and sludge from a lagoon at the only primary aluminum production plant in Sweden showed no or little CDD/CDF. A brief summary of the processes involved in primary aluminum smelting is presented in the following paragraphs.

Bauxite ore, a hydrated oxide of aluminum consisting of 30 to 56 percent alumina (Al_2O_3), is refined into alumina by the Bayer Process and the alumina is then shipped to a primary aluminum smelter for electrolytic reduction to aluminum. Electrolytic reduction of alumina occurs in shallow rectangular cells, or "pots," which are steel shells lined with carbon. Carbon electrodes (petroleum coke mixed with a pitch binder) extending into the pot serve as the anodes, and the carbon lining serves as the cathode. Three types of pots are used: prebaked anode cell, horizontal stud Soderberg anode cell, and vertical stud Soderberg anode cell. Most of the aluminum produced in the United States is produced using the prebaked cells. Molten cryolite (Na_3AlF_6) functions as both the electrolyte and the solvent for the aluminum. Aluminum is deposited at the cathode as molten metal (U.S. EPA, 1998a).

Prior to casting, the molten aluminum may be batch treated in reverberatory furnaces (like those used in secondary aluminum smelting) to remove oxides, gaseous impurities, and active metals such as sodium and magnesium. One process consists of

adding a flux of chloride and fluoride salts and then bubbling chlorine gas through the molten mixture (U.S. EPA, 1998a).

U.S. production of primary aluminum was 3.343 million metric tons in 1987 and 3.375 million metric tons in 1995. In 1995, 13 companies operated 22 primary aluminum reduction plants (USGS, 1997d, 1997e).

7.1.5. Primary Titanium Smelting and Refining

No sampling of emissions or products from this industry for CDD/CDF content has been reported. However, Bramley (1998) and the Peer Review Panel (Eastern Research Group, 1998) suggested that carbochlorination processes used in this industry may be a source of CDD/CDFs. A brief summary of the processes used in this industry is presented in the following paragraphs.

Titanium oxide ores and concentrates are chlorinated in fluidized-bed reactors in the presence of coke at 925 to 1,010°C to form titanium tetrachloride ($TiCl_4$). The $TiCl_4$ is separated from other chlorides by double distillation. The $TiCl_4$ is then either oxidized at 985°C to form pigment-grade titanium dioxide or is reduced using sodium or magnesium to form titanium sponge (i.e., metallic titanium) (Knittel, 1983). Titanium ingot is produced by melting titanium sponge or scrap or a combination of both using electron beam, plasma, and vacuum arc methods. Scrap currently supplies about 50 percent of ingot feedstock (Gambogi, 1996).

Titanium sponge is currently produced at two facilities in the United States, one in Albany, Oregon, and the other in Henderson, Nevada. In 1995, the U.S. production volume of titanium sponge was withheld to avoid disclosing company proprietary data; domestic sponge capacity was 29,500 metric tons per year. In 1987, U.S. production of titanium sponge was 17,849 metric tons. The majority of titanium dioxide (i.e., greater than 90 percent) is produced using the process described above. Titanium dioxide is produced at nine facilities in the United States. Production volumes in 1987 and 1995 were 821,000 and 1,180,000 metric tons, respectively (Gambogi, 1996; USGS, 1997f).

7.2. SECONDARY NONFERROUS METAL SMELTING

Secondary smelters primarily engage in the recovery of nonferrous metals and alloys from new and used scrap and dross. The principal metals of this industry both in

terms of volume and value of product shipments are aluminum, copper, lead, zinc, and precious metals (U.S. DOC, 1990a). Scrap metal and metal wastes may contain organic impurities such as plastics, paints, and solvents. Secondary smelting/refining processes for some metals (e.g., aluminum, copper, and magnesium) use chemicals such as NaCl, KCl, and other salts. The combustion of these impurities and chlorine salts in the presence of various types of metal during reclamation processes can result in the formation of CDDs and CDFs, as evidenced by the detection of CDDs and CDFs in the stack emissions of secondary aluminum, copper, and lead smelters (Aittola et al., 1992; U.S. EPA, 1987a, 1997b).

7.2.1. Secondary Aluminum Smelters

Secondary aluminum smelters reclaim aluminum from scrap. This recycling involves two processes—precleaning and smelting. Both processes may produce CDD/CDF emissions.

Precleaning processes involve sorting and cleaning scrap to prepare it for smelting. Cleaning processes that may produce CDD/CDF emissions use heat to separate aluminum from contaminates and other metals; these techniques are "roasting" and "sweating." Roasting uses rotary dryers with a temperature high enough to vaporize organic contaminants, but not high enough to melt aluminum. An example of roasting is the delacquering and processing of used beverage cans. Sweating involves heating aluminum-containing scrap metal to a temperature above the melting point of aluminum, but below the melting temperature of other metals such as iron and brass. The melted aluminum trickles down and accumulates in the bottom of the sweat furnace and is periodically removed (U.S. EPA, 1997b).

After precleaning, the treated aluminum scrap is smelted and refined. This usually takes place in a reverberatory furnace. Once smelted, flux is added to remove impurities. The melt is "demagged" to reduce the magnesium content of the molten aluminum by the addition of chlorine gas. The molten aluminum is then transferred to a holding furnace and alloyed to final specifications (U.S. EPA, 1997b).

CDD/CDF emissions to air have been measured at six U.S. secondary aluminum operations. Four facilities were tested in 1995 and two facilities were tested in 1992. Three of the four 1995 tests were conducted by EPA in conjunction with The Aluminum

Association for the purpose of identifying emission rates from facilities with potentially MACT-grade operations and APCD equipment; the other test performed in 1995 (U.S. EPA, 1995h) was performed by EPA. Two facilities tested by the California Air Resources Board in 1992 were reported in two confidential reports.

The first facility tested in 1995 was a top-charge melt furnace (Advanced Technology Systems, Inc., 1995). During testing, the charge material to the furnace was specially formulated to contain no oil, paint, coatings, rubber, or plastics (other than incidental amounts). The CDD/CDF emissions from such a clean charge, 0.26 ng I-TEQ_{DF}/kg charge material (0.27 ng TEQ_{DF}-WHO_{98}/kg), would be expected to represent the low end of the normal industry range.

The second facility operated a sweat furnace to preclean the scrap and a reverberatory furnace to smelt the precleaned aluminum (U.S. EPA, 1995h). Stack emissions were controlled by an afterburner operated at 1,450° F. The TEQ emission factor for this facility was 3.22 ng I-TEQ_{DF}/kg aluminum produced (3.37 ng TEQ_{DF}-WHO_{98}/kg).

The third facility employed a crusher/roasting dryer as a precleaning step, followed by a reverberatory furnace (Galson Corporation, 1995). The emissions from the two units were vented separately. The exhaust from the crusher/dryer was treated with an afterburner and a baghouse. The exhaust from the furnace passed through a baghouse with lime injection. Both stack exhausts were tested and the combined TEQ emission factor was 12.95 ng I-TEQ_{DF}/kg aluminum produced (13.55 ng TEQ_{DF}-WHO_{98}/kg). Because the activity level of the facility at the time of sampling was treated as confidential business information, the calculated emission factor was based on the reported typical production rates of the two operations, 26,000 lbs/hr for the crusher/dryer and 6,700 lbs/hr for the furnace.

The fourth facility operated a scrap roasting dryer followed by a sidewell reverberatory furnace (Envisage Environmental Inc., 1995). The emissions from the two units were vented separately. Exhaust from the dryer passed through an afterburner and a lime-coated baghouse. The exhaust from the furnace passed through a lime-coated baghouse. Both stack exhausts were tested and the combined TEQ emission factor was 36.03 ng I-TEQ_{DF}/kg of charge material (37.94 ng TEQ_{DF}-WHO_{98}/kg). Problems with the

scrap dryer were discovered after the testing was completed. Also, operating conditions during testing were reported to represent more worst-case than typical operations.

Two facilities tested by CARB in 1992 and reported in two confidential reports (CARB, 1992a, as reported in U.S. EPA, 1997b; CARB, 1992b, as reported in U.S. EPA, 1997b) were reported to have TEQ emission factors of 52.21 and 21.67 ng I-TEQ_{DF}/kg of scrap aluminum consumed (55.68- and 23.44-ng TEQ_{DF}-WHO_{98}/kg). One facility was equipped with a venturi scrubber; the other was assumed in U.S. EPA (1997b) to be uncontrolled.

The congener and congener group emission factors derived from these stack tests are presented in Table 7-1. The average congener and congener group profiles are presented in Figure 7-1. The average of the TEQ emission factors measured at the six tested facilities (including the facility at which a specially formatted clean charge was used) is 21.1 ng I-TEQ_{DF}/kg of scrap feed (22.4 ng TEQ_{DF}-WHO_{98}/kg). [Note: Although the emission factors at two of the facilities tested in 1995 are based on the output rather than input rate, the two rates are assumed, for purposes of this report, to be roughly equivalent.] Although the testing was recently conducted at U.S. facilities, a low confidence rating is assigned to this average emission factor because it is based on the results of testing at only six facilities, several of which may have more effective APCD than the other facilities in the industry.

For comparison purposes, The European Commission uses 22 ng I-TEQ_{DF}/kg scrap aluminum as the "typical" emission factor for the European Dioxin Inventory (Quab and Fermann, 1997). Umweltbundesamt (1996) reported stack testing results for 25 aluminum smelters/foundries in Germany. Sufficient data were provided in Umweltbundesamt (1996) to enable calculation of TEQ emission factors for 11 of the tested facilities. The calculated emission factors ranged from 0.01 to 167 ng I-TEQ_{DF}/kg of scrap feed. Three facilities had emission factors exceeding 100 ng I-TEQ_{DF}/kg, and two facilities had emission factors less than 1 ng I-TEQ_{DF}/kg. The mean emission factor for the 11 facilities was 42 ng I-TEQ_{DF}/kg.

An approximate total of 727,000 metric tons of scrap aluminum were consumed by 67 secondary aluminum smelters in 1987 (U.S. DOC, 1995c). In 1995, consumption of scrap aluminum by the 76 facilities that compose the secondary aluminum smelting industry had nearly doubled to 1.3 million metric tons (USGS, 1997a; The Aluminum

Association, 1997). A high confidence rating is assigned to these production estimates, because they are based on government survey data. Applying the I-TEQ_{DF} emission factor of 21.1 ng TEQ/kg of scrap feed to these consumption values yields estimated annual emissions of 15.3 g I-TEQ_{DF} in 1987 and 27.4 g I-TEQ_{DF} in 1995. Applying the TEQ_{DF}-WHO_{98} emission factor of 22.4 ng TEQ/kg to the consumption values yields estimated annual emissions of 16.3 g TEQ_{DF}-WHO_{98} in 1987 and 29.1 g TEQ_{DF}-WHO_{98} in 1995.

It should be noted that a significant amount of scrap aluminum is also consumed by other segments of the aluminum industry. However, this scrap is generally scrap from metal manufacturing processes, including metal and alloy production (e.g., borings, turnings, and dross), rather than old scrap that results from consumer products (e.g., cans, radiators, auto shredders). Integrated aluminum companies consumed 1.4 million metric tons of scrap aluminum in 1995, and independent mill fabricators consumed 0.68 million metric tons (USGS, 1997a).

7.2.2. Secondary Copper Smelters

Secondary copper smelting is part of the scrap copper, brass, and bronze reprocessing industry. Brass is an alloy of copper and zinc; bronze is an alloy of copper and tin. Facilities in this industry fall into three general classifications: secondary smelting, ingot making, and remelting. Similar process equipment may be used at all three types of facilities, so the distinguishing features are not immediately apparent (U.S. EPA, 1994g).

The feature that distinguishes secondary smelters from ingot makers and remelters is the extent to which pyrometallurgical purification is performed. A typical charge at a secondary smelter may contain from 30 to 98 percent copper. The secondary smelter upgrades the material by reducing the quantity of impurities and alloying materials, thereby increasing the relative concentration of copper. This degree of purification and separation of the alloying constituents does not occur at ingot makers and remelters. Feed material to a secondary copper smelter is a mixture of copper-bearing scrap such as tubing, valves, motors, windings, wire, radiators, turnings, mill scrap, printed circuit boards, telephone switching gear, and ammunition casings. Nonscrap items like blast furnace slags and drosses from ingot makers or remelters may represent a portion of the charge. The secondary smelter operator uses a variety of processes to separate the

alloying constituents. Some purify the scrap in the reductive atmosphere of a blast furnace. The charge may be subsequently purified in the oxidizing atmosphere of a converter. Other secondary smelters perform all purification by oxidation in top-blown rotary converters or in reverberatory furnaces (U.S. EPA, 1994g).

The ingot makers blend and melt scrap copper, brass, and bronze of various compositions to produce a specification brass or bronze ingot. When necessary, the ingot makers add ingots of other metals (e.g., zinc or tin) to adjust the metallurgy of the final product. The feed materials for ingot makers contain relatively high amounts of copper. Examples of feed materials include copper tubing, valves, brass and bronze castings, ammunition shell casings, and automobile radiators. "Fire-refined" anode copper or cathode copper may also be charged. Items such as motors, telephone switchboard scrap, circuit board scrap, and purchased slags are not used by ingot makers. The reductive step (melting in a reducing atmosphere, as in a blast furnace) that some secondary smelters employ is not used by ingot makers. Ingot makers do, however, use some of the other types of furnaces used by secondary smelters, including direct-fired converters, reverberatory furnaces, and electric induction furnaces (U.S. EPA, 1994g).

Remelting facilities do not conduct any substantial purification of the incoming feeds. These facilities typically just melt the charge and cast or extrude a product. The feeds to a remelter are generally alloy material of approximately the desired composition of the product (U.S. EPA, 1994g).

Emissions Data

Stack emissions of CDD/CDFs from a secondary copper smelter were measured by EPA during 1984–1985 as part of the National Dioxin Tier 4 Study (U.S. EPA, 1987a). The facility chosen for testing was estimated to have high potential for CDD/CDF emissions because of the abundance of chlorinated plastics in the feed. This facility ceased operations in 1986. The tested facility was chosen for testing by EPA because the process technology and air pollution control equipment in place were considered typical for the source category. Copper and iron-bearing scrap were fed in batches to a cupola blast furnace, which produced a mixture of slag and black copper. Four to 5 tons of metal-bearing scrap were fed to the furnace per charge, with materials typically being charged 10 to 12 times per hour. Coke fueled the furnace and represented approximately

14 percent by weight of the total feed. During the stack tests, the feed consisted of electronic telephone scrap and other plastic scrap, brass and copper shot, iron-bearing copper scrap, precious metals, copper-bearing residues, refinery by-products, converter furnace slag, anode furnace slag, and metallic floor-cleaning material. The telephone scrap made up 22 percent by weight of the feed and was the only scrap component that contained plastic materials. Oxygen-enriched combustion air for combustion of the coke was blown through tuyeres (nozzles) at the bottom of the furnace. At the top of the blast furnace were four natural gas–fired afterburners to aid in completing combustion of the exhaust gases. Fabric filters controlled particulate emissions, and the flue gas then was discharged into a common stack. The estimated emission factors derived for this site are presented in Table 7-2. The emission factors are based on the total weight of scrap fed to the furnace. The TEQ emission factor, based on the measured congener and congener group emission factors, is 779 ng I-TEQ_{DF}/kg of scrap metal smelted (810 ng $TEQ_{DF}WHO_{98}$/kg). Figure 7-2a presents the congener group profile based on these emission factors.

In 1992, stack testing of the blast furnace emissions of a secondary smelter located in Philadelphia, Pennsylvania (Franklin Smelting and Refining Co.), was conducted by Applied Geotechnical & Environmental Services Corporation (AGES, 1992). Similar to the facility tested by EPA in 1984–1985, this facility processed low-purity copper-bearing scrap, telephone switch gear, and slags, as well as higher copper content materials (U.S. EPA, 1994g). The facility used a blast (cupola-type) furnace coupled with a pair of rotary converters to produce blister copper. The blast furnace used coke as both the fuel and the agent to maintain a reducing atmosphere. The black copper/slag mixture from the blast furnace was charged to the rotary converters for further refining with the aid of oxygen, sand, and oak logs (AGES, 1992; U.S. EPA, 1994g). The APCD equipment installed on the blast furnace included an afterburner, cooling tower, and baghouse. During testing, the afterburner was reported to be operating erratically and was particularly low during one of the two sampling episodes. Stack gas flow was also low during both sampling episodes because one or more baghouse compartments were inoperable (AGES, 1992). The estimated emission factors derived for this site from the AGES results are presented in Table 7-2. The emission factors are based on the total weight of scrap fed to the blast furnace. The TEQ emission factor was 16,618 ng I-

TEQ_{DF}/kg of scrap (16,917 ng TEQ_{DF}-WHO_{98}/kg). Figure 7-2b presents the congener and congener group profiles based on these emission factors.

In 1991, stack testing of the rotary furnace stack emissions of a secondary smelter located in Alton, Illinois (Chemetco, Inc.) was conducted by Sverdrup Corp. (1991). The Chemetco facility used four tap down rotary (i.e., oxidizing) furnaces. Furnace process gas emissions were controlled by a primary quencher and a venturi scrubber. The feed was relatively high-purity copper scrap containing minimal, if any, plastics. The same manufacturing process and APCD equipment were in place in 1987 and 1995 (U.S. EPA, 1994g). Because this facility operated under oxidizing rather than reducing conditions and processed relatively high-purity scrap, the potential for CDD/CDF formation and release was expected to be dramatically different than that of the two tested facilities reported above. The estimated emission factors derived for this site from the results of Sverdrup Corp. (1991) are presented in Table 7-2. The emission factors are based on the total weight of scrap feed to the furnace. The TEQ emission factor was 3.60 ng I-TEQ_{DF}/kg of scrap (3.66 ng TEQ_{DF}-WHO_{98}/kg).

Only limited data on emissions from secondary copper smelters are reported in the European Dioxin Inventory (LUA, 1997). I-TEQ_{DF} emission factors reported for German shaft furnaces/converters and reverberatory furnaces range from 5.6 to 110 ng I-TEQ_{DF}/kg and from 0.005 to 1.56 ng I-TEQ_{DF}/kg. Emission factors reported for two "smelter and casting furnaces" in Sweden in which "relatively clean scrap is used as input" are 0.024 and 0.04 ng I-TEQ_{DF}/kg. A smelter in Austria is reported to have an I-TEQ emission factor of 4 ng I-TEQ_{DF}/kg. The minimum, typical, and maximum default emission factors selected in LUA (1997) are 5, 50, and 400 ng I-TEQ_{DF}/kg, respectively.

Activity Level Information

In 1987, four secondary copper smelters were in operation: Franklin Smelting and Refining Co. (Philadelphia, PA), Chemetco (Alton, IL), Southwire Co. (Carrollton, GA), and a facility located in Gaston, SC, that was owned by American Telephone and Telegraph (AT&T) until 1990 when it was purchased by Southwire Co. In 1987, estimated smelter capacities were 13,600 kkg for the Franklin Smelting and Refining Co. facility, 120,000 kkg for the Chemetco facility, 48,000 kkg for the Southwire Co. facility, and 85,000 kkg for the AT&T facility (Edelstein, 1999). In 1995, only three of these four facilities were in

operation. The Southwire facility in Gaston (previously owned by AT&T) was closed in January 1995. The Franklin facility subsequently ceased operations in August 1997. Estimated smelter capacities in 1995 were 16,000 kkg for the Franklin Smelting and Refining Co. facility, 135,000 kkg for the Chemetco facility, and 92,000 kkg for the Southwire Co. facility (Edelstein, 1999).

Emission Estimates

Although little research has been performed to define the CDD/CDF formation mechanism(s) in secondary copper smelting operations, two general observations have been made (Buekens et al., 1997). The presence of chlorinated plastics in copper scraps used as feed to the smelters is believed to increase the CDD/CDF formation. Second, the reducing or pyrolytic conditions in blast furnaces can lead to high CDD/CDF concentrations in the furnace process gases. As noted in "Emission Data," above, two of the U.S. facilities that have been tested (i.e., U.S. EPA, 1987a; AGES, 1992) each had the following characteristics. Both processed low-purity scrap containing significant quantities of plastics, and both facilities used blast furnaces. The APCD equipment at both facilities consisted of an afterburner, cooling tower (Franklin facility only), and a baghouse (U.S. EPA, 1994g). The other tested U.S. facility (i.e., Sverdrup, 1991) used oxidizing rather than reducing conditions and processed relatively high purity scrap.

For purposes of this report, the TEQ emission factor measured at the Franklin Smelting and Refining Co. facility in 1992 is considered to be representative of the TEQ emission factor in 1987 and 1995. Combining this emission factor (16,618 ng I-TEQ_{DF}/kg scrap feed, or 16,917 ng TEQ_{DF}-WHO_{98}/kg) with the estimated smelter capacities (data are not available on the amount of scrap processed) for this facility in 1987 (13,600 kkg) and 1995 (16,000 kkg) yields I-TEQ_{DF} emission estimates of 226 g (230 g TEQ_{DF}-WHO_{98}) in 1987 and 266 g (271 g TEQ_{DF}-WHO_{98}) in 1995. This facility ceased operations in 1997.

Similarly, for purposes of this report, the TEQ emission factor for the Chemetco, Inc., facility is considered to be representative of the TEQ emission factor in 1987 and 1995. Combining this emission factor (3.60 ng I-TEQ_{DF}/kg scrap feed or 3.66 ng TEQ_{DF}-WHO_{98}/kg) with the estimated smelter capacities (data are not available on the amount of scrap processed) for this facility in 1987 (120,000 kkg) and 1995 (135,000 kkg) yields I-

TEQ_{DF} estimates of 0.43 g (0.44 g TEQ_{DF}-WHO_{98}) in 1987 and 0.49 g (0.49 g TEQ_{DF}-WHO_{98}) in 1995.

The facility in Gaston, South Carolina, was in operation during 1987, but not in 1995. Prior to 1990, when this facility was owned by AT&T, the plant processed a great deal of high-plastics-content scrap (such as whole telephones). This scrap was fed to a pyrolysis unit prior to entering the blast furnace. In addition to a blast furnace, the facility also had an oxidizing reverberatory furnace for processing higher purity scrap. The facility had separate baghouses for the blast furnace, the converters, and the reverberatory furnace (U.S. EPA, 1994g). Because this facility processed low-purity, high-plastics-content scrap in 1987, and presumably processed much of this in the reducing atmosphere of a pyrolysis unit and blast furnace, the average of the TEQ emission factors for the Tier 4 (U.S. EPA, 1987a) and Franklin facilities (8,700 ng I-TEQ_{DF}/kg, or 8,860 ng TEQ_{DF}-WHO_{98}/kg) was used to estimate potential emissions in 1987 of 740 g I-TEQ_{DF} or 753 g TEQ_{DF}-WHO_{98} (assuming an activity level of 85,000 kkg). This activity level is the estimated capacity of the facility; data are not available on the amount of scrap processed.

The Southwire facility in Carrollton, Georgia, had both a blast furnace and a reverberatory furnace. In 1992, approximately 50 percent of incoming scrap was processed in each furnace (U.S. EPA, 1994g). Unlike the two tested facilities and the Gaston facility, the Southwire facility stopped processing plastic-coated scrap in the 1970s. In addition, this facility had a more complex APCD system, which may have reduced the formation and release of CDD/CDFs. The blast furnace process gases passed through an afterburner (1,600°F), U-tube coolers, and an evaporative spray system before entering the baghouse at a temperature of 225 to 375°F. For these reasons, EPA has determined that the existing emissions data for secondary smelters cannot reliably be used to generate a quantitative estimate of potential emissions during 1987 and 1995 for this facility.

A high confidence rating is assigned to the production estimates, because they are based on government survey data. A low confidence rating is assigned to the TEQ emission estimates because they are based on limited measurements made at three smelters, one of which was not in operation in 1987 or 1995.

It should be noted that a significant amount of scrap copper is consumed by other segments of the copper industry. In 1995, brass mills and wire-rod mills consumed 886,000 metric tons of copper-based scrap; foundries and miscellaneous manufacturers consumed 71,500 metric tons (USGS, 1997a). As noted above, however, these facilities generally do not conduct any significant purification of the scrap. Rather, the scrap consumed is already of alloy quality and processes employed typically involve only melting, casting and extruding. Thus, the potential for formation of CDD/CDFs is expected to be much less than the potential during secondary smelting operations.

7.2.3. Secondary Lead Smelters

The secondary lead smelting industry produces elemental lead through the chemical reduction of lead compounds in a high-temperature furnace (1,200 to 1,260° C). Smelting is performed in reverberatory, blast, rotary, or electric furnaces. Blast and reverberatory furnaces are the most common types of smelting furnaces used by the 23 facilities that make up the current secondary lead smelting industry in the United States. Of the 45 furnaces at these 23 facilities, 15 are reverberatory furnaces, 24 are blast furnaces, 5 are rotary furnaces, and 1 is an electric furnace. The one electric furnace and 11 of the 24 blast furnaces are co-located with reverberatory furnaces, and most share a common exhaust and emissions control system (U.S. EPA, 1994h).

Furnace charge materials consist of lead-bearing raw materials, lead-bearing slag and drosses, fluxing agents (blast and rotary furnaces only), and coke. Scrap motor vehicle lead-acid batteries represent about 90 percent of the lead-bearing raw materials at a typical lead smelter. Fluxing agents consist of iron, silica sand, and limestone or soda ash. Coke is used as fuel in blast furnaces and as a reducing agent in reverberatory and rotary furnaces. Organic emissions from co-located blast and reverberatory furnaces are more similar to the emissions of a reverberatory furnace than the emissions of a blast furnace (U.S. EPA, 1994h).

The total annual production capacity of the 23 companies that make up the U.S. lead smelting industry is 1.36 million metric tons. Blast furnaces not co-located with reverberatory furnaces account for 21 percent of capacity (or 0.28 million metric tons). Reverberatory furnaces and blast and electric furnaces co-located with reverberatory furnaces account for 74 percent of capacity, or 1.01 million metric tons. Rotary furnaces

account for the remaining 5 percent of capacity, or 0.07 million metric tons (U.S. EPA, 1994h). Actual production volume statistics by furnace type are not available. However, if it is assumed that the total actual production volume of the industry, 0.97 million metric tons in 1995 (USGS, 1997a) and 0.72 million metric tons in 1987 (U.S. EPA, 1994h), reflect the production capacity breakdown by furnace type, then the estimated actual production volumes of blast furnaces (not co-located), reverberatory and co-located blast/ electric and reverberatory furnaces, and rotary furnaces were 0.20, 0.72, and 0.05million metric tons, respectively, in 1995, and 0.15, 0.53, and 0.04 million metric tons, respectively, in 1987. In 1987, the industry consisted of 24 facilities.

CDD/CDF emission factors can be estimated for lead smelters using the results of emission tests recently performed by EPA at three smelters (a blast furnace, a co-located blast/reverberatory furnace, and a rotary kiln furnace) (U.S. EPA, 1992e, 1995d, 1995e). The air pollution control systems at the three tested facilities consisted of both baghouses and scrubbers. Congener-specific measurements were made at both APCD exit points at each facility. Table 7-3 presents the congener and congener group emission factors from the baghouse and the scrubber for each site. Figure 7-3 presents the corresponding profiles for the baghouse emissions from the tested blast furnace and reverberatory furnace. Although all 23 smelters employ baghouses, only 9 employ scrubber technology. Facilities that employ scrubbers account for 14 percent of the blast furnace (not co-located) production capacity, 52 percent of the reverberatory and co-located furnace production capacity, and 57 percent of the rotary furnace production capacity. TEQ emission factors (ng TEQ/kg lead processed) from the reported data for each of the three furnace configurations are presented below as a range reflecting the presence or absence of a scrubber.

Emission factors when nondetected values are set equal to zero:

- Blast furnace:
  - 0.63 to 8.31 ng I-TEQ_{DF}/kg lead produced
  - 0.64 to 8.81 ng TEQ_{DF}-WHO_{98}/kg lead produced
- Reverberatory/co-located furnace:
  - 0.05 to 0.41 ng I-TEQ_{DF}/kg lead produced
  - 0.05 to 0.42 ng TEQ_{DF}-WHO_{98}/kg lead produced

- Rotary furnace:
  - 0.24 to 0.66 ng I-TEQ_{DF}/kg lead produced
  - 0.24 to 0.66 ng TEQ_{DF}-WHO_{98}/kg lead produced

If it is assumed that these ranges of emission rates are representative of those at nontested facilities with the same basic furnace configuration and presence or absence of scrubbers, then combining these emission rate ranges with the estimated volume of secondary lead production derived above and the percentage of each configuration type that have scrubbers, yields the following estimated air emissions in units of grams TEQ per year:

Configuration	Estimated Annual TEQ Emissions (g TEQ)*			
	Ref. Year 1995		Ref. Year 1987	
	I-TEQ_{DF}	TEQ_{DF}-WHO_{98}	I-TEQ_{DF}	TEQ_{DF}-WHO_{98}
Blast furnaces w/scrubbers	0.018	0.018	0.013	0.013
Blast furnaces w/o scrubbers	1.429	1.515	1.072	1.136
Reverberatory furnaces w/ scrubbers	0.019	0.019	0.014	0.014
Reverberatory furnaces w/o scrubbers	0.142	0.145	0.104	0.106
Rotary furnaces w/ scrubbers	0.019	0.019	0.015	0.015
Rotary furnaces w/o scrubbers	0.005	0.005	0.004	0.004
	1.632	1.721	1.223	1.288

* Calculated using emission factors based on nondetected values set equal to zero.

A medium confidence rating is assigned to the emission factors derived above because stack test data were available for 3 of the 23 smelters in the United States (of which only 16 were in operation as of December 1993), and the stack test data used represent the three major furnace configurations. The activity level estimate has been assigned a medium confidence rating because, although it is based on a U.S. Department of Commerce estimate of total U.S. production, no production data were available on a furnace type or furnace configuration basis.

7.3. PRIMARY FERROUS METAL SMELTING/REFINING

Iron is manufactured from its ores (i.e., magnetic pyrites, magnetite, hematite, and carbonates of iron) in a blast furnace, and the iron obtained from this process is further refined in steel plants to make steel. The primary production of iron and steel involves two operations identified by European researchers as potential emission sources of CDD/CDFs: iron ore sinter production and coke production. Each of these potential sources is discussed in the following subsections.

7.3.1. Sinter Production

At some iron manufacturing facilities, iron ores and waste iron-bearing materials undergo sintering to convert the materials to usable feed for the blast furnace. In the sintering process, iron ore fines and waste materials are mixed with coke fines, and the mixture is placed on a grate, which is then heated to a temperature of 1,000–1,400°C. The heat generated during combustion sinters the small particles. Iron-bearing dusts and slags from processes in the steel plant are the types of iron-bearing waste materials used as a feed mix for the sinter plant (Knepper, 1981; Capes, 1983; U.S. EPA, 1995b).

Several European investigators have reported that iron ore sinter plants are major sources of airborne emissions CDD/CDFs (Rappe, 1992b; Lexen et al., 1993; Lahl, 1993, 1994). Lahl (1993, 1994) reports that the management practice of recycling dusts and scraps from other processes in the steel plant into the sintering plant introduces traces of chlorine and organic compounds that generate the CDD/CDFs found in these plants.

Organic compounds that are potential precursors to CDD/CDF formation come primarily from the oil, which is found in mill scale, as well as some blast furnace sludges that are used as part of the sinter feed mixture. Most U.S. plants limit the amount of oil because it increases emissions of volatile organic compounds (VOCs) and may create a fire hazard. In addition, plants with baghouses must limit the oil content because the oil tends to blind the fabric filters. Typical oil contents of the feed at U.S. sinter plants range from 0.1 to 0.75 percent (Calcagni et al., 1998).

Sinter plants in Sweden were reported to emit up to 3 ng I-TEQ_{DF}/Nm^3 stack gas or 2 to 4 g I-TEQ_{DF}/yr per plant to the air (Rappe, 1992b; Lexen et al., 1993). Bremmer et al. (1994) reported the results of stack testing at three iron ore sintering plants in The Netherlands. One facility equipped with wet scrubbers had an emission factor of 1.8 ng

I-TEQ_{DF}/dscm (at 11 percent O_2). The other two facilities, both equipped with cyclones, had emission factors of 6.3 and 9.6 ng I-TEQ_{DF}/dscm (at 7 percent O_2). Lahl (1993, 1994) reports stack emissions for sintering plants in Germany (after passage through mechanical filters and electrostatic precipitators) ranging from 3 to 10 ng I-TEQ_{DF}/Nm^3. A recent compilation of emission measurements by the German Federal Environmental Agency indicates stack emission concentrations ranging from 1.2 to 60.6 ng I-TEQ_{DF}/m^3 (at 7 percent O_2); the majority of emissions in 1996 were around 3 ng I-TEQ_{DF}/m^3 (Umweltbundesamt, 1996).

EPA conducted tests at two of the nine U.S. sinter plants operating in 1997 in order to quantify emissions of CDD/CDFs (Calcagni et al., 1998). In choosing representative plants for testing, EPA considered a variety of issues, including the types and quantities of feed materials, types of emission controls, and the oil content of the sinter feed. EPA decided to test a plant with a baghouse and a plant with a venturi (or wet) scrubber. Baghouses and wet scrubbers are the principal air pollution control devices employed to control emissions from the sinter plant windbox. Four plants used a baghouse and five plants used a wet scrubber. The types of feed materials and oil content at the two selected plants were determined to be representative of other plants in the industry. Sampling was performed over 3 days (4 hours per day) at each plant.

The average CDD/CDF TEQ concentrations measured in the stack emissions were 0.19 ng I-TEQ_{DF}/Nm^3 and 0.81 ng I-TEQ_{DF}/Nm^3 for the wet scrubber and baghouse, respectively. The corresponding TEQ emission factors are 0.55 ng I-TEQ_{DF}/kg sinter (0.62 ng TEQ_{DF}-WHO_{98}/kg) and 4.14 ng I-TEQ_{DF}/kg sinter (4.61 ng TEQ_{DF}-WHO_{98}/kg), respectively, for wet scrubbers and baghouses. These emission factors are assigned a high rating because they are based on recent EPA testing at two facilities considered by EPA to be representative of both current and 1995 standard industry practices. Congener-specific emission factors for these two facilities are presented in Table 7-4. Figure 7-4 presents the congener profiles for these facilities. Although concentrations were higher from the baghouse than from the scrubber, both concentrations are low relative to what had been reported from testing at German, Dutch, and Swedish sinter plants. These differences may be due to differences between the operation or APCD of U.S. sinter plants and the tested European plants. Most of the U.S. integrated iron and steel plants, including those with sinter plants, have eliminated the purchase and use of

chlorinated organics in their facilities. Their rolling mill oils (lubricants and hydraulic fluids) do not contain chlorinated compounds. In addition, routine analysis of waste materials going to the sinter plant have not detected any chlorinated solvents. Finally, none of the U.S. plants currently use an electrostatic precipitator to control emissions from the sinter windbox (Calcagni et al., 1998).

In 1996 (data were not readily available for 1995), 11 sintering plants were operating in the United States, with a total annual production capacity of about 17.6 million metric tons (Metal Producing, 1996). Over the past two decades, the size of this industry has decreased dramatically. In 1982, 33 facilities operated with a combined total capacity of 48.3 million metric tons (U.S. EPA, 1982b). The nine currently operating U.S. sinter plants have a combined capacity of 15.6 million metric tons (Calcagni et al., 1998). In 1987, sinter consumption by iron and steel plants was 14.5 million metric tons (AISI, 1990); in 1995, consumption was 12.4 million metric tons (Fenton, 1995), or approximately 70 percent of production capacity, assuming that production capacity in 1995 was the same as in 1996. These activity level estimates are assigned a confidence rating of medium.

As shown in Table 7-5, 59 percent of current (i.e., 1998) sinter production capacity is at facilities with wet scrubbers and 41 percent is at facilities with baghouses. If it is assumed that these same relative proportions of APCD to production capacity existed in 1995, and it is assumed that actual production in 1995 was equal to sinter consumption at iron and steel plants (i.e., 12.4 million metric tons), then estimated TEQ emissions from wet scrubber-equipped facilities were 4.0 g I-TEQ_{DF} (4.5 g TEQ_{DF}-WHO_{98}) and emissions from baghouse-equipped facilities were 21.0 g I-TEQ_{DF} (23.4 g TEQ_{DF}-WHO_{98}), for a total of 25.1 g I-TEQ_{DF} (28.0 g TEQ_{DF}-WHO_{98}). These emission estimates are assigned an overall medium confidence rating on the basis of the medium rating for the activity level estimates.

If these same assumptions are applied to the 1987 sinter consumption rate of 14.5 million metric tons, then estimated TEQ emissions from wet scrubber-equipped facilities were 4.7 g I-TEQ_{DF} (5.3 g TEQ_{DF}-WHO_{98}) and emissions from baghouse-equipped facilities were 24.6 g I-TEQ_{DF} (27.4 g TEQ_{DF}-WHO_{98}), for a total of 29.3 g I-TEQ_{DF} (32.7 g TEQ_{DF}-WHO_{98}). These emission estimates are less certain than the estimates for 1995 because of uncertainties concerning actual APCD in place in 1987 and content of waste feed (i.e.,

oil content and presence of chlorinated organics in the oil) at that time. Consequently, a low confidence rating is assigned to the emission factor.

7.3.2. Coke Production

Coke is the principal fuel used in the manufacture of iron and steel. Coke is the solid carbonaceous material produced by the destructive distillation of coal in high-temperature ovens. No testing of CDD/CDF emissions from U.S. coke facilities has been reported. However, at a facility in The Netherlands, Bremmer et al. (1994) measured a CDD/CDF emission rate to air during the water quenching of hot coke of 0.23 ng I-TEQ_{DF}/kg of coal consumed. Minimal CDD/CDF air emissions, 0.002 ng I-TEQ_{DF}/kg of coal, were estimated by Bremmer et al. (1994) for flue gases generated during the charging and emptying of the coke ovens.

In 1995, an estimated 30 million metric tons of coal were consumed by coke plants in the United States (EIA, 1997b). No testing of CDD/CDF emissions from U.S. coke plants has been reported upon which to base an estimate of national emissions. The limited data available were thus judged inadequate for developing national emission estimates that could be included in the national inventory. However, a preliminary estimate of potential TEQ annual emissions from U.S. coke plants can be made by combining the consumption value of 30 million metric tons and the emission factor reported by Bremmer et al. (1994) for a Dutch coke plant (0.23 ng I-TEQ_{DF}/kg of coal consumed). This calculation yields an annual emission of 6.9 g I-TEQ_{DF} in 1995. This estimate should be regarded as a preliminary indication of possible emissions from this source category; further testing is needed to confirm the true magnitude of these emissions.

7.4 SECONDARY FERROUS METAL SMELTING/REFINING

Electric arc furnaces (EAFs) have been reported to be sources of CDD/CDF emissions in Europe; no testing has been reported at U.S. facilities. EAFs are used to produce carbon and steel alloys primarily from scrap material. The production of steel in an EAF is a batch process, and the input material is typically 100 percent scrap. Scrap, alloying agents, and fluxing materials are loaded into the cylindrical, refractory-lined EAF, and then carbon electrodes are lowered into the EAF. The current of the opposite polarity

electrodes generates heat between the electrodes and through the scrap. Processing time of a batch ranges from about 1.5 to 5 hours to produce carbon steel and from 5 to 10 hours to produce alloy steel (U.S. EPA, 1995b).

The melting of scrap ferrous material contaminated with metalworking fluids and plastics that contain chlorine provides the conditions conducive to formation of CDD/CDFs. Tysklind et al. (1989) studied the formation and releases of CDD/CDFs at a pilot 10 ton electric furnace in Sweden. Scrap ferrous metal feedstocks containing varying amounts of chlorinated compounds (i.e., PVC plastics, cutting oils, or $CaCl_2$) were charged into the furnace under different operating conditions (i.e., continuous feed, batch feed into the open furnace, or batch feed through the furnace lid). During continuous charging operations, the highest emissions, 1.5 ng Nordic TEQ/dry Nm^3 (i.e., after a baghouse filter), were observed with a feedstock consisting of scrap metal with PVC plastics (1.3 g of chlorine per kg of feedstock). This emission equates to 7.7 ng Nordic TEQ/kg of feedstock. The highest emissions during batch charging also occurred when the scrap metal with PVC plastic was combusted (0.3 ng Nordic TEQ/dry Nm^3 or 1.7 ng Nordic TEQ/kg of feedstock). Much lower emissions (0.1 ng Nordic TEQ/dry Nm^3 or 0.6 ng Nordic TEQ/kg of feedstock) were observed when scrap metal with cutting oils that contained chlorinated additives (0.4 g of chlorine per kg of feedstock) was melted. Although these cutting oil-related emissions were not significantly different than the emissions observed from the melting of no-chlorine scrap metal, relatively high levels of CDD/CDF (i.e., 110-ng Nordic TEQ/dry Nm^3) were detected in flue gases prior to the baghouse. The congener profiles of raw flue gas samples (i.e., prior to APCD) showed that CDFs, rather than CDDs, were predominant in all three feedstock types. The congener profile from the test burn with PVC-containing feedstock showed a higher chlorinated congener content than was observed with the other feedstocks.

Eduljee and Dyke (1996) used a range of 0.7 to 10 ng I-TEQ_{DF}/kg of scrap feed to estimate national emissions for the United Kingdom. The range was assumed to be representative of no-chlorine and high-chlorine operations. However, Eduljee and Dyke (1996) provided little information on the supporting emission test studies (i.e., tested facility operational materials, feed rates, congener-specific emission rates).

Umweltbundesamt (1996) reported stack testing results for a variety of EAFs in Germany. Sufficient data were provided in Umweltbundesamt (1996) to enable

calculation of TEQ emission factors for six of the tested facilities. Two facilities had emission factors exceeding 1 ng I-TEQ_{DF}/kg of scrap processed, and two facilities had emission factors less than 0.1 ng I-TEQ_{DF}/kg of scrap. The mean emission factor was 1.15 ng I-TEQ_{DF}/kg of scrap. The TEQ concentrations in the stack gases at these facilities (corrected to 7 percent O_2) ranged from less than 0.1 to 1.3 ng I-TEQ_{DF}/m^3.

In 1995, electric arc furnaces accounted for 40.4 percent of U.S. steel production (or 38.4 of the total 95.2 million metric tons of raw steel produced) (Fenton, 1996). No testing of CDD/CDF emissions from U.S. electric arc furnaces has been reported upon which to base an estimate of national emissions, and the limited European data available were thus judged inadequate for developing national emission estimates that could be included in the national inventory. However, a preliminary estimate of potential TEQ annual emissions from U.S. electric arc furnaces can be made by combining the production estimate of 38.4 million metric tons and the average emission factor derived from the data reported in Umweltbundesamt (1996) for six EAFs (i.e., 1.15 ng I-TEQ_{DF}/kg scrap). This calculation yields an annual emission estimate of 44.3 g I-TEQ_{DF} in 1995. This estimate should be regarded as a preliminary indication of possible emissions from this source category; further testing is needed to confirm the true magnitude of these emissions.

7.5. FERROUS FOUNDRIES

Ferrous foundries produce high-strength iron and steel castings used in industrial machinery, pipes, and heavy transportation equipment. Iron and steel castings are solid solutions of iron, carbon, and various alloying materials. Castings are produced by injecting or pouring molten metal into cavities of a mold made of sand, metal, or ceramic material. Metallic raw materials are pig iron, iron and steel scrap, foundry returns, and metal turnings (U.S. EPA, 1995b, 1997b).

The melting process takes place primarily in cupola (or blast) furnaces and to a lesser extent in electric arc furnaces. About 70 percent of all iron castings are produced using cupolas, although steel foundries rely almost exclusively on EAFs or induction furnaces for melting. The cupola is typically a vertical, cylindrical steel shell with either a refractory-lined or water-cooled inner wall. Charges are loaded at the top of the unit; the iron is melted as it flows down the cupola, and is removed at the bottom. (EAFs are

discussed in Section 7.4.3.) Electric induction furnaces are batch-type furnaces in which the charge is melted by a fluctuating electromagnetic charge produced by electrical coils surrounding the unit (U.S. EPA, 1995b, 1997b).

Iron and steel foundries, particularly those using EAFs, are highly dependent on iron and steel scrap. Of the estimated 72 million metric tons of iron and steel scrap consumed by the iron and steel industry in 1995, 25 percent (or 18 million metric tons) were used by ferrous foundries. The other 75 percent were used by primary ferrous metal smelters (principally those using EAFs) (USGS, 1997b). Thus, foundries face the same potential for CDD/CDF emissions as EAFs because of their use of scrap that contains chlorinated solvents, plastics, and cutting oils. (See Section 7.4.3.) The potential for formation and release of CDD/CDFs during the casting process (i.e., pouring of molten metal into molds and cores made of sand and various organic binders and polymers) is not known.

The results of emissions testing have been reported for only one U.S. ferrous foundry (CARB, 1993a, as reported in U.S. EPA, 1997b). The tested facility consisted of a batch-operated, coke-fired cupola furnace charged with pig iron, scrap iron, scrap steel, coke, and limestone. Emission control devices operating during the testing were an oil-fired afterburner and a baghouse. The congener and congener group emission factors derived from the testing are presented in Table 7-6. The calculated TEQ emission factor for this set of tests is 0.37 ng I-TEQ_{DF}/kg of metal charged to the furnace (0.42 ng TEQ_{DF}-WHO_{98}).

Umweltbundesamt (1996) reported stack testing results for a variety of ferrous foundries in Germany. Sufficient data were provided in Umweltbundesamt (1996) to enable calculation of TEQ emission factors for eight of the tested facilities. Three facilities had emission factors exceeding 1 ng I-TEQ_{DF}/kg of metal charge, and four facilities had emission factors less than 0.1 ng I-TEQ_{DF}/kg of metal charge. The emission factors span more than four orders of magnitude. The mean emission factor was 1.26 ng I-TEQ_{DF}/kg of metal feed.

Because of the wide range of emissions for the tested German foundries reported in Umweltbundesamt (1996), the confidence in the degree to which the one tested U.S. facility represents the mean emission factor for the approximate 1,000 U.S. foundries is considered very low. Therefore, the limited data available were judged inadequate for developing national emission estimates that could be included in the national inventory.

However, a preliminary estimate of potential TEQ annual emissions from U.S. ferrous foundries can be made by combining the mean emission factor derived from the data reported in Umweltbundesamt (1996) for eight foundries (1.26 ng I-TEQ_{DF}/kg of metal feed) with an activity level for U.S. foundries. In 1995, U.S. shipments from the approximate 1,000 U.S. ferrous foundries were 13.9 million metric tons, of which about 90 percent were iron castings and 10 percent were steel castings (Fenton, 1996). This calculation yields an annual emission estimate of 17.5 g I-TEQ_{DF} in 1995. This estimate should be regarded as a preliminary indication of possible emissions from this source category; further testing is needed to confirm the true magnitude of these emissions.

7.6. SCRAP ELECTRIC WIRE RECOVERY

The objective of wire recovery is to remove the insulating material and reclaim the metal (e.g., copper, lead, silver, and gold) in the electric wire. The recovery facility then sells the reclaimed metal to a secondary metal smelter. Wire insulation commonly consists of a variety of plastics, asphalt-impregnated fabrics, or burlap. Chlorinated organics are used to preserve the cable casing in ground cables. The combustion of chlorinated organic compounds in the cable insulation, catalyzed by the presence of wire metals such as copper and iron, can lead to the formation of CDDs and CDFs (Van Wijnen et al., 1992).

Although in the past, scrap electric wire was commonly recovered using thermal processing to burn off the insulating material, current recovery operations no longer typically involve thermal treatment according to industry and trade association representatives. Instead, scrap electric wire is mechanically chopped into fine particles. The insulating material is then removed by air blowing and, followed by gravitational settling of the heavier metal (telephone conversations between T. Leighton, Versar, Inc., R. Garino, Institute of Scrap Recycling Industries, March 2, 1993; and J. Sullivan, Triple F. Dynamics, March 8, 1993).

EPA measured dioxin-like compounds emitted to the air from a scrap wire reclamation incinerator during its 1986 National Dioxin Study of combustion sources (U.S. EPA, 1987a). Testing determined that the facility was typical of this industrial source category at that time. Insulated wire and other metal-bearing scrap material were fed to the incinerator on a steel pallet. The incinerator operated in a batch mode, with the

combustion cycles for each batch of scrap feed lasting between 1 and 3 hours. Natural gas was used to incinerate the material. Although most of the wire had a tar-based insulation, PVC-coated wire was also fed to the incinerator. Temperatures during combustion in the primary chamber furnace were about 570°C. The tested facility was equipped with a high-temperature natural gas-fired afterburner (980 to 1,090°C). Emission factors estimated for this facility are presented in Table 7-7. The estimated TEQ emission factor (based only on 2,3,7,8-TCDD, 2,3,7,8-TCDF, OCDD, and OCDF) is 16.9 ng I-TEQ_{DF}/kg scrap feed (15.8 ng TEQ_{DF}-WHO_{98}). Figure 7-5 presents a congener group profile based on these emission factors.

Bremmer et al. (1994) reported emission factors for three facilities in The Netherlands, which have subsequently ceased operations. Emission rates at a facility burning underground cables and cables containing PVC ranged from 3.7 ng I-TEQ_{DF}/kg to 14 ng I-TEQ_{DF}/kg. The emission rate at a second facility ranged from 21 ng I-TEQ_{DF}/kg of scrap (when burning copper core coated with greasy paper) to 2,280 ng I-TEQ_{DF}/kg of scrap (when burning lead cable). The third facility, which burned motors, was reported to have an emission rate of 3,300 ng I-TEQ_{DF}/kg of scrap. On the basis of these measurements, Bremmer et al. (1994) used emission rates of 40 ng I-TEQ_{DF}/kg of scrap and 3,300 ng I-TEQ_{DF}/kg of scrap for estimating national emissions in The Netherlands for facilities burning wires and cables and those burning motors.

Although limited emission testing has been conducted at one U.S. facility, the activity level for this industry sector in reference years 1987 and 1995 is unknown; therefore, an estimate of national emissions cannot be made. It is uncertain how many facilities still combust scrap wire in the United States. Trade association and industry representatives state that U.S. scrap wire recovery facilities now burn only minimal quantities of scrap wire. However, a recent inventory of CDD/CDF sources in the San Francisco Bay area noted that two facilities in the Bay area thermally treat electric motors to recover electrical windings (BAAQMD, 1996).

In addition to releases from regulated recovery facilities, CDD/CDF releases from small-scale burning of wire at unregulated facilities and open air sites have occurred; however, the current magnitude of small-scale, unregulated burning of scrap wire in the United States is not known. For example, Harnly et al. (1995) analyzed soil/ash mixtures from three closed metal recovery facilities and from three closed sites of open burning for

copper recovery near a California desert town. The geometric mean of the total CDD/CDF concentrations at the facility sites and the open burning sites was 86,000 and 48,500 ng/kg, respectively. The geometric mean TEQ concentrations were 2,900 and 1,300 ng I-TEQ_{DF}/kg, respectively. A significantly higher geometric mean concentration (19,000 ng I-TEQ_{DF}/kg) was found in fly ash located at two of the facility sites. The congener-specific and congener group results from this study are presented in Table 7-8. The results show that the four dominant congeners in the soil samples at both the facility and open burning sites were OCDF, 1,2,3,4,6,7,8-HpCDF, 1,2,3,4,7,8-HxCDF, and 2,3,7,8-TCDF. A slightly different profile was observed in the fly ash samples, with 1,2,3,7,8-PeCDF and 1,2,3,4,7,8,9-HpCDF replacing OCDD and 2,3,7,8-TCDF as dominant congeners.

Van Wijnen et al. (1992) reported similar results for soil samples collected from unpermitted incineration sites of former scrap wire and cars in The Netherlands. Total CDD/CDF concentrations in the soil ranged from 60 to 98,000 ng/kg, with 9 of the 15 soil samples having levels above 1,000 ng/kg. Chen et al. (1986) reported finding high levels of CDD/CDFs in residues from open air burning of wire in Taiwan, and Huang et al. (1992) reported elevated levels in soil near wire scrap recovery operations in Japan. Bremmer et al. (1994) estimated an emission rate to air of 500 ng I-TEQ_{DF}/kg of scrap for illegal, unregulated burning of cables in The Netherlands.

7.7. DRUM AND BARREL RECLAMATION FURNACES

Hutzinger and Fiedler (1991b) reported detecting CDD/CDFs in stack gas emissions from drum and barrel reclamation facilities at levels ranging from 5 to 27 ng/m^3. EPA measured dioxin-like compounds in the stack gas emissions of a drum and barrel reclamation furnace as part of the National Dioxin Study (U.S. EPA, 1987a).

Drum and barrel reclamation furnaces operate a burning furnace to thermally clean used 55-gallon steel drums of residues and coatings. The drums processed at these facilities come from a variety of sources in the petroleum and chemical industries. The thermally cleaned drums are then repaired, repainted, relined, and sold for reuse. The drum-burning process subjects used drums to an elevated temperature in a tunnel furnace for a sufficient time so that the paint, interior linings, and previous contents are burned or disintegrated. The furnace is fired by auxiliary fuel. Used drums are loaded onto a conveyor that moves at a fixed speed. As the drums pass through the preheat and

ignition zone of the furnace, additional contents of the drums drain into the furnace ash trough. A drag conveyor moves these sludges and ashes to a collection pit. The drums are air cooled as they exit the furnace. Exhaust gases from the burning furnace are typically drawn through a breeching fan to a high-temperature afterburner.

The afterburner at the facility tested by EPA operated at an average of 827°C during testing and achieved a 95 percent reduction in CDD/CDF emissions (U.S. EPA, 1987a). Emission factors estimated for this facility are presented in Table 7-9. On the basis of the measured congener and congener group emissions, the average TEQ emission factor is estimated to be 16.5 ng I-TEQ_{DF} per drum (17.5 ng TEQ_{DF}-WHO_{98}/drum). The congener group profile is presented in Figure 7-6.

Approximately 2.8 to 6.4 million 55-gallon drums are incinerated annually in the United States (telephone conversation between C. D'Ruiz, Versar, Inc., and P. Rankin, Association of Container Reconditioners, December 21, 1992). This estimate is based on the following assumptions: (1) 23 to 26 incinerators are currently in operation; (2) each incinerator, on average, handles 500 to 1,000 drums per day; and (3) on average, each incinerator operates 5 days per week, with 14 days downtime per year for maintenance activities. The weight of 55-gallon drums varies considerably; however, on average, a drum weighs 38 lbs (or 17 kg); therefore, an estimated 48 to 109 million kg of drums are incinerated annually. Assuming that 4.6 million drums are burned each year (i.e., the midpoint of the range) and applying the emission factors developed above, the estimated annual emission of TEQ is 0.08 g I-TEQ_{DF} (0.08 g TEQ_{DF}-WHO_{98}). No activity level data are available that would enable annual emission estimates to be made specifically for reference years 1987 and 1995.

A low confidence rating is assigned to the activity level estimate because it is based on expert judgment rather than a published reference. A low confidence rating is also assigned to the emission factor, because it was developed from stack tests conducted at just one U.S. drum and barrel furnace and thus may not represent average emissions from current operations in the United States.

7.8. SOLID WASTE FROM PRIMARY/SECONDARY IRON/STEEL MILLS/FOUNDRIES

Literature on the Identification of Relevant Industrial Sources of Dioxins and Furans in Europe (Quab, 1997), Table 17, contains summary data on the typical annual quantities

and ranges of TEQ (Norwegian-TEQ [NTEQ] and I-TEQ) from various solid residuals from the metallurgical industries in Europe. No support information accompanies the tabular data. Specific congeners are not discussed. However, the summary data for annual TEQ generation in grams are as follows:

Grey Iron Foundries: baghouse dust and scrubber sludge	0.817 NTEQ
Steel Mill Coke Oven Door Leakage Dust	0.31 NTEQ
Steel Mill Coke Oven Door Leakage Dust	0.04 I-TEQ
Pig Iron Tapping Slag	0.041 NTEQ
Basic Oxygen Furnace Scrubber Sludge	1.53 NTEQ (range of 0.30 - 7.81)
Electric Furnace Baghouse Dust	3.1 I-TEQ (range of 0.4 - 2.4)
Electric Furnace Slag or Baghouse Dust	19.2 NTEQ

8. CHEMICAL MANUFACTURING AND PROCESSING SOURCES

8.1. BLEACHED CHEMICAL WOOD PULP AND PAPER MILLS

In March 1988, EPA and the U.S. pulp and paper industry jointly released the results from a screening study that provided the first comprehensive data on formation and discharge of CDDs and CDFs from pulp and paper mills (U.S. EPA, 1988d). This early screening study of five bleached kraft mills ("Five Mill Study") confirmed that the pulp bleaching process was primarily responsible for the formation of the CDDs and CDFs. The study results showed that 2,3,7,8-TCDD was present in seven of nine bleached pulps, five of five wastewater treatment sludges, and three of five treated wastewater effluents. The study results also indicated that 2,3,7,8-TCDD and 2,3,7,8-TCDF were the principal CDDs and CDFs formed.

To provide EPA with more complete data on the release of these compounds by the U.S. industry, EPA and the U.S. pulp and paper industry jointly conducted a survey during 1988 of 104 pulp and paper mills in the United States to measure levels of 2,3,7,8-TCDD and 2,3,7,8-TCDF in effluent, sludge, and pulp. This study, commonly called the 104 Mill Study, was managed by the National Council of the Paper Industry for Air and Stream Improvement, Inc. (NCASI), with oversight by EPA, and included all U.S. mills where chemically produced wood pulps were bleached with chlorine or chlorine derivatives. The final study report was released in July 1990 (U.S. EPA, 1990a).

An initial phase of the 104 Mill Study involved the analysis of bleached pulp (10 samples), wastewater sludge (9 samples), and wastewater effluent (9 samples) from eight kraft mills and one sulfite mill for all 2,3,7,8-substituted CDDs and CDFs. These analyses were conducted to test the conclusion drawn in the Five Mill Study that 2,3,7,8-TCDD and 2,3,7,8-TCDF were the principal CDDs and CDFs found in pulp, wastewater sludge, and wastewater effluent on a toxic equivalents basis. Although at the time of this study there were no reference analytical methods for many of the 2,3,7,8-substituted CDDs/CDFs, the data obtained were considered valid by EPA for the purposes intended because of the identification and quantification criteria used, duplicate sample results, and limited matrix spike experiments. Table 8-1 presents a summary of the results obtained in terms of the median concentrations and the range of concentrations observed for each matrix (i.e., pulp, sludge, and effluent). Figures 8-1 through 8-3 present congener profiles

for each matrix (normalized to total CDD/CDF and to total I-TEQ_{DF}) using the median reported concentrations. After examination of the raw, mill-specific data, EPA (1990a) concluded that the congener profiles were fairly consistent across matrices within mills and that 2,3,7,8-TCDD and 2,3,7,8-TCDF account for the majority of TEQ in the samples. Using the median concentrations and treating nondetected values as either zero or one-half the detection limit, EPA concluded that 2,3,7,8-TCDF accounted for 95.8 to 99.0 percent of the total I-TEQ_{DF} in pulp (95.4 to 99.5 percent of TEQ_{DF}-WHO_{98}), 94.1 to 95.8 percent of the I-TEQ_{DF} in sludge (94.1 to 96.5 percent of TEQ_{DF}-WHO_{98}), and 81.1 to 91.7 of the I-TEQ_{DF} in effluent (81.7 to 96.4 percent of TEQ_{DF}-WHO_{98}).

NCASI reported on a similar full-congener analysis study for samples collected from eight mills during the mid-1990s (Gillespie, 1997). The results of these analyses are presented in Table 8-2. The frequencies of detection of 2,3,7,8-TCDD and 2,3,7,8-TCDF were significantly lower than in the 1988 study. Therefore, deriving meaningful summary statistics concerning the relative importance of 2,3,7,8-TCDD and 2,3,7,8-TCDF to the total TEQ is difficult. With all nondetected values assumed to be zero, 2,3,7,8-TCDD and 2,3,7,8-TCDF account for 91 percent of the total effluent I-TEQ_{DF} (97 percent of TEQ_{DF}-WHO_{98}), 46 percent of the total sludge I-TEQ_{DF} (53 percent of TEQ_{DF}-WHO_{98}), and 87 percent of the total pulp I-TEQ_{DF} (87 percent of TEQ_{DF}-WHO_{98}). Because of the high frequency of nondetects, when all nondetected values are one-half the detection limits, 2,3,7,8-TCDD and 2,3,7,8-TCDF account for only 13 percent of the total effluent I-TEQ_{DF}, 13 percent of the total sludge I-TEQ_{DF}, and 28 percent of the total pulp I-TEQ_{DF}.

In 1992, the pulp and paper industry conducted its own NCASI-coordinated survey of 2,3,7,8-TCDD and 2,3,7,8-TCDF emissions (NCASI, 1993). Ninety-four mills participated in the NCASI study, and NCASI assumed that the remaining 10 (of 104) operated at the same levels as measured in the 1988 104 Mill Study. All nondetected values were counted as half the detection limit. If detection limits were not reported, they were assumed to be 10 pg/L for effluent and 1 ng/kg ppt for sludge or bleached pulp. The data used in the report were provided by individual pulp and paper companies that had been requested by NCASI to generate the data using the same protocols used in the 104 Mill Study.

As part of its efforts to develop revised effluent guidelines and standards for the pulp, paper, and paperboard industry, EPA in 1993 published the development document

for the guidelines and standards being proposed for this industry (U.S. EPA, 1993d). The development document presents estimates of the 2,3,7,8-TCDD and 2,3,7,8-TCDF annual discharges in wastewater from the mills in this industry as of January 1, 1993. To estimate these discharges, EPA used the most recent information about each mill from four databases (104 Mill Study, EPA short-term monitoring studies at 13 mills, EPA long-term monitoring studies at 8 mills, and industry self-monitoring data submitted to EPA). The 104 Mill Study data were used for only those mills that did not report making any process changes subsequent to the 104 Mill Study and did not submit any more recent effluent monitoring data.

Gillespie (1994, 1995) reported the results of 1993 and 1994 updates, respectively, to the 1992 NCASI survey. As in the 1992 survey, companies were requested to follow the same protocols for generating data used in the 104 Mill Study. Gillespie (1994, 1995) reported that less than 10 percent of mills had 2,3,7,8-TCDD and 2,3,7,8-TCDF concentrations in effluent above the nominal detection limits of 10 pg/L and 100 pg/L, respectively. EPA obtained similar results in its short- and long-term sampling for 18 mills; 2,3,7,8-TCDD was detected at four mills, and 2,3,7,8-TCDF was detected at nine mills (U.S. EPA, 1993d). Gillespie (1994) reported that wastewater sludges at most mills (i.e., 90 percent) contained less than 31 ng/kg of 2,3,7,8-TCDD and less than 100 ng/kg of 2,3,7,8-TCDF. Gillespie (1995) also reported that 90 percent of the mills reported 2,3,7,8-TCDD and 2,3,7,8-TCDF concentrations in sludge of less than 17 ng/kg and 76 ng/kg, respectively, in 1994. U.S. EPA (1993d) reported similar results but found detectable levels of 2,3,7,8-TCDD and 2,3,7,8-TCDF in sludges from 64 percent and 85 percent of the facilities sampled, respectively. Gillespie (1994) reported that nearly 90 percent of the bleached pulps contained less than 2 ng/kg of 2,3,7,8-TCDD and less than 160 ng/kg of 2,3,7,8-TCDF. Gillespie (1995) reported that 90 percent of the bleached pulps contained 1.5 ng/ng or less of 2,3,7,8-TCDD and 5.9 ng/kg or less of 2,3,7,8-TCDF. The final levels in white paper products would correspond to levels in bleached pulp, so bleached paper products would also be expected to contain less than 2 ng/kg of 2,3,7,8-TCDD.

On April 15, 1998, EPA promulgated effluent limitations guidelines and standards for certain segments of the pulp, paper and paperboard industry (Federal Register, 1998c). The industry segments covered by this rulemaking (i.e., the bleached papergrade kraft and

soda subcategory and the papergrade sulfite subcategory) are those segments responsible for more than 90 percent of the bleached chemical pulp production in the United States. For this rule, EPA updated the estimates of baseline loadings made in 1993 for the proposed rule by using more recent data collected by EPA, NCASI (including the 1994 NCASI survey), and individual facilities (U.S. EPA, 1997f). These revised estimates are presented in the last column in Table 8-3. EPA projects that, after full compliance with these rules, annual TEQ discharges will be reduced to 5 grams in effluent and 7 grams in sludge.

Estimates of National Emissions in 1987 and 1995 - The U.S. annual discharges of 2,3,7,8-TCDD and 2,3,7,8-TCDF are summarized in Table 8-3 for each of the six surveys discussed above. The release estimates for 1995 from U.S. EPA (1997f) and for 1988 from U.S. EPA (1990a) are believed to best represent emissions in the reference years 1995 and 1987, respectively. During the period between EPA's 104 Mill Study and issuance of the development document (U.S. EPA, 1993d), the U.S. pulp and paper industry reduced releases of CDD/CDFs primarily by instituting numerous process changes to reduce the formation of CDD/CDFs during the production of chemically bleached wood pulp. Details on the process changes implemented are provided in U.S. EPA (1993d) and Gillespie (1995). Much of the reduction between 1988 and 1995 can be attributed to process changes for pollution prevention.

The confidence ratings for these release estimates were judged to be high because direct measurements were made at virtually all facilities, indicating a high level of confidence in both the production and emission factor estimates. The best estimates of annual emissions in 1995 (i.e., the 1995 estimates presented in Table 8-3) are 28 g TEQ/yr for effluent, 50 g TEQ/yr for sludge, and 40 g TEQ/yr for pulp (i.e., TEQs that will enter the environment in the form of paper products). The best estimates of annual emissions in 1987 (i.e., the 1988 estimates presented in Table 8-3) are 356 g TEQ/yr for effluent, 343 g TEQ/yr for sludge, and 505 g TEQ/yr for pulp.

In 1990, the majority of the wastewater sludge generated by these facilities was placed in landfills or in surface impoundments (75.5 percent), with the remainder incinerated (20.5 percent), applied to land directly or as compost (4.1 percent), or distributed as a commercial product (less than 1 percent) (U.S. EPA, 1993e). Data more recent than 1995 or earlier than 1988 are not available on disposition of wastewater

sludges. On the basis of these statistics, the best estimate of TEQ applied to land (i.e., not incinerated or landfilled) in 1995 is 2.0 g (i.e., 4.1 percent of 50 g). The estimate for 1987 is 14.1 g TEQ (i.e., 4.1 percent of 343 g).

8.2. MANUFACTURE OF CHLORINE, CHLORINE DERIVATIVES, AND METAL CHLORIDES

No testing of CDD/CDF emissions to air, land, or water from U.S. manufacturers of chlorine, chlorine derivatives, and metal chlorides has been reported on which to base estimates of national emissions. Sampling of graphite electrode sludges from European chlorine manufacturers indicates high levels of CDFs. Limited sampling of chlorine derivatives and metal chlorides in Europe indicates low-level contamination in some products.

8.2.1. Manufacture of Chlorine

Chlorine gas is produced by electrolysis of brine electrolytic cells. Until the late 1970s, the primary type of electrolytic process used in the chloralkali industry to produce chlorine consisted of mercury cells containing graphite electrodes. As shown in Table 8-4, high levels of CDFs have been found in several samples of graphite electrode sludge from facilities in Europe. The CDFs predominate in these sludges, and the 2,3,7,8-substituted congeners account for a large fraction of the respective congener totals (Rappe et al., 1990b; Rappe et al., 1991; Rappe, 1993; Strandell et al., 1994). During the 1980s, titanium metal anodes were developed to replace graphite electrodes (U.S. EPA, 1982a; Curlin and Bommaraju, 1991). Currently, no U.S. facility is believed to use graphite electrodes in the production of chlorine gas (telephone conversation between L. Phillips, Versar, Inc., and T. Fielding, U.S. EPA, Office of Water, February 1993).

Although the origin of the CDFs in graphite electrode sludge is uncertain, chlorination of the cyclic aromatic hydrocarbons (such as dibenzofuran) present in the coal tar used as a binding agent in the graphite electrodes has been proposed as the primary source (Strandell et al., 1994). For this reason, sludges produced using metal electrodes were not expected to contain CDFs. However, results of an analysis of metal electrode sludge from a facility in Sweden, analyzed as part of the Swedish Dioxin Survey, showed the sludge contained high levels of CDFs (similar to those of the graphite sludge) and

primarily nondetectable levels of CDDs (Strandell et al., 1994). The sludge showed the same type of CDF congener pattern reported by Rappe et al. (1991) and Rappe (1993). Strandell et al. (1994) suggested that chlorination of PAHs present in the rubber linings of the electrolytic cell may have formed the CDFs found in the one sample analyzed.

Although EPA does not regulate CDD/CDFs specifically, it issued restrictions under the Resource Conservation and Recovery Act (RCRA) on the land disposal of wastewater and sludges generated by chlorine manufacturers that use the mercury cell process and the diaphragm process (with graphite electrodes) (Waste Codes K071, K073, and K106) (40 CFR 268).

8.2.2. Manufacture of Chlorine Derivatives and Metal Chlorides

The limited sampling of chlorine-derivative products indicates that these products contain very low, if any, concentrations of CDD/CDFs. Rappe et al. (1990c) analyzed a sample of chlorine bleach consisting of 4.4 percent sodium hypochlorite. Most of the 2,3,7,8-substituted CDD/CDF congeners were below the limits of detection (0.3 to 7 pg/L for all congeners, except OCDD and OCDF, which were 12 and 20 pg/L, respectively). No 2,3,7,8-substituted CDDs were detected. Tetra-, penta-, and hexa-CDFs were detected at levels of 13 pg/L or lower. The TEQ content of the sample was 4.9 pg I-TEQ_{DF}/L. Hutzinger and Fiedler (1991a) reported finding no CDD/CDFs at a detection limit of 4 μg/kg in chlorine gas or in samples of 10 percent sodium hypochlorite, 13 percent sodium hypochlorite, and 31–33 percent hydrochloric acid at a detection limit of 1 μg/kg.

Hutzinger and Fiedler (1991a) reported the results of analyses of samples of $FeCl_2$, $AlCl_3$, $CuCl_2$, CuCl, $SiCl_4$, and $TiCl_4$ for their content of HpCDF, OCDF, HpCDD, and OCDD. The sample of $FeCl_3$ contained HpCDF and OCDF in the low μg/kg range, but no HpCDD or OCDD were detected at a detection limit of 0.02 μg/kg. One of the two samples of $AlCl_3$ analyzed also contained a low μg/kg concentration of OCDF. The samples of $CuCl_2$ and CuCl contained concentrations of HpCDF, OCDF, and OCDD less that 1 μg/kg. The results are presented in Table 8-5.

8.3. MANUFACTURE OF HALOGENATED ORGANIC CHEMICALS

Several chemical production processes generate CDDs and CDFs (Versar, 1985; Hutzinger and Fiedler, 1991a). CDDs and CDFs can be formed during the manufacture of

chlorophenols, chlorobenzenes, and chlorobiphenyls (Versar, 1985; Ree et al., 1988). Consequently, disposal of industrial wastes from manufacturing facilities producing these compounds may result in the release of CDDs and CDFs to the environment. Also, the products themselves may contain these compounds, and their use or consumption, may result in additional releases to the environment. CDD and CDF congener distribution patterns indicative of noncombustion sources have been observed in sediments in southwest Germany and The Netherlands. According to Ree et al (1988), the congener patterns found suggest that wastes from the production of chlorinated organic compounds may be important historical sources of CDD and CDF contamination in these regions. The production and use of many of the chlorophenols, chlorophenoxy herbicides, and PCB products are now banned or strictly regulated in most countries. However, these products may have been a source of the environmental contamination that occurred prior to the 1970s and may continue to be a source of environmental releases under certain limited use and disposal conditions (Rappe, 1992a).

8.3.1. Chlorophenols

Chlorophenols have been widely used for a variety of pesticidal applications. The higher chlorinated phenols (i.e., tetrachlorophenol and pentachlorophenol) and their sodium salts have been used primarily for wood preservation. The lower chlorinated phenols have been used primarily as chemical intermediates in the manufacture of other pesticides. For example, 2,4-dichlorophenol is used to produce the herbicides 2,4-Dichlorophenoxyacetic acid (2,4-D), 4-(2,4-Dichlorophenoxy)butanoic acid (2,4-DB), 2-(2,4-Dichlorophenoxy)-propanoic acid (2,4-DP), Nitrophen, Genite, and Zytron, and 2,4,5-trichlorophenol was used to produce hexachlorophene, 2,4,5-T, Silvex, Erbon, Ronnel, and Gardona (Gilman et al., 1988; Hutzinger and Fiedler, 1991a). [Note: Sections 8.3.7 and 8.3.8 contain information on EPA actions to control CDD/CDF contamination of pesticides (including pentachlorophenol and its salts) and to obtain additional data on CDD/CDF contamination of pesticides.]

The two major commercial methods used to produce chlorophenols are (1) electrophilic chlorination of molten phenol by chlorine gas in the presence of catalytic amounts of a metal chloride and organic chlorination promoters and stabilizers, and (2) alkaline hydrolysis of chlorobenzenes under heat and pressure using aqueous methanolic

sodium hydroxide. Other manufacturing methods include conversion of diazonium salts of various chlorinated anilines, and chlorination of phenolsulfonic acids and benzenesulfonic acids, followed by the removal of the sulfonic acid group (Gilman et al., 1988; Hutzinger and Fiedler, 1991a).

Because of the manufacturing processes employed, commercial chlorophenol products can contain appreciable amounts of impurities (Gilman et al., 1988). During the direct chlorination of phenol, CDD/CDFs can form either by the condensation of tri-, tetra-, and pentachlorophenols or by the condensation of chlorophenols with hexachlorocyclohexadienone (which forms from excessive chlorination of phenol). During alkaline hydrolysis of chlorobenzenes, CDD/CDFs can form through chlorophenate condensation (Ree et al., 1988; Gilman et al., 1988; Hutzinger and Fiedler, 1991a).

The limited information on CDD/CDF concentrations in chlorophenols published in the 1970s and early 1980s was compiled by Versar (1985) and Hutzinger and Fiedler (1991a). The results of several major studies cited by these reviewers (Firestone et al., 1972; Rappe et al., 1978a, 1978b) are presented in Table 8-6. Typically, CDD/CDFs were not detected in monochlorophenols (MCP) and dichlorophenols (DCP) but were reported in trichlorophenols (TrCP) and tetrachlorophenols (TeCP). More recent results of testing of 2,4-dichlorophenol (2,4-DCP), performed in response to the Toxic Substances Control Act (TSCA) Dioxin/Furan Test Rule, showed no detectable concentrations of 2,3,7,8-substituted tetra- through hepta-CDD/CDFs. Other than a study by Hagenmaier (1986) that reported finding 2,3,7,8-TCDD at a concentration of 0.3 μg/kg in a sample of 2,3,4,5-tetrachlorophenol, no more recent data on concentrations of CDDs and CDFs could be found in the literature for the mono- through tetra-chlorophenols. Tables 8-7 and 8-8 present summaries of several studies that reported CDD/CDF concentrations in PCP and in PCP-Na products, respectively. Many of these studies do not report congener-specific concentrations, and many are based on products obtained from non-U.S. sources.

Regulatory Actions - Section 8.3.8 of this report describes regulatory actions taken by EPA to control the manufacture and use of chlorophenol-based pesticides.

In the mid-1980s, EPA's Office of Solid Waste promulgated land disposal restrictions on wastes under RCRA (i.e., wastewaters and nonwastewaters) resulting from the manufacture of chlorophenols (40 CFR 268). Table 8-9 lists all wastes in which CDDs and CDFs are specifically regulated as hazardous constituents by EPA, including

chlorophenol wastes (waste codes F020 and F021). The regulations prohibit the land disposal of these wastes until they are treated to a level below the routinely achievable detection limits in the waste extract listed in Table 8-9 for each of the following congener groups: TCDDs, PeCDDs, HxCDDs, TCDFs, PeCDFs, and HxCDFs. Wastes from PCP-based wood-preserving operations (waste codes K001 and F032) are also regulated as hazardous wastes under RCRA (40 CFR 261).

EPA's Office of Water promulgated effluent limitations for facilities that manufacture chlorinated phenols and discharge treated wastewater (40 CFR 414.70). These effluent limitations do not specifically regulate CDDs and CDFs. The effluent limitations for the individually regulated chlorinated phenols are less than or equal to 39 μg/L for facilities that use biological end-of-pipe treatment.

DCPs and TrCPs are subject to reporting under the Dioxin/Furan Test Rule, which is discussed in Section 8.3.7 of this report. Since the effective date of that rule (i.e., June 5, 1987), only the 2,4-DCP isomer has been commercially produced (or imported) in the United States, and as noted in Table 8-6, no CDD/CDFs were detected in the product. Testing is required for the other DCPs and TrCPs, if manufacture or importation resumes. Similarly, TeCPs were subject to reporting under the Dioxin/Furan Pesticide Data Call-In or DCI (discussed in Section 8.3.8 of this report). Since issuance of the DCI, the registrants of TeCP-containing pesticide products have elected to no longer support the registration of their products in the United States.

In January 1987, EPA entered into a Settlement Agreement with pentachlorophenol (PCP) manufacturers, which set limits on allowed uses of PCP and its salts and set maximum allowable concentrations of 2,3,7,8-TCDD and HxCDDs, effective in February 1989. Section 8.3.8 discusses the 1987 PCP Settlement Agreement and estimates current releases of CDD/CDFs associated with use of PCP in the United States. Section 12.3.1 provides an estimate of the amount of CDD/CDFs that may have entered the environment or that are contained within treated wood products as a result of prior use of PCP and PCP-Na.

Since the late 1980s, U.S. commercial production of chlorophenols has been limited to 2,4-dichlorophenol (2,4-DCP) and PCP. As noted above, disposal of wastes generated during the manufacture of chlorophenols is strictly regulated, and thus releases to the environment are expected to be negligible. With regards to releases associated

with the use of 2,4-DCP, no CDD/CDFs have been detected in 2,4-DCP. Releases associated with the use of PCP are presented in Sections 8.3.8 and 12.3.1.

8.3.2. Chlorobenzenes

Chlorobenzenes have been produced in the United States since 1909. U.S. production operations were developed primarily to provide chemical raw materials for the production of phenol, aniline, and various pesticides based on the higher chlorinated benzenes. Because of [incremental] changes in the processes used to manufacture phenol and aniline and the phaseout of highly chlorinated pesticides such as DDT and hexachlorobenzene, by 1988 U.S. production of chlorobenzenes had decreased to 50 percent of the peak production level in 1969.

Chlorobenzenes can be produced via three methods: (1) electrophilic substitution of benzene (in liquid or vapor phase) with chlorine gas in the presence of a metal salt catalyst; (2) oxidative chlorination of benzene with HCl at 150–300°C in the presence of a metal salt catalyst; and (3) dehydrohalogenation of hexachlorocyclohexane wastes at 200–240°C with a carbon catalyst to produce trichlorobenzene, which can be further chlorinated to produce higher chlorinated benzenes (Ree et al., 1988; Hutzinger and Fiedler, 1991a; Bryant, 1993).

All chlorobenzenes currently manufactured in the United States are produced using the electrophilic substitution process using liquid-phase benzene (i.e., temperature is at or below 80°C). Ferric chloride is the most common catalyst employed. Although this method can be used to produce mono- through hexachlorobenzene, the extent of chlorination is controlled to yield primarily MCBz and DCBz. The finished product is a mixture of chlorobenzenes, and refined products must be obtained by distillation and crystallization (Bryant, 1993).

CDD/CDFs can be produced inadvertently during the manufacture of chlorobenzenes by nucleophilic substitution and pyrolysis mechanisms (Ree et al., 1988). The criteria required for production of CDD/CDFs via nucleophilic substitution are (1) oxygen as a nuclear substituent (i.e., presence of chlorophenols) and (2) production or purification of the substance under alkaline conditions. Formation via pyrolysis requires reaction temperatures above 150°C (Ree et al., 1988; Hutzinger and Fiedler, 1991a). The liquid-phase electrophilic substitution process currently used in the United States does not

meet either of these criteria. Although Ree et al. (1988) and Hutzinger and Fiedler (1991a) state that the criteria for formation of CDD/CDFs via nucleophilic substitution may be present in the catalyst neutralization and purification/distillation steps of the manufacturing process, Opatick (1995) states that the chlorobenzene reaction product in U.S. processes remains mildly acidic throughout these steps.

Table 8-10 summarizes the very limited published information on CDD/CDF contamination of chlorobenzene products. The presence of CDD/CDFs has been reported in TCBz, PeCBz, and HCBz. No CDD/CDFs have been reported in monochlorobenzene (MCBz) and DCBz. Conflicting data exist concerning the presence of CDD/CDFs in TCBz. One study (Villanueva et al., 1974) detected no CDD/CDFs in one sample of 1,2,4-TCBz at a detection limit of 0.1 μg/kg. Hutzinger and Fiedler (1991a) reported unpublished results of Dr. Hans Hagenmaier showing CDD/CDF congener group concentrations ranging from 0.02 to 0.074 μg/kg in a sample of mixed TCBz. Because the TCBz examined by Hagenmaier contained about 2 percent hexachlorocyclohexane, it is reasonable to assume that the TCBz was produced by dehydrohalogenation of hexachlorocyclohexane (a manufacturing process not currently used in the United States).

Regulatory Actions - EPA has determined, as part of the Federal Insecticide, Fungicide, and Rodenticide Act (FIFRA) Pesticide Data Call-In (discussed in Section 8.3.8), that the 1,4-DCBz manufacturing processes used in the United States are not likely to form CDD/CDFs. MCBz, DCBz, and TCBz are listed as potential precursor chemicals under the TSCA Dioxin/Furan Test Rule and are subject to reporting. (See Section 8.3.7.) In addition, EPA issued a Significant New Use Rule (SNUR) under Section 5(a)(2) of TSCA on December 1, 1993 (effective January 14, 1994) for PeCBz and 1,2,4,5-TeCBz (Federal Register, 1993c). This rule requires persons to submit a notice to EPA at least 90 days before manufacturing, importing, or processing either of these compounds in amounts of 10,000 pounds or greater per year per facility for any use. All registrations of pesticide products containing HCBz were cancelled in the mid-1980s (Carpenter et al., 1986).

EPA's Office of Solid Waste promulgated land disposal restrictions on wastes (i.e., wastewaters and nonwastewaters) resulting from the manufacture of chlorobenzenes (40 CFR 268). Table 8-9 lists all solid wastes for which EPA specifically regulates CDDs and CDFs as hazardous constituents, including chlorobenzene wastes. The regulations prohibit the land disposal of these wastes until they are treated to a level below the routinely

achievable detection limits in the waste extract listed in Table 8-9 for each of the following congener groups: TCDDs, PeCDDs, HxCDDs, TCDFs, PeCDFs, and HxCDFs.

EPA's Office of Water promulgated effluent limitations for facilities that manufacture chlorinated benzenes and discharge treated wastewater (40 CFR 414.70). These effluent limitations do not specifically address CDDs and CDFs. The following chlorinated benzenes are regulated: chlorobenzene; 1,2-dichlorobenzene; 1,3-dichlorobenzene; 1,4-dichlorobenzene; 1,2,4-trichlorobenzene; and hexachlorobenzene. The effluent limitations for the individual regulated chlorinated benzenes are less than or equal to 77 μg/L for facilities that use biological end-of-pipe treatment and are less than or equal to 196 μg/L for facilities that do not use biological end-of-pipe treatment.

Since at least 1993, U.S. commercial production of chlorobenzenes has been limited to MCBz, 1,2-dichlorobenzene (1,2-DCBz), 1,4-dichlorobenzene (1,4-DCBz), and, to a much lesser extent, 1,2,4-trichlorobenzene (1,2,4-TCBz). As noted above, CDD/CDF formation is not expected under the normal operating conditions of the processes currently used in the United States to produce these four chemicals. No tetra-, penta-, or hexachlorinated benzenes are now intentionally produced or used in the United States (Bryant, 1993). Thus, releases of CDD/CDFs from manufacture of chlorobenzenes in 1995 were estimated to be negligible. Because the information available on CDD/CDF content of MCBz to PeCBz is very limited and is based primarily on unpublished European data, and because information on the chlorobenzene manufacturing processes in place during 1987 is not readily available, no emission estimates can be made for 1987.

8.3.3. Chlorobiphenyls

PCBs are manufactured by the direct batch chlorination of molten biphenyl in the presence of a catalyst, followed by separation and purification of the desired chlorinated biphenyl fractions. During the manufacture of PCBs, the inadvertent production of CDFs also occurrs. This section addresses potential releases of CDD/CDFs associated with leaks and spills of PCBs. CDFs have been shown to form when PCB-containing transformers and capacitors undergo malfunctions or are subjected to fires that result in accidental combustion of the dielectric fluid. This combustion source of PCB-associated CDFs is discussed in Section 6.6. Section 11.2 addresses releases of dioxin-like PCBs.

PCB production is believed to have occurred in 10 countries. The total amount of PCBs produced worldwide since 1929 (i.e., the first year of known production) is estimated to total 1.5 billion kg. Initially, PCBs were primarily used as dielectric fluids in transformers. After World War II, PCBs found steadily increasing use as dielectric fluids in capacitors, as heat-conducting fluids in heat exchangers, and as heat-resistant hydraulic fluids in mining equipment and vacuum pumps. PCBs also were used in a variety of "open" applications (i.e., uses from which PCBs cannot be re-collected) including in plasticizers, carbonless copy paper, lubricants, inks, laminating agents, impregnating agents, paints, adhesives, waxes, additives in cement and plaster, casting agents, dedusting agents, sealing liquids, fire retardants, immersion oils, and pesticides (DeVoogt and Brinkman, 1989).

PCBs were manufactured in the United States from 1929 until 1977. U.S. production peaked in 1970, with a volume of 85 million pounds. Monsanto Corporation, the major U.S. producer, voluntarily restricted the use of PCBs in 1971, and annual production fell to 40 million pounds in 1974. Monsanto ceased PCB manufacture in mid-1977 and shipped the last inventory in October 1977. Regulations issued by EPA beginning in 1977, principally under TSCA (40 CFR 761), strictly limited the production, import, use, and disposal of PCBs. (See Section 4.1 for details on TSCA regulations.) The estimated cumulative production and consumption volumes of PCBs in the United States from 1930 to 1975 were 1,400 million pounds produced; 3 million pounds imported (primarily from Japan, Italy, and France), 1,253 million pounds sold in the United States; and 150 million pounds exported (ATSDR, 1993; DeVoogt and Brinkman, 1989).

Monsanto Corporation marketed technical-grade mixtures of PCBs primarily under the trade name Aroclor. The Aroclors are identified by a four-digit numbering code in which the last two digits indicate the chlorine content by weight percent. The exception to this coding scheme is Aroclor 1016, which contains only mono- through hexachlorinated congeners with an average chlorine content of 41 percent. The following list shows the percentages of total Aroclor production, by Aroclor mixture, during 1957 to 1977, as reported by Brown (1994).

Aroclor	1957–1977 U.S. Production (%)
1221	0.96
1016	12.88
1232	0.24
1242	51.76
1248	6.76
1254	15.73
1260	10.61
1262	0.83
1268	0.33

The trade names of the major commercial technical-grade mixtures of PCBs manufactured in other countries included *Clophen* (Germany), *Fenclor* and *Apirolio* (Italy), *Kanechlor* (Japan), *Phenoclor* and *Pyralene* (France), *Sovtel* (USSR), *Delor* and *Delorene* (Czechoslovakia), and *Orophene* (German Democratic Republic) (DeVoogt and Brinkman, 1989). Some of the mixtures marketed under these trade names were similar in terms of chlorine content (by weight percent and average number of chlorines per molecule) to various Aroclors, as shown below. Mixtures that are comparable in terms of chlorine content were marketed under several trade names, as shown below.

Aroclor	Clophen	Pyralene	Phenoclor	Fenclor	Kanechlor
1232		2000			200
1242	A-30	3000	DP-3	42	300
1248	A-40		DP-4		400
1254	A-50		DP-5	54	500
1260	A-60		DP-6	64	600

During the commercial production of PCBs, thermal oxidative cyclization under alkaline conditions resulted in the inadvertent production of CDFs in most of the commercial PCB mixtures (Brown et al., 1988; ATSDR, 1993). Bowes et al. (1975a) first reported detection of CDFs in Aroclor products; samples of unused Aroclors manufactured in 1969 and 1970 were found to have CDF (i.e., TCDF through HxCDF) concentrations ranging from 0.8 to 2.0 mg/kg. Bowes et al. (1975b) employed congener-specific analytical methodology and detected 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF at concentrations ranging from 0.11 to 0.33 mg/kg and 0.12 to 0.83 mg/kg, respectively, in unused samples of Aroclor 1254 and Aroclor 1260. The presence of CDDs in commercial

PCB mixtures, although at much lower concentrations than those of the CDFs, was reported by Hagenmaier (1987) and Malisch (1994). Table 8-11 presents the CDF and CDD congener group concentrations reported by Bowes et al. (1975a) and those reported in subsequent years for unused PCBs by Erickson (1986), ATSDR (1993), Hagenmaier (1987), and Malisch (1994).

Several researchers reported concentrations of specific CDD/CDF congeners in commercial PCB mixtures (Bowes et al., 1975b; Brown et al., 1988; Hagenmaier, 1987; Malisch, 1994). Only the Hagenmaier (1987) and Malisch (1994) studies, however, reported the concentrations of all 2,3,7,8-substituted CDDs and CDFs. Table 8-12 presents the results of these four studies. It is evident from the table that major variations are found in the levels of 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF in the Clophen mixtures reported by Hagenmaier (1987) and Malisch (1994) and the corresponding levels in the Aroclor mixtures reported by Bowes et al. (1975b) and Brown et al. (1988).

Brown et al. (1988) compared the levels of 2,3,7,8-TCDF, 2,3,4,7,8-PeCDF, and 1,2,3,7,8,9-HxCDF in used samples (i.e., samples from previously used capacitors and transformers) and unused samples of Aroclors 1016, 1242, 1254, and 1260. The concentration ranges reported for the used and unused Aroclors were similar, leading Brown et al. (1988) to conclude that CDFs are not formed during the normal use of PCBs in electrical equipment.

Amounts of CDD/CDF TEQ that may have been released to the environment during 1987 and 1995 from spills and leaks of in-service PCBs cannot be accurately estimated because reliable data regarding leaked and spilled PCBs are not available. However, preliminary estimates can be made using the release data reported to EPA's Toxics Release Inventory (TRI) by those manufacturing facilities required to submit annual reports to TRI. Table 11-6 in Section 11 lists the amounts of PCBs reported to TRI to have been released to the environment during 1988 through 1996. These TRI data include emissions to the air, discharges to bodies of water, and releases to land. On the basis of these data, annual emissions of PCBs to air during 1988 and 1996 could have been as high as 2.7 kg and as low as 0 kg, respectively. If it is further assumed that the ratio of TEQ (I-TEQ_{DF} and TEQ_{DF}-WHO_{98}) to total PCB in the air emissions was 0.17:1,000,000 (i.e., the average of the TEQ contents for Clophen A-30 and Clophen A-50, or 170 μg/kg, as reported by Hagenmaier (1987) and presented in Table 8-12), then annual emissions of I-TEQ_{DF} to air

in 1988 and 1995 could have been 0.5 and 0 mg, respectively. Similar assumptions for PCB releases to water of 4.5 kg in 1988 and 0 kg in 1995 yield estimated TEQ emissions during 1988 and 1995 of 0.8 and 0 mg, respectively. For land releases of 341 kg in 1988 and 0 kg in 1995, estimated TEQ emissions during 1988 and 1995 are 58 and 0 mg, respectively. All of these estimated releases are considered to be negligible.

8.3.4. Polyvinyl Chloride

Polyvinyl chloride (PVC) resins are produced when free radical initiators are used to induce the polymerization of vinyl chloride monomer (VCM). VCM is typically produced by the thermal dehydrochlorination (commonly known as cracking) of ethylene dichloride (EDC). One plant in the United States still uses the catalytic reaction of acetylene and HCl to manufacture VCM directly. The cracking of EDC requires elevated pressure (20 to 30 atmospheres) and temperature (450 to 650°C) and yields VCM and HCl at about a 1:1 molar ratio. EDC is produced by two different methods: (1) direct chlorination of ethylene with chlorine in the presence of a catalyst at a temperature of 50 to 60°C and pressure of 4 to 5 atmospheres; and (2) oxychlorination, which involves reaction of ethylene with HCl and oxygen in the presence of a catalyst at temperatures generally less than 325°C. The primary source of HCl for the oxychlorination process is the HCl produced from the cracking of EDC to form VCM; all VCM plants, with the exception of the one facility noted above, are integrated with EDC production facilities (The Vinyl Institute, 1998).

Although it has generally been recognized that CDD/CDFs are formed during the manufacture of EDC/VCM/PVC, manufacturers and environmental public interest groups have disagreed as to the quantity of CDD/CDFs that are formed and released to the environment in wastes and possibly in PVC products. Although EPA regulates emissions from EDC/VCM production facilities under the Clean Water Act (40 CFR 61), the Clean Air Act (40 CFR 414), and RCRA (40 CFR 268 - Waste Codes F024, K019, and K020), CDD/CDFs are not specifically regulated pollutants; as a consequence, monitoring data for CDD/CDFs in emissions are generally lacking.

In 1993, Greenpeace International issued a report on CDD/CDF emissions associated with the production of EDC/VCM (Greenpeace, 1993). Greenpeace estimated that 5 to 10 g I-TEQ_{DF} are released to the environment (air, water, and ground combined) annually for every 100,000 metric tons of VCM produced. This emission factor was

based on data gathered by Greenpeace on four European plants. The Vinyl Institute responded with a critique of the Greenpeace report (ChemRisk, 1993). Miller (1993) summarized the differing views of the two parties. According to Miller (1993), European PVC manufacturers claim the emission factor is 0.01 to 0.5 g I-TEQ_{DF}/100,000 metric tons of VCM. Although Greenpeace (1993) and ChemRisk (1993) used basically the same monitoring information to develop their emission factors, Greenpeace adjusted the emission factor to account for unquantified fugitive emissions and waste products that contain unspecified amounts of CDD/CDFs.

In 1995, Greenpeace issued another report reiterating the organization's concern that the generation and emission of CDD/CDFs may be significant and urging that further work be initiated to quantify and prevent emissions (Stringer et al., 1995). Stringer et al. (1995) presented the results of analyses of three samples of chlorinated wastes obtained from U.S. EDC/VCM manufacturing facilities. The three wastes were characterized according to EPA hazardous waste classification numbers as follows: (1) an F024 waste (i.e., waste from the production of short chain aliphatics by free radical catalyzed processes), (2) a K019 waste (i.e., heavy ends from the distillation of ethylene from EDC production), and a probable K020 waste (i.e., heavy ends from distillation of VC in VCM manufacture). Table 8-13 presents the analytical results reported by Stringer et al. (1995). This study acknowledged that because EDC/VCM production technologies and waste treatment and disposal practices are very site-specific, the limited information available on CDD/CDF generation and emissions made it difficult to quantify amounts of CDD/CDFs generated and emitted.

In response to the lack of definitive studies and at the recommendation of EPA, U.S. PVC manufacturers initiated an extensive monitoring program, the Dioxin Characterization Program, to evaluate the extent of any CDD/CDF releases to air, water, and land, as well as any product contamination. Manufacturers performed emission and product testing at various facilities that were representative of various manufacturing and process control technologies. The Vinyl Institute has completed studies of CDD/CDF releases in wastewater, wastewater treatment plant solids, and stack gases, as well as studies of CDD/CDF content of products (i.e., PVC resins and "sales" EDC). The following subsections discuss the results for each of these media (The Vinyl Institute, 1998).

The Vinyl Institute created an External Advisory Group to advise the institute on the conduct of the Dioxin Characterization Program and to provide an independent review of the Program results. In their final evaluation report, the Advisory Group judged the industry's coverage, in terms of the number of facilities and waste streams sampled, to be fairly comprehensive. The number of samples of PVC product, stack emissions, wastewaters, and wastewater sludges obtained from the different types of manufacturing facilities was deemed by the Advisory Group to provide a sufficient database to evaluate industrywide annual releases. The Advisory Group concluded that the process established by The Vinyl Institute to ensure that data collected as part of its Dioxin Characterization Program are representative of normal process operations was a good one. After auditing The Vinyl Institute's estimates of annual releases, the Advisory Group concluded that the data were properly validated and the results were extrapolated to annual industrywide release estimates in a creditable, scientific manner.

EPA has reviewed The Vinyl Institute (1998) study and concurs with the conclusions of the External Advisory Group. EPA assigns a high confidence rating to the activity level estimates and a medium confidence rating to the emission factor estimates developed by The Vinyl Institute (1998).

Wastewater - The Vinyl Institute (1998) presented results for treated wastewater samples collected during April and May of 1995 at six sites that manufactured only PVC, at three sites that manufactured EDC and VCM, and at one site that manufactured EDC, VCM, and PVC. In terms of production, the six PVC-only sites represent approximately 15 percent of the total estimated 1995 U.S. and Canadian PVC production. The three EDC/VCM sites and the one EDC/VCM/PVC site together represent 27 percent of the total estimated 1995 U.S. EDC production. Samples taken from PVC-only sites were taken from sites that manufactured suspension PVC resin as well as sites that manufactured dispersion PVC resin. Samples for the other four sites were taken from sites that used direct and oxychlorination processes, fixed and fluidized beds, and low- and high-temperature direct chlorination. The wastewater samples from one of the EDC/VCM sites, one of the PVC-only sites, and the EDC/VCM/PVC site were taken from effluents derived from process areas not limited to EDC/VCM, EDC/VCM/PVC, or PVC manufacturing.

The results of the sampling are presented in Table 8-14. The method detection limits (MDLs) for all congeners except OCDD and OCDF in all samples were 10 pg/L or

less. The MDLs for OCDD and OCDF were 50 pg/L or less. CDD/CDFs were detected in two of the six samples from PVC-only sites (0.52 and 2.0 pg I-TEQ_{DF}/L, assuming ND = 0). The overall mean TEQ concentrations were 0.88 pg I-TEQ_{DF}/L (ND = 0) and 4.7 pg I-TEQ_{DF}/L (ND = 1/2 MDL). CDD/CDFs were detected in all four of the samples from EDC/VCM/PVC sites. The overall mean TEQ concentrations were 0.42 pg I-TEQ_{DF}/L (ND = 0) and 4.4 pg I-TEQ_{DF}/L (ND = 1/2 MDL).

Based on these sample results, The Vinyl Institute developed I-TEQ_{DF} emission factors for PVC-only and EDC/VCM/PVC manufacturing facilities. First, individual site release rates were estimated using the treated wastewater effluent flow rate recorded by the site during sampling and assuming that the site continuously releases CDD/CDFs at its calculated total I-TEQ_{DF}, 24 hours per day, 360 days per year, at the recorded water effluent rate. The total releases from each site-type category (i.e., PVC-only or EDC/VCM/PVC facilities) were then estimated by averaging the individual release rates on a per-1,000-metric-ton-of-PVC basis or per-1,000-metric-ton-of-EDC basis using the estimated 1995 PVC and EDC production statistics for the sampled sites. These values were then "scaled up" to estimate total U.S. releases in treated wastewater from the site-type categories. It is not possible using the data presented in the Vinyl Institute (1998) to calculate emission factors for TEQ_{DF}-WHO_{98}. However, because 1,2,3,7,8-PeCDD was not detected in any wastewater sample, the TEQ_{DF}-WHO_{98} emission factors would be lower than the I-TEQ_{DF} emission factors.

The mean emission factors derived from the sample results for the PVC-only facilities are 2.3 μg I-TEQ_{DF}/1,000 metric tons of PVC (ND = 0) and 29 μg I-TEQ_{DF}/1,000 metric tons of PVC (ND = 1/2 MDL). The mean emission factors for the EDC/VCM/PVC facilities are 2.9 μg I-TEQ_{DF}/1,000 metric tons (ND = 0) and 15 μg I-TEQ_{DF}/1,000 metric tons of EDC (ND = 1/2 MDL).

The Vinyl Institute (1998) combined these emission factors with 1995 industry production statistics (i.e., 5,212 thousand metric tons of PVC and 11,115 thousand metric tons of EDC), to yield release estimates of 0.011 grams I-TEQ_{DF} (ND = 0) and 0.15 g I-TEQ_{DF} (ND = 1/2 DL) from PVC-only manufacturing sites and 0.032 g I-TEQ_{DF} (ND = 0) and 0.17 g I-TEQ_{DF} (ND = 1/2 DL) from EDC/VCM and EDC/VCM/PVC facilities for a total I-TEQ_{DF} release in 1995 of 0.043 g (ND = 0) and 0.32 g (ND = 1/2 DL).

Wastewater Treatment Plant Solids - The Vinyl Institute (1998) presented results for 14 samples collected in 1996 from 9 EDC/VCM/PVC manufacturing sites. Samples were collected from 4 of the 5 U.S. sites that manufactured EDC, VCM, and PVC; 3 of the 7 U.S. sites that manufactured EDC and VCM, but not PVC; and 2 of the 21 sites that manufacture PVC, but not EDC or VCM. On the basis of 1995 production data, the two PVC-only sites manufactured approximately 4.7 percent of the total estimated U.S. and Canadian PVC resin production. The sampled EDC/VCM and EDC/VCM/PVC sites manufactured 56 percent of the total estimated 1995 U.S. EDC production. Samples from the PVC-only sites were taken from sites that manufactured suspension PVC resin as well as sites that manufactured dispersion PVC resin. Samples taken from the EDC/VCM and EDC/VCM/PVC sites were taken from sites that used direct and oxychlorination processes; fixed and fluidized EDC reactor beds; low- and high-temperature direct chlorination; and air, oxygen, and mixed air/oxygen feeds.

Using the sample results and their determination that the results for facilities using different EDC reactor bed technologies (i.e., fluidized bed vs. fixed bed) appear to differ significantly, The Vinyl Institute developed annual I-TEQ_{DF} emission estimates for three categories: PVC-only, EDC/VCM/PVC fixed bed, and EDC/VCM/PVC fluidized bed facilities. Nine U.S. sites use fixed bed technology and six use fluidized bed technology. Four of each type of facility were sampled by The Vinyl Institute. It is not possible using the data presented in The Vinyl Institute (1998) to calculate emission factors for TEQ_{DF}-WHO_{98}. Because 1,2,3,7,8-PeCDD was detected in only 3 of 10 samples, but OCDD and OCDF were detected in all samples, it is likely that the TEQ_{DF}-WHO_{98} emission factors would not be significantly different from the I-TEQ_{DF} emission factors.

Results of the sampling are presented in Table 8-14. The MDLs for all congeners were less than 150 ng/kg, and usually were less than 10 ng/kg. CDD/CDFs were detected in all samples. The ranges of TEQ concentrations (dry weight basis) for the two PVC-only facilities were 1.1 to 2.6 ng I-TEQ_{DF}/kg (ND = 0) and 2.8 to 4.4 ng I-TEQ_{DF}/kg (ND = 1/2 MDL). On an emission factor basis, the ranges were 1.7 to 46 μg I-TEQ_{DF}/1,000 metric tons of PVC produced (ND = 0) and 4.3 to 78 μg I-TEQ_{DF}/1,000 metric ton of PVC produced (ND = 1/2 DL). The range of TEQ concentrations for the samples from the EDC/VCM or EDC/VCM/PVC sites were 88 to 6,850 ng I-TEQ_{DF}/kg (ND = 0) and 93 to 6,850 ng I-TEQ_{DF}/kg (ND = 1/2 DL). On an emission factor basis, the

ranges were 28 to 4,000 μg I-TEQ$_{DF}$/1,000 metric tons of EDC (ND = 0) and 29 to 4,000 μg I-TEQ$_{DF}$/1,000 metric tons of EDC (ND = 1/2 DL).

The annual amounts of I-TEQ$_{DF}$ generated in 1995 in each of the three facility categories were estimated by The Vinyl Institute as follows. First, total annual contributions at each sampled site were estimated by multiplying the I-TEQ$_{DF}$ from the sample by the annual production of wastewater solids at that site. These annual site contributions of I-TEQ$_{DF}$ were then summed for each of the three facility types and multiplied by the ratio of each category's total annual production of PVC or EDC to the sum of the annual production of the sampled sites in that category.

The Vinyl Institute (1998) combined these emission factors with 1995 industry production statistics (i.e., 5,212 thousand metric tons of PVC and 11,115 thousand metric tons of EDC) to yield estimated amounts of I-TEQ$_{DF}$ in wastewater treatment plant solids. For PVC-only facilities, estimated amounts are 0.069 g I-TEQ$_{DF}$ per year (ND = 0) and 0.12 g I-TEQ$_{DF}$ per year (ND = 1/2 DL), assuming an annual PVC production of 5,212 thousand metric tons. For EDC/VCM/PVC fixed bed facilities, the estimated amounts of TEQ are 1.0 g I-TEQ$_{DF}$ per year (ND = 0 or ND = 1/2 DL), assuming an EDC annual production volume of 5,400 thousand metric tons. For EDC/VCM/PVC fluidized bed facilities, the estimated amount of TEQ is 11 g I-TEQ$_{DF}$ per year (ND = 0 or ND = 1/2 DL), assuming EDC annual production volume of 5,600 thousand metric tons. Thus, total amounts of TEQ in wastewater treatment plant solids are estimated to have been 12.1 g I-TEQ$_{DF}$ in 1995 (ND = 0 or ND = 1/2 DL).

Based on The Vinyl Institute survey data, Institute member companies dispose of wastewater solids by three methods: (1) RCRA hazardous waste landfilling (approximately 1 percent of industry total solids), (2) landfarming (approximately 6 percent), and (3) "secure" on-site landfilling (93 percent of industry total solids). Solids disposed of by methods 1 and 3 are assumed to be well controlled to prevent release into the general environment, whereas solids disposed of by landfarming are not as well controlled and could be released to the environment. Therefore, an estimated 0.73 g I-TEQ$_{DF}$ (i.e., 6 percent of 12.1 g I-TEQ$_{DF}$) can be considered as potentially released to the environment.

Stack Gas Emissions - By grouping similarities of design and service, The Vinyl Institute (1998) subcategorized thermal destruction units at EDC/VCM and/or PVC manufacturing units into three categories: (a) type A—vent gas incinerators at PVC-only

resin plants; (b) type B—vent gas thermal oxidizers at EDC/VCM plants; and (c) type C—liquid only and liquid/vent gas thermal oxidizers at EDC/VCM plants. Using an industrywide survey, The Vinyl Institute (1998) identified 22 type A units at 11 facilities, 23 type B units at 10 facilities, and 17 type C units at 10 facilities. The Vinyl Institute gathered test data from 5 of the 22 type A units (from three facilities representing 7 percent of total U.S. and Canadian EDC/VCM/PVC production in 1995), 14 of the 23 type B units (from 8 facilities), and 13 of the 17 type C units (from 7 facilities). The sampled types B and C units represent 70 percent of total U.S. and Canadian EDC/VCM/PVC production in 1995.

Annual I-TEQ_{DF} emission estimates were generated by The Vinyl Institute by combining estimated emissions from tested units (i.e., based on measured stack gas results and plant-specific activity data) with an estimate of emissions from untested units. The emissions from the untested units were estimated by multiplying the average emission factor for the tested units in the category (i.e., called the "most likely" estimate by The Vinyl Institute) or by multiplying the average emission factor of the three highest tested units in each class (i.e., the "upper bound" estimate) by the activity level for the untested units. It is not possible using the data presented in The Vinyl Institute (1998) to calculate emission factors for TEQ_{DF}-WHO_{98}.

The Vinyl Institute (1998) estimates of "most likely" and "upper-bound" emissions during 1995 for these three categories are as follows:

Category	"Most Likely" Emission Estimate (g I-TEQ_{DF}/yr)	"Upper Bound" Emission Estimate (g I-TEQ_{DF}/yr)
PVC-only incinerators	0.0014	0.0019
EDC/VCM liquid and liquid/vents	3.7	7.2
EDC/VCM vents for VCM only	6.9	21.6

The Vinyl Institute (1998) also estimated emissions that may result from incineration of EDC/VCM/PVC wastes processed by off-site third-party processing. Using the emission factors for liquid and liquid/vents developed in their study, The Vinyl Institute estimated that potential emissions to air from this source category would be 0.65 g I-

TEQ_{DF}/yr (most likely estimate) and 2.3 g I-TEQ_{DF}/yr (upper-bound estimate). Including these third-party release estimates with those developed above yields a most likely estimate of 11.2 g I-TEQ_{DF}/yr and an upper-bound estimate of 31 g I-TEQ_{DF}/yr.

Products - The Vinyl Institute (1998) presented results for 22 samples from 14 of the 24 U.S. and Canadian facilities manufacturing suspension and mass PVC resins (i.e., 13 pipe resins, 3 bottle resins, and 6 packaging resins). The results are summarized in Table 8-15. The 14 sampled sites represent approximately 74 percent of estimated 1995 U.S. and Canadian suspension and mass PVC resin production. CDD/CDFs were detected in only one sample (0.043 ng I-TEQ_{DF}/kg, assuming ND = 0). The overall mean TEQ concentrations were 0.002 ng I-TEQ_{DF}/kg (ND = 0) and 0.7 ng I-TEQ_{DF}/kg (ND = 1/2 MDL). The MDLs were 2 ng/kg or less for all congeners in all samples except for OCDD and OCDF, which had MDLs of 6 ng/kg or less.

The Vinyl Institute (1998) also presented results for six samples from four of the seven U.S. facilities manufacturing dispersion PVC resins. CDD/CDFs were detected in five of the samples. The results are summarized in Table 8-15. In terms of production, the four sampled sites represent approximately 61 percent of estimated 1995 U.S. dispersion PVC resin production. The results ranged from not detected to 0.008 ng I-TEQ_{DF}/kg (overall mean = 0.001 ng I-TEQ_{DF}/kg assuming ND = 0, and 0.4 ng I-TEQ_{DF}/kg, assuming ND = 1/2 MDL). The MDLs were 2 ng/kg or less for all congeners in all samples except OCDD and OCDF, which had MDLs of 4 ng/kg or less.

The Vinyl Institute (1998) also presented results for 5 samples from 5 of the 15 U.S. facilities manufacturing EDC. The results are summarized in Table 8-15. In terms of production, the five sampled sites represent approximately 71 percent of total U.S. estimated 1995 "sales" EDC production. CDD/CDFs were detected in only one sample (0.03 ng I-TEQ_{DF}/kg). The overall mean TEQ concentrations were 0.006 ng I-TEQ_{DF}/kg (ND = 0) and 0.21 ng I-TEQ_{DF}/kg (ND = 1/2 MDL). The MDLs for all congeners were 1 ng/kg or less.

Using 1995 U.S. production data (i.e., 4.846 million metric tons of suspension and mass PVC, 0.367 million metric tons of dispersion PVC resins, and 1.362 million metric tons of "sales" EDC) and the average TEQ observed for the samples analyzed, The Vinyl Institute estimated the total I-TEQ_{DF} contents of suspension/mass PVC resins, dispersion PVC resins, and "sales" EDC in 1995 to be 0.01 g, 0.004 g, and 0.008 g, respectively

(ND = 0) and 3.39 g, 0.15 g, and 0.29 g, respectively (ND = 1/2 MDL). Therefore, total I-TEQ_{DF} present in PVC in 1995 was estimated at between 0.02 g (ND = 0) and 3.83 g (ND = 1/2 MDL). It is not possible using the data presented in The Vinyl Institute (1998) to calculate emission factors for TEQ_{DF}-WHO_{98}. However, because neither 1,2,3,7,8-PeCDD nor OCDD were detected in any sample, the TEQ_{DF}-WHO_{98} emission factors would be very similar to the I-TEQ_{DF} emission factors.

8.3.5. Other Aliphatic Chlorine Compounds

Aliphatic chlorine compounds are used as monomers in the production of plastics, as solvents and cleaning agents, and as precursors for chemical synthesis (Hutzinger and Fiedler, 1991a). These compounds are produced in large quantities. In 1992, 14.6 million metric tons of halogenated hydrocarbons were produced (U.S. International Trade Commission, 1946–1994). The production of 1,2-dichloroethane and vinyl chloride accounted for 82 percent of this total production. Highly chlorinated CDDs and CDFs (i.e., hexa- to octachlorinated congeners) have been found in nanograde-quality samples of 1,2-dichloroethane (55 ng/kg of OCDF in one of five samples), tetrachloroethene (47 ng/kg of OCDD in one of four samples), epichlorohydrin (88 ng/kg of CDDs and 33 ng/kg of CDFs in one of three samples), and hexachlorobutadiene (360 to 425 ng/kg of OCDF in two samples) obtained in Germany from the company Promochem (Hutzinger and Fiedler, 1991a; Heindl and Hutzinger, 1987). No CDD/CDFs were detected in two samples of allyl chloride, three samples of 1,1,1-trichloroethane, and four samples of trichloroethylene (detection limit ranged from 5 to 20 ng/kg) (Heindl and Hutzinger, 1987). Because no more recent or additional data could be found in the literature to confirm these values for products manufactured or used in the United States, no national estimates of CDD/CDF emissions are made for the inventory.

EPA's Office of Water promulgated effluent limitations for facilities that manufacture chlorinated aliphatic chlorine compounds and discharge treated wastewater (40 CFR 414.70). These effluent limitations do not specifically address CDDs and CDFs. The following chlorinated aliphatic compounds are regulated: 68 μg/L for 1,2-dichloroethane and 22 μg/L for tetrachloroethylene. Similarly, EPA's Office of Solid Waste promulgated restrictions on land disposal of wastes generated during manufacture of

many chlorinated aliphatics (40 CFR 268); however, these restrictions do not specifically regulate CDD/CDFs.

8.3.6. Dyes, Pigments, and Printing Inks

Several researchers analyzed various dyes, pigments, and printing inks obtained in Canada and Germany for the presence of CDDs and CDFs (Williams et al., 1992; Hutzinger and Fiedler, 1991a; Santl et al., 1994c). The following paragraphs discuss the findings of those studies.

Dioxazine Dyes and Pigments - Williams et al. (1992) analyzed the CDD/CDF content in dioxazine dyes and pigments available in Canada. As shown in Table 8-16, OCDD and OCDF concentrations in the ng/kg range, and HpCDD, HxCDD, and PeCDD concentrations in the μg/kg range were found in Direct Blue 106 dye (3 samples), Direct Blue 108 dye (1 sample), and Violet 23 pigments (6 samples) (Williams et al., 1992). These dioxazine pigments are derived from chloranil, which has been found to contain high levels of CDD/CDFs and has been suggested as the source of contamination among these dyes (Christmann et al., 1989a; Williams et al., 1992; U.S. EPA, 1992b). In May 1990, EPA received test results showing that chloranil was heavily contaminated with dioxins; levels as high as 3,065 μg I-TEQ_{DF}/kg (2,903 μg TEQ_{DF}-WHO_{98}/kg) were measured in samples from four importers (mean value of 1,754 μg I-TEQ_{DF}/kg or 1,388 μg TEQ_{DF}-WHO_{98}/kg) (U.S. EPA, 1992b; Remmers et al., 1992). (See Section 8.3.7 for analytical results.)

In the early 1990s, EPA learned that I-TEQ_{DF} levels in chloranil could be reduced by more than two orders of magnitude (to less than 20 μg/kg) through manufacturing feedstock and process changes. EPA's Office of Pollution Prevention and Toxics (OPPT) subsequently began efforts to complete an industrywide switch from the use of contaminated chloranil to low-dioxin chloranil. Although chloranil is not manufactured in the United States, significant quantities are imported. As of May 1992, EPA had negotiated agreements with all chloranil importers and domestic dye/pigment manufacturers known to EPA that use chloranil in their products to switch to low-dioxin chloranil. In May 1993, when U.S. stocks of chloranil with high levels of CDD/CDFs had been depleted, EPA proposed a significant new use rule (SNUR) under Section 5 of TSCA that requires industry to notify EPA at least 90 days prior to the manufacture, import, or

processing, for any use, of chloranil containing CDD/CDFs at a concentration greater than 20 μg I-TEQ$_{DF}$/kg (Federal Register, 1993a; U.S. EPA, 1993c).

In 1983, approximately 36,500 kg of chloranil were imported (U.S. ITC, 1984). The U.S. International Trade Commission (ITC) has not published quantitative import data for chloranil since 1984. If it is assumed that this import volume reflects actual usage of chloranil in the United States during 1987, and the CDD/CDF contamination level was 1,754 μg I-TEQ$_{DF}$/kg (1,388 μg TEQ$_{DF}$-WHO$_{98}$/kg), then the maximum release into the environment via processing wastes and finished products was 64.0 g I-TEQ$_{DF}$. If it is assumed that the import volume in 1995 was also 36,500 kg, but that the imported chloranil contained 10 μg I-TEQ$_{DF}$/kg on average, then the total potential annual TEQ release associated with chloranil in 1995 was 0.36 g I-TEQ$_{DF}$ (50.6 g TEQ$_{DF}$-WHO$_{98}$).

Phthalocyanine Dyes and Printing Inks - Hutzinger and Fiedler (1991a) found CDD/CDFs (tetra-, penta-, and hexachlorinated congeners) in the μg/kg range in a sample of a Ni-phthalocyanine dye. No CDD/CDFs were detected (detection limit of 0.1 to 0.5 μg/kg) in two samples of Cu-phthalocyanine dyes and in one Co-phthalocyanine dye (Hutzinger and Fiedler, 1991a).

Santl et al. (1994) reported the results of analyses of four printing inks obtained from a supplier in Germany. Two of the inks are used for rotogravure printing, and two are used for offset printing. The results of the analyses are presented in Table 8-17. The I-TEQ$_{DF}$ content of the inks ranged from 15.0 to 88.6 ng/kg (17.7 to 87.2 ng/kg on a TEQ$_{DF}$-WHO$_{98}$ basis). Primarily non-2,3,7,8-substituted congeners were found. The identities of the dyes and pigments in these inks were not reported.

8.3.7. TSCA Dioxin/Furan Test Rule

Citing evidence that halogenated dioxins and furans may be formed as by-products during chemical manufacturing processes (Versar, 1985), EPA issued a rule under Section 4 of TSCA that requires chemical manufacturers and importers to test for the presence of chlorinated and brominated dioxins and furans in certain commercial organic chemicals (Federal Register, 1987c). The rule listed 12 manufactured or imported chemicals that required testing and 20 chemicals not currently manufactured or imported that would require testing if manufacture or importation resumed. These chemicals are listed in Table 8-18. The specific dioxin and furan congeners that require quantitation and

the target limits of quantitation (LOQ) that are specified in the rule are listed in Table 8-19. Under Section 8(a) of TSCA, the final rule also required that chemical manufacturers submit data on manufacturing processes and reaction conditions for chemicals produced using any of the 29 precursor chemicals listed in Table 8-20. The rule stated that subsequent to this data-gathering effort, testing may be proposed for additional chemicals if any of the manufacturing conditions used favored the production of dioxins and furans.

Sixteen sampling and analytical protocols and test data for 10 of the 12 chemicals that required testing were submitted to EPA (Holderman and Cramer, 1995). Data from 15 submissions were accepted; one submission is under review. Manufacture or import of two substances (tetrabromobisphenol-A-bis-2,3-dibromopropylether and tetrabromobisphenol-A-diacrylate) have stopped since the test rule was promulgated. [Note: All data and reports in the EPA TSCA docket are available for public review and inspection at EPA Headquarters in Washington, DC.]

Table 8-21 presents the results of analytical testing for CDDs and CDFs for the chemicals that have data available in the TSCA docket. Five of these 10 chemicals contained CDD/CDFs. Positive results were obtained for 2,3,5,6-tetrachloro-2,5-cyclohexadiene-1,4-dione (chloranil), pentabromodiphenyloxide, octabromodiphenyloxide, decabromodiphenyloxide, and 1,2-Bis(tribromophenoxy)-ethane. Table 8-22 presents the quantitative analytical results for the four submitted chloranil samples, as well as the results of an EPA analysis of a sample of carbazole violet, which is manufactured from chloranil.

Although testing conducted under this test rule for 2,4,6-tribromophenol indicated no halogenated dioxins or furans above the LOQs, Thoma and Hutzinger (1989) reported detecting BDDs and BDFs in a technical-grade sample of this substance. Total TBDD, TBDF, and PeBDF were found at 84 µg/kg, 12 µg/kg, and 1 µg/kg, respectively. No hexa-, hepta-, or octa-BDFs were detected. Thoma and Hutzinger (1989) also analyzed analytical-grade samples of two other brominated flame retardants, pentabromophenol and tetrabromophthalic anhydride; no BDDs or BDFs were detected (detection limits not reported).

8.3.8. Halogenated Pesticides and FIFRA Pesticides Data Call-In

In the late 1970s and early 1980s, attention began to focus on pesticides as potential sources of CDDs and CDFs in the environment. Up to that time, CDD and CDF levels were not regulated in end-use pesticide products. Certain pesticide active ingredients, particularly chlorinated phenols and their derivatives, were known or suspected, however, to be contaminated with CDDs and CDFs. During the 1980s and 1990s, EPA took several actions to investigate and control CDD/CDF contamination of pesticides.

Actions to Regulate 2,4,5-T and Silvex: In 1983, EPA cancelled the sale of Silvex and 2,4,5-T for all uses (Federal Register, 1983). Earlier, in 1979, EPA had ordered emergency suspension of the forestry, rights-of-way, and pasture uses of 2,4,5-T. Emergency suspensions of the forestry, rights-of-way, pasture, home and garden, commercial/ornamental turf, and aquatic weed control/ditch bank uses of Silvex were also ordered (Federal Register, 1979; Plimmer, 1980). The home and garden, commercial/ornamental turf, and aquatic weed control/ditch bank uses of 2,4,5-T had been suspended in 1970.

Actions to Regulate pentachlorophenol (PCP): In 1984, EPA issued a notice of intent to cancel registrations of pesticide products containing PCP (including its salts) for all wood preservative uses (Federal Register, 1984). This notice specified modifications to the terms and conditions of product registrations that were required in order to avoid cancellation of the products. In response to this notice, several trade associations and registrants requested administrative hearings to challenge EPA's determinations. After carefully considering the comments and alternatives suggested during the prehearing stage of the administrative proceedings, EPA concluded that certain changes to the 1984 notice were appropriate. These were finalized in 1986 (Federal Register, 1986) and included the following: (i) all wood preservative uses of PCP and its salts were classified as "restricted use" only by certified applicators; (ii) specific worker protection measures were required; (iii) limits were placed on the HxCDD content of PCP; and (iv) label restrictions for home and farm uses of PCP prohibiting its application indoors and to wood intended for interior use (with a few exceptions), as well as prohibiting application of these products in a manner that may result in direct exposure of domestic animals or livestock, or in the contamination of food, feed, or drinking and irrigation water.

EPA subsequently amended the wood preservative uses Notice to establish reliable and enforceable methods for implementing certified limits for HxCDD and 2,3,7,8-TCDD in registered wood-preservative pesticide products (Federal Register, 1987a). Levels of 2,3,7,8-TCDD were not allowed to exceed 1.0 ppb in any product, and after February 2, 1989, any manufacturing-use PCP released for shipment could not contain HxCDD levels that exceeded an average of 2 ppm over a monthly release or a batch level of 4 ppm (a gradually phased in requirement). On January 21, 1987, EPA prohibited the registration of PCP and its salts for most nonwood uses (Federal Register, 1987b). EPA deferred action on several uses (i.e., uses in pulp/paper mills, oil wells, and cooling towers) pending receipt of additional exposure, use, and ecological effects data. On January 8, 1993, EPA issued a press advisory stating that the EPA special review of these deferred nonwood uses was being terminated, because all of these uses either had been voluntarily cancelled by the registrants or had been cancelled by EPA for failure of the registrants to pay the required annual maintenance fees (U.S. EPA, 1993f).

Pentachlorophenol (PCP) was one of the most widely used biocides in the United States prior to the regulatory actions to cancel and restrict certain wood and nonwood preservative uses of PCP. PCP was registered for use as a herbicide, defoliant, mossicide, and as a mushroom house biocide. It also found use as a biocide in pulp-paper mills, oil wells, and cooling towers. These latter three uses were terminated on or before 1993 (U.S. EPA, 1993f). However, the major use (greater than 80 percent of consumption) of PCP was and continues to be wood preservation.

The production of PCP for wood preserving began on an experimental basis in the 1930s. In 1947, nearly 3,200 metric tons of PCP were reported to have been used in the United States by the commercial wood preserving industry. Use in this industry steadily increased through the mid-1970s (American Wood Preservers Institute, 1977). Although domestic consumption volumes are not available for all years, based on historical production/export data for PCP reported in Mannsville (1983), it is estimated that 90 to 95 percent of production volume have typically been consumed domestically rather than exported. A reasonable estimate of average annual domestic PCP consumption during the period 1970 to 1995 is about 400,000 metric tons. This estimate assumes an average annual consumption rate of 20,000 metric tons/yr during the 1970s, 15,000 metric tons/yr during the 1980s, and 10,000 metric tons/yr during the 1990s.

Table 8-7 presents a compilation of published data on the CDD/CDF content of technical grade PCP. The only samples that have been analyzed for all dioxin-like CDD/CDFs were manufactured in the mid to late 1980s. Figure 8-4 presents these data in graphical form. It is evident from the figures that the predominant congener groups are OCDD, OCDF, HpCDF, and HpCDD, and the dominant 2,3,7,8-substituted congeners are OCDD, 1,2,3,4,6,7,8-HpCDD, and OCDF. Waddell et al. (1995) tested analytical grade PCP (from Aldrich Chemical Co.) for CDD/CDF content and found the same congener profile; however, the CDD/CDF levels were three to four orders of magnitude lower. Table 8-8 presents a similar compilation of published data on the CDD/CDF content of PCP-Na. The table shows the same patterns of dominant congeners and congener groups reported for PCP.

Samples of technical PCP manufactured during the mid to late 1980s contained about 3 mg I-TEQ/kg, (1.7 mg TEQ_{DF}-WHO_{98}/kg) based on the data presented in Table 8-7. No published reports could be located that present the results of any congener-specific analyses of PCP manufactured since the late 1980s. However, monthly measurements of CDD/CDF congener group concentrations in technical PCP manufactured for use in the United States have been reported to EPA from 1987 to the present (KMG-Bernuth, 1997; Pentachlorophenol Task Force, 1997; U.S. EPA, 1999a). The average congener group concentrations reported to EPA for the years 1988 (i.e., 1 year after EPA regulations were imposed limiting HxCDD and 2,3,7,8-TCDD concentrations in PCP) to 1999 are presented in Table 8-7. In general, the average congener group concentrations during the period 1988-1999 are lower by factors of 2 to 4 than observed in the mid to late 1980s full congener analysis samples. If it is assumed that the toxic CDD/CDF congeners have also been reduced by similar factors, then the TEQ content of PCP manufactured since 1988 is about 1 mg I-TEQ/kg (0.6 mg TEQ_{DF}-WHO_{98}/kg).

An estimated 8,400 metric tons of PCP were used for wood preservation in the United States in 1994 (American Wood Preservers Institute, 1995); for purposes of this report, it is assumed that an identical amount was used in 1995. An estimated 12,000 metric tons were used in 1987 (WHO, 1991). Combining these activity level estimates with the TEQ concentration estimates presented above indicates that 8,400 g I-TEQ_{DF} (4,800 g TEQ_{DF}-WHO_{98}) and 36,000 g I-TEQ_{DF} (20,000 g TEQ_{DF}-WHO_{98}) were incorporated into PCP-treated wood products in 1995 and 1987, respectively. This estimate for 1987

is assigned a high confidence rating, indicating high confidence in both the activity level and TEQ concentration in PCP estimates. The estimate for 1995 is assigned a medium confidence estimate because of uncertainties about the actual TEQ content of PCP manufactured in 1995.

Although the estimates of the mass of TEQ in treated wood are fairly certain, no studies are available that provide measured CDD/CDF release rate data from which a reliable estimate can be made of the amount of CDD/CDFs that have or will volatilize or leach from treated wood. Several recent field studies, discussed in the following paragraphs demonstrate that CDD/CDFs do apparently leach into soil from PCP-treated wood, but the studies do not provide release rate data. No studies were located that provide any measured CDD/CDF volatilization rates from PCP-treated wood. Although CDD/CDFs have very low vapor pressures, they are not bound nor react with the wood in any way that would preclude volatilization. Several studies, discussed below, have attempted to estimate potential CDD/CDF volatilization releases using conservative assumptions or modeling approaches, but these estimates span many orders of magnitude.

Gurprasad et al. (1995) analyzed three PCP-treated utility poles and their surrounding surface soils for penta- through octa-CDD content. All three poles showed significant levels of HxCDD (0.29 to 0.47 mg/kg), HpCDD (4.69 to 6.63 mg/kg), and OCDD (27.9 to 42.1 mg/kg), but no PeCDD. Surface soils collected 2 cm from the poles also had detectable levels of HxCDD, HpCDD, and OCDD; however, no consistent pattern was found between the CDD concentrations in the poles and in the adjacent soils. The soil concentrations did, however, show the same relative congener group pattern observed in the wood. CDD concentrations in soils obtained 20 cm from the poles were an order of magnitude less than the soil concentrations measured at 2 cm. Soils 26 meters from the poles showed nondetected values or values close to the detection limit of 0.01 to 0.02 mg/kg.

In a study of the leaching of PCP from 31 utility poles, the Electric Power Research Institute (EPRI) (1995) found similar patterns of PCP distribution in soils surrounding poles as those found by Gurprasad et al. (1995) for CDDs. PCP concentrations decreased by as much as two orders of magnitude between 7.5 cm from the poles and 20 cm from the poles, with an average decrease of slightly more than one order of magnitude over this

distance. EPRI (1995) also found no obvious trend between PCP concentration in the wood (eight poles analyzed) and the age of the poles (4 to 11 years) or the PCP concentration in the surface soil. Based on their results and those of EPRI (1995), Gurprasad et al. (1995) concluded that CDDs probably leach from PCP-treated utility poles with the PCP/oil carrier and travel in the soil in a similar manner.

Wan (1995) and Wan and Van Oostdam (1995) measured CDD/CDF concentrations in waters and sediments from ditches surrounding utility poles and railroad ties and demonstrated that chlorophenol-treated wood could serve as a source of CDD/CDFs to the aquatic environment. Ten samples were collected at each of six utility pole sites and five railroad tie sites 1 to 2 days after major rainfall events and then were composited into one sample per site prior to analyses. Total CDDs (mean value of 76.7 mg/kg) and total CDFs (mean value of 18.7 mg/kg) detected in chlorophenol/creosote-treated utility poles were about 6 to 8 times greater, respectively, than the CDD and CDF concentrations detected in chlorophenol/creosote-treated railroad ties. Total CDDs found in water from railway ditches without utility poles (i.e., only treated railroad ties were present) were approximately 20 times higher than the background level found in farm ditch water. Total CDDs in railway ditches with utility poles were 4,300 times higher than the background levels. Water from railway ditches without utility poles contained total CDF levels 13 times higher than background, whereas water in ditches adjacent to poles were 8,500 times higher than background. Total CDDs in ditches adjacent to, and 4 m downstream of, utility poles were about 5,900 and 2,200 times, respectively, higher than background; total CDFs for the same sites were about 8,100 and 1,700 times, respectively, higher than background. Total CDDs found in ditch sediments of railway and ditch sediments adjacent to utility poles were about 5 and 700 times, respectively, higher than background; while total CDFs were about 9 and 1,800 times, respectively, higher than background. Both CDDs and CDFs were found in utility ditch sediments 4 m downstream of treated power poles, but at levels of 200 and 400 times, respectively, lower than those found adjacent to poles, indicating that they were transported from point sources of contamination. The corresponding values for CDFs were 5,400 and 8,000 times, respectively, higher in concentration.

Bremmer et al. (1994) estimated an annual release of 15 to 125 g of I-TEQ_{DF} from PCP-treated wood in The Netherlands. The lower estimate was based on three basic

assumptions: (1) the half-life of PCP in treated wood is 15 years (according to industry sources); (2) the half-life of CDD/CDFs in treated wood is 10 times that of PCP (i.e., 150 years) because of the lower vapor pressures of CDD/CDFs relative to PCP; and (3) the typical CDD/CDF concentration in PCP has been 3,000 μg/kg. The higher estimate was based on an assumed half-life of PCP in wood of 15 years and the results of an indoor air study by Papke et al. (1989) conducted at several kindergartens where PCP-treated wood had been used. Although Papke et al. (1989) found no clear correlation between indoor air concentrations of CDD/CDF and PCP across the range of CDD/CDF concentrations observed in the 20-plus samples (2.6 to 427 pg CDD/CDF/m^3), there did appear to be a positive correlation at the sites with more elevated CDD/CDF concentrations. Bremmer et al. (1994) reported that the average ratio of PCP to I-TEQ $_{DF}$ air concentrations at these elevated sites was found to be $1{:}5x10^{-6}$ (or about the same ratio as the concentration of I-TEQ $_{DF}$ in technical PCP). The results of the Papke et al. (1989) study imply that CDD/CDFs may be released from PCP-treated wood at the same rate as PCP, rather than at a rate 10 times slower.

Rappe (1995) used the emission factor approach developed by Bremmer et al. (1994) and an assumed U.S. usage volume of PCP over the past 50 years (0.5 million metric tons) to estimate that as much as 10.5 kg of I-TEQ$_{DF}$ could volatilize from PCP-treated wood in the United States annually. Eitzer and Hites (1987) derived a dramatically different estimate of CDD/CDF volatilization from PCP-treated wood in the United States, 3 kg of total CDD/CDF per year (or 66 g of I-TEQ$_{DF}$ per year assuming an I-TEQ$_{DF}$ content in PCP of 3 mg/kg). Eitzer and Hites (1987) based their estimate on: (1) an assumption that 0.1 percent of the PCP produced annually enters the atmosphere, and (2) that the CDD/CDF contaminants present in the PCP (assumed to be 130 mg/kg) are released to the atmosphere at the same rate as the PCP (i.e., 0.1 percent). The basis for the first assumption of Eitzer and Hites (1987) is not clear because U.S. EPA (1980), which was cited as the source of the 0.1 percent emission factor, does not appear to address volatilization of PCP from in-service treated wood. The report does, however, estimate that most PCP in treated wood leaches relatively rapidly from the wood, presumably to land, within a period of 12 years.

Eduljee and Dyke (1996) and Douben et al. (1995) estimate that 0.8 g of I-TEQ$_{DF}$ is released to the air annually from PCP-treated wood in the U.K. This estimate is based on

the assumed emission of 0.1 percent of the CDD/CDF present in PCP-treated wood during the first year of the service life of the wood that was assumed by Eitzer and Hites (1987). No emission is assumed for subsequent years of use of the treated wood.

The California Air Resources Board (Chinkin et al., 1987) generated estimates of CDD/CDF volatilization releases at wood treatment facilities from bundles of treated wood that remain on-site for 1 month prior to shipment. An "adapted" version of a model developed by McCord (1981) was used for estimating volatile releases from a constantly filling lagoon. The model is primarily driven by chemical-specific vapor pressures and air diffusivity coefficients. Chinkin et al. (1987) do not provide all model input parameter values used to generate the emission estimates. However, running the model with typical dimensions for treated poles yields an I-TEQ_{DF} emission rate on the order of 6E-12 g/yr-pole, an extremely low number (i.e., 170 billion poles would together emit 1 g TEQ/yr).

Actions to Identify Other Pesticides Containing CDD/CDFs: In addition to cancelling some pesticide registrations and establishing product standards, EPA's Office of Pesticide Programs (OPP) issued two Data Call-Ins (DCIs) in 1987. Pesticide manufacturers are required to register their products with EPA in order to market them commercially in the United States. Through the registration process, mandated by FIFRA, EPA can require that the manufacturer of each active ingredient generate a wide variety of scientific data through several mechanisms. The most common process is the five-phase reregistration process with which the manufacturers (i.e., registrants) of older pesticide products must comply. In most registration activities, registrants must generate data under a series of strict testing guidelines, 40 CFR 158--Pesticide Assessment Guidelines (U.S.EPA, 1988b). EPA can also require additional data from registrants, when necessary, through various mechanisms, including the DCI process.

The purpose of the first DCI, dated June and October 1987, "Data Call-In Notice for Product Chemistry Relating to Potential Formation of Halogenated Dibenzo-p-dioxin or Dibenzofuran Contaminants in Certain Active Ingredients," was to identify, using an analysis of raw materials and process chemistry, those pesticides that may contain halogenated dibenzo-p-dioxin and dibenzofuran contaminants. The 93 pesticides (76 pesticide active ingredients) to which the DCI applied, along with their corresponding Shaughnessey and Chemical Abstract code numbers, are presented in Table 8-23. [Note: The Shaughnessey code is an internal EPA tracking system--it is of interest because

chemicals with similar code numbers are similar in chemical nature (e.g., salts, esters, and acid forms of 2,4-D).] All registrants supporting registrations for these chemicals were subject to the requirements of the DCI, unless their product qualified for a Generic Data Exemption (i.e., a registrant exclusively used a FIFRA-registered pesticide product(s) as the source(s) of the active ingredient(s) identified in Table 8-23 in formulating their product(s)). Registrants whose products did not meet the Generic Data Exemption were required to submit the types of data listed below to enable EPA to assess the potential for formation of tetra- through hepta-halogenated dibenzo-p-dioxin or dibenzofuran contaminants during manufacture. Registrants, however, had the option to voluntarily cancel their product or "reformulate to remove an active ingredient," to avoid having to comply with the DCI.

- Product Identity and Disclosure of Ingredients: EPA required submittal of a Confidential Statement of Formula (CSF), based on the requirements specified in 40 CFR 158.108 and 40 CFR 158.120 - Subdivision D: Product Chemistry. Registrants who had previously submitted still-current CSFs were not required to resubmit this information.
- Description of Beginning Materials and Manufacturing Process: Under the requirements mandated by 40 CFR 158.120 - Subdivision D, EPA required submittal of a manufacturing process description for each step of the manufacturing process, including specification of the range of acceptable conditions of temperature, pressure, or pH at each step.
- Discussion of the Formation of Impurities: Under the requirements mandated by 40 CFR 158.120 - Subdivision D, EPA required submittal of a detailed discussion and assessment of the possible formation of halogenated dibenzo-p-dioxins and dibenzofurans.

The second DCI, dated June and October 1987, “Data Call-In for Analytical Chemistry Data on Polyhalogenated Dibenzo-p-Dioxins/Dibenzofurans (HDDs and HDFs),” was issued for 68 pesticides (16 pesticide active ingredients) suspected to be contaminated by CDD/CDFs. (See Table 8-24.) All registrants supporting registrations for these pesticides were subject to the requirements of this DCI, unless the product qualified

for various exemptions or waivers. Pesticides covered by the second DCI were strongly suspected by EPA to contain detectable levels of CDD/CDFs.

Under the second DCI, registrants whose products did not qualify for an exemption or waiver were required to generate and submit the following types of data in addition to the data requirements of the first DCI:

- Quantitative Method for Measuring CDDs or CDFs: Registrants were required to develop an analytical method for measuring the HDD/HDF content of their products. The DCI established a regimen for defining the precision of the analytical method. Target limits of quantitation were established in the DCI for specific CDD and CDF congeners. (See Table 8-25.)
- Certification of Limits of CDDs or CDFs: Registrants were required to submit a "Certification of Limits" in accordance with 40 CFR 158.110 and 40 CFR 158.120 - Subdivision D. Analytical results were required that met the guidelines described above.

Registrants could select one of two options to comply with the second DCI. The first option was to submit relevant existing data, develop new data, or share the cost to develop new data with other registrants. The second option was to alleviate the DCI requirements through several exemption processes, including a Generic Data Exemption, voluntary cancellation, reformulation to remove the active ingredient of concern, an assertion that the data requirements do not apply, or the application or award of a low-volume, minor-use waiver.

The data contained in CSFs, as well as any other data generated under 40 CFR 158.120 - Subdivision D, are typically considered Confidential Business Information (CBI) under the guidelines prescribed in FIFRA, because they usually contain information regarding proprietary manufacturing processes. In general, all analytical results submitted to EPA in response to both DCIs are considered CBI and cannot be released by EPA into the public domain. Summaries based on the trends identified in that data, as well as data made public by EPA, are summarized below.

The two DCIs included 161 pesticides. Of these, 92 are no longer supported by registrants. Following evaluation of the process chemistry submissions required under the

DCIs, OPP determined that formation of CDD/CDFs was not likely during the manufacture of 43 of the remaining 69 pesticides; thus, analysis of samples of these 43 pesticides was not required by OPP. Evaluation of process chemistry data is ongoing at OPP for an additional seven pesticides. Tables 8-23 and 8-24 indicate which pesticides are no longer supported, those for which OPP determined that CDD/CDF formation is unlikely, and those for which process chemistry data or analytical testing results are under review in OPP (U.S. EPA, 1995f).

OPP required that analysis of production samples be performed on the remaining 19 pesticides. (See Table 8-26.) The status of the analytical data generation/evaluation to date is summarized as follows: (1) no detection of CDD/CDFs above the LOQs in registrant submissions for 13 active ingredients, (2) detection of CDD/CDFs above the LOQs for 2,4-D acid (two submissions) and 2,4-D 2-ethyl hexyl acetate (one submission), and (3) ongoing data generation or evaluation for four pesticides.

Table 8-25 presents a summary of results obtained by EPA for CDDs and CDFs in eight technical 2,4-D herbicides; these data were extracted from program files in OPP. Because some of these files contained CBI, the data in this table were reviewed by OPP staff to ensure that no CBI was being disclosed (Funk, 1996). Figure 8-5 presents a congener profile for 2,4-D based on the average congener concentrations reported in Table 8-25.

Schecter et al. (1997) reported the results of analyses of samples of 2,4-D manufactured in Europe, Russia, and the United States. (See Table 8-27.) The total TEQ concentrations measured in the European and Russian samples are similar to those measured in the EPA DCI samples; however, the levels reported by Schecter et al. (1997) for U.S. samples are significantly lower.

As discussed in Section 12.2.1, an estimated 26,300 metric tons of 2,4-D were used in the United States in 1995, making it one of the top 10 pesticides in terms of quantity used (U.S. EPA, 1997e). An estimated 30,400 metric tons were used during 1987 (U.S. EPA, 1988c). On the basis of the average CDD/CDF congener concentrations in 2,4-D presented in Table 8-25 (not including OCDD and OCDF), the corresponding I-TEQ_{DF} concentration is 0.70 μg/kg (1.10 μg TEQ_{DF}-WHO_{98}/kg). Combining this TEQ concentration with the activity level estimates for 1995 and 1987 indicates that 18.4 g I-TEQ_{DF} (28.9 g TEQ_{DF}-WHO_{98}) may have entered the environment in 1995 and 21.3 g I-

TEQ_{DF} (33.4 g TEQ_{DF}-WHO_{98}) may have entered the environment in 1987. These release estimates are assigned a high confidence rating, indicating high confidence in both the production and emission factor estimates.

8.4. OTHER CHEMICAL MANUFACTURING AND PROCESSING SOURCES

8.4.1. Municipal Wastewater Treatment Plants

Sources - CDD/CDFs have been measured in nearly all sewage sludges tested, although the concentrations and, to some extent, the congener profiles and patterns differ widely. Potential sources of the CDD/CDFs include microbial formation (discussed in Chapter 9), runoff to sewers from lands or urban surfaces contaminated by product uses or deposition of previous emissions to air (discussed in Section 12.2.1), household wastewater, industrial wastewater, chlorination operations within the wastewater treatment facility, or a combination of all the above (Rappe, 1992a; Rappe et al., 1994; Horstmann et al., 1992; Sewart et al., 1995; Cramer et al., 1995; Horstmann and McLachlan, 1995).

The major source(s) for a given Publicly Owned Treatment Works (POTW) is likely to be site-specific, particularly in industrialized areas. For example, Rieger and Ballschmiter (1992) traced the origin of CDDs and CDFs found in municipal sewage sludge in Ulm, Germany, to metal manufacturing and urban sources. The characteristics of both sources were similar and suggested generation via thermal processing. However, in a series of recent studies, Horstmann et al. (1992, 1993a, 1993b) and Horstmann and McLachlan (1994a, 1994b, 1995) demonstrated that wastewater generated by laundering and bathing could be the major source at many, if not all, POTWs that serve primarily residential populations. Although runoff from streets during precipitation events, particularly from streets with high traffic density, was reported by these researchers as contributing measurably, the total contribution of TEQ from household wastewater was eight times greater than that from surface runoff at the study city.

Horstmann et al. (1992) provided initial evidence that household wastewater could be a significant source. Horstmann et al. (1993a) measured CDD/CDF levels in the effluent from four different loads of laundry from two different domestic washing machines. The concentrations of total CDD/CDF in the four samples ranged from 3,900 to 7,100 pg/L and were very similar in congener profile, with OCDD being the dominant

congener followed by the hepta- and hexa-CDDs. Because of the similar concentrations and congener profiles found, Horstmann et al. (1993a) concluded that the presence of CDD/CDF in washing machine wastewater is widespread. A simple mass balance performed using the results showed that the CDD/CDFs found in the four washing machine wastewater samples could account for 27 to 94 percent of the total CDD/CDF measured in the sludge of the local wastewater treatment plant (Horstmann and McLachlan, 1994a).

Horstmann et al. (1993a) also performed additional experiments that showed that detergents, commonly used bleaching agents, and the washing cycle process itself were not responsible for the observed CDD/CDFs. To determine if the textile fabric or fabric finishing processes could account for the observed CDD/CDFs, Horstmann et al. (1993b), Horstmann and McLachlan (1994a, 1994b), and Klasmeier and McLachlan (1995) analyzed the CDD/CDF content of eight different raw (unfinished) cotton cloths containing fiber from different countries and five different white synthetic materials (acetate, viscose, bleached polyester, polyamide, and polyacrylic), as well as more than 100 new textile finished products. Low concentrations were found in most products (i.e., less than 50 ng/kg of total CDD/CDF), but a small percentage contained high concentrations up to 290 μg/kg of total CDD/CDF. On the basis of the concentrations and patterns found, the authors concluded that neither unfinished new fabrics nor common cotton finishing processes can explain the CDD/CDF levels found in wastewater. Rather, the use of CDD/CDF-containing textile dyes and pigments and the use in some developing countries of pentachlorophenol to treat unfinished cotton appear to be the sources of the detected CDDs/CDFs.

Horstmann and McLachlan (1994a, 1994b, 1995) reported the results of additional experiments that demonstrated that the small percentage of clothing items with high CDD/CDF levels could be responsible for the quantity of CDD/CDFs observed in household wastewater and sewage sludge. They demonstrated that the CDD/CDFs can be gradually removed from the fabric during washing, can be transferred to the skin, subsequently transferred back to other textiles, and then washed out, or can be transferred to other textiles during washing and then removed during subsequent washings.

Releases to Water - The presence of CDD/CDFs in sewage sludge suggests that CDD/CDFs may also be present in the wastewater effluent discharges of POTWs;

however, few studies reporting the results of effluent analyses for CDD/CDFs have been published.

Rappe et al. (1989a) tested the effluent from two Swedish POTWs for all 2,3,7,8-substituted CDD/CDF congeners. OCDD was detected in the effluents from both facilities at concentrations ranging from 14 to 39 pg/L. Rappe et al. detected 1,2,3,4,6,7,8-HpCDD and 1,2,3,4,6,7,8-HpCDF in the effluent of one facility at concentrations of 2.8 and 2.0 pg/L, respectively. No 2,3,7,8-substituted tetra-, penta-, and hexa-CDDs and CDFs were detected (detection limits of 0.2 to 20 pg/L).

Ho and Clement (1990) reported the results of sampling during the late 1980s of 37 POTWs in Ontario, Canada, for each of the five CDD/CDF congener groups with four to eight chlorines. The sampled facilities included 27 secondary treatment facilities, 7 primary treatment facilities, 1 tertiary plant, and 2 lagoons. The facilities accounted for about 73 percent of the sewage discharged by POTWs in Ontario. No CDDs/CDFs were detected (detection limit in low ng/L range) in the effluents from the lagoons and the tertiary treatment facility. Only OCDD and TCDF were detected in the effluents from the primary treatment facilities (two and one effluent samples, respectively). HpCDD, OCDD, TCDF, and OCDF were detected in the effluents from the secondary treatment facilities (detected in four or fewer samples at levels ranging from 0.1 to 11 ng/L).

Gobran et al. (1995) analyzed the raw sewage and final effluent of an Ontario, Canada, wastewater treatment plant for CDD/CDF congeners over a 5-day period. Although HpCDD, OCDD, HpCDF, and OCDF were detected in the raw sewage (12 to 2,300 pg/L), no CDD/CDFs were detected in the final effluent at congener-specific detection limits ranging from 3 to 20 pg/L.

The California Regional Water Quality Control Board (CRWQCB, 1996) reported the results of effluent testing at nine POTWs in the San Francisco area. A total of 30 samples were collected during 1992-1995; 1 to 6 samples were analyzed for each POTW. Table 8-28 summarizes the sampling results. With the exception of OCDD, most 2,3,7,8-substituted CDD/CDF congeners were seldom detected.

The CRWQCB (1996) data were collected to provide representative effluent concentrations for the San Francisco area; these data cannot be considered to be representative of CDD/CDF effluent concentrations at the 16,000-plus POTWs nationwide. Therefore, the data can only be used to generate a preliminary estimate of the potential

mass of CDD/CDF TEQ that may be released annually by U.S. POTWs. Approximately 122 billion liters of wastewater are treated daily by POTWs in the United States (U.S. EPA, 1997c). Multiplying this value by 365 days/year and by the "overall mean" TEQ concentrations listed in Table 8-28 (i.e., 0.29 pg I-TEQ_{DF}/L and 0.27 pg TEQ_{DF}-WHO_{98}/L) yields annual TEQ release estimates of 13 g of I-TEQ_{DF} or 12 g of TEQ_{DF}-WHO_{98}.

Sewage Sludge Land Disposal - EPA conducted the National Sewage Sludge Survey in 1988 and 1989 to obtain national data on sewage sludge quality and management. As part of this survey, EPA analyzed sludges from 174 POTWs that employed at least secondary wastewater treatment for more than 400 analytes, including CDD/CDFs. Although sludges from only 16 percent of the POTWs had detectable levels of 2,3,7,8-TCDD, all sludges had detectable levels of at least one CDD/CDF congener (U.S. EPA, 1996a). I-TEQ_{DF} concentrations as high as 1,820 ng/kg dry weight were measured. The congener-specific results of the survey are presented in Table 8-29. If all nondetected values found in the study are assumed to be zero, then the mean and median I-TEQ_{DF} concentrations of the sludges from the 174 POTWs are 50 and 11.2 ng/kg (dry weight basis), respectively. If the nondetected values are set equal to the detection limit, then the mean and median I-TEQ_{DF} concentrations are 86 and 50.4 ng/kg, respectively (U.S. EPA, 1996a; Rubin and White, 1992).

Green et al. (1995) and Cramer et al. (1995) reported the results of analyses of 99 samples of sewage sludge collected from wastewater treatment plants across the United States during the summer of 1994. These data are summarized in Table 8-30. To calculate average results in units of TEQ, Green et al. (1995) averaged results from all samples collected from the same facility to ensure that results were not biased toward the concentrations found at facilities from which more than one sample were collected. Also, eight samples were excluded from the calculation of the overall TEQ averages because it was unclear as to whether they were duplicate samples from other POTWs. POTW average TEQ concentrations were calculated for 74 POTWs. If all nondetected values are assumed to be zero, then the overall study mean and median I-TEQ_{DF} concentrations were 47.7 and 33.4 ng I-TEQ_{DF}/kg (dry weight basis), respectively (standard deviation of 44.7 ng I-TEQ_{DF}/kg). The corresponding mean and median TEQ_{DF}-WHO_{98} concentrations were 36.3 and 25.5 ng TEQ_{DF}-WHO_{98}/kg, respectively (standard deviation of 38.6 ng TEQ_{DF}-WHO_{98}/kg). The mean and median results reported by Green et al. (1995) and Cramer et

al. (1995) are very similar in terms of total TEQ to those reported by EPA for samples collected 5 years earlier (U.S. EPA, 1996a; Rubin and White, 1992). The predominant congeners in both data sets are the octa- and hepta-CDDs and -CDFs. Although not present at high concentrations, 2,3,7,8-TCDF was commonly detected.

The CDD/CDF concentrations and congener group patterns observed in these two U.S. surveys are similar to the results reported for sewage sludges in several other Western countries. Stuart et al. (1993) reported mean CDD/CDF concentrations of 23.3 ng I-TEQ_{DF}/kg (dry weight) for three sludges from rural areas, 42.3 ng I-TEQ_{DF}/kg for six sludges from light industry/domestic areas, and 52.8 ng I-TEQ_{DF}/kg for six sludges from industrial/domestic areas collected during 1991-1992 in England and Wales. Näf et al. (1990) reported concentrations ranging from 31 to 40 ng I-TEQ_{DF}/kg (dry weight) in primary and digested sludges collected from the POTW in Stockholm, Sweden, during 1989. Gobran et al. (1995) reported an average concentration of 15.7 ng I-TEQ_{DF}/kg in anaerobically digested sludges from an industrial/domestic POTW in Ontario, Canada. In all three studies, the congener group concentrations increased with increasing degrees of chlorination, with OCDD the dominant congener. Figure 8-6 presents congener profiles, using the mean concentrations reported by Green et al. (1995).

Approximately 5.4 million dry metric tons of sewage sludge are estimated by EPA to be generated annually in the United States according to the results of the 1988/1989 EPA National Sewage Sludge Survey (Federal Register, 1993b). Table 8-31 lists the volume, by use and disposal practices, of sludge disposed of annually. More recent comprehensive survey data are not available to characterize sludge generation and disposal practices during 1995. For this reason, and because the mean I-TEQ_{DF} concentration values reported in the 1988/1989 survey (U.S. EPA, 1996a) and the 1995 survey (Green et al., 1995; Cramer et al., 1995) were very similar, the estimated amounts of TEQs that may have been present in sewage sludge and been released to the environment in 1987 and 1995 were assumed to be the same. These values, presented in Table 8-31, were estimated using the average (i.e., 49 ng I-TEQ_{DF}/kg) of the mean I-TEQ_{DF} concentration values (nondetected values set at detection limits) reported by EPA (1996a) (i.e., 50 ng I-TEQ_{DF}/kg) and by Green et al. (1995) and Cramer et al. (1995) (i.e., 47.7 ng I-TEQ_{DF}/kg). Multiplying this mean total TEQ concentration by the sludge volumes generated yields an annual potential total release of 204 g I-TEQ_{DF} or 151 g TEQ_{DF}-WHO_{98}

for nonincinerated sludges. Of this 204 g I-TEQ_{DF}, 3.5 g enter commerce as a product for distribution and marketing. The remainder is applied to land (103 g) or is landfilled (97 g). In units of TEQ_{DF}-WHO_{98}, the comparable estimates are 2.6 g to commerce, 76.6 g applied to land, and 71.7 g landfilled.

These release estimates are assigned a high confidence rating for both the production and emission factor estimates. The high rating was based on the judgment that the 174 facilities tested by EPA (U.S. EPA, 1996a) and the 74 facilities tested by Green et al. (1995) and Cramer et al. (1995) were reasonably representative of the variability in POTW technologies and sewage characteristics nationwide.

8.4.2. Drinking Water Treatment Plants

There is no strong evidence that chlorination of water for drinking purposes results in the formation of CDD/CDFs. Few surveys of CDD/CDF content in finished drinking water have been conducted. The few that have been published only rarely report the presence of any CDD/CDF even at low pg/L detection limits, and in those cases, the CDD/CDFs were also present in the untreated water.

Rappe et al. (1989b) reported the formation of CDFs (tetra- through octa-chlorinated CDFs) when tap water and double-distilled water were chlorinated using chlorine gas. The CDF levels found in the single samples of tap water and double-distilled water were 35 and 7 pg I-TEQ_{DF}/L, respectively. No CDDs were detected at detection limits ranging from 1 to 5 pg/L. However, the water samples were chlorinated at a dosage rate of 300 mg of chlorine per liter of water, which is considerably higher (by a factor of one to two orders of magnitude) than the range of dosage rates typically used to disinfect drinking water. Rappe et al. (1989b) hypothesized that the CDFs or their precursors are present in chlorine gas. Rappe et al. (1990a) analyzed a 1,500-liter sample of drinking water from a municipal drinking water treatment plant in Sweden. Although the untreated water was not analyzed, a sludge sample from the same facility was. The large sample volume enabled detection limits on the order of 0.001 pg/L. The TEQ content of the water and sludge was 0.0029 pg I-TEQ_{DF}/L and 1.4 ng/kg, respectively. The congener patterns of the drinking water and sludge sample were very similar, suggesting that the CDD/CDFs detected in the finished water were present in the untreated water.

8.4.3. Soaps and Detergents

As discussed in Section 8.4.1, CDD/CDFs were detected in nearly all sewage sludges tested, whether obtained from industrialized areas or rural areas. Because of the ubiquitous presence of CDD/CDFs in sewage sludge, several studies have been conducted to determine the source(s). A logical category of products to test, because of their widespread use are detergents, particularly those that contain or release chlorine during use (i.e., hypochlorite-containing and dichloroisocyanuric acid-containing detergents). The results of studies conducted to date, which are summarized below, indicate that CDD/CDFs are not formed during use of chlorine-free detergents, chlorine-containing or chlorine-releasing detergents, and chlorine bleach during household bleaching operations.

Sweden's Office of Nature Conservancy (1991) reported that the results of a preliminary study conducted at one household indicated that CDD/CDFs may be formed during use of dichloroisocyanurate-containing dishwasher detergents. A more extensive main study was then conducted using standardized food, dishes, cutlery, etc., and multiple runs. Testing of laundry washing and fabric bleaching, and actual testing of the CDD/CDF content of detergents, was also performed. The study examined (1) hypochlorite- and dichloroisocyanurate-containing dish-washing machine detergents; (2) sodium hypochlorite-based bleach (4.4 percent NaOCl) in various combinations with and without laundry detergent; and (3) sodium hypochlorite-based bleach, used at a high enough concentration to effect bleaching of a pair of imported blue jeans. CDD/CDFs were not detected in either the chlorine-free detergent or the detergent with hypochlorite; 0.6 pg TEQ/g was detected in the detergent containing dichloroisocyanurate. The results of all dish and laundry washing machine tests showed very low levels of CDD/CDFs, often nondetected values. There was no significant difference between the controls and test samples. In fact, the control samples contained higher TEQ content than some of the experimental samples. The drain water from the dish washing-machine tests contained <1.0 to <3.0 pg I-TEQ_{DF}/L (the water-only control sample contained <2.8 pg I-TEQ_{DF}/L). The CDD/CDF content of the laundry drain water samples ranged from <1.1 to <4.6 pg I-TEQ_{DF}/L (the water-only control sample contained <4.4 pg I-TEQ_{DF}/L).

Thus, under the test conditions examined by Sweden's Office of Nature Conservancy (1991), CDD/CDFs are not formed during dish washing and laundry washing nor during bleaching with hypochlorite-containing bleach. No definitive reason could be

found to explain the difference in results between the preliminary study and the main study for dish washing with dichloroisocyanurate-containing detergents. The authors of the study suggested that differences in the foods used and the prewashing procedures employed in the two studies were the likely causes of the variation in the results.

Rappe et al. (1990c) analyzed a sample of a Swedish commercial soft soap, as well as a sample of tall oil and a sample of tall resin, for CDD/CDF content. Tall oil and tall resin, by-products of the pulping industry, are the starting materials for the production of soft, liquid soap. Crude tall oil, collected after the Kraft pulping process, is distilled under reduced pressure at temperatures of up to 280-290°C, yielding tall oil and tall resin. The measured TEQ content of the liquid soap was 0.447 ng I-TEQ_{DF}/L (0.647 ng TEQ_{DF}-WHO_{98}/L). PeCDDs were the dominant congener group followed by HpCDDs, HxCDDs, PeCDFs, and OCDD with some tetra-CDFs and -CDDs also present. The TEQ content of the tall oil (9.4 ng I-TEQ_{DF}/kg, or 12.0 ng TEQ_{DF}-WHO_{98}/kg) and tall resin (200 ng I-TEF_{DF}/kg, 196 ng TEQ_{DF}-WHO_{98}/kg) was significantly higher than the level found in the liquid soap. The tall oil contained primarily tetra- and penta-CDDs and -CDFs, while the tall resin contained primarily HpCDDs, HxCDDs, and OCDD. Rappe et al. (1990c) compared the congener patterns of the three samples and noted that although the absolute values for the tetra- and penta-CDDs and -CDFs differed between the tall oil, tall resin and liquid soap samples, the same congeners were present in the samples. The congener patterns for the more chlorinated congeners were very similar. Table 8-32 presents the results reported by Rappe et al. (1990c).

In 1987, 118 million liters of liquid household soaps were shipped in the United States (U.S. DOC, 1990b); shipment quantity data are not available for liquid household soap in the 1992 U.S. Economic Census (U.S. DOC, 1996). Because only one sample of liquid soap has been analyzed for CDD/CDF content (Rappe et al., 1990c), only a very preliminary estimate of the annual release of CDD/CDF TEQ from liquid soap can be made. If it is assumed that an average 118 million liters of liquid soap contain 0.447 ng I-TEQ_{DF}/L (0.647 ng TEQ_{DF}-WHO_{98}/L), then the resulting estimate is 0.05 g I-TEQ_{DF}/yr (0.08 g TEQ_{DF}-WHO_{98}/yr).

8.4.4. Textile Manufacturing and Dry Cleaning

As discussed in Section 8.4.1, CDD/CDFs have been detected in nearly all sewage sludges tested, whether obtained from industrialized areas or rural areas. To determine if the textile fabric or fabric finishing processes could account for the observed CDD/CDFs, several studies were conducted in Germany. These studies, summarized in the following paragraphs, indicate that some finished textile products do contain detectable levels of CDD/CDFs and that these CDD/CDFs can be released from the textile during laundering or dry cleaning; however, textile finishing processes are typically not sources of CDD/CDF formation. Rather, the use of CDD/CDF-containing dyes and pigments and the use in some countries of pentachlorophenol to treat unfinished cotton appear to be the sources of the detected CDD/CDFs.

Horstmann et al. (1993b) analyzed the CDD/CDF content of eight different raw (unfinished) cotton cloths containing fiber from different countries and five different white synthetic materials (acetate, viscose, bleached polyester, polyamide, and polyacrylic). The maximum concentrations found in the textile fabrics were 30 ng/kg in the cotton products and 45 ng/kg in the synthetic materials. Also, a cotton finishing scheme was developed that subjected one of the cotton materials to a series of 16 typical cotton finishing processes; one sample was analyzed following each step. The fabric finishing processes showing the greatest effect on CDD/CDF concentration were the application of an indanthrene dye and the "wash and wear" finishing process, which together resulted in a CDD/CDF concentration of about 100 ng/kg. On the basis of the concentrations found, the authors concluded that neither unfinished new fabrics nor common cotton finishing processes can explain the CDD/CDF levels found in laundry wastewater.

Fuchs et al. (1990) reported that dry-cleaning solvent redistillation residues that were collected from 12 commercial and industrial dry-cleaning operations contained considerable amounts of CDD/CDFs. The reported I-TEQ_{DF} content ranged from 131 to 2,834 ng/kg, with the dominant congeners always OCDD and the HpCDDs. Towara et al. (1992) demonstrated that neither the use of chlorine-free solvents nor variation of the dry-cleaning process parameters lowered the CDD/CDF content of the residues.

Umlauf et al. (1993) conducted a study to characterize the mass balance of CDD/CDFs in the dry-cleaning process. The soiled clothes (containing 16 pg total CDD/CDF per kg) accounted for 99.996 percent of the CDD/CDF input. Input of CDD/CDF

from indoor air containing 0.194 pg/m^3 accounted for the remainder (i.e., 0.004 percent). The dry-cleaning process removed 82.435 percent of the CDD/CDF in the soiled clothing. Most of the input CDD/CDF (82.264 percent) was found in the solvent distillation residues. Air emissions (at 0.041 pg/m^3) accounted for 0.0008 percent of the total input, which was less than the input from indoor air. The fluff (at a concentration of 36 ng/kg) accounted for 0.1697 percent, and water effluent (at a concentration of 0.07 pg/L) accounted for 0.0000054 percent.

Horstmann and McLachlan (1994a, 1994b, 1995) analyzed 35 new textile samples (primarily cotton products) obtained in Germany for CDD/CDFs. Low levels were found in most cases (total CDD/CDF less than 50 ng/kg). The dominant congeners found were OCDD and the HpCDDs. However, several colored T-shirts from a number of clothing producers had extremely high levels, with concentrations up to 290,000 ng/kg. Because the concentrations in identical T-shirts purchased at the same store varied by up to a factor of 20, the authors concluded that the source of CDD/CDFs is not a textile finishing process, because a process source would have resulted in a more consistent level of contamination. Klasmeier and McLachlan (1995) subsequently analyzed 68 new textile products obtained in Germany for OCDD and OCDF. Most samples had nondetectable levels (42 samples $<$60 ng/kg). Only four samples had levels exceeding 500 ng/kg.

Horstmann and McLachlan (1994a, 1994b) reported finding two different congener group patterns in the more contaminated of the 35 textile products. One pattern agreed with the congener pattern for PCP reported by Hagenmaier and Brunner (1987), while the other pattern was similar to that reported by Remmers et al. (1992) for chloranil-based dyes. The authors hypothesize that the use of PCP to preserve cotton, particularly when it is randomly strewn on bales of cotton as a preservative during sea transport, is the likely source of the high levels occasionally observed. Although the use of PCP for nonwood uses was prohibited in the United States in 1987 (see Section 8.3.8), PCP is still used in developing countries, especially to preserve cotton during sea transport (Horstmann and McLachlan, 1994a).

Horstmann and McLachlan (1994a, 1994b) conducted additional experiments that demonstrated that the small percentage of clothing items with high CDD/CDF levels could be responsible for the quantity of CDD/CDFs observed in household wastewater. They demonstrated that the CDD/CDFs can be gradually removed from the fabric during

washing, can be transferred to the skin and subsequently transferred back to other textiles and then washed out, or can be transferred to other textiles during washing and then removed during subsequent washings.

NR = Not reported.
g/year = grams per year

[a] The total discharge rate of congener or TEQ (based only on 2,3,7,8-TCDD and 2,3,7,8-TCDF concentration) was summed across all 104 mills. 104-Mill Study (U.S. EPA, 1990a).

[b] The total discharge rate of congener or TEQ (based only on 2,3,7,8-TCDD and 2,3,7,8-TCDF concentration) was summed across all 104 mills. The daily discharge rates reported in NCASI (1993), Gillespie (1994), and Gillespie (1995) were multiplied by a factor of 350 days/yr to obtain estimates of annual discharge rates. NCASI 1992 Survey (NCASI, 1993), 1993 Update (Gillespie, 1994), and 1994 Update (Gillespie, 1995).

[c] The discharges in effluent and sludge were estimated in U.S. EPA (1993d; 1997f) for January 1, 1993. The TEQ discharge in pulp was estimated by multiplying the 1988 discharge estimate by the ratio of the 1993 and 1988 effluent discharge estimates (i.e., the estimate of the reduction in 1988 discharges achieved by pollution prevention measures taken by the industry between 1988 and 1993).

[d] Approximately 20.5 percent of the sludge generated in 1990 were incinerated. The remaining 79.5 percent were predominantly landfilled (56.5 percent) or placed in surface impoundments (18.1 percent); 4.1 percent were land-applied directly or as compost, and 0.3 percent were distributed/marketed (U.S. EPA, 1993e).

[e] The discharges in effluent and sludge were estimated in U.S. EPA (1997f) for mid-1995. The TEQ discharge in pulp was estimated by multiplying the 1988 discharge estimate by the ratio of the 1995 and 1988 effluent discharge estimates (i.e., the estimate of the reduction in 1988 discharges achieved by pollution prevention measures taken by industry between 1988 and 1995).

Table 8-9. Summary of Specific Dioxin-Containing Wastes That Must Comply with Land Disposal Retrictions

EPA Hazardous Waste Number	Waste Description	Land Disposal Restriction Effective Date	Regulated Waste Constituent	Treatment Standard[a] (ppb)	
				Wastewaters (μg/L)	Nonwastewaters (μg/kg)
F020	Wastes (except wastewater and spent carbon from hydrogen chloride purification) from the production or manufacturing use (as a reactant, chemical intermediate, or component in a formulating process) of tri- or tetrachlorophenol, or of intermediates used to produce their pesticide derivatives. (This listing does not include wastes from the production of hexachlorophene from highly purified 2,4,5-trichlorophenol.)	November 8, 1988	TCDDs PeCDDs HxCDDs TCDFs PeCDFs HxCDFs	0.063 0.063 0.063 0.063 0.035 0.063	1 1 1 1 1 1
F021	Wastes (except wastewater and spent carbon from hydrogen chloride purification) from the production or manufacturing use (as a reactant, chemical intermediate, or component in a formulating process) of pentachlorophenol, or of intermediates used to produce its derivatives.	November 8, 1988	TCDDs PeCDDs HxCDDs TCDFs PeCDFs HxCDFs	0.063 0.063 0.063 0.063 0.035 0.063	1 1 1 1 1 1
F022	Wastes (except wastewater and spent carbon from hydrogen chloride purification) from the manufacturing use (as a reactant, chemical intermediate, or component in a formulating process) of tetra-, penta-, or hexachlorobenzenes under alkaline conditions.	November 8, 1988	TCDDs PeCDDs HxCDDs TCDFs PeCDFs HxCDFs	0.063 0.063 0.063 0.063 0.035 0.063	1 1 1 1 1 1
F023	Wastes (except wastewater and spent carbon from hydrogen chloride purification) from the production of materials on equipment previously used for the production or manufacturing use (as a reactant, chemical intermediate, or component in a formulating process) of tri- and tetrachlorophenols. (This listing does not include wastes from equipment used only for the production or use of hexachlorophene from highly purified 2,4,5-trichlorophenol.)	November 8, 1988	TCDDs PeCDDs HxCDDs TCDFs PeCDFs HxCDFs	0.063 0.063 0.063 0.063 0.035 0.063	1 1 1 1 1 1
F026	Wastes (except wastewater and spent carbon from hydrogen chloride purification) from the production of materials on equipment previously used for the manufacturing use (as a reactant, chemical intermediate, or component in a formulating process) of tetra-, penta-, or hexachlorobenzene under alkaline conditions.	November 8, 1988	TCDDs PeCDDs HxCDDs TCDFs PeCDFs HxCDFs	0.063 0.063 0.063 0.063 0.035 0.063	1 1 1 1 1 1
F027	Discarded unused formulations containing tri-, tetra-, or pentachlorophenol or discarded unused formulations containing compounds derived from these chlorophenols. (This listing does not include formulations containing hexachlorophene synthesized from prepurified 2,4,5-trichlorophenol as the sole component.)	November 8, 1988	TCDDs PeCDDs HxCDDs TCDFs PeCDFs HxCDFs	0.063 0.063 0.063 0.063 0.035 0.063	1 1 1 1 1 1

Table 8-9. Summary of Specific Dioxin-Containing Wastes That Must Comply with Land Disposal Retrictions (continued)

EPA Hazardous Waste Number	Waste Description	Land Disposal Restriction Effective Date	Regulated Waste Constituent	Treatment Standard[a] (ppb)	
				Wastewaters (μg/L)	Nonwastewaters (μg/kg)
F028	Residues resulting from the incineration or thermal treatment of soil contaminated with EPA Hazardous Waste Nos. F020-F023, F026, and F027	November 8, 1988	TCDDs PeCDDs HxCDDs TCDFs PeCDFs HxCDFs	0.063 0.063 0.063 0.063 0.035 0.063	1 1 1 1 1 1
F039	Leachate (liquids that have percolated through land disposed wastes) resulting from the disposal of more than one restricted waste classified as hazardous under subpart D of 40 CFR 268. (Leachate resulting from the disposal of one or more of the following EPA Hazardous Wastes and no other Hazardous Wastes retains its EPA Hazardous Waste Number(s): F020, F021, F022, F026, F027, and/or F028.)	August 8, 1990 (wastewater) May 8, 1992 (non-wastewater)	TCDDs PeCDDs HxCDDs TCDFs PeCDFs HxCDFs	0.063 0.063 0.063 0.063 0.035 0.063	1 1 1 1 1 1
K043	2,6-dichlorophenol waste from the production of 2,4-D.	June 8, 1989	TCDDs PeCDDs HxCDDs TCDFs PeCDFs HxCDFs	0.063 0.063 0.063 0.063 0.035 0.063	1 1 1 1 1 1
K099	Untreated wastewater from the production of 2,4-D.	August 8, 1988	TCDDs PeCDDs HxCDDs TCDFs PeCDFs HxCDFs	0.063 0.063 0.063 0.063 0.035 0.063	1 1 1 1 1 1

[a] Treatment standards (i.e., maximum allowable concentration in waste extract) are based on incineration to 99.9999 percent destruction and removal efficiency.

μg/L = micrograms per liter
μg/kg = micrograms per kilogram

ND = Not detected.

a Method detection limits (MDLs) for individual samples were less than 10 pg/L for all congeners and congener groups except OCDD and OCDF, which had MDLs less than 50 pg/L.

b Dry weight basis.

c MDLs for all congeners were less than 150 ng/kg, and usually were less than 10 ng/kg.

nd = Not detected.

ng/kg = nanograms per kilogram

a Method detection limits (MDLs) for individual samples were less than 2 ng/kg for all congeners and congener groups except OCDD and OCDF, which had MDLs less than 6 ng/kg.

b Two of these 22 samples were duplicate samples from two sites. The results were averaged and treated as one sample for each site.

c MDLs for individual samples were less than 2 ng/kg for all congeners and congener groups except OCDD and OCDF, which had MDLs less than 4 ng/kg.

d "Sales" EDC is defined as EDC sold commercially for non-VCM uses or exported from the United States.

e MDLs were less than 1 ng/kg for all congeners in all samples.

Table 8-18. Chemicals Requiring TSCA Section 4 Testing under the Dioxin/Furan Rule

Currently Manufactured or Imported as of June 5, 1987[a]	
CAS No.	Chemical Name
79-94-7	Tetrabromobisphenol-A
118-75-2	2,3,5,6-Tetrachloro-2,5-cyclohexadiene-1,4-dione
118-79-6	2,4,6-Tribromophenol
120-83-2	2,4-Dichlorophenol
1163-19-5	Decabromodiphenyloxide
4162-45-2	Tetrabromobisphenol-A-bisethoxylate
21850-44-2	Tetrabromobisphenol-A-bis-2,3-dibromopropylether [a]
25327-89-3	Allyl ether of tetrabromobisphenol-A
32534-81-9	Pentabromodiphenyloxide
32536-52-0	Octabromodiphenyloxide
37853-59-1	1,2-Bis(tribromophenoxy)-ethane
55205-38-4	Tetrabromobisphenol-A-diacrylate [a]
Not Currently Manufactured or Imported as of June 5, 1987[b]	
CAS No.	Chemical Name
79-95-8	Tetrachlorobisphenol-A
87-10-5	3,4',5-Tribromosalicylanide
87-65-0	2,6-Dichlorophenol
95-77-2	3,4-Dichlorophenol
95-95-4	2,4,5-Trichlorophenol
99-28-5	2,6-Dibromo-4-nitrophenol
120-36-5	2[2,4-(Dichlorophenoxy)]-propanoic acid
320-72-9	3,5-Dichlorosalicyclic acid
488-47-1	Tetrabromocatechol
576-24-9	2,3-Dichlorophenol
583-78-8	2,5-Dichlorophenol
608-71-9	Pentabromophenol
615-58-7	2,4-Dibromophenol
933-75-5	2,3,6-Trichlorophenol
1940-42-7	4-Bromo-2,5-dichlorophenol
2577-72-2	3,5-Dibromosalicylanide
3772-94-9	Pentachlorophenyl laurate
37853-61-5	Bismethylether of tetrabromobisphenol-A
-	Alkylamine tetrachlorophenate
-	Tetrabromobisphenol-B

[a] Tetrabromobisphenol-A-bis-2,3-dibromopropylether and tetrabromobisphenol-A-diacrylate are no longer manufactured in or imported into the United States (Cash, 1993).

[b] As of August 5, 1995, neither manufacture nor importation of any of these chemicals had resumed in the United States (Holderman, 1995).

				TOTAL[c]	5.60
				I-TEQ_{DF}	0.70
				TEQ_{DF}-WHO_{98}	1.10

[a] Limit of quantitation required by EPA in the Data Call-In.

[b] Average of the mean results for multiple analyses of four technical 2,4-D and/or 2,4-D ester products for which detectable CDD/CDF congener concentrations less than the LOQs were quantified; not-detected values were assumed to be zero.

[c] Total equals the sum of the individual congener averages.

μg/kg = micrograms per kilogram

-- = Analyses not performed.

Table 8-26. Summary of Analytical Data Submitted to EPA in Response to Pesticide Data Call-Ins

Shaughnessey Code	Pesticide		Number of Positive Submissions[a] to Date
	Common Name	Chemical Name	
019201	MCPB, 4-butyric acid	4-(2-methyl-4-chlorophenoxy)butyric acid	0
019401	4-CPA	4-Chlorophenoxyacetic acid	0
027401	Dichlobenil	2,6-Dichlorobenzonitrile	0
029801	Dicamba	3,6-Dichloro-o-anisic acid	0
029802	Dicamba, dimethylamine	3,6-Dichloro-o-anisic acid, dimethylamine salt	0
030001	2,4-D	2,4-Dichlorophenoxy acetic acid	2
030063	2,4-D, 2EH	Isooctyl(2-ethylhexyl)2,4-dichlorophenoxyacetate	1
030801	2,4-DB	4-(2,4-Dichlorophenoxy)butyric acid	0
031301	DCNA	2,6-Dichloro-4-nitroaniline	Pending
031401	2,4-DP	2-(2,4-Dichlorophenoxy)propionic acid	0
031501	Mecoprop (MCPP)	2-(2-methyl-4-chlorophenoxy)propionic acid	0
035301	Bromoxynil	3,5-Dibromo-4-hydroxybenzonitrile	0
054901	Irgasan	5-Chloro-2-(2,4-dichlorophenoxy)phenol	0
078701	Dacthal (DCPA)	Dimethyl tetrachloroterephthalate	Pending
081901	Chlorothalonil	Tetrachloroisophthalonitrile	Pending
083701	Tetrachlorvinphos	2-Chloro-1-(2,4,5-trichlorophenyl)vinyl dimethyl phosphate	0
108201	Diflubenzuron	N-(((4-chlorophenyl)amino)carbonyl)-2,6-difluorobenzamide	0
109001	Oxadiazon	2-Tert-butyl-4(2,4-dichloro-5-isopropoxyphenyl)-delta2-1,3,4-oxadiazoline-5-one	Pending
110902	Dichlofop-methyl	Methyl-2-(4-(2,4-dichlorophenoxy)phenoxy) propanoate	0

[a] "Positive" is defined as the detection of any congener at a concentration equal to or exceeding the LOQs listed in Table 8-24.

Sources: U.S. EPA (1995a); personal communication with S. Funk (EPA/OPP/HED) on March 27, 1996.

Total 2,3,7,8-CDD/CDF		73,520	7,916	7,881	14,110 (14,390)	13,880 (14,200)
Average TEQ_{DF}-WHO_{98} (facility basis)[b]			44.6	25.5	57.2 (44.4)	36.3 (38.6)

[a] Values in parentheses are standard deviations.

[b] For POTWs with multiple samples, the sample TEQ concentrations were averaged to POTW averages before calculation of the total TEQ mean and median values presented in the table. A total of 74 POTW average concentrations were used in the calculations. In addition, the following sample ID numbers were not included in the averaging because, according to Green et al. (1995), it was not possible to determine if they were duplicate or multiple samples from other POTWs: 87, 88, 89, 90, 91, 97, 98, and 106.

Source: Green et al. (1995); Cramer et al. (1995).

Table 8-31. Quantity of Sewage Sludge Disposed of Annually by Primary, Secondary, or Advanced Treatment POTWs and Potential Dioxin TEQ Releases

Use/Disposal Practice	Volume Disposed (thousands of dry metric tons/year)	Percent of Total Volume	Potential Dioxin Release[c] (g of TEQ/yr)	
			$I\text{-}TEQ_{DF}$	$TEQ_{DF}\text{-}WHO_{98}$
Land Application	1,714	32.0[e]	84.0	62.2
Distribution and Marketing	71	1.3	3.5	2.6
Surface Disposal Site/Other	396	7.4	19.4	14.4
Sewage Sludge Landfill	157	2.9	7.7	5.7
Co-disposal Landfills[a]	1,819	33.9	89.1	66.0
Sludge Incinerators and Co-incinerators[b]	865	16.1	(f)	(f)
Ocean Disposal	(336)[d]	(6.3)[d]	(0)[d]	(0)[d]
TOTAL	5,357	100.0	204.0	151.0

[a] Landfills used for disposal of sewage sludge and solid waste residuals.

[b] Co-incinerators treat sewage sludge in combination with other combustible waste materials.

[c] Potential dioxin TEQ release for nonincinerated sludges was estimated by multiplying the sludge volume generated (i.e., column 2) by the average of the mean $I\text{-}TEQ_{DF}$ concentrations in sludge reported by Rubin and White (1992) (i.e., 50 ng/kg dry weight) and Green et al. (1995) and Cramer et al. (1995) (i.e., 47.7 ng/kg). The calculations of $TEQ_{DF}\text{-}WHO_{98}$ used the mean concentration of 36.3 ng $TEQ_{DF}\text{-}WHO_{98}$/kg for the results reported by Green et al. (1995) and Cramer et al. (1995).

[d] The Ocean Dumping Ban Act of 1988 generally prohibited the dumping of sewage sludge into the ocean after December 31, 1991. Ocean dumping of sewage sludge ended in June 1992 (Federal Register, 1993b). The current method of disposal of the 336,000 metric tons of sewage sludge that were disposed of in the oceans in 1988 has not been determined.

[e] Includes 21.9 percent applied to agricultural land, 2.8 percent applied as compost, 0.6 percent applied to forestry land, 3.1 percent applied to "public contact" land, 1.2 percent applied to reclamation sites, and 2.4 percent applied in undefined settings.

[f] See Section 3.6.5 for estimates of CDD/CDF releases to air from sewage sludge incinerators.

9. BIOLOGICAL SOURCES OF CDD/CDF

Recent laboratory and field research studies demonstrate that biochemical formation of CDD/CDFs from chlorophenol precursors is possible. In addition, under certain conditions, some CDD/CDFs can be biodegraded to form less chlorinated (and possibly more toxic) CDD/CDFs. Both of these mechanisms are discussed in this chapter. However, the extent to which CDD/CDFs are formed by either mechanism in the environment is not known at present.

The origin of CDD/CDFs that were recently discovered in ball clay deposits is not yet determined, and natural occurrence is still considered a possibility. Chapter 13 discusses this topic in detail.

9.1. BIOTRANSFORMATION OF CHLOROPHENOLS

Biochemical formation of CDD/CDFs, particularly the higher chlorinated congeners, from chlorophenol precursors is possible, as indicated by laboratory studies with solutions of trichlorophenols and pentachlorophenol (PCP) in the presence of peroxidase enzymes and hydrogen peroxide (Svenson et al., 1989; Oberg et al., 1990; Wagner et al., 1990; Oberg and Rappe, 1992; Morimoto and Kenji, 1995) and with sewage sludge spiked with PCP (Oberg et al., 1992). However, the extent to which CDD/CDFs are formed in the environment via this mechanism cannot be estimated at this time.

In 1991, Lahl et al. (1991) reported finding CDD/CDFs in all 22 samples of various types of composts analyzed. The hepta- and octa-substituted CDDs and CDFs were typically the dominant congener groups found. The I-TEQ_{DF} content of the composts ranged from 0.8 to 35.7 ng I-TEQ_{DF}/kg. The CDD/CDFs found in compost may be primarily the result of atmospheric deposition onto plants that are subsequently composted but may also be caused by uptake of CDD/CDFs from air by the active compost (Krauss et al., 1994). Similarly, CDD/CDFs are frequently detected in sewage sludges. The CDD/CDFs found in sewage sludge may be primarily from the sources identified in Section 8.4.1.

Peroxidases are common enzymes in nature. For example, the initial degradation of the lignin polymer by white- and brown-rot fungi is peroxidase catalyzed (Wagner et al., 1990). The conversion efficiency of chlorinated phenols to CDD/CDFs that has been

observed is low. In the solution studies, Oberg and Rappe (1992) reported a conversion efficiency of PCP to OCDD of about 0.01 percent, Morimoto and Kenji (1995) reported a conversion efficiency of PCP to OCDD of 0.8 percent, and Wagner et al. (1990) reported a conversion efficiency of trichlorophenol to HpCDD of about 0.001 percent. Oberg et al. (1990) reported a conversion efficiency of trichlorophenols to CDD/CDFs of about 0.001 percent. In their sewage sludge study, Oberg et al. (1992) reported a conversion efficiency of PCP to total CDDs of 0.0002 to 0.0004 percent.

Several researchers recently conducted both laboratory and field studies in an attempt to better understand the extent of and factors affecting the fate or formation of CDD/CDFs in composts and sewage sludges. The findings of several of these studies are discussed in the following paragraphs. The findings are not always consistent, the congener profiles and patterns detected, and the extent, if any, of CDD/CDF "formation," may vary with the compost materials studied, differences in experimental or field composting design, and duration of the studies.

Harrad et al. (1991) analyzed finished composts and active compost windrows from a municipally operated yard-waste composting facility in Long Island, New York. Concentrations measured in 12 finished composts ranged from 14 to 41 ng I-TEQ_{DF}/kg (mean of 3 ng I-TEQ_{DF}/kg). The concentrations in the five active compost samples (1 to 30 days in age) ranged from 7.7 to 54 ng I-TEQ_{DF}/kg (mean of 21 ng I-TEQ_{DF}/kg). The authors observed that CDD/CDF concentrations measured in two soil samples from the immediate vicinity of the composting facility were significantly lower (1.0 and 1.3 ng I-TEQ_{DF}/kg) than the levels found in the composts, suggesting that the source(s) of CDD/CDFs in the composts was different than the source(s) affecting local soils. The authors also noted a strong similarity between the congener profiles observed in the composts and the congener profile of a PCP formulation (i.e., predominance of 1,2,4,6,8,9-HxCDF and 1,2,3,4,6,8,9-HpCDF in their respective congener groups), which indicated to the authors that leaching of CDD/CDFs from PCP-treated wood in the compost piles was the likely source of the observed CDD/CDFs. The levels of PCP in the 12 finished composts ranged from 7 to 190 μg/kg (mean of 33 μg/kg), and the PCP levels in the active compost samples ranged from 17 to 210 μg/kg (mean of 68 μg/kg). The PCP level in both soil samples was 1.5 μg/kg.

Goldfarb et al. (1992) and Malloy et al. (1993) reported the results of testing of composts at three municipal yard-waste composting facilities (5 to 91 ng I-TEQ_{DF}/kg; mean of 30 ng I-TEQDF/kg), two municipal solid waste composting facilities (19 to 96 ng I-TEQ_{DF}/kg; mean of 48 ng I-TEQ_{DF}/kg), and one municipal facility composting solid waste and dewatered sewage sludge (37 to 87 ng I-TEQ_{DF}/kg; mean of 56 ng I-TEQ_{DF}/kg). All facilities were located in the United States. Two general trends were observed. First, an increase in analyte levels was observed, with an increasing degree of chlorination for each compound type (i.e., CDDs, CDFs, chlorophenols, and chlorobenzenes). Second, an increase in concentration of each congener or homologue group, with a progression from yard waste to solid waste to solid waste/sewage sludge composts, was observed. As noted above, TEQ concentrations showed this same trend, which was primarily due to increasing levels of 1,2,3,4,6,7,8-HpCDD and OCDD. The mean PCP concentrations in the three compost types were 20 μg/kg (yard waste), 215 μg/kg (solid waste), and 615 μg/kg (solid waste/sewage sludge). Comparison of congener profiles by the authors indicated that the CDD/CDF residue in PCP-treated wood in the compost feedstock was a major but not exclusive contributor of the observed CDD/CDFs. The authors postulated that biological formation of HxCDDs, HpCDDs, and OCDD from chlorophenols (tri-, tetra-, and penta-) in the compost could be responsible for the elevated levels of these congener groups relative to their presence in PCP.

Oberg et al. (1993) measured the extent of CDD/CDF formation in three conventional garden composts; two were spiked with PCP, and one was spiked with hexachlorobenzene. The two PCP-spiked composts were monitored for periods of 55 days and 286 days, respectively. A significant increase in the concentrations of the higher chlorinated congeners, particularly the HpCDDs, OCDD, and, to a lesser extent, OCDF, were observed. Similar results were reported for the hexachlorobenzene-spiked compost, which was monitored for a period of 49 days. Oberg et al. (1993) state that for a "typical" composting event, a two- to threefold increase in TEQ content corresponds to an elevation by 0.2 to 0.5 ng I-TEQ_{DF}/kg dry weight.

Weber (1995) subjected sewage sludges from two German communities to anaerobic digestion in laboratory reactors for 60 days. The two sludges were spiked with 2,3,5-trichlorophenol (10 to 25 mg/kg), a mixture of 2,3,5-trichlorophenol and dichlorophenols (2.5 to 25 mg/kg), or a mixture of di-, tri-, and tetrachlorobenzenes (4 to

40 mg/kg). In nearly all of the digestion experiments, the addition of these precursors did not lead to any significant changes in CDD/CDF concentrations. The initial CDD/CDF concentrations in the two sludges were 9 and 20 ng I-TEQ_{DF}/kg. The only exceptions were increased 2,3,7,8-TCDF concentrations in the mixed chlorophenol experiments and decreased 2,3,7,8-TCDF concentrations in the mixed chlorobenzene experiments. However, the same increases or decreases for this congener were also observed in the controls (i.e., no precursors added).

Researchers at the U.S. Department of Agriculture (USDA) (Fries et al., 1997) reported that dairy cows that were fed PCP-treated wood excreted OCDD in amounts almost four times what they ingested. Feil and Tiernan (1997) reported that rats fed technical PCP had liver concentrations of HxCDD, HpCDD, HpCDF, OCDD, and OCDF two to three orders of magnitude higher than rats fed purified PCP. These results suggest the in vivo formation of CDD/CDFs from pre-dioxins (i.e., chlorinated phenoxy phenols present as contaminants in the PCP). A followup USDA study (Huwe et al., 1998) investigated the metabolic conversion of a pre-dioxin (monochloro-2-phenoxyphenol) to OCDD in a feeding study with rats. The results of the study demonstrate the formation of OCDD from the pre-dioxin, although the conversion was estimated to be less than 2 percent. Interestingly, the study noted that the presence of added OCDD in the feed material increased the percentage of pre-dioxin conversion.

Wittsiepe et al. (1998) demonstrated that CDD/CDF can be formed through reaction of chlorophenols with myeloperoxidase (a component of neutrophile granulocytes, a subgroup of human leucocytes). The CDD/CDFs formed showed different homologue patterns and formation rates depending upon the degree of chlorination of the chlorophenol substrate. The formation rates ranged from 1 to 16 u mol of CDD/CDF per mole of chlorophenol substrate.

9.2. BIOTRANSFORMATION OF HIGHER CDD/CDFS

Results of several recent studies examining the fate of a range of CDD/CDF congeners in pure cultures, sediments, and sludges indicate that under certain conditions some CDD/CDF congeners will undergo biodegradation to form less chlorinated (and possibly more toxic) CDD/CDFs. However, the extent to which more toxic CDD/CDFs are formed in the environment via this mechanism cannot be estimated at this time. The

following paragraphs discuss studies that examined the products of biodegradation in sediments, compost, and sewage sludge.

Several recent reports indicate that CDDs and CDFs may undergo microbial dechlorination in anaerobic sediments. Adriaens and Grbic-Galic (1992; 1993) and Adriaens et al. (1995) reported the results of a series of microcosm studies using Hudson River sediment (contaminated with Aroclor 1242) and aquifer material (contaminated with CDDs) from Pensacola, Florida. Both types of substrates were spiked with several CDDs (1,2,3,4,6,7,8-HpCDD; 1,2,3,4,7,8-HxCDD; and 1,2,4,6,8,9-/1,2,4,6,7,9-HxCDD) and CDFs (1,2,3,4,6,7,8-HpCDF and 1,2,4,6,8-PeCDF) and monitored over a 16-month period, at an incubation temperature of 30°C. The Hudson River sediment was spiked with 144 μg/kg of each congener, and the Pensacola aquifer material was spiked with 63 μg/kg of each congener.

All of the congeners, with the exception of 1,2,3,4,6,7,8-HpCDF, showed a slow decrease in concentration over time, attributed to biologically mediated reductive dechlorination, with net disappearance rates ranging from 0.0031 $week^{-1}$ to 0.0175 $week^{-1}$ (i.e., half-lives of approximately 1 to 4 years). However, Adriaens et al. (1995) conclude that the actual half-lives may be orders of magnitude higher. The experiment with 1,2,3,4,6,7,8-HpCDD yielded formation of two HxCDDs (1,2,3,4,7,8- and 1,2,3,6,7,8-). Thus, removal of the peri-substituted (1,4,6,9) chlorines was favored, with enrichment of 2,3,7,8-substituted congeners. No lesser chlorinated congeners were identified from incubation with the other tested congeners. 1,2,4,6,8-PeCDF was also examined in dichlorophenol-enriched cultures. After 6 months incubation, several TCDFs were identified, which also indicated that peri-dechlorination was the preferred route of reduction.

Barkovskii and Adriaens (1995, 1996) reported that 2,3,7,8-TCDD (extracted from Passaic River sediments) was susceptible to reductive dechlorination when incubated at 30°C under methanogenic conditions in a mixture of aliphatic and organic acids inoculated with microorganisms obtained from Passaic River sediments. The initial concentration of 2,3,7,8-TCDD (20 $\pm$ 4 μg/L) decreased by 30 percent to 14 $\pm$ 2 μg/L over a period of 7 months with the consecutive appearance and disappearance of tri-, di-, and mono-CDDs. Experiments were also conducted by spiking the sediment with HxCDDs, HpCDDs, and OCDD. Up to 10 percent of the spiked OCDD was converted to hepta-, hexa-, penta-,

tetra-, tri-, di-, and monochlorinated isomers, but the reaction stoichiometry was not determined. Two distinct pathways of dechlorination were observed: the *peri*-dechlorination pathway of 2,3,7,8-substituted hepta- to penta-CDDs, resulting in the production of 2,3,7,8-TCDD, and the *peri*-lateral dechlorination pathway of non-2,3,7,8-substituted congeners.

Several studies reported that CDD/CDFs can be formed during composting operations through biological action on chlorophenols present in the compost feed material. The results of studies that specify likely involvement of chlorophenols are described in Section 9.1. Another possible formation mechanism was suggested by Vikelsoe et al. (1994), who reported that higher chlorinated CDD/CDF congeners are formed when humic acid is reacted with a peroxidase enzyme, hydrogen peroxide, and sodium chloride. It is expected that some organic material in compost and sewage sludge has a humic-like structure. Several additional studies are described below in which the potential involvement of chlorophenols could not be assessed because chlorophenol concentrations in the composts were not reported.

Schäfer et al. (1993) monitored the seasonal changes in the CDD/CDF content, as well as the extent of CDD/CDF formation, in the composts from a vegetable and garden waste composting operation in Germany. Finished compost samples were collected and analyzed every 2 months for 1 year. An annual cycle was observed in TEQ concentrations, with peak concentrations in the summer (approximately 8.5 ng I-TEQ_{DF}/kg) that were 2.5 times higher than the lowest concentrations observed in the winter (approximately 3.5 ng I-TEQ_{DF}/kg). No seasonal source was apparent that could explain the observed differences in seasonal levels. The CDD/CDF contents of the starting waste materials for two compost cycles (March and September) were measured to monitor the extent of CDD/CDF formation during composting. For the March cycle sample, most 2,3,7,8-substituted CDD/CDF congeners decreased in concentration during composting. Four CDF congeners showed a slight increase in concentration (less than 10 percent). For the September cycle sample, OCDD and HpCDD concentrations increased 300 percent during composting. Less than 10 percent increases were observed for HxCDDs and OCDF; all other 2,3,7,8-substituted CDD/CDF congeners showed decreases in concentrations during composting.

Krauss et al. (1994) measured the extent of CDD/CDF formation during the composting of household waste using a laboratory compost reactor. After 11 weeks, the TEQ content of the compost increased from 3.0 to 4.5 ng. The largest increases in mass content were observed for HpCDD (primarily 1,2,3,4,6,7,8-HpCDD) and OCDD. TCDD, PeCDD, and HxCDD showed no change in mass content. All CDF congener groups showed decreases in mass content; however, the concentrations in both the starting and finished compost were close to the analytical detection limits.

Oberg et al. (1994) reported the results of monitoring of two household waste composts and two garden composts. For the two household waste composts, total CDD/CDF content decreased in both composts over the 12-week test period. Total CDD content and PCB content decreased, but total CDF content increased in contrast to the findings of Krauss et al. (1994). However, a small increase in OCDD content in both composts was observed. The two garden composts were monitored by Oberg et al. (1994) for a 60-week period. Total CDD/CDF concentration increased, with the largest increases observed for OCDD and HpCDDs. The lower chlorinated CDFs decreased in concentration.

As a followup to a preliminary study (Hengstmann et al., 1990) that indicated CDD/CDF concentrations may increase and congener profiles may change during anaerobic digestion of sewage sludge, Weber et al. (1995) subjected sewage sludges from two German communities to anaerobic digestion and aerobic digestion in laboratory reactors for 60 days and 20 days, respectively. The initial average I-TEQ_{DF} concentrations in the raw sludges were 20 and 200 ng I-TEQ_{DF}/kg. No significant increase or decrease in total CDD/CDF content or congener group content was observed with either sludge. In contrast, a significant decrease in CDD/CDF content was observed in the aerobic digestion experiments on both sludges. The greatest percentage decreases in congener group concentrations (i.e., greater than 40 percent) were observed for TCDF, PeCDF, HxCDF, TCDD, and PeCDD in the sludge initially containing 20 ng I-TEQ_{DF}/kg and for TCDF, TCDD, HpCDD, and OCDD in the initially high-content sludge. The greatest percentage decreases in congener concentrations (i.e., greater than 40 percent) were observed for non-2,3,7,8-substituted congeners.

10. PHOTOCHEMICAL SOURCES OF CDD/CDF

10.1. PHOTOTRANSFORMATION OF CHLOROPHENOLS

Several researchers demonstrated that CDD/CDFs can be formed via photolysis of pentachlorophenol (PCP) under laboratory conditions. These studies are described below. However, the extent to which CDD/CDFs are formed in the environment via this mechanism cannot be estimated at this time.

Lamparski et al. (1980) conducted laboratory studies to determine the effect of simulated summer sunlight on the formation of OCDD, HpCDDs, and HxCDDs in wood that was pressure treated in the laboratory with PCP. In the first set of experiments, wood veneers (southern pine) treated with purified PCP or with Dowicide EC-7, using methylene chloride as the PCP carrier, were exposed to light for 70 days. The PCP concentration in the treated wood was 5 percent by weight, which approximates the concentration in the outer layer of PCP-treated wood utility poles. Photolytic condensation of PCP to form OCDD was observed, with the OCDD concentration increasing by a maximum factor of 3,000 for the purified PCP and by a factor of 20 for EC-7 at about day 20 before leveling off. HpCDD and HxCDD were also formed, apparently by photolytic degradation of OCDD rather than by condensation of PCP and tetrachlorophenols. The HxCDD concentration increased by a factor of 760 for the purified PCP and by a factor of 50 for EC-7 over the 70-day exposure period. The predominant HpCDD congener formed was 1,2,3,4,6,7,8-HpCDD as a result of an apparent preferential loss of chlorine at the peri position (i.e., positions 1, 4, 6, and 9).

In a second set of experiments conducted by Lamparski et al. (1980), a hydrocarbon oil (P-9 oil) was used as the carrier to treat the wood. The increases observed in the OCDD, HpCDD, and HxCDD were reported to be much lower relative to the increases observed in the first set of experiments, which used methylene chloride as the carrier. Results were reported only for OCDD. The OCDD concentration increased by a maximum factor of 1.5 for both EC-7 and technical PCP, and by a factor of 88 for purified PCP. The authors concluded that the oil either reduced condensation of PCP to OCDD or accelerated degradation to other species by providing a hydrocarbon trap for free-radical species.

Vollmuth et al. (1994) studied the effect of irradiating laboratory water and landfill seepage water that contained PCP under conditions simulating those used to purify water with ultraviolet (UV) radiation (i.e., 5-hour exposure to 254 nm radiation from low-pressure mercury lamps). Before irradiation, the three solutions tested contained approximately 1 mg/L of PCP or PCP-Na but the CDD/CDF content varied dramatically (1.5, 2,066, and 2,071 pg I-TEQ_{DF}/L). Irradiation resulted in nearly total destruction of PCP (greater than 99 percent loss) in all three experiments. An overall net increase in I-TEQ_{DF} content was observed in the initially low I-TEQ_{DF} content water, but a net decrease was observed for the two initially high I-TEQ_{DF} content waters.

- Irradiation of laboratory water containing purified PCP showed an increase in I-TEQ_{DF} concentration from 1.5 pg/L to 214.5 pg/L. The increase in I-TEQ_{DF} was due entirely to the formation of 1,2,3,4,6,7,8-HpCDD, OCDD, and 1,2,3,4,6,7,8-HpCDF. Formation of non-2,3,7,8-substituted HpCDDs and HpCDFs was also observed. The ratios of the concentrations of these non-2,3,7,8-congeners to the concentrations of the 2,3,7,8-congeners were 0.6 for HpCDDs and 5.0 for HpCDFs. The HpCDD and HpCDF congeners formed indicated that the operative mechanism is photoinduced dechlorination of OCDD at a peri position and dechlorination of OCDF at only the 1- and 9-peri positions.

- Irradiation of water containing technical PCP-Na (Dowicide-G) resulted in a net loss in I-TEQ_{DF} content, from 2,065.5 pg/L to 112.7 pg/L. The only 2,3,7,8-substituted congener showing an increased concentration was 1,2,3,6,7,8-HxCDD. The other congeners originally present in the technical PCP-Na showed reductions of 80.6 to 100 percent.

- The I-TEQ_{DF} content of seepage water from a landfill (2,071 pg I-TEQ_{DF}/L) was reduced by a factor of two to 1,088 pg I-TEQ_{DF}/L. However, several 2,3,7,8-substituted congeners did increase in concentration (1,2,3,6,7,8-HxCDD, 1,2,3,4,6,7,8-HpCDD, 1,2,3,4,6,7,8-HpCDF, and OCDF).

Waddell et al. (1995) also studied the effect of irradiating distilled laboratory water containing PCP under conditions simulating those used to purify water with UV radiation. The results obtained were similar to those of Vollmuth et al. (1994). Analytical-grade PCP at a concentration of 10 mg/L was exposed for 12 minutes to 200–300 nm radiation from a medium-pressure mercury lamp. All CDD/CDF congener groups increased in concentration over the 12-minute exposure period, with the greatest increases observed for OCDD (75-fold increase) and HpCDDs (34-fold increase). The I-TEQ_{DF} content of the solution increased from 4.2 pg I-TEQ_{DF}/L to 137 pg I-TEQ_{DF}/L over the 12-minute period.

The dominant congeners formed, in terms of both concentration and contribution to I-TEQ_{DF}, were 1,2,3,4,6,7,8-HpCDD, OCDD, and 1,2,3,7,8,9-HxCDD.

10.2. PHOTOLYSIS OF HIGHER CDD/CDFS

Photolysis appears to be one of the few environmentally significant degradation mechanisms for CDD/CDFs in water, air, and soil. Although in most studies good mass balances were not obtained and the photolytic pathways for CDD/CDFs were not fully identified, a major photolysis pathway appears to be photodechlorination, resulting in formation of lower chlorinated CDD/CDFs. A preferential loss of chlorines from the peri positions (i.e., chlorines at the 1, 4, 6, and 9 positions) rather than from the lateral positions (i.e., chlorines at the 2, 3, 7, and 8 positions) was reported for some congener groups when irradiated as dry films, sorbed to soil, and as gas-phase CDD/CDFs (Choudhry and Webster, 1989; Kieatiwong et al., 1990; Sivils et al., 1994, 1995; Tysklind et al., 1992). Several researchers reported that carbon-oxygen cleavage and other mechanisms may be similarly or more important pathways for CDD/CDFs containing four or fewer chlorines.

Because of the difficulties inherent in controlling experimental variables for nonvolatile and highly lipophilic compounds like CDD/CDFs, few photolysis studies have been performed on natural waters, on soils, or particulates, and on atmospheric gases to examine the rates and products of photolysis under environmentally relevant conditions. Thus, it is not possible at this time to quantitatively estimate the mass of various CDD/CDF congeners formed in the environment annually via photolytic mechanisms. Sections 10.2.1–10.2.4 summarize the key findings of recent environmentally significant studies for the water, soil, and air media.

10.2.1 Photolysis in Water

Numerous studies demonstrate that CDD/CDFs will undergo photodechlorination following first order kinetics in organic solution, with preferential loss of chlorine from the lateral positions. Photolysis is slow in pure water, but it increases dramatically when solvents serving as hydrogen donors such as hexane, benzene, methanol, acetonitrile, hexadecane, ethyl oleate, dioxane, and isooctane are present. However, only a few studies have examined the photolysis of CDD/CDFs using natural waters and sunlight.

Choudhry and Webster (1989) experimentally determined the sunlight photolysis half-life of 1,3,6,8-TCDD in pond water to be 3.5 days (i.e., more than 10 times greater than the half-life predicted by laboratory experiments using a water/acetonitrile solution). The authors attributed this significant difference in photolysis rates to the light screening/quenching effects of dissolved organic matter.

Friesen et al. (1990) examined the photolytic behavior of 1,2,3,4,7-PeCDD and 1,2,3,4,6,7,8-HpCDD in water:acetonitrile (2:3, v/v) and in pond water under sunlight at 50 degrees north latitude. The observed half-lives of these two compounds in the water:acetonitrile solution were 12 and 37 days, respectively, but much shorter in pond water, 0.94 and 2.5 days, respectively. Similarly, Friesen et al. (1993) studied the photodegradation of 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF by sunlight using water:acetonitrile (2:3, v/v) and lake water. The observed half-lives of the 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF in the water:acetonitrile solution were 6.5 and 46 days, respectively, and 1.2 and 0.19 days, respectively, in lake water. The significant differences between the natural water and water:acetonitrile solution results were attributed to indirect or sensitized photolysis due to the presence of naturally occurring components in the lake and pond water.

Dung and O'Keefe (1992), in an investigation of aqueous photolysis of 2,3,7,8-TCDF and 1,2,7,8-TCDF, reported findings similar to those of Friesen et al. (1993). The photolysis rates of the two TCDF congeners observed in the river and lake water (half-lives of about 4 to 6 hours) were double the rates observed in pure water (half-lives of about 8 to 11 hours). Dung and O'Keefe (1992) attributed the difference in rates to the presence of natural organics in the river and lake water that may be acting as sensitizers.

10.2.2 Photolysis on Soil

Photolysis of CDD/CDFs on soil has not been well characterized. According to the data generated to date, however, photolysis is an operative degradation process only in the near-surface soil where UV light penetrates (i.e., the top few millimeters or less of soil), and dechlorination of peri-substituted chlorines appears to occur preferentially.

Miller et al. (1989) studied the CDD degradation products resulting from irradiation of ^{13}C-labeled OCDD on two soil types using sunlamps. Approximately 38 to 42 percent of the OCDD was degraded by day 5 of the experiment; no significant further loss of

OCDD was observed over the following 10 days. Although the authors determined that photodechlorination was not the dominant photolysis pathway, it was observed in both soils; approximately 10 to 30 percent of the lower chlorinated congeners were produced from the immediate higher chlorinated congeners. The HpCDD and HxCDD congeners observed as degradation products were present in proportions similar to the number of congeners in each congener group. However, Miller et al. (1989) observed greater yields of 2,3,7,8-TCDD and 1,2,3,7,8-PeCDD than would be expected on the basis of the number of potential TCDD and PeCDD congeners. One-fifth to one-third of the total yield of PeCDDs was 1,2,3,7,8-PeCDD, and one-half of the total yield of TCDDs was 2,3,7,8-TCDD.

Kieatiwong et al. (1990) performed similar experiments to those of Miller et al. (1989) using natural sunlight rather than sunlamps for irradiation of ^{13}C-labeled OCDD on soils. Photodechlorination was estimated to account for approximately 10 percent of the loss of OCDD. One-third to one-half of the total yield of PeCDDs was 1,2,3,7,8-PeCDD, and one-half of the total yield of TCDDs was 2,3,7,8-TCDD. The findings of Miller et al. (1989) and Kieatiwong et al. (1990) indicate that the 2,3,7,8-substituted TCDD and PeCDD congeners were either preferentially formed or were photochemically less reactive than the other congeners that were formed.

Tysklind et al. (1992) studied the sunlight photolysis of OCDD on soil and reported results similar to those of Miller et al. (1989) and Kieatiwong et al. (1990). Photodechlorination was observed with production of HpCDDs, HxCDDs, PeCDDs, and TCDDs over the 16-day irradiation period. Photodechlorination at the peri-substituted positions was the preferred photodechlorination mechanism; the proportions of 2,3,7,8-substituted congeners present in the soils after 16 days for each congener group were as follows: HxCDD - 65 percent; PeCDD—40 percent; and TCDD—75 percent. Tysklind et al. (1992) also studied the sunlight photolysis of OCDF on soil. Photodechlorination was observed; however, unlike the case with OCDD, photodechlorination of the lateral-substituted positions was found to be the dominant photodechlorination mechanism, resulting in a relative decreasing proportion of 2,3,7,8-substituted congeners during the irradiation period. 2,3,7,8-TCDF was not observed in any of the irradiated samples.

10.2.3 Photolysis on Vegetation

Photolysis of CDD/CDFs sorbed on the surface of vegetation has not been well characterized, and the findings to date are somewhat contradictory. McCrady and Maggard (1993) reported that 2,3,7,8-TCDD sorbed on the surface of reed canary grass (*Phalaris arundinacea L.*) undergoes photolytic degradation with a half-life of 44 hours in natural sunlight. In contrast, Welsch-Pausch et al. (1995) found little difference in the CDD/CDF congener patterns between grass (*Lolium multiflorum*) grown on an outdoor plot and grass grown in a greenhouse (i.e., UV light transmission blocked). In an attempt to clarify this contradiction, Welsch-Pausch and McLachlan (1995) studied the photodegradation of CDD/CDFs on pasture grass (*Arrhenatherion elatioris*) during two growing cycles (summer and autumn) using two greenhouses. One greenhouse was constructed of glass that blocks UV transmission, and the other was constructed of plexiglass (4 mm) with a UV-light transmission of greater than 50 percent in the 280-320 mm range. In both the summer and autumn exposure periods, the concentrations of CDD/CDFs (on a congener group basis) were similar in the grass exposed to UV light and the grass that was not exposed. Welsch-Pausch and McLachlan (1995) concluded that if photodegradation was occurring, it was a relatively insignificant factor in the accumulation of CDD/CDF in pasture grass.

10.2.4 Photolysis in Air

Photolysis of CDD/CDFs in the atmosphere has not been well characterized. On the basis of data generated to date, however, photolysis appears to be a significant mechanism for degradation (principally, dechlorination of the peri-substituted chlorines) of those CDD/CDFs present in the atmosphere in the gas phase. For airborne CDD/CDFs sorbed to particulates, photolysis appears to proceed very slowly, if at all. Because of the low volatility of CDD/CDFs, few studies have been attempted to measure actual rates of photodegradation of gas-phase CDD/CDF, and only recently have studies examined the relative importance of photolysis to particulate-bound CDD/CDFs.

Sivils et al. (1994; 1995) studied the gas-phase photolysis of several CDDs (2,3,7-TrCDD; 2,3,7,8-TCDD; 1,2,3,4-TCDD; 1,2,3,7,8-PeCDD, and 1,2,4,7,8-PeCDD) by irradiating the effluent from a gas chromatograph with broadband radiation in the UV/visible region for periods up to 20 minutes. The irradiated sample was then introduced

into a second gas chromatograph to measure the extent of dechlorination. The results showed that degradation followed first order kinetics and that an inverse relationship exists between the degree of chlorination and the rate of disappearance. Although the lack of photoproducts prevented an independent confirmation of the preferential loss mechanism, the results indicated that laterally substituted congeners (i.e., chlorines at the 2, 3, 7, and 8 positions) degrade at a slower rate than the peri-substituted congeners (i.e., chlorines at the 1, 4, 6, and 9 positions). Although Sivils et al. (1994) did not present the rate constants, the degradation rate for 2,3,7,8-TCDD (30 percent loss in 20 minutes) was reported to be slower than the rates for all other tested CDDs. Also, 1,2,4,7,8-PeCDD (with two perichlorines) degraded significantly faster than 1,2,3,7,8-PeCDD (with only one perichlorine).

Mill et al. (1987) studied the photolysis of 2,3,7,8-TCDD sorbed onto small diameter fly ash particulates suspended in air. The results indicated that fly ash confers photostability on 2,3,7,8-TCDD. Little (8 percent) to no loss was observed on the two fly ash samples after 40 hours of illumination. Tysklind and Rappe (1991) and Koester and Hites (1992) reported similar results of photolysis studies with fly ash. Tysklind and Rappe (1991) subjected fly ash from two German incinerators to various simulated environmental conditions. The fraction of photolytically degradable CDD/CDF after 288 hours of exposure was in the range of 20 to 40 percent of the extractable CDD/CDF. However, a 10 to 20 percent reduction was also observed in the darkened control samples. With the exception of HpCDD and HpCDF, the concentration of all other congener groups either increased or stayed the same during the exposure period from hour 144 to hour 288. Koester and Hites (1992) studied the photodegradation of CDD/CDFs naturally adsorbed to fly ash collected from five electrostatic precipitators. They observed no significant degradation in 11 photodegradation experiments performed on the ash for periods ranging from 2 to 6 days. Koester and Hites (1992) concluded that (1) the absence of photodegradation is not due to the absence of a hydrogen-donor organic substance; (2) other molecules on the ash, as determined by a photolysis experiment with an ash extract, inhibit photodegradation, either by absorbing light and dissipating energy or by quenching the excited states of the CDD/CDFs; and (3) the surface of the ash itself may hinder photolysis by shielding the CDD/CDFs from light.

11. SOURCES OF DIOXIN-LIKE PCBs

The purpose of this chapter is twofold: (1) to identify sources that release dioxin-like polychlorinated biphenyls (PCB) congeners into the environment and (2) to derive national estimates for releases from these sources in the United States. PCBs have been found in all media and all parts of the world. PCBs were produced in relatively large quantities for use in commercial products such as dielectrics, hydraulic fluids, plastics, and paints. They are no longer commercially produced in the United States, but continue to be released to the environment through the use and disposal of these products. PCBs may also be inadvertently produced as by-products during the manufacture of certain organic chemicals and also as products of the incomplete combustion of some waste materials.

11.1. GENERAL FINDINGS OF THE EMISSIONS INVENTORY

Table 11-1 provides a list of known or suspected dioxin-like PCB-emitting source categories in the United States. The source categories included in this table represent a compilation of source categories for which dioxin-like PCB congener, PCB Aroclor, or PCB congener group emission measurements have been reported in government, industry, and trade association reports; in conference proceedings and journal articles; and in comments submitted to the Agency on previous versions of this document. The intent of Table 11-1 is to clearly present those source categories and media (i.e., air, water, land, and products) for which available data are either adequate or inadequate for reliably quantifying emissions of dioxin-like PCBs.

Nationwide emission estimates for the United States inventory are presented in Table 11-2 (emissions to air, water, land, and product) for those source categories for which emission estimates can be reliably quantified (i.e., the category has been assigned a confidence rating of A, B, or C) (see Section 1.4.2 of this report for details on confidence ratings). Table 11-2 also lists, in the far right column, preliminary estimates of the potential magnitude of emissions from "unquantified" sources (i.e., sources assigned a confidence rating of D) in reference year 1995. Because of large uncertainties for these category D estimates, they are not included in the "quantitative inventory."

Releases of "old" dioxin-like PCBs (i.e., dioxin-like PCBs manufactured prior to the ban) to the environment can occur from ongoing use and disposal practices. Prior to

regulations enacted beginning in the late 1970s that limited the manufacture/use/disposal of PCBs, significant quantities of PCBs were released to the environment in association with (1) the manufacture of PCBs; (2) the manufacture of products containing PCBs; and (3) the use and disposal of products containing PCBs, as well as materials that may have been contaminated with trace levels of PCBs from prior PCB use or disposal. Following the ban on PCB production, releases from these first two categories ceased to exist. The third type of releases, those associated with product use and disposal, will continue in at least four ways:

- Products containing greater than 2 pounds of PCBs (e.g., dielectric fluids in transformers and large capacitors) are controlled by disposal regulations that have minimized environmental releases.
- Disposal of products containing small quantities of PCBs (e.g., small capacitors, fluorescent lighting fixtures) or trace quantities of PCBs (e.g., wastepapers) are subject to disposal as municipal solid waste but may result in some release to the general environment.
- Leaks and spills occur in still-in-service PCBs.
- PCBs are disposed of illegally.

No significant release of newly formed dioxin-like PCBs is occurring in the United States. Unlike CDD/CDFs, PCBs were intentionally manufactured in the United States in large quantities from 1929 until production was banned in 1977. Although it has been demonstrated that small quantities of dioxin-like PCBs can be produced during waste combustion, no strong evidence exists that the dioxin-like PCBs are produced in significant quantities as byproducts during combustion or chemical processes. The widespread occurrence of dioxin-like PCBs in the U.S. environment most likely reflects past releases associated with PCB production, use, and disposal. Further support for this finding is based on observations of reductions since the 1980s in PCB concentrations in Great Lakes sediment and other areas.

11.2 RELEASES OF COMMERCIAL PCBs

PCBs were commercially manufactured by the direct batch chlorination of molten biphenyl with anhydrous chlorine in the presence of a catalyst, followed by separation and

purification of the desired chlorinated biphenyl fractions. The degree of chlorination was controlled by the chlorine contact time in the reactor. Commercial PCBs production is believed to have been confined to 10 countries. Total PCBs produced worldwide since 1929 (i.e., the first year of known production) has been estimated to total 1.5-million metric tons. Initially, PCBs were primarily used as dielectric fluids in transformers. After World War II, PCBs found steadily increasing use as dielectric fluids in capacitors, as heat-conducting fluids in heat exchangers, and as heat-resistant hydraulic fluids in mining equipment and vacuum pumps. PCBs also were used in a variety of "open" applications (i.e, uses from which PCBs cannot be recollected) including: plasticizers, carbonless copy paper, lubricants, inks, laminating agents, impregnating agents, paints, adhesives, waxes, additives in cement and plaster, casting agents, dedusting agents, sealing liquids, fire retardants, immersion oils, and pesticides (DeVoogt and Brinkman, 1989).

PCBs were manufactured in the United States from 1929 until 1977. U.S. production peaked in 1970 with a volume of 39,000 metric tons. In 1971, Monsanto Corporation, the major U.S. producer, voluntarily restricted the sales of PCBs to all applications with the exception of "closed electrical systems," and annual production fell to 18,000 metric tons in 1974. Monsanto ceased PCB manufacture in mid-1977 and shipped the last inventory in October 1977. Regulations issued by EPA beginning in 1977, principally under the Toxic Substances Control Act (TSCA) (40 CFR 761), have strictly limited the production, import, use, and disposal of PCBs. The estimated cumulative production and consumption volumes of PCBs in the United States from 1930 to 1975 were 635,000 metric tons produced, 1,400 metric tons imported (primarily from Japan, Italy, and France), 568,000 metric tons sold in the United States; and 68,000 metric tons exported (Versar, 1976). The reliability of these values is +5 percent and -20 percent (Versar, 1976).

Monsanto Corporation marketed technical grade mixtures of PCBs primarily under the trade name *Aroclor*. The Aroclors are identified by a four-digit numbering code in which the last two digits indicate the chlorine content by weight percent. The exception to this coding scheme is Aroclor 1016, which contains only mono- through hexachlorinated congeners with an average chlorine content of 41 percent. From 1957 until 1972, Monsanto also manufactured several blends of PCBs and polychlorinated terphenyls (PCTs) under the trade names Aroclor 2565 and Aroclor 4465; manufacture

and sales volumes are not available for these blends. Listed below are the percentages of total Aroclor production during the years 1957 to 1977 by Aroclor mixture as reported by Brown (1994).

Aroclor	1957-1977 U.S. Production (%)
1016	12.88
1221	0.96
1232	0.24
1242	51.76
1248	6.76
1254	15.73
1260	10.61
1262	0.83
1268	0.33

The trade names of the major commercial PCB technical grade mixtures manufactured in other countries included *Clophen* (Germany), *Fenclor* and *Apirolio* (Italy), *Kanechlor* (Japan), *Phenoclor* and *Pyralene* (France), *Sovtel* (USSR), *Delor* and *Delorene* (Czechoslovakia), and *Orophene* (German Democratic Republic) (DeVoogt and Brinkman, 1989). The mixtures marketed under these trade names had similar chlorine content (by weight percent and average number of chlorines per molecule) to those of various Aroclors. Listed below are comparable mixtures in terms of chlorine content marketed under several trade names.

Aroclor	Clophen	Pyralene	Phenoclor	Fenclor	Kanechlor
1232		2000			200
1242	A-30	3000	DP-3	42	300
1248	A-40		DP-4		400
1254	A-50		DP-5	54	500
1260	A-60		DP-6	64	600

Major advances in analytical separation and resolution techniques beginning in the 1970s enabled various researchers to identify and quantify PCB congeners present in Aroclors, Clophens, and Kanechlors (Jensen et al., 1974; Albro and Parker, 1979; Huckins et al., 1980; Albro et al., 1981; Duinker and Hillebrand, 1983; Kannan et al., 1987; Tanabe et al., 1987; Duinker et al., 1988; Schulz et al., 1989; Himberg and Sippola, 1990; Larsen et al., 1992; deBoer et al., 1993; Schwartz et al., 1993; Frame et al.,

1996a; Frame et al., 1996b; and Frame, 1997). Schulz et al. (1989) were the first to identify and quantify all PCB congeners present in a series of Aroclors and Clophens. Frame (1995) reported preliminary results of a nearly completed round robin study, one goal of which was to determine the distribution of all PCB congeners above 0.05 weight percent in various Aroclors (1221, 1016, 1242, 1260, and 1262) using 18 state-of-the-art gas chromatography/mass spectrometry (GC-MS) or electron capture detector (GC-ECD) systems.

Table 11-3 presents mean summary statistics on the concentrations of the dioxin-like PCBs in each mixture group (i.e., Aroclor 1248, Clophen A-40, and Kanechlor 400 are in one mixture group) reported by these researchers. Table 11-3 also presents calculation of the corresponding mean TEQ concentration of each congener in each mixture group as well as the total mean TEQ concentration in the mixture group. For each mixture group, the congeners detected were generally similar. There was, however, wide variability in the concentrations reported by some researchers for some congeners. Brown et al. (1995) compiled similar statistics using a somewhat different set of studies and derived significantly lower mean concentrations of some congeners in several Aroclors. Frame (1995) and Larsen (1995) attribute such differences either to potential limitations in the GC columns used by various researchers to separate similar eluting congeners or to actual differences in the congener concentrations in the Aroclor, Clophen, and Kanechlor lots analyzed by various research groups. In addition to the specific congener concentrations, the congener distributions also vary among the different mixtures. Therefore, the calculated TEQs also vary. The congener distributions for various lots of Aroclor 1254, and the corresponding TEQs, are presented in another study by Frame (1999). In this study, Frame (1999) reports that the relative TEQs for late production lots are much higher than the earlier production lots; however, the late production lots are estimated to account for only about one percent of the total production volume of Aroclor 1254. Therefore, the data for the later production lots were not included in the average TEQ calculation for Aroclor 1254 in Table 11-3. Because of the wide variability in the reported results, the uncertainty associated with the mean concentrations reported in Table 11-3 is very large.

In the environment, PCBs also occur as mixtures of congeners, but their composition will differ from the commercial mixtures. This is because after release to the

environment, the composition of PCB mixtures changes over time, through partitioning, chemical transformation, and preferential bioaccumulation (U.S. EPA, 1996g). Dioxin-like PCB congeners differ by up to one to two orders of magnitude in their water solubilities, vapor pressures, K_{ow} values, and Henry's Law constants. Thus, although all the dioxin-like PCB congeners are poorly soluble in water and have very low vapor pressures, they will volatilize and leach at different rates. Similarly, because the congeners differ somewhat in their rates of biodegradation, bioaccumulation, and photodegradation, the congener patterns found in environmental media and biota will vary from those found in commercial mixtures.

Although environmental mixtures are often characterized in terms of Aroclors, this characterization can be both imprecise and inappropriate. Qualitative and quantitative errors can arise from judgements in comparing GC/MS peaks for a sample with the characteristic peak patterns for different Aroclors, particularly for environmentally altered patterns (U.S. EPA, 1996g). For the same reason, it can be both imprecise and inappropriate to infer concentrations of dioxin-like PCB congeners in an environmental sample based on characterization of the sample's Aroclor content and knowledge of the dioxin-like congener content in the commercial Aroclor. Safe (1994) wrote, "Regulatory agencies and environmental scientists have recognized that the composition of PCBs in most enviromental extracts does not resemble the compositions of the commercial product." Similarly, ATSDR (1993) stated, "It is important to recognize that the PCBs to which people may be exposed are likely to be different from the original PCB source because of changes in congener and impurity composition resulting from differential partitioning and transformation in the environment and differential metabolism and retention."

11.2.1. Approved PCB Disposal/Destruction Methods

In 1978, EPA began regulating the disposal of PCBs and PCB-contaminated waste under the TSCA, PL 94-469. The disposal regulations, published in the Code of Federal Regulations, 40 CFR, Part 761, state that the preferred disposal method is incineration at 1,200°C or higher. If the waste contains material that can not be destroyed by incineration, EPA clearance must be obtained to dispose of the waste in a chemical waste landfill, or in another approved manner.

The PCB disposal regulations describe disposal of three distinct types of PCB waste: PCBs, PCB articles (i.e., items containing PCBs), and PCB containers. Within these categories of PCB waste, further distinctions are made based on the PCB concentration in the waste. The acceptable disposal methods are based on the PCB concentrations in the specific waste to be destroyed. The acceptable disposal methods are: Annex I incinerators, high-efficiency boilers, Annex II chemical waste landfills, and other approved methods. The following subsections and Table 11-4 provide brief descriptions of these disposal methods. More complete descriptions of the specific methodologies are provided in the Code of Federal Regulations, 40 CFR, Part 761.

Approved Incinerators/High Efficiency Boilers - PCB Annex I incinerators must meet the specific technical standards and criteria listed in Annex I of EPA's PCB regulations. The minimum operating requirements for disposal of liquid wastes are 2 seconds at 1,200°C (2,190°F) with 3 percent excess oxygen (measured in the stack gas), or 1.5 seconds at 1,600°C (2,910°F) and 2 percent excess oxygen (measured in the stack gas). Monitoring requirements, approval conditions, and trial burn requirements are prescribed in Annex I. Commercial or industrial incinerators intending to destroy liquid PCB wastes must demonstrate compliance with the Annex I requirements through a comprehensive trial burn program. Annex I incinerators operating at optimum performance level should destroy 99.997 percent of liquid PCB waste with a resulting maximum emission factor of 0.03 grams per kilogram (g/kg).

Criteria for Annex I incinerators were established for the destruction of liquid PCB wastes; however, these incinerators also may be used for disposal of nonliquid PCB items (such as capacitors), provided that a destruction and removal efficiency of 99.9999 percent and a maximum emission factor of 0.001 g/kg are met.

High-efficiency boilers may be used to destroy PCBs and PCB-contaminated waste with PCB concentrations not exceeding 500 ppm. Conventional industrial and utility boilers may be designated as high-efficiency boilers, if they are operated under the prescribed combustion conditions defined in the PCB disposal regulations. The PCB regulations do not specify a minimum PCB destruction efficiency for high-efficiency boilers; however, EPA-approved boilers operated according to the regulations have reported destruction efficiencies in excess of 99.99 percent, with a corresponding maximum emission factor of 0.1 g/kg (U.S. EPA, 1987c).

Approved Chemical Waste Landfills - Approved chemical waste landfills can be used for the disposal of some, but not all, PCB wastes. PCB-contaminated materials acceptable for land disposal in an approved landfill include PCB mixtures (e.g., certain PCB-contaminated soil/solid debris, PCB-contaminated dredged materials, and PCB-contaminated municipal sewage sludge), PCB articles that cannot feasibly be incinerated (e.g., drained and flushed transformers), and drained PCB containers. EPA must issue written approval to landfill PCB articles other than transformers. PCB-contaminated materials not acceptable for land disposal in an approved landfill include nonliquid PCB mixtures in the form of contaminated soil, rags, or other solid debris, and sealed capacitors. Typically, PCBs disposed in these landfills are placed in sealed containers, thereby, minimizing any PCB emissions.

Other Approved Disposal Methods - Other thermal and nonthermal destruction techniques may be approved by EPA Regional Administrators, if these processes can effect destruction of PCBs equivalent to that of incinerators or boilers. Subsequent to April 29, 1983, all other PCB disposal technologies (thermal and nonthermal) that are to be used in more than one EPA Region must be approved by EPA Headquarters. Examples of thermal technologies approved for commercial-scale use or for research and development projects include a pyrolysis process to treat contaminated soils, a fluid wall reactor, a cement kiln, a diesel engine, a steam-stripping operation, an aluminum melting furnace, and a molten salt process. Examples of approved nonthermal processes include chemical dechlorination processes, physical/chemical extraction techniques, and biological reduction methods. The physical/chemical techniques extract the PCBs from transformers or capacitors and concentrate them for disposal; they do not destroy the PCBs.

Emission Estimates - Table 11-5 lists the amounts of PCBs reported in EPA's Toxics Release Inventory (TRI) as transferred off-site for treatment, energy recovery, or disposal during the years 1988 through 1996. These quantities do not necessarily represent entry of PCBs into the environment. If it is assumed that all transferred PCBs are incinerated in high-efficiency boilers with a destruction and removal efficiency of 99.99 percent, then annual emissions of PCBs to air during 1988 and 1993 could have been as high as 264 kg and 31 kg, respectively. Because no stack testing data are available for dioxin-like PCBs, it is not possible to estimate what fraction of these potential PCB releases would have been the dioxin-like congeners.

11.2.2. Accidental Releases of In-Service PCBs

EPA banned PCB production and use in open systems in 1977. Subsequent to the 1977 ban, releases of commercially produced PCB to the environment (aside from minimal releases occurring during approved disposal and/or destruction) have been limited to accidental release of in-service PCBs (U.S. EPA, 1987c). Accidental releases are the result of leaks or spills during failure/breakage of an existing piece of PCB-containing equipment, or incomplete combustion occurring during accidental fires involving PCB-containing equipment. These two types of accidental releases are discussed in this section.

Leaks and Spills - PCBs that remain in active service at this time are those contained in "closed system" (i.e., those pieces of electrical equipment that completely enclose the PCBs and do not provide direct atmospheric access of the PCBs during normal use). This equipment includes PCB transformers, capacitors, voltage regulators, circuit breakers, and reclosures. With the exception of PCB transformers and probably small PCB capacitors, the majority of the PCB-containing electrical equipment in-service during 1981 was owned by the electrical utility industry. Approximately 70 percent of the estimated 140,000 PCB transformers in-service in 1981 were owned by nonutilities. No information was available on the relative distribution of small PCB capacitors (Versar, 1988).

The number of each of these items owned by the utility industry, the quantity of PCBs each contains, and an estimate of the annual quantity of PCBs leaked and/or spilled were investigated by the Edison Electric Institute and the Utility Solid Wastes Activity Group (EEI/USWAG) for EPA in 1981. The findings of this investigation were reported in a proposed modification to the PCB regulations (Federal Register, 1982a). The findings indicated that over 99 percent of the total quantity of PCBs contained in utility-owned electrical equipment in 1981 (73,700 metric tons) were in 40,000 PCB transformers (those containing > 500 ppm of PCBs) and large PCB capacitors (those containing > 3 lb of PCBs). An upper-bound estimate of the mass of PCBs that leached or spilled from this equipment in 1981 was 177 metric tons. Approximately 95 percent of the estimated releases were the result of leaks from large PCB capacitors (Federal Register, 1982a). Leaks/spills typically occur in transformers when the gasket joining the top to the body corrodes, tears, or physically fails. PCBs can then leak past this failed section and potentially spill onto the surrounding ground. PCB capacitors typically fail by rupturing,

exposing the contained PCBs to the environment. Failure is caused by environmental and weathering effects (e.g., lightning) or material failures (e.g., metal fatigue).

As of mid-1988, the total population of in-service PCB transformers and large PCB capacitors was estimated to have decreased from 140,000 to 110,000 and from 3.3 million to 1.9 million, respectively (Versar, 1988). PCB transformers have normal operating lifetimes of 30 years and 40 years, respectively. The accelerated retirement rate over this 7-year period was attributed to EPA's PCB Electrical Use Rule (Federal Register, 1982b), which required the removal of 950 food/feed industry transformers by 1985 and removal of 1.1 million unrestricted-access large PCB capacitors by October 1988. In addition, EPA's PCB Transformer Fires Rule (Federal Register, 1985b) required the removal by 1990 of 7,600 480-volt network transformers. More recent inventories of PCB-containing electrical equipment are not available. However, a recent Information Collection Request submitted by EPA to the Office of Management and Budget for information on uses, locations, and conditions of PCB electrical equipment estimated that there may be 150,000 owners of PCB-containing transformers used in industry, utilities, government buildings, and private buildings (Federal Register, 1997a). It is expected, and is demonstrated by the reported PCB transfers in TRI (see Table 11-5), that many owners of PCB electrical equipment have removed PCB-containing equipment to eliminate potential liability.

The proportion of spilled PCB that enters the atmosphere, runs off to surface water, or remains in or on the surface depends on a variety of factors including the porosity of the surface onto which the PCBs are spilled (concrete, soil), the PCB isomers that are spilled, ambient conditions (i.e., temperature, wind speed, precipitation), and the cleanup schedule. The number and diversity of factors affecting PCB emissions from spills and leaks make estimation of an emission factor difficult. A rough approximation of the annual amount that may be released to the environment from spills and leaks can be made using the release data reported by manufacturing facilities to EPA's TRI. Table 11-6 lists the amounts of PCBs reported in TRI to be released to the environment during 1988 through 1996. These data include emissions to the air, discharges to bodies of water, releases at the facility to land, as well as contained disposal into underground injection wells.

On the basis of TRI data, annual reported emissions of PCBs to air during 1988 and 1995 could have been as high as 2.7 kg and 0 kg, respectively. For purposes of deriving a preliminary rough estimate of potential releases of dioxin-like PCBs, it can be assumed that the ratio of TEQ to total PCB in the air emissions was 67:1-million (i.e., the average of the estimated mean TEQ contents for Aroclors 1242 and 1254 presented in Table 11-3). Based on this assumption, annual emissions of PCB TEQs in 1988 and 1995 could have been 0.2 and 0 grams, respectively. Similar assumptions for releases to water listed in Table 11-6 yield estimated TEQ emissions during 1988 and 1995 of 0.3 and 0 grams, respectively. For land, estimated TEQ emissions during 1988 and 1995 could have been 23 and 0 grams, respectively.

Accidental Fires - The available information is not adequate to support an estimate of potential annual releases of dioxin-like PCBs from accidental electrical equipment fires. For fires involving PCB transformers or capacitors, the amount of PCBs released is dependent upon the extensiveness of the fire and the speed at which it is extinguished. A number of these fires are documented. A New York fire, involving 200 gallons of transformer fluid containing some 65 percent by weight PCBs, resulted in a release of up to 1,300 pounds of PCBs. A capacitor fire that burned uncontrolled for 2 hours in Sweden resulted in the destruction of 12 large utility capacitors containing an estimated 25 pounds of PCBs each, for a total potential release of 300 pounds. However, data are incomplete on the exact amount of PCBs released as a result of these two fires.

EPA has imposed reporting requirements to ensure that the National Response Center is informed immediately of fires involving PCB transformers (40 CFR 761). The recordkeeping requirements are used to document the use, location, and condition of PCB equipment. Responses are mandatory, but may be claimed by the submitter to be confidential information. The annual number of PCB transformer fires is estimated at approximately 20 per year; the number of PCB capacitor fires is unknown (U.S. EPA, 1987c). As these PCB items reach the end of their useful lives and are retired, their susceptibility to fires will be eliminated, and the overall number of PCB transformer and capacitor fires will be reduced.

11.2.3. Municipal Wastewater Treatment

EPA conducted the National Sewage Sludge Survey in 1988 and 1989 to obtain national data on sewage sludge quality and management. As part of this survey, EPA analyzed sludges from 175 publicly owned treatment works (POTWs) that employed at least secondary wastewater treatment for more than 400 analytes including 7 of the Aroclors. Sludges from 19 percent of the POTWs had detectable levels of at least one of the following Aroclors: 1248, 1254, or 1260; none of the other Aroclors were detected in any sample (detection limit was typically about 200 μg/kg dry weight) (U.S. EPA, 1996a). Analyses were not performed for dioxin-like PCB congeners. The Aroclor-specific results of the survey are presented in Table 11-7. Gutenmann et al. (1994) reported similar results in a survey of sludges from 16 large U.S. cities for Aroclor 1260 content. At a detection limit of 250-μg/kg (dry weight), Gutenmann et al. (1994) detected Aroclor 1260 at only one facility (4,600 μg/kg). These results indicate that PCBs are not likely to be formed at POTWs, but rather are present because of disposal of PCB products or recirculation of previously disposed PCB.

Although PCBs, measured as Aroclors, were not commonly detected in sewage sludge at μg/kg levels by U.S. EPA (1996a) and Gutenmann et al. (1994), the presence of dioxin-like PCB congeners at lower concentrations may be more common. Green et al. (1995) and Cramer et al. (1995) reported the results of analyses of 99 samples of sewage sludge for PCB congener numbers 77, 81, 126, and 169. The sludge samples were collected from 74 wastewater treatment plants across the United States during the summer of 1994. These data are summarized in Table 11-8. Results from all samples collected from the same facility were averaged by Green et al. (1995) and Cramer et al. (1995) to ensure that results were not biased towards the concentrations found at facilities from which more than one sample were collected. If all nondetected values are assumed to be zero, then the POTW mean TEQ_p-WHO_{94} and TEQ_p-WHO_{98} concentrations were 25.1 and 24.2 ng TEQ/kg (dry weight basis), respectively. If the nondetected values are set equal to the detection limits, then the POTW mean TEQ_p-WHO_{94} and TEQ_p-WHO_{98} concentrations were 25.2 and 24.3 ng TEQ/kg, respectively.

EPA recently analyzed samples of sewage sludge collected from a POTW in Ohio for all of the TEQ_P-WHO_{94} and TEQ_P-WHO_{98} dioxin-like PCB congeners, with the exception of PCB 81 (Battelle, 1999). The results of the analyses presented in the draft test report

are listed in Table 11-9. The average TEQ content of the POTW sludge was 158 ng TEQ_P-WHO_{94}/kg (141 ng TEQ_P-WHO_{98}/kg). Three PCB congeners, 77, 126, and 169, accounted for more than 97 percent of the total TEQ in each sample.

Approximately 5.4 million dry metric tons of sewage sludge are estimated by EPA to be generated annually in the United States based on the results of the 1988/1989 EPA National Sewage Sludge Survey (Federal Register, 1993b). Table 11-10 lists the volume of sludge disposed of annually by use and disposal practices. Table 11-10 also lists the estimated amount of dioxin-like PCB TEQs that may be present in sewage sludge and potentially be released to the environment. These values were estimated using the POTW mean TEQ_p-WHO_{98} concentration calculated from the results reported by Green et al. (1995) and Cramer et al. (1995). Multiplying this TEQ concentration by the sludge volumes generated yields an annual potential total release of 101 g TEQ_P-WHO_{98} for nonincinerated sludges. Of this 101 g TEQ_P-WHO_{98}, 1.7 grams enter commerce as a product for distribution and marketing. The remainder is applied to land (51.1 grams) or is landfilled (48.2 grams).

These release estimates are assigned a confidence rating of B indicating high confidence in the production estimate and "medium" confidence in the emission factor estimates. The medium rating was based on the judgment that, although the 74 facilities tested by Green et al. (1995) and Cramer et al. (1995) may be reasonably representative of the variability in POTW technologies and sewage characteristics nationwide, the sample size was still relatively small, and not all dioxin-like PCB congeners were monitored.

11.3. CHEMICAL MANUFACTURING AND PROCESSING SOURCES

In the early 1980s, EPA investigated the extent of inadvertent generation of PCBs during the manufacture of synthetic organic chemicals (Hammerstrom et al., 1985). For example, phthalocyanine dyes and diarylide pigments were reported to contain PCBs in the mg/kg range. EPA subsequently issued regulations under TSCA (40 CFR 761.3) that banned the distribution in commerce of any products containing an annual average PCB concentration of 25 mg/kg (50 mg/kg maximum concentration at any time). In addition, EPA required manufacturers with processes inadvertently generating PCBs and importers of products containing inadvertently generated PCBs to report to EPA any process or

import for which the PCB concentration is greater than 2 mg/kg for any resolvable PCB gas chromatographic peak.

11.4. COMBUSTION SOURCES

11.4.1 Municipal Solid Waste Incineration

Municipal solid waste incinerators have long been identified as potential PCB air emission sources. Stack gas concentrations of PCBs for three incinerators were reported in U.S. EPA (1987c), and the average test results yields an emission factor of 18 μg PCBs/kg refuse. Stack gas emissions of PCBs from the three incinerators were quantified without determining the incinerator's PCB destruction efficiency. The PCB content of various consumer paper products was analyzed as part of the study. This study indicates that paper products such as magazine covers and paper towels contained up to 139 micrograms of PCB per kilogram of paper (μg/kg). These levels, which were reported in 1981, were attributed to the repeated recycle of waste paper containing PCBs. For example, carbonless copy paper manufactured prior to 1971 contained PCB levels as high as 7 percent. This copy paper then became a component of waste paper, which was recycled. The PCBs inevitably were introduced into other paper products, resulting in continued measurable levels in municipal refuse some 4 years after the PCB manufacturing ban was imposed. Refuse-derived fuel (RDF) manufactured from these paper products had PCB levels of 8,500 μg/kg, indicating that this fuel could be a source of atmospheric PCBs. Therefore, it was assumed in U.S. EPA (1987c) that municipal refuse does contain detectable levels of PCBs, and that some of these PCBs may enter the atmosphere when the refuse is incinerated.

Shane et al. (1990) analyzed fly ashes from five municipal solid waste (MSW) incinerators for PCB congener group content. Total PCB levels ranged from 99 to 322 μg/kg in these ashes with the tri-, tetra-, and penta-congener groups occurring in the highest concentrations. Shane et al. (1990) also analyzed seven bottom ashes and eight bottom ash/fly ash mixtures for total PCB measured as Aroclor 1254. The detection limit for this Aroclor analysis was 5 μg/kg. Aroclor 1254 was detected in two of the seven bottom ash samples (26 and 8 μg/kg) and in five of the eight fly ash/bottom ash mixtures (range of 6 to 33 μg/kg).

The development of more sensitive analytical methodologies has enabled researchers in recent years to detect dioxin-like PCB congeners in the stack gases and fly ash from full-scale and pilot-scale MSW incinerators (Sakai et al., 1993a; Sakai et al., 1993b; Boers et al., 1993; Schoonenboom et al., 1993; Sakai et al., 1994). Similarly, the advances in analytical techniques have enabled researchers to determine that dioxin-like PCBs can be formed during the oxidative solid combustion phase of incineration presumably due to dimerization of chlorobenzenes. Laboratory-scale studies have also recently demonstrated that dioxin-like PCBs can be formed from heat treatment of fly ash in air (Schoonenboom et al., 1993; Sakai et al., 1994). However, the available data are not adequate to support development of a quantitative estimate of a dioxin-like PCB emission factor for this source category.

11.4.2. Industrial Wood Combustion

Emissions of PCB congener groups, not individual congeners, were measured during stack testing of two industrial wood burning facilities by the State of California Air Resources Board (CARB, 1990e; 1990f). Table 11-11 presents the average of the congener group (i.e., mono- through decachlorobiphenyl) emission factors for these two facilities. No tetra- or more chlorinated congeners (i.e., the congener groups containing the dioxin-like PCBs) were detected at either facility at detection limits corresponding to emission factors in the low range of ng/kg of wood combusted.

In CARB (1990e), PCBs were measured in the emissions from two spreader stoker wood-fired boilers operated in parallel by an electric utility for generating electricity. The exhaust gas stream from each boiler is passed through a dedicated ESP after which the gas streams are combined and emitted to the atmosphere through a common stack. Stack tests were conducted both when the facility burned fuels allowed by existing permits and when the facility burned a mixture of permitted fuel supplemented by urban wood waste at a ratio of 70:30.

In CARB (1990f), PCBs were measured in the emissions from twin fluidized bed combustors designed to burn wood chips to generate electricity. The APCD system consisted of ammonia injection for controlling nitrogen oxides, and a multiclone and electrostatic precipitator for controlling particulate matter. During testing, the facility burned wood wastes and agricultural wastes allowed by existing permits.

11.4.3. Medical Waste Incineration

As discussed in Section 3.3, EPA recently issued nationally applicable emission standards and guidelines for medical waste incinerators (MWI) that address CDD/CDF emissions. Although PCBs are not addressed in these regulations, the data base of stack test results at MWIs compiled for this rulemaking does contain limited data on PCB congener group emission factors. Data are available for two MWIs lacking add-on APCD equipment and for two MWIs with add-on APCD equipment in place. The average congener group emission factors derived from these test data are presented in Table 11-12. Because data are available for only 4 of the estimated 2,400 facilities that make up this industry and because these data do not provide congener-specific emission factors, no national estimates of total PCB or dioxin-like PCB emissions are being made at this time.

11.4.4. Tire Combustion

Emissions of PCB congener groups, not individual congeners, were measured during stack testing of a tire incinerator by the State of California Air Resources Board (CARB, 1991a). The facility consists of two excess air furnaces equipped with steam boilers to recovery the energy from the heat of combustion. Discarded whole tires were fed to the incineration units at rates ranging from 2,800 to 5,700 kg/hr during the 3 testing days. The furnaces are equipped to burn natural gas as auxiliary fuel. The steam produced from the boilers drives electrical turbine generators that produce 14.4 megawatts of electricity. The facility is equipped with a dry acid gas scrubber and fabric filter for the control of emissions prior to exiting the stack. Table 11-13 presents the congener group (i.e., mono- through decachlorobiphenyl) emission factors for this facility. The emission factor for the total of the tetra- through hepta-chlorinated congener groups is about 1.2 μg/kg of tire processed.

EPA estimated that approximately 0.50 million metric tons of tires were incinerated in 1990 in the United States (U.S. EPA, 1992a). This production estimate is given a medium confidence rating, because it is based on both published data and professional judgment. The use of scrap tires as a fuel increased significantly during the late 1980s; however, no quantitative estimates were provided in U.S. EPA (1992a) for this period. In 1990, 10.7 percent of the 242 million scrap tires generated were burned for fuel. This percentage is expected to continue to increase (U.S. EPA, 1992a). Of the tires burned for

energy recovery purposes, pulp and paper facilities used approximately 46 percent; cement kilns, 23 percent; and one tire-to-energy facility, 19 percent (U.S. EPA, 1997b).

If it is assumed that 500 million kg of discarded tires are incinerated annually in the United States, then, using the sum of the average emission factors for the total tetra- through heptachlorinated congener groups (1.2 μg/kg tire processed) derived from stack data from the one tested facility, yields a total emission of 610 g/yr. However, it is not known what fraction of this emission is dioxin-like PCBs.

11.4.5. Cigarette Smoking

Using high-resolution mass spectrometry, Matsueda et al. (1994) analyzed tobacco from 20 brands of commercially available cigarettes collected in 1992 from Japan, the United States, Taiwan, China, the United Kingdom, Germany, and Denmark for the PCB congeners 77, 126, and 169. Table 11-14 presents the results of the study.

However, no studies have been reported which examined the tobacco smoke for the presence of these congeners. Thus, it is not known whether the PCBs present in the tobacco are destroyed or volatilized during combustion, or whether PCBs are formed during combustion. The combustion processes operating during cigarette smoking are complex and could be used to support either of these potential mechanisms. As reported by Guerin et al. (1992), during a puff, gas phase temperatures reach 850°C at the core of the firecone, and solid phase temperatures reach 800°C at the core and 900°C or greater at the char line. Thus, temperatures are sufficient to cause at least some destruction of CDD/CDFs initially present in the tobacco. Both solid and gas phase temperatures rapidly decline to 200 to 400°C within 2 mm of the char line. Formation of dioxin-like PCBs has been reported in combustion studies with other media in this temperature range (Sakai et al., 1994). However, it is known that a process likened by Guerin et al. (1992) to steam distillation takes place in the region behind the char line because of high localized concentrations of water and temperatures of 200 to 400°C. At least 1,200 tobacco constituents (e.g., nicotine, n-paraffin, some terpenes) are transferred intact from the tobacco into the smoke stream by distillation in this area, and it is plausible that PCBs present in the unburned tobacco would be subject to similar distillation.

In 1995, approximately 487 billion cigarettes were consumed in the United States and by U.S. Armed Forces personnel stationed overseas. Per capita U.S. cigarette

consumption in 1995, based on total U.S. population aged 16 and over, declined to 2,415 from a record high of 4,345 in 1963. In 1987, approximately 575 billion cigarettes were consumed domestically (The Tobacco Institute, 1995; USDA, 1997).

A preliminary rough estimate of potential emissions of dioxin-like PCBs can be made using the following assumptions: (1) the average TEQ_p-WHO_{98} content of seven brands of U.S. cigarettes reported by Matsueda et al. (1994), 0.64 pg/pack (or 0.032 pg/cigarette) is representative of cigarettes smoked in the United States; (2) dioxin-like PCBs are neither formed nor destroyed, and the congener profile reported by Matsueda et al. (1994) is not altered during combustion of cigarettes; and (3) all dioxin-like PCBs contributing to the TEQ are released from the tobacco during smoking. Based on these assumptions, the calculated annual emissions would be 0.018 g TEQ_p-WHO_{98} and 0.016 g TEQ_p-WHO_{98} for reference years 1987 and 1995, respectively.

11.4.6. Sewage Sludge Incineration

U.S. EPA (1996f) derived an emission factor of 5.4 μg of total PCBs per kg of dry sludge incinerated. This emission factor was based on measurements conducted at five multiple hearth incinerators controlled with wet scrubbers. In 1992, approximately 199 sewage sludge incineration facilities combusted 0.865 million metric tons of dry sewage sludge (Federal Register, 1993b). Given this mass of sewage sludge incinerated, the estimated annual release of total PCBs to air annually is 4,670 g. However, it is not known what fraction of this annual emission is dioxin-like PCBs.

EPA recently conducted stack testing at a sewage sludge incinerator in Ohio (Battelle, 1999) for all of the TEQ_P-WHO_{94} and TEQ_P-WHO_{98} dioxin-like PCB congeners with the exception of PCB 81. The results of the analyses (ng/dscm) presented in the draft test report are listed in Table 11-15. The average TEQ content of the stack gas was 0.119 ng TEQ_P-WHO_{94}/dscm (0.106 ng TEQ_P-WHO_{98}/dscm). Three PCB congeners, 77, 126, and 169, accounted for more than 97 percent of the total TEQ in each sample.

11.4.7. Backyard Barrel Burning

In many rural areas of the United States, disposal of residential solid waste may take place via open backyard burning in barrels or similar homemade devices. Although no national statistics on the prevalence of this practice have been reported, the results of a

telephone survey conducted in the early 1990s of residents in five central Illinois counties indicate that about 40 percent of the residents in a typical rural Illinois county burn household waste. The survey also found that, on average, those households that burn waste dispose of approximately 63 percent of their household waste through burning in barrels (Two Rivers Region Council of Public Officials and Patrick Engineering, 1994).

The low combustion temperatures and oxygen-starved conditions associated with this method may result in incomplete combustion and increased pollutant emissions (Lemieux, 1997). EPA's Control Technology Center, in cooperation with the New York State Departments of Health (NYSDOH) and Environmental Conservation (NYSDEC), recently conducted a study to examine, characterize, and quantify emissions from the simulated open burning of household waste materials in barrels (Lemieux, 1997). A representative waste to be burned was prepared based on the typical percentages of various waste materials disposed by New York State residents (i.e., nonavid recyclers); hazardous wastes (i.e., chemicals, paints, oils, etc.) were not included in the test waste. A variety of compounds, including dioxin-like PCBs, were measured in the emissions from the simulated open burning. The measured TEQ emission factors for waste, which had not been separated for recycling purposes, were 1.02E-2 μg TEQ_p-WHO_{94}/kg of waste burned and 5.26E-03 μg TEQ_p-WHO_{98}/kg (see Table 11-16).

The limited emission factor and activity level data available were judged inadequate for developing national emission estimates that could be included in the national inventory. The number of households nationwide burning waste in barrels and the total amount and variability of burned waste is unknown. The representativeness of the trash and burning conditions used in the experiments to conditions nationwide are unknown. However, combining the emission factor of 5.26E-03 μg TEQ_p-WHO_{98}/kg of waste burned with the following information/assumptions, allows a preliminary order of magnitude estimate to be made of potential national dioxin-like PCB TEQ emissions from backyard household trash burning.

- Forty percent of the rural population in the United States are assumed to burn their household waste in a barrel (Two Rivers Region Council of Public Officials and Patrick Engineering, 1994).

- On average, each U.S. citizen generates 3.72 pounds of solid waste (excluding yard waste) per day (or 616 kg/person-year) (U.S. EPA, 1996b).

- On average, for those individuals burning household waste, approximately 63 percent of waste generated are burned (i.e., 63 percent of 616 kg/person-year = 388 kg/person-year) (Two Rivers Region Council of Public Officials and Patrick Engineering, 1994).

- In 1992, 51.8 million people lived in nonmetropolitan areas (U.S. DOC, 1997).

Emissions = $(51.8 \times 10^6$ people)(40%)(388 kg/person-yr)(5.26E-03 µg TEQ_P-WHO_{98}/kg)(10^{-6} g/µg)
= 42.3 g TEQ_P-WHO_{98}/yr (82.1 g TEQ_P-WHO_{94}/yr)

11.4.8. Petroleum Refining Catalyst Regeneration

As discussed in Section 5.3, regeneration of spent catalyst used in catalytic reforming to produce high-octane reformates is a potential source of CDD/CDF air emissions. In 1998, emissions from the caustic scrubber used to treat gases from the external catalyst regeneration unit of a refinery in California were tested for CDD/CDFs, as well as PCB congener groups (CARB, 1999). This facility uses a continuous regeneration process. The reactor is not taken off line during regeneration; rather, small amounts of catalyst are continuously withdrawn from the reactor and are regenerated. The emissions from the regeneration unit are neutralized by a caustic scrubber before being vented to the atmosphere. The catalyst recirculation rate during the three tests ranged from 733 to 1,000 lb/hr.

All PCB congener groups were detected in each of the three samples collected. The average congener group emission factors in units of ng per barrel of reformer feed are presented in Table 11-17. The total PCB emission factor was 118 ng/barrel. This emission factor assumes that emissions are proportional to reforming capacity; emission factors may be more related to the amount of coke burned, APCD equipment present, and/or other process parameters.

Because emissions data are available for only one U.S. petroleum refinery (which represents less than 1 percent of the catalytic reforming capacity at U.S. refineries) and because these data do not provide congener-specific emission factors, no national estimates of total PCB or dioxin-like PCB emissions are being made at this time.

11.5. NATURAL SOURCES

11.5.1. Biotransformation of Other PCBs

Studies show that under anaerobic conditions, biologically mediated reductive dechlorination to less chlorinated congeners, followed by slow anaerobic and/or aerobic biodegradation, is a major pathway for destruction of PCBs in the environment. Research reported to date and summarized below indicates that biodegradation should result in a net decrease rather than a net increase in the environmental load of dioxin-like PCBs.

Laboratory studies (e.g., Bedard et al., 1986; Pardue et al., 1988; Larsson and Lemkemeier, 1989; Hickey, 1995; and Schreiner et al., 1995) have revealed that more than two dozen strains of aerobic bacteria and fungi, which are capable of degrading most PCB congeners with five or fewer chlorines, are widely distributed in the environment. Many of these organisms are of the genus *Pseudomonas* or the genus *Alcaligenes*. The major metabolic pathway involves addition of O_2 at the 2,3-position by a dioxygenase enzyme with subsequent dehydrogenation to the catechol followed by ring cleavage. Several bacterial strains have been shown to possess a dioxygenase enzyme that attacks the 3,4-position.

However, only a few strains have demonstrated the ability to degrade hexa- and more chlorinated PCBs. The rate of aerobic biodegradation decreases with increasing chlorination. The half-lives for biodegradation of tetra-PCBs in fresh surface water and soil are 7 to 60+ days and 12 to 30 days, respectively. For penta-PCBs and higher chlorinated PCBs, the half-lives in fresh surface water and soil are likely to exceed 1 year. PCBs with all or most chlorines on one ring and PCBs with fewer than two chlorines in the ortho position tend to degrade more rapidly. For example, Gan and Berthouex (1994) monitored over a 5-year period the disappearance of PCB congeners applied to soil with sewage sludge. Three of the tetra- and pentachlorinated dioxin-like PCBs (IUPAC Nos. 77, 105, and 118) followed a first-order disappearance model with half-lives ranging from 43 to 69 months. A hexa-substituted congener (IUPAC No. 167) and a hepta-substituted congener (IUPAC No. 180) showed no significant loss over the 5-year period.

Until recent years, little investigation focused on anaerobic microbial dechlorination or degradation of PCBs even though most PCBs eventually accumulate in anaerobic sediments (Abramowicz, 1990; Risatti, 1992). Environmental dechlorination of PCBs via losses of meta and para chlorines has been reported in field studies for freshwater,

estuarine, and marine anaerobic sediments including those from the Acushnet Estuary, the Hudson River, the Sheboygan River, New Bedford Harbor, Escambia Bay, Waukegan Harbor, the Housatonic River, and Woods Pond (Brown et al., 1987; Rhee et al., 1989; Van Dort and Bedard, 1991; Abramowicz, 1990; Bedard et al., 1995; and Bedard and May, 1996). The altered PCB congener distribution patterns found in these sediments (i.e., different patterns with increasing depth or distance from known sources of PCBs) have been interpreted as evidence that bacteria may dechlorinate PCBs in anaerobic sediment.

Results of laboratory studies reported recently confirm anaerobic degradation of PCBs. Chen et al. (1988) found that "PCB-degrading" bacteria from the Hudson River could significantly degrade the mono-, di-, and tri-PCB components of a 20 ppm Aroclor 1221 solution within 105 days. These congener groups make up 95 percent of Aroclor 1221. No degradation of higher chlorinated congeners (present at 30 ppb or less) was observed, and a separate 40-day experiment with tetra-PCB also showed no degradation.

Rhee et al. (1989) reported degradation of mono- to penta-substituted PCBs in contaminated Hudson River sediments held under anaerobic conditions in the laboratory (N_2 atmosphere) for 6 months at 25°C. Amendment of the test samples with biphenyl resulted in greater loss of PCB. No significant decreases in the concentrations of the more highly chlorinated (i.e., more than five chlorines) were observed. No evidence of degradation was observed in samples incubated in CO_2/H_2 atmospheres. Abramowicz (1990) hypothesized that this result could be an indication that, in the absence of CO_2, a selection is imposed favoring organisms capable of degrading PCBs to obtain CO_2 and/or low molecular weight metabolites as electron receptors.

Risatti (1992) examined the degradation of PCBs at varying concentrations (10,000 ppm, 1,500 ppm, and 500 ppm) in the laboratory with "PCB-degrading" bacteria from Waukegan Harbor. After 9 months of incubation at 22°C, the 500 ppm and 1,500 ppm samples showed no change in PCB congener distributions or concentrations, thus indicating a lack of degradation. Significant degradation was observed in the 10,000 ppm sediment with at least 20 congeners ranging from TrCBs to PeCBs showing decreases.

Quensen et al. (1988) also demonstrated that microorganisms from PCB-contaminated sediments (Hudson River) dechlorinated most tri- through hexa-PCBs in Aroclor 1242 under anaerobic laboratory conditions. The Aroclor 1242 used to spike the

sediment contained predominantly tri- and tetra-PCBs (85 mole percent). Three concentrations of the Aroclor, corresponding to 14-, 140-, and 700-ppm on a sediment dry-weight basis, were used. Dechlorination was most extensive at the 700-ppm test concentration; 53 percent of the total chlorine were removed in 16 weeks, and the proportion of TeCBs through HxCBs decreased from 42 to 4 percent. Much less degradation was observed in the 140-ppm sediment, and no observable degradation was found in the 14-ppm sediment. These results and those of Risatti (1992) suggest that the organism(s) responsible for this dechlorination may require relatively high levels of PCB as a terminal electron acceptor to maintain a growing population.

Quensen et al. (1990) reported that dechlorination of 500-ppm spike concentrations of Aroclor 1242, 1248, 1254, and 1260 by microorganisms from PCB-contaminated sediments in the Hudson River and Silver Lake occurred primarily at the meta- and para- positions; ortho-substituted mono- and di-PCBs increased in concentration. Significant decreases over the up to 50-week incubation period were reported for the following dioxin-like PCBs: 156, 167, 170, 180 and 189. Of the four dioxin-like TeCBs and PeCBs detected in the Aroclor spikes (i.e., IUPAC Nos. 77, 105, 114, and 118), all decreased significantly in concentration, with the possible exception of PeCB 114 in the Aroclor 1260-spiked sediment.

Nies and Vogel (1990) reported similar results with Hudson River sediments incubated anaerobically and enriched with acetone, methanol, or glucose. Approximately 300 ppm of Aroclor 1242 (31-mole percent TeCBs, 7-mole percent PeCBs, and 1-mole percent HxCBs) were added to the sediments prior to incubation for 22 weeks under an N_2 atmosphere. Significant dechlorination was observed, with dechlorination occurring primarily at the meta- and para-positions on the more highly chlorinated congeners (i.e., TeCBs, PeCBs, and HxCBs), resulting in the accumulation of less-chlorinated, primarily ortho-substituted mono- through tri-substituted congeners. No significant dechlorination was observed in the control samples (i.e., samples containing no added organic chemical substrate and samples that were autoclaved).

Bedard and May (1996) also reported similar findings in the sediments of Woods Pond, believed contaminated with Aroclor 1260. Significant decreases in the sediment concentrations of PCBs 118, 156, 170, and 180 (relative to their concentrations in

Aroclor 1260) were observed. No increases or decreases were reported for the other dioxin-like PCBs.

Bedard et al. (1995) demonstrated that it is possible to stimulate substantial microbial dechlorination of the highly chlorinated PCB mixture Aroclor 1260 *in situ* with a single addition of 2,6-dibromobiphenyl. Bedard et al. (1995) added 365 g of 2,6-dibromobiphenyl to 6-foot-diameter submerged caissons containing 400-kg sediment (dry weight) and monitored the change in PCB congener concentrations for a period of 1 year. At the end of the observation period, the hexa- through monochlorinated PCBs decreased 74 percent in the top of the sediment and 69 percent in the bottom. The average number of chlorines per molecule dropped 21 percent from 5.83 to 4.61, with the largest reduction observed in meta-chlorines (54 percent reduction) followed by para-chlorines (6 percent). The dechlorination stimulated by 2,6-dibromobiphenyl selectively removed meta-chlorines positioned next to other chlorines.

The findings of these latter studies are significant, because removal of meta- and para-chlorines from the dioxin-like PCBs should reduce their toxicity and bioaccumulative potential and also form less chlorinated congeners that are more amenable to aerobic biodegradation.

Van Dort and Bedard (1991) reported the first experimental demonstration of biologically mediated ortho-dechlorination of a PCB and stoichiometric conversion of that PCB congener (2,3,5,6-TeCB) to less chlorinated forms. In that study, 2,3,5,6-TeCB was incubated under anaerobic conditions with unacclimated methanogenic pond sediment for 37 weeks, with reported dechlorination to 2,5-DCB (21 percent); 2,6-DCB (63 percent); and 2,3,6-TrCB (16 percent).

11.5.2. Photochemical Transformation of Other PCBs

Photolysis and photo-oxidation may be major pathways for destruction of PCBs in the environment. Research reported to date and summarized below indicates that ortho-substituted chlorines are more susceptible to photolysis than are meta- and para-substituted congeners. Thus, photolytic formation of more toxic dioxin-like PCBs may occur. Oxidation by hydroxyl radicals, however, apparently occurs preferentially at the meta- and para-positions thus resulting in a net decrease rather than a net increase in the environmental load of dioxin-like PCBs.

Based on the data available in 1983, Leifer et al. (1983) concluded that all PCBs, especially the more highly chlorinated congeners and those that contain two or more chlorines in the ortho-position, photodechlorinate. In general, as the chlorine content increases, the photolysis rate increases. More recently, Lepine et al. (1992) exposed dilute solutions (4 ppm) of Aroclor 1254 in cyclohexane to sunlight for 55 days in December and January. Congener-specific analysis indicated that the amounts of many higher chlorinated congeners, particularly mono-ortho-substituted congeners decreased, while those of some lower chlorinated congeners increased. The results for the dioxin-like PCBs indicated a 43.5 percent decrease in the amount of PeCB 114; a 73.5 percent decrease in the amount of HxCB 156; and a 24.4 percent decrease in the amount of HxCB 157. However, TeCB 77 and PeCB 126 (the most toxic of the dioxin-like PCB congeners), which were not detected in unirradiated Aroclor 1254, represented 2.5 percent and 0.43 percent, respectively, of the irradiated mixture.

With regard to photo-oxidation, Atkinson (1987) and Leifer et al. (1983), using assumed steady-state atmospheric OH concentrations and measured oxidation rate constants for biphenyl and monochlorobiphenyl, estimated atmospheric decay rates and half-lives for gaseous-phase PCBs. Atmospheric transformation was estimated to proceed most rapidly for those PCB congeners containing either a small number of chlorines or those containing all or most of the chlorines on one ring. Kwok et al. (1995) extended the work of Atkinson (1987) by measuring the OH radical reaction rate constants for 2,2'-, 3,3'-, and 3,5-dichlorobiphenyl. These reaction rate constants, when taken together with the Atkinson's measurements for biphenyl and monochlorobiphenyl and the estimation method described in Atkinson (1991), were used to generate more reliable estimates of the gas-phase OH radical reaction rate constants for the dioxin-like PCBs. The persistence of the PCB congeners increases with increasing degree of chlorination. Table 11-18 presents these estimated rate constants and the corresponding tropospheric lifetimes and half-lives.

Sedlak and Andren (1991) demonstrated in laboratory studies that OH radicals, generated with Fenton's reagent, rapidly oxidized PCBs (i.e., 2-mono-PCB and the DiCBs through PeCBs present in Aroclor 1242) in aqueous solutions. The results indicated that the reaction occurs via addition of a hydroxyl group to one nonhalogenated site; reaction rates are inversely related to the degree of chlorination of the biphenyl. The results also

indicated that meta- and para-sites are more reactive than ortho-sites due to stearic hindrance effects. Based upon their kinetic measurements and reported steady-state aqueous system OH concentrations or estimates of OH radical production rates, Sedlak and Andren (1991) estimated environmental half-lives for dissolved PCBs (mono-through octa-PCB) in fresh surface water and in cloud water to be 4 to 11 days and 0.1 to 10 days, respectively.

11.6. PAST USE OF COMMERCIAL PCBS

An estimated 1.5 million metric tons of PCBs were produced worldwide (DeVoogt and Brinkman, 1989). Slightly more than one-third of these PCBs (568,000 metric tons) were used in the United States (Versar, 1976). Although the focus of this section is on reservoir sources of PCBs within the United States, it is necessary to note that the use and disposal of PCBs in many countries, coupled with the persistent nature of PCBs, have resulted in their movement and presence throughout the global environment. The ultimate sink of most PCBs released to the environment will be aquatic sediments. Currently, however, large quantities of PCBs are estimated to be circulating between the air and water environments or are present in landfills and dumps, some of which may offer the potential for re-release of PCBs into the air. Tanabe (1988) presented a global mass balance for PCBs that indicated that as of 1985, 20 percent of the total PCBs produced were present in seawater, whereas only 11 percent were in sediments. (See Table 11-19.) Nearly two-thirds of total global PCB production was estimated by Tanabe (1988) to still be in use in electrical equipment or to be present in landfills and dumps.

As discussed in Section 11.2, an estimated 568,000 metric tons of PCBs were sold in the United States during the period 1930-1975 (Versar, 1976). Table 11-20 presents annual estimates of domestic sales by year for each Aroclor during the period 1957-1974. Estimates of PCB usage in the United States by usage category during the period 1930-1975 are presented in Table 11-21. Prior to voluntary restrictions by Monsanto Corporation in 1972 on sales for uses other than "closed electrical systems," approximately 13 percent of the PCBs were used in "semi-closed applications," and 26 percent were used in "open-end applications." Most of this usage of PCBs for "semi-closed" and "open-end" applications occurred between 1960 and 1972 (Versar, 1976).

Table 11-22 presents estimates of the amounts of individual Aroclors that were released to the environment (i.e., to water, air, or soil) during the period 1930-1974. Because detailed usage data were not available for the period 1930-1957, Versar (1976) assumed that the usage pattern for this period followed the average pattern for the period 1957-1959. The basic assumptions used by Versar (1976) in deriving these estimates were that 5 percent of the PCBs used in "closed electrical systems" were released; 60 percent of the PCBs used in "semi-closed applications" were released; 25 percent of the PCBs used for plasticizers were released; and 90 percent of PCBs used for miscellaneous industrial uses had escaped. The reliability of these release estimates was assumed to be ±30 percent (Versar, 1976).

In addition to these estimates of direct releases to the environment, Versar (1976) estimated that 132,000 metric tons of PCBs were landfilled. This total was comprised of 50,000 metric tons from capacitor and transformer production wastes, 36,000 metric tons from disposal of obsolete electrical equipment, and 46,000 metric tons from disposal of material from "open-end applications." An additional 14,000 metric tons of PCBs, although still "in service" in various "semi-closed" and "open-end" applications in 1976 were estimated to ultimately be destined for disposal in landfills.

An estimated 3,702 kg of TEQ_P-WHO_{98} were released directly to the U.S. environment during the period 1930-1977 (See Table 11-23). These estimates are based on the Aroclor release estimates presented in Table 11-22 and the mean TEQ_p-WHO_{98} concentrations in Aroclors that were presented in Table 11-3.

g/kg = grams per kilogram.
mg/kg = milligrams per kilogram.

Table 11-4. Disposal Requirements for PCBs and PCB Items

	Waste Characterization		Disposal Requirements
PCBs	Mineral oil dielectric fluids from PCB transformers	Those analyzing > 500 ppm PCB	Annex I incinerator[a]
	Mineral oil dielectric fluids from PCB-contaminated transformers	Those analyzing 50-500 ppm PCB	Annex I incinerator High efficiency boiler (40 CFR 761.10(a)(2)(iii)) Other approved incinerator[b] Annex II chemical waste landfill[c]
	PCB liquid wastes other than mineral oil dielectric fluid	Those analyzing > 500 ppm PCB	Annex I incinerator
		Those analyzing 50-500 ppm PCB	Annex I incinerator High efficiency boiler (40 CFR 761.10(a)(2)(iii)) Other approved incinerator[b] Annex II chemical waste landfill[c]
	Nonliquid PCB wastes (e.g., contaminated materials from spills)		Annex I incinerator Annex II chemical waste landfill
	Dredged materials and municipal sewage treatment sludges containing PCBs		Annex I incinerator Annex II chemical waste landfill Other approved disposal method (40 CFR 761.10(a)(5)(iii)
PCB Articles	Transformers	PCB transformers	Annex I incinerator Drained and rinsed transformers may be disposed of in Annex II chemical waste landfill
		PCB contaminated transformers	Disposal of drained transformers is not regulated
	PCB capacitors		Annex I incinerator
	PCB hydraulic machines	Those containing > 1,000 ppm PCB	Drained and rinsed machines may be disposed of as municipal solid waste or salvaged
		Those containing < 1,000 ppm PCB	Drained machines may be disposed of as municipal solid waste or salvaged
	Other PCB articles	Those containing PCB fluids	Drained machines may be disposed of per Annex I or Annex II
		Those not containing PCB fluids	Annex I incinerator or Annex II chemical waste landfill
PCB Containers	Those used to contain only PCBs at a concentration < 500 ppm		As municipal solid waste provided any liquid PCBs are drained prior to disposal
	Other PCB containers		Annex I incinerator Annex II, provided any liquid PCBs are drained prior to disposal Decontaminate per Annex IV

[a] Annex I incinerator defined in 40 CFR 761.40.
[b] Requirements for other approved incinerators are defined in 40 CFR 761.10(e).
[c] Annex II chemical waste landfills are described in 40 CFR 761.41. Annex II disposal is permitted if the PCB waste contains less than 500 ppm PCB and is not ignitable as per 40 CFR Part 761.41(b)(8)(iii).
[d] Disposal of containerized capacitors in Annex II landfills was permitted until March 1, 1981; thereafter, only Annex I incineration has been permitted.
ppm = parts per million

Table 11-10. Quantity of Sewage Sludge Disposed of Annually by Primary, Secondary, or Advanced Treatment POTWs and Potential Dioxin-Like PCB TEQ Releases

Use/Disposal Practice	Volume Disposed (thousands of dry metric tons/year)	Percent of Total Volume	Potential TEQ_p-WHO_{98} Release[c] (g of TEQ/yr)	Potential TEQ_p-WHO_{94} Release[c] (g of TEQ/yr)
Land Application	1,714	32.0[e]	41.5	43.0
Distribution and Marketing	71	1.3	1.7	1.8
Surface Disposal Site/Other	396	7.4	9.6	9.9
Sewage Sludge Landfill	157	2.9	4.2	3.9
Co-Disposal Landfills[a]	1,819	33.9	44.0	45.6
Sludge Incinerators and Co-Incinerators[b]	865	16.1	(f)	
Ocean Disposal	(336)[d]	(6.3)[d]	(0)[d]	
TOTAL	5,357	100.0	101.0	104.2

[a] Landfills used for disposal of sewage sludge and solid waste residuals.

[b] Co-incinerators treat sewage sludge in combination with other combustible waste materials.

[c] Potential TEQ release for nonincinerated sludges was estimated by multiplying the sludge volume generated (i.e., column 2) by the mean dioxin-like PCB TEQ concentration in 74 POTW sludges reported by Green et al. (1995) and Cramer et al. (1995) (i.e., 24.2 ng TEQ_p-WHO_{98}/kg and 25.1 ng TEQ_p-WHO_{94}/kg).

[d] The Ocean Dumping Ban Act of 1988 generally prohibited the dumping of sewage sludge into the ocean after December 31, 1991. Ocean dumping of sewage sludge ended in June 1992 (Federal Register, 1993b). The current method of disposal of the 336,000 metric tons of sewage sludge that were disposed in the oceans in 1988 has not been determined.

[e] Includes 21.9 percent applied to agricultural land, 2.8 percent applied as compost, 0.6 percent applied to forestry land, 3.1 percent applied to "public contact" land, 1.2 percent applied to reclamation sites, and 2.4 percent applied in undefined settings.

[f] See Section 11.4.6 for for a discussion of dioxin-like PCB releases to air from sewage sludge incinerators.

Sources: Federal Register (1990); Federal Register (1993b); Green et al. (1995); Cramer et al. (1995).

Table 11-11. PCB Congener Group Emission Factors for Industrial Wood Combustors

Congener Group	Number of Sites	Number of Detections	Maximum Concentration Detected (ng/kg wood)	Mean Concentration (ng/kg)

Aroclor 1268	0.33%	--	--	--
				Total = 3,702

μg/kg = micrograms per kilogram.

"--" indicates that release estimates were not been made because of relatively low usage amounts.

[a] Sales during the period 1957-1974 constitute 63% of all PCB sales during 1930-1977; sales data for individual Aroclors are not available for years prior to 1957. However, sales of Aroclors 1221, 1232, 1262, and 1268 were minor even prior to 1957.

[b] From Table 11-22.

[c] From Table 11-3 (assumes not detected values are zero).

[d] Data are available for only a few samples of Aroclor 1016 where only 2 dioxin-like PCB congeners were detected. The total TEQ_P-WHO_{98} released is less than 0.01 kilograms.

12.0 RESERVOIR SOURCES OF CDD/CDF AND DIOXIN-LIKE PCBs

National CDD/CDF source inventories have been conducted in several nations, including the United Kingdom, The Netherlands, Germany, Austria, and Sweden to characterize emissions from various source categories and estimate annual CDD/CDF emissions to air (and sometimes other media). These inventories focused primarily on emissions from primary sources (i.e., emissions from the site or process where the CDD/CDF are formed). The authors of these inventories (Rappe, 1991; Harrad and Jones, 1992b; Bremmer et al., 1994; Thomas and Spiro, 1995 and 1996; Eduljee and Dyke, 1996; Jones and Alcock, 1996; Duarte-Davidson et al., 1997) indicated that the annual estimates of releases to air provided in these inventories may be underestimates of actual emissions for several reasons. First, from an empirical basis, estimates of the amounts of CDD/CDFs deposited annually from the atmosphere were greater than the estimates of annual CDD/CDF emissions to the atmosphere. Second, the investigators indicated that because of limited emission test data the inventories may underestimate releases from known sources or may not identify all primary sources. Third, the investigators acknowledged the existence of potential reservoir (or secondary) sources but were not able to reliably quantify emissions from these sources. Potential reservoir sources identified by these investigators included volatilization of CDD/CDFs from PCP-treated wood, volatilization from soil, and resuspension of soil particles. Relatively little research of either a monitoring or theoretical nature has been performed to identify reservoir sources and to quantify the magnitude of current or potential future releases from these sources.

This chapter presents background information on reservoir sources of CDD/CDF/PCBs. Section 12.1 presents a working definition for reservoir sources. Section 12.2 describes major environmental reservoirs (i.e., soil, water, sediment, and biota) and presents information on: (1) the potential magnitude (mass) of CDD/CDF/PCBs in each reservoir; (2) the chemical/physical mechanisms responsible for releases of these compounds; and (3) estimates of potential annual releases from each reservoir, if such estimates are feasible, given the available state of knowledge. Section 12.3 presents a summary of the information presented in this chapter.

12.1. POTENTIAL RESERVOIRS

Chapters 2 through 11 have discussed both known and suspected sources of newly formed dioxin-like compounds to the environment in the United States. Once released into the open environment, CDDs, CDFs, PCBs partition to air, soils, water, sediments and biota according to both the nature of the release, and the contaminant's chemical and physical properties (see Volume 2, Chapter 2). The definitions adopted for this analysis of reservoirs and reservoir sources are as follows:

> *Reservoirs* are materials or places that contain previously formed CDD/CDFs or dioxin-like PCBs and have the potential for redistribution and circulation of these compounds into the environment. Potential reservoirs include soils, sediments, biota, water and some anthropogenic materials. Reservoirs become sources when they have releases of dioxin-like compounds to the circulating environment over a defined time and space. Like other sources they would not include purely intermediate products or materials properly disposed in a secure landfill.

Reservoir sources are not included in the quantitative inventory of contemporary sources because they do not involve original releases, but rather the recirculation of past releases. They can, however, contribute to human exposure and, therefore, are important to consider. Figure 12-1 presents a conceptual diagram of flux and exchange of dioxin-like compounds to multiple environmental compartments including the principal environmental reservoirs: soil, water, air, sediment, and biota. This dynamic system consists of fluxes in and out of the atmosphere, as well as other exchanges between reservoirs and the atmosphere. Movement between media can be induced by volatilization, wet and dry atmospheric particle and vapor deposition, adsorption, erosion and runoff, resuspension of soils into air, and resuspension of sediments into water. The rate of movement from one environmental medium to another is termed 'flux,' and refers to the direction and magnitude of flow and exchange over a reference time period and space.

12.2. CHARACTERIZATION OF RESERVOIR SOURCES

This section is organized according to reservoir type (soil, water, sediment, and biota) with each subsection providing information in three parts: (1) the potential magnitude (mass) of dioxin-like compounds in the reservoir; (2) the chemical/physical mechanisms responsible for releases of these compounds; and (3) estimates of potential annual releases from the reservoir, if such estimates are feasible, given the available state of knowledge. Although, anthropogenic structures are potential reservoir sources, they are not discussed here because they were covered earlier in Chapter 8 (the most detailed discussion is on PCP, Section 8.3.8.).

12.2.1. Soil

Potential Mass of Dioxin-Like Compounds Present

The companion document to this report, Volume 2 (Fate, Environmental Levels, and Exposure), presents a compilation of CDD/CDF/PCB concentrations in surface soils reported in various published studies. Based on this compilation of studies, the mean TEQ values for background urban and rural soils are estimated to be 13.4 and 4.1 ng I-TEQ_{DF}/kg of soil, respectively (or 11.9 and 3.6 ng TEQ_{DF}-WHO_{98}/kg, respectively). It should be noted that no comprehensive survey of CDD/CDF concentrations in U.S. soils has yet been performed. The surface area of the United States (excluding Alaska) is approximately 7.85 million square kilometers (sq km). Land use statistics for 1992 indicate that 0.37 million sq km are classified as "developed" and can be considered to be principally urban areas. The remaining 7.48 million sq km are considered rural. Of this rural area, 1.55 million sq km are cropland (U.S. DOC, 1997). Further breakdown of the rural land area into pasture land, range land, and forest land is available, but the available monitoring data are considered to be inadequate for deriving background CDD/CDF concentrations for these land use types.

In estimating burdens for the United Kingdom, Harrad and Jones (1992) and Duarte-Davidson et al. (1997) assumed that the majority of CDD/CDFs in soil is present in the top 5 centimeters (except possibly in cropland, which may involve a deeper depth due to plowing) and that the soil density is 1,000 kg/m^3. Coupling these assumptions regarding depth of contamination and average soil density with the rural and urban U.S. surface areas and TEQ concentrations yields soil burden estimates of 1,530 kg I-TEQ_{DF} (1,350 kg

TEQ_{DF}-WHO_{98}) in rural soils and 250 kg I-TEQ_{DF} (220 kg TEQ_{DF}-WHO_{98}) in urban soils in the United States.

Higher concentrations of CDD/CDFs than those presented above for background urban and rural soils may be present in soils underlain by municipal and industrial waste and in soils at contaminated industrial sites. The lack of comprehensive data on CDD/CDF concentrations in these soils, as well as the lack of data on the mass of these soils nationwide, precludes estimating total national soil burdens for these soils at present. Higher concentrations of CDD/CDFs may also be present in the soils of areas that have been treated with pesticides contaminated with CDD/CDFs. For the same reasons presented above for industrially contaminated soil, it is not possible to estimate current soil burdens of CDD/CDF associated with past pesticide use. However, estimates can be made of the total mass of CDD/CDF TEQs that have been applied to soil from past use of the pesticides 2,4-D and 2,4,5-T.

2,4-Dichlorophenoxy acetic acid (2,4-D) and its salts and esters are widely used in agricultural and nonagricultural settings in the United States as post-emergence herbicides for control of broadleaf weeds and brush. In terms of volumes of pesticides used annually, 2,4-D ranks among the top 10 pesticides in the United States (U.S. EPA, 1994b, 1997e) and has been in large-scale, large-volume commercial use for many years (U.S. EPA, 1975). Commercial production of 2,4-D in the United States started in 1944 (Esposito et al., 1980). Table 12-1 presents a compilation of historical domestic production, sales, and usage volumes for 2,4-D and its salts and esters.

As described in Section 8.3.8, CDD/CDFs were detected in several formulations of 2,4-D and its derivatives during analyses performed to comply with EPA's 1987 Data Call-In (DCI) for CDD/CDFs. Although the analytical results of these tests indicated that CDD/CDFs were seldom above the regulatory limits of quantification (LOQ) established by EPA for the DCI, several registrants detected and quantified CDD/CDFs at lower LOQs. The results of these tests are summarized in Table 8-25. The average TEQ in these tests was 0.70 μg I-TEQ_{DF}/kg (1.10 μg TEQ_{DF}-WHO_{98}/kg). Schecter et al. (1997) recently reported similar concentrations in 2,4-D samples manufactured in Europe and Russia; lower levels were observed in U.S. products. The results of Schecter et al. (1997) are presented in Table 8-27.

If it is assumed that the EPA DCI results (i.e., average TEQ level of 0.70 μg I-TEQ_{DF}/kg or 1.10 μg TEQ_{DF}-WHO_{98}/kg) are typical of CDD/CDF levels in 2,4-D pesticides over the past 20 years and that the average annual use of these pesticides in the United States has been approximately 25,000 metric tons, then the estimated CDD/CDF TEQ released to the environment from 2,4-D use during the period 1975 to 1995 was 350 g I-TEQ_{DF} (550 g TEQ_{DF}-WHO_{98}).

2,4,5-Trichlorophenoxy acetic acid (2,4,5-T) was used in the United States for a variety of herbicidal uses until the late 1970s to early 1980s. The major use of 2,4,5-T (about 41 percent of annual usage) was for control of woody and herbaceous weed pests on rights-of-way. The other major herbicidal uses were forestry (28 percent of usage), rangeland (20 percent of usage), and pasture (5 percent of usage). As discussed in Section 3.4.2.8, uses of 2,4,5-T for home or recreation areas and for lakes, ponds, and ditches were suspended by EPA in 1970. Rights-of-way, forestry, and pasture uses were suspended by EPA in 1979, and all uses were canceled in 1983.

Table 12-2 presents a compilation of historical domestic production, sales, and usage volumes for 2,4,5-T and its salts and esters. As shown in Table 12-2, production and use of 2,4,5-T generally increased each year following its introduction in the 1940s until the late 1960s. Production, sales, and usage information for the 1970s are generally not available but are reported to have steadily declined during that period (Federal Register, 1979; Esposito et al., 1980).

Some information is available on the 2,3,7,8-TCDD content of 2,4,5-T, but little information is available on the concentrations of the other 2,3,7,8-substituted CDD/CDFs that may have been present.

- Plimmer (1980) reported that 2,3,7,8-TCDD concentrations as high as 70,000 μg/kg were detected in 2,4,5-T during the late 1950s.

- In a study of 42 samples of 2,4,5-T manufactured before 1970, Woolson et al. (1972) found 500 to 10,000 μg/kg of TCDDs in 7 samples, and another 13 samples contained 10,000 to 100,000 μg/kg of TCDDs. HxCDDs were found in four samples at levels between 500 and 10,000 μg/kg and in one sample at a concentration exceeding 10,000 μg/kg, but less than 100,000 μg/kg. The detection limit in the study was 500 μg/kg.

- The average 2,3,7,8-TCDD concentration in 200 samples of Agent Orange, a defoliant containing about a 50/50 mixture of the butyl esters of 2,4,5-T and

2,4-D that was used by the U.S. Air Force in Vietnam, was 1,910 μg/kg (Kearney et al., 1973). Of the 200 samples, 64 (or 32 percent) contained more than 500 μg/kg of 2,3,7,8-TCDD, with the highest concentration reported to be 47,000 μg/kg.

- Storherr et al. (1971) reported detecting 2,3,7,8-TCDD at concentrations ranging from 100 to 55,000 μg/kg in five samples of 2,4,5-T.

- Kearney et al. (1973) reported that production samples of 2,4,5-T obtained from the three principal 2,4,5-T manufacturers in 1971 contained 2,3,7,8-TCDD at levels of $<$100 μg/kg, 100μg/kg, and 2,300 μg/kg.

- A 1975 survey of 10 lots of a commercial formulation containing 2,4,5-T showed 2,3,7,8-TCDD concentrations ranging from 10 to 40 μg/kg (Dow Chemical Co., undated).

- Analyses by EPA of 16 technical grade 2,4,5-T samples from five different manufacturers revealed 2,3,7,8-TCDD contents ranging from $<$10 to 25 μg/kg (Federal Register, 1979).

- Schecter et al. (1997) recently reported the analytical results of one sample of 2,4,5-T purchased from Sigma Chemical Co. (product number T-5785, lot number 16H3625). The results, presented in Table 12-3, indicate a total I-TEQ_{DF} concentration of 2.88 μg/kg (3.26 μg TEQ_{DF}-WHO_{98}/kg).

Because of the wide variability (i.e., three orders of magnitude) in the available limited information on the 2,3,7,8-TCDD content of 2,4,5-T (particularly the 2,4,5-T used in the 1950s) and incomplete information on domestic usage, it is difficult to reliably estimate the amount of 2,3,7,8-TCDD that was released to the U.S. environment as a result of 2,4,5-T use. A very uncertain estimate can be made using the following assumptions: (1) the average annual consumptions during the 1950s, 1960s, and 1970s were 2,000 metric tons/yr, 4,000 metric tons/yr, and 1,500 metric tons/yr, respectively; and (2) the average 2,3,7,8-TCDD concentrations in 2,4,5-T used over these three decades were 10,000 μg/kg in the 1950s, 4,000 μg/kg in the 1960s, and 100 μg/kg in the 1970s. Based on these assumptions, the very uncertain estimate of 2,3,7,8-TCDD input from 2,4,5-T use over the period 1950-1979 is 36,000 g.

Another source contributing to the soil reservoir is CDD/CDF in sewage sludge applied to land (i.e., surface disposal or land farming) is estimated to have been 103 g I-TEQ_{DF} in 1995 (75 g TEQ_{DF}-WHO_{98}) [Note: See Section 8.4.1 for details]. If this same amount of TEQ had been applied each year during the period 1975 to 1995, the total amount applied would have been 2,000 g I-TEQ_{DF} (1,500 g TEQ_{DF}-WHO_{98}).

Mechanisms Responsible for Releases from Surface Soils

Atmospheric deposition is believed to be the current primary means of supply of dioxin-like compounds to surface soil. CDD/CDFs/PCBs are highly lipid soluble, low volatility compounds, and tend to partition to soil instead of into air or water. Once present in or on soils, physical/chemical and biological mechanisms (i.e., photolysis and biodegradation) can slowly alter the composition and amount of CDD/CDFs/PCBs present. Studies indicate that the dioxin-like compounds (particularly the more highly chlorinated CDD/CDFs) exhibit little downward mobility once deposited in or on soil (Puri et al. 1989; Freeman and Schroy, 1985; Orazio et al., 1992; and Paustenbach et al., 1992). However, remobilization of the compounds to the atmosphere is possible through volatilization and resuspension of soil particles.

For example, Young (1983) conducted field studies on the persistence and movement of 2,3,7,8-TCDD during 1973-1979 on a military test area that had been aerially sprayed with 73,000 kg of 2,4,5-T during 1962-1970. TCDD levels of 10 to 1,500 ng/kg could be found in the top 15 cm of soil 14 years after the last application of herbicide at the site. Although actual data were not available on the amount of 2,3,7,8-TCDD originally applied as a contaminant of the 2,4,5-T, best estimates indicated that less than 1 percent of the applied 2,3,7,8-TCDD remained in the soil after 14 years. Photodegradation at the time of and immediately after aerial application was believed by Young (1983) to be responsible for most of the disappearance. However, once incorporated into the soil, the data indicated a half-life of 10 to 12 years (Young, 1983). Similarly, Paustenbach et al. (1992), concluded that half-lives of 2,3,7,8-TCDD in soils at the surface might be 9 to 15 years and half-lives below the surface could be 25 to 100 years.

Ayris and Harrad (1997) studied the mechanisms affecting volatilization fluxes of several PCB congeners (PCB numbers 28, 52, 101, 138, and 180) from soil and found positive correlations between flux and soil temperature, soil moisture content, and soil PCB concentration. For PCBs, secondary releases from soils (primarily via volatilization) are believed to currently exceed primary emissions in the United Kingdom (Harner et al., 1995; Jones and Alcock, 1996). Lee et al. (1998) recently quantified PCBs in air samples taken every 6 hours over a 7-day period in the summer at a rural site in England and found a strong correlation between air temperature and PCB congener concentrations. The

concentrations followed a clear diurnal cycle, thus providing some evidence that rapid, temperature controlled soil to air exchange of PCBs influences air concentrations and enables regional/global scale cycling of these compounds.

CDD/CDFs and PCBs sorbed to soil and urban dust particles can also be moved from the terrestrial environment to the aquatic environment via stormwater runoff/erosion. Results of recent research indicate that, for at least some waterbodies, erosion/stormwater runoff is currently the dominant mechanism for CDD/CDF input. For example, Smith et al. (1995) analyzed CDD/CDF concentrations in sediment cores, air, precipitation, soil, and stormwater runoff in an effort to determine the contributing sources of these compounds to the lower Hudson River. The mass balance estimates developed from these data for 1990-1993 are: stormwater runoff entering tributaries (76 percent of total CDD/CDF input), anthropogenic wastes (19 percent), atmospheric deposition (4 percent), and shoreline erosion (less than 1 percent). Smith et al. (1995) also projected the percent contribution of these same sources for 1970 as: anthropogenic wastes (70 percent), stormwater runoff into tributaries (15 percent), atmospheric deposition (15 percent), and shoreline erosion (0.1 percent).

Lebeuf et al. (1996) analyzed sediment cores from different locations in the lower St. Lawrence River Estuary and the Gulf of St. Lawrence. The congener group profiles found in the samples indicate that the input of CDD/CDFs is primarily from the atmosphere. Comparison of the CDD/CDF concentrations in sediments collected from areas where sediment accumulation is due primarily to fluvial transport with sediments from areas where sediment accumulation is due primarily to direct atmospheric deposition onto the water indicates that the contribution of CDD/CDF from direct atmospheric deposition represents less than 35 percent of the sediment burden. Thus, the primary source of CDD/CDFs is emissions to the atmosphere upwind of the Estuary that are deposited within the watershed and subsequently transported downstream by fluvial waters.

Paustenbach et al. (1996) and Mathur et al. (1997) reported that stormwater runoff from 15 sites in the San Francisco area contained CDD/CDF TEQ at levels ranging from 0.01 to 65 pg I-TEQ_{DF}/L; most samples contained less than 15 pg I-TEQ_{DF}/L. The sites differed widely in land use; the highest levels measured were obtained from an urban, but nonindustrialized area. A distinct variability was noted in the results obtained at the same sampling location during different rain events. The profiles of CDD/CDFs in the urban

stormwater samples were similar particularly in samples collected at the onset of rain events. Stowe (1996) reported similar findings from analyses of sediments from three stormwater basins collecting runoff from a military base, city street, and parking lots.

Fisher et al. (1998) reported that urban runoff samples from eight sites (15 samples) in the Santa Monica Bay watershed contained CDD/CDF TEQ at levels ranging from 0.7 to 53 pg I-TEQ_{DF}/L (all but one sample were in the range of 0.7 to 10 pg I-TEQ_{DF}/L). The samples were collected in 1988/1989 from continuously flowing storm drains during both dry and storm periods. The mean concentration measured during storm events, 18 pg I-TEQ_{DF}/L, was higher than concentration observed during dry periods, 1 pg I-TEQ_{DF}/L.

Estimated Annual Releases from Soil to Water

Nonpoint sources of CDD/CDFs to waterways include stormwater runoff from urban areas and soil erosion in rural areas during storms. Approaches to estimate national loadings to water for both of these sources are described below. The estimate derived below for the potential annual national loading of CDD/CDFs in urban runoff to waterways is uncertain, but suggests that the loading may be comparable to the contribution from known industrial point sources (at least 20 g I-TEQ_{DF} in 1995). Similarly, the estimate derived below for the potential annual national loading of CDD/CDFs in rural eroded soils to waterways is uncertain, but has a stronger analytical base than the urban run off estimate. This loading estimate, however, is significantly higher than the contribution from known industrial point sources.

Urban Runoff - Few data on CDD/CDF concentrations in urban runoff have been reported. The most recent and largest data sets were reported in studies conducted in the San Francisco Bay and Santa Monica Bay regions (Mathur et al, 1997; Fisher et al., 1998). These studies found a wide range of CDD/CDF levels in samples of stormwater runoff from 23 sites, varying from 0.01 to 83 pg I-TEQ_{DF}/L. The wide variability and limited geographic coverage of these data preclude derivation of a national emission estimate at this time. However, by making a number of assumptions, a preliminary estimate of the potential CDD/CDF magnitude from this source can be made. In order to estimate the amount of rainfall in urbanized areas of the conterminous United States, a Geographic Information Systems (GIS) analysis was performed to: determine the total area of every U.S. Census

urbanized area; to determine the 30-year annual average rainfall for each of those areas; and to calculate the product of the total areas of urbanized areas with the annual average rainfall (Lockeed Martin, 1998). This approach yields an estimate of 1.9×10^{14} L/year. If it is assumed that urban runoff in the United States averages 1 pg I-TEQ_{DF}/L (or 1 pg TEQ_{DF}-WHO_{98}/L) (i.e., approximately the midpoint of the range reported by Mathew et al. (1997) and Fisher et al. (1998)), this source could contribute a total of 190 g I-TEQ_{DF} or TEQ_{DF}-WHO_{98} per year to U.S. waterways. No data were available to make similar estimates for PCBs.

Rural Soil Erosion - The total annual sheet and rill erosion in the United States during 1992 has been estimated as 1.6 billion metric tons from rangeland and 1.1 billion metric tons from cropland (USDA, 1995). The total amount of eroded soil entering waterways is greater than this value, because this value does not include soil erosion from construction areas, forests, and other non-crop and non-rangelands. The data summarized in the companion document to this report (Volume 2) suggest that typical concentrations of CDD/CDFs in soils in rural areas is about 4.1 ng I-TEQ_{DF}/kg (or 3.6 ng TEQ_{DF}-WHO_{98}/kg. It is not known how well this estimate represents eroded soil from cropland and rangeland. If these soils contain an average of 1 ng TEQ/kg (i.e., slightly lower than the background value for all types of rural soil), they would contribute 2,700 g TEQ/yr (I-TEQ_{DF} and TEQ_{DF}-WHO_{98}) to the Nation's waterways. As with urban runoff, no data were available to make similar estimates for PCBs.

Estimated Annual Releases from Soil to Air

No quantitative estimates of the mass of dioxin-like compounds that may be released to the atmosphere annually from U.S. soils have been published in the literature and none are developed in this report. As noted above, the vapor flux of these compounds from soil to air is dependent on the soil and air concentrations of dioxin-like compounds, and the temperature, moisture content, and organic carbon content of the soil. Most of these parameters are not adequately characterized for the United States as a whole to enable a reliable estimate to be made at present. Particle flux is dependent on many factors including wind speed, vegetative cover, activity level, particle size, soil type/conditions, moisture content and particle density. Through use of models and various assumptions, Kao and Venkataraman (1995) estimated the fraction of ambient air

CDD/CDF concentrations in the upper Midwest United States that may be the result of atmospheric reentrainment of soil particles. Similarly, through use of models and various assumptions, Jones and Alcock (1996) and Harner et al. (1995) reached tentative conclusions about the relative importance of volatilization of dioxin-like compounds from soils in the United Kingdom.

Modeling re-entrainment of soil to the atmosphere was conducted by Kao and Venkataraman (1995). The soil re-entrainment model incorporated information on particle sizes, deposition velocities, and concentrations of CDD/CDFs in soils. Smaller particulates, with median diameters ranging from about 0.01 μm to 0.3 μm, are primarily formed from combustion sources when hot vapors condense and through accumulation of secondary reaction products on smaller nuclei. Particles at the upper end of this size range will deposit to the ground in several days. Large or coarse particles, having median diameters of about 8 μm, are generated from wind-blown dust, sea spray, and mechanically-generated particles. CDD/CDFs absorbed onto re-entrained soil would be included in this larger particle size. These larger particles have a lifetime in the atmosphere from a few to many hours (Kao and Venkataraman, 1995).

The fraction of ambient air concentration of CDD/CDF that results from soil re-entrainment was established based on the contribution of crustal sources to the ambient aerosol. Data on typical crustal soil concentrations in air (15 to 50 $\mu g/m^3$ for rural areas and 5 to 25 $\mu g/m^3$ for urban areas) were combined with data on the average concentrations of CDD/CDFs in soils (73 ng/kg for rural, 2,075 ng/kg for urban, and 8,314 ng/kg for industrial soils) published by Birmingham (1990) for Ontario, Canada, and several Midwest States. This analysis estimated the concentrations of CDD/CDFs in the ambient aerosol that originate from soils to be 1×10^{-3} to 4×10^{-3} pg/m^3 in rural areas and 0.01 to 0.05 pg/m^3 in urban areas. These particulate dioxin concentrations were compared to average total particulate dioxin levels of 1.36 pg/m^3 by Eitzer and Hites (1989) to arrive at the conclusion that soil re-entrainment could only account for 1 to 4 percent of the particulate dioxins in the atmosphere in urban areas and 0.1 to 0.3 percent for rural regions (Kao and Venkataraman, 1995).

This information on the size distribution of ambient aerosols and relative CDD/CDF concentrations in different particle size fractions was integrated with particle size-deposition velocities to estimate the relative contribution to the total mass deposition flux

for small and large particle sizes. Even though re-entrained soil may constitute only a small fraction of the atmospheric levels of CDD/CDFs, the contribution of dioxins in re-entrained surface soil to the total deposition flux could be significant, because coarse particles dominate dry deposition. Soil re-entrainment could possibly account for as much as 70 to 90 percent of the total dry deposition of CDD/CDFs in urban areas and 20 to 40 percent in rural regions (Kao and Venkataraman, 1995).

Two approaches were used by Jones and Alcock (1996) to assess the potential significance of CDD/CDF volatilization from soils: (1) the fugacity quotient concept and (2) a simple equilibrium partitioning model. The fugacity quotient model compares fugacities of individual CDD/CDF compounds in different environmental media to determine the tendency for these compounds to accumulate in particular environmental compartments (McLachlan, 1996). Fugacities for individual compounds, by media, were estimated by Jones and Alcock (1996) based on physical/chemical properties of the compounds, as well as the concentrations in the media. In this instance, fugacity quotients were calculated for air and soil by dividing each compound's fugacity for air by that of soil. Quotients near 1 indicate equilibrium conditions between media; values greater than 1 represent a tendency for flux (volatilization) from soil to air, while values less than 1 indicate a net flux to the soil from the air. The equilibrium partitioning model used by Jones and Alcock (1996) predicts the maximum (possible 'worst case') flux of CDD/CDFs from soil to the atmosphere. Air phase to soil partition coefficients were calculated using the ratios of soil and air fugacity capacities. Equilibrium air concentrations were then calculated using typical U.K. soil concentrations for both urban and rural settings.

From the fugacity quotient model, Jones and Alcock (1996) concluded that the lower-chlorinated CDD/CDFs may be close to soil-air equilibrium in the United Kingdom while for other congeners, soil is a sink rather than a source to the atmosphere. Jones and Alcock (1996) reported that the equilibrium partitioning model predicted that 0.15 kg I-TEQ volatilizes annually from soil in the United Kingdom. However, the authors discounted this estimate and concluded that soil volatilization is unlikely to be a significant contributor to emissions. The likelihood that these estimates were high was attributed to the fact that: (1) assumptions were made that the concentrations of CDD/CDFs in air were zero and (2) the model does not consider the resistance of CDD/CDFs to volatilize from soil.

Harner et al. (1995) developed a model to predict the long-term fate of PCBs in soils, with emphasis on soil to air exchanges. Using data on levels of PCBs in air, soil, and vegetation in the U.K., Harner et al. (1995) developed a mass balance model to simulate the fate of PCBs in U.K. soils from 1935 to 1994. Specifically, monitoring data and physical/chemical property data were compiled to calculate fugacities for PCB congeners 28, 52, 138, and 153. The model was designed to provide an order-of-magnitude-level of accuracy, due in part to the inherent variability in the input data. The mass balance equations in the model included a bell-shaped function for rates of emissions of PCBs, with the maximum emission rate occurring in 1967. From these emissions rates, fluxes between air and soil over several decades were estimated. Table 12-4 summarizes the calculated fluxes. During the 1960s and 1970s, levels of total PCBs in U.K. soils reached average levels of approximately 300 μg/kg as a result of atmospheric deposition. Because of restrictions on PCB use during the last two decades, air concentrations have fallen, and the primary source to the atmosphere is now believed to be volatilization from soils. The mass balance model estimated a net flux of 700 kg/yr of total PCBs from soils to the atmosphere in 1994. However, this estimate is presented with the caveat that the model tends to underestimate the rate of reduction of PCB concentrations in recent years, which could be attributed to other mechanisms such as biodegradation, photolysis, and other degradation processes.

12.2.2. Water

Potential Mass of Dioxin-Like Compounds Present

The surface area of inland waters (including the Great Lakes) in the United States is about 359,000 sq km (U.S. DOC, 1995a). Assuming that the mean depth of inland water is 10 meters (Duarte-Davidson et al., 1997), the total inland water volume is approximately 3,600 billion m^3. No compilation of CDD/CDF measurements in inland surface waters is made for this report. However, if it is assumed that the "typical" value used by Duarte-Davidson et al. (1997) for rivers in the United Kingdom, 38 pg I-TEQ_{DF}/m^3, is representative of U.S. waters, then the burden is calculated to be 137 g I-TEQ_{DF}.

Mechanisms Responsible for Supply to and Releases from Water

As discussed previously in Section 12.2.1, dioxin-like compounds enter surface water from atmospheric deposition, stormwater runoff erosion, and discharges of anthropogenic wastes. Volatilization is the primary mechanism for release of dioxin-like compounds from the water column to the atmosphere. Several studies have addressed the water-air exchange of dioxin-like PCBs through volatilization in the Great Lakes (Achman et al., 1993; Hornbuckle et al., 1993; Swackhamer and Armstrong, 1986; Baker and Eisenreich, 1990). No similar body of literature has been developed to address volatilization of CDD/CDFs from water.

Most studies that have addressed PCB water/air exchange have used the two-film model developed by Whitman (1927) and made popular by Liss and Slater (1974). When assessing gas exchange between air and water, the interface between the two phases can be considered as a two-layer (film) system consisting of well-mixed gas and liquid films adjacent to the interface; the rate of transfer is controlled by molecular diffusion through the stagnant boundary layer (Achman et al., 1993). Liss and Slater (1974) applied the model to assess the flux of various gases, specifically in the air-sea systems, and indicated the possibility of its use at any air-water interface in the environment, if the necessary data are available. Hornbuckle et al. (1993) concluded that the two-film model is the best available tool for estimating regional and local flux of PCBs from natural waters. The following paragraph, from Achman et al. (1993), succinctly summarizes the model. The basic equation used to describe the rate of transfer across the interface is

$$F = K_{ol}(C_w - C^*) \qquad \text{(Eqn. 12-1)}$$

where F is the flux (mol/m^2-day), C_w (mol/m^3) is the dissolved PCB concentration in the bulk water, and C* (P/H, mol/m^3) is the air concentration expressed as a water concentration in equilibrium with the air. The variable P is the vapor-phase air concentration measured (mol/m^3) and converted to units of pressure using the ideal gas law. H is Henry's Law constant (atm•m^3/mol). The overall mass-transfer coefficient, K_{ol}, has units of velocity (m/day). The concentration gradient determines the direction of flux and drives the mass transfer; whereas, K_{ol} is a kinetic parameter that quantifies the rate of transfer. The value of K_{ol} is dependent on the physical and chemical properties of the

compound as well as environmental conditions. The reciprocal of K_{ol} is the total resistance to transfer expressed on a gas- (RT/Hk_a) and liquid- ($1/k_w$) phase basis:

$$1/K_{ol} = 1/k_w + RT/Hk_a \qquad \text{(Eqn. 12-2)}$$

where k_w is the water-side mass-transfer coefficient (m/day) and k_a is the air-side mass-transfer coefficient (m/day). H is Henry's Law constant, R is the universal gas constant (8.2057×10^{-5} atm•m^3/mol K), and T is the absolute temperature, K.

Achman et al. (1993) and Hornbuckle et al. (1993) calculated the volatilization rates of PCBs from Green Bay on Lake Michigan, based on air and water samples simultaneously collected over a 14-day period above and below the air-water interphase and analyzed for 85 PCB congeners. Air samples collected over nearby land were also analyzed for the 85 PCB congeners. The direction and magnitude of flux for each congener were then calculated using Henry's Law and meteorological and hydrological parameters in the "two-film" model. (See Eqn. 12-1.)

The net total PCB transfer rate (i.e., sum of all congener transfer rates) was found to be from water to air (i.e., volatilization). However, during cool water temperature periods (i.e., October), the direction of transfer reversed for many congeners. Calculated transfer rates to air ranged from 15 to 300 ng/m^2 per day at low wind speeds (1-3 m/sec) to 50 to 1,300 ng/m^2 per day at higher wind speeds (4-6 m/sec). On a congener basis, the lower chlorinated congeners dominated total fluxes. The summary of flux calculations is presented in Table 12-5. The most important factors influencing the magnitude of volatilization were the water concentration of PCBs, wind speed, and water temperature. In addition, Achman et al. (1993) and Hornbuckle et al. (1993) found that (1) atmospheric PCB concentrations are higher over contaminated water than over nearby land, (2) atmospheric PCBs over water tend to increase with increasing dissolved PCB concentrations, and (3) the congener distribution in the atmosphere correlates linearly with the congener distributions in the adjacent water.

Achman et al. (1993) also summarized the PCB volatilization rates reported by other researchers (Baker and Eisenreich, 1990; Swackhamer and Armstrong, 1986; Strachan and Eisenreich, 1988; and Swackhamer et al., 1988) for Great Lakes water bodies. The results of these other studies, presented below, also show net flux of PCBs from water to air.

Water Body	Total PCB Volatilization Rate (ng/m^2-day)	Reference
Lake Superior	141	Baker and Eisenreich (1990)
Lake Michigan	240	Strachan and Eisenreich (1988)
Lake Superior	63	Strachan and Eisenreich (1988)
Siskiwit Lake	23	Swackhamer et al. (1988)
Lake Michigan	15	Swackhamer and Armstrong (1986)

12.2.3. Sediment

Potential Mass of Dioxin-Like Compounds Present

EPA conducted congener-specific measurements of CDD/CDFS in the sediments from 11 U.S. lakes located in areas relatively unimpacted by nearby industrial activity. The mean TEQ concentration in the uppermost sediment layers from these 11 lakes is 5.3 ng I-TEQ_{DF}/kg (dry weight) (or 5.3 ng TEQ_{DF}-WHO_{98}/kg). For most of the lakes, the uppermost layer represents about 10 years worth of sedimentation. CDD/CDF concentrations in lakes impacted by industrial activity may have higher concentrations. For example, Duarte-Davidson et al. (1997) report a TEQ concentration of 54 ng I-TEQ_{DF}/kg for urban sediments in the United Kingdom.

The surface area of inland waters in the United States is approximately 359,000 sq km (U.S. DOC, 1995a). In their calculations of sediment burdens in the United Kingdom, Duarte-Davidson et al. (1997) assumed that (1) the sediment surface area equals the water surface area, (2) the majority of CDD/CDF are located in the top 5 cm of sediment, and (3) that sediment density is 0.13 g dry weight/cm^3. Applying these assumptions to the water surface area and background TEQ concentration for U.S. sediments yields a burden of at least 120 kg I-TEQ_{DF} (or 120 kg TEQ_{DF}-WHO_{98}).

Mechanisms Responsible for Supply to and Releases from Sediment

Because sediment is closely connected to the water column above it, evaluating the potential for sediment to act as a reservoir of dioxin-like compounds is complex and likely to be more difficult than studying dioxin-like compounds in a single medium such as water or soil. Volatilization and sedimentation are two mechanisms whereby persistent chemicals such as CDD/CDF/PCBs are lost from water bodies/columns. Numerous authors

have noted that sediments are a likely sink for persistent hydrophobic organic compounds, because these compounds are likely to be strongly bound to organic particles in the sediment (Swackhamer and Armstrong, 1986; Muir et al., 1985; Ling et al., 1993).

For example, Muir et al. (1985) radiolabeled 2,3,7,8-TCDD and studied its dissipation from sediments (collected from a farm pond and a lake) to the water column in laboratory studies under static aerobic conditions at 10°C. After 675 days, more than 80 percent of the labeled TCDD were still present in the pond sediment, and 87 percent were still present in the lake sediment. Aeration had little effect on the dissipation rates.

The concept of fugacity is a useful way to estimate the behavior of dioxin-like compounds in sediments. Fugacity (tendency of a chemical to escape from a phase) is expressed in units of pressure (pascals or Pa) and is the partial pressure exerted by the chemical in each medium. Fugacity models estimate equilibrium concentrations in specific media at given chemical concentrations in the environment. Clark et al. (1988) suggested evaluating contaminant concentrations in multiple environmental media by comparing fugacity of adjoining media (e.g., comparing sediment fugacity with water column fugacity to determine the chemical's tendency to move from one to the other). The authors evaluated fugacities of certain organochlorine compounds, including PCBs, in air, water, sediment, fish, fish-eating birds, and their eggs. The authors presented PCBs fugacities developed from data collected in a study of the Lake Ontario region. The fugacities of PCBs in various media can be ranked as birds > fish > water > bottom sediment, indicating that PCBs and other similar chemicals are likely to remain in bottom sediment and are less likely to re-enter the water column (Clark et al., 1988).

Estimated Annual Releases from Sediment to Water

Ling et al. (1993) evaluated the fate of various chemicals, including PCBs, in Hamilton Harbour, located in Ontario, Canada, using a modified version of the Quantitative Water Air Sediment Interaction (QWASI) fugacity model. Among the processes evaluated were diffusion between air and water, and sediment and water; sediment deposition, resuspension, and burial; and sediment transformation. Three primary compartments were studied: air, water, and bottom sediments. The sediment was treated as a simple, well-mixed surface layer of active sediment and the buried sediment underneath. Chemicals in the active sediment were assumed to be able to exchange with the overlying

water; chemicals in the buried sediment were assumed to be isolated from the sediment-water exchange. Sediment is assumed to be homogenous instead of heterogenous. The epi- and hypolimnetic compartments of the water column were defined based on a thermocline, and the atmosphere was defined as a semi-infinite medium of constant, defined composition.

Ling et al. (1993) estimated rates of PCB movement based on 1987 loadings using two models: a model with and a model without a thermocline. The results for the water-sediment transfer using the model with a thermocline were: ~32 kg/yr enter the hypolimnion from the epilimnion; ~27 kg/yr enter the surface sediment from the hypolimnion; and ~18 kg/yr (> 50%) go to burial. For sediment to water transfer, ~7 kg/yr and 12.5 kg/yr transfer to the hypolimnion and then to the epilimnion, respectively. Similar numbers were found in the single water column model (i.e., model without a thermocline). Both models predicted volatilization from the water to the atmosphere: 1.6 and 1.8 kg/yr for thermocline and the single water column models, respectively. However, the actual contribution of PCBs from sediment to air was not determined. A comparison of estimated concentrations with observed values are presented in Table 12-6. For PCBs, 68 percent were buried in the sediment, 20 percent exported to Lake Ontario, 5.4 percent degraded in the water and sediment, and 6 percent volatilize. The authors note that these percentages are uncertain. At the sediment water exchange, more than 90 percent of each chemical are contained in the sediment because of particle deposition and the high affinity of the chemical for sediment. There was no indication that contaminants buried in the bottom sediments are transferred through diffusion mechanisms back to the surface sediments. However, episodic release of these chemicals from surface sediments can occur through mechanisms such as resuspension during flooding or lake inversions and uptake/ingestion by benthic biota.

12.2.4. Biota

Potential Mass of Dioxin-Like Compounds Present

The mass of CDD/CDFs in biota in the United States was not estimated as part of this reassessment. However, to place perspective on the potential magnitude of this reservoir, 82 g I-TEQ_{DF} have been estimated to be present in biota in the United Kingdom (50 g in humans and 32 g in vegetation), which is about three orders of magnitude less

than that estimated to be present in U.K. surface soils (Duarte-Davidson et al., 1997; Eduljee and Dyke, 1996). Applying this ratio to the estimates of CDD/CDF TEQ soil burden in the United States that were presented in Section 12.2.1 (i.e., 1,780 kg I-TEQ_{DF}) yields a biota burden in the United States of about 2 kg I-TEQ_{DF}.

Mechanisms Responsible for Supply to and Releases from Biota

Apparently, very little of the dioxin-like compounds contained in contaminated soil, unlike certain other compounds and heavy metals, is ultimately taken up by the vegetation growing in the soil. For example, Kjeller et al. (1991) analyzed concentrations of CDD/CDFs in archived soil and grass samples collected at an English experimental station from mid-1840s to the present and found that only 0.006 to 0.02 percent of the soil burden of CDD/CDFs was taken up by the grass. In addition, scientists generally agree that, once taken up by plant tissue, CDD/CDFs are not translocated to other parts of the plant (e.g., fruits, shoots, etc.) (Bacci and Gaggi, 1985; Hülster and Marschner, 1993, 1994; Nakamura et al., 1994).

Researchers have found that the concentration of dioxin-like compounds in the plant should reach equilibrium with the vapor phase concentrations of dioxin-like compounds in the surrounding air (Bacci et al., 1990a, 1990b; Frank and Frank, 1989; Horstman and McLachlan, 1992; McCrady and Maggard, 1993; McLachlan et al., 1995; Paterson et al., 1991; Simonich and Hites, 1994; Tolls and McLachlan, 1994; Welsch-Pausch et al., 1995). Horstman and McLachlan (1992) stated that the leaf-air transfer of volatile compounds is a reversible process governed by concentration gradients. If CDD/CDF concentrations are higher in the surrounding air than they are in the air spaces within plant tissue, CDD/CDF should diffuse into the plant. Once equilibrium is reached and CDD/CDF concentrations in the plant equal that of surrounding air, no more CDD/CDF should be taken into the plant. When CDD/CDF concentrations in surrounding air begin to decrease, CDD/CDFs should diffuse (probably at a slow rate) out of the plant tissue. Apparently, CDD/CDFs are not bioconcentrated to a significant extent in the lipid portion of the leaf cuticle (Gaggi et al., 1985). The CDD/CDFs present in the leaf tissue are predominantly released from the plant through leaf fall onto soil. As a result, vegetation is not likely to be a long-term reservoir of dioxin-like compounds.

Research suggests that dioxin-like compounds within animal tissue, unlike in vegetation, seldom, if ever, reach equilibrium with vapor phase concentrations in the surrounding atmosphere (or water column concentrations in the case of aquatic life). Rather, animals exposed to dioxin-like compounds are known to bioaccumulate these compounds, primarily in body fat (U.S. EPA, 1993a; 1993j). Nonetheless, animals, unlike plants, can metabolize certain chlorinated hydrocarbons after they enter the body (Carlberg et al., 1983). Dioxin-like compounds can be released from an animal's body (at congener-specific rates) through metabolic processes or through weight loss, breast-feeding, or sweating. McLachlan (1996) reported the half-life for the clearance of 2,3,7,8-TCDD from humans to be 7 years. As a result, animal life has a greater potential than does vegetation for being a long-term reservoir source of CDD/CDFs. The majority of the dioxin-like compounds released by animals in the form of waste materials will be released to water or soil. Similarly, upon death, the dioxin-like compounds remaining in the body will be deposited onto soil or aquatic sediments or will be ingested by other animals.

Approaches to Measure and Estimate Releases from Biota - Researchers have investigated the uptake and release of CDD/CDFs by vegetation through measurement of actual concentrations of CDD/CDFs during uptake and release by vegetation grown in closed systems (greenhouses). Bacci et al. (1992) conducted uptake and release studies of 1,2,3,4-TCDD by plant foliage in a closed system (specially constructed greenhouse). Concentrations of TCDD vapor in the greenhouse air were maintained during the 370-hour uptake phase at a mean concentration of 0.0062 ng/L (air concentration varied slightly from 0.0050 to 0.0075 ng/L). To begin the release phase, the TCDD vapor source (amended sand), as well as the greenhouse walls were removed, and release of CDD/CDFs from the leaves was measured for 500 hours. Bacci et al. (1992) concluded that during uptake, TCDD concentration in the leaves varied as a function of time and was dependent on the concentration of vapor-phase TCDD in the surrounding air. These researchers estimated the release of TCDD from the vegetation to be relatively slow with a half-life of TCDD of 3,300 hours.

McCrady and Maggard (1993) conducted a mass balance study of uptake and release of dioxin in grass foliage. The results indicated a half-life of dioxin in grass of 128 hours (McCrady and Maggard, 1993). These researchers also noted that photodegradation

of dioxins on the foliage appeared to be a significant removal mechanism in addition to volatilization. They calculated the photodegradation half-life to be 44 hours (McCrady and Maggard, 1993).

Interpretation of uptake and release data over variable exposure times and contaminant concentrations has led to the development of models describing air-to-vegetation equilibrium and kinetics controlling the behavior of dioxin in vegetation. Some earlier fugacity modeling attempts described the leaf of a plant as behaving as a single compartment. One-compartment models were described by Bacci et al. (1990a; 1990b), Trapp et al. (1990), and Schramm et al. (1987) (as cited in Tolls and McLachlan, 1994). Researchers presenting most of the recently developed models claim that the available data better support the concept of a leaf behaving as two-compartments (Riederer, 1990; Paterson et al., 1991; Horstman and McLachlan, 1992; McCrady and Maggard, 1993; Tolls and McLachlan, 1994; McLachlan et al., 1995). Input parameters considered by most models include critical chemical characteristics of the contaminant, characteristics of the plant, exposure times, and contaminant concentrations measured within the plant.

Riederer (1990) suggested treating a leaf as multiple compartments, having different accessibility to the atmosphere and different diffusion resistances. Input parameters for the two-compartment model are octanol/water coefficients, cuticle/water partition coefficients, aqueous solubility, and saturation vapor pressure of the chemical of concern. Outputs of the model are prediction of equilibrium concentration in different leaf tissues, estimates of air-to-vegetation bioconcentration equilibria, and identification of leaf compartments in which compounds are likely to accumulate. Riederer (1990) also presents an approach for using the model to semiquantitatively assess the potential for revolatilization of dioxins from vegetation.

One advantage of the model presented by Riederer (1990) is that it considers critical plant characteristics in the release of dioxins. A plant is an active organism, responding to changes in its environment, and acting accordingly to ensure its survival. Certain plant characteristics, such as the action of stomata (specialized cells usually on the lower leaf surface that open and close to control passage of vapors into and out of the leaf interior) and total leaf volume, are important factors that effect the release rates of vapor phase contaminants from vegetation.

Paterson et al. (1991) also presented a two-compartment model for release of dioxin-like compounds from vegetation. This model describes a plant as being made up of compartments in terms of their volume fractions of air, water, and nonpolar (lipid-soluble, or octanol-equivalent) organic matter. Paterson et al. (1991) attempted to show that leaf-air equilibrium and kinetics can be correlated with chemical properties of the contaminant and properties of the leaf. Paterson et al. (1991) suggest that the clearance rate constant (k_2) can be correlated with the bioconcentration factor (BCF). This model does not consider critical plant characteristics, such as action of the stomata, and for this reason may be less reliable than models that do consider plant characteristics, such as the model presented by Riederer (1990).

Horstman and McLachlan (1992) developed a fugacity model to describe release of semivolatile organic compounds from the surface of a solid (spruce needles). Their approach was slightly different in that their goal was instrument/method development, but their data supported the behavior of a leaf as a two-compartment system.

McCrady and Maggard (1993) also collected data supporting the importance of viewing a leaf as a two-compartment system. They used a two-compartment model similar to the one described by Paterson et al. (1991), which also does not consider critical plant characteristics, and may be less reliable than models that do (e.g., Reiderer, 1990).

Tolls and McLachlan (1994) exposed grass cultures for up to 240 hours to several semivolatile organic compounds and then measured the release of contaminants from the grass. They developed a two-compartment partitioning model based on the data they collected. The model consisted of a small surface compartment (the leaf cuticle) and large interior reservoir (air spaces within the leaf). Their model assumes the flux of a chemical is the product of the fugacity difference (surface fugacity minus reservoir fugacity) and the conductance between the leaf compartments.

In an attempt to validate this model, McLachlan et al. (1995) compared concentrations of semivolatile organic compounds measured in grass grown under field conditions with concentrations predicted by their previous laboratory work with a fugacity meter. The concentrations measured in the grass cultures agreed with results predicted by the mathematical model described by Tolls and McLachlan (1994).

12.3. SUMMARY AND CONCLUSIONS

As depicted in Figure 12-1 a set of complex relationships exist among reservoirs and between reservoirs and contemporary formation sources. The significance of reservoirs for human exposure is more dependent on their ability to affect the concentration of dioxin-like compounds in other media than on their size or net release rate. This Section, first summarizes and draws conclusions from the limited information available regarding the character and magnitude of reservoir sources. Second, it uses this information to discuss the implications of reservoir sources to human exposure.

12.3.1. Reservoir Sources

Noted below are some summary statements about soil reservoir sources

- Soil is likely to be the reservoir source with the greatest potential for release of CDD/CDFs to other environmental media, particularly to water. This is due in part to its relatively large mass of stored CDD/CDF, but more importantly, it is due to the existence of demonstrated transport mechanisms for intermedia exchange, i.e. soil erosion to surface waters and particle resuspension to air.

- The preliminary estimates of CDD/CDF runoff from urban areas to waterways is comparable to known industrial point source releases and runoff from agricultural areas to surface waters is over 100 times greater. It is unclear how much of the soil erosion and runoff represents recently deposited CDD/CDFs from primary sources or longer term accumulation. Much of the eroded soil comes from tilled agricultural lands which would include a mix of CDD/CDFs from various deposition times. The age of CDD/CDFs in urban runoff is less clear.

- Based on the limited information currently available (i.e., primarily fugacity modeling), volatilization of CDD/CDFs from soils is not believed to significantly alter ambient air concentrations. However, volatilization of PCBs from soil may be a significant process.

- Based on the limited information currently available, resuspension of soil may account for a small fraction (~4 percent) of CDD/CDF concentrations in air. This resuspended soil may, however, constitute a more significant portion of dry deposition.

Noted below are some summary statements about water reservoir sources:

- It is unclear if volatilization of CDD/CDFs from water can significantly alter air concentrations. For PCBs, however, the water-air exchange appears to

be significant and for some water bodies results in a net transfer from water to air.

- Water is the major media contributing CDD/CDF/PCBs to sediment. Note that most of the CDD/CDF in sediments originally came from soils. For specific water bodies, however, the CDD/CDFs/PCBs in sediments may have been dominated by local industrial discharges to water.

Noted below are some summary statements about sediment reservoir sources:

- It is important to distinguish between surface and deep sediments. Surface sediments are commonly resuspended and introduced back into the water and deep sediments generally do not interact with the water column. Surface sediments can contribute significantly to the CDD/CDF/PCB concentration in water; whereas deep sediments do not.

- There is little, if any, movement of dioxin-like compounds once they are buried in the bottom sediments. Bottom sediments may be considered as sinks.

Noted below are some summary statements about biota reservoir sources:

- The mass of CDD/CDF in vegetation at any given time is likely to be small compared to the mass in soil. Vegetation does play an important role in transferring CDD/CDF from the air to the soil via the decay of plant biomass.

- Release by volatilization from vegetation has been studied and modeled using the fugacity approach, and half-lives have been estimated. Based on these results, volatilization is not believed to be a significant mechanism for release of CDD/CDFs or PCBs except possibly during forest/brush fires.

- The mass of CDD/CDF in animals at any given time is likely to be small compared to the mass in soil. Similarly releases are small and occur primarily by excretion and decomposition of dead biomass.

12.3.2. Implications for Human Exposure

Although, the ability to make quantitative estimates of releases from reservoir sources is limited at present, it is reasonable to conclude that the contribution of reservoir sources to human exposure may be significant. As explained in Volume 2, the diet accounts for over 95% of human exposure. Although the size of the biota reservoir is small compared to the soil and sediment reservoirs, it is clearly the key contributor to human exposure. The potential contribution of the other reservoirs to human exposure is discussed below.

PCB Reservoir Releases: Since current sources of newly formed PCBs are most likely negligible, human exposure to the dioxin-like PCBs is thought to be derived almost completely from current releases of old PCBs stored in reservoir sources. Key pathways involve releases from both soils and sediments to both aquatic and terrestrial food chains. As discussed in Volume 2, one third of general population TEQ_{DFP} exposure is due to PCBs. Thus, at least one third of the overall risk to the general population from dioxin-like compounds comes from reservoir sources.

CDD/CDF Releases from Soil and Sediments to Water and Exposure via the Aquatic Pathway: The earlier discussion has shown that soils can have significant inputs to waterways via soil erosion and runoff. Similarly the sediment reservoir contributes significantly to CDD/CDF concentration in water. These releases appear to be greater than those from the primary sources included in the inventory. Dioxins in waterways bioaccumulate in fish and fish consumption causes human exposure. Fish consumption makes up about one third of the total general population CDD/CDF TEQ exposure. This suggests that a significant portion of the CDD/CDF TEQ exposure could be due to releases from the soil and sediment reservoir.

CDD/CDF Releases from Soil to Air and Exposure via the Terrestrial Pathway: Potentially, soil reservoirs could have vapor and particulate releases which deposit on plants and enter the terrestrial food chain. The magnitude of this contribution, however, is unknown. EPA plans future studies in agricultural areas which will compare modeled air concentrations from primary sources to measured levels as a way to get further insight to this issue.

13. BALL CLAY

13.1 INTRODUCTION

The purpose of this chapter is to evaluate the potential for environmental releases of dioxin-like compounds during the mining of ball clay and its subsequent uses. The presence of dioxin-like compounds in ball clay was discovered in 1996 as a result of an investigation to determine the sources of relatively high levels of dioxin found in two chicken fat samples during a national survey of poultry. The survey was conducted jointly by the U.S. Department of Agriculture and U.S. Environmental Protection Agency to assess the national prevalence and concentrations of CDDs, CDFs, and coplanar PCBs in poultry (Ferrario et al., 1997). The results of the investigation indicated soybean meal added to chicken feed was the source of dioxin contamination (Ferrario, Byrne and Cleverly, 2000). Further investigation showed that the CDD contamination came from the ball clay added to the soymeal as an anticaking agent. The ball clay was added at approximately 0.3% to 0.5% of the soybean meal. Samples of raw ball clay were subsequently taken at the mine of origin in Mississippi. Analysis of the ball clay obtained from the active mine showed elevated levels of CDDs having a congener profile similar to the CDD profiles found in the soymeal, chicken feed and immature chickens.

13.2 CHARACTERISTICS OF MISSISSIPPI EMBAYMENT BALL CLAYS

The ball clays from the mine discussed above are part of a larger ball clay resource which spans portions of western Kentucky, Tennessee, and Mississippi. These clays were deposited along the shores of the Mississippi Embayment during the early to middle Eocene Epoch which occurred approximately 40-45 million years ago. The Mississippi Embayment ball clays are secondary clays comprised mainly of poorly defined crystalline kaolinite. Other minerals present include illite, smectite, and chlorite. Quartz sand is the major nonclay mineral. These deposits of ball clay occur in lenses surrounded by layers of sand, silt, and lignite. These clays can have a gray appearance caused by the presence of finely divided carbonaceous particles. It is not uncommon to find black carbonized imprints of fossil leaves and other plant debris in the clay (Patterson and Murray, 1984).

The plasticity of ball clay makes this an important natural resource for the ceramic industry. The breakdown of the ceramic uses of ball clay include: 33% floor and wall tile;

24% sanitary ware; 11% pottery; and 32% other industrial and commercial uses (Virta, 2000). A minor use of ball clay was as an anticaking agent in animal feeds, which has subsequently been discontinued by the U.S. Food and Drug Administration (Headrick et al., 1999). Total mining of ball clay in 1999 was 1.14 million metric tons (Virta, 2000).

13.3 LEVELS OF DIOXIN-LIKE COMPOUNDS IN BALL CLAY

The joint EPA/FDA and USDA investigation of ball clay as a source of dioxin contamination in animal feeds resulted in sampling the clay at an operational mine in western Mississippi. Eight samples of raw (unprocessed) ball clay were collected from an open mining pit at a depth of about 10 to 15 m. Samples were prepared and analyzed by EPA using high resolution gas chromatography coupled with high resolution mass spectrometry (HRGC/HRMS) using EPA Method 1613 (Ferrario et al., 2000). The concentrations of the CDD/CDFs present in the raw ball clay samples from the one mine are shown in Table 13-1. The Limits of Detection (LOD):Limits of Quantification (LOQ) for the CDD/CDFs in the clay samples were 0.5:1 pg/g (ppt) d.w for the tetras, 1.0:2.0 pg/g for the pentas, hexas, and heptas, and 5.0/10.0 pg/g for the octas. The mean concentrations of all of the CDDs exceeded 100 ppt (d.w.). OCDD is found at the highest concentration in all of the samples followed by either 1,2,3,4,6,7,8-HpCDD or 1,2,3,7,8,9-HxCDD. The maximum OCDD concentration in the eight samples was approximately 59,000 pg/g. The most toxic tetra- and penta-congeners were present at unusually high concentrations in all of the samples with average concentrations of 711 pg/g and 508 pg/g for 2,3,7,8-TCDD and 1,2,3,7,8-PeCDD, respectively. Although the ball clays show elevated levels of 2,3,7,8-substituted CDDs, they show very low levels of 2,3,7,8-substituted CDFs. In addition, there was a consistent ratio within the HxCDD congener distribution across all samples (i.e., 1,2,3,7,8,9-HxCDD was present at higher concentrations than the other 2,3,7,8-substituted HxCDD congeners). The average percent distribution among the three individual 2,3,7,8-hexa congeners was 5:17:78. This congener pattern was observed in all the raw ball clay samples analyzed. The mean total TEQ_{DF}-WHO_{98} for the raw ball clay was determined to be 1,513 pg/g, d.w. 2,3,7,8-TCDD accounted for 47% of the TEQ_{DF}-WHO_{98}, followed by 1,2,3,7,8-PeCDD at 34%. As expected, even though present at the highest concentration, OCDD contributed less than 1% percent of the total TEQ_{DF}-WHO_{98} due to its relatively small WHO-TEF. In

comparison, the typical range of background TEQ_{DF}-WHO_{98} concentrations in North American urban and rural surface soils samples are 2 to 21 pg/g and 0.1 to 6 pg/g, respectively (see Volume 3: Properties, Environmental Levels, and Background Exposures, EPA/600/P-00/001Bc). In soil samples, all 2,3,7,8-CDD/CDF congeners are detected, and 2,3,7,8-TCDD represents less than one percent of total CDD/CDF present. The most prevalent congeners in soils are OCDD followed by OCDF. Table 13-2 compares the mean CDD/CDF congener group concentrations in ball clay to the mean congener group concentrations in rural and urban background soils. This comparison indicates there are no similarities in the congener group distributions between the ball clay and soils.

13.4 EVIDENCE FOR BALL CLAY AS A NATURAL SOURCE

Several lines of evidence suggest that dioxin-like compounds in ball clay are of natural origin:

- The clay samples were obtained from undisturbed deposits. It is unknown how human activity could have contaminated these deposits without disturbing them.

- EPA's Laboratory in Athens, Georgia, analyzed the Mississippi mine clays using a broad screen for anthropogenic contaminants and no compounds were found outside of the normal range. All known anthropogenic sources of dioxin have associated with them a wide variety of other contaminants. The absence of elevated levels of other compounds is strong evidence that the dioxins found in the clay are not the result of waste disposal.

- The congener profiles of ball clay do not match known anthropogenic sources (these profiles are presented in Chapters 2 - 8 of this Volume). Cleverly et al. (1997) reported on the congener profiles that are typical of known anthropogenic sources of dioxin-like compounds in the United States. These analyses were used as a basis for comparison to the profile of the raw ball clay.

    - The congener pattern characteristic of waste combustion sources differs significantly from the ball clay profile in several aspects. In combustion source emissions, all 2,3,7,8-substituted CDD and CDF congeners are measured and 2,3,7,8-TCDD is usually 0.1 to 1.0 percent of total CDD/CDF mass emitted. In ball clay, 2,3,7,8-TCDD is approximately 5% of total mass of dioxins present. As with the ball clay, the most prevalent 2,3,7,8-Cl substituted CDD congeners in most incinerator emissions are OCDD and 1,2,3,4,6,7,8-HpCDD. However, combustion emissions contain appreciable amounts of CDFs of which the 1,2,3,4,6,7,8-HpCDF, OCDF, 1,2,3,4,7,8-HxCDF, 2,3,7,8-TCDF and 2,3,4,6,7,8-HxCDF congeners dominate.

    - The combustion of wood generates a congener profile not unlike that of waste incinerator, (i.e., the ratio of CDD/CDF <1), and all laterally substituted

congeners can be detected in emissions. The combustion of tree bark produces a congener profile in which the CDD/CDF ratio is >1, showing only minimal and barely detectable levels of CDFs in the smoke, the exception being that 2,3,7,8-TCDF is present at approximately 2% of total mass. The dominant congener in tree bark combustion emissions is OCDD (>30% total CDD/CDF mass), followed by 1,2,3,4,6,7,8-HpCDD and 1,2,3,7,8,9-HxCDD.

- The congener profile of 2,4-D salts and esters seems to mimic a combustion source profile in the number of congeners represented, and in the minimal amount of 2,3,7,8-TCDD relative to all 2,3,7,8-Cl substituted congeners. Nevertheless, unlike the combustion source profile, the 1,2,3,7,8-PeCDD and the 1,2,3,4,6,7,8-HpCDF constitute major fractions of total CDD/CDF contamination present in 2,4-D.

- The congener profile of technical grade pentachlorophenol (PCP) is clearly dominated by OCDD and 1,2,3,4,6,7,8-HpCDD. However, only trace amounts of 2,3,7,8-TCDD are detected in PCP, and 1,2,3,4,6,7,8-HpCDF and OCDF constitute roughly 15% of typical formulations.

- Metal smelting and refining processes, such as secondary aluminum, copper and lead smelting, also have all the 2,3,7,8-Cl substituted CDD/CDF congeners in stack emissions. In secondary aluminum smelting, 2,3,7,8-TCDD is less than 0.1% of total CDD/CDFs whereas PeCDF is nearly 25% of total emissions of dioxin-like compounds, and the CDD/CDF ratio is <1. Secondary copper operations show a similar pattern of CDD/CDF emissions, but with five compounds dominating emissions: 1,2,3,4,7,8-HxCDF, 1,2,3,6,7,8-HxCDF, 1,2,3,4,6,7,8-HpCDF, OCDF, OCDD, and 1,2,3,4,6,7,8-HpCDD. In iron ore sintering, the dominant congener in emissions of 2,3,7,8-Cl substituted compounds is 2,3,7,8-TCDF.

- A number of studies have shown that natural processes can produce chlorinated aromatic compounds including dioxin-like compounds. Gribble (1994) reviewed the biological production of a wide variety of halogenated organic compounds in nature. For example, the Mississippi salt march grass "needlerush" (*Juncus roemerianus*) contains the aromatic compound 1,2,3,4-tetrachlorobenzene and the blue-green alga, *Anacystis marina* naturally contains chlorophenol (Gribble, 1994). The soil fungus, *Penicillium sp.*, produces 2,4-dichlorophenol, and the common grasshopper is known to secrete 2,5-dichlorophenol (Gribble, 1994). Urhahn and Ballschmiter (1998) also provide a good review of the chemistry of the biosynthesis of chlorinated organic compounds under natural conditions. It has been hypothesized that CDDs, CDFs, and other chlorinated aromatic compounds can be naturally formed from halogenated humic substances and halomethanes through chloroperoxidase-mediated reactions in undisturbed peat bogs (Silk et al., 1997). A similar chloroperoxidase-mediated biochemical formation of CDD/CDFs from chlorophenols was achieved under laboratory conditions by Oberg and Rappe (1992). It has been observed that chlorophenols can be biosynthesized (Gribble, 1994; Silk et al., 1997), and that chorophenols are readily adsorbed into peat-bentonite mixtures (Virarghavan and Slough, 1999). Hoekstra et al. (1999) offered

the hypothesis that 2,3,7,8-TCDD, 1,2,3,7,8-PeCDD, and 1,2,3,7,8,9-HxCDD can be naturally formed in soils of coniferous forests from chlorinated phenol. These same congeners are also the predominant congeners in the ball clay from the Mississippi Embayment. Although none of these natural processes can be directly attributed to the presence of dioxin in ball clay, the existence of such mechanisms lends plausibility to a hypothesis that they are of natural origin.

- CDD/CDFs have been found in other clays quite distant from Mississippi Embayment ball clay deposits. No evidence of anthropogenic sources have been discovered in these areas either. Recently the presence of the CDDs have been discovered in kaolinitic clay mined in Germany (Jobst and Aldag, 2000). Because no anthropogenic source could be determined to explain the presence and levels of CDDs in the ball clay, Jobst and Aldag (2000) speculated that the CDDs were the result of an unknown geologic process. In addition, the German clay also has a congener profile similar to that observed in the Mississippi ball clay with an absence of CDFs at comparable concentrations and the predominance of the 1,2,3,7,8,9-HxCDD among the toxic hexa-CDDs. The similarity in the congener profiles in ball clay mined in the United States and Germany suggests a common origin to the CDDs present in these clays (Ferrario, Byrne, and Cleverly, 2000).

In summary, no anthropogenic sources have been identified that explain the levels and profiles of CDD/CDFs present in the clay. On the other hand, no definitive scientific evidence has been brought forward that identifies the principal chemical and physical mechanism involved to cause the selective chemical synthesis of CDDs under the conditions inherent to the formation of ball clays some 40 million years ago. In order to further understand the origin of CDDs in these clays, EPA is currently planning systematic evaluation of the distribution of CDDs in these clay deposits and the surrounding area.

13.5 ENVIRONMENTAL RELEASES OF DIOXIN-LIKE COMPOUNDS FROM THE MINING AND PROCESSING OF BALL CLAY

In 1995, approximately 993 million kg ball clay was mined in the United States (Virta, 2000). Multiplication of the mean TEQ_{DF}-WHO_{98} concentration in mined ball clay by the total amount of ball clay mined in 1995 gives an estimate of 1,502 grams TEQ_{DF}-WHO_{98} contained in all the ball clay mined in 1995. It is unknown if any of these CDDs are released to the environment during the mining, initial refining and product handling. As discussed above, most ball clay is used to produce ceramics through a process of high temperature vitrification. The temperatures found in ceramic kilns are well above the levels needed for both volatilization and destruction of CDDs. Even though these high

temperatures exist, it is unclear whether some release occurs and no stack measurements have yet been made. Therefore, insufficient evidence is available to make even a preliminary estimate of releases and this activity is classified as a category "E" source.

Table 13-1. Concentrations of CDDs Determined in Eight (8) Ball Clay Samples in the U.S.

Congener	Concentrations (pg/g, dry weight)				
	Mean	Median	Minimum	Maximum	TEQ_{DF}-WHO_{98}
2,3,7,8-TCDD	711	617	253	1,259	711
1,2,3,7,8-PeCDD	508	492	254	924	508
1,2,3,4,7,8-HxCDD	131	134	62	193	13

1.0. BACKGROUND AND SUMMARY

1.1. BACKGROUND

This reassessment is comprised of three reports:

Part 1. *Estimating Exposure to Dioxin-Like Compounds* (U.S. EPA, 2000a) (which expanded upon a 1988 draft exposure report titled, *Estimating Exposure to 2,3,7,8-TCDD* [U.S. EPA, 1988]);
Part 2. *Health Assessment of 2,3,7,8-Tetrachlorodibenzo-p-Dioxin (TCDD) and Related Compounds* (U.S. EPA, 1994; U.S. EPA, 2000b); and
Part 3. *Dioxin: Integrated Summary and Risk Characterization for 2,3,7,8-Tetrachlorodibenzo-p-Dioxin (TCDD) and Related Compounds* (U.S. EPA, 2000c).

Throughout the remainder of this document, these three parts as a whole will be abbreviated as the Reassessment Documents, and the individual parts will be referred to as the Exposure Reassessment Document, the Health Reassessment Document, and the Risk Characterization. The Exposure Reassessment Document has expanded to three volumes, as discussed below. Volumes 1 and 2 of the Exposure Reassessment Document are summarized in Section 4 of the Risk Characterization.

The process for developing the Reassessment Documents has been open and participatory. Each of the documents has been developed in collaboration with scientists from inside and outside the Federal Government. Each document has undergone extensive internal and external review, including review by EPA's Science Advisory Board (SAB). In September 1994, drafts of each document were made available for public review and comment. This included a 150-day comment period and 11 public meetings around the country to receive oral and written comments. These comments, along with those of the SAB (U.S. EPA, 1995), have been considered in the drafting of this final document. The Dose-Response Chapter of the Health Document underwent peer review in 1997 (U.S. EPA, 1997); an earlier version of the Integrated Summary and Risk Characterization underwent development and review in 1997 and 1998, and comments have been incorporated. In 1998, EPA released a workshop review version of the sources inventory (U.S. EPA, 1998), one of the three volumes of the Exposure Reassessment Document. In addition, as requested by the SAB, a chapter on Toxic Equivalency has been developed and underwent external peer review in parallel with the Integrated Summary and Risk Characterization in July 2000. The November 2000, review by the SAB of the Dose-Response Chapter, the Toxic Equivalency Chapter and the Integrated

Summary and Risk Characterization was the final step in this open and participatory process of reassessment. The full set of background documents and the integrative summary and risk characterization replace the previous dioxin assessments as the scientific basis for EPA decision-making.

The final Exposure Reassessment Document reflects changes made as a result of both review comments and analyses of a variety of other types of information that has come available. These include relevant information obtained from published peer-reviewed literature, EPA program offices, and other Federal agencies. This version of the Exposure Reassessment Document is current in this regard through 2000.

The purpose of the Exposure Reassessment Document is threefold: 1) to inventory the known sources of release of dioxins into the environment, 2) to develop an understanding of dioxins in the environment, including fate and transport properties, environmental and exposure media concentrations, background as well as elevated exposures, and temporal trends in exposure, and 3) provide site-specific procedures for evaluating the incremental exposures due to specific sources of dioxin-like compounds. Following this structure, the Exposure Reassessment Document is presented in three volumes:

Volume 1 - Sources of Dioxin-Like Compounds in the United States

This volume presents a comprehensive review of known sources of environmental releases of dioxin-like compounds in the United States. It includes an inventory of known source activity in terms of estimates of annual releases of dioxin-like compounds into the U.S. environment (i.e., air, water and land). This inventory is specific for two reference years, 1987 and 1995. From these data, it is possible to compare and contrast releases of dioxin-like compounds among the sources and between the reference years.

Volume 2 - Properties, Environmental Levels, and Background Exposures

This volume presents and evaluates information on the physical-chemical properties, environmental fate, environmental and exposure media levels, background and elevated human exposures, and temporal trends of dioxin-like compounds in the U.S. environment during the 20th century.

Volume 3 - Site-Specific Assessment Procedures

This volume presents procedures for evaluating the incremental impact from sources of dioxin release into the environment. The sources covered include contaminated soils, stack emissions, and point discharges into surface water. This volume includes sections on: exposure parameters and exposure scenario development; stack emissions and atmospheric transport modeling; aquatic and

terrestrial fate, and food chain modeling; demonstration of methodologies; and uncertainty evaluations including exercises on sensitivity analysis and model validation, review of Monte Carlo assessments conducted for dioxin-like compounds, and other discussions.

The primary technical resource supporting the development of the inventory of sources of dioxin-like compounds discussed in Volume I (above) is the Database of Sources of Environmental Releases of Dioxin-Like Compounds in the United States (EPA/600/C-01/012. March 2001). This database includes congener-specific CDD and CDF emissions data extracted from original engineering test reports. It has been published independently from the Reassessment and is available on Compact Disk-Read only Memory (CD-ROM), without cost, from EPA's National Service Center for Environmental Publications (NSCEP) in Cincinnati, Ohio (telephone: 1-800-490-9198, or 513-489-8190; fax: 513-489-8695). Summary files from the database will be available for downloading from the Web page of the National Center for Environmental Assessment, www.epa.gov/ncea/dioxin.htm. Instructions on how to order and obtain the CD-ROM will also be available on the Web page.

1.2. DEFINITION OF DIOXIN-LIKE COMPOUNDS

This assessment addresses specific compounds in the following chemical classes: polychlorinated dibenzo-*p*-dioxins (PCDDs or CDDs), polychlorinated dibenzofurans (PCDFs or CDFs), polybrominated dibenzo-*p*-dioxins (PBDDs or BDDs), polybrominated dibenzofurans (PBDFs or BDFs), and polychlorinated biphenyls (PCBs), and describes this subset of chemicals as "dioxin-like." Dioxin-like refers to the fact that these compounds have similar chemical structure, similar physical-chemical properties, and invoke a common battery of toxic responses. Because of their hydrophobic nature and resistance towards metabolism, these chemicals persist and bioaccumulate in fatty tissues of animals and humans. The CDDs include 75 individual compounds; CDFs include 135 different compounds. These individual compounds are referred to technically as congeners. Likewise, the BDDs include 75 different congeners and the BDFs include an additional 135 congeners. Only 7 of the 75 congeners of CDDs, or of BDDs, are thought to have dioxin-like toxicity; these are ones with chlorine/bromine substitutions in, at a minimum, the 2, 3, 7, and 8 positions. Only 10 of the 135 possible congeners of CDFs or of BDFs are thought to have dioxin-like toxicity; these also are ones with substitutions in the 2, 3, 7, and 8 positions. This suggests that 17 individual CDDs/CDFs, and an additional 17 BDDs/BDFs, exhibit dioxin-like toxicity. The database on many of the brominated

compounds regarding dioxin-like activity has been less extensively evaluated, and these compounds have not been explicitly considered in this assessment.

There are 209 PCB congeners. Only 13 of the 209 congeners are thought to have dioxin-like toxicity; these are PCBs with 4 or more lateral chlorines with 1 or no substitution in the ortho position. These compounds are sometimes referred to as coplanar, meaning that they can assume a flat configuration with rings in the same plane. Similarly configured polybrominated biphenyls (PBBs) are likely to have similar properties. However, the database on these compounds with regard to dioxin-like activity has been less extensively evaluated, and these compounds have not been explicitly considered in this assessment. Mixed chlorinated and brominated congeners of dioxins, furans, and biphenyls also exist, increasing the number of compounds potentially considered dioxin-like within the definitions of this assessment. The physical/chemical properties of each congener vary according to the degree and position of chlorine and/or bromine substitution. Very little is known about occurrence and toxicity of the mixed (chlorinated and brominated) dioxin, furan, and biphenyl congeners. Again, these compounds have not been explicitly considered in this assessment. Generally speaking, this assessment focuses on the 17 CDDs/CDFs and a few of the coplanar PCBs that are frequently encountered in source characterization or environmental samples. While recognizing that other "dioxin-like" compounds exist in the chemical classes discussed above (e.g., brominated or chlorinated/brominated congeners) or in other chemical classes (e.g., halogenated naphthalenes or benzenes, azo- or azoxybenzenes), the evaluation of less than two dozen chlorinated congeners is generally considered sufficient to characterize environmental "dioxin."

The chlorinated dibenzodioxins and dibenzofurans are tricyclic aromatic compounds with similar physical and chemical properties. Certain of the PCBs (the so-called coplanar or mono-ortho coplanar congeners) are also structurally and conformationally similar. The most widely studied of this general class of compounds is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). This compound, often called simply "dioxin," represents the reference compound for this class of compounds. The structure of TCDD and several related compounds is shown in Figure 1-1. Although sometimes confusing, the term "dioxin" is often also used to refer to the complex mixtures of TCDD and related compounds emitted from sources, or found in the environment or in biological samples. It can also be used to refer to the total TCDD "equivalents" found in a sample. This concept of toxic equivalency is discussed below.

1.3. TOXIC EQUIVALENCY FACTORS

CDDs, CDFs, and PCBs are commonly found as complex mixtures when detected in environmental media and biological tissues, or when measured as environmental releases from specific sources. Humans are likely to be exposed to variable distributions of CDDs, CDFs, and dioxin-like PCB congeners that vary by source and pathway of exposures. This complicates the human health risk assessment that may be associated with exposures to variable mixtures of dioxin-like compounds. In order to address this problem, the concept of toxic equivalency has been considered and discussed by the scientific community, and TEFs have been developed and introduced to facilitate risk assessment of exposure to these chemical mixtures.

On the most basic level, TEFs compare the potential toxicity of each dioxin-like compound comprising the mixture to the well-studied and understood toxicity of TCDD, the most toxic member of the group. The background and historical perspective regarding this procedure is described in detail in Part II, Chapter 9, Section 9.1, 9.2, and in Agency documents (U.S. EPA, 1987; 1989a,b; 1991). This procedure involves assigning individual TEFs to the 2,3,7,8-substituted CDD/CDF congeners and "dioxin-like" PCBs. To accomplish this, scientists have reviewed the toxicological databases along with considerations of chemical structure, persistence, and resistance to metabolism, and have agreed to ascribe specific, "order of magnitude" TEFs for each dioxin-like congener relative to TCDD, which is assigned a TEF of 1.0. The other congeners have TEF values ranging from 1.0 to 0.00001. Thus, these TEFs are the result of scientific judgment of a panel of experts using all of the available data and are selected to account for uncertainties in the available data and to avoid underestimating risk. In this sense, they can be described as

$$\text{TEQ} \cong \sum_{i=n}\left(\text{Congener}_i \times \text{TEF}_i\right) + \left(\text{Congener}_j \times \text{TEF}_j\right) + \ldots\ldots \left(\text{Congener}_n \times \text{TEF}_n\right) \quad (1\text{-}1)$$

"public health conservative" values. To apply this TEF concept, the TEF of each congener present in a mixture is multiplied by the respective mass concentration and the products are summed to represent the 2,3,7,8-TCDD Toxic Equivalence (TEQ) of the mixture, as determined by Equation (1-1):

The TEF values for PCDDs and PCDFs were originally adopted by international convention (U.S. EPA, 1989a). Subsequent to the development of the first international TEFs for CDD/CDFs, these values were further reviewed and/or revised and TEFs were also developed for PCBs (Ahlborg et al., 1994; van den Berg et al., 1998). A problem arises in that past and present quantitative exposure and risk assessments may not have clearly identified which of three TEF schemes was used to estimate the TEQ. This reassessment introduces a new uniform TEQ nomenclature that clearly distinguishes between the

different TEF schemes and identifies the congener groups included in specific TEQ calculations. The nomenclature uses the following abbreviations to designate which TEF scheme was used in the TEQ calculation:

1. I-TEQ refers to the International TEF scheme adopted by EPA in 1989 (U.S. EPA, 1989a). See Table 1-1.
2. TEQ-WHO_{94} refers to the 1994 WHO extension of the I-TEF scheme to include 13 dioxin-like PCBs (Ahlborg et al., 1994). See Table 1-2.
3. TEQ-WHO_{98} refers to the 1998 WHO update to the previously established TEFs for dioxins, furans, and dioxin-like PCBs (van den Berg et al., 1998). See Table 1-3.

The nomenclature also uses subscripts to indicate which family of compounds is included in any specific TEQ calculation. Under this convention, the subscript D is used to designate dioxins, the subscript F to designate furans and the subscript P to designate PCBs. As an example, "TEQ_{DF}-WHO_{98}" would be used to describe a mixture for which only dioxin and furan congeners were determined and where the TEQ was calculated using the WHO_{98} scheme. If PCBs had also been determined, the nomenclature would be "TEQ_{DFP}-WHO_{98}." Note that the designations TEQ_{DF}-WHO_{94} and I-TEQ_{DF} are interchangeable, as the TEFs for dioxins and furans are the same in each scheme. Note also that in this document, I-TEQ sometimes appears without the D and F subscripts. This indicates that the TEQ calculation includes both dioxins and furans.

This reassessment recommends that the WHO_{98} TEF scheme be used to assign toxic equivalency to complex environmental mixtures for assessment and regulatory purposes. Sections in the Health Reassessment Document, and summarized in the Risk Characterization, describe the mode(s) of action by which dioxin-like chemicals mediate biochemical and toxicological actions. These data provide the scientific basis for the TEF/TEQ methodology. In its 20-year history, the approach has evolved, and decision criteria supporting the scientific judgment and expert opinion used in assigning TEFs has become more transparent. Numerous states, countries, and several international organizations have evaluated and adopted this approach to evaluating complex mixtures of dioxin and related compounds. It has become the accepted methodology, although the need for research to explore alternative approaches is widely endorsed. Clearly, basing risk on TCDD alone or assuming all chemicals are equally potent to TCDD is inappropriate on the basis of available data. Although uncertainties in the use of the TEF methodology have been identified (which are described in detail in the Health Reassessment Document, Chapter 9, Section 9.5), one must examine the use of this method in the broader context of the need to evaluate the potential public health impact of complex mixtures of

persistent, bioaccumulative chemicals. It can be generally concluded that the use of TEF methodology for evaluating complex mixtures of dioxin-like compounds decreases the overall uncertainties in the risk assessment process as compared to alternative approaches. Use of the latest consensus values for TEFs assures that the most recent scientific information informs this "useful, interim approach" (U.S. EPA, 1989a; Kutz et al., 1990) to dealing with complex environmental mixtures of dioxin-like compounds. As stated by the U.S. EPA Science Advisory Board (U.S. EPA, 1995), "The use of the TEFs as a basis for developing an overall index of public health risk is clearly justifiable, but its practical application depends on the reliability of the TEFs and the availability of representative and reliable exposure data." EPA will continue to work with the international scientific community to update these TEF values to assure that the most up-to-date and reliable data are used in their derivation and to evaluate their use on a periodic basis.

A chemical is assigned a TEF value based on all the available data comparing the chemical to either TCDD or PCB 126. In addition, there are weighting criteria that place more emphasis on chronic and subchronic studies examining toxic endpoints (van den Berg et al., 1998). There is a broad range in the quantity and quality of the data available for individual congeners. For example, the TEF for PCB 126 is based on over 60 in vivo endpoints examining responses as diverse as enzyme induction, developmental toxicity, immunotoxicity, hepatic toxicity, alterations in hormones and tumor promotion, while the TEF for 3,4,4',5-tetrachlorobiphenyl (PCB 81) is based on in vitro CYP1A induction and QSAR calculations. Fortunately, PCB 81 does not significantly contribute to human TEQ exposures. There are 5 congeners that contribute approximately 80% of the total TEQ in humans: 2,3,7,8-TCDD, 1,2,3,7,8-PCDD, 1,2,3,6,7,8-HxCDD, 2,3,4,7,8-PCDF, and PCB 126 (See Part I, Volume 2 and Section 4.4.3 of this document). With the exception of 1,2,3,6,7,8-HxCDD, the TEFs for these chemicals are based on a number of different endpoints from multiple studies performed in different laboratories. The TEF for 1,2,3,6,7,8-HxCDD is based on a two-year bioassay in which rats were exposed to a mixture of 1,2,3,6,7,8-HxCDD and 1,2,3,7,8,9-HxCDD. The TEFs for 2,3,4,7,8-PCDF and PCB 126 are similar to the mean REP value for all in vivo endpoints and are similar to their REPs for tumor promotion. The TEF for 12378-PCDD is based largely on its REP for tumor promotion in rats. From these data, it is clear that the chemicals that contribute approximately 80% to the total human TEQ are well studied and the assigned TEFs provide reasonable estimates of the relative potency of these chemicals. In contrast, while there are some chemicals in the TEF methodology which have minimal data sets to reliably assess their relative potency, these chemicals do not contribute substantially to the human blood TEQ.

The ability of the TEF methodology to predict the biological effects of mixtures containing dioxin-like chemicals has been evaluated in a number of experimental systems. These studies generally demonstrate that the assumption of additivity provides a reasonable estimate of the dioxin-like potential of a mixture (described in the Health Reassessment Document, Chapter 9, Section 9.4). In addition, there are examples of non-additive interactions between dioxins and non-dioxins. Both greater than additive and less than additive interactions have been observed in these studies. In general the non-additive interactions between the dioxins and non-dioxins have been observed at doses that are considerably higher than present background human exposures.

There are a number of natural chemicals that bind and activate the AhR and induce some dioxin-like effects. It has been proposed by some scientists that these chemicals contribute significantly to the total TEQ exposures and that these exposures far out weigh those from PCDDs, PCDFs and PCBs (Safe, 1995). While this hypothesis is intriguing, there are several limitations to these analyses. The in vivo data on the natural aromatic hydrocarbon receptor (AhR) ligands is limited to enzyme induction and a single developmental study. Few, if any, toxicology studies demonstrating clear dioxin-like toxicities have been published. The natural AhR ligands are rapidly metabolized and result in both transient tissue concentrations and transient effects. The natural ligands also have significant biological effects that are independent of the AhR and it is not clear as to the role of the AhR in the biological effects of these chemicals. Clearly this issue requires further research in order to better understand the relative potential health effect of dioxin and related chemicals as compared to natural AhR ligands.

One of the limitations of the use of the TEF methodology in risk assessment of complex environmental mixtures is that the risk from non-dioxin-like chemicals is not evaluated in concert with that of dioxin-like chemicals. Another limition of the TEF methodology is their application to non-biological samples. The fate and distribution of PCDDs, PCDFs and PCBs are not necessarily related to their TEF. Thus, the use of the TEF for non-biological media must be done cautiously. Future approaches to the assessment of environmental mixtures should focus on the development of methods that will allow risks to be predicted when multiple mechanisms are present from a variety of contaminants.

1.4. CONTENTS OF THIS VOLUME

The purpose of this volume is to: (1) summarize information on the physical and chemical properties of dioxin-like compounds; (2) provide an overview of the levels of dioxin-like compounds found in environmental media and food; (3) estimate background

exposures to dioxin-like compounds for the general population of the United States; (4) provide information on the potential for elevated exposures among certain subpopulations of the United States; and (5) summarize the evidence that suggests a downward trend in dioxin-like concentrations in the environment, as well as trends in exposure. These topics are organized in this volume as follows:

Chapter 2 - Physical and Chemical Properties and Fate

This chapter summarizes available information regarding the physical and chemical properties and fate of the dioxin-like compounds. Physical/ chemical properties addressed in Chapter 2 include melting point, water solubility, vapor pressure, Henry's Law constant, octanol/water partition coefficient, organic carbon partition coefficient, and photochemical quantum yield. Fate and transport processes addressed include photolysis, oxidation, hydrolysis, biodegradation, volatilization, and sorption. Biologically-mediated transport properties (i.e., bioconcentration, plant uptake, etc.) are also addressed in this volume. (These properties are also addressed in Volume 3: Site-Specific Assessment Procedures.) These data were compiled from a review of the current scientific literature on dioxin-like compounds.

Chapter 3 - Levels of CDD, CDF, and PCB Congeners

This chapter provides an overview of the concentrations at which dioxin-like compounds have been found in the environment and food based on data presented in the recent published literature. Data are presented for air, soil, sediment, water, and foods. For foods, the general focus is on foods with relatively high fat content (i.e., beef, pork, poultry and eggs, milk and dairy products, fish, and vegetable fats) because these items are most likely to contain dioxins and related compounds. Data from Government-sponsored monitoring studies and studies reported in the peer-reviewed literature are used in this chapter to estimate U.S. background concentrations of dioxin-like compounds in the various environmental media and foods. In order to represent current exposure concentrations, data used for the calculation of background media levels are based on studies published in the late 1980s and 1990s, but primarily in the 1990s. The studies used for the estimation of background concentrations were also chosen on the basis of credibility and representativeness. CDD/CDF profiles for environmental media are also presented in this chapter.

Chapter 4 - Human Exposures to CDD/CDF, and PCB Congeners

This chapter assesses background exposures to the dioxin-like compounds among the general population of the United States. Recent assessments of background exposures cited in the scientific literature are summarized, and background exposure estimates, based on the data presented in Chapter 3, are presented. Data on the concentrations of dioxin-like compounds in human tissue (i.e., adipose tissue, blood, and human breast milk) are also presented. Two methods are used in to estimate background daily intake of dioxin-like compounds. One method estimates background exposures based on pharmacokinetic modeling using the human tissue data. The other derives background exposure estimates from dietary intake and contact with other media containing dioxin-like compounds. The primary focus of this chapter is background exposure among the general population.

Chapter 5 - Potentially Elevated Populations

This chapter focuses on elevated exposures that may occur among the general population from dietary habits such as breast feeding or high rates of fish ingestion, increased environmental levels of dioxin-like compounds from localized sources, or cigarette smoking. This chapter does not, however, address occupational or accidental exposure. Epidemiological studies that have evaluated whether elevated dioxin exposure has occurred to certain workers in the chemical industry, members of the Air Force who worked with Agent Orange, and residents of Seveso, Italy, who were exposed as a result of a pesticide plant explosion are fully discussed in the Epidemiology Chapter of the Dioxin Health Reassessment Document.

Chapter 6 - Temporal Trends

This chapter describes trends in the levels of dioxin-like compounds that have been observed in various environmental media and foods, as well as evidence of downward trends in exposure to dioxin-like compounds in humans. The downward trend in human exposure is supported by a modeling exercise that reconstructs the most likely past doses of dioxin-like compounds contributing to observed body burdens. Reviews of several studies and the modeling exercise are followed by several key observations with regard to temporal trends of dioxin-like compounds.

1.5. SUMMARY OF FINDINGS IN THIS VOLUME

1.5.1. Physical and Chemical Properties and Fate

The physical/chemical properties of individual dioxin congeners vary and the various congeners behave differently in the environment. For example, the relative mix of congeners released from a stack cannot be assumed to remain constant during transport through the atmosphere and deposition to various media. Therefore, for purposes of environmental fate modeling, it is important to use the individual CDD/CDF and PCB congeners values, rather than TEQs. Estimates of environmental releases are presented in Volume 1. Full congener-specific release rates for most sources are provided in an electronic database which is available as a companion to this document (Database of Sources of Environmental Releases of Dioxin-Like Compounds in the United States (EPA/600/C-01/012). In Volume 3, site-specific procedures are provided for estimating the impact of emissions on local populations and this section emphasizes that congener specific emission values should be used in modeling their environmental fate. The following paragraphs provide a summary of the fate of dioxin-like compounds.

Dioxin-like compounds are widely distributed in the environment as a result of a number of physical and biological processes. The dioxin-like compounds are essentially insoluble in water, generally classified as semivolatile, and tend to bioaccumulate in animals. Some evidence has shown that these compounds can degrade in the environment, but in general they are considered very persistent and relatively immobile in soils and sediments. These compounds are transported through the atmosphere as vapors or attached to airborne particulates and can be deposited on soils, plants, or other surfaces (by wet or dry deposition). The dioxin-like compounds enter water bodies primarily via direct deposition from the atmosphere, or by surface runoff and erosion. From soils, these compounds can reenter the atmosphere either as resuspended soil particles or as vapors. In water, they can be resuspended into the water column from sediments, volatilized out of the surface waters into the atmosphere or become buried in deeper sediments. Immobile sediments appear to serve as permanent sinks for the dioxin-like compounds. Though not always considered an environmental compartment, these compounds are also found in anthropogenic materials (such as PCP) and have the potential to be released from these materials into the broader environment.

Atmospheric transport and deposition of the dioxin-like compounds are a primary means of dispersal of these compounds throughout the environment. The dioxin-like compounds can be measured in wet and dry deposition in most locations including remote areas. Numerous studies have shown that they are commonly found in soils throughout the world. Industrialized countries tend to show similar elevated concentrations in soil,

and detectable levels have been found in nonindustrialized countries. The only satisfactory explanation available for this distribution is air transport and deposition. Finally, by analogy these compounds would be expected to behave similarly to other compounds with similar properties, and this mechanism of global distribution is becoming widely accepted for a variety of persistent organic compounds.

The two primary pathways for the dioxin-like compounds to enter the ecological food chains and human diet are air-to-plant-to-animal and water/sediment-to-fish. Vegetation receives these compounds via atmospheric deposition in the vapor and particle phases. The compounds are retained on plant surfaces and bioaccumulated in the fatty tissues of animals that feed on these plants. Vapor phase transfers onto vegetation have been experimentally shown to dominate the air-to-plant pathway for the dioxin-like compounds, particularly for the lower chlorinated congeners. In the aquatic food chain, dioxins enter water systems via direct discharge or deposition and runoff from watersheds. Fish accumulate these compounds through their direct contact with water, suspended particles, bottom sediments, and through their consumption of aquatic organisms. Although these two pathways are thought to normally dominate contribution to the commercial food supply, others can also be important. Elevated dioxin levels in cattle resulting from animal contact with PCP-treated wood have been documented by the U.S. Department of Agriculture. Animal feed contamination episodes have led to elevations of dioxins in poultry in the United States, milk in Germany, and meat/dairy products in Belgium.

1.5.2. Environmental Media and Food Concentrations

Background levels of dioxin-like compounds in various environmental media including food are presented in Table 1-4 in terms of means, variability and sample sizes used to support the background estimates.

Estimates for background levels of dioxin-like compounds in environmental media are based on a variety of studies conducted at different locations in North America. Of the studies available for this compilation, only those conducted in locations representing "background" were selected. The amount and representativeness of the data vary, but in general these data were derived from studies that were not designed to estimate national background means. The environmental media concentrations were similar to studies in Western Europe. These data are the best available for comparing with site-specific values. Because of the limited number of locations examined, it is not known if these estimates adequately capture the full national variability. As new data are collected, these ranges are likely to be expanded and refined. The limited data on dioxin-like PCBs in environmental media are summarized in this document (Chapter 3).

Estimates for levels of dioxin-like compounds in food are based on data from a variety of studies conducted in North America. Beef, pork, and poultry were derived from statistically based national surveys. Milk estimates were derived from a survey of a nationwide milk sampling network. Dairy estimates were derived from milk fat concentrations, coupled with appropriate assumptions for the amount of milk fat in dairy products. The background egg concentrations were based on an analysis of 15 egg samples collected from retail stores in 8 states (CA, OH, GA, NY, PA, OR, MN, WS; 2 samples/state except one in OR), where each sample was a composite of 24 individual eggs (i.e., 15 samples represented 360 eggs). The fish data, as discussed below, were derived from multiple studies with samples collected both directly from water bodies and from retail outlets. All fish concentrations were expressed on the basis of fresh weight in edible tissue. As with other environmental media, food levels found in the United States are similar to levels found in Europe.

The procedure to evaluate background fish exposures emphasizes the use of both species-specific consumption rates and species-specific concentrations. EPA's National Bioaccumulation Study (U.S. EPA, 1992) provides some species-specific information on freshwater/estuarine fish caught in the wild at various locations in the United States. Additional species-specific data on store bought fish are available from studies conducted by the Food and Drug Administration during the mid to latter1990s (Jensen and Bolger, 2000; Jensen et al., 2000). An important aspect of the U.S. Food and Drug Administration (FDA) studies is that they include data on store-bought catfish, tuna, shellfish, and salmon which are some of the most highly consumed species. Accordingly, the data used to characterize CDD/CDF fish levels are much improved over previous estimates with over 300 individual samples and good representation of the most highly consumed species. However, the levels of dioxins in fish remain more uncertain than the other foods. The compilation of data from different studies still lacks the geographic coverage and statistical power of the other food surveys. The EPA and FDA studies did not address dioxin-like PCBs, rather these are based on a much smaller data set derived from the open literature. Also, the estimates of dioxin intake resulting from fish consumption do not include consumption of fish oils. Currently insufficient data are available to support estimates of dioxin intake from direct fish oil consumption.

The general population dioxin intake calculations used in this document are a function of both consumption rate and dioxin concentration in food. The concentration data used in this document were measured in raw foods. Therefore, if cooking significantly alters the dioxin concentration in consumed portions it must be accounted for in estimating dioxin intake. This issue has been examined in a number of studies which measured the effects of cooking on the levels of CDDs, CDFs and PCBs in foods (see

Chapter 3, Section 3.7.5). These studies have a range of results depending on food type and cooking method. Most of the cooking experiments suggested that cooking reduces the total amount of dioxins in food but causes relatively little change in its concentration. Although some cooking experiments have shown increases and others have shown decreases in dioxin concentrations, the relative prevalence of these impacts have not been established. Therefore given that most experiments show little change and that others show change in both directions, the most reasonable assumption that can be made from the existing data is that dioxin concentration in uncooked food is a reasonable surrogate for dioxin concentration in cooked food.

Some evidence from Europe suggests that during the 1990s a decline has occurred in concentrations of dioxins and furans in food products, particularly dairy products (see Chapter 6, Section 6.5). For example, the United Kingdom's Ministry of Agriculture, Fisheries, and Food (MAFF) collected milk samples in 1990 and again from similar locations in 1995. In 1990, the I-TEQ_{DF} ranged from 1.1 to 3.3 ppt, while the 1995 I-TEQ_{DF} ranged from 0.7 to 1.4. In Germany, a sampling of 120 dairy products in 1994 found I-TEQ_{DF} concentrations that were 25% lower than a similar sampling program in 1990. Liem et al. (2000) reports on a European cooperative study coordinated by the National Institute of Public Health and the Environment in the Netherlands, and the Swedish National Food Administration. Ten countries supplied data on food concentrations, food consumption patterns, and other data used to evaluate exposure to dioxins in Europe. Some of the data suggested reductions in concentrations over time, but the available information was insufficient to draw general conclusions. No systematic study of temporal trends in dioxin levels in food has been conducted in the United States. Although not statistically based, one U.S. study examined dioxin levels in 14 preserved food samples from various decades in the twentieth century (Winters et al., 1998). It was found that meat samples of the 1950s through the 1970s had concentrations that were 2-3 times higher for the CDD/CDF TEQs and about 10 times higher for the PCB TEQs, as compared to current meat concentrations.

1.5.3. Background Exposures

The average CDD/CDF/PCB tissue level for the general adult U.S. population appears to be declining, and the best estimate of current (late 1990s) levels is 25 ppt (TEQ_{DFP}-WHO_{98}, lipid basis).

The tissue samples collected in North America in the late 1980s and early 1990s showed an average TEQ_{DFP}-WHO_{98} level of about 55 pg/g lipid. This finding is supported by a number of studies which measured dioxin levels in adipose, blood, and human milk, all conducted in North America. The number of people in most of these studies, however,

is relatively small and the participants were not statistically selected in ways that assure their representativeness of the general U.S. adult population. One study, the 1987 National Human Adipose Tissue Survey (NHATS), involved over 800 individuals and provided broad geographic coverage, but did not address coplanar PCBs. Similar tissue levels of these compounds have been measured in Europe and Japan during similar time periods.

Because dioxin levels in the environment have been declining since the 1970s (see trends discussion in Chapter 6), it is reasonable to expect that levels in food, human intake, and ultimately human tissue have also declined over this period. The changes in tissue levels are likely to lag the decline seen in environmental levels, and the changes in tissue levels cannot be assumed to occur proportionally with declines in environmental levels. CDC (2000) summarized levels of CDDs, CDFs, and PCBs in human blood collected during the time period 1995 to 1997. The individuals sampled were all U.S. residents with no known exposures to dioxin other than normal background. The blood was collected from 316 individuals in six different locations with an age range of 20 to 70 years. While the samples in this data set were not collected in a manner that can be considered statistically representative of the national population and lack wide geographic coverage, they are judged to provide a better indication of current tissue levels in the United States than the earlier data. PCBs 105, 118, and 156 are missing from the blood data for the comparison populations reported by CDC (2000). These congeners account for 62% of the total PCB TEQ estimated in the early 1990s. Assuming that the missing congeners from the CDC study data contribute the same proportion to the total PCB TEQ as in earlier data, they would increase our estimate of current body burdens by another 3.3 pg TEQ/g lipid for a total PCB TEQ of 5.3 pg/g lipid and a total of 25.4 pg TEQ_{DFP}-WHO_{98} /g lipid. A summary of the CDC (2000) data is shown in Table 1-5.

This finding regarding a current tissue level of 25.4 pg/g lipid TEQ_{DFP}-WHO_{98} is further supported by the observation that this mean tissue level is consistent with our best estimate of current adult intake, i.e., 66 pg WHO_{98}-TEQ_{DFP}/d. Using this intake in a one-compartment, steady-state pharmacokinetic model yields a tissue level estimate of about 11.2 pg TEQ/g lipid (assumes TEQ_{DFP} has an effective half-life of 7.1 yr, 80% of ingested dioxin is absorbed into the body, and lipid weight is 25% of the adult assumed body weight of 70 kg, or 17.5 kg). Because intake rates appear to have declined in recent years and steady-state is not likely to have been achieved, it is reasonable to observe higher measured tissue levels, such as the 25.4 pg TEQ/g lipid that was observed, than predicted by the model.

Characterizing national background levels of dioxins in tissues is uncertain because the current data cannot be considered statistically representative of the general

population. It is also complicated by the fact that tissue levels are a function of both age and birth year. Because intake levels have varied over time, the accumulation of dioxins in a person who turned 50 years old in 1990 is different than in a person who turned 50 in 2000. Future studies should help address these uncertainties. The National Health and Nutrition Examination Survey (NHANES) began a new national survey in 1999 that will measure blood levels of CDDs, CDFs, and PCBs 126, 77, 169, and 81 in about 1,700 people per year (see http:www.cdc.gov/nchs/nhanes.htm). The survey is conducted at 15 different locations per year and is designed to select individuals statistically representative of the civilian U.S. population in terms of age, race, and ethnicity. These new data should provide a much better basis for estimating national background tissue levels and evaluating trends than the currently available data.

Intake Estimates

Adult daily intakes of CDD/CDFs and dioxin-like PCBs are estimated to average 43 and 23 pg TEQ_{DFP}-WHO_{98}/day, respectively, for a total intake of 66 pg/day TEQ_{DFP}-WHO_{98}. Daily intake is estimated by combining exposure media concentrations (food, soil, air) with contact rates (ingestion, inhalation). Table 1-6 summarizes the media concentrations, contact rates and resulting intake estimates.

The intake estimate is supported by an extensive database on food consumption rates and estimates of dioxin-like compounds in food (as discussed above). Pharmacokinetic (PK) modeling provides further support for the intake estimates. Applying a simple steady-state PK model to an adult average blood level of 25 ppt TEQ_{DFP}-WHO_{98} (on a lipid basis) yields a daily intake of 146 pg TEQ_{DFP}-WHO_{98}/day (assumes TEQ_{DFP} has an effective half-life of 7.1 yr, 80% of ingested dioxin is absorbed into the body, and lipid weight is 25% of the adult assumed body weight of 70 kg, or 17.5 kg). This PK-modeled CDD/CDF/PCB intake estimate is about 2.2 times higher than the direct intake estimate of 66 pg TEQ_{DFP}-WHO_{98}/day. This difference is to be expected with this application of a simple steady-state PK model to current average adipose tissue concentrations. Current adult tissue levels reflect intakes from past exposure levels that are thought to be higher than current levels (see Chapter 6). Because the direction and magnitude of the difference in intake estimates between the two approaches are understood, the PK-derived value is judged supportive of the pathway-derived estimate. It should be recognized, however, that the pathway-derived value will underestimate exposure if it has failed to capture all significant exposure pathways.

Variability in Intake Levels

CDD/CDF and dioxin-like PCB intakes for the general population may extend to levels at least three times higher than the mean. Variability in general population exposure is primarily the result of the differences in dietary choices that individuals make. These are differences in both quantity and types of food consumed. An increased background exposure can result from either a diet that favors consumption of foods high in dioxin content or a diet that is disproportionately high in overall consumption of animal fats.

The best data available to determine the variability of total fat consumption comes from several analyses of the Bogalusa Heart Study (Cresanta et al., 1988; Nicklas et al., 1993; Nicklas et al., 1995; Nicklas et al., 1995; Frank et al., 1986). These data show that the 95th percentile of total fat consumption is about twice the mean and the 99th percentile is approximately three times the mean. For a diet which has a broad distribution of animal fats (as does the typical U.S. diet), this same distribution can be assumed for dioxin intake.

Although body burden data cannot be assumed to be perfectly representative of current intakes (because they reflect past exposures as well as current ones), they also provide some support for this finding. This is based on the observation that the 95th percentile blood level in the CDC (2000) study was almost twice the mean level.

Intakes of CDD/CDFs and dioxin-like PCBs are over three times higher for a young child as compared to that of an adult, on a body weight basis. This is based on combining age-specific food consumption rate and average food concentrations, as was done above for adult intake estimates (see Table 1-7).

Only four of the 17 toxic CDD/CDF congeners and one of the 11 toxic PCBs account for most of the toxicity in human tissue concentrations: 2,3,7,8-TCDD, 1,2,3,7,8-PCDD, 1,2,3,6,7,8-HxCDD, 2,3,4,7,8-PCDF, and PCB 126. This finding is derived directly from the data described earlier on human tissue levels and is supported by intake estimations indicating that these congeners are also the primary contributors to dietary dose. These five compounds make up about 80% of the total WHO_{98}-TEQ tissue level.

1.5.4. Potentially Highly Exposed Populations or Developmental Stages

As discussed earlier, background exposures to dioxin-like compounds may extend to levels at least three times higher than the mean. This upper range is assumed to result from the normal variability of diet and human behaviors. Exposures from local elevated sources or exposures resulting from unique diets would be in addition to this background variability. Such elevated exposures may occur in small segments of the population such as individuals living near discrete local sources. Nursing infants represent a special case:

for a limited portion of their lives, these individuals may have elevated exposures on a body weight basis when compared with non-nursing infants and adults.

CDD/CDF contamination incidents involving the commercial food supply have occurred in the United States and other countries. For example, in the United States, contaminated ball clay was used as an anti-caking agent in soybean meal and resulted in elevated dioxin levels in some poultry and catfish. This incident, which occurred in 1998, involved less than 5% of the national poultry production and has since been eliminated. Elevated dioxin levels have also been observed in a few beef and dairy animals where the contamination was associated with contact with pentachlorophenol-treated wood. Evidence of this kind of elevated exposure was not detected in the national beef survey. Consequently its occurrence is likely to be low, but it has not been determined. These incidents may have led to small increases in dioxin exposure to the general population. However, it is unlikely that such incidents have led to disproportionate exposures to populations living near where these incidents have occurred, because in the United States, meat and dairy products are highly distributed on a national scale. If contamination events were to occur in foods that are predominantly distributed on a local or regional scale, then such events could lead to highly exposed local populations.

Elevated exposures associated with the workplace or industrial accidents have also been documented. U.S. workers in certain segments of the chemical industry had elevated levels of TCDD exposure, with some tissue measurements in the thousands of ppt TCDD. There is no clear evidence that elevated exposures are currently occurring among United States workers. Documented examples of past exposures for other groups include certain Air Force personnel exposed to Agent Orange during the Vietnam War and people exposed as a result of industrial accidents in Europe and Asia.

Consumption of breast milk by nursing infants leads to higher levels of exposure and higher body burdens of dioxins during early years of life as compared with non-nursing infants. Three German studies have compared dioxin levels in infants who have been breast-fed with those who have been formula-fed. All have shown elevations in the concentrations of dioxins in infants being breast-fed. Collectively these studies included 99 infants and found that blood levels (in units of pg TEQ_{DF}-WHO_{98}/g lipid - i.e., dioxin-like PCBs not included) in infants aged 4-12 months were generally more than 20 in nursing infants and less than 5 in formula fed infants. The most comprehensive of these studies was by Abraham et al. (2000) who reported on 80 breast-fed infants. In that study, the median concentration was 25.3 pg/g TEQ_{DF}-WHO_{98}. Six of the nursing infants in the Abraham et al. (2000) study had lipid levels greater than 50 pg/g TEQ_{DF}-WHO_{98} and the maximum was 107 pg/g TEQ_{DF}-WHO_{98}. Five of these six children were from a region where mother's milk was found to be elevated due to regional contamination by a copper

recycling plant. These data suggest that breast-fed infants could have body burdens more than five times higher than formula-fed infants, depending on length of breast-feeding, dioxin concentrations in mother's milk, and other factors.

U.S. dioxin intakes from nursing were calculated using time dependent values for breast milk concentrations, consumption rates and body weights. These calculations estimated an intake immediately after birth of 242 pg TEQ_{DFP}-WHO_{98}/kg/day. This dropped to 22 pg TEQ_{DFP}-WHO_{98}/kg/day after 12 months of nursing. The average intake over one year of nursing was calculated to be 92 pg TEQ_{DFP}-WHO_{98}/kg/day. The cumulative intake for a one year nursing scenario represented about 12% of the total lifetime cumulative intake (see Chapter 5, Section 5.2 for details on these calculations).

The CDC (1997) reported that in 1995, 55% of all babies experience some breast feeding, with about half of those breast feeding beyond 5 months. The average duration of breast feeding was 28.7 weeks. In a policy statement, the American Academy of Pediatrics (1997) stated that exclusive breast feeding is ideal nutrition and sufficient to support optimal growth and development for 6 months after birth. They recommended that breast feeding continue for at least 12 months, and thereafter for as long as mutually desired.

To better evaluate the impact of nursing on infants, changes in body burden were calculated using a one-compartment, first-order pharmacokinetic model. Changes in TEQ tissue concentration over time were modeled for a variety of nursing scenarios: formula only, 6 weeks nursing, 6 months nursing, and one year. These scenarios reasonably capture the range of current nursing practice. This modeling effort required using the intake assumptions described earlier and a variety of additional assumptions including: the fraction of the oral dose which is absorbed into the body, changes in body weight over time, and changes in body fat fraction over time. Assumptions were also made about changes in the biological half-life of dioxins as a function of body fat fraction. For the infant, the half-life was less than one year, and during adulthood the half-life increased as the fraction of body fat increased. The short half-life at birth was based on a study by Kreuzer et al. (1997) and the longer half-life during the later years of life, when body fat fraction increased, was based on a model presented in Michalek et al. (1996). The complete set of input values are listed in Chapter 5, Section 5.2.

The modeling results in terms of changes in lipid concentrations and body burdens as a function of age are shown in Figure 1-2. Some key observations include:

- For the 6 and 12 month nursing scenarios, lipid concentrations peaked at around 4 months at about 46 ppt TEQ_{DFP}-WHO_{98}. The formula-fed infants peaked at less than 10 ppt after the first year.

- In all four scenarios, the lipid concentrations merged at about 10 years of age, at a concentration of about 13 ppt TEQ_{DFP}-WHO_{98}. Lipid and body burdens declined slightly from age 10 to about age 20, and then rose gradually through adulthood. This rise was due to the increase in half-life with age. At age 70, the modeled lipid and body burden concentrations were 13 ppt TEQ_{DFP}-WHO_{98} lipid and 5 ppt TEQ_{DFP}-WHO_{98}.whole body weight.

A sensitivity analysis was performed to test the assumptions about changes in breast milk concentrations during lactation and changes in half-life over time. In this analysis, breast milk concentrations were held steady at 25 pg TEQ_{DFP}-WHO_{98}/g lipid for a 6-month nursing scenario, and the half-life of dioxins in the body remained steady at 7.1 years from birth until 70 years of age. With these two changes, the maximum infant lipid concentration increased from 46 to 70 pg TEQ_{DFP}-WHO_{98}/g lipid. The major impact of a steady half-life assumption, instead of one which increased with increasing body lipid fractions in the aging adult, was that the lipid concentrations stabilized at about 8 pg TEQ_{DFP}-WHO_{98}/g lipid in the adult, instead of rising to 13 pg TEQ_{DFP}-WHO_{98}/g lipid at age 70.

The above analysis indicates that the average annual infant intake resulting from one year of nursing, 92 pg TEQ_{DFP}-WHO_{98}/kg/day, significantly exceeds the currently estimated adult intake of 1 pg TEQ_{DFP}-WHO_{98}/kg/day. The impact of nursing on infant body burdens, however, is much less, i.e. infant body burdens will not exceed adult body burdens by 92 times. Rather, the modeling suggests that peak infant body burdens are only about 2 times current adult body burdens (46 vs 25 pg TEQ_{DFP}-WHO_{98}/g lipid). The reduced body burden impacts in nursing infants (relative to the intake) is thought to be due to the rapidly expanding infant body weight and lipid volume and the possibly faster elimination rate in infants. Impacts to nursing infants should decline in the future if, as discussed earlier, general population exposures decline.

Consumption of fish, meat, or dairy products containing elevated levels of dioxins and dioxin-like PCBs can lead to elevated exposures in comparison with the general population. Most people eat some fish from multiple sources, both fresh and salt water. The estimated dioxin concentrations in these fish and the typical rates of consumption are included in the mean background calculation of exposure. People who consume large quantities of fish at estimated contamination levels may have elevated exposures. These kinds of exposures are addressed within the estimates of variability of background and are not considered to result in highly exposed populations. If individuals obtain their fish from areas where the concentration of dioxin-like chemicals in the fish is elevated, they may constitute a highly exposed subpopulation. Although this scenario seems reasonable, very

little supporting data could be found for such a highly exposed subpopulation in the United States. One study measuring dioxin-like compounds in the blood of sport fishers in the Great Lakes area showed elevations over mean background, but within the range of normal variability. Another study measuring 90 PCB congeners (seven of which were dioxin-like PCBs, although PCB 126 was not measured) in the blood of sport fishers consuming high amounts of fish caught from Lake Michigan (>26 pounds of sport fish/yr) did, however, show significant elevations of PCBs in their blood as compared to a control population (individuals consuming < 6 pounds of sport fish/yr). The average total concentration of PCBs in the blood of these sport fishers was over three times higher than that of the control population. Similarly, elevated levels of coplanar PCBs have been measured in the blood of fishers on the north shore of the Gulf of the St. Lawrence River who consume large amounts of seafood. Elevated CDD/CDF levels in human blood have been measured in Baltic fishermen. For further details on these studies see Chapter 5.

High exposures to dioxin-like compounds as a result of consuming meat and dairy products would most likely occur in situations where individuals consume large quantities of these foods and the level of these compounds is elevated. Most people eat meat and dairy products from multiple sources and, even if large quantities are consumed, they are not likely to have unusually high exposures. Individuals who raise their own livestock for basic subsistence have the potential for higher exposures if local levels of dioxin-like compounds are high. One study in the United States showed elevated levels in chicken eggs near a contaminated soil site. European studies at several sites have shown elevated CDD/CDF levels in milk and other animal products near combustion sources, and some of these have also documented elevations in the levels of dioxin-like compounds in blood from the families consuming their home products.

1.5.5. Temporal Trends Information

Some general observations can be made about changes in levels of dioxin-like compounds in the environment over time. These are discussed below and summarized in Table 1-8.

Concentrations of CDD/CDFs and PCBs in the U.S. environment were consistently low prior to the 1930s. Then, concentrations rose steadily until about 1970. At that time, the trend reversed and the concentrations began to decline. That trend has continued to the present. The most compelling supportive evidence of this trend for the CDD/Fs and PCBs comes from dated sediment core studies. Sediment concentrations in these studies are generally assumed to be an indicator of the rate of atmospheric deposition. CDD/F and PCB concentrations in sediments began to increase around the 1930s, and continued to increase until about 1970. Decreases began in 1970 and have

continued to the time of the most recent sediment samples (about 1990). Sediment data from 20 U.S. lakes and rivers from seven separate research efforts consistently support this trend. Additionally, sediment studies in lakes located in several European countries have shown similar trends.

It is reasonable to assume that sediment core trends should be driven by a similar trend in emissions to the environment. The period of increase generally matches the time when a variety of industrial activities began rising and the period of decline appears to correspond with growth in pollution abatement. Many of these abatement efforts should have resulted in decreases in dioxin emissions, i.e. elimination of most open burning, particulate controls on combustors, phase out of leaded gas, and bans on PCBs, 2,4,5-T, hexachlorophene, and restrictions on use of pentachlorophenol. Also, the national source inventory of this assessment documented a significant decline in emissions from the late 1980s to the mid-1990s. Further evidence of a decline in CDD/F levels in recent years is emerging from data, primarily from Europe, showing declines in foods and human tissues.

In addition to the congener specific PCB data discussed earlier, a wealth of data on total PCBs and aroclor mixtures exist which also supports these trends. It is reasonable to assume that the trends for dioxin-like PCBs are similar to those for PCBs as a class because the predominant source of dioxin-like PCBs is the general production of PCBs in aroclor mixtures. PCBs were intentionally manufactured in large quantities from 1929 until production was banned in 1977. U.S. production peaked in 1970, with a volume of 39,000 metric tons. Further support is derived from data showing declining levels of total PCBs in Great Lakes sediments and biota during the 1970s and 1980s. These studies indicate, however, that during the 1990s the decline is slowing and may be leveling off.

Past human exposures to dioxins were most likely higher than current estimates. This is supported by a study which applied a non-steady state pharmacokinetic model to data on background U.S. tissue levels of 2,3,7,8-TCDD from the 1970s and 80s. Various possible intake histories (pg/kg-day over time) were tested to see which best-fit the data. An assumption of a constant dose over time resulted in a poor fit to the data. The "best-fit" (statistically derived) to the data was found when the dose, like the sediment core trends, rose through the 60s into the 70s, and declined to low current levels. Some additional support for this finding comes from a limited study of preserved meat samples from several decades in the twentieth century. One sample, from before 1910, showed very low concentrations of dioxins and coplanar PCBs. Thirteen other samples, from the 1940s until the early 1980s, consistently showed elevated levels of all dioxin-like compounds as compared to food surveys conducted during the 1990s.

Table 1-4. Summary of North American CDD/CDF and PCB TEQ-WHO_{98} Levels in Environmental Media and Food (whole weight basis; concentrations provided in parenthesis for food products are calculated at ND = 0).

Media	CDD/CDFs[a]	PCBs[a]
Urban Soil, ppt	n=270 9.3 ± 10.2[d] Range = 2 - 21	n=99 2.3[d]
Rural Soil, ppt	n = 354 2.7[d] Range = 0.1 - 6	n=62 0.59[d]
Sediment, ppt	n=11 5.3 ± 5.8 Range = <1 - 20	n = 11 0.53 ± 0.69
Urban Air, pg/m^3	n=106 0.12 ± 0.094 Range = 0.03 - 0.2	0.0009
Rural Air, pg/m^3	n=60 0.013 Range = 0.004 - 0.02	n=53 0.00071
Freshwater Fish and Shellfish, ppt	n=289 1.0 (NA[b])	n = 1 composite of 10 samples plus 6 composites 1.2[c] (NA[b])
Marine Fish and Shellfish, ppt	n=158 0.26 (NA[b])	n = 1 composite of 13 samples plus 5 composites 0.25[e] (NA[b])
Water, ppq	n=236 0.00056 ± 0.00079 (NA[b])	Nab
Milk, ppt (Note: each composite for CDD/F/PCB comprised of 40+ U.S. regional samples)	n=8 composites 0.018 ± 0.0012 (0.017)	n = 8 composites 0.0088 (0.0088)
Dairy, ppt[e]	n = 8 composites 0.12 ± 0.22 (0.12)	n = 8 composites 0.058 (0.058)
Eggs, ppt (Note: each composite for CDD/F data comprised of 24 eggs)	n=15 composites 0.081[c] (0.013)	n = 18 plus 6 composites 0.10[c] (NA[b])
Beef ppt	n=63 0.18 ± 0.11 (0.061) Range = 0.11 - 0.95	n = 63 0.084 (0.084)
Pork, ppt	n=78 0.28 ± 0.28 (0.080) Range = 0.15 - 1.8	n = 78 0.0093 (0.006)
Poultry, ppt	n=78 0.068 ± 0.070 (0.043) Range = 0.03 - 0.43	n = 78 0.026 (0.026)
Vegetable Fats, ppt	n=30 0.056 ± 0.24[d] (NA[b])	n = 5 composites 0.037[c]

[a] Values are the arithmetic mean TEQs, in ppt, and standard deviations. Nondetects were set to one-half the limit of detection, except for soil and CDD/CDFs in vegetable fats for which nondetects were set to zero.

[b] NA = not available; Congener-specific PCB data, and data to calculate TEQ concentrations at ND = 0, are limited.

[c] Standard deviations could not be calculated due to limitations associated with the data (i.e., composite analyses).

[d] TEQ calculated by setting nondetects to zero.

[e] Dairy concentration calculated from milk lipid concentrations and then assuming a fat fraction for dairy.

Table 1-5. Background Serum Levels in the United States 1995 - 1997

	TEQ_{DFP}-WHO_{98} (pg/g lipid)	2,3,7,8-TCDD (pg/g lipid)
Median	18.7	1.9
Mean	22.1*	2.1
95th Percentile	38.8	4.2

* After adjusting to account for missing PCBs, the mean is 25.4 pg/g lipid.

Adult	66	0.94

Table 1-8. Summary of Findings with Regard to Trends in Dioxin Levels in the Environment and in Humans

Finding	Support	Uncertainty
Concentrations of CDD/CDFs in the environment were consistently low for centuries until the 1930s. Then, concentrations rose steadily until about the 1960s, at which point concentrations began to drop. Evidence suggests that the drop in concentrations is continuing to the present.	***Sediment core studies show a trend of rising concentrations in 1930s and 1940s through the 1960s and 1970s and a subsequent decline to the present.*** - 11 lakes/reservoirs in the U.S.: Cleverly et al., 1996; Versar, 1996 - Lake Huron: Czuczwa et al., 1985 - Green Lake, NY: Smith et al., 1992, 1993 - Hudson River: Smith et al., 1995 - Lakes Superior, Michigan, and Ontario: Pearson et al., 1995 - Straight of Georgia, British Columbia: MacDonald et al., 1992 - A remote arctic lake: Tan et al., 1993; Vartiainen et al., 1995	The assumption of nondegradation of CDD/CDFs in sediment cores.
	Analogous trends in environmental loadings - Rise of the manufacture and use of chlorinated phenolic intermediates and products - Banning of leaded gasoline, certain phenoxy herbicides, PCBs - Reductions in pulp and paper mill discharges - EPA National Source Inventory showing 60% reduction in CDD/CDF TEQ emissions between 1987 and 1995 (see Volume 1)	Indirect measure of environmental levels.
	Limited trend for other environmental concentrations - Rises and declines in historical food products in the U.S.: Winters et al., 1998 - Rises and declines in herbage, soil, and air measured in archived samples in UK: Kjeller et al., 1991, 1996; Harner et al., 1995 - Reductions in the past two decades in herring gull eggs in the Great Lakes and the Gulf of St. Lawrence River (Hebert et al., 1994); pike in Sweden (DeWit et al., 1994); pike in Finland (Korhonen et al., 1995); air in Germany (Hiester et al., 1995); German dairy products and human milk between 1990 and 1994 (Fürst and Wilmers, 1995; 1997)	Very few archived environmental measurements to ascertain trends beyond the past decade or so. More recent data showing a decline in trends is limited.
	Suggestive evidence of declines in human body burdens in recent decade - National Human Adipose Tissue Survey: U.S. EPA, 1991 - Ministry of Agriculture, Fisheries, and Food's calculations of declines in dose based on market basket surveys showing reductions in levels in combination with reductions in consumption of key food items: MAFF (1995)	Long half-lives in humans impede responses in body burdens to changes in environmental levels.
Environmental levels of coplanar PCBs began increasing in the 1920s, peaking in the 1970s, and decreasing after that	***PCB production data*** - Rise in the manufacture from the latter 1920s to the early 1970s; complete ban in 1977	Nearly all trends data are specific to PCBs or Aroclors, and not to coplanar PCBs.
	PCB declining environmental levels - Evidence of declines in biota and sediment levels in the Great Lakes

2. PHYSICAL AND CHEMICAL PROPERTIES AND FATE

2.1. INTRODUCTION

This chapter summarizes available information regarding the physical and chemical properties and fate of the dioxin-like CDDs, CDFs, BDDs, BDFs, and PCBs. Physical/ chemical properties addressed in this chapter include melting point, water solubility, vapor pressure, Henry's Law constant, octanol/water partition coefficient, organic carbon partition coefficient, and photochemical quantum yield. Fate and transport processes addressed include photolysis, oxidation, hydrolysis, biodegradation, volatilization, and sorption. Biologically-mediated transport properties (i.e., bioconcentration, plant uptake, etc.) are also addressed in this volume, but are also addressed in the companion volume to this report, Volume 3: Site-Specific Assessment Procedures.

Knowledge of physical and chemical properties is essential to understanding and modeling the environmental transport and transformation of organic compounds such as the dioxin-like compounds. The properties most important for understanding the environmental behavior of the dioxin and dioxin-like compounds appear to be water solubility (WS), vapor pressure (VP), octanol/water partition coefficient (K_{ow}), organic carbon partition coefficient (K_{oc}), and photochemical quantum yield. The ratio of VP to WS (VP/WS) can be used to calculate the Henry's Law constant (H_c) for dilute solutions of organic compounds when the VP and WS are measured at the same temperature and for the same physical state. Henry's Law constant is an index of partitioning for a compound between the atmospheric and the aqueous phase (Mackay et al., 1982).

To maximize and optimize the identification of information on the physical/chemical properties of these compounds, a thorough search of the recent literature was conducted. A computer literature search was conducted using the on-line Chemical Abstracts (CA) data base maintained by the Scientific Technical Network (STN). Printed abstracts were obtained and screened, and selected literature were retrieved and critically evaluated. The most definitive value for each physical/ chemical property for each congener was selected. The evaluation method used to select the most definitive physical/chemical property values is detailed in Section 2.3. The property values obtained from the scientific literature are summarized in Appendix A. Sections 2.4 and 2.5 present the property values for the dioxin-like compounds that are considered to be the most definitive. These

values are utilized in the modeling equations in the companion volume to this report, Volume 3 Site-Specific Assessment Procedures. Appendix A lists reported chemical property values for the CDDs, CDFs, and dioxin-like PCBs. Where technically feasible and appropriate, estimation procedures have been used to provide values where measured data are not available. For those compounds for which data could not be found and estimates are not appropriate, the field is left blank, and a congener group average is presented as the property value for that congener group. The congener group average was calculated by averaging the selected (i.e., most definitive) property values listed for the congeners in that group.

The values suggested in this document as most definitive are, in the authors' opinion, the best values derivable from current data. Because the document has undergone extensive review inside the Agency, by scientific community outside the Agency, and by the Science Advisory Board, the values can be interpreted as generally representative of the Agency and scientific community. The authors recommend that document users consider the values as defaults in the sense that users are encouraged to accept them as a starting point but should feel free to modify them as new data become available.

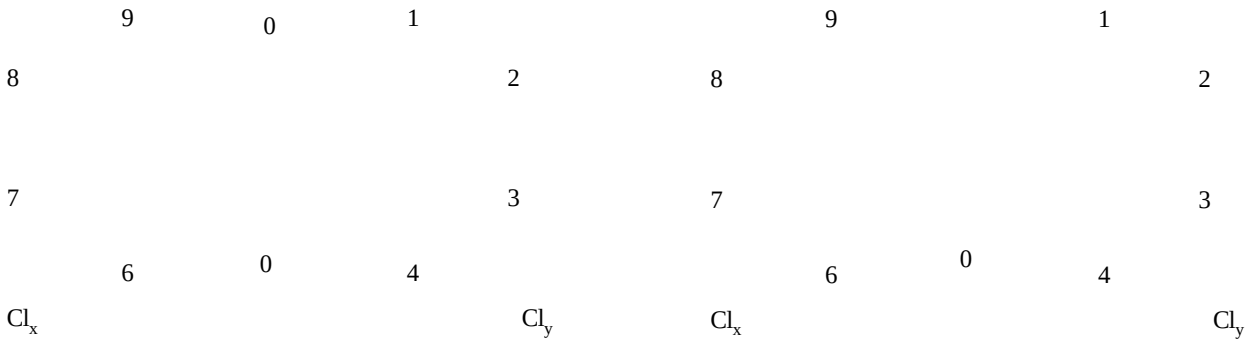
Brief summaries of the recent and relevant scientific literature on the environmental fate of the polychlorinated and polybrominated dibenzodioxins, dibenzofurans, and biphenyls are provided in Sections 2.6 and 2.7.

2.2. GENERAL INFORMATION

Polychlorinated dibenzo-p-dioxins (CDDs), polychlorinated dibenzofurans (CDFs), and polychlorinated biphenyls (PCBs) are chemically classified as halogenated aromatic hydrocarbons. CDDs and CDFs can be formed as unintentional by-products through a variety of chemical reactions and combustion processes. Both compound classes have a triple-ring structure that consists of two benzene rings connected by a third oxygenated ring. For CDDs, the benzene rings are connected by a pair of oxygen atoms. CDFs are connected via a single oxygen atom. (See structures below.) PCBs are a class of compounds formed by the chlorination of a biphenyl molecule.

There are 75 possible different positional congeners of CDDs and 135 different congeners of CDFs. Likewise, there are 75 possible different positional congeners of

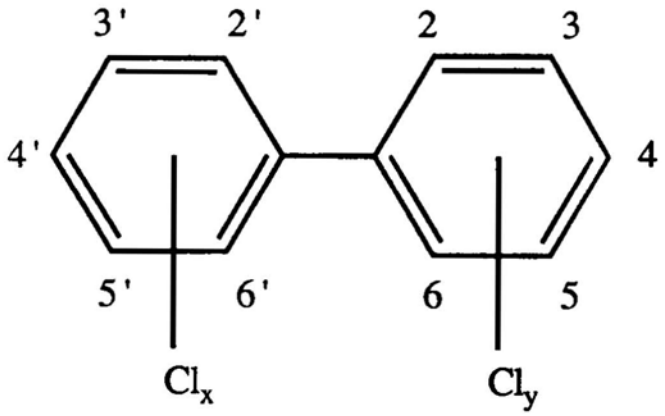
BDDs and 135 different congeners of BDFs. (See Table 2-1.) The basic structure and numbering of each chemical class is shown below.



PCDDs **PCDFs**

X = 0 to 4, Y = 0 to 4, X + Y > 1

There are 209 possible PCB congeners. (See Table 2-1.) The physical/ chemical properties of each congener vary according to the degree and position of chlorine substitution. The list of dioxin-like PCBs can be found in Table 1-2. The PCBs assume a dioxin-like structure when the substituent chlorines occupy: (a) usually no more than one of the ortho positions; (b) both para positions; and (c) at least two meta positions; and (d) the structure is not hindered from assuming the preferred planar configuration. The basic structure and numbering scheme for PCBs is shown below.



X = 1 to 5, Y = 1 to 5, X + Y > 1

2.3. PHYSICAL/CHEMICAL PROPERTY EVALUATION METHODOLOGY

As discussed above, a thorough search of the recent published scientific literature was conducted to maximize and optimize the identification of measured physical/chemical properties. For the purpose of identifying the most definitive of two or more physical/chemical property values reported in the literature for a given dioxin-like compound, a ranking methodology was developed to evaluate the degree of confidence in the reported values. A property value with a ranking of 1 is considered to have the highest level of confidence; a property value with a ranking of 5 is considered to have the lowest level of confidence. The ranking scheme assumes that measured values are more definitive than estimated values. The ranking scheme is based on five ranking criteria or factors. These factors are described below:

Factor 1: *Confirmation.* Value, measured or derived, confirmed by at least one other laboratory, or different experimental technique. Confirmation was assumed if the reported values were within 50 percent of the highest value (within 5 percent for values reported in logarithmic units).

Factor 2: *Measurement Technique.* Direct measurement technique used. No measurements reported less than 10 times the method detection limit.

Factor 3: *GLP Followed.* Good Laboratory Practice was followed in the experimental work. This includes the use of traceable, pure standards; sensitive, selective detection technique was employed; repeatability of measurements demonstrated; all experimental details sufficiently documented so others could reproduce experiments; and sources of determinate error considered - error analysis conducted.

Factor 4: *Derived Value.* Value derived from other directly measured physical/chemical properties by use of known physical/chemical relationships developed for structurally similar chemicals (e.g., other dioxin, furan, and PCB congeners, multiple-ring halogenated compounds). The input value (i.e., the independent variable) used to derive the property value of interest from the equation (i.e., the physical/chemical relationship) is a directly measured value.

Factor 5: *Estimated Value.* Value estimated using a physical/chemical relationship that was developed using estimated values or a combination of

estimated and measured values; this includes QSAR (Quantitative Structure Activity Relationship) methods. Also includes values derived from other directly measured physical/chemical properties by use of known physical/chemical relationships developed, in large part, for structurally dissimilar compounds.

Although this ranking scheme is subjective in nature, it is a reasonable method for identifying the most definitive physical/chemical property value. The ranking scheme has several advantages. First, it identifies where more work is needed to obtain a more definitive p-chem property value. Second, it allows for later adjustments in these values when more definitive studies are conducted. A low ranking for a study does not mean that a particular reported value is incorrect - only that insufficient evidence exists to determine its accuracy. The ranking scheme is as follows:

Rank 1: Confirmed Measured Values. The reported value has met Factors 1, 2, and 3. (See Table 2-2.) This value is considered definitive.
Rank 2: Unconfirmed Measured Values. The reported value has met Factors 2 and 3. The value is considered accurate; it could be definitive subject to confirmation.
Rank 3: Confirmed Derived Values. The reported value has met Factors 1, 3, and 4. The value is considered to be a close approximation.
Rank 4: Unconfirmed Derived Value. The reported value has met Factors 3 and 4. The value is considered to be an approximation.
Rank 5: Estimated Value. The reported value has met Factor 5 only. The value is considered to be an "order-of-magnitude" estimate.

If two or more values have the same ranking, then the value that has been selected as most definitive by Mackay et al. (1992a, 1992b), by other EPA offices, other government agencies, or scientific data bases (e.g., the Syracuse Research Corporation (SRC) Chemfate Data Base) was deemed to be the most definitive value for this document. If two or more values with the same ranking have not been peer reviewed as above, typically the most current value was chosen as the most definitive value. This

decision was made on the assumption that the most current value would have been developed by the latest scientific method; however, an evaluation of the techniques used to derive the values was also considered in choosing the more definitive value. The ranking of the literature can be found in Table A-2 in Appendix A. Table 2-3 lists the property values for the dioxin-like compounds that are considered to be most definitive.

2.4. PHYSICAL/CHEMICAL PROPERTIES - CHLORINATED COMPOUNDS

Limited research has been conducted to determine physical and chemical properties of CDFs, CDDs, and the dioxin-like PCBs. The CDD/CDF congeners having 2,3,7,8-chlorination have received the most research attention, with 2,3,7,8,-TCDD being the most intensely studied compound. All 2,3,7,8-substituted CDD/CDF congeners are now available commercially, but many of these congeners have not been prepared in pure form. Another factor that is likely to have limited research on these compounds is the high toxicity of these compounds, which necessitates extreme precautions to prevent potential adverse effects.

2.4.1. Water Solubility

Although water solubility data are not directly used in the exposure scenario equations in Volume 3, water solubility data can be used to estimate Henry's Law constants (using the VP/WS ratio technique) that are used in the equations in Volume 2. Very few measured water solubility values are available in the literature. Marple et al. (1986a) reported the water solubility of 2,3,7,8-TCDD as 19.3 $\pm$ 3.7 parts per trillion (nanograms per liter, ng/L) at 22°C. Marple et al. (1986a) used a procedure of equilibrating thin films of resublimed 2,3,7,8-TCDD with a small volume of water followed by gas chromatography (GC) analysis with 63Ni electron capture detection. Other water solubility values for 2,3,7,8-TCDD have been reported in the literature and are summarized in U.S. EPA (1990) and Mackay et al. (1992a). Values ranging from 7.9 ng/L to 483 ng/L are reported in U.S. EPA (1990) and Mackay et al. (1992a) with 19.3 ng/L selected as the recommended value. The value of 19.3 ng/L was confirmed by Marple et al. (1987) using both radio-labeled and unlabeled 2,3,7,8-TCDD. Marple et al. (1987) reported values of 10.6 ng/L and 10.4 ng/L for the labeled and unlabeled compounds respectively. Because

the value of 19.3 ng/L was confirmed by other techniques and was recommended by U.S. EPA (1990), it was chosen as the most definitive value.

Friesen et al. (1985) and Shiu et al. (1988) used high-performance liquid chromatography (HPLC) generator column techniques to measure the water solubilities of a series of chlorinated dioxins including the following dioxin-like congeners: 1,2,3,4,7,8-HxCDD; 1,2,3,4,6,7,8-HpCDD; and OCDD. Reported water solubilities ranged from 4.42 ng/L to 0.074 ng/L for the 1,2,3,4,7,8-HxCDD and OCDD congeners, respectively. Friesen et al. (1990b) used a gas chromatography/mass spectrometry detection (GC/MSD) generator column technique to measure the water solubilities of a series of 2,3,7,8-substituted CDFs (2,3,7,8-TCDF; 2,3,4,7,8-PeCDF; 1,2,3,6,7,8- and 1,2,3,4,7,8-HxCDF; and 1,2,3,4,6,7,8-HpCDF) and reported a decrease in water solubility with an increase in the number of chlorine substituents. The reported water solubility values ranged from 419 ng/L for 2,3,7,8-TCDF to 1.35 ng/L for 1,2,3,4,6,7,8-HpCDF.

Few measured data have been reported for the dioxin-like PCB compounds. The selected water solubility values for the dioxin-like PCB compounds are typically one to two orders of magnitude greater than the similarly chlorinated CDD and CDF congeners. For example, the selected value for 3,3',4,4'-TCB is 1 μg/l whereas the selected water solubility values averages for 2,3,7,8-TCDD and 2,3,7,8-TCDF are 0.019 and 0.42 μg/l, respectively.

For those compounds without reported measured water solubility values, estimations were calculated by the congener group-average method. For example, for the tetra-chlorinated dioxins, values reported in the literature were averaged to yield an estimated water solubility value for the tetra-chlorinated dioxin congener group. A similar procedure was used to develop the average value for each of the other CDD and CDF congener groups. The most definitive value for each isomer was used to derive the congener group average.

2.4.2. Vapor Pressure

Vapor pressure data are not directly used in the exposure scenario equations in Volume 3. However, vapor pressure data can be used to estimate Henry's Law constant using the VP/WS ratio technique. Very few measured vapor pressure values are available

in the literature for the CDDs and CDFs, but the majority of the measured vapor pressures are for the 2,3,7,8-substituted congeners.

Mackay et al. (1992a) reviewed the published vapor pressure data for 2,3,7,8-TCDD and selected a recommended value of 1.50×10^{-9} mm Hg at 25°C. This value had been measured by Rordorf (1987, 1989) using a gas-flow method in a saturation oven. SRC (1991) reported this same value by extrapolating the vapor pressures measured by Schroy et al. (1985) at four higher temperatures, 30°, 55°, 62°, and 71°C. Rordorf (1987, 1989) also reported experimental vapor pressure values for OCDD (8.25×10^{-13}mm Hg) and OCDF (3.75×10^{-12} mm Hg). These values were chosen as the most definitive because they were the most current directly measured values and also because they were selected by Mackay et al. (1992a) as the most definitive values.

Eitzer and Hites (1988) reported experimental vapor pressure values for several dioxin-like compounds utilizing GC capillary column retention time data. The values were reported as subcooled liquids and then converted to solid-phase vapor pressures. The solid-phase vapor pressures ranged from 2.16×10^{-12} mm Hg to 9.48×10^{-10} mm Hg for the CDDs and from 1.07×10^{-10} mm Hg to 8.96×10^{-9} for the CDFs. Rordorf (1987, 1989) used a vapor pressure correlation method to predict the vapor pressures of 15 CDDs and 55 CDFs (including most of the 2,3,7,8-substituted CDDs and CDFs) based on the measured vapor pressures for 10 CDDs, 4 CDFs, and the deduced boiling point and enthalpy data for the larger series of CDDs and CDFs. Measured boiling point and enthalpy data are in good agreement with the deduced data used in the correlation method. The values from Rordorf (1987, 1989) were considered the more definitive based on the review of the data from these two studies by Mackay et al. (1992a).

The ranges of selected values reported within various congener groups are as follows:

Congener Group	Vapor Pressure Range (mm Hg)		
TCDD	1.5×10^{-9}	to	4.80×10^{-8}
PeCDD	4.4×10^{-10}	to	6.6×10^{-10}
HxCDD	3.6×10^{-11}	to	5.1×10^{-11}
HpCDD	5.6×10^{-12}		
OCDD	8.2×10^{-13}		
TCDF	1.5×10^{-8}	to	4.0×10^{-8}
PeCDF	1.5×10^{-9}	to	4.3×10^{-9}
HxCDF	1.80×10^{-10}	to	5.70×10^{-10}
HpCDF	3.53×10^{-11}	to	5.8×10^{-11}
OCDF	3.75×10^{-12}		

The selected vapor pressure values reported for the dioxin-like PCBs are typically one to two orders of magnitude greater than the similarly chlorinated CDD and CDF congeners. (See Table 2-3.) The directly measured values of Murphy et al. (1987) and the derived values of Foreman and Bidleman (1985) were considered the most definitive. As with the CDDs and CDFs, the vapor pressures of the PCBs decrease with an increase in the number of chlorine substituents. The highest selected value for the dioxin-like PCBs is 1.09×10^{-6} mm Hg for 2,3,3',4,4'-PeCB, and the lowest value selected is 1.46×10^{-8} mm Hg for 2,3,3',4,4',5,5'-HpCB.

Estimated vapor pressure values for those CDDs and CDFs for which measured values were not found in the literature were calculated by the congener group-average method using the literature-reported values within a congener group. For example, the literature values for the TCDDs were averaged to obtain an estimated vapor pressure assumed to apply to the TCDD congeners that did not have literature values. A similar procedure was used to develop a congener-average for each of the other congener groups. The most definitive value for each isomer was used to derive the congener group average. Compounds with vapor pressures in the ranges reported for these compounds are considered to have very low vapor pressures.

2.4.3. Henry's Law Constant

Henry's Law constants are used in Volume 3 to estimate the volatilization of the dioxin-like compounds from soil. They are also utilized in estimating the vapor-phase bioconcentration factor from air to plant leaves. Directly measured Henry's Law constants

have been reported for only three compounds. Measured values have been reported for 1,2,3,4-TCDD, 1.99 x 10^{-5} atm-m^3/mol (Santl et al., 1994); 1,3,6,8-TCDD, 6.81 x 10^{-5} atm-m^3/mol (Webster et al., 1985); and for 3,3',4,4'-PCB, 9.4 x 10^{-5} atm-m^3/mol (Dunnivant and Elzerman, 1988). These three values were considered the most definitive. Other values reported in the literature for CDDs, CDFs, and PCBs were calculated by the vapor pressure/water solubility (VP/WS) ratio technique or by structure-activity relationship techniques. A derived VP/WS ratio value, Rank 4, was determined to be more definitive than an estimated value, Rank 5.

Congener group-average Henry's Law constants were estimated for each congener group based on the selected congener values within that group. The Henry's Law constant values for the PCBs are similar to those for the CDDs and CDFs.

Lyman et al. (1982) offers guidelines, though not specific to these compounds, for comparing the degree to which organic compounds volatilize from water. These guidelines suggest that volatilization of polycyclic aromatic hydrocarbons and halogenated aromatics (which includes all the dioxin-like compounds) from water represents a significant transfer mechanism from the aqueous to the atmospheric phase.

2.4.4. Octanol/Water Partition Coefficient

The octanol/water partition coefficient (K_{ow}) is used in several exposure estimation procedures in Volume 3. The log K_{ow} is used to estimate log K_{oc} when measured data are not available, and it is utilized in estimating the root concentration factor (RCF). RCF is used to estimate the uptake of contaminants by plant roots. Log K_{ow} is also used to estimate the vapor-phase bioconcentration factor from air to plant leaves.

Marple et al. (1986b) reported the octanol/water partition coefficient of 2,3,7,8-TCDD as 4.24 ($\pm$ 2.73) x 10^6 at 22 $\pm$ 1°C, yielding a log K_{ow} of 6.64 (Table A-1). Two similar experimental techniques were used, but the more reliable method involved equilibration of water-saturated octanol, containing the 2,3,7,8-TCDD, with octanol-saturated water, over 6 to 31 days. U.S. EPA (1990) reported that the available low K_{ow} data ranged from 6.15 to approximately 8.5. The 6.64 value reported by Marple et al. (1986b) was the value recommended in U.S. EPA (1990). More recently, Mackay et al. (1992a) evaluated all published measured and estimated log K_{ow} values for 2,3,7,8-TCDD and recommended a value of 6.80.

Burkhard and Kuehl (1986) used reverse-phase High Pressure Liquid Chromatography (HPLC) and Liquid Chromatography/Mass Spectrometry (LCMS) detection to determine octanol/water partition coefficients for 2,3,7,8-TCDD and a series of seven other tetrachlorinated planar molecules, including three other TCDD isomers (1,2,3,4-TCDD; 1,3,7,9-TCDD; 1,3,6,8-TCDD), 2,3,7,8-TCDF, and 3,3',4,4'-tetrachlorobiphenyl. The log K_{ow} values for the four TCDD isomers ranged from 7.02 to 7.20. The log K_{ow} for 2,3,7,8-TCDF was 5.82, and the log K_{ow} for 3,3',4,4'-TCB was 5.81.

Burkhard and Kuehl (1986) also re-evaluated data on 13 CDDs and CDFs previously reported by Sarna et al. (1984) under similar experimental techniques. In the re-evaluation, Burkhard and Kuehl (1986) used experimental rather than estimated log K_{ow} values in correlations with gas chromatographic retention times. This approach yielded log octanol-water partition coefficients ranging from about 4.0 for the nonchlorinated parent molecules to about 8.78 for the octa-chlorinated compounds, much lower than the values originally reported by Sarna et al. (1984).

Sijm et al. (1989) used a slow stirring method to obtain log K_{ow} values for 73 CDD and CDF congeners; values ranged from 6.10 to 7.92. Mackay et al. (1992a) reviewed all published measured and estimated log K_{ow} values for eight tetra- through octa-substituted CDDs and seven tetra- through octa-substituted CDFs; recommended values were selected by Mackay et al. (1992a) for the eight CDDs and for five of the CDFs. The most definitive values chosen were either those selected by Mackay et al. (1992a), a directly measured value, or the most current derived value. Selected values reported for congeners within the various congener groups ranged as follows:

Congener Group	Log K_{ow}
TCDD	6.1 to 7.1
PeCDD	6.2 to 7.4
HxCDD	6.85 to 7.8
HpCDD	8.0
OCDD	8.2
TCDF	5.6 to 6.79
PeCDF	6.19 to 6.92
HxCDF	7.0
HpCDF	7.4
OCDF	8.0

The selected log K_{ow} values for the PCBs are similar to those reported for the CDDs and CDFs. The values range from 6.5 (measured) for 3,3',4,4'-TeCB to 7.71 (literature-estimate) for 2,3,3',4,4',5,5'-HpCB. The log K_{ow} values increase with an increase in the number of chlorine substituents.

Partition coefficient values were calculated for those compounds for which no measured data were reported in the literature by averaging the literature values within congener groups, as were done for vapor pressure and water solubility. Partition coefficients in the ranges of these reported values indicate that the substances tend to adsorb strongly to organic components in the soil and may bioconcentrate in those organisms exposed to the compounds.

2.4.5. Organic Carbon Partition Coefficient

The organic carbon partition coefficient (K_{oc}) is used in several exposure estimations in Volume 3. K_{oc} is used in the estimation of the adsorption partition coefficient, which describes the partitioning of contaminants between suspended sediment and the water column. K_{oc} is also used in estimating the concentration of contaminants in below ground vegetables grown in contaminated soil.

Log K_{oc} values for 2,3,7,8-TCDD have been measured in several studies. Lodge and Cook (1989) used contaminated sediments from Lake Ontario and distilled water in glass cylinders to measure the log K_{oc} of 2,3,7,8-TCDD. Log K_{oc} values ranged from 7.25 to 7.59. Jackson et al. (1986) used 10 contaminated soil samples in a batch extraction procedure to measure log K_{oc}. The average log K_{oc} of the 10 soils was reported as 7.39. Marple et al. (1987) used two uncontaminated soils spiked by two different methods with 2,3,7,8-TCDD to obtain the log K_{oc} value. The soil was stirred with water in 2-liter flasks. The log K_{oc} values ranged from 5.96 to 6.54 for both soils, with an average value of 6.40 for the red clay soil and 6.02 for the alluvial soil.

Puri et al., (1989) studied log K_{oc} of 2,3,7,8-TCDD with several other co-contaminants such as crankcase oils and surfactants. An average log K_{oc} value of 5.68 was reported for 2,3,7,8-TCDD in the presence of 0.01 percent surfactant. Walters and Guiseppi-Elie (1988) used several soils and water/methanol mixtures in a batch shake testing procedure to determine the log K_{oc} of 2,3,7,8-TCDD. The study resulted in a log K_{oc} value of 6.6.

Five studies for log K_{oc} of 2,3,7,8-TCDD were ranked number 1. The studies by Jackson et al. (1986) and Lodge and Cook (1989) had confirming values of 7.39 and 7.42, respectively. The studies by Walters and Guiseppi-Elie (1988), Walters et al. (1989), and Marple et al. (1987) had confirming values of 6.6, 6.66, and 6.4, respectively. The 6.6 value reported by Walters and Guiseppi-Elie (1988) was chosen by Syracuse Research Corporation (SRC) in the CHEMFATE Database (SRC, 1991) as the most definitive. This value was determined in a mixed solvent system, water and methanol; therefore, it is not considered as appropriate as a pure water equilibration system determined value. The values reported by Marple et al. (1987) and Walters et al. (1989) were determined in uncontaminated soil and with pure water; therefore, these values are selected as the most definitive for this document.

Definitive values were not selected for other congeners because of few measured data points and, oftentimes, considerable differences in the reported values for those congeners with reported values. The ranges of reported values are presented in Table A-1 in Appendix A.

2.4.6. Photo Quantum Yields

Photo quantum yields, good semi-quantitative measures of phototransformation efficiency (Yan et al., 1995), have been reported for several CDD/CDF congeners. No values were located for the dioxin-like PCBs.

Congener	Photo Quantum Yield (mole/einstein)	Reference
1,2,3,7-TCDD	5.42×10^{-4}	(Choudhry and Webster, 1989)
1,3,6,8-TCDD	2.17×10^{-3}	(Choudhry and Webster, 1989)
2,3,7,8-TCDD	2.2×10^{-3}	(Dulin et al., 1986)
2,3,7,8-TCDD	3.3×10^{-2}	(Rapaport and Eisenreich, 1984)
2,3,7,8-TCDD	1.62×10^{-2}	(Yan et al., 1995)
1,2,3,4,7-PeCDD	9.78×10^{-5}	(Choudhry and Webster, 1987)
1,2,3,4,7,8-HxCDD	1.10×10^{-4}	(Choudhry and Webster, 1987)
1,2,3,4,7,8-HxCDD	1.58×10^{-3}	(Yan et al., 1995)
1,2,3,4,6,7,8-HpCDD	1.53×10^{-5}	(Choudhry and Webster, 1987)
OCDD	2.26×10^{-5}	(Choudhry and Webster, 1987)
OCDD	1.25×10^{-3}	(Yan et al., 1995)
1,2,4,7,8-PeCDF	1.29×10^{-2}	(Choudhry et al., 1990)
1,2,3,4,7,8-HxCDF	6.96×10^{-4}	(Choudhry et al., 1990)

All quantum yields were measured in a water-acetonitrile solution at 313 nm, except those reported by Rapaport and Eisenreich (1984) which were measured in the vapor phase and those reported by Yan et al. (1995) which were carried out in a butanol/decane mixture. Yan et al. (1995) also examined the effect of co-contaminants (pentachlorophenol, naphthalene, phenanthrene, and anthracene) on the photoquantum yield of OCDD and 2,3,7,8-TCDD. The presence of the co-contaminants decreased the photoquantum yield at a degree dependent upon both the concentration and extinction coefficient of the co-contaminants.

Congener group averages were not calculated because photo quantum yields are very sensitive to chlorine position and also to the physical medium (e.g., vapor or dilute solution) and conditions (e.g., the solvent system) used in the experiments (Yan et al, 1995).

2.5. PHYSICAL CHEMICAL PROPERTIES - BROMINATED COMPOUNDS

Information on the physical and chemical properties of the polybrominated dioxins and furans is very limited and has not been compiled for this report.

2.6. ENVIRONMENTAL FATE - CHLORINATED COMPOUNDS

CDD/CDFs and dioxin-like PCBs have been found throughout the world in practically all media including air, soil, water, sediment, and biota. The widespread occurrence observed is not unexpected considering the numerous sources that have emitted these compounds into the atmosphere and the overall resistance of these chemicals to abiotic and biotic transformation. Consequently, CDD/CDFs and PCBs emitted to the atmosphere can be transported long distances in the atmosphere before they are deposited onto vegetation, soil, and water via dry and wet deposition.

As depicted in Figure 2-1, deposition onto vegetation and subsequent ingestion of that plant material by animals is hypothesized to be the primary mechanism by which CDD/CDFs enter the terrestrial/agricultural food chain. Deposition onto soil with subsequent erosion and runoff into water bodies with subsequent bioaccumulation by aquatic biota is believed to be the major pathway by which CDD/CDFs enter the aquatic food chain in most freshwater bodies. These two pathways are also expected to be major pathways for entry of dioxin-like PCBs into the terrestrial and aquatic food chains.

However, because PCBs are more mobile in the environment (i.e., greater vapor pressures and water solubilities) than CDD/CDFs, there will be greater inter-media transport of PCBs (e.g., greater volatilization from soil and water to air). In addition, because of the previous widespread use and disposal of PCBs, localized sources of contamination may dominate aquatic food chain sources in more water bodies than is the case for CDD/CDFs.

The growing body of literature from laboratory, field, and monitoring studies examining the environmental transport, transformation, and distribution of CDD/CDFs and dioxin-like PCBs has increased the understanding of the fate of these environmentally ubiquitous compounds. The purpose of this section is to summarize the key findings from the growing body of literature dealing with the environmental fate of CDD/CDFs and PCBs.

Figure 2-2 presents a conceptual diagram of the intermedia movement of CDD/CDFs and PCBs among the five major environmental media: air, soil, water, sediment, and biota. As will be discussed in this section, the primary mechanism currently believed to be responsible for the widespread occurrence of CDD/CDFs and PCBs is long range atmospheric transport and deposition onto vegetation and soil.

2.6.1. Environmental Fate of CDDs and CDFs

2.6.1.1. Summary

Because of their high lipophilicity and low water solubility, CDD/CDFs are primarily associated with particulate and organic matter in soil, sediment, and the water column. Current understanding of CDD/CDF behavior on atmospheric particulate matter is that there is a partitioning between the particles and the gas phase. The two key parameters controlling the phase in which a particular congener is predominantly found are the congener's vapor pressure and the atmospheric temperature. Congeners with higher vapor pressures (i.e., the less chlorinated congeners) are found to a greater extent in the gas phase. CDD/CDFs sorbed to soil exhibit little potential for significant leaching or volatilization once sorbed to particulate matter.

The available evidence indicates that CDDs and CDFs, particularly the tetra- and higher chlorinated congeners, are extremely stable compounds under most environmental conditions. The only environmentally significant transformation processes for these congeners are believed to be atmospheric photooxidation and photolysis of nonsorbed

species in the gaseous phase or at the soil or water-air interface. Several studies have, however, indicated that certain ligninolytic fungi can degrade these higher-chlorinated congeners and that anaerobic degradation in sediment may occur at a slow rate. To a large extent, these degradation processes involve dechlorination to less-chlorinated (and possibly more toxic) congeners.

Burial in-place or erosion of soil to water bodies appears to be the predominant fate of CDD/CDFs sorbed to soil. CDD/CDFs entering the water column primarily undergo sedimentation and burial with some uptake by aquatic biota. The ultimate environmental sink of CDD/CDFs is believed to be aquatic sediments. CDD/CDFs entering the atmosphere are removed either by photodegradation or by dry or wet deposition.

Vapor-phase dry deposition of CDD/CDFs onto vegetation is hypothesized to be the primary route of entry of CDD/CDFs into the terrestrial/agricultural food chain. Atmospheric deposition of CDD/CDFs onto land followed by runoff/erosion to water bodies is hypothesized to be the major route of entry of CDD/CDFs into the aquatic food chain of most freshwater bodies.

2.6.1.2. Transport Mechanisms in Air

Once released into the atmosphere, CDDs and CDFs can become widely dispersed throughout the environment by atmospheric transport and deposition. In an assessment of the atmospheric transport and deposition of CDDs and CDFs for EPA, Hites and Harless (1991) generated data and analyses that support the contention that background environmental levels and congener profiles of CDDs and CDFs in soils and sediment (i.e., higher rather than lower chlorinated congener patterns predominate) can be attributed, in large part, to the atmospheric transport and transformation of CDDs and CDFs released from combustion sources. More recently, Tysklind et al. (1993) reported the results of measurements of CDD/CDFs in the ambient air from a rural site in Sweden collected during 1989 and 1990. The highest concentrations of total CDD/CDFs were measured during sampling events with air masses coming with westerly to southerly winds, thus indicating long range transport. The congener profiles were found to vary depending on wind trajectories implicating source influences from industrialized and urbanized areas of Europe.

Deposition is a broad term defining a number of atmospheric phenomena, including the wet and dry deposition of CDD/CDF-contaminated airborne particulate matter onto soils and vegetation, and the wet and dry deposition of vapor-phase CDD/CDFs onto soils and vegetation. Mass-balance studies have been conducted in several countries in an effort to establish the mechanisms associated with the generation, transport, and environmental fate of CDD/CDFs. A wide range of estimated deposition rates have been developed in these studies. The variation in estimates may be attributed, in part, to the likely differences in precision and accuracy of the various sampling methods used, as well as the inherent difficulty in comparing results from differing collection devices. Table 2-4 presents a summary of some of the deposition rates generated by investigators in Sweden, the United Kingdom, Belgium, Germany and the United States. As noted in Table 2-4, deposition fluxes appear to be greater in urban areas than in rural areas.

A variety of methods have been developed by researchers in several countries for measuring dry and wet deposition of CDD/CDFs. However, because of the complexity of deposition as it occurs in the natural environment, all of these methods, with the possible exception of wet deposition monitoring techniques, have major drawbacks which limit their utility for generating data that provide a reliable and accurate measure of deposition as it naturally occurs. Methods have also been developed for measurement of total CDD/CDF concentrations in air; modifications to these methods have been developed that can enable consistent and reproducible measurements of particulate and vapor-phase ambient air concentrations. Mathematical models have also been developed to estimate dry and wet deposition rates. [Volume 3 provides a detailed discussion of these modeling techniques]. Because the current state of knowledge concerning deposition mechanisms/rates and methods to accurately measure deposition is not well-developed, the most effective program that could be deployed today to better understand deposition would consist of ambient air measurements coupled with specific deposition studies designed to improve the accuracy of deposition modeling.

Because of the importance of atmospheric deposition as a pathway for contamination of the terrestrial/agricultural food chain, the remainder of this section (i.e., Section 2.6.1.2) presents an overview discussion of three areas: (1) vapor/particle partitioning; (2) dry deposition processes relevant for CDD/CDF; and (3) wet deposition processes relevant for CDD/CDF.

2.6.1.2.1. Vapor/Particle (V/P) Partitioning. The relative importance of the various deposition processes (and associated phases) is related to congener-specific vapor/particle partitioning. Hites and Harless (1991), Hippelein et al. (1996), and others have demonstrated that partitioning of CDD/CDFs between the vapor and particle-associated phases occurs in the atmosphere. The key parameters controlling the phase in which a particular congener is found are the congener's vapor pressure, the atmospheric temperature, and the particulate matter concentration in the atmosphere. Congeners with higher vapor pressures (i.e., the less-chlorinated compounds) are found to a greater extent in the vapor phase. For a given congener, the fraction in the vapor phase increases with increasing ambient temperature and decreases with increasing particle concentration. A portion of the particle-associated compound appears to be freely exchangeable between the particulate and vapor phases. A second portion may be irreversibly sorbed or occluded by the particles and not in equilibrium with the gas phase.

A comprehensive review of the published literature addressing vapor/particle (V/P) partitioning of CDD/CDFs in stack gases and ambient air is provided in Volume 3. The Volume 3 review includes an evaluation of the results of stack testing data, ambient air sampling data, and theory rooted in basic physical chemistry that either imply, directly deduce, or theoretically calculate V/P partitioning. Table 2-5 presents a summary of the Volume 3 review of the ambient air monitoring studies. The most comprehensive set of partitioning data were collected by Hippelein et al. (1996); data were collected continuously over the course of 48 weeks at six urban sites on the outskirts of Augsburg, Germany, during 1992 and 1993.

A theoretical approach developed by Bidleman (1988) for predicting V/P partitioning of CDD/CDFs is described in detail in the Volume 3 review. Table 2-6 presents, for each of the 2,3,7,8-substituted CDD/CDFs, the percentage of mass predicted in Volume 3 using this theoretical approach to be in the particle phase under four airshed conditions: "clean continental," "average background," "background plus local sources," and "urban." From the review in Volume 3, the following conclusions were made:

- The stack test methods in use today to monitor and measure the concentration of CDD/CDFs emitted to the air from combustion sources have given inconclusive and contradictory V/P partitioning results and thus do not provide a credible basis, at

present, for determining V/P partitioning at the point of release. There is no consistent pattern to the interpretation of V/P based on where the CDD/CDF segregate in the instrument (e.g., the glass fiber filter or the XAD resin). Factors that may contribute to this inconsistent pattern are: the relatively long residence time spent traversing the stack interior; the location of the probe to the instrument in a relatively hostile environment of the hot combustion gas; the static temperature of the particulate filter caused by heating the particulate filter housing; and the fact that located between the particulate trap and the vapor trap is a condensing section consisting of glass tubing surrounded by an ice bath.

- The use of a high-volume ambient air sampler consisting of a glass fiber particulate filter (GFF) and polyurethane foam adsorbent trap (PUF) is a reliable method for the collection and retention of CDD/CDFs in ambient air. Because the sampler is not artificially heated or cooled, but is allowed to operate at ambient air temperatures, the method can be used to imply the V/P partitioning of CDD/CDFs in ambient air. This is accomplished by separately extracting and analyzing the GFF and PUF. However, the method may only give an approximate indication of the V/P ratio since mass transfer of CDD/CDF from the particulate matter on the GFF to the PUF cannot be ruled out. For example, it is possible that a portion of the CDD/CDFs that are sorbed to particulate matter captured by the filter may be volatilized and carried with the air flow to the PUF sorbent trap (blow-off effect). If this were to occur, the observed V/P ratio would be overestimated. Also, the GFF will collect particles $\geq$0.1 microns in diameter and, therefore, it is possible that smaller particles will pass through the GFF and be trapped in the PUF. If this does occur, the observed V/P ratio will be overestimated.

  There are currently no empirical data that demonstrate the magnitude of these effects or that these effects actually occur. However, the potential impact of particle breakthrough may be ascertainable, if it is assumed that the CDD/CDF congener group pattern is the same on all particle size fractions. This assumption is supported by the findings of Kaupp et al. (1994) who demonstrated that CDD/CDF congener group profiles were nearly identical in four particle size ranges (1.35 to 4.05 um; 0.45 to 1.35 um; 0.15 to 0.45 um; and $<$0.15 um) collected in a rural area of Germany during the summer of 1992. Thus, if OCDD is, as is typical, the dominant congener in the collected material on the GFF, then the mass of any other CDD/CDF on the PUF that may be due to particle breakthrough can be estimated by multiplying: (1) the ratio of that congener's mass on the GFF to the mass of OCDD on the GFF by (2) the mass of OCDD in the PUF.

- Neither the currently available monitoring techniques nor the available models necessarily give the "correct" V/P partitions. Until the state of knowledge of CDD/CDF partitioning in air is improved through development of improved monitoring devices and laboratory investigations of the kinetics and thermodynamics of CDD/CDF sorption, the theoretical construct described in Chapter 3 of Volume 2 is the recommended approach for estimating V/P partitioning of CDD/CDFs at this time. Key advantages to the theoretical approach are that it relies on current adsorption theory, considers the molecular weight and the degree of halogenation of the congeners, uses the boiling points and vapor

pressures of the congeners, and uses the availability of surface area for adsorption of atmospheric particles that correspond to a variety of ambient air shed classifications having variable particulate matter densities.

2.6.1.2.2. Dry Deposition. Dry deposition can involve two phases, dry particulate deposition and vapor phase deposition, the relative importance of which for a given congener is dependent primarily on the V/P partitioning. First, dioxin-like compounds associated with particulate matter can deposit by gravitational settling or turbulent diffusion. Secondly, dioxin-like compounds can be deposited by vapor-phase diffusion into the soil, vegetation, and the surface layer of water bodies. The rate at which atmospheric chemicals are deposited is termed the "deposition flux". The deposition flux is derived as the product of the concentration of the chemical in the vapor phase or on/in the particulate and the deposition velocity of the contaminated particles. The downward motion represented by deposition velocity is controlled by the gravitational settling velocity, atmospheric resistance, surface resistance and the atmospheric surface friction layer. The factors that most influence deposition flux can be divided into two types: (1) meteorological influences and (2) the properties of the chemical influencing it's V/P partitioning. A detailed list of the many factors that can affect dry deposition is shown in Table 2-7.

Dry Particulate Deposition. Dry particulate deposition is the best characterized of the dry deposition processes. As noted in Table 2-5, the vast majority of the atmospheric burden of hepta- and octa-chlorinated CDD/CDF (and, to a lesser extent, the burden of hexa- and penta-chlorinated congeners) is associated with particulate matter. As such, dry particulate deposition is a major mechanism for removal of these congeners from the atmosphere. The major factors controlling the transfer of particulate from some height above the surface through the surface layer down to the immediate vicinity of the receptor surface are the forces of gravity and turbulent diffusion. As a general rule, very large particles (i.e., greater than 20 μm) will be removed from the atmosphere fairly rapidly by the force of gravity (Kaupp et al., 1994). Particles less than 20 μm will be removed at a slower rate primarily by atmospheric turbulence and Brownian diffusion through the laminar sub-layer which often has a thickness of 10^{-1} to 10^{-2} cm. The deposition flux for these smaller particles is influenced by many factors, including: the distribution of particles

by diameter and density; the atmospheric turbulence; and the friction and morphology of the impacted ground and vegetative surfaces.

Few studies have been published that have attempted to measure only dry particulate deposition of CDD/CDFs. Koester and Hites (1992a) used inverted frisbees and flat glass plates to collect dry particulate deposition. The collectors were coated with mineral oil and then deployed uncovered (except during precipitation events) for exposure periods of several weeks. The mineral oil is removed from the frisbees/plates after the exposure period and analyzed for CDD/CDF content. The extent to which these devices may also be acting as vapor phase collectors is not thought to be significant but has not been tested. Similarly, the extent of photodegradation of collected CDD/CDFs is not thought to be significant but has not been tested. Hall and Upton (1988) had previously conducted wind tunnel studies of the particle collection efficiency of inverted frisbees and had found an overall collection efficiency of approximately 50 percent with efficiencies decreasing as wind speed increased and particle diameter decreased.

The deposition velocity of particulate matter containing CDD/CDFs onto various surfaces has not been well characterized and is a major source of uncertainty in modeling particulate deposition. Bidleman (1988) estimated that particulates with diameters ranging from 0.08 to 2 μm have deposition velocities that vary from 0.003 to 0.036 cm/sec. Coarser particulates (i.e., >2 μm) were estimated to have much higher deposition velocities, 0.5 to 2.5 cm/sec (Bidleman, 1988). From the results of their study with inverted frisbees and glass plates, Koester and Hites (1992a) calculated an average deposition velocity for particulate-associated CDD/CDFs of 0.2 cm/sec; calculated deposition velocities for the tetra- through octa-chlorinated congener groups ranged from 0.086 to 0.6 cm/sec. Trapp and Matthies (1995) estimated that the fine particulates (i.e., diameters of 0.1 to 1.0 μm) that are responsible for the long range transport of atmospheric particle bound pollutants have deposition velocities of about 0.01 cm/sec.

Dry Vapor-Phase Deposition. Although not as well characterized, several studies have concluded that the transfer of all non-hepta- and non-octa-chlorinated dioxin-like compounds to leafy vegetation is dominated by vapor phase deposition which involves the movement of vapor-phase dioxin from ambient air into leafy vegetation (Bacci, et. al., 1990; Gaggi and Bacci, 1985; McLachlan, et. al., 1995; Rippen and Wesp, 1993; Simonich and Hites, 1995). Dry particulate and wet deposition are believed to be the

dominant mechanisms by which vegetation and soil are exposed to hepta- and octa-chlorinated congeners. Vapor phase deposition directly onto soil is not believed to be a dominant process in most settings because soil is usually covered by vegetation or detritus which are likely to serve as more important exchange sites.

Major factors governing vapor-phase deposition include the ambient air concentration of CDD/CDFs, the exposed surface area of vegetation, the plant morphology/canopy density, and the air side resistance (i.e., a function of air turbulence which is dependent on wind speed and canopy structure). The latter two factors control, to a large extent, the vapor phase deposition velocity. Bidleman (1988) reported that vapor phase deposition velocities calculated from the results of field studies with Aroclors, p,p'-DDT, and chlordane ranged from 0.01 to 1.0 cm/sec. The limited studies that have modeled deposition of CDD/CDFs onto vegetation have employed deposition velocities of 0.5 cm/sec or higher. Trapp and Matthies (1995) used a default vapor phase deposition velocity of 0.5 cm/sec for modeling vapor phase deposition of CDD onto meadow vegetation. Smith et al. (1995) used a deposition velocity of 0.78 cm/sec for deposition of 2,3,7,8-TCDD onto tall grass. A deposition velocity of 0.5 cm/sec (calculated from the data of a ryegrass experiment) was used by McLachlan et al. (1995) to predict gaseous uptake of semivolatile organic compounds (such as CDD/CDFs and PCBs) by grass.

There are two principal applications for vegetation monitoring of gas phase deposition of CDD/CDFs: (1) monitoring short-term trends (i.e., week, month or season), and (2) long-term temporal trends (i.e., over the course of a year). To date, three methods have been employed for each of these two principal applications. Each method has its own advantages and disadvantages and each measures different components of total deposition.

Short-term monitoring methods include collection of pasture grass, grass from grass cultures, and passive collectors (e.g., McLachlan et al., 1995; McLachlan, 1995). These three types of methods differ in their ability to serve as measures of "true" deposition onto natural vegetation. However, the methods can be appropriate monitoring tools depending upon the objective(s) of the monitoring task at hand. Collection of pasture grass is easy and inexpensive and represents "true" deposition onto native pasture grass. However, it cannot be standardized and is a function of uncontrollable factors (i.e., weather, species present, and growth rate). Collection of grass from a grass culture can

be semi-standardized but it may not accurately represent "true" deposition on native vegetation. Grass cultures can be elaborate and relatively costly, and it may be difficult to replicate rate of growth across sites and times. Passive collectors are easy to deploy, inexpensive, and easily standardized. However, there are no accepted, standardized passive methods available at present and the results obtained are not likely to be representative of "true" deposition on native vegetation.

The long-term methods include collection of conifer needles, canopy fall, and leaf fall. Collection of conifer needles is easy, inexpensive, and can integrate an entire year's deposition. Although the use of pine needles as CDD/CDF passive biomonitors has been extensively reported in Europe, few studies have been reported to date in the United States (Safe et al., 1992; Fiedler et al., 1995). Disadvantages of this method include potential loss of some CDD/CDFs because of wax erosion from needles over the year. Also, the method may not be an appropriate technique for a multi-year monitoring program because the canopy structure of a conifer forest will change over the course of many years. That is, the aerodynamic properties of a conifer forest, and consequently the extent and nature of deposition, will differ significantly over a 10 or 20 year period.

Collection of canopy fall using vessels to collect leaf fall, dry deposition, and wet deposition integrates the total deposition under the canopy for the entire exposure period. It is maintenance intensive and the canopy structure may change over the course of many years. The method captures most gas phase deposition, but not direct gaseous deposition to the forest floor; deposition onto the forest floor is likely to be much smaller than the deposition to the canopy. Collection of leaf fall in deciduous is easy, inexpensive, and can be easily standardized. In conifer forests, because only a small fraction of total annual deposition is reflected in fallen needles, the collection vessels must catch the eroded needle waxes as well as fallen needles. Leaf fall collection will also include measurement of some wet and dry particulate deposition that is retained on the leaves (personal communication with Dr. Michael McLachlan, University of Bayreuth, July 1996).

Investigations into the role of conifer forests in removing CDD/CDFs from the atmosphere and the consequences for accumulation in soil have recently been reported (Horstmann et al., 1995; Horstmann and McLachlan, 1996). These researchers measured bulk CDD/CDF deposition in a nature spruce forest and in an adjacent clearing over a 1-year period. Litter fall samples were also collected in the forest. The annual deposition

flux of hepta- and octa-chlorinated CDD/CDFs was approximately equal in the clearing and in the spruce forest. However, the deposition flux of the lower chlorinated congeners was up to five times higher in the forest. During the warmest month of the year, the bulk deposition flux of some congener groups in the forest was up to 16 times higher than in the clearing. However, litter fall accounted for only 16 percent (OCDF) to 48 percent (TCDD) of total deposition in the forest, and canopy throughfall of wet or dry particulate deposition was demonstrated not to be responsible for the large forest deposition rates observed. The researchers hypothesize that the high deposition rates are due to dry gaseous deposition onto conifer needles followed by shedding or erosion of needle waxes, which may be enhanced during hot weather.

2.6.1.2.3. Wet Deposition. In the case of wet deposition, dioxin-like compounds can enter the soil and water and impact on the vegetation in one of two phases: either dissolved in the precipitation or associated with particulate material scavenged by the precipitation. Over the long term, wet deposition processes are believed to dominate dry deposition in terms of total mass deposition of CDD/CDFs. Wet deposition is the primary mechanism responsible for removal of small particulates from the atmosphere. For removal of particulate-associated chemicals, wet deposition flux is the product of the particulate scavenging ratio and the chemical concentration on/in various particulate size fractions. The scavenging ratio is calculated as the product of the scavenging coefficient and precipitation rate. The scavenging coefficient depends on the size distribution of the particulates and the intensity and form of precipitation (i.e., liquid or frozen). Scavenging coefficients have been developed for varying types and intensities of precipitation relative to different particle diameters based on measurements of scavenging of aerosol particles during precipitation events.

CDDs and CDFs are removed physically from the atmosphere by wet deposition (i.e., scavenged by precipitation), particle dry deposition (i.e., gravitational settling of particles), and gas-phase dry deposition (i.e., sorption of CDD/CDFs in the vapor phase onto plant surfaces) (Marklund et al., 1990; Rippen and Wesp, 1993; Welsch-Pausch et al., 1993). Precipitation can be very effective in removing CDDs and CDFs from the atmosphere. Listed in Table 2-8 are the average precipitation scavenging ratios for congener groups reported by Hites and Harless (1991) and Koester and Hites (1992a) for

Bloomington, Indiana, and Indianapolis, Indiana, respectively. The scavenging ratio is the ratio of the concentration of a chemical in precipitation (rain in these studies) to the concentration in the atmosphere and is a measure of the effectiveness of rain in removing the chemical. Also listed in Table 2-8 are the percentages of congener groups scavenged as particles in rain rather than as dissolved solutes in rain. Total rain scavenging ratios ranged from 10,000 to 150,000; hepta- and octa- CDDs (i.e., the congeners most strongly associated with particulates) were scavenged most efficiently.

Wet deposition samplers have been used to collect both rainfall and snow samples. Several types are available, including those which are equipped with photovoltaic cells or moisture sensors, which selectively open and close the sampler in response to weather changes. Precipitation samplers not equipped with moisture sensors are uncovered at all times and thus are subject to bias (i.e., due to collection of dryfall particles as well as wet particulate deposition). Wet deposition collectors have been designed to measure total wet deposition (i.e., dissolved and particulate-associated deposition combined) and dissolved deposition and particulate deposition separately.

The Bergerhoff method is a standard method specified in the German Clean Air Act for monitoring CDD/CDF deposition. The method consists of deploying open-mouth jars for a one month exposure period. Ten Bergerhoff jars have a combined sample collection area of about 0.1 m^2. The Bergerhoff method was designed to collect wet and dry particulate deposition. The samplers have the potential for evaporative loss of CDD/CDFs both in the collected wet and dry deposition. The addition of a water/solvent solution to the jar is reported to minimize this potential problem. The samplers are not thought to be collecting gas phase CDD/CDFs but no confirmatory testing has been reported.

2.6.1.2.4. Mechanisms for Entry of CDD/CDFs into the Terrestrial Food Chain

Air to Plant to Animal Hypothesis. Based on information currently available, the primary mechanism by which CDD/CDFs appear to enter the terrestrial food chain is by vapor phase atmospheric deposition (and to a lesser extent, dry particulate deposition) onto plant surfaces which are subsequently ingested by animals (e.g., cattle). This hypothesis was originally advanced by McLachlan and Hutzinger (1990). Deposits onto the soil can enter the food chain via direct ingestion (e.g., soil ingestion by earthworms, fur preening by burrowing animals, incidental ingestion by grazing animals, etc).

CDD/CDFs in soil can also become available to plants and thus enter the food chain by volatilization and vapor sorption or particle resuspension and adherence to plant surfaces. Although CDD/CDFs in soil can adsorb directly to underground portions of plants, uptake from soil via the roots into above ground portions of plants is thought to be insignificant (McCrady et al., 1990).

Support for this air-to-food hypothesis is provided by Hites and Harless (1991) who concluded that "background environmental levels of PCD/F are caused by PCD/F entering the environment through the atmospheric pathway." Their conclusion was based on demonstrations that the congener profiles in lake sediments could be linked to congener profiles of combustion sources. Further argument supporting this hypothesis is offered below:

- Numerous studies have shown that CDD/CDFs are emitted into the air from a wide variety of sources and that CDD/CDFs can be commonly detected in air at low concentrations. (See Chapter 3 and Volume 1.)

- Studies have shown that CDD/CDFs can be measured in wet and dry deposition in most locations including remote areas (Koester and Hites, 1992a; Rappe, 1991).

- Numerous studies have shown that CDD/CDFs are commonly found in soils throughout the world. (See Chapter 3.) Atmospheric transport and deposition is the most plausible mechanism that could lead to this widespread distribution.

- Models of the air-to-plant-to-animal food chain have been constructed. Exercises with these models show that measured deposition rates and air concentrations can be used to predict food levels that are similar to levels actually measured in food (Travis and Hattemer-Frey, 1991; also Volume 3).

- Alternative mechanisms of uptake into food appear less plausible:

    - Uptake in food crops and livestock from water is minimal due to the hydrophobic nature of these compounds. Travis and Hattemer-Frey (1987, 1991) estimate water intake accounts for less than 0.01 percent of the total daily intake of 2,3,7,8-TCDD in cattle. Experiments by McCrady et al. (1990) show very little uptake in plants from aqueous solutions.

    - Relatively little impact on the general food supply is expected from soil residues that originate from site-specific sources such as sewage sludge and other waste disposal operations. Sewage sludge application onto agricultural fields is not currently a widespread practice in the United States. Waste disposal operations can be the dominant source of CDD/CDFs in soils

at isolated locations such as Times Beach, but are not sufficiently widespread to explain the ubiquitous nature of these compounds.

- The release of CDD/CDFs to the environment from the use of pesticides contaminated with CDD/CDFs is believed to have declined in recent years; however, the past and current impact of pesticide use on CDD/CDF levels in the food supply is uncertain. CDD/CDFs have been associated with certain phenoxy herbicides most of which are no longer produced or have restricted uses. EPA has issued data call-ins requiring certain pesticide manufacturers to test their products for CDD/CDF content. The responses, so far, indicate that current levels in these products are below or near the limit of quantitation. (See Volume 1.)

- Current CDD/CDF levels in food resulting from the use of bleached paper products containing CDD/CDFs appears to be minimal. In the early 1980s, testing showed that CDD/CDFs could migrate from paper containers into food. Current CDD/CDF levels in paper products are now much lower than in the early 1980s. Also, testing of products such as milk and beef prior to packaging has shown detectable levels which cannot be attributed to the packaging. (See Chapter 3.)

A related issue is whether the CDD/CDFs in food result more from current or past emissions. Sediment core sampling indicates that CDD/CDF levels in the environment began increasing around the turn of the century, but also that CDF levels have been declining since about 1980 (Smith et al., 1992). Thus, CDD/CDFs have been accumulating for many years and may have created reservoirs that continue to impact the food chain. Researchers in several countries have attempted to compare known emissions with deposition rates. All of these studies suggest that annual atmospheric depositions exceed annual emissions by a factor of 2 to 10. One possible explanation for this discrepancy between source emissions and deposition may be that volatilization or particle resuspension from these reservoir sources followed by atmospheric scavenging is responsible. These mass balance studies are highly uncertain, and it remains unknown how much of the food chain impact is due to current vs past emissions.

Plant Accumulation Models. McLachlan (1995) presents a simple "scavenging" approach for predicting grass concentrations from air concentrations. He suggests that grass scavenges the equivalent of 9 m^3 or air per gram of grass, and that corn scavenges 4.5 m^3 of air per gram of corn. These scavenging ratios were empirically derived from a set of monitoring data including air, pasture, and corn samples. CDD/CDF concentrations

in grass can be estimated by multiplying the air concentration by this scavenging coefficient of 9. McLachlan (1995) suggests that this simple scavenging coefficient would work with all CDD/CDF congeners since the deposition velocities of vapor and particle bound CDD/CDF appear to be similar.

EPA has developed an air-to-leaf transfer approach to estimate the concentration of CDD/CDFs in vegetation resulting from dry and wet deposition. The EPA approach, fully described in Volume 3, was developed from field test data. The approach is summarized below followed by a brief description of an alternative approach (the deposition velocity approach) recently applied to CDD/CDFs by Smith et al. (1995) and Trapp and Mattheis (1995).

EPA Empirical Air-to-Leaf Approach. Two processes, air-borne vapor phase absorption and air-borne particle deposition, are assumed to contribute to above ground vegetation concentrations:

$$C_{abv} = C_{vpa} + C_{ppa} \qquad \text{(Eqn. 2-1)}$$

where:

C_{abv} = concentration in above-ground vegetation, expressed on a dry weight basis (pg/g)
C_{vpa} = contribution of concentration due to vapor-phase absorption or airborne contaminants (pg/g)
C_{ppa} = contribution of concentration due to wet plus dry deposition of contaminated particulates onto plant matter (pg/g)

The algorithm estimating plant concentrations as a function of vapor-phase air concentrations, C_{vpa}, is:

$$C_{vpa} = \frac{B_{vpa} \; C_{va} \; VG_{ag}}{d_a} \qquad \text{(Eqn. 2-2)}$$

where:

C_{vpa} = contribution concentration due to vapor-phase absorption or airborne contaminants (pg/g)

B_{vpa} = mass-based air-to-leaf biotransfer factor, [(pg contaminant/g plant dry)/(pg contaminant/g air)]
C_{va} = vapor-phase concentration of contaminant in air (pg/m^3)
VG_{ag} = empirical correction factor which reduces vegetative concentrations considering that B_{vpa} was developed for transfer of air-borne contaminants into leaves rather than into bulky above ground vegetation
d_a = density of air (1,190 g/m^3)

The steady state solution for plant concentrations attributed to wet plus dry particle deposition, C_{ppa}, is:

$$C_{ppa} = \frac{F_p}{k_v Y_j} \quad \text{(Eqn. 2-3)}$$

where:

C_{ppa} = vegetative concentration due to settling of contaminated particulates onto plant matter (pg/g)
F_p = unit contaminant wet plus dry deposition rate onto plant surfaces (pg/m^2-yr)
k_v = first-order dissipation constant (1/yr)
Y_j = dry matter yield of crop j (g/m^2)

The non-steady state solution has an additional term in the numerator of Equation 2-3, $1\text{-}e^{(-kw\ t)}$, where t is the time to harvest or removal by grazing. Given that the k_v is relatively large (i.e., a relatively short half-life on the order of weeks), and the growing period for vegetation of concern can be weeks to months, this additional term reaches unity quickly, so a steady state solution is justified. The total deposition rate onto plants, F_p , is given as:

$$F_p = C_{pa} (V_d I_j + RN R_w W_p I_j) \quad \text{(Eqn. 2-4)}$$

where:

F_p = unit contaminant wet plus dry deposition rate onto plant surfaces (pg/m^2-yr)
C_{pa} = air-borne particulate phase contaminant concentration (pg/m^3)

V_d = deposition velocity (m/yr)
I_j = fraction of particulates intercepted by crop j during deposition
RN = annual rainfall (m/yr)
R_w = fraction of particles retained on vegetation after rainfall
W_p = scavenging coefficient (unitless)

The major uncertainties of this modeling approach are:

- Vapor/particle partitioning: The V/P partitioning modeling approach (i.e., Junge-Pankow model) yields different partitioning ratios than suggested by the results of some monitoring studies (i.e., monitoring suggests a greater percentage in the vapor phase). The model could be inaccurate or the monitoring data could be biased to vapor (i.e., blow-off potential).

- Vapor transfers to vegetation: The basis for the vapor-phase biotransfer factors (B_{vpa}) is the research performed Welsch-Pausch et al. (1995). There is some uncertainty that the Welsch-Pausch experiments may not be representative of field situations (e.g., pots were raised off the ground, and the grass was a dense monoculture) and that more typical field situations (e.g., at ground level with varied vegetation of lesser density) may lead to lower vapor-phase transfer factors. However, because the vapor phase transfer factor is also a function of the length of exposure, grass that is several months old may have higher levels than the grass used by Welsch-Pausch et al. (1995).

- Particle deposition: There is uncertainty surrounding the following factors: R_w (fraction retained on vegetation from wet deposition), the weathering half-life on vegetation, absorption of particulate-associated dioxin by vegetation, and the particle deposition velocity.

Deposition Velocity Approach for Vapor Phase CDD/CDFs. This alternative approach is based on a transfer velocity (or conductance) term, a plant dissipation term, and a plant yield term as shown in Equation 2-5. The approach is exactly analogous to the EPA approach for modeling particle phase deposition. This approach has been described and parameterized for vapor phase 2,3,7,8-TCDD impacts to grassy plants in two articles, Trapp and Matthies (1995) and Smith et al. (1995). The steady state solution for the transfer velocity approach is given as:

$$C_{vpa} = \frac{F_v}{k_v \, Y_j} \qquad \text{(Eqn. 2-5)}$$

where:

C_{vpa} = plant concentration due to vapor-phase transfer (pg/g dry weight)
F_v = deposition of vapor-phase congener (pg/m^2-day)
k_v = first-order dissipation constant (day^{-1})
Y_j = yield of crop j (g/m^2)

Like the solution for particle phase deposition to plants, the non-steady state solution for Equation (2-5) has an additional term in the numerator, $1\text{-}e^{(-kv\ t)}$, where t is the time to harvest or removal by grazing. Both authors who applied this approach assumed a half-life for vapor phase dioxins on plants on the order of days to weeks. Because the "time to harvest" for grasses is also on the order of days to weeks, the additional term reaches unity quickly and again a steady state solution is justified.

The two articles evaluated do diverge at this point. The Trapp and Matthies (1995) approach is actually a comprehensive approach involving particle phase impacts and soil to plant impacts. Their analysis suggests vapor phase impacts to foliar vegetation dominate for 2,3,7,8-TCDD. They also present their solution in a more generalized fashion by having a volume term in the denominator of Equation 2-5 instead of a plant yield term; the volume term is easily converted to a mass (or yield) term with a plant density factor. Their solution for F_v is:

$$F_v = A \; g \; C_{va} \; 86400 \qquad \text{(Eqn. 2-6)}$$

where:

F_v = deposition of vapor-phase congener (pg/m^2-day)
A = leaf area index (m^2 leaf area/m^2 ground area)
g = conductance (m/sec)
C_{va} = vapor phase air concentration (pg/m^3)
86400 = conversion factor (sec to days)

Trapp and Matthies (1995) used a default value of 0.1 cm/sec for the conductance term, g, when modeling the deposition of 2,3,7,8-TCDD onto meadow grass. The appropriate value to use for conductance for a given chemical depends upon the plant species, the

environmental conditions, and the lipophilicity of the vapor phase chemical. The possible range reported by Trapp and Matthies (1995) is 0.01 to 0.5 cm/sec with the appropriate value increasing as lipophilicity increases. Trapp and Matthies (1995) used a value of 5 for the leaf area index, A, in their TCDD modeling exercise. The product of the A term and the g term (i.e., 0.5 cm/sec) is analogous to a deposition velocity.

Smith et al. (1995) estimate the F_v as a multiplication of the vapor phase air concentration, C_{va} (pg/m^3), the transfer velocity, V_t, (cm/sec), and the plant interception fraction (unitless). They state that the transfer velocity is represented as the inverse of the sum of the resistances to transfer to the plant surface as:

$$V_t = \frac{1}{R_a + R_b + R_c} \qquad \text{(Eqn. 2-7)}$$

where:

V_t = transfer velocity (cm/sec)
R_a = atmospheric resistance (sec/cm) a function of vertical turbulent transport
R_b = surface boundary layer resistance (sec/cm) a function of molecular diffusivity
R_c = plant canopy/leaf resistance (sec/cm) a function of vegetative density, stomatal uptake, surface effects, and humidity

Smith et al. (1995) assumed the following reasonably conservative resistance values for deposition of 2,3,7,8-TCDD onto a flat open area with tall grass under neutral atmospheric stability conditions: R_a = 0.4 sec/cm; R_b = 0.38 sec/cm; and R_c = 0.5 sec/cm. The resulting transfer velocity is 0.78 cm/sec.

The deposition velocity approach is not uniform among researchers, and has the two key uncertain quantities: the velocity itself (termed V_t by Smith et al. (1995) and estimated as gA by Trapp and Matthies (1995)) and the plant degradation term - assigned values ranging by a factor of three by the two research efforts. The companion document to this report (i.e., Volume 3) provides a detailed comparison of the empirical EPA model, the Trapp and Matthies (1995) model, and the Smith et al. (1995) model.

2.6.1.3. Transport Mechanisms in Soil

Upon deposition of CDD/CDFs onto soil or plant surfaces, there can be an initial loss due to photodegradation and/or volatilization. The extent of initial loss due to volatilization and/or photodegradation is difficult to predict and is controlled by climatic factors, soil characteristics, and the concentration and physical form of the deposited CDD/CDFs (i.e., particulate-bound, dissolved in solvent, etc.) (Freeman and Schroy, 1989; Paustenbach et al., 1992; Nicholson et al., 1993). For example, observations from the Seveso incident indicated that the levels of 2,3,7,8-TCDD aerially deposited on the soil surface decreased substantially in the first six months (diDomenico et al., 1982) but that rate of disappearance then slowed by over two orders of magnitude (diDomenico et al., 1990). Nash and Beall (1980) reported that 12 percent of the 2,3,7,8-TCDD applied to bluegrass turf as a component (7.5 ppm concentration) of an emulsifiable Silvex concentrate volatilized over a period of 9 months. Schwarz and McLachlan (1993) observed no significant changes in CDD/CDF concentrations in sewage sludge amended soil that was exposed to natural sunlight for six weeks in the late summer/early fall in Germany. Similarly, Cousins et al. (1996) detected no volatilization from sludge-amended soils through which air was pumped for 30 days.

Although few studies have evaluated quantitatively the transport of soil-bound CDD/CDFs, the very low water solubilities, high K_{oc}s, and persistent nature of these chemicals indicate that erosion of soil to water bodies may be the dominant surface transport mechanism for CDD/CDFs sorbed to soil in settings where erosion is possible (Paustenbach et al., 1992; Nicholson et al., 1993). Because of their very low water solubilities and vapor pressures, CDD/CDFs below the soil surface (i.e., below the top few millimeters) are strongly adsorbed and show little upward or downward vertical migration, particularly in soils with a high organic carbon content (Yanders et al., 1989). Freeman et al. (1987) found no statistically meaningful changes in the concentration profile of 1,2,7,8-TCDD in the top 1 cm of Time Beach Soil over a 16-month period, with the exception of the top 3 mm of soil exposed to water and sunlight in which 50 percent reduction in 2,3,7,8-TCDD concentration was observed. In addition, the more chlorinated congeners do not show any significant degree of degradation below the soil surface.

Although for several years it was believed that near-surface (i.e., the top 1cm) CDD/CDFs could volatilize slowly to the surface (Freeman and Schroy, 1985), recent

research has indicated that CDD/CDFs, particularly the tetra and higher chlorinated congeners, show little or no movement upward or downward in the subsurface unless surfactants or a carrier such as waste oil or diesel fuel is present to act as a solvent (Kapila et al., 1989; Puri et al., 1989; Puri et al., 1990; Yanders et al., 1989; Schramm et al., 1995). For example, Palausky et al. (1986) injected 2,3,7,8-TCDD dissolved in various organic solvents into soil columns to determine the extent of vapor phase diffusion; little movement due to volatilization was observed unless the soil was incubated at 40°C. However, laboratory studies have shown that 2,3,7,8-TCDD moves readily through soil with waste oil components and that mobility can also be enhanced by the presence of surfactants such as sodium lauryl sulfate (Yanders et al., 1989; Puri et al., 1989; Schramm et al., 1995). Overcash et al. (1991) developed a model that considers diffusive transport of 2,3,7,8-TCDD in solvents and takes into account the rate of adsorption and desorption of 2,3,7,8-TCDD from the soil particles.

Paustenbach et al. (1992) reviewed many major published studies on dioxin persistence in soil and concluded that 2,3,7,8-TCDD probably has a half-life of 25 to 100 years in subsurface soil and 9 to 15 years at the soil surface (i.e., the top 0.1 cm). Several major studies reviewed by Paustenbach et al. (1992) and additional recent studies are summarized below. Some of these recent studies have concluded that the binding of dioxin-like compounds to soil approaches irreversibility over time due to the encapsulation of the compounds in soil organic and mineral matter (Puri et al., 1989; Puri et al., 1992; Adriaens and Grbic-Galic, 1992).

McLachlan et al. (1996) presented data on CDD/CDF persistence in a sludge-amended soil sampled from a long-term field experiment started in 1968. Over 50 percent of the CDD/CDFs present in the soil in 1972 were still present in 1990. The concentrations of all congeners were observed to decrease gradually and in the same manner over this time, indicating that either physical loss of material from the experimental plot had occurred or all congeners had undergone a uniform reduction in extractability over time. Half-lives for the disappearance of CDD/CDFs from the sludge-amended soil after 1972 were on the order of 20 years. These half-lives were believed by McLachlan et al. (1996) to principally reflect physical removal rather than degradation.

Young (1983) conducted field studies on the persistence and movement of 2,3,7,8-TCDD during 1973-1979 on a military test area that had been aerially sprayed

with 73,000 kg of 2,4,5-T during the period 1962-1970. TCDD levels of 10 to 1,500 ng/kg could be found in the top 15 cm of soil 14 years after the last application of herbicide at the site. Although actual data were not available on the amount of 2,3,7,8-TCDD originally applied as a contaminant of the 2,4,5-T, best estimates indicated that less than one percent of the applied 2,3,7,8-TCDD remained in the soil after 14 years. Photodegradation at the time of and immediately after aerial application was believed by Young (1983) to be responsible for most of the disappearance. However, once incorporated into the soil, the data indicated a half-life of 10 to 12 years.

Orazio et al. (1992) studied the persistence of di- to octa-chlorinated CDDs and CDFs in sandy loam soil held in laboratory columns under water-saturated soil conditions for a period of 15 months. Measurable upward movement was reported only for the dichlorofurans and dichlorodioxins. Downward movement was only noticeable for the dichloro- and trichloro-congeners. The mobility of the CDDs and CDFs was not significantly affected by co-contaminants (i.e., pentachlorophenol and creosote components) present at concentrations as high as 6,000 mg/kg. As much as 35 percent loss of the di- and trichloro-congeners due to degradation was observed; no significant degradation of the tetra- through octa-chlorinated congeners was reported (Orazio et al., 1992).

Hagenmaier et al. (1992) collected soil samples around two industrial plants in Germany in 1981, 1987, and 1989 at the same site and from the same depth, using the same sampling method. There was no indication (within the limits of analytical accuracy (+/- 20 percent)) of appreciable loss of CDDs and CDFs by vertical migration, volatilization, or degradation over the 8-year period. Also, there were no significant changes in the congener distribution pattern (i.e., tetra- through octa-) over this time period.

Yanders et al. (1989) reported that 12 years after oil containing 2,3,7,8-TCDD was sprayed on unpaved roads at Times Beach, Missouri, no dioxin was discovered deeper than 20 cm. However, these roads were paved about 1 year after the spraying episode, thus preventing volatilization to the atmosphere. Yanders et al. (1989) excavated this soil and placed the soil in bins located outdoors, subject to the natural conditions of sunlight and precipitation. They reported no appreciable loss nor vertical movement of 2,3,7,8-TCDD from the soil, even in the uppermost sections, during a 4-year study period. Puri et

al. (1992) reported no migration or loss of 1,2,3,4-TCDD, 1,2,3,7,8-PeCDD, OCDD, and OCDF from samples of this soil which were examined for 2 years in controlled laboratory column experiments.

Hallett and Kornelson (1992) reported finding 2,3,7,8-TCDD at levels as high as 20 pg/g in the upper 2 inches of soil obtained from areas of cleared forest in New Brunswick, Canada, where the pesticides 2,4-D and 2,4,5-T had been applied in one or more applications 24 to 33 years earlier.

Pereira et al. (1985) reported contamination by CDDs of the sand and gravel aquifer underlying unlined surface impoundments at a wood-treatment facility that had utilized creosote and pentachlorophenol. CDDs migrated both vertically and horizontally in the subsurface. Puri et al. (1992), using soil column experiments in the laboratory, demonstrated that pentachlorophenol and naphthalene and methylnaphthalene (components of creosote) readily transported CDD/CDFs through soil. Puri et al. (1989) and Kapila et al. (1989) demonstrated that application of waste oil and anionic surfactant solutions to field and laboratory columns of Times Beach soil can move 2,3,7,8-TCDD through soil. Walters and Guiseppe-Elie (1988) showed that methanol/water solutions (1g/L or higher) substantially increase the mobility of 2,3,7,8-TCDD in soils.

2.6.1.4. Transport Mechanisms in Water

The dominant transport mechanism for removal of CDD/CDFs from the water column is believed to be sedimentation and, ultimately, burial in sediments. Sediment resuspension and remobilization of CDD/CDFs will vary on a site-by-site basis depending on the nature and extent of physical processes (e.g., winds/waves/currents) and biological processes (disturbance by benthic organisms) (Fletcher and McKay, 1992).

Even though CDD/CDFs have very low vapor pressures, they can volatilize from water. However, volatilization is not expected to be a significant loss mechanism for the tetra- and higher chlorinated CDD/CDFs from the water column under most non-spill scenarios. Podoll et al. (1986) calculated volatilization half-lives of 15 days and 32 days for 2,3,7,8-TCDD in rivers and ponds/lakes, respectively. Broman et al. (1992) used measured concentrations of CDD/CDFs in ambient air (gaseous phase) and in Baltic Sea water (truly dissolved concentrations) to calculate the fugacity gradient over the air-water

interface. The fugacity ratios obtained indicated a net transport from air to water (ratios between 0.4 and 0.004).

Aquatic organisms can bioaccumulate significant levels of CDD/CDFs. Although the mass of CDD/CDFs in the biota in a given water body will account for only a small fraction of the total mass of CDD/CDFs in that water body (Mackay et al., 1992a), these bioaccumulated CDD/CDFs have entered the aquatic food chain and can lead to potentially significant human and wildlife exposures and cause sensitive fish species to be at increased risk (U.S. EPA, 1993).

2.6.1.4.1. Sorption to Particulates and Sedimentation

Most CDD/CDFs entering the aquatic environment are associated with particulate matter (i.e., dry and wet deposition of atmospheric particles, eroded soil/stormwater runoff solids, and solids in municipal and industrial discharges) and are likely to remain sorbed to the particulate matter once in the aquatic environment. Recent studies have demonstrated that dissolved CDD/CDFs entering the aquatic environment will, like other lipophilic, low water solubility organic compounds, partition to suspended solids or dissolved organic matter such as humic substances.

Muir et al. (1992) and Servos et al. (1992) recently reported that 48 hours after the addition of 2,3,7,8-TCDF, 1,3,6,8-TCDD, and OCDD in a sediment slurry to natural lake water/sediment limnocorrals, between 70 and 90 percent had partitioned to suspended particulates. The proportion freely dissolved in water ranged from <2 percent for 2,3,7,8-TCDF and OCDD to 10 to 15 percent for 1,3,6,8-TCDD. The remainder was associated with dissolved organic substances.

Broman et al. (1992) analyzed water collected from nine sampling points in the Baltic Sea selected to be representative of background levels. The concentration of particle-associated (>0.45mm) total CDD/CDFs varied between 0.170 and 0.390 pg/L with an average concentration of 0.230 pg/L (or 66 percent of total CDD/CDFs). The total CDD/CDF concentration of the "apparently" dissolved fraction varied between 0.036 and 0.260 pg/L with an average concentration of 0.120 pg/L (or 34 percent of the total). Subsequent calculations estimated that, on average, only 0.070 pg/L of the "apparently" dissolved CDD/CDFs were truly dissolved.

Servos et al. (1992) reported that the 1,3,6,8-TCDD and OCDD added as a sediment slurry to lake limnocorrals rapidly partitioned/settled to surficial sediments where they persisted over the 2 years of the study. The half-lives of 1,3,6,8-TCDD and OCDD in the water column were reported as 2.6 and 4.0 days, respectively. Based on sediment trap and mixed surface layer studies of the Baltic Sea, Broman et al. (1992) report that the mass of CDD/CDFs in the mixed surface layer at any moment represents about 1 percent of the total flux of CDD/CDFs to the sediment annually; this implies little recirculation of these compounds within the water column of the Baltic Sea. Broman et al. (1992) also reported that the concentration of CDD/CDFs in settling solids (i.e., sediment trap collected material) is approximately one order of magnitude greater than the concentration in suspended particulates. They attributed this elevated concentration to the capacity of settling solids to scavenge the dissolved fraction as the solids settle through the water column. Similar findings have been reported elsewhere (e.g., Baker et al., 1991) for PCBs and PAHs in the Great Lakes.

2.6.1.4.2. Bioaccumulation

Fish and invertebrates can strongly bioaccumulate 2,3,7,8-substituted CDD/CDFs, although the benthic and pelagic pathways by which the accumulation occurs are not well understood. Organisms have been shown to accumulate CDD/CDFs when exposed to contaminated sediments and also to bioconcentrate CDD/CDFs dissolved in water. However, because most CDD/CDFs in the water column and sediment are associated with particulate matter and dissolved organic matter, the accumulation observed in the environment may be primarily food chain-based starting with uptake by benthic organisms (e.g., mussels, chironomids) directly from sediment pore waters and/or by ingestion or filtering of contaminated particles. Those organisms consuming benthic organisms (e.g., crayfish, suckers) would then pass the contaminants up the food chain (Muir et al., 1992; Fletcher and McKay, 1992; U.S. EPA, 1993).

A thorough review of the concepts and available information on the bioaccumulation of 2,3,7,8-substituted CDD/CDFs is presented in U.S. EPA (1993) and U.S. EPA (1995). A brief overview of the material presented in these reports is provided in the remainder of this section.

Bioconcentration. For aquatic organisms, bioconcentration refers to the net accumulation (i.e., intake less elimination and metabolic transformation) of a chemical resulting from direct uptake from the water by gill membranes or other external body surfaces. A bioconcentration factor (BCF) is the ratio (in L/kg) of a chemical's concentration in the tissue of an aquatic organism to its concentration in the ambient water (U.S. EPA, 1993; 1995):

$$BCF = \frac{C_a}{C_w} \qquad \text{(Eqn. 2-8)}$$

where:

C_a = concentration of the chemical in the aquatic biota

C_w = concentration of the chemical in the ambient water

BCFs are measured in laboratory experiments. To be of most use in predicting bioaccumulation in natural settings, BCFs should be determined under steady-state conditions (i.e., conditions under which the concentrations in the biota and other ambient water are stable over a period of time). For highly hydrophobic chemicals like CDD/CDFs, steady-state takes a long time to reach and often may not be reached in laboratory experiments particularly with larger organisms which tend to have slower uptake rates and longer half-lives for elimination. Also, for highly hydrophobic compounds, a significant fraction of the chemical concentration in the water can be associated with suspended particles and dissolved organic matter and be less available for uptake by the organism.

In general, BCFs for a given species (particularly BCFs calculated using dissolved chemical concentrations rather than total water concentrations) are expected to be largely independent of site water characteristics (U.S. EPA, 1993). For hydrophobic compounds, the lipid component of an organism is believed to dominate partitioning of the chemical between the organism and water. Therefore, it is often useful to express BCFs on the basis of organism lipid content in order to reduce variability among whole weight BCFs reported for species differing in lipid content.

The expected equilibrium values for steady-state BCFs (lipid content basis) for 2,3,7,8-substituted CDD/CDFs are the corresponding K_{ow} values. However, because most reported BCFs for CDD/CDFs are calculated on the basis of total water concentrations, the

reported BCFs are significantly less than these values. U.S. EPA (1993) presents a compilation of measured steady-state BCFs for 2,3,7,8-TCDD. The log BCFs vary by more than an order of magnitude (4.91 to 6.63 on a lipid content basis; 3.97 to 5.20 on a whole body basis). This variability is likely due to incomplete characterization of exposure concentrations or experimental shortcomings, including partitioning onto organic matter in test systems, oversaturation of the chemical in water, and time-varying concentrations in static systems (U.S. EPA, 1993). Table 2-9 presents log BCF values reported by various researchers for CDD/CDFs.

Bioaccumulation. For aquatic organisms, bioaccumulation refers to the net accumulation of a chemical from exposure via food and sediments as well as water. A bioaccumulation factor (BAF) is the ratio (in L/kg) of a chemical's concentration in the tissue of an aquatic organism to its concentration in the ambient water, in situations where both the organism and its food are exposed and the ratio does not change substantially over time (U.S. EPA, 1993; 1995).

$$BAF = \frac{C_a}{C_w} \qquad \text{(Eqn. 2-9)}$$

where:

C_a = concentration of the chemical in the aquatic biota

C_w = concentration of the chemical in the ambient water

The difference between BAFs and BCFs is primarily in the routes of exposure involved and the levels of accumulation attained because of these exposure routes. BCFs are measured in laboratory experiments designed to measure the chemical uptake by the organism only from water. BAFs are usually determined from measurements of chemical concentration in water and organism tissue samples that are obtained in the field from aquatic systems at presumed steady-state exposure conditions. Thus, BAFs include both direct uptake from the water as well as uptake from intake of food and sediments. The previous discussion under "Bioconcentration" concerning the form of the chemical in the water (i.e., dissolved or total) and the value of lipid normalization also applies to BAFs.

Because reliable measurements of trace levels of CDD/CDFs in ambient water are generally not available, it is not practical to develop measured BAFs for these compounds.

However, detectable concentrations of CDD/CDFs are generally measurable in sediments. The relationship between chemical concentrations in organisms and sediments is defined as the biota-sediment accumulation factor (BSAF). BSAFs can be used to measure and predict bioaccumulation directly from measured concentrations of chemicals in surface sediments and biota. They may also be used to estimate BAFs. Because BSAFs are based on field measurements and incorporate uptake from water and food, and the effects of metabolism and growth, BAFs estimated from BSAFs will incorporate the net affect of all these factors (U.S. EPA, 1993; 1995).

BSAFs are measured by relating lipid-normalized concentrations of a chemical in an organism to the organic carbon-normalized concentration of the chemical in surface sediment samples associated with the average exposure of the organism (U.S. EPA, 1995). The BSAF equation is:

$$\mathbf{BSAF} = \frac{C_l}{C_s} \qquad \text{(Eqn. 2-10)}$$

where:

C_l = lipid-normalized concentration of the chemical in aquatic biota

C_s = organic carbon-normalized concentration of the chemical in surface sediment

The ratios of BSAFs of CDD/CDFs to a BSAF for 2,3,7,8-TCDD yield bioaccumulation equivalency factors (BEFs) which can be used to estimate the combined toxic potential of CDD/CDFs as a toxic equivalence concentration. Table 2-10 presents BSAFs and BEFs derived for CDD/CDFs from Lake Ontario lake trout and sediment. A compilation of additional BSAFs is presented in the companion document to this report (i.e., Volume 3). Chapter 3 of this report summarizes concentrations of CDD/CDFs in aquatic organisms that have been reported in the literature.

2.6.1.4.3. Mechanisms for Entry of CDD/CDFs Into the Aquatic Food Chain

Air to Land to Water to Animal Hypothesis. Based on information currently available, the primary mechanism by which CDD/CDFs enter the aquatic food chain in most freshwater bodies is by atmospheric deposition onto land followed by transport of the deposited material in stormwater runoff/erosion into water bodies. Once in the water

body, entry into the food chain starts with uptake by benthic organisms as described in Section 2.6.1.4.2.

CDD/CDFs can also enter aquatic systems directly from industrial and POTW effluent discharges, from deposition of CDD/CDFs in the atmosphere directly onto water bodies (of importance for the Great Lakes), and in erosion/stormwater runoff from areas where dioxin-containing material is present (e.g., a contaminated industrial or waste disposal site). Thus, for any given water body, the dominant transport mechanism will depend on site-specific conditions. For example, Pearson and Swackhammer (1997) report that atmospheric deposition is the dominant source of CDD/CDFs to Lake Superior, but not to Lake Michigan or Lake Ontario. However, for most freshwater bodies today, erosion/ stormwater runoff is the probable dominant mechanism for CDD/CDF input and the CDD/CDFs present in that runoff can be attributed to atmospheric deposition. Several studies support this hypothesis.

For example, Smith et al. (1995) analyzed CDD/CDF concentrations in sediment cores, air, precipitation, soil, and stormwater runoff in an effort to determine the contributing sources of these compounds to the lower Hudson River. The mass balance estimates developed from these data are, for the period 1990-1993: stormwater runoff entering tributaries (76 percent of total CDD/CDF input); anthropogenic wastes (19 percent); atmospheric deposition (4 percent); and shoreline erosion (less than 1 percent). Smith et al. (1995) also projected the percent contribution of these same sources for the year 1970 to be: anthropogenic wastes (70 percent); stormwater runoff into tributaries (15 percent); atmospheric deposition (15 percent); and shoreline erosion (0.1 percent).

Lebeuf et al. (1996) analyzed sediment cores from different locations in the lower St. Lawrence River Estuary and the Gulf of St. Lawrence. The congener group profiles found in the samples indicate that the input of CDD/CDFs is primarily from the atmosphere. Comparison of the CDD/CDF concentrations in sediments collected from areas where sediment accumulation is due primarily to fluvial transport with sediments from areas where sediment accumulation is due primarily to direct atmospheric deposition onto the water indicates that the contribution of CDD/CDF from direct atmospheric deposition represents less than 35 percent of the sediment burden. Thus, the primary source of CDD/CDFs was determined to be emissions to the atmosphere upwind of the

Estuary that are deposited within the watershed and subsequently transported downstream by fluvial waters.

Paustenbach et al. (1996) and Mathur et al. (1997) reported that stormwater runoff from 15 sites in the San Francisco area contained CDD/CDF I-TEQ_{DF} at levels ranging from 0.01 to 65 pg/L; most samples contained less than 15 pg/L. The sites differed widely in land use; the highest levels measured were obtained from an urban, but nonindustrialized area. A distinct variability was noted in the results obtained at the same sampling location during different rain events. However, the profiles of CDD/CDFs in the urban stormwater samples were similar at all sites, particularly in samples collected at the onset of rain events. Stowe (1996) reported similar findings from analyses of sediments from three stormwater basins collecting runoff from a military base, city street, and parking lots.

Further argument supporting this hypothesis is offered below:

- Much less data have been published on CDD/CDF discharges in wastewater than have been published on emissions to air. Nonetheless, the general scientific consensus is that because of their extremely low water solubilities and the restrictions on suspended particulate discharges in wastewater discharges, CDD/CDF emissions via wastewater are negligible compared to atmospheric emissions and land-disposed waste material. This is the conclusion drawn in the U.S. Inventory (see Volume 1), the European Dioxin Inventory (Quab and Fermann, 1997), and the recent United Nations compilation of national and regional CDD/CDF emissions inventories (UNEP, 1999).
- Studies have measured CDD/CDFs in wet and dry deposition in most locations, including remote areas (see Table 2-4).
- Studies have measured CDD/CDFs in soils in most locations, including remote areas (see Chapter 3). Volume 1 of this Reassessment presents preliminary rough estimates of the potential magnitude of soil erosion via rural runoff sources to be 2,700 grams of I-TEQ_{DF} annually.
- The Paustenbach et al. (1996) and Mather et al. (1997) studies cited above detected CDD/CDFs in all stormwater samples collected in the San Francisco area. However, CDD/CDFs were only rarely detected in discharges collected

from nine POTWs in the San Francisco area during the same approximate time period (California Regional Water Quality Control Board, 1996).

- Fisher et al. (1998) reported that urban runoff samples from eight sites (15 samples) in the Santa Monica Bay watershed contained CDD/CDF I-TEQ_{DF} at levels ranging from 0.7 to 53 pg/L (all but one sample were in the range of 0.7 to 10 pg/L). The samples were collected in 1988/1989 from continuously flowing storm drains during both dry and storm periods. Concentrations measured during storm events (mean = 18 pg/L) were higher than concentrations observed during dry periods (mean = 1 pg/L).

2.6.1.5. Transformation Processes

2.6.1.5.1. Photolysis. Photolysis appears to be one of the most environmentally significant degradation mechanisms for CDD/CDFs in water and soil, and possibly in the atmosphere. CDD/CDFs absorb electromagnetic radiation at wavelengths greater than 290 nm (i.e., the lower bound of the Sun's radiation reaching the Earth's surface) and, therefore, can be expected to be subject to photolysis by sunlight. Numerous studies have demonstrated that CDD/CDFs undergo relatively rapid photolysis in a variety of organic solvents and at much slower rates in water, typically following first order kinetics. Because of the difficulties inherent in controlling experimental variables for nonvolatile and highly lipophilic compounds like CDD/CDFs, few photolysis studies have been performed with natural waters, with CDD/CDFs sorbed to soil or particulate matrices, and with gas phase CDD/CDFs. The photochemistry of CDD/CDFs has been reviewed by Miller and Zepp (1987), Choudry and Webster (1987), Atkinson (1991; 1996), and others.

The major products from photolysis are complex and, in most studies, good mass balances have not been obtained. Although, the photolytic pathway(s) for CDD/CDFs has not been fully identified, a major photolysis pathway appears to be photodechlorination resulting in formation of lower chlorinated CDD/CDFs. Several researchers have reported that carbon-oxygen cleavage and other mechanisms may be similarly or more important pathways for CDD/CDFs containing four or fewer chlorines (Choudry and Webster, 1989; Dulin et al., 1986; Miller et al., 1989; Kieatiwong et al., 1990). Studies performed to date suggest that the photolytic degradation products from irradiation of CDD/CDFs in

organic solvents may be significantly different than those observed when surface-sorbed and gas-phase CDD/CDFs are irradiated. A preferential loss of chlorines from the lateral positions (i.e., chlorines at the 2, 3, 7, and 8 positions) rather than from the peri positions (i.e., chlorines at the 1, 4, 6, and 9 positions) has been reported for solution studies (Crosby et al., 1973; Dobbs and Grant, 1979; Tysklind and Rappe, 1991); the opposite trend is observed for some congener groups when irradiated as dry films, sorbed to soil, and as gas-phase CDD/CDFs (Choudry and Webster, 1989; Kieatiwong et al., 1990; Sivils et al., 1994; Sivils et al., 1995).

Most studies performed until recently have been conducted using artificial light, pure congeners, and reaction media consisting of homogenous solutions in aqueous-organic solvent mixtures, silica gel, or clean solid surfaces. Thus, although photolysis of CDD/CDFs at environmentally significant rates has been observed in laboratory studies, the results of these studies may not be representative of photolysis rates that occur under actual environmental conditions. The following subsections summarize the key findings of recent environmentally significant studies for the water, soil, and air media.

Photolysis in Solution. Numerous studies have demonstrated that CDD/CDFs will undergo photodechlorination following first order kinetics in solution with preferential loss of chlorine from the lateral positions. Photolysis is slow in pure water but increases dramatically when solvents serving as hydrogen donors are present such as hexane, benzene, methanol, acetonitrile, hexadecane, ethyl oleate, dioxane, and isooctane (Buser, 1976; Buser, 1988; Choudry and Webster, 1987; Choudry et al., 1990; Crosby et al., 1971; Crosby, 1978; Crosby, 1981; Dobbs and Grant, 1979; Dougherty et al., 1991; Dulin et al., 1986; Friesen et al., 1990a; Hutzinger, 1973; Koester and Hites, 1992b; Koshioka et al., 1990; Wagenaar et al., 1995; and others).

The photolytic behavior of CDD/CDFs in organic solvents or in pure water, however, is not expected to accurately reflect the photolytic behavior of these compounds in natural waters. Natural waters have differing quantities and types of suspended particulates and dissolved organic material that could either retard or enhance the photolysis of CDD/CDFs. However, only a few studies have been performed that have examined the photolysis of CDD/CDFs using natural waters and sunlight. Several other published studies have used a mixture of water and acetonitrile to enhance the solubility

of CDD/CDFs. The following paragraphs summarize the results of these studies. Table 2-11 presents selected results from these studies.

Dulin et al. (1986) studied the photolysis of 2,3,7,8-TCDD in a water:acetonitrile solution (1:1, v/v) under sunlight and artificial light (i.e., a mercury lamp). The quantum yield for photodegradation of 2,3,7,8-TCDD in water was three times greater under artificial light at 313 nm than under sunlight which suggests that the medium-pressure mercury lamp used was a more efficient light source than the sun (Koester and Hites, 1992b). Podoll et al. (1986) used the Dulin et al. (1986) reaction rate data from the artificial light experiment to calculate seasonal half-life values for 2,3,7,8-TCDD at 40 degrees north latitude in clear near-surface water. The calculated seasonal values for half-lives ranged from 0.9 days in summer to 4.9 days in winter. Using the Dulin et al. (1986) reaction rate data from the sunlight experiment yields calculated seasonal values for half-lives ranging from 2.7 days in summer to 16 days in winter.

Choudry and Webster (1989) studied the photolytic behavior of a series of CDDs in a water:acetonitrile solution (2:3, v/v) using a low-pressure mercury lamp. Choudry et al. (1990) investigated the photolytic behavior of two CDFs (1,2,4,7,8-PeCDF and 1,2,3,4,7,8-HxCDF) using a similar experimental setup but with a 1:1 water:acetonitrile solution. Assuming that the quantum yields observed in these studies are the same as would be observed in natural waters, Choudry and Webster (1989) and Choudry et al. (1990) estimated the mid-summer half-life values at 40 degrees north latitude in clear near-surface water to be as follows: 1,2,3,7-TCDD (1.8 days); 1,3,6,8-TCDD (0.3 days); 1,2,3,4,7-PeCDD (15 days); 1,2,3,4,7,8-HxCDD (6.3 days); 1,2,3,4,6,7,8-HpCDD (47 days); OCDD (18 days); 1,2,4,7,8-PeCDF (0.2 hours); and 1,2,3,4,7,8-HxCDF (6 hours). However, Choudry and Webster (1989) also experimentally determined the sunlight photolysis half-life of 1,3,6,8-TCDD in pond water to be 3.5 days (i.e., more than 10 times greater than the half-life predicted by laboratory experiments). The authors attributed this significant difference in photolysis rates to the light screening/quenching effects of dissolved organic matter.

Friesen et al. (1990a) examined the photolytic behavior of 1,2,3,4,7-PeCDD and 1,2,3,4,6,7,8-HpCDD in water:acetonitrile (2:3, v/v) and in pond water under sunlight at 50 degrees north latitude. The observed half-lives of these two compounds in the water:acetonitrile solution were 12 and 37 days, respectively, which are very similar to

the results observed by Choudry and Webster (1989) for these two congeners using artificial light. However, in contrast to the results observed by Choudry and Webster (1989) for 1,3,6,8-TCDD, Friesen et al. (1990a) found that the half-lives of 1,2,3,4,7-PeCDD and 1,2,3,4,6,7,8-HpCDD were much shorter in pond water (0.94 and 2.5 days, respectively) than in the water:acetonitrile solution. Similarly, Friesen et al. (1993) studied the photodegradation of 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF by sunlight using water:acetonitrile (2:3, v/v) and lake water. The observed half-lives of the 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF in the water:acetonitrile solution were 6.5 and 46 days, respectively, and 1.2 and 0.19 days in lake water, respectively. Friesen et al. (1990a) and Friesen et al (1993) attributed the significant differences between the natural water and water:acetonitrile solution results to indirect or sensitized photolysis due to the presence of naturally occurring components in the lake and pond water.

Dung and O'Keefe (1992), in their investigation of aqueous photolysis of 2,3,7,8-TCDF and 1,2,7,8-TCDF, reported findings similar to those of Friesen et al. (1993). Dung and O'Keefe prepared aqueous solutions by pumping water through "generator columns" containing particles coated with a thin film of the respective TCDF congener. Solutions in high purity HPLC water, distilled water, Hudson River water, and Saratoga Lake water were exposed to sunlight during September at approximately 42.5 degrees north latitude. The photolysis rates of the two TCDF congeners observed in the river and lake water (half-lives of about 4 to 6 hours) were double the rates observed in pure water (half-lives of about 8 to 11 hours). Dung and O'Keefe (1992) attribute the difference in rates to the presence of natural organics in the river and lake water that may be acting as sensitizers.

Kim and O'Keefe (1998) confirmed the results observed in Dung and O'Keefe (1992) by photolyzing 1,2,7,8-TCDD; 2,3,7,8-TCDF; OCDD; and OCDF in natural water from seven different locations. The values reported in Table 2-11 are the average values for the seven natural waters. The half-lives of TCDD and TCDF were at least two times shorter in all the natural waters than in pure water. However, the natural water half-lives of OCDD and OCDF showed greater variability with some half-lives greater than pure water and some less than pure water. Because there was no apparent relationship between the dissolved organic content of the water and the observed half-lives, it was hypothesized that certain waters may contain organic molecules which either act as photosensitizers or as photodesensitizers.

Photolysis on Soil. Photolysis of CDD/CDFs on soil has been reported but the factors affecting the rate and extent of photolysis have not been well characterized. Based on the data generated to date, photolysis is an operative degradation process only in the near-surface soil where UV light penetrates (i.e., the top few millimeters or less of soil) and dechlorination of peri-substituted chlorines appears to occur preferentially. Even within this near surface area, the rate of photolysis is substantially slower than the rate of photolysis that would be observed in a solution of same depth presumably as a result of the light-attenuating effects of soils. Below this near-surface level, photolysis is not a significant process, and CDD/CDFs present in soil at any greater depth are likely to persist (Miller et al., 1989; Puri et al., 1989; Yanders et al., 1989; Kieatiwong et al., 1990). The substantial research performed on the environmental persistence of 2,3,7,8-TCDD in the area around the ICMESA chemical plant in Seveso, Italy, demonstrates that photolysis in soils is a near-surface process. The Seveso area was contaminated when a trichloro-phenol reaction vessel overheated in 1976, blowing out the safety devices and spraying 2,3,7,8-TCDD-contaminated material into the environment. The levels of dioxin in the soil decreased substantially during the first 6 months following the accident before reaching a relatively steady state of 1/5 to 1/11 of the initial levels (DiDomenico et al., 1982).

Kieatiwong et al. (1990) investigated the photolysis of 2,3,7,8-TCDD added to two agricultural soils (350 ug/kg) of approximately 0.3 mm depth and irradiated for 15 days with a mercury lamp. A loss of approximately 15 percent of 2,3,7,8-TCDD was observed on the soil of higher organic carbon and clay content. A loss of approximately 45 percent of 2,3,7,8-TCDD was observed on the soil of lower organic carbon and clay content. There was no significant loss on either soil after the first 5 days.

Miller et al. (1989) studied the CDD degradation products resulting from irradiation of ^{13}C-labeled OCDD on two soil types using sunlamps. Approximately 38 to 42 percent of the OCDD were degraded by day five of the experiment; no significant further loss of OCDD was observed over the following 10 days. Although determined not to be the dominant photolysis pathway, photodechlorination was observed in both soils; approximately 10 to 30 percent of the lower chlorinated congeners were produced from the immediate higher chlorinated congeners. The HpCDD and HxCDD congeners observed as degradation products were present in approximately similar proportions to the number of congeners in each congener group. However, Miller et al. (1989) found that, unlike the

results reported for photolysis of OCDD in solution by Choudry and Webster (1989) and Dobbs and Grant (1979), 2,3,7,8-TCDD and 1,2,3,7,8-PeCDD were observed in greater yields than would be expected on the basis of the number of potential TCDD and PeCDD congeners. One-fifth to one-third of the total yield of PeCDDs was 1,2,3,7,8-PeCDD, and one-half of the total yield of TCDDs was 2,3,7,8-TCDD.

Kieatiwong et al. (1990) performed similar experiments to those of Miller et al. (1989) using natural sunlight rather than sunlamps for irradiation of ^{13}C-labeled OCDD on soils. Photodechlorination was estimated to account for approximately 10 percent of the loss of OCDD. One-third to one-half of the total yield of PeCDDs was 1,2,3,7,8-PeCDD, and one-half of the total yield of TCDDs was 2,3,7,8-TCDD. The findings of Miller et al. (1989) and Kieatiwong et al. (1990) indicate that the 2,3,7,8-substituted TCDD and PeCDD congeners were either preferentially formed or were photochemically less reactive than the other congeners that were formed.

Tysklind et al. (1992) also studied the sunlight photolysis of OCDD on soil and reported results in good agreement with those of Miller et al. (1989) and Kieatiwong et al. (1990). Photodechlorination was observed with production of HpCDDs, HxCDDs, PeCDDs, and TCDDs over the 16-day irradiation period. Photodechlorination at the peri-substituted positions was the preferred photodechlorination mechanism; the proportions of 2,3,7,8-substituted congeners present in the soils after 16 days for each congener group were as follows: HxCDD - 65 percent; PeCDD - 40 percent; and TCDD - 75 percent.

The sunlight photolysis of OCDF on soil was also studied by Tysklind et al. (1992). Photodechlorination was observed. However, unlike the case with OCDD, photodechlorination of the lateral-substituted positions was found to be the dominant photodechlorination mechanism resulting in a relative decreasing proportion of 2,3,7,8-substituted congeners during the irradiation period. 2,3,7,8-TCDF was not observed in any of the irradiated samples.

Schwarz and McLachlan (1993) studied the photolysis of CDD/CDFs in an experiment designed to simulate the application of sewage sludge to an agricultural field. No significant changes in CDD/CDF concentrations were observed during the 43-day exposure period to late summer/early fall natural sunlight. Although the OCDD concentration in the sludge had been increased by a factor of 1,000 through spiking, no increase in HpCDD concentrations were observed. The absence of any changes indicates

that neither photodegradation nor volatilization are important mechanisms in the fate of CDD/CDF in sewage sludge following agricultural applications.

The addition of solvents to soil can increase the rate and extent of photolysis. Botre et al. (1978) reported the destruction of 8 μg/mL of 2,3,7,8-TCDD in 0.02 M hexadecylpyridinium chloride (an aqueous surfactant) applied to soil in 4 hours. Kieatiwong et al. (1990) reported that addition of hexadecane to soil containing 2,3,7,8-TCDD resulted both in an increased rate of photolysis and continued photochemical loss of 2,3,7,8-TCDD beyond the point at which soil containing no hexadecane showed photochemical loss.

Although only minimally related to soil environmental conditions, Buser (1988) studied the photolytic decomposition rates of 2,3,7,8-TCDF, 1,2,3,4-TCDF, and 1,2,7,8-TCDF dried as thin films on quartz vials. When exposed to sunlight, the substances slowly degraded with reported half-lives of 5 days, 4 days, and 1.5 days, respectively. Similarly, Koester and Hites (1992b) studied the photodegradation of a series of tetra- through octa-chlorinated CDDs and CDFs on silica gel. In general, the CDFs degraded much more rapidly than the CDDs, and half-lives increased with increasing level of chlorination (1,2,7,8-TCDF excluded). The half-lives for CDDs ranged from 3.7 days for 1,2,3,4-TCDD to 11.2 days for OCDD. The half-lives for CDFs ranged from 0.1 day for 1,2,3,8,9-PeCDF to 0.4 days for OCDF.

Photolysis on Vegetation. Photolysis of CDD/CDFs sorbed on the surface of vegetation has not been well characterized and the findings to date are somewhat contradictory. McCrady and Maggard (1993) reported that 2,3,7,8-TCDD sorbed on the surface of reed canary grass (*Phalaris arundinacea L.*) undergoes photolytic degradation with a half-life of 44 hours in natural sunlight. In contrast, Welsch-Pausch et al. (1995) found little difference in the CDD/CDF congener patterns between grass (*Lolium multiflorum*) grown on an outdoor plot and grass grown in a greenhouse (i.e., UV-light transmission blocked). In an attempt to clarify this contradiction, Welsch-Pausch and McLachlan (1995) studied the photodegradation of CDD/CDFs on pasture grass (*Arrhenatherion elatioris*) during two growing cycles (summer and autumn) using two greenhouses. One greenhouse was constructed of glass which blocks UV transmission and the other was constructed of plexiglass (4 mm) with an UV-light transmission of greater than 50 percent in the 280-320 mm range. In both the summer and autumn

exposure periods, the concentrations of CDD/CDFs (on a congener group basis) were similar in the grass exposed to UV-light and the grass that was not exposed. Welsch-Pausch and McLachlan (1995) concluded that if photodegradation is occurring, it is a relatively insignificant factor in the accumulation of CDD/CDF in pasture grass.

Photolysis in Air. Photolysis of CDD/CDFs in the atmosphere has not been well-characterized. Based on the data generated to date, however, photolysis appears to be a significant mechanism for degradation (i.e., principally dechlorination of the peri-substituted chlorines) of those CDD/CDFs present in the atmosphere in the gas phase. For airborne CDD/CDFs sorbed to particulates, photolysis appears to proceed very slowly and may be influenced by the organic content of the particle. Because of the low volatility of CDD/CDFs, few studies have been attempted to measure actual rates of photodegradation of gaseous-phase CDD/CDF, and only recently have studies been undertaken to examine the relative importance of photolysis for particulate-bound CDD/CDFs.

Gas-Phase Photolysis - Podoll et al. (1986) estimated the photolysis rate of 2,3,7,8-TCDD vapors in the atmosphere based on the quantum yield for photolysis in hexane. The half-life in summer sunlight at 40 degrees north latitude was estimated to be 1 hour as an upper limit.

Mill et al. (1987) reported that photolysis of vapor phase 2,3,7,8-TCDD at 145°C in a flow system using a pulsed 308 nm laser light gave a photolysis quantum yield ranging from 0.013 to 0.03, equivalent to an atmospheric half-life of a few hours. However, the true gas phase quantum yield at 25°C is uncertain, and, therefore, the atmospheric lifetime in sunlight is uncertain.

Orth et al. (1989) conducted photolysis experiments with vapor-phase 2,3,7,8-TCDD under illumination with a Hg-Xe light source and filters to achieve radiation in the UV region from 250 nm to 340 nm. The temperature in the photolysis cell was approximately 150°C. Carrier gases included air and helium. No significant difference in the rate constants was observed in helium and air, 5.4×10^{-3} sec^{-1} and 5.9×10^{-3} sec^{-1}, respectively, which correspond to half-lives of a few minutes. The average quantum yield in air over the absorption band was found to be 0.033 ± 0.046. As with the results of Mill et al. (1987), the true gas phase quantum yield at 25°C is uncertain, and, therefore, the atmospheric lifetime in sunlight is uncertain.

Sivils et al. (1994; 1995) studied the gas phase photolysis of several CDDs (2,3,7-TrCDD; 2,3,7,8-TCDD; 1,2,3,4-TCDD; 1,2,3,7,8-PeCDD, and 1,2,4,7,8-PeCDD) by irradiating the effluent from a gas chromatograph with broadband radiation in the UV/visible region for periods of time up to 20 minutes. The irradiated sample was then introduced into a second gas chromatograph to measure the extent of dechlorination. The results showed that degradation followed first order kinetics and that there was an inverse relationship between the degree of chlorination and the rate of disappearance. Although the lack of photoproducts prevented an independent confirmation of the preferential loss mechanism, the results indicated that laterally-substituted congeners (i.e., chlorines at the 2, 3, 7, and 8 positions) degrade at a slower rate than the peri-substituted congeners (i.e., chlorines at the 1, 4, 6, and 9 positions). Although the rate constants were not presented in Sivils et al. (1994), the degradation rate for 2,3,7,8-TCDD (30 percent loss in 20 minutes) was reported to be slower than the rates for all other tested CDDs. Also, 1,2,4,7,8-PeCDD (with 2 peri-chlorines) degraded significantly faster than 1,2,3,7,8-PeCDD (with only 1 peri-chlorine).

Particulate Phase Photolysis - The photolysis of 2,3,7,8-TCDD sorbed onto small diameter fly ash particulates suspended in air was measured by Mill et al. (1987). The results indicated that fly ash appears to confer photostability on 2,3,7,8-TCDD. Little (8 percent) to no loss was observed on the two fly ash samples after 40 hours of illumination.

Koester and Hites (1992b) studied the photodegradation of CDD/CDFs naturally adsorbed to five fly ashes collected from electrostatic precipitators (one from a hospital incinerator, two from municipal incinerators, and two from coal-fired power plants) using a rotary reactor and a medium-pressure mercury lamp. Although they found that CDD/CDFs underwent photolysis in solution and when spiked onto silica gel, no significant degradation was observed in 11 photodegradation experiments performed on the ashes for periods ranging from 2 to 6 days. Three additional experiments were performed to determine what factors may have been inhibiting photolysis. From the results of these additional experiments, Koester and Hites (1992b) concluded that: (1) the absence of photodegradation was not due to the absence of a hydrogen-donor organic substance; (2) other molecules or the ash, as determined by a photolysis experiment with an ash extract, inhibit photodegradation either by absorbing light and dissipating energy or by quenching

the excited states of the CDD/CDFs; and (3) the surface of the ash itself may hinder photolysis by shielding the CDD/CDFs from light.

Pennise and Kamens (1996) injected the emissions from the combustion of wood chips treated with PCP, plastic PVC pipe shavings, and solid 2,4,6-trichlorophenol into 25-m^3 outdoor Teflon film chambers. The behavior of the eight congener groups was monitored for approximately one day. Experiments were performed during January, June, and October of 1994 in North Carolina. Experiments with combustion temperatures ranging from 350 to 380°C were categorized as low-temperature experiments, and those ranging from 760 to 800°C were categorized as high temperature experiments. Little or no reactivity was observed for CDD/CDFs sorbed to particles resulting from the high temperature experiments. Greater photochemical reactivity was observed for CDD/CDFs sorbed to particles resulting from the low combustion experiments, where photolysis appeared to compete with a CDD/CDF production mechanism believed to be associated with non-combusted PCP. Photolysis rates appeared to decrease with increasing levels of chlorination. On low temperature combustion particles, estimated TCDD half-lives (excluding the impact of the observed formation from PCP) increased from 0.4 hours under summer conditions to 17 hours under winter conditions. On high-temperature particles, estimated TCDD half-lives ranged from 6.8 to 62 hours. Estimated OCDD half-lives ranged from 5 to 38 hours in low combustion temperature experiments to 36 to 257 hours in high temperature combustion experiments.

2.6.1.5.2. Photooxidation. Until recently, the reaction rates of hydroxyl (OH) radicals, ozone (O_3), and nitrate (NO_3) radicals with CDDs and CDFs had not been measured because, in large part, the low vapor pressures of these compounds make direct measurements very difficult with currently available techniques. In the absence of experimental data, Podoll et al. (1986) and Atkinson (1987) estimated the half-life of 2,3,7,8-TCDD vapor via OH oxidation in the atmosphere to be 8.3 days and 3 days, respectively. In a subsequent study, Atkinson (1991) used published reaction rate data for other organic compounds to estimate the OH radical reaction rate constants for vapor-phase dibenzofuran and dibenzo-p-dioxin, and from these estimates, Atkinson (1991) estimated the OH radical reaction rate constants for the CDDs and CDFs. Based on these empirical estimates, Atkinson (1991) concluded that the OH radical reaction is

likely to be the dominant gas-phase transformation process for vapor phase CDDs and CDFs. The tropospheric lifetimes calculated by Atkinson (1991) from the rate constant estimates increased with increasing levels of chlorination from 2.0 days for 2,3,7,8-TCDD and 4.4 days for 2,3,7,8-TCDF to 9.6 days for OCDD and 39 days for OCDF.

Kwok et al. (1994) expanded the work of Atkinson (1991) by experimentally determining the room temperature gas-phase reaction rate constants of dibenzofuran and dibenzo-p-dioxin with hydroxyl radical to be 3.9E-12 cm^3 $molecule^{-1}$ s^{-1} and 1.48E-11 cm^3 $molecule^{-1}$ s^{-1}, respectively. These measured rate constants for dibenzo-p-dioxin and dibenzofuran are lower than those estimated by Atkinson (1991) by factors of 2.5 and 8. Assuming a 12-hour average daytime OH radical concentration of 8 x 10^5 molecule/cm^3, Kwok et al. (1994) estimated the atmospheric lifetimes for gas phase reactions of dibenzofuran and dibenzo-p-dioxin with OH radicals to be 3.7 days and 1.0 day, respectively. Also, based on experimental data, Kwok et al. (1994) calculated lifetimes for the gas phase reaction of dibenzofurans with NO_3 and O_3 to be greater than 7 years and greater than 205 days, respectively; the calculated lifetimes for the gas phase reaction of dibenzo-p-dioxin with NO_3 and O_3 were 4.9 days and greater than 330 days, respectively. The latter results indicate that reaction with the OH radical is the dominant photooxidation mechanism.

Kwok et al. (1995) extended the work of Kwok et al. (1994) by measuring the OH radical reaction rate constants for 1-chlorodibenzo-p-dioxin, diphenyl ether, and 1,2-dimethoxybenzene. These new reaction rate data when taken together with the measurements of Kwok et al. (1994) and the estimation method described in Atkinson (1991) were used to generate more reliable estimates of the reaction rate constants for the 2,3,7,8-substituted CDDs and CDFs (Atkinson, 1996). Table 2-12 presents these recalculated rate constants and tropospheric lifetimes and half-lives. As can be seen from Table 2-12, the persistence of CDD/CDFs increases with increasing degree of chlorination.

Recently, Brubaker and Hites (1997) measured the OH radical reaction rate constants for dibenzo-p-dioxin, dibenzofuran, 2,7-dichlorodibenzo-p-dioxin (2,7-D), 2,8-dichlorodibenzofuran (2,8-F), and 1,2,3,4-dibenzo-p-dioxin (1,2,3,4-D) over temperatures ranging from 72 to 159°C. From these results, OH reaction rate constants were estimated for each compound at 25°C. When these estimated values were compared to the previously measured rate constants reported by Kwok et al. (1994; 1995) and the

values predicted by Atkinson (1995; 1996), Brubaker and Hites (1997) concluded that Atkinson's structure activity method is reliable.

2.6.1.5.3. Hydrolysis. There is no available evidence indicating that hydrolysis would be an operative environmental process for degradation of CDDs or CDFs. The attachment of chlorines directly to the aromatic ring in CDDs and CDFs confers hydrolytic stability. Specifically, S_N1 and S_N2 reactions do not take place readily at sp2 hybridized carbons (Leifer et al., 1983; Miller and Zepp, 1987).

2.6.1.5.4. Biotransformation and Biodegradation. Most investigations examining the biodegradability of CDDs and CDFs have, until recently, focused on the microbial degradation of 2,3,7,8-TCDD. Arthur and Frea (1989) provided a comprehensive review of studies conducted during the 1970s and 1980s and concluded that 2,3,7,8-TCDD is recalcitrant to microbial degradation. Several major studies conducted during that time period as well as more recent studies are discussed below.

Matsumura and Benezet (1973) tested approximately 100 strains of micro-organisms that were shown previously to degrade persistent pesticides; only five strains showed any ability to metabolize 2,3,7,8-TCDD, based on autoradiographs of thin-layer chromatograms. Hutter and Philippi (1982) concluded that although it is possible that the less chlorinated dioxins are more susceptible to biodegradation, microbial action on 2,3,7,8-TCDD is very slow under optimum conditions; the long-term incubations of radiolabeled 2,3,7,8-TCDD yielded no radioactivity in carbon dioxide traps after 1 year, and analyses of the cultures showed that, at most, 1 to 2 percent of the initial 2,3,7,8-TCDD were recovered as a potential metabolite (assumed to be a hydroxylated derivative of 2,3,7,8-TCDD). Camoni et al. (1982) added organic compost to contaminated soil from the Seveso area to enrich the soil and enhance the 2,3,7,8-TCDD biodegradation rate; however, the soil amendment had no clear effect on degradation. Quensen and Matsumura (1983) reported that low concentrations (5 ppb) of radiolabeled 2,3,7,8-TCDD were metabolized by pure cultures of *Nocardiopsis* spp. and *Bacillus megaterium* that had been isolated from farm soil. The extent of metabolism after 1-week incubation was strongly dependent on the carrier solvent used to dissolve and introduce the 2,3,7,8-TCDD to the culture medium. The solvent ethyl acetate gave the best results; 52 percent

of ^{14}C were recovered as 2,3,7,8-TCDD out of a total of 77 percent ^{14}C recovered. However, incubation of 2,3,7,8-TCDD in farm soil, garden soil, and forest soil resulted in little, if any, metabolism of 2,3,7,8-TCDD.

Bumpus et al. (1985) tested the white rot fungus, *Phanerochaete chrysosporium*, which secretes a unique H_20_2-dependent extracellular lignin-degrading enzyme system capable of generating carbon-centered free radicals (Tien and Kirk, 1983; Tien and Kirk, 1984). Lignin is resistant to attack by all microorganisms except some species of fungi and a relatively small number of bacteria species. Radiolabeled 2,3,7,8-TCDD was oxidized to labeled $C0_2$ by nitrogen-deficient, ligninolytic cultures of *P. chrysosporium;* because the label was restricted to the ring, it was concluded that the strain was able to degrade halogenated aromatic rings. In 10 mL cultures containing 1,250 pmol of substrate, 27.9 pmol of 2,3,7,8-TCDD were converted to labeled-CO_2 during the 30-day incubation period; thus, only about 2 percent of the starting material were converted.

Hofmann et al. (1992) demonstrated that the fungi, *Fusarium redolens*, could degrade 3-chlorodibenzofuran and, to a lesser degree, mono- and di-CDDs. Hoffman et al. (1992) also identified 14 other strains of fungi that demonstrated the capability to degrade dibenzofuran (nonchlorinated). The strains are members of the following genera: *Mucor, Chaetomium, Phoma, Fusarium, Paecilomyces, Papulaspora, Inonotus, Lentinus, Phanerochaete, Polyporus, Pycnoporus, Schizophyllum*, and *Trametes*.

Takada et al. (1994; 1996) reported significant degradation of 2,3,7,8-substituted CDDs and CDFs by low-nitrogen medium cultures of the white rot fungus, *Phanerochaete sordida YK-624 strain*. Tetra- through octa- CDDs and CDFs were incubated for 14 days in glucose-amended cultures at 30°C. For both CDDs and CDFs, the 1,2,3,6,7,8-congeners showed the highest degradation values, 75 percent and 70 percent, respectively. The lowest degradation values were for 2,3,7,8-TCDD (40 percent), 1,2,3,7,8-TCDF (45 percent), and 1,2,3,7,8-PeCDF. Similar results were obtained under the same conditions for *P. chrysoporium IFO 31249 strain*.

Several recent reports indicate that CDDs and CDFs, like PCBs, may undergo microbial dechlorination in anaerobic sediments. Adriaens and Grbic-Galic (1992; 1993) and Adriaens et al. (1995) have reported the results of a series of microcosm studies utilizing Hudson River sediment (contaminated with Aroclor 1242) and aquifer material (contaminated with CDDs) from Pensacola, Florida. Both types of substrates were spiked

with several CDDs (1,2,3,4,6,7,8-HpCDD; 1,2,3,4,7,8-HxCDD; and 1,2,4,6,8,9-/1,2,4,6,7,9-HxCDD) and CDFs (1,2,3,4,6,7,8-HpCDF and 1,2,4,6,8-PeCDF) and monitored over a period of 16 months at an incubation temperature of 30°C. The Hudson River sediment was spiked with 144 μg/kg of each congener and the Pensacola aquifer material was spiked with 63 μg/kg of each congener. Recoveries of the CDD/CDF congeners from the control samples decreased with increasing incubation time indicating that these congeners are strongly sorbed to the substrates. For example, after 50 days of incubation, the fraction of CDD/CDF that could be recovered by manual extraction had already decreased to 20-40 percent.

All of the congeners, with the exception of HpCDF, showed a slow decrease in concentration over time attributed to biologically mediated reductive dechlorination with net disappearance rates ranging from 0.0031 wk^{-1} to 0.0175 wk^{-1} (i.e., half-lives of approximately 1 to 4 years). However, Adriaens et al. (1995) conclude that the actual half-lives may be orders of magnitude higher. If it is assumed that transformation/degradation occurs only for CDD/CDF in the aqueous phase, then the CDD/CDF that sorb to the sediments may never be biologically available because of the apparent very slow rates of desorption. The experiment with 1,2,3,4,6,7,8-HpCDD yielded formation of two HxCDD (1,2,3,4,7,8- and 1,2,3,6,7,8-). Thus, removal of the peri-substituted (1,4,6,9) chlorines was favored with enrichment of 2,3,7,8-substituted congeners. No lesser chlorinated congeners were identified from incubations with the other tested congeners. 1,2,4,6,8-PeCDF was also examined in dichlorophenol-enriched cultures. After 6 months incubation, several TCDFs were identified which also indicated that peri-dechlorination was the preferred route of reduction.

Barkovskii et al. (1994) expanded the testing of Adriaens and Grbic-Galic (1992; 1993) by spiking the sediments with higher doses to determine if faster rates could be achieved. Passaic River sediments (contaminated with CDD/CDFs) were spiked with 4,500 μg/kg of OCDD and incubated under anaerobic conditions for 6 months. Although no significant degradation of OCDD was observed, significant reductions in the concentrations of the hepta-, hexa-, penta-, and tetra-CDDs were observed.

Barkovskii and Adriaens (1995; 1996) reported that 2,3,7,8-TCDD (extracted from Passaic River sediments) was susceptible to reductive dechlorination when incubated at 30°C under methanogenic conditions in a mixture of aliphatic and organic acids inoculated

with microorganisms obtained from Passaic River sediments. The initial concentration of 2,3,7,8-TCDD (20 ± 4 μg/L) decreased by 30 percent to 14 ± 2 μg/L over a period of 7 months with the consecutive appearance and disappearance of tri-, di-, and mono-CDDs. Experiments were also conducted by spiking the sediment with HxCDDs, HpCDDs, and OCDD. Up to 10 percent of the spiked OCDD was converted to hepta-, hexa-, penta-, tetra-, tri-, di-, and monochlorinated isomers, but the reaction stoichiometry was not determined. Two distinct pathways of dechlorination were observed: the *peri*-dechlorination pathway of 2,3,7,8-substituted hepta- to penta-CDDs, resulting in the production of 2,3,7,8-TCDD, and the *peri*-lateral dechlorination pathway of non-2,3,7,8-substituted congeners. Direct evidence of further lateral dechlorination of 2,3,7,8-TCDD was obtained from the historically contaminated incubations. Pasteurized cells exhibited no *peri*-dechlorination pathway, and triCDDs were the least-chlorinated congeners produced in these treatments. These results demonstrate that: (I) both freshly spiked and aged CDDs are available to microbial reductive dechlorination; (ii) the *peri* and triCDD dechlorinations are attributed to activities of nonmethanogenic, non-spore-forming microbial subpopulations; and (iii) the 2,3,7,8-residue patterns in historically contaminated sediments are likely affected by microbial activity.

2.6.2. Environmental Fate of Dioxin-Like PCBs

2.6.2.1. Summary

Little specific information exists on the environmental transport and fate of the dioxin-like PCBs. However, the available information on the physical/chemical properties of dioxin-like PCBs coupled with the body of information available on the widespread occurrence and persistence of PCBs in the environment indicates that these dioxin-like PCBs are likely to be associated primarily with soils and sediments, and to be thermally and chemically stable. Soil erosion and sediment transport in waterbodies and volatilization from the surfaces of soils/water bodies with subsequent atmospheric transport and deposition are believed to be the dominant current transport mechanisms responsible for the widespread environmental occurrence of PCBs. Photodegradation and biologically-mediated reductive dechlorination to less chlorinated congeners followed by slow anaerobic and/or aerobic biodegradation in soils/sediments are believed to be the

principal paths for destruction of PCBs. Of note, however, is that the available photolysis studies to date indicate that the more toxic coplanar PCBs are more resistant to photolysis and are formed as products during the photolysis of more chlorinated less toxic congeners.

2.6.2.2. Transport Mechanisms

Based on their low vapor pressures, low water solubilities, and high K_{oc} values, dioxin-like PCBs are expected primarily to be associated with soils, sediments, and particulates. PCBs move from land to aquatic environments primarily associated with runoff sediments (Gan and Berthouex, 1994). However, due to the stability and persistence of dioxin-like PCBs via other transformation and transport pathways, volatilization is likely to be a significant transport mechanism from a global perspective. It should be noted that although dioxin-like PCBs have low vapor pressures and water solubilities, the Henry's Law constants for the similarly substituted CDDs and CDFs are expected to be one to two orders of magnitude lower. Therefore, it can be expected that volatilization of PCBs from soil and water into air is likely to be a more significant transport mechanism for PCBs than for CDDs and CDFs. For example, Cousins et al. (1996) recently demonstrated that PCBs with fewer than eight chlorines will volatilize but 2,3,7,8-substituted CDD/CDFs do not volatilize from sewage sludge amended soil. The rate of volatilization will be affected by soil characteristics (e.g., temperature, moisture content, and organic carbon content) and the concentration and physical form of the PCBs present (Ayris and Harrad, 1997).

Recent studies have shown that PCBs are cycling between the atmosphere and the terrestrial and aquatic environments. For example, Murray and Andren (1992) studied the precipitation scavenging of PCBs in the Great Lakes region. They reported that atmospheric PCBs are largely in the gas phase (typically >90 percent) rather than bound to particulate material. The results of their study support the hypothesis that precipitation provides episodic inputs of PCBs to the Great Lakes. However, several published studies indicate that, on an annual basis (and particularly during the summer and autumn), the Great Lakes are net sources of PCBs to the atmosphere through the process of volatilization. Shallow, warm, and impacted aquatic systems such as Green Bay, Lake Michigan and Chesapeake Bay exhibit the highest net volatilization fluxes due partially to

intimate contact with contaminated sediments (Baker and Eisenreich, 1990; Eisenreich, 1997). Gregor et al. (1992) reported similar findings in a study of PCB deposition in the Arctic during the winter of 1990/1991. The results of the study indicated that snowfall and ice crystal deposition were scavenging the full range of PCB congeners from the atmosphere. The daily deposition rate during winter was about 2 ng/m^2/day. Also, a comparison of the PCB content of snow/ice samples from collectors and end of season samples from the snowpack suggested that volatilization of the PCBs, particularly of the lower chlorinated congeners, was occurring.

Like CDD/CDFs, the dioxin-like PCBs have a high potential for bioaccumulation in aquatic organisms thereby leading to elevated exposures to humans and wildlife from ingestion of contaminated fish. Table 2-13 presents BAFs, BCFs, and BSAFs reported in the literature for dioxin-like PCBs. A compilation of additional reported BSAFs is provided in the companion document to this report (i.e., Volume 3). Chapter 3 of this report summarizes concentrations of dioxin-like PCBs in fish that have been reported in the literature.

2.6.2.3. Transformation Processes

2.6.2.3.1. Photolysis. Based on the data available in 1983, Leifer et al. (1983) concluded that all PCBs, especially the more highly chlorinated congeners and those that contain two or more chlorines in the ortho position, photodechlorinate. In general, as the chlorine content increases, the photolysis rate increases. The products of photolysis are predominantly lower chlorinated PCBs.

More recently, Lepine et al. (1992) exposed dilute solutions (4 ppm) of Aroclor 1254 in cyclohexane to sunlight for 55 days in December and January. Isomer-specific analysis indicated that the amounts of many higher chlorinated congeners decreased while those of some lower chlorinated congeners increased. These results are consistent with the studies reviewed in Leifer et al. (1983) that indicated photodegradation of PCBs proceeds through successive dechlorination of the biphenyl molecule. The results for the dioxin-like PCBs indicated a 43.5 percent decrease in the amount of 2,3,4,4',5-PeCB; a 73.5 percent decrease in the amount of 2,3,3',4,4',5-HxCB; and a 24.4 percent decrease in the amount of 2,3,3',4,4',5'-HxCB. However, the more toxic 3,3',4,4'-TeCB (PCB77)

and 3,3',4,4',5-PeCB (PCB126), which were not detected in unirradiated Aroclor 1254, represented 2.5 percent and 0.43 percent, respectively, of the irradiated mixture. The authors postulated that formation of these two congeners probably occurred, at least in part, from dechlorination at the ortho position of their mono-ortho-substituted precursors, considering the greater reactivity of PCB ortho chlorines toward photodechlorination. Dechlorination was reported to proceed by the loss of chlorine in the order of ortho > para > meta.

Brown et al. (1995) examined the changes in congener levels that occurred after exposing hexane solutions of various Aroclors and specific congeners in quartz tubes to direct summer sunlight (43°N). The reported disappearance rates and estimated half-lives for several of the dioxin-like PCBs are as follows:

PCB Congener	Substitution Pattern	Disappearance Rate (day^{-1})	Half-life (days)
105	234-34	0.11	6.3
156	2345-34	0.3	2.3
167	245-345	0.08	8.7
170	2345-234	0.006	115
180	2345-245	0.004	173
189	2345-345	0.08	8.7

Barr et al. (1997) irradiated several PCB congeners in solution on silica gel for up to 30 minutes. The results indicated that dechlorination in the ortho position is favored but also that steric congestion and structural symmetry are major factors in determining the relative reactivity of chlorines in the meta and para positions. The following conclusions were made:

- In all cases, the ring with the greatest degree of chlorination is the primary ring where the dechlorination occurs.
- Ortho-chlorine substituents and para-chlorine substituents that have two adjacent chlorines were preferentially lost in coplanar (non-ortho-substituted) PCBs.
- Chlorine substituents having neighboring chlorines are replaced more easily than isolated chlorines.
- Para-chlorine substituents were lost preferentially from coplanar hexa-, penta- or tetrachlorobiphenyls, while meta-chlorine was lost preferentially from trichlorobiphenyls.

- More symmetrical isomers tend to be formed more easily, and are more stable.

2.6.2.3.2. Oxidation. Reaction of PCBs with common environmental oxidants such as hydroperoxy radicals (HO_2) and ozone (O_3) has not been reported and is probably not very important because only very strong oxidant species can react with PCBs (Sedlak and Andren, 1991). However, reaction of gas-phase PCBs in the atmosphere and dissolved PCBs in certain surface waters with hydroxyl radicals (OH) (one of the strongest environmental oxidants known) may be an important degradation mechanism.

Oxidation in Air. Atkinson (1987) and Leifer, et al. (1983), using assumed steady-state atmospheric OH concentrations and measured oxidation rate constants for biphenyl and monochlorobiphenyl, estimated atmospheric decay rates and half-lives for gaseous-phase PCBs. Atmospheric transformation was estimated to proceed most rapidly for those PCB congeners containing either a small number of chlorines or those containing all or most of the chlorines on one ring. The predicted half-lives for the congener groups containing the 13 dioxin-like PCBs were as follows:

Congener Group	Half-Life in Air (days)
TeCBs	11 to 20
PeCBs	12 to 31
HxCBs	32 to 62
HpCBs	94+

Kwok et al. (1995) extended the work of Atkinson (1987) by measuring the OH radical reaction rate constants for 2,2'-, 3,3'-, and 3,5-dichlorobiphenyl. These reaction rate constants when taken together with the measurements of Atkinson (1987) for biphenyl and monochlorobiphenyl and the estimation method described in Atkinson (1991; 1995; 1996) have been used to generate more reliable estimates of the gas-phase OH radical reaction rate constants for the dioxin-like PCBs. Table 2-14 presents these estimated rate constants and the corresponding tropospheric lifetimes and half-lives. As can be seen from Table 2-14, the persistence of the PCB congeners increases with increasing degree of chlorination.

Oxidation in Water. Sedlak and Andren (1991) demonstrated in laboratory studies that OH radicals, generated with Fenton's reagent, rapidly oxidized PCBs (i.e., 2-mono-PCB and the DiCBs through PeCBs present in Aroclor 1242) in aqueous solutions. The

results indicated that the reaction occurs via addition of a hydroxyl group to one nonhalogenated site; reaction rates are inversely related to the degree of chlorination of the biphenyl. The results also indicated that meta and para sites are more reactive than ortho sites due to stearic hindrance effects. Based upon their kinetic measurements and reported steady-state aqueous system OH concentrations or estimates of OH radical production rates, Sedlak and Andren (1991) estimated environmental half-lives for dissolved PCBs (mono-through octa-PCB) in several water systems as listed below.

Water System	Half-Life in Water (days)
Fresh surface water	4 to 11
Marine surface water	1,000 to 10,000
Cloud water	0.1 to 10

Estimates for dissolved PCBs in marine surface water are in excess of 1,000 days due to the very low concentration of OH radicals in these waters (10^{-18}M or about two orders of magnitude lower than in freshwater systems). The results of studies to date indicate that OH oxidation of PCBs dissolved in cloud water may be an important, although not very fast, degradation mechanism for PCBs from a global perspective.

2.6.2.3.3. Hydrolysis. PCBs are unlikely to be affected by hydrolysis under environmental conditions because the attachment of chlorines directly to the aromatic ring in PCBs confers hydrolytic stability. Specifically, S_N1 and S_N2 reactions do not take place readily at sp2 hybridized carbons (U.S. EPA, 1988; Leifer et al., 1983).

2.6.2.3.4. Biotransformation and Biodegradation. Leifer et al. (1983), Brown and Wagner (1990), and Abramowicz (1990) summarized the available information on the degradation of PCBs by microorganisms. Laboratory studies (e.g., Bedard et al., 1986; Pardue et al., 1988; Larsson and Lemkemeier, 1989; Hickey, 1995; Schreiner et al., 1995; and Fukuda et al., 1997) have revealed that more than two dozen strains of aerobic bacteria and fungi are widely distributed in the environment that are capable of degrading most PCB congeners with five or fewer chlorines. Many of these organisms are members of the genus *Pseudomonas* or the genus *Alcaligenes*. Only a few strains have been demonstrated to have the ability to degrade higher chlorinated congeners. The major

metabolic pathway involves addition of O_2 at the 2,3-position by a dioxygenase enzyme with subsequent dehydrogenation to the catechol followed by ring cleavage. Several bacterial strains have been shown to possess a dioxygenase enzyme that attacks the 3,4-position.

In general, the rate of aerobic biodegradation decreases with increasing chlorination. Growth on biphenyl as the sole carbon source is required for optimal PCB degradative activity. Degradation in soil systems where numerous carbon sources are present is more than 50-fold slower compared to biphenyl assays. The half-lives for biodegradation of tetra-PCBs in fresh surface water and soil are 7 to 60+ days and 12 to 30 days, respectively. For penta-PCBs and higher chlorinated PCBs, the half-lives in fresh surface water and soil are likely to exceed 1 year. PCBs with all or most chlorines on one ring and PCBs with fewer than two chlorines in the ortho position tend to degrade more rapidly. For example, Gan and Berthouex (1994) monitored over a 5-year period the disappearance of PCB congeners applied to soil with sewage sludge. Three of the tetra- and penta-chlorinated dioxin-like PCBs (IUPAC Nos. 77, 105, and 118) followed a first-order disappearance model with half-lives ranging from 43 to 69 months. A hexa-substituted congener (IUPAC No. 167) and a hepta-substituted congener (IUPAC No. 180) showed no significant loss over the 5-year period.

Until recent years, little investigation focused on anaerobic microbial dechlorination or degradation of PCBs even though most PCBs eventually accumulate in anaerobic sediments (Abramowicz, 1990; Risatti, 1992). Environmental dechlorination of PCBs via losses of meta and para chlorines has been reported in field studies for freshwater, estuarine, and marine anaerobic sediments including those from the Acushnet Estuary, the Hudson River, the Sheboygan River, New Bedford Harbor, Escambia Bay, Waukegan Harbor, and the Housatonic River (Brown et al., 1987; Rhee et al., 1989; Van Dort and Bedard, 1991; Abramowicz, 1990; Bedard et al., 1995). The altered PCB congener distribution patterns found in these sediments (i.e., different patterns with increasing depth or distance from known sources of PCBs) have been interpreted as evidence that bacteria may dechlorinate PCBs in anaerobic sediment.

Results of laboratory studies have been reported recently that confirm anaerobic degradation of PCBs. Chen et al. (1988) found that "PCB-degrading" bacteria from the Hudson River could significantly degrade the mono-, di-, and tri-PCB components of a 20

ppm Aroclor 1221 solution within 105 days. These congeners make up 95 percent of Aroclor 1221. No degradation of higher chlorinated congeners (present at 30 ppb or less) was observed, and a separate 40-day experiment with tetra-PCB also showed no degradation.

Rhee et al. (1989) reported degradation of mono- to penta-substituted PCBs in contaminated Hudson River sediments held under anaerobic conditions in the laboratory (N_2 atmosphere) for 6 months at 25°C. Amendment of the test samples with biphenyl resulted in greater loss of PCB. No significant decreases in the concentrations of the more highly chlorinated (i.e., more than five chlorines) were observed. No evidence of degradation was observed in samples incubated in CO_2/H_2 atmospheres. Abramowicz (1990) hypothesized that this result could be an indication that, in the absence of CO_2, a selection is imposed favoring organisms capable of degrading PCBs to obtain CO_2 and/or low molecular weight metabolites as electron receptors.

VanDort and Bedard (1991) reported the first experimental demonstration of biologically-mediated ortho dechlorination of a PCB and stoichiometric conversion of that PCB congener (2,3,5,6-TeCB) to less-chlorinated forms. In that study, 2,3,5,6-TeCB was incubated under anaerobic conditions with unacclimated methanogenic pond sediment for 37 weeks with reported dechlorination to 2,5-DCB (21%); 2,6-DCB (63%); and 2,3,6-TrCB (16%).

Risatti (1992) examined the degradation of PCBs at varying concentrations (10,000 ppm, 1,500 ppm, and 500 ppm) in the laboratory with "PCB-degrading" bacteria from Waukegan Harbor. After 9 months of incubation at 22°C, the 500 ppm and 1,500 ppm samples showed no change in PCB congener distributions or concentrations, thus indicating a lack of degradation. Significant degradation was observed in the 10,000 ppm sediment with at least 20 congeners ranging from TrCBs to PeCBs showing decreases.

Quensen et al. (1988) also demonstrated that microorganisms from PCB-contaminated sediments (Hudson River) dechlorinated most PCBs in Aroclor 1242 under anaerobic laboratory conditions. Aroclor 1242 contains predominantly tri- and tetra-PCBs. Three concentrations of the Aroclor corresponding to 14, 140, and 700 ppm on a sediment dry-weight basis were used. Dechlorination was most extensive at the 700 ppm test concentration; 53 percent of the total chlorine were removed in 16 weeks, and the proportion of TeCBs through HxCBs decreased from 42 to 4 percent. Much less

degradation was observed in the 140 ppm sediment, and no observable degradation was found in the 14 ppm sediment. These results and those of Risatti (1992) suggest that the organism(s) responsible for this dechlorination may require relatively high levels of PCB as a terminal electron acceptor to maintain a growing population.

Quensen et al. (1990) reported that dechlorination of Aroclor 1242, 1254, and 1260 by microorganisms from PCB-contaminated sediments in the Hudson River and Silver Lake occurred primarily at the meta and para positions; ortho-substituted mono- and di-PCBs increased in concentration.

Nies and Vogel (1990) reported similar results with Hudson River sediments incubated anaerobically with acetone, methanol, or glucose. Approximately 300 μg/g of Aroclor 1242 was added to the sediments to increase the concentrations of higher chlorinated congeners in the sediments prior to incubation for 22 weeks under an N_2 atmosphere. Significant dechlorination over time was observed with dechlorination occurring primarily at the meta- and para-positions on the highly chlorinated congeners resulting in the accumulation of less-chlorinated, primarily ortho-substituted congeners. No significant dechlorination was observed in the control samples (i.e., samples containing no added organic chemical substrate and samples which had been autoclaved).

Bedard et al. (1995) demonstrated that it is possible to stimulate substantial microbial dechlorination of the highly chlorinated PCB mixture Aroclor 1260 *in situ* with a single addition of 2,6-dibromobiphenyl. Bedard et al. (1995) added 365 g of 2,6-dibromobiphenyl to 6-foot diameter submerged caissons containing 400 kg sediment (dry weight) and monitored the change in PCB congener concentrations for a period of 1 year. At the end of the observation period, the hexa- through mono-chlorinated PCBs had decreased by 74 percent in the top of the sediment and 69 percent in the bottom. The average number of chlorines per molecule dropped by 21 percent from 5.83 to 4.61 with the largest reduction observed in meta-chlorines (54 percent reduction) followed by para-chlorines (6 percent). The dechlorination stimulated by 2,6-dibromobiphenyl selectively removed meta-chlorines positioned next to other chlorines.

The findings of these latter studies are significant because removal of meta and para chlorines from the dioxin-like PCBs should reduce their toxicity and bioaccumulative potential and also form less chlorinated congeners that are more amenable to aerobic biodegradation. In support of the findings of these studies, Mousa et al. (1997)

demonstrated that the PCBs present in extracts from PCB-contaminated sediments (i.e., Aroclor 1242 and 1254) that had been incubated for nine months under anaerobic conditions had either reduced biological activities or did not manifest any significant change, depending upon the toxicological endpoint used.

2.7. ENVIRONMENTAL FATE - BROMINATED COMPOUNDS

2.7.1. Summary

Although there are few published studies documenting measured fate rate constants, relatively few studies with measured physical/chemical property data, and few relevant environmental monitoring studies, it is possible to estimate the environmental transport and transformation processes for the brominated dioxin-like compounds using the available published information and using structure activity and property estimation methods. Mill (1989) performed such an assessment, and much of the limited information published since 1989 supports the conclusions of Mill (1989).

Mill (1989) concluded that the estimated physical/chemical properties of these compounds indicate they will behave in a similar fashion to their chlorinated analogues. In general, these chemicals are expected to be stable under normal environmental conditions, relatively immobile in the environment, and primarily associated with particulate and organic materials. The only environmentally significant path for destruction is photodegradation. If discharged to the atmosphere, any vapor-phase compounds will probably be rapidly photolyzed. The higher brominated congeners, like their chlorinated counterparts, may be present primarily in a particle-bound rather than gaseous phase. If so, they likely will be more resistant to photolysis and become more widely dispersed in the environment.

Upon deposition onto surfaces, there can be an initial loss due to photodegradation and/or volatilization. Once sorbed onto soils or sediments, however, they are expected to be strongly sorbed with erosion and aquatic transport of sediment the dominant physical transport mechanism. If discharged to water, they are expected to preferentially sorb to solids. Volatilization may also be a significant transport mechanism for nonsorbed chemicals even though they have negligible estimate vapor pressures.

2.7.2. Transport Mechanisms

Little information exists on the environmental transport of brominated dioxin-like compounds. For example, Jacobs et al. (1978) reported that less than 0.2 percent of 2,2',4,4',5,5'-hexa-PBB (14μg PBB/g of soil) and 2,2',3,4,4',5,5'-hepta-PBB (7μg PBB/g of soil) volatilized from soil incubated for 1 year at 28°C. However, the available information on the physical/chemical properties of these compounds and their chlorinated analogs coupled with the body of information available on the widespread occurrence and persistence of the chlorinated analogs in the environment indicate that these compounds are likely to be strongly sorbed by soils, sediments, and other particulate material, and to be resistant to leaching and volatilization.

2.7.3. Transformation Processes

2.7.3.1. Photolysis. Photolysis appears to be a major potential pathway for loss of brominated dioxin-like compounds in water, air, and soil. The available data indicate that BDDs and BDFs undergo photolytic degradation more readily than their chlorinated analogs. Also, BCDDs and BCDFs appear to undergo debromination more readily than dechlorination. However, no photolysis studies have been published that used natural waters as the reaction medium or that measured gas-phase photolysis rates. Most studies have been conducted using reaction media consisting of homogenous solutions in organic solvent mixtures or clean solid surfaces. Thus, although photolysis of brominated dioxin-like compounds at environmentally significant rates has been observed in laboratory studies, the results of these studies may not be representative of photolysis rates that occur under actual environmental conditions. The following subsections summarize the key findings of recent environmentally significant studies for the water, soil, and air media.

Photolysis in Organic Solvents. Buser (1988) studied the photolytic decomposition rates of the following compounds in dilute isooctane solutions in quartz vials and as solid phases on quartz surfaces under sunlight (47 degrees north latitude): 1,2,3,4-TBDD; 2,3,7,8-TBDD; 2,3,7,8-TBDF; and mono- and dibrominated 2,3,7,8-TCDD and 2,3,7,8-TCDF. Estimated half-lives were very short, on the order of minutes for solution photolysis. Solid-phase photolysis was significantly slower with half-lives in the range of 7 to 35 hours. The major photolytic pathway was reductive dehalogenation with the

formation of lower halogenated or unsubstituted dibenzo-p-dioxins and dibenzofurans. The bromo-chlorodibenzofurans degraded faster than either the brominated or chlorinated congeners. The major pathway of photolysis was debromination to form a chlorinated dibenzofuran.

Lenoir et al. (1991) studied the photolysis in hexane and methanol of a series of mono-through octa-substituted BDD. Several BDFs (di-, tetra-, and hepta-BDF) were also studied as were a series of CDDs for comparison purposes. The results reported by Lenoir et al. (1991) were similar to those reported by Buser (1988) with half-lives on the order of minutes. Bromines at the lateral positions (i.e., 2, 3, 7, and 8 positions) reacted faster than bromines at the peri-positions (i.e., 1, 4, 6, and 9 positions). The bromine compounds reacted nearly an order of magnitude faster than the chlorine analogs. Photolysis in methanol was found to be nearly six times faster than in hexane.

Chatkittikunwong and Creaser (1994) studied the fate of a mixture of mono-through penta-substituted BDDs and BCDDs dissolved in dodecane in borosilicate glass vials exposed to sunlight through a laboratory window. The results indicated that for both the BDDs and the BCDDs the major mechanism of degradation was consecutive debromination from higher congeners to lower congeners. The half-lives calculated by Chatkittikunwong and Creaser (1994) for various congener groups (listed below) are much greater than those reported by Buser (1988). Chatkittikunwong and Creaser (1994) attribute the difference to the fact that borosilicate glass is more effective than quartz at absorbing those wavelengths most likely to cause degradation of these compounds.

Congener Group	Estimated Average Half-Life in Dodecane (hrs)
PeBDD	150
TBDD	480
Br_2Cl_2DD	580
Br_3Cl_1DD	650
Br_1Cl_4DD	480
Br_2Cl_3DD	995
Br_3Cl_2DD	300
Br_4Cl_1DD	520
Br_1Cl_5DD	520

Watanabe et al. (1994) extracted BDFs and BCDFs from the soil at a metal reclamation facility using hexane and exposed the hexane solution to natural sunlight. The half-lives calculated by Watanabe et al. (1994) for various congener groups are listed below. The half-lives decrease with increasing number of bromines.

Congener Group	Estimated Average Half-Life in Hexane (min)
Br_1Cl_3DF	43
Br_2Cl_2DF	11
Br_3Cl_1DF	6.5
TBDF	4.0
Br_1Cl_4DF	18
Br_2Cl_3DF	4.9
Br_3Cl_2DF	5.4
Br_4Cl_1DF	3.1
PeBDF	2.7
Br_1Cl_5DF	9.8
Br_2Cl_4DF	5.7
Br_1Cl_6DF	12

Photolysis in Water. No published studies were located that measured the photolysis rates of brominated dioxin-like compounds in water. Mill (1989) used the results obtained by Buser (1988) together with assumptions to overcome the lack of quantum yield data from Buser (1988) to estimate the photolysis half-lives of the three brominated-only compounds tested by Buser (1988). Mill (1989) estimated the following half-lives in water (top 1 meter) for clear-sky conditions in mid-summer at 40 degrees north latitude:

Congener	Estimated Half-Life in Water (hrs)
1,2,3,4-TBDD	7
2,3,7,8-TBDD	2
2,3,7,8-TBDF	1.7

Photolysis in Soil. Chatkittikunwong and Creaser (1994) studied the fate of a mixture of mono- through penta-substituted BDDs and BCDDs spiked onto soil (5 mm depth) exposed to full sun outdoors for a 3-month period. The pattern of degradation was

similar to that observed in solution (i.e., debromination of higher congeners with formation of lower congeners) although the rate of degradation was much slower (by a factor of about 4) than observed in solution. For example, the calculated average half-lives for PeBDDs and TBDDs were 600 hours and 2,330 hours, respectively.

Photolysis in Air. No published studies were located that measured the photolysis rates of brominated dioxin-like compounds in the gas phase in air. Mill (1989) used the results obtained by Buser (1988) together with assumptions to overcome the lack of quantum yield data from Buser (1988) to estimate the photolysis half-lives of the three brominated-only compounds tested by Buser (1988). Mill (1989) estimated the following gas-phase half-lives (first kilometer above surface) for clear-sky conditions in mid-summer at 40 degrees north latitude:

Congener	Estimated Half-Life in Air (min)
1,2,3,4-TBDD	<1
2,3,7,8-TBDD	0.3
2,3,7,8-TBDF	0.2

Lutes et al. (1992a, 1992b) studied the short-term photochemistry of tetra- and penta-BDDs and BDFs sorbed onto airborne soot particles in 25 m^3 outdoor Teflon film chambers. The emissions from high temperature (640 to 760°C) controlled burning of polyurethane foam containing polybrominated diphenyl ether flame retardants served as the source of the particulate-bound BDDs and BDFs. Initial experiments demonstrated that more than 95 percent of the BDDs/BDFs were associated with airborne particulate material; less than 5 percent were in the vapor phase. Particulate phase concentrations of tetra- and penta-CDD/CDFs were monitored for 3 to 6 hours after introduction of the emissions from the foam burn to the chamber under winter and spring temperatures and sunlight regimes in Pittsboro, North Carolina. No significant reduction in concentration was observed. The authors concluded that if photolytic degradation was occurring, then the half-lives are much greater than 3 to 6 hours.

Birla and Kamens (1994) expanded the research of Lutes et al. (1992a; 1992b) by examining the effect of combustion temperature on the atmospheric stability of BDDs and BDFs generated using the same polyurethane combustion apparatus. Both "high temperature" (745 to 780°C) and "low temperature" (400 to 470°C) combustion

temperatures were studied. The results obtained from the high temperature experiments were similar to those obtained by Lutes et al. (1992a; 1992b) in that there was little evidence of any decay in particulate-bound BDDs and BDFs. In the low temperature experiments, production of TBDFs and PeBDFs and decay of TBDDs were observed. Birla and Kamens (1994) attributed the increase in particulate-bound TBDF and PeBDF levels to photolysis of unburned polybrominated diphenyl ether flame retardants. The decay of TBDD was attributed to differences in physical and chemical properties of the particles generated from the high and low temperature experiments.

Watanabe et al. (1994) collected air dust on glass filters for a period of 24 hours in Osaka, Japan, and then exposed the glass filters to 24 hours of sunlight. More than 10 congener groups of BCDFs as well as TBDFs and PeBDFs were measured in the collected dust prior to irradiation. Although there was a reduction in the concentration of every congener group over the exposure period with the largest decrease observed for the lower halogenated congeners, Watanabe et al. (1994) concluded that most of the decrease was probably due to volatilization rather than photolysis.

2.7.3.2. Oxidation

No reaction rate data for OH radicals with gas-phase brominated dioxin-like compounds could be located. The low vapor pressures of these compounds make direct measurements very difficult with the current techniques. However, Mill (1989), using a structure activity relationship developed by Atkinson (1987), has estimated the half-lives of OH oxidation for the tetra- through octa- BDDs and BDFs. The estimated half-lives listed below indicate that OH oxidation is probably too slow to compete with photolysis.

Number of Bromines	BDD Half-Life in Air (hrs)	BDF Half-Life in Air (hrs)
4	50	420
5	50	430
6	100	960
7	200	1900
8	770	3800

2.7.3.3. Hydrolysis

No evidence is available indicating that hydrolysis would be a significant degradation process for these compounds.

2.7.3.4. Biotransformation and Biodegradation

Although no data are available concerning the biodegradability of the brominated dioxin-like compounds, it is expected that these brominated compounds, especially the more halogenated congeners, will be recalcitrant to biodegradation. The limited data available on PBBs (discussed below) indicate recalcitrance.

Jacobs et al. (1976) examined the distribution and fate of PBBs in the environment following the accidental contamination of livestock feed in Michigan in 1973 with the brominated flame retardant, FireMaster BPG. FireMaster BPG (a.k.a., PBB) was found by Jacobs et al. (1976) to be comprised of 2,2',4,4',5,5'-hexabromobiphenyl as the major component, two isomers of pentabromobiphenyl, three additional isomers of hexabromobiphenyl, and two isomers of heptabromobiphenyl. Jacobs et al. (1976) reported that PBBs are extremely persistent based on the results of aerobic and anaerobic soil incubation studies for 24 weeks with the flame retardant, PBB. Only one major PBB component, a pentabromobiphenyl isomer, showed any significant disappearance; however, Jacobs et al. (1976) were not certain whether the disappearance was due to microbial degradation, to poor soil extraction efficiency, or to sorption onto glassware. Jacobs et al. (1976) also detected components of PBB in soils from a field that had received manure from a PBB-contaminated dairy herd 10 months earlier (quantitative changes in PBB were not possible because no earlier soil samples had been obtained). Additional soil studies by Jacobs et al. (1978) found no degradation of 2,2',4,4',5,5'-hexa-PBB (14μg/25g soil) or 2,2',3,4,4',5,5'-hepta-PBB (7μg/25g soil) after incubation at 28°C for 1 year.

Table 2-1. Possible Number of Positional CDD (or BDD) and CDF (or BDF) Congeners

Halogen Substitution	Number of Congeners		
	CDDs (or BDDs)	CDFs (or BDFs)	PCBs
Mono	2	4	3
Di	10	16	12
Tri	14	28	24
Tetra	22	38	42
Penta	14	28	46
Hexa	10	16	42
Hepta	2	4	24
Octa	1	1	12
Nona	0	0	3
Deca	0	0	1

Table 2-2. Ranking Scheme for P-Chem Property Evaluation

Ranking	Factors				
	1	2	3	4	5
1	✓	✓	✓	x	x
2	x	✓	✓	x	x
3	✓	x	✓	✓	x
4	x	x	✓	✓	x
5	x	x	x	x	✓

Notes:

✓ indicates all specifications of the Factor have been met.
x indicates the specifications of the Factor have not been met, or the Factor does not apply.

Table 2-3. Selected Physical-Chemical Property Values for the "Dioxin-Like" CDD, CDF, and PCB Congeners

Footnote References

a Values are presented as they appeared in the referenced article. Values in ( ) are either estimated or are calculated/extrapolated from experimental values.

b [R] is the ranking of the value from the cited reference.

c For several PCB congeners, subcooled liquid values were converted to solid values using the melting points presented in this table and the conversion methodology presented in Eitzer and Hites (1988) and Mackay et al. (1992).

$\ln (P_{sc}/P_s) = 6.79 (T_m\text{-}T)/T$

where: P_{sc} = subcooled value
P_s = solid value
T_m = melting point (°K)
T = ambient temperature (°K)

d The melting point value for this congener obtained from Ref. 21; however, it was attributed through a probably typographical error to 1,2,3,6,8,9-HxCDF.

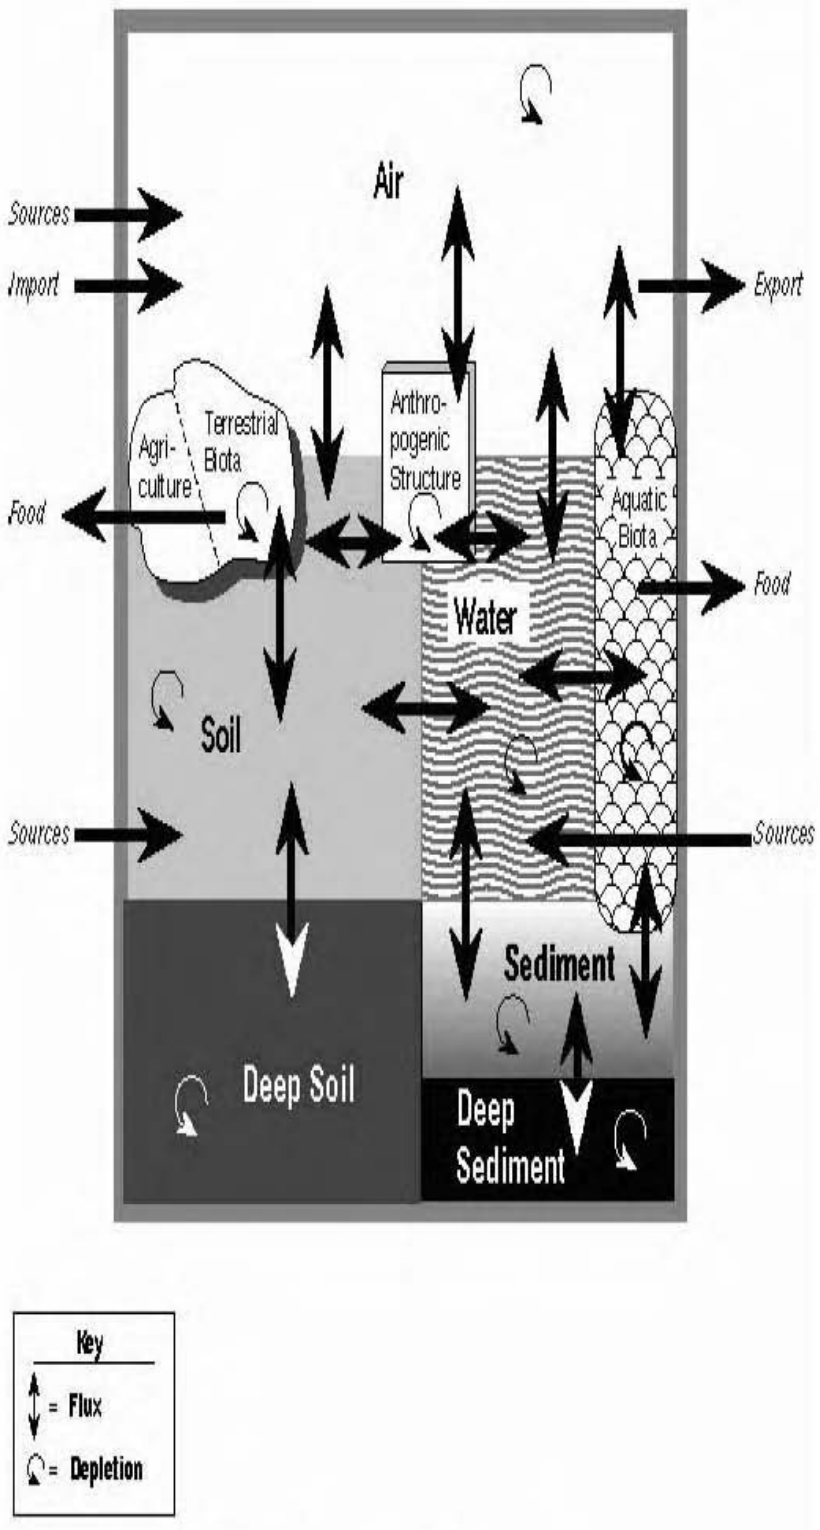

Figure 2-2. Intermedia Movement of CDD/CDFs and PCBs Among Major Environmental Media

3. LEVELS OF CDD, CDF, AND PCB CONGENERS IN ENVIRONMENTAL MEDIA AND FOOD

3.1. INTRODUCTION

Polychlorinated dibenzo-*p*-dioxins (CDDs), polychlorinated dibenzofurans (CDFs), and polychlorinated biphenyls (PCBs) have been found throughout the world in practically all media including air, soil, water, sediment, fish and shellfish, and other food products such as meat and dairy products. Also, not unexpectedly, considering the recalcitrant nature of these compounds and their physical/chemical properties (i.e., low water solubilities, low vapor pressures, and high K_{ow}s and K_{oc}s), the highest levels of these compounds are found in soils, sediments, and biota (parts-per-trillion (ppt) and higher); very low levels are found in water (parts-per-quadrillion (ppq) and lower) and air (pg/m^3). The widespread occurrence observed is not unexpected considering the numerous sources that emit these compounds into the atmosphere (See Volume 1), and the overall resistance of these compounds to biotic and abiotic transformation. (See Chapter 2 of this volume.) Part-per-trillion levels of CDDs/CDFs have been found in everyday materials that are contaminated with dust--clothes dryer lint (2.4 to 6.0 ng I-TEQ_{DF}/kg); vacuum cleaner dust (8.3 to 12 ng I-TEQ_{DF}/kg); room air filters (27 to 29 ng I-TEQ_{DF}/kg); and house furnace filter dust (170 ng I-TEQ_{DF}/kg) (Berry et al., 1993). Although Berry et al. (1993) only analyzed one or two samples of these materials, the findings suggest that these compounds may be ubiquitous.

This chapter provides an overview of the concentrations at which dioxin-like compounds have been found in the U.S. environment and food based on data presented in the published literature. This literature summary is not all inclusive, but is meant to present the reader with a general overview of values reported in the recent literature. Only data from Government-sponsored monitoring studies and studies reported in the peer-reviewed literature are discussed in this chapter. Data are presented as presented in the original studies/reports. No attempt was made to verify or assess the adequacy of the quality assurance/quality control (QA/QC) measures employed in these studies beyond those described in the published reports. In order to represent current exposure concentrations, data used for the calculation of background media levels were based on studies published in the late 1980s and 1990s, but primarily in the 1990s. The studies

used for the estimation of background concentrations were also chosen on the basis of credibility and representativeness.

CDD/CDF profiles for environmental media are also presented in this chapter. CDD/CDF homologue group and 2,3,7,8-substituted congener profiles were calculated for each medium by dividing the mean concentration of individual homologue groups or congeners by the mean total CDD/CDF concentrations for a group of studies or samples. Total CDD/CDF concentration was calculated as the sum of homologue group concentrations. In some cases, however, homologue group concentrations were not available. When this occurred (i.e., for foods), total concentration was redefined as the sum of the concentrations of the 2,3,7,8-substituted congeners rather than the sum of the homologue group concentrations. The fractions of the total for each congener add up to 1.00 in this case rather than some fraction of 1.00, as they would if the total concentration were, more appropriately, the sum of the homologue group concentrations. The text carefully identifies where this occurred. Nondetects were assumed to be zero in the calculation of CDD/CDF profiles. This was done as a matter of consistency - some studies used did not report on the detection limits for some congeners; some had high detection limits such that an assumption of one-half the detection limit would have led to unreasonably high contributions of some congeners to total CDD/CDFs. When available, data on media levels in European countries and in other parts of the world are also presented for comparison to U.S. values. These data are not intended to provide estimates that are representative of CDD/CDF levels in all parts of Europe or the world, but are used to depict similarities or differences between U.S. levels and those observed by researchers in other parts of the world.

Media levels discussed in this chapter that represent background conditions in the United States are used in Chapter 4 to estimate background exposures to dioxin-like compounds. For the purposes of this document, background is defined as the level of dioxin-like compounds in samples of environmental media originating from sites not known to be impacted by point source releases. For soil and air, background concentrations of CDD/CDFs were calculated for both rural and urban background locations. However, urban background concentrations were used in calculating human exposures to CDD/CDFs because a large percentage of the population resides in urban environments. Also, it should be noted that background levels in environmental media are represented by mean

concentrations of multiple background samples. Because mean values are used, it is likely that some background sites may have concentrations that are less than the mean concentration, while others may have higher levels. It should be noted that background concentrations were calculated based on the best available, current (i.e., late 1980s in a few cases, but primarily from the 1990s) studies. For most media, background concentrations used to assess exposure in Chapter 4 were calculated by setting nondetectable concentrations to one-half the detection limit. For some media (i.e., soil, vegetable oil), however, nondetects were set to zero because detection limits were unavailable for some studies or the detection limits were too high. These instances are noted in the text. In general, mean background concentrations were calculated as the average value over all sample locations rather than the average concentration over all samples. For example, if the available background data for a particular medium (e.g., soil, air, fish) were derived from multiple samples collected at multiple locations, the overall mean background concentration was calculated by first averaging the data for each site and then calculating the mean of the site averages. This method ensures that each site is weighted equally; heavily sampled sites do not have any greater impact on the mean than sites with fewer samples.

Studies used for development of background concentrations were also chosen to be representative of nationwide exposures. In general, data were selected that represent typical exposure conditions, so that these levels could be combined with typical ingestion/contact values to estimate background exposures (see Chapter 4). However, the data and strategy used for estimating background media levels varied somewhat, depending on the media:

- **Air and Soil** - Urban data were used to derive background estimates because most people are exposed to these levels. No data were included that were collected near known uncommon point sources (i.e., large incinerators, cement kilns, smelters, etc.). Vehicles, fireplaces, home heating furnaces, etc., are all recognized potential point sources, but are so ubiquitous as to be considered a normal part of the urban background. Estimates are also presented for rural areas, and these are more relevant for evaluating impacts in rural areas. Also a degree of uncertainty is expected from the air and soil concentration estimates due to a lack of geographic coverage and non-uniform study design.

- **Water and Sediment** - No data were included that were collected near known uncommon point sources (pulp and paper mills, POTWs, etc.). No distinction was made between urban and rural sites. For water, the data for treated drinking water were very limited (i.e., based on octa-chlorinated compounds only). Sediment data were collected from non-impacted lakes.

- **Fish** - No data were included that were collected near known uncommon point sources (pulp and paper mills, POTWs, etc.). Background data for freshwater and marine fish and shellfish were based on species-specific data from various studies, including a national survey conducted by EPA, market basket surveys conducted by FDA, and individual site-specific studies were used.

- **Food** - Only samples from national EPA/USDA surveys and grocery stores (e.g., eggs) were used. National EPA/USDA surveys used statistically-based sampling methods to collect samples representative of the national food supply. Grocery store samples represent the most common source of foods.

3.2. CONCENTRATIONS IN AIR

Tables B-1 through B-3 (Appendix B) contain summaries of data from studies of ambient air measurements of CDDs, CDFs, and PCBs in the United States and Europe. Environmental levels of PCBs in North American air are based on a single source of information (Hoff et al., 1992). Relatively few studies have been conducted to measure ambient air levels of CDDs/CDFs. This may be, in part, because of the low analytical detection limits required to detect the expected low concentrations of specific CDD/CDF congeners and the relatively large volumes of air (e.g., 350 to 450 cubic meters of ambient air over a 24-hour period) required to obtain subparts-per-trillion levels of analytical detection. These low detection limits in ambient air samples were not achieved until the mid 1980s. The results of several of these more recent ambient air studies are summarized in the following paragraphs. It should be noted, however, that these studies lack geographic coverage and may not be representative of the nation as a whole. Currently, EPA is establishing a network of stations equipped with high-volume air samplers capable of detecting concentrations of dioxin and dioxin-like compounds as low as 0.1 parts per trillion. The network, known as the National Dioxin Air Monitoring Network (NDAMN), will provide information on background concentrations of dioxin-like compounds, as well as data for use in tracking long-range transport of dioxin and calibrating atmospheric models. The sampling sites included in the network were selected with the intent of covering a wide geographic region, with special attention to rural,

agricultural areas. Many of the sites are shared with the National Atmospheric Deposition Program (NADP), which is a collaborative effort involving dozens of public and private research and educational institutions. The NDAMN project calls for a total of 29 sites in 24 states. Currently, results are available for 9 monitoring locations. These data are reported in this chapter. Additional data from the other sites will eventually be used to update the background air concentration data presented in this chapter.

It should also be noted that this chapter focuses on the concentrations of CDD/CDF/PCBs in outdoor air. Data on indoor air concentrations are extremely limited. PCB data for one recent indoor air study in the United Kingdom are presented. No background CDD/CDF data for indoor environments were available.

3.2.1. U.S. Data

An extensive ambient air monitoring study of CDD/CDFs was conducted as part of a multiyear monitoring effort at eight sampling locations in the Southern California area by the Research Division of the California Air Resources Board from December 1987 through March 1989 (Hunt et al., 1990). The monitoring network "included a number of sites situated in primarily residential areas (San Bernadino, El Toro, and Reseda), as well as several sites in the vicinity of suspected sources of CDD/CDFs (Cal. Trans, Commerce, North Long Beach, and West Long Beach) (Hunt et al., 1990)." The seven sites mentioned above were classified as urban locations by the definitions used in this document, while the eighth site was classified as an industrial site (i.e., Carson--onsite at manufacturer of gas cooking equipment). Additionally, four of the eight sites were part of the South Coast Air Quality Management District (SCAQMD) monitoring network. All totaled, there were nine sample collection intervals throughout this study. "Typically, five to seven stations were in contemporaneous operation during a particular session" (i.e., samples were not collected from each location at each interval). Total tetra- through octa-chlorinated CDDs and CDFs were screened for in the study as well as various 2,3,7,8-substituted CDD and CDF congeners. A total of 34 analyses were performed throughout the study for all congeners except for OCDD and OCDF, respectively, for which only 31 analyses were performed. Samples were collected over a maximum of seven intervals at each site throughout the study (i.e., Reseda and El Toro--six dates, duplicate samples on one date), while a sample was collected from the Commerce site during only a single

collection interval. Sample collection intervals generally averaged 24 hours (Hunt et al., 1990).

Generally, higher substituted CDD and CDF congeners accounted for the majority of positive samples containing quantifiable CDD/CDF residues in this study (i.e., total HxCDD/HxCDF and above). In fact, over 90 percent of the samples collected contained quantifiable levels of 1,2,3,4,6,7,8-HpCDD, total HpCDD, and OCDD. Additionally, approximately 50 to 70 percent of the samples collected contained quantifiable levels of total HxCDD; 2,3,7,8-TCDF; total TCDF; total PeCDF; total HxCDF; 1,2,3,4,6,7,8-HpCDF; total HpCDF; and OCDF. For all other congeners, quantifiable residues were detected in less than 25 percent of the samples collected. All CDD congener concentrations ranged from nonquantifiable levels (low limit of 0.0026 pg/m^3) to an upper limit of 18.0 pg/m^3. Additionally, CDF congener levels ranged from nonquantifiable levels (low limit of 0.0040 pg/m^3) to an upper limit of 2.70 pg/m^3.

According to Hunt et al. (1990), "The highest concentration of CDDs/CDFs congener class sums (Cl_4-Cl_8) and 2,3,7,8-substituted species were noted during a period predominated by off-shore air flows in December 1987, suggesting a regional air mass and transport phenomena. Concentrations of the CDDs/CDFs were diminished markedly in subsequent sessions where air flow patterns were primarily off-shore or of coastal origin." Hunt et al. (1990) indicated that the "CDD/CDF congener profiles (Cl_4-Cl_8) and 2,3,7,8-substituted isomeric patterns strongly suggest combustion source influences in the majority" of the samples collected.

Smith et al. (1989) quantified CDD/CDFs in air samples collected from two locations in Niagara Falls, New York, over a 6-month period in 1986/87. One site was located upwind of a large industrial complex (i.e., background), and the other site was located downwind of the complex (i.e., industrial). OCDD concentrations at the downwind location were more variable, but consistently higher, than at the upwind location. The maximum OCDD concentration observed at the downwind site was 8.8 pg/m^3. Total I-TEQ_{DF}s for the two locations were estimated to be 0.038 pg/m^3 (TEQ_{DF}-WHO_{98} = 0.041 pg/m^3) (n = 3) for the upwind (i.e., background) site and 0.84 pg/m^3 (TEQ_{DF}-WHO_{98} = 0.92 pg/m^3) (n = 3) for the downwind site, using one-half the detection limit to represent nondetects (Table 3-1). In another study, Smith et al. (1990a) analyzed ambient air samples from several other New York cities for CDD/CDFs. Samples were

collected in Albany (n = 3), Binghamton (n = 1), and Utica (n = 2). Total CDD/CDF concentrations ranged from 3.02 pg/m^3 to 13.1 pg/m^3. None of the samples had detectable levels of 2,3,7,8-TCDD, but 2,3,7,8-TCDF was detected at concentrations ranging from 0.18 pg/m^3 to 1.24 pg/m^3.

Maisel and Hunt (1990) reported on ambient air concentrations of CDD/CDFs in Los Angeles, California, during the winter of 1987. Concentrations were highest for OCDD, and the estimated I-TEQ_{DF} concentration was 0.12 pg/m^3 (TEQ_{DF}-WHO_{98} = 0.13 pg/m^3, assuming that nondetects equal one-half the detection limits. Edgerton et al. (1989) measured CDD/CDFs in air samples from Ohio during 1987 to evaluate the impact of potential CDD/CDF sources on ambient levels in air. Samples were collected from various locations, including those at an industrial site, near a municipal refuse-derived fuel power plant, near a sewage sludge incinerator, downwind of a municipal incinerator, at a high traffic density site, and at a rural background site in Waldo, Ohio. Total CDD/CDF concentrations were found to be higher in samples collected near incinerators than at the background site. None of the samples had detectable levels of 2,3,7,8-TCDD, and the hepta- and octachlorinated CDD/CDFs were the most abundant. Using congener profiles developed for several source categories, Edgerton et al. (1989) compared the CDD/CDF patterns in ambient air from this study to the profiles for each source and found that the profile for the background sample was "almost identical to the profile constructed for municipal incinerators."

The Ohio Environmental Protection Agency, Division of Air Pollution Control, conducted an ambient air monitoring study in 1994/1995 for CDD and CDF compounds in the vicinity of the Columbus Waste to Energy (WTE) facility. The purpose of the study was to evaluate the impact of the facility on air quality. The Columbus WTE was a major source of dioxins to the Columbus environment. Based on a 1992 stack emission test, the Ohio EPA estimated that annual emissions from the facility exceeded 900 g I-TEQ_{DF}/yr (OEPA, 1994a). The sampling in 1994 occurred while the facility was operating. The facility ceased operation in December 1994; therefore, the 1995 sampling did not include impacts from the facility. A total of seven sites were sampled; six were located in the urban area of Columbus, within 1-2 miles of the facility, and mostly in the historically predominant downwind direction, and the seventh was located 28 miles away in the upwind direction in a rural background setting. Five urban samples were taken in both

March and April 1994 (one of the six samplers was not operating on each of these sampling dates), and six urban samples were taken in June 1995, for a total of 16 urban samples. One rural sample was taken on each sampling date for a total of three background samples. All samples were collected over a 48-hour sampling period using modified high-volume air samplers. Further details on these studies can be found in OEPA (1994b, 1995).

Table 3-2 presents the mean concentrations of congeners and homologue groups from four groups of air samples:

1. The "impacted air" samples include one sample taken in each of the March and April 1994 sampling periods. Wind rose data in OEPA (1994b) show that the samplers from which these samples came from were downwind of the Columbus WTE during the 48-hour sample.
2. The 1994 urban samples include the eight other samples taken in 1994 while the Columbus WTE was still operating.
3. The 1995 urban samples include the six samples taken in the urban setting once the incinerator was no longer operating.
4. The three rural samples include those taken at a site 28 miles away in the historical upwind direction from the Columbus WTE.

OEPA (1994b) also notes that the highest air concentrations were found in the downwind samples.

Generally, total CDD/CDF concentrations were higher for the urban sites than for the background sites. Overall, the average total urban background air CDD/CDF concentration was 3.5 pg/m^3, and the I-TEQ_{DF} and TEQ_{DF}-WHO_{98} concentrations were 0.050 pg/m^3 and 0.055 pg/m^3, respectively. These values were the average of the 1994 and 1995 urban samples. The rural background total CDD/CDF concentration was 2.2 pg/m^3, and the I-TEQ_{DF} and TEQ_{DF}-WHO_{98} concentrations were 0.022 pg/m^3 and 0.024 pg/m^3, respectively. The impact of the Columbus facility can be seen by examining the impacted air samples. As noted above, one sample in each of the two 1994 sampling dates was downwind of the Columbus facility. In fact, the air sampler was the same in both cases and was located about 1.5 miles in the easterly direction. The air

concentration in this sampler was the highest in both these sampling dates, equaling 9.2 pg/m^3 total and 0.17 pg I-TEQ_{DF}/m^3 in March and 19.0 pg/m^3 total and 0.35 pg I-TEQ_{DF}/m^3 in April. The average total CDD/CDF concentration for these impacted samples was 14 pg/m^3, and the I-TEQ_{DF} and TEQ_{DF}-WHO_{98} concentrations were 0.26 pg/m^3 and 0.29 pg/m^3, respectively. Further analysis of these Columbus air data can be found in Lorber et al. (1998a).

In accordance to the Connecticut Ambient Air Quality standards, the State of Connecticut's Department of Environmental Protection (CDEP) implemented a monitoring program which measured CDD/CDFs in ambient air at six sites in Connecticut (CDEP, 1995). The air monitoring program was conducted from fall 1993 through summer 1994 in the vicinity of five Resource Recovery Facilities (RRFs), located in Bridgeport, Hartford (mid-Connecticut), Bristol, Preston, and Wallingford, Connecticut, as well as one background rural site located at Mohawk Mountain. The monitoring activity involved four quarterly 1-month sampling periods (CDEP, 1995). Ambient concentrations measured for the four quarterly monitoring sessions at the rural background site (Mohawk Mountain) are presented in Table 3-3. Based on the CDD congeners, OCDD had the highest background concentration (0.451, 0.196, 0.155, and 0.056 pg/m^3) for all four sampling periods. The total I-TEQ_{DF}s for these rural background samples were 0.015 pg/m^3, 0.009 pg/m^3, 0.006 pg/m^3, and 0.005 pg/m^3 for the November 1993, February 1994, May 1994, and August 1994 sampling periods, respectively. The average I-TEQ_{DF} for these sampling periods was 0.0087 pg/m^3 (TEQ_{DF}-WHO_{98} = 0.010). The average I-TEQ_{DF} and TEQ_{DF}-WHO_{98} values for the five urban locations, over the four sampling periods, were 0.026 pg/m^3 and 0.029 pg/m^3, respectively. Data for all samples collected during the monitoring program show that the I-TEQ_{DF} concentrations were below the 1.0 annualized pg/m^3 ambient standard adopted by the State of Connecticut for CDD/CDFs (CDEP, 1995).

In an earlier study of ambient air monitoring in the vicinity of Wallingford, Connecticut, CDEP (1988) reported on CDD/CDF levels in 28 ambient air samples collected in 1988. The mean total I-TEQ_{DF} for these samples was 0.05 pg/m^3, when nondetects were set to one-half the detection limit. Hunt and Maisel (1990) conducted pre-operational air monitoring in the vicinity of the site of a municipal solid waste incinerator. I-TEQ_{DF} concentrations, averaged over seven sites and all seasons, were 0.1 pg/m^3, when nondetects set to one-half the detection limit. Mean concentrations were

highest for the higher-chlorinated dioxin homologue groups and lower furan homologue groups.

In a long-term study of CDD/CDFs in the ambient air around Bloomington, Indiana, methods were developed for measuring individual CDD/CDFs at concentrations as low as 0.001 pg/m^3 (Eitzer and Hites, 1989). Total CDD/CDF concentrations were 0.480 pg/m^3 and 1.360 pg/m^3 for the vapor phase and the particle-bound phase, respectively. For individual congeners, CDFs were found to decrease in concentration with increasing levels of chlorination, and CDD concentrations were found to increase with increasing levels of chlorination (Eitzer and Hites, 1989).

Fiedler et al. (1995a) conducted a sampling and monitoring program in rural Mississippi using pine needles as indicators of the presence of CDDs and CDFs in the atmosphere. Pine needles have been shown to be passive samplers for lipophilic substances present in the air, because their outer waxy surface absorbs these atmospheric pollutants. Pine needle samples were collected from eight locations in southern Mississippi. CDD and CDF I-TEQ_{DF} concentrations ranged from 0.11 to 0.23 pg/kg dry mass for 1994 shoots and 0.07 to 0.51 pg/kg dry mass for 1993 shoots. The authors concluded that the data suggest that the atmospheric concentrations of CDDs and CDFs in rural Mississippi are relatively low, but higher concentrations were observed at more populated sites.

In a subsequent study, Fiedler et al. (1997a) analyzed CDD/CDF levels in ambient air in a rural area in southern Mississippi using three sampling methodologies: high-volume ambient air sampling to measure direct atmospheric levels of CDD/CDFs; Bergerhoff samplers to collect atmospheric deposition samples; and pine needles as passive samplers. The study was conducted from December 1995 to January 1996 and from June to July 1996 to assess the concentrations of CDD/CDFs during these time periods. The sampling location had no known local sources of CDD/CDFs. In general, winter CDD/CDF concentrations were higher than summer concentrations. CDD/CDF concentrations measured using high-volume air samples averaged 1.126 pg/m^3 in the winter and 0.36 pg/m^3 in the summer (i.e., three times higher in winter than in summer). The mean I-TEQ_{DF} concentrations were 0.0109 pg I-TEQ_{DF}/m^3 in the winter and 0.0037 pg I-TEQ_{DF}/m^3 in the summer, when using one half the limit of quantification for nonquantifiable congeners. The results of the deposition study suggested that deposition is also higher in

winter than in summer. The mean CDD/CDF deposition rate was 152 pg/m^3-day in winter and 108 pg/m^3-day in summer, when nonquantifiable congeners were set to one-half the limit of quantification. Normalized to pg I-TEQ_{DF}/m^3-day, the deposition rate was 2.6 pg I-TEQ_{DF}/m^3-day in winter and 0.58 pg I-TEQ_{DF}/m^3-day in summer. Analysis of the pine needles showed that CDD/CDF concentrations increase with increasing exposure times. Concentrations in pine needles ranged from 10 to 54 pg/g d.m. (0.16 to 0.79 pg I-TEQ_{DF}/g d.m.), when nonquantifiable congeners were set to one-half the limit of quantification. The authors concluded that the CDD/CDF concentrations observed in ambient air in this study (0.0023 to 0.017 pg I-TEQ_{DF}/m^3) were lower than similar remote locations in Germany (0.015 to 0.020 pg I-TEQ_{DF}/m^3). Deposition rates were also lower in southern Mississippi (0.42 to 3.1 pg I-TEQ_{DF}/(m^2-day)) than in rural areas of Germany (5 to 7 pg I-TEQ_{DF}/(m^2-day).

Hunt et al. (1997) conducted a study in Phoenix, Arizona, aimed at assessing the influence of motor vehicle emissions on ambient air concentrations of CDD/CDFs. Four sets of 24-hour integrated samples were collected between December 15 and 20, 1994. The sampling site was located near a heavily traveled roadway in metropolitan Phoenix. The month of December was chosen for sampling, because inversion conditions are expected during the winter months. CDD/CDFs were detected in all four sample sets. Average total I-TEQ_{DF} values varied from 0.092 pg/m^3 (December 15) and 0.094 pg/m^3 (December 19) to 0.37 pg/m^3 (December 16) and a high of 0.45 pg/m^3 (December 20). Average congener-specific I-TEQ_{DF} (and TEQ_{DF}-WHO_{98}) values are shown in Table 3-4. The average total I-TEQ_{DF} value of 0.25 pg/m^3 and TEQ_{DF}-WHO_{98} values of 0.27 pg/m^3 are higher than the TEQ data reported for other U.S. urban locations, such as Los Angeles and Connecticut (Maisel and Hunt, 1990). The first 2 sampling days of this study demonstrated congener class profiles typical of those reported in the literature for urban U.S. settings, showing a predominance of CDDs over CDFs. Hunt et al. (1997) also noted that the "predominance of 1,2,3,4,6,7,8-HpCDD as the most persistent 2,3,7,8-substituted CDD congener is consistent with the observations of others in the open literature, and is prevalent at sites known to be influenced by stationary or mobile combustion source emissions." Data from the last 2 sampling days of this study produced distinctly different congener profiles from the first 2 days. The last 2 sample dates' results showed a predominance of CDFs over CDDs. On December 20, for example,

1,2,3,4,6,7,8-HpCDF was present at a level of 2.16 pg/m^3, while the typically most predominant isomer 1,2,3,7,8-HpCDD had a value of 1.30 pg/m^3. Hunt et al. (1997) stated that further study "beyond examination of CDDs/CDFs data alone is warranted to provide a more conclusive source determination." Data from this study are not included in the ambient background level determinations in this chapter due to recommendations of the authors that "due to site-specific bias likely introduced by vehicular traffic at the Indian School Road site, the ambient CDDs/CDFs measured should not be construed to be representative of ambient CDDs/CDFs burdens in metropolitan Phoenix, as a whole."

Beginning in September 1996, a Canadian survey of CDD/CDFs in air was conducted at locations across Canada (Belzer et al., 1998). Some of the samples were collected near a coastal pulp mill operation at a location 1 kilometer southeast of a mill area. Data analysis indicated that CDD/CDFs concentrations from the mill area ranged from 0.006 to 0.067 pg I-TEQ_{DF}/m^3. These values were similar to those observed in other Canadian urban sites (0.01 to 0.08 pg I-TEQ_{DF}/m^3), but were lower than those measured near industrial point sources (0.01 - 0.4 pg I-TEQ_{DF}/m^3). The total CDD and CDF congener values for the mill area ranged from 0.17-3.94 pg/m^3, and the values of total homologue groups ranged from 0.77-5.53 pg/m^3. The results of this study suggest that production of CDD/CDFs from combustion sources is highly dependent on combustion material, temperature and moisture values (Belzer at al., 1998).

In 1997, EPA established the National Dioxin Air Monitoring Network (NDAMN) to determine the temporal and geographical variability of atmospheric CDDs, CDFs, and dioxin-like PCBs at rural locations through out the United States. NDAMN consists of 29 sampling stations whose three primary purposes are: (1) to determine the atmospheric levels and occurrences of dioxin-like compounds in rural and agricultural areas where livestock, poultry, and animal feed crops are grown; (2) to provide measurements of atmospheric levels of dioxin-like compounds in different geographic regions of the U.S.; and (3) to provide information regarding the long-range transport of dioxin-like compounds in air over the U.S. The first phase of NDAMN, which operated from June 1998 to June 1999, consisted of an array of 10 monitors at 9 sites spread out across the mid- to eastern-U.S. in the States of Pennsylvania (2), North Carolina, Florida, Wisconsin, Illinois, Iowa, Arkansas, Kansas, and Oklahoma. The sampling regime consisted of sampling 24 days (i.e., 6 days per week for 4 weeks), every other month, starting in the month of

June. This produced six sampling moments over a period of 1 year, with four composite samples (i.e., 4 weeks) per sampling moment. The analytes of interest in this monitoring program are the 17 CDD/CDFs and the coplanar PCBs (77, 105, 118, 126, 156, 157, and 169). The interim results from the nine monitoring stations are shown in Table 3-5, and are summarized as follows:

1. The overall annual average TEQ_{DF}-WHO_{98} air concentration was 12 fg/m^3.

2. All congeners were detected at a frequency >95%.

3. There was a 6-fold range in TEQ_{DF}-WHO_{98} annual average air concentrations from the lowest to the highest: 4.2 fg/m^3 at Lake Scott, Kansas, to 25.4 fg/m^3 at Monmouth, Illinois.

4. The variability of TEQ_{DF}-WHO_{98} over 6 monitoring moments at the 9 sites indicate a significant increase in TEQ_{DF}-WHO_{98} across all sites during the November/ December monitoring period. During this month, the TEQ_{DF}-WHO_{98} increased by up to 9-fold over any other moment during the year. The increase in TEQ was characterized by a large increase in actual measured concentrations of 1,2,3,7,8-PeCDD and 2,3,7,8-TCDD. This is consistent with the seasonal patterns reported in previous studies.

5. The TEQ_P-WHO_{98} was small compared to TEQ_{DF}-WHO_{98} (range: 0.2 to 1.3 fg/m^3; mean: 0.7 fg/m^3).

PCBs in ambient Canadian air were evaluated by Hoff et al. (1992). A total of 143 air samples from Egbert, Ontario, Canada, taken in 1988 and 1989 were analyzed for various vapor-phase PCB congeners. The annual mean concentrations for these samples are presented in Table 3-6. These means were calculated by assuming that nondetectable concentrations were zero. Based on the mean concentrations for the limited set of toxic PCB congeners in Hoff et al. (1992) (i.e., PCBs 105, 114, 118, 156, 170, 180, and 189),

the total TEQ_P-WHO_{94} concentration is estimated to be 0.00094 pg/m^3 (TEQ_P-WHO_{98} = 0.00088 pg/m^3).

3.2.2. European Data

Clayton et al. (1993) conducted a study of CDDs and CDFs in the ambient air of three major cities (London, Manchester, and Cardiff) and an industrial town (Stevenage) in the United Kingdom. Annual median I-TEQ_{DF} concentrations of CDDs and CDFs ranged from 0.04 to 0.10 pg/m^3. Hepta- and octachlorinated dioxin congeners contributed the most to the total concentration of 2,3,7,8-substituted CDD/CDFs, and a large number of nondetect values were reported for the tetra-, penta-, and hexachlorinated dioxins. Congeners that contributed most to the total I-TEQ_{DF} concentrations were 2,3,7,8-TCDF; 1,2,3,4,7,8-; 1,2,3,6,7,8-; and 2,3,4,6,7,8-HxCDF. The United Kingdom's Department of the Environment, Transport and the Regions has posted air monitoring data from 1991 through 1993 on the Internet (Department of the Environment, Transport and the Regions, 1998). Sampling locations include the same UK cities monitored by Clayton et al. (1993), as well as an urban site in Middlesbrough and a rural site at Hazelrigg. Mean CDD/CDF I-TEQ_{DF} concentrations from the quarterly sampling periods ranged from 0.15 to 0.34 pg/m^3 for Cardiff (8 quarters monitored), 0.10 to 0.34 pg/m^3 for Stevenage (5 quarters), 0.012 to 0.33 pg/m^3 for Middlesbrough (7 quarters), 0.044 to 1.4 pg/m^3 for Manchester (12 quarters), 0.016 to 0.28 pg/m^3 for London (12 quarters), and 0.004 to 0.21 pg/m^3 for Hazelrigg (12 quarters), when nondetects were set at the detection limit. When nondetects were set to zero, mean I-TEQ_{DF} concentrations ranged from 0.063 to 0.30 pg/m^3 for Cardiff, 0.034 to 0.30 pg/m^3 for Stevenage, $<$0.001 to 0.21 pg/m^3 for Middlesbrough, 0.036 to 0.69 pg/m^3 for Manchester, 0.008 to 0.24 pg/m^3 for London, and 0.003 to 0.17 pg/m^3 for Hazelrigg. The sum of the quarterly mean PCB concentrations of PCBs 2, 52, 101, 118, 138, 153, and 180, for these same cities, ranged from 164 to 985 pg/m^3 for Cardiff (10 quarters monitored), 189 to 395 pg/m^3 for Stevenage (5 quarters), 78 to 359 pg/m^3 for Middlesbrough (9 quarters), 181 to 704 pg/m^3 for Manchester (14 quarters), 651 to 2,482 pg/m^3 for London (14 quarters), and 77 to 198 pg/m^3 for Hazelrigg (8 quarters). These CDD/CDF values are relatively consistent with the concentrations in ambient German air observed by Liebl et al. (1993) and König et al. (1993a). Liebl et al. (1993) analyzed ambient air samples collected from 10 sites in

Hessen, Germany, from 1990 through 1992. Concentrations ranged from 0.04 to 0.15 pg I-TEQ_{DF}/m^3. The higher concentrations were presumed to result from direct local industrial sources. König et al. (1993a) collected air samples from six sites in Hessen, Germany. CDD/CDF concentrations ranged from 0.048 pg I-TEQ_{DF}/m^3 at a rural reference site to 0.146 pg I-TEQ_{DF}/m^3 at an industrial site. The results of the study also indicated that concentrations of CDDs and CDFs are typically higher in the winter than in the summer. Sugita et al. (1993) also observed higher concentrations of CDDs and CDFs in winter than in summer in an ambient air study in urban Japan. The average concentration of CDDs and CDFs was 0.788 pg I-TEQ_{DF}/m^3 in the summer and 1.464 pg I-TEQ_{DF}/m^3 in winter.

Fiedler et al. (1997b) conducted a 3-year air monitoring study that examined the CDD/CDF levels near two municipal solid waste incinerators (MSWI) located in Bavaria, Germany (Augsburg and Burgkirchen). The authors observed that the I-TEQ_{DF} concentrations at these locations were comparable and concentrations were consistently higher during winter months that in summer months. For example, at Augsburg, the lowest concentration (0.009 pg I-TEQ_{DF}/m^3) was obtained during the summer of 1995, and the highest concentration (0.206 pg I-TEQ_{DF}/m^3) was observed in the winter of 1994/1995. Background concentrations for these time periods ranged from 0.0076 to 01.29 pg I-TEQ_{DF}/m^3. For Burgkirchen, the lowest concentration (0.0044 pg I-TEQ_{DF}/m^3) was observed during the summer of 1994, and the highest concentration (0.078 pg I-TEQ_{DF}/m^3) was observed during the winter of 1995/1996.

In a Swedish study, air samples were collected from a city center, suburb, remote countryside, and open coastal area (Broman et al., 1991). Analyses of the samples for dioxins and furans indicated that the concentrations of these compounds decreased with increasing distance from the city center. Total CDD/CDF concentrations were 1.40 pg/m^3, 1.10 pg/m^3, 0.40 pg/m^3, and 0.22 pg/m^3 for the city center, suburb, countryside, and open coastal areas, respectively. Similar patterns of decreasing concentrations with increasing distances from urban areas were also observed for individual CDD/CDF congeners (Broman et al., 1991). In a study of ambient air concentrations of CDDs and CDFs in Flanders, samples were collected and analyzed at rural, industrial, and urban sites (Wevers et al., 1993). Average ambient air concentrations ranged from 0.0696 pg I-TEQ_{DF}/m^3 at a rural site to 0.254 pg I-TEQ_{DF}/m^3 at a site believed to be influenced by a

chemical industry and a highway. Naf et al. (1990) analyzed urban air samples from a site near a wastewater treatment plant in Sweden. The samples were collected as part of a study to estimate the flux of CDD/CDFs through the treatment plant. All 2,3,7,8-substituted congeners (except 1,2,3,7,8,9-HxCDD and 1,2,3,4,7,8,9-HpCDF) were detected. The mean I-TEQ_{DF} for urban air was estimated to be 0.02 pg/m^3.

Hiester et al. (1995) observed a decrease of CDD/CDF concentrations in Germany's ambient air over a 6-year period. Ambient air samples were collected over 12 sampling intervals from 4 sites in the heavily industrialized Rhine-Ruhr region of Germany during 1987/88 and 1993/94. Total I-TEQ_{DF}s for these sites ranged from 0.13 pg/m^3 to 0.33 pg/m^3 during 1987/88 and from 0.04 pg/m^3 to 0.12 pg/m^3 for the 1993/94 time period. Reductions in I-TEQ_{DF}s ranged from 46 to 69 percent at these sites over the 6-year period (i.e, from 0.22 pg/m^3 to 0.13 pg/m^3 at Dortmund and from 0.13 pg/m^3 to 0.04 pg/m^3 at Köln). These reductions were attributed to abatement actions taken since 1989 (Hiester et al. 1995).

Between November 1992 and October 1993, the Austrian Federal Environmental Agency monitored six air stations for ambient air concentrations of CDD/CDFs (Umweltbundesamt, 1994; 1996). One hundred samples were taken from industrial and population sites; three sites in Vienna, one in Steyregg, one in Linz, and one in Graz. The arithmetic annual average value of ambient levels for all samples ranged from 0.03 to 0.12 pg I-TEQ_{DF}/Nm^3. Average winter levels ranged from 0.05 to 0.24 pg I-TEQ_{DF}/Nm^3; while the summer levels ranged from 0.02 to 0.04 pg I-TEQ_{DF}/Nm^3. Winter levels observed in Graz were two times the winter concentrations found at the other sampling sites. Levels were consistently highest (i.e., two to three times higher) for the measuring period between February 1 and 4 at all the measuring sites. This time period coincided with an extremely stable meteorological condition or inversion. All locations demonstrated a decrease in the proportion of CDFs from the tetra- to octachlorinated congeners, while the opposite was true for CDDs. However, there were differences in the congener profiles for different locations. For example, the Graz location showed a higher proportion of octa- and heptachlorinated dioxins, while tetrachlorofurans predominated at the hospital site in Vienna and also at the Steyregg and Linz sites.

Samples of ambient air were collected from 15 locations throughout Slovakia, including urban, industrial, agricultural and rural sites, between October 1996 and August

1997 (Stenhouse et al., 1998). A total of 113 samples were analyzed for CDD/CDFs. The average ambient I-TEQ_{DF} concentrations for these locations ranged from 0.05 pg/m^3 to 0.13 pg/m^3 at urban/industrial areas (with an average of 0.1 pg/m^3), 0.07 pg/m^3 for agricultural areas and 0.04 pg/m^3 for rural background. The values of any congeners below the detection limit (0.01 pg/m^3) were included in the I-TEQ_{DF} at the detection limit. Higher ambient I-TEQ_{DF} values were observed in the winter than in the summer at the places where the major source was combustion. Stenhouse et al. (1998) suggested that seasonal variation would not be expected if industrial processes and traffic were significant contributors.

PCBs have also been evaluated in European air samples (Halsall and Jones, 1993; König et al., 1993b). Halsall and Jones (1993) monitored urban air at two sites in the United Kingdom. The annual mean total PCB concentrations were 520 and 590 pg/m^3. PCBs existed in ambient air predominantly in the vapor phase. This study also indicated that summer PCB concentrations were higher than winter concentrations. These researchers attributed the differences in seasonal patterns to volatilization from soil during summer months. Ambient air concentrations of PCBs in Hessen, Germany, ranged from 350 to 1630 pg/m^3 during the period of 1990 to 1992 (König et al., 1993b). Urban areas characterized by industry and/or heavy traffic had the highest PCB concentrations in ambient air. Hiester et al. (1995) also evaluated total PCB concentrations in ambient air samples from several sites in Germany during 1993/94. Table 3-7 presents the annual average dioxin-like PCB concentrations in ambient air of several German cities. Annual mean total PCB concentrations ranged from 1,000 pg/m^3 to 2,000 pg/m^3 in urban locations and from 100 pg/m^3 to 300 pg/m^3 in rural locations.

Recently, Currado and Harrad (1997) measured indoor air concentrations of PCBs from nine different indoor environments, including two laboratories, two offices, and five residential homes in the United Kingdom. The results indicated that the total PCB levels found in indoor air (1.4 to 19.1 ng/m^3; mean 7.1 ng/m^3) were between 2 and 19 times higher than the levels in outdoor air (0.77 to 0.87 ng/m^3; mean 0.82 ng/m^3). It should be noted that the study did not focus on dioxin-like PCBs; only concentrations of four dioxin-like PCB congeners were reported in indoor and outdoor areas. Thus, TEQ concentrations in indoor air were not calculated. Studies that examine background CDD/CDF levels in indoor environments were not available.

3.2.3. Air Observations and Trends

Some general observations for CDD/CDF levels in air are possible from the various air studies discussed in this chapter:

- Concentrations in urban settings are higher than those in rural settings.
- Concentrations associated with source impacted areas are the highest.
- As the degree of chlorination increases, so does the congener concentration.
- Based on the limited ambient air measurements made in selected cities in the United States and Europe, there appears to be good agreement with respect to the magnitude of specific congeners of CDDs and CDFs in urbanized areas in the United States and Europe.
- Many of the air measurements tend to be very close to the current analytical detection limit. This increases the probability that congeners indicated as not detected (ND) may actually be present.

3.2.4. Air CDD/CDF Profiles and Background TEQ Concentrations

CDD/CDF profiles were calculated for rural and urban air. Rural air profiles used data from OEPA (1995), CDEP (1988), and Cleverly et al. (2000). Urban air profiles used data from CDEP (1988, 1995), Smith et al. (1989, 1990a), Maisel and Hunt (1990), Hunt et al. (1990), and OEPA (1995). CDD/CDF homologue group and 2,3,7,8-substituted congener profiles for air are presented in Table 3-8 and Figures 3-1 and 3-2. The CDD/CDF homologue profile was calculated by dividing individual homologue group concentrations by the total CDD/CDF concentration. This profile indicates that OCDD is the predominant homologue group in rural and urban background air followed by HpCDD. TCDD accounts for the lowest percentage of total CDD/CDFs. Congener group profiles were calculated as the ratio of individual 2,3,7,8-substituted congener concentrations to total CDD/CDF concentration (i.e., the sum of homologue group concentrations). The concentration of 2,3,7,8-substituted congeners accounts for 57 percent of the total CDD/CDF concentration in urban background air. In rural background air, 2,3,7,8-substituted CDD/CDFs account for 59 percent of the total CDD/CDF concentration. Of the 2,3,7,8-substituted CDD/CDF congeners, OCDD accounts for the highest percentage (i.e., 39 percent rural; 34 percent urban) of total CDD/CDFs, followed by the 1,2,3,4,6,7,8-HpCDD in rural and urban background air.

Table 3-9 presents a summary of the TEQ_{DF}-WHO_{98} concentrations of CDD/CDFs in the United States. Assuming that nondetects are equal to one-half the detection limit, the mean TEQ_{DF}-WHO_{98} concentration was 0.013 pg/m^3 for rural background sites (i.e., sites in Connecticut and Ohio, and NDAMN sites in Pennsylvania (2), North Carolina, Florida, Wisconsin, Illinois, Iowa, Arkansas, Kansas, and Oklahoma) (n = 60; CDEP, 1995 (n = 4); OEPA, 1995 (n = 3); Cleverly et al., 2000 (n = 53)), and 0.12 pg/m^3 for urban background sites (i.e., from 14 sites in Connecticut, California, Ohio, and New York) (n = 106; CDEP, 1988; CDEP, 1995; Hunt and Maisel, 1990; Maisel and Hunt, 1990; OEPA, 1995; Smith et al., 1989; Smith et al., 1990a). These mean concentrations represent the average of the mean concentrations for the various sites and not the mean of all individual samples. (See weighted mean in Table 3-9.) The mean value is used to ensure that each site is weighted equally (i.e., heavily sampled sites do not have any greater impact on the overall mean than sites with fewer samples). Samples collected from urban locations not expected to be impacted by industrial point sources were assumed to represent "background" conditions for the majority of the U.S. population. The "typical" urban background TEQ_{DF}-WHO_{98} level was estimated to be 0.12 pg/m^3 based on the mean of the background samples collected in urban environments. (The I-TEQ_{DF} value for these sites is 0.11 pg/m^3). This value was used in Chapter 4 to characterize background exposures. The mean TEQ_P-WHO_{98} for rural sites was estimated to be 0.00071 pg/m^3 based on data from Cleverly et al. (2000).

Based on the results of European studies, ambient air concentrations of CDDs and CDFs appear to be similar to those found in the United States. Based on the midpoints of the European studies for which I-TEQ_{DF} concentrations were reported (Clayton et al. 1993; Liebl et al. 1993; König et al. 1993a; Wevers et al. 1993), the I-TEQ_{DF} air concentration for Europe is 0.11 pg/m^3. Data for these European studies are not included in Tables B-1 and B-2 of Appendix B because individual congener data were not reported.

It is interesting to compare these background air values with the CDD/CDF concentrations in air measured by Lugar (1993) in and around McMurdo Station, Antarctica, a logistics and staging facility with a population of about 1,100. Four locations were sampled: a site upwind of the station, downwind of the station, in the center of the station, and a remote unpopulated island 30 kilometers distant from the station. CDD/CDFs were not detected in the samples from the upwind site (congener

detection limits ranged from <0.01 to 0.03 pg/m^3), and few CDD/CDF congeners were detected at the remote island sites (congener detection limits ranged from 0.001 to 0.008 pg/m^3). CDD/CDFs were detected only sporadically at the downwind site (some congeners detected in three of five samples) and in all five samples collected from the station center site (mean I-TEQ$_{DF}$ concentration of 0.0153 pg/m^3). Similar results were obtained in a follow-up study during the austral summers 1992/93 and 1993/94. A total of 28 air samples were collected from these four sites (Lugar et al., 1996). CDD/CDFs were not detected at the upwind or remote island sites and trace levels of only a few CDD/CDFs were found in the downwind site. The highest CDD/CDF concentrations were observed at the downtown site, where CDD concentrations ranged from 0.12 to 1.80 pg/m^3, and CDFs ranged from 0.02 to 2.77 pg/m^3. I-TEQ$_{DF}$ values for this central McMurdo location were 0.074 pg/m^3 for 1992/93 and 0.0015 pg/m^3 for 1993/94. The most frequently detected congeners were the octa- and hepta-chlorinated CDDs.

3.3. CONCENTRATIONS IN SOIL

Tables B-4 and B-5 (Appendix B) contain summaries of data from several of the numerous studies in the published peer-reviewed literature regarding concentrations of CDDs and CDFs in soil. Only limited data on dioxin-like PCB congener soil concentrations were found in the literature (e.g., EPA Region 8, 2000); most of the PCB soil concentration data found in the literature were reported as either total PCB concentrations or concentrations of Aroclor PCB mixtures. Descriptions of several of the studies summarized in Appendix B are presented below. It should be noted that, the review of soil data presented here is not based on a comprehensive review of the published studies on CDD/CDFs in soil. Instead, it is intended to provide a brief overview of soil levels of CDD/CDFs from a sampling of representative studies. Because of the lack of geographic coverage and non-uniform study design associated with the soil data presented in this section, there is a degree of uncertainty associated with the estimates of background concentrations of CDD/CDFs in soil.

3.3.1. North American Data

Soil sampled in 1987 from the vicinity of a sewage sludge incinerator was compared with soil from rural and urban sites in Ontario, Canada, by Pearson et al.

(1990). Soil in the vicinity of the incinerator showed a general increase in CDD concentration with increasing degree of chlorination (Table 3-10). Of the CDFs, only OCDF was detected (mean concentration 43 ppt). Rural woodlot soil samples contained only OCDD (mean concentration of 30 ppt). Soil samples from undisturbed urban parkland settings revealed only HpCDDs and OCDD, but all CDF congener groups (Cl_4 to Cl_8) were present. Those samples showed an increase in concentration from the HpCDDs to OCDD and PeCDFs to OCDF. TCDFs had the highest mean value (29 ppt) of all the CDF congener groups. Resampling of one urban site in 1988, however, showed high variability in the concentrations of CDDs and CDFs.

Reed et al. (1990) analyzed background soil samples from a semi-rural location in Elk River, Minnesota, as part of a baseline assessment prior to the operation of a refuse-derived fuel-powered electric generation station. Four soil samples (two from an untilled site and two from a tilled site) were collected and analyzed for CDD/CDFs. Of the CDD/CDF congeners, OCDD concentrations were the highest, ranging from 340 ppt to 3,300 ppt. OCDF concentrations ranged from nondetect to 270 ppt. The 2,3,7,8-tetra and penta chlorinated congeners were not detected in any of the samples analyzed (Table 3-11).

Data were collected on CDD and CDF levels in soil samples from industrial, urban, and rural sites in Ontario and some U.S. Midwestern States (Birmingham, 1990). CDD/CDF levels in rural soils were primarily nondetect (ND), although the HpCDDs and OCDD were found in a few samples. In urban soils, the tetra- through octa-homologue groups were measured for both CDDs and CDFs. The HpCDDs and OCDD dominated and were two orders of magnitude greater than in the rural soils. These soils also contained measurable quantities of the TCDDs and PeCDDs. Industrial soils did not contain any TCDDs or PeCDDs, but they contained the highest levels of the TCDFs, HpCDFs, and OCDF. Total CDD/CDF concentrations averaged 73 $\pm$ 50 ppt in rural soils (n = 30), 2,075 $\pm$ 3,608 ppt in urban soils (n = 47), and 8,314 $\pm$ 9,955 ppt in industrial soils (n = 20) when nondetects were assumed to be zero. I-TEQ_{DF}s were also calculated for these three types of sites by Birmingham (1990) by assuming that the 2,3,7,8-substituted CDD/CDF congeners represent specified proportions of the homologue group concentrations and by applying I-TEF_{DF}s. Birmingham (1990) estimated the I-TEQ_{DF}s to be

0.4 ± 0.6 ppt for rural soil, 11.3 ± 21.8 ppt for urban soils, and 40.8 ± 33.1 for industrial soils.

In another study, soils from industrialized areas of a group of cities from Midwestern and Mid-Atlantic States (Michigan, Illinois, Ohio, Tennessee, Pennsylvania, New York, West Virginia, Virginia) were analyzed for levels of 2,3,7,8-TCDD (Nestrick et al., 1986). Many of the samples were taken within 1 mile of major steel, automotive, or chemical manufacturing facilities, or municipal solid waste incinerators. Concentrations of 2,3,7,8-TCDD measured in this study ranged from ND to 9.4 ppt.

Nine background soil samples were collected from the Yarmouth Pole Yard Site located in Yarmouth, Maine (Tewhey Associates, 1997). One of these samples, collected from soil near the base of a utility pole, yielded an I-TEQ_{DF} concentration of 57,000 pg/g. The I-TEQ_{DF} concentrations for the other eight samples ranged from 0.73 pg/g to 5.9 pg/g when nondetects were assumed to be zero, and 1.46 pg/g to 6.07 pg/g when nondetects were assumed to be one-half the detection limit. These samples are from rural background locations. The mean I-TEQ_{DF} for these eight samples was 3.58 pg/g (TEQ_{DF}-WHO_{98} was 2.89 pg/g) when nondetects were set to zero and 3.93 pg/g when nondetects were set to one-half the detection limit. The sample collected near the utility pole was not included in these mean TEQ values, because its results were not considered to be representative of typical rural background concentrations.

In an effort to determine whether incineration of municipal waste influenced CDD/CDF levels in the immediate area of waste incineration facilities, soil samples were collected from cities with, and without operating incinerators throughout Connecticut. Between the years of 1987 and 1990, 34 soil samples were collected from eight different Connecticut cities where no municipal waste incinerators were operating (MRI, 1992). These pre-operational samples were considered to be representative of rural background concentrations. The total I-TEQ_{DF} reported for these samples was 6.07 pg/g, with nondetects assumed to be one-half the detection limit. When the total TEQ was recalculated in units of TEQ_{DF}-WHO_{98}, the total TEQ for these samples was 5.74 pg TEQ_{DF}-WHO_{98}/g. The proportion of nondetects ranged from 3 to 11 percent of samples for each analyte, with the exception of 2,3,7,8-TCDD and 1,2,3,7,8,9-HxCDF, which had 56 and 49 percent nondetects, respectively (MRI, 1992).

The Ministry of Environment in British Columbia conducted a 2-year monitoring study during 1990/91 and 1991/92 to evaluate the levels of CDD/CDF contamination in various types of environmental media (BC Environment, 1995). Soil samples were collected from sites close to a source (primary sites), in the receiving environment adjacent to a suspected source (secondary sites), and in areas not expected to be contaminated (background). Primary and secondary sources were identified as chemical or combustion sources. Chemical sources included sites associated with chlorophenol, herbicide, or PCB contamination; oil refineries; pulpmill landfills; or sewage facilities. Combustion sources included biomedical, industrial, municipal, or sewage sludge incineration; PCB or forest fires; pulp mill boilers; salt-laden wood burning, woodwaste burners, or slash burning; and scrap iron yards or smelters. The highest mean concentrations of 2,3,7,8-TCDD and 2,3,7,8-TCDF were observed in primary and secondary soils associated with chemical sources (Table 3-12). For the 53 background samples, 2,3,7,8-TCDD was not detected, and 2,3,7,8-TCDF concentrations ranged from nondetected to 3.2 ppt. For the purposes of calculating I-TEQ_{DF} values for this study, nondetects were set to zero. I-TEQ_{DF}s were highest among samples associated with primary and secondary chemical sources (Table 3-12). The mean I-TEQ_{DF} for the background soil samples was 5.0 ppt (BC Environment, 1995). When the mean TEQ was recalculated in units of TEQ_{DF}-WHO_{98}, the total TEQ for these samples was 4.4 pg TEQ_{DF}-WHO_{98}/g.

Grundy et al. (1995) and Bright et al. (1995) collected soil samples from remote locations in the Canadian Arctic as part of an environmental assessment of abandoned military installations in the Canadian North. Four soil samples from remote pristine areas (i.e., at least 20 km away from any human activity) were analyzed for CDD/CDFs. The total I-TEQ concentrations for these samples ranged from 0.2 to 0.9 ppt (Grundy et al., 1995). Of the CDD/CDF homologue groups, OCDD and TCDF levels were the highest among these remote soil samples, and the HxCDFs made up the smallest portion of the total CDD/CDF concentrations (Bright et al., 1995).

EPA conducted a 2-year nationwide study to investigate the national extent of 2,3,7,8-TCDD contamination (U.S. EPA, 1987). Results of this large study were summarized broadly in the primary reference (i.e., the number and types of samples per site and range of detection). The method used to analyze samples for five of the seven

study "tiers" had a detection limit in soil, sediment, and water of 1 part per billion (ppb). [Each "tier" of sites is a grouping of sites with a common past or present use (e.g., industrialized, pristine, etc.)]. Only Tier 5 (sites where pesticides derived from 2,4,5-trichlorophenol (TCP) had been or were being used for commercial purposes) and Tier 7 (ambient sampling for fish and soil) had detection limits of 1 ppt. Consequently, the data from this study are not included in the Appendix B tables; however, some observations from this study with regard to soil contamination are discussed below.

Soil concentrations found in most of the 100 Tier 1 and 2 sites (i.e., sites already on or expected to be on the NPL list) were in the ppb range; although in a few sites where concentrated 2,4,5-TCP production wastes were stored or disposed, concentrations were as high as 2,000 parts per million (ppm). Off-site soil contamination of concern was confirmed in 7 of the 100 Tier 1 and 2 sites, with soil concentrations in the ppb range. Eleven of the 64 Tier 3 sites (facilities and associated disposal sites where 2,4,5-TCP and its derivatives were formulated into pesticide products) were found to have soil concentrations exceeding 1 ppb, and in 7 of 11 sites where contamination was found, only one or two soil samples were above 1 ppb. Fifteen of the 26 Tier 5 sites (areas where 2,4,5-TCP and pesticide derivatives had been or were being used) had concentrations above 1 ppt, and one of those had a single detection of 6 ppb. Two-thirds of all detections at the Tier 5 sites were below 5 ppt. Three of the 18 Tier 6 sites (organic chemical and pesticide manufacturing facilities where improper quality control on production processes could have resulted in 2,3,7,8-TCDD being introduced into the wastestreams) had soil concentrations that exceeded the detection limit of 1 ppb, although these levels were limited to one or two samples per site. Seventeen of the 221 urban soil sites and 1 of the 138 rural sites from Tier 7 (background sites not expected to have contamination) had soil concentrations exceeding 1 ppt. The highest concentration detected (11.2 ppt) was found in an urban sample. Results from Tier 7 are consistent with the other studies discussed in this chapter regarding soil concentrations of 2,3,7,8-TCDD in nonindustrial settings.

Rappe et al. (1995a) and Fiedler et al. (1995a) analyzed soil samples collected from rural sites in southern Mississippi for CDDs and CDFs. Sites not directly impacted by human activities such as heavy traffic or dust were selected. A total of 36 composite soil samples from 8 Mississippi counties were analyzed. The I-TEQ_{DF} concentration of

CDD/CDFs in soil ranged from 0.16 to 22.9 ppt dry mass (Fiedler et al., 1995a). The mean I-TEQ_{DF} concentration was 3.1 ppt dry mass, and the median I-TEQ_{DF} concentration was 0.8 ppt dry mass (Fiedler et al., 1995a). CDDs were found at higher concentrations than CDFs, and OCDD was the most dominant congener.

Soil samples were collected from the National Institutes of Health (NIH) campus in Bethesda, Maryland, during 1995 in an effort to determine the effect of 30 years of pathological waste incineration on the campus and its surroundings (NIH, 1995). Thirty-seven samples were collected from the soil at a depth of 6 inches. The total I-TEQ_{DF} for these samples was 7.83 pg/g, when nondetects were assumed to be zero, and 8.49 pg/g, when nondetects were assumed to be one-half the detection limit. OCDD, at a I-TEQ_{DF} concentration of 6.29 pg/g, was the principal contributor to the total I-TEQ_{DF} for these samples, regardless of whether nondetects were assumed to be zero or one-half the detection limit. It should be noted that using the new TEF_{DF}-WHO_{98}s, the TEQ for OCDD would be 10 times lower (i.e., 0.63 pg/g). This reduction would also result in a significant decrease in the total TEQ. The total TEQ_{DF}-WHO_{98} would be 2.21 pg/g, when nondetects were set to zero. Samples were also collected at depths of 12 and 24 inches for comparison to levels found in the shallow (6-inch) samples. While CDD/CDF concentrations found at the surface indicate deposition, strong correlation with I-TEQ_{DF} concentrations at the deeper depths were observed. This seemed to indicate either long-term presence of the source (i.e., greater than 40 years), or soil mixing that has occurred either during or after deposition. An expert panel (comprised of toxicologists, chemists, soil scientists, engineers, risk assessors, and public health professionals) concluded that the levels of I-TEQ_{DF} in the samples are low and not significantly different from background. Thus, these samples are assumed to be representative of urban background concentrations. The spatial pattern of I-TEQ_{DF} concentrations showed no particular trends that could be related to the incinerator. Other anthropogenic activities, such as vehicular traffic, other medical waste incinerators not related to NIH, and fireplaces burning in the vicinity, may have contributed to the deposition (NIH, 1995).

U.S. EPA (1996) collected soil samples in the vicinity of a municipal waste-to-energy (WTE) facility in Columbus, Ohio, to determine whether surface soils around the incinerator contained higher CDD/CDF levels than soils collected from background sites. The facility is not currently in operation, but CDD/CDF residues may be present in the soil

near the facility as a result of past emissions. Samples were collected from (1) on-site, (2) urban background locations near the incinerator, and (3) areas remote from the facility (i.e., rural background sites). The results of the analyses indicate that soil from the rural background sites had the lowest I-TEQ_{DF} concentrations and on-site samples had the highest I-TEQ_{DF} concentrations (Table 3-13). For rural background soil samples, total I-TEQ_{DF}s ranged from 0.9 to 1.3 ppt (n = 3) with a mean of 1.1 ppt (TEQ_{DF}-WHO_{98} = 0.9 ppt), when nondetects were assumed to be zero, and 1.0 to 2.0 ppt with a mean of 1.4 ppt (TEQ_{DF}-WHO_{98} = 1.3 ppt), when nondetects were set to one-half the detection limit. Total I-TEQ_{DF}s for urban background soils ranged from approximately 3 to 60 ppt (n = 18) with a mean of 19 ppt (TEQ_{DF}-WHO_{98} = 21 ppt), when nondetects were set to either zero or one-half the detection limit. For on-site samples, all 2,3,7,8-CDD/CDF congeners were detected in all samples (n = 4). Total I-TEQ_{DF} concentrations ranged from 50 to 760 ppt with a mean of 356 ppt (TEQ_{DF}-WHO_{98} = 444 ppt). Additional detail and analyses of these data are presented in Lorber et al. (1998a).

Brzuzy and Hites (1995) examined soil cores from four U.S. locations to evaluate the accuracy of using measurements of CDD/CDF homologue groups in estimating the atmospheric flux of these compounds into the environment. Soil cores were collected from undisturbed areas near Shingleton, Grayling, and Verona, Michigan, and near Mitchell, Indiana. CDD/CDF concentrations varied according to depth of the soil samples, with deeper samples having lower CDD/CDF concentrations. Approximately 80 percent of the CDD/CDF load were contained in the top 15 cm of the cores, and CDD/CDF concentrations were close to the detection limit in samples collected at a depth of 20-25 cm. Based on the graphs presented in Brzuzy and Hites (1995), total CDD/CDF concentrations in the uppermost 5 cm of the core ranged from approximately 60 pg/g to 200 pg/g for the three Michigan sites. CDD/CDFs in these soil cores were also found to be highly correlated with the organic carbon content of the soil, indicating that organic carbon is an important factor in the sorption of CDD/CDFs to soil (Brzuzy and Hites, 1995). Higher concentrations of CDD/CDFs were observed in two cores taken from the Indiana site. Concentrations in the uppermost layer (i.e., 9 cm) of these cores ranged from approximately 700 pg/g to nearly 10,000 pg/g. CDD/CDF concentrations in these cores peaked at a depth of approximately 40 to 50 cm with concentrations ranging from approximately 1,000 pg/g to over 20,000 pg/g. Brzuzy and Hites (1995) used the

Michigan data to estimate soil-derived CDD/CDF flux rates ranging from 264 ng/m^2/yr for upper Michigan to 663 ng/m^2/yr for lower Michigan. These soil-derived flux estimates were compared to sediment-derived fluxes from previous studies to determine if soil samples can also be used to accurately predict atmospheric flux. Good agreement for the fluxes to these two media was observed. In addition, the CDD/CDF homologue profiles for soil and sediment were similar.

Recently, Washington State Department of Ecology (Rogowski et al., 1999) collected soil samples as part of a study of metals and dioxin-like compounds in agricultural fertilizers and soil amendments. Soils were analyzed to evaluate whether these compounds had accumulated as a result of fertilizer use and to assess typical concentrations of dioxin-like compounds in Washington State soils. A total of 30 soil samples were collected from urban (N = 14), rangeland (N = 8), and forested (N = 8) locations. Each sample was a composite of 10 sub-samples collected within a 1-acre sampling unit. The sampling units were selected to represent typical or background locations for each land use. Mean TEQ_{DF}-WHO_{98} concentrations were higher in urban locations (4.1 ppt) than in open rangeland/forest locations (1.8 ppt). During a later sampling event (Rogowski and Yake, 1999), agricultural soils were collected to characterize typical or background concentrations of dioxin-like concentrations in soil. Fifty-four samples were collected. Each sample was a composite of 10 sub-samples collected from each sampling location to a depth of 5 cm. The mean TEQ_{DF}-WHO_{98} concentration for the agricultural samples was 0.12 ppt.

U.S. EPA Region 8 (2000a) is conducting a set of four related studies on dioxin-like compounds in surficial soils along Denver, Colorado's, Front Range. One of these studies (U.S. EPA Region 8, 2000b) evaluated regional background soil; other sampling efforts include characterization of the Rocky Mountain arsenal using random samples at the site or from historic use sites. A large number of reference soils were collected and analyzed for CDD/CDFs and dioxin-like PCBs. These data will be used to assess whether the soil concentrations observed in the Western Tier Parcel of the Rocky Mountain Arsenal, an EPA National Priority List site, are higher than regional background levels. U.S. EPA Region 8 (2000b) collected and analyzed 162 surface soil samples for investigation into background concentrations of dioxin-like compounds at multiple locations within 1,000 square miles of Denver, Colorado's, front range. The multi-land use areas that were

sampled were situated on public lands and were categorized as agricultural (n = 27), commercial (n = 31), industrial (n = 29), open space (n = 36), and residential (i.e., within 200 feet of private land) (n = 39). The fine-soil fractions of samples obtained in the upper two inches of the soil were analyzed for the 17 dioxins and furans and 12 PCBs (77, 81, 105, 114, 118, 123, 126, 156, 157, 167, 169, and 189). The mean TEQ_{DFP}-WHO_{98} ranged from less than 1 ppt TEQ to approximately 100 ppt TEQ (with two outliers of 142 and 155 ppt removed; one from a residential site and one from a commercial site). The mean TEQ_{DFP}-WHO_{98} values were: 1.9 ppt for agricultural sites, 8.5 ppt for commercial sites, 15.4 ppt for industrial sites, 2.8 ppt for open space, and 8.6 ppt for residential locations, with a total mean of 7.5 ppt when non-detects were set to one-half the detection limit (U.S. EPA Region 8, 2000b, with revised data provided by Gerry Henningsen, Region 8 to Jim Buchert, Versar, Inc., March 2001). PCBs comprised approximately 20 percent of the TEQ_{DFP}-WHO_{98}. The analytical values indicate that open space and agricultural lands have the lowest TEQ_{DFP}-WHO_{98} concentrations, while industrial, commercial, and residential locations have slightly higher concentrations. It should be noted that because sieved samples were analyzed, these results may be higher than if bulk samples had been analyzed. Further testing is being conducted to identify if the increased total organic carbon content of agricultural and open space soils have a higher affinity for dioxin-like compounds than other soil types, thereby skewing the analytical results to produce lower than actual values.

3.3.2. European Data

Soil samples from rural and semi-urban sites in England, Wales, and lowland Scotland showed a general increase in concentration from the TCDDs to OCDD, whereas CDF levels showed very little variation between the congener groups (Creaser et al., 1989). Concentrations of 2,3,7,8-TCDD at those sites ranged from <0.5 to 2.1 ppt. The median values for the TCDDs to OCDD were 6.0, 4.6, 31, 55, and 143 ppt, respectively. The median values for the TCDFs to OCDF were 16, 17, 32, 15, and 15 ppt. Evaluation of soil data from urban sites in the same geographical area showed that the mean levels for the CDD and CDF congeners were significantly greater ($p<0.01$) than those for rural and semi-urban background soils (Creaser et al., 1990). Concentrations of 2,3,7,8-TCDD at the urban sites ranged from <0.5 to 4.2 ppt. The median values for the

TCDDs to OCDD were 40, 63, 141, 256, and 469 ppt, respectively. The median values for the TCDFs to OCDF were 140, 103, 103, 81, and 40 ppt. Significantly elevated levels of the lower congeners, together with higher overall CDD/CDF concentrations, are indicative that local sources and short-range transport mechanisms are major contributors of CDDs and CDFs to urban soils. Cox and Creaser (1995) evaluated soils from urban and rural locations in the United Kingdom before the introduction of Integrated Pollution Control in 1991. I-TEQ_{DF}s for 11 rural locations ranged from 0.78 ppt to 17.48 ppt, with a mean of 5.17 ppt, and the I-TEQ_{DF}s for 5 urban samples ranged from 4.88 pt to 87.34 ppt with a mean of 28.37 ppt.

Analysis of four sites in Hamburg, Germany, contaminated by an organochlorine pesticide manufacturing company showed patterns of CDD and CDF distribution similar to the urban and industrial sites examined in England, Wales, and Scotland (Sievers and Friesel, 1989). The study indicated that CDDs and CDFs showed a regular increase in concentration with increasing degree of chlorination (although individual data points were not presented). Maximum concentrations of 2,3,7,8-TCDD ranged from 900 ppt to 874,000 ppt. Very high concentrations of 2,3,7,8-TCDD at the sites were attributed to an admixture of wastes from 2,4,5-T production.

A soil sampling survey in Salzburg, Austria, also showed that the concentrations of CDD/CDFs were higher in urban and industrial sites than in rural sites (Boos et al., 1992). The total CDD content of the soils ranged from 33.7 to 1236.7 ppt for urban sites, 92.2 to 455 ppt for industrial sites, and 7.1 to 183.6 ppt for rural sites. The total CDF content of the soils ranged from 45.6 to 260.8 ppt for urban sites, 53.0 to 355.3 ppt for industrial sites, and 12.0 to 77.7 ppt for rural sites. I-TEQ_{DF}s ranged from 0.1 ppt to 3.1 ppt for rural sites, 1.0 ppt to 8.3 ppt for urban sites, and 3.5 ppt to 11.5 ppt for industrial sites, when nondetects were assumed to be zero. When nondetects were set to one-half the limit of detection, I-TEQ_{DF}s ranged from 1.3 ppt to 3.8 ppt for rural sites, 2.0 ppt to 8.6 ppt for urban sites, and 4.1 ppt to 12.5 ppt for industrial sites.

Rappe and Kjeller (1987) presented data on CDD/CDFs in soil collected from rural ($n = 3$) and industrial ($n = 2$) sites in various parts of Europe. Concentrations were higher among industrial soils than rural soils for all of the CDD/CDF homologue groups, and the hepta-chlorinated compounds made up the largest portion of the total CDD/CDF concentrations in both rural and industrial samples. HpCDDs ranged from nondetected to

17 ppt in rural samples and 370 to 1,600 ppt in industrial samples. HpCDFs ranged from 14 to 22 ppt in rural soils and 260 to 4,500 ppt in industrial soils.

Rotard et al. (1994) measured CDD/CDFs in soil samples collected from forest, grassland, and plowland sites in western Germany. The highest mean concentration of CDD/CDFs were found in the subsoil and topsoil layers of deciduous (38.0 ng I-TEQ_{DF}/kg dry matter; n = 9) and coniferous forests (36.9 ng I-TEQ_{DF}/kg dry matter; n = 11). Grassland and plowland sites had mean concentrations of 2.3 ng I-TEQ_{DF}/kg dry matter (n = 7) and 1.7 ng I-TEQ_{DF}/kg dry matter (n = 14), respectively.

Stenhouse and Badsha (1990) collected baseline data for soils around a site proposed for a chemical waste incinerator in Great Britain. All of the 2,3,7,8-substituted CDD/CDF congeners, except PeCDD, were detected in all samples. Concentrations were highest for the octa-chlorinated CDD/CDFs. Background I-TEQ_{DF} concentrations ranged from 3 to 20 ppt. The mean I-TEQ_{DF} concentration was 8 ppt (n=12), with a standard deviation of 4 ppt.

Buckland et al. (1998) evaluated soils collected in New Zealand. Dry weight CDD/CDF concentrations ranged from 0.17 to 1.99 pg I-TEQ_{DF}/g for pristine soils, 0.17 to 0.90 pg I-TEQ_{DF}/g for agricultural soils, and 0.52 to 6.67 pg I-TEQ_{DF}/g for urban soils. The PCB concentrations ranged from 0.067 to 2.3 pg TEQ_P/g (the TEFs used for PCBs were not identified) for provincial centers and 0.087 to 1.33 pg TEQ_P/g for metropolitan centers. The congeners below the detection limit were included in the total TEQ using half their limits of detection.

Masahide et al. (1998a) examined soil samples collected at the depth of 0-10 cm from various sites located in Poland between 1990 and 1994. The mean dry weight total PCB concentration was 8.6 ng/g for agricultural and forest soils, 170 ng/g (n=31) for urban soils, and 900 ng/g for the soils sampled at the military area. Dry weight PCB concentrations increased from 21 ng/g in Northern Poland to 48-380 ng/g in highly populated and industrialized regions in Southern Poland.

3.3.3. Soil Observations and Trends

Some general observations for CDD and CDF levels in soils are possible from the data presented in the various soil studies discussed above:

- As the degree of chlorination increases, the concentrations increase. Concentrations of the hepta- and octa-chlorinated congeners are generally higher than the tetra-, penta-, and hexa-chlorinated congeners.
- Concentrations in settings identified as urban are higher than those in areas identified as rural.
- Concentrations associated with industrial sites clearly are the highest, with concentrations in the hundreds to thousands of parts per trillion.

3.3.4. Soil CDD/CDF Profiles and Background TEQ Concentrations

CDD/CDF homologue group profiles for soil were calculated as the mean homologue group concentrations divided by the mean total CDD/CDF concentration. Nondetects were assumed to be zero in these calculations. For rural background soil, homologue group profiles were calculated based on data from Reed et al. (1990), Birmingham (1990), Pearson et al. (1990), BC Environment (1995), U.S. EPA (1985, 1996), Tewhey Associates (1997), MRI (1992), Rogowski et al. (1999), and Rogowski and Yake (1999). They indicate that of the homologue groups, the higher chlorinated compounds dominate. OCDD and HpCDD account for the highest percentages of total CDD/CDFs (Figure 3-3; Table 3-14). CDD/CDF homologue group profiles for urban background samples, based on Birmingham (1990), Pearson et al. (1990), NIH (1995), U.S. EPA (1996), and Rogowski et al. (1999), are similar (Figure 3-4; Table 3-14). The sum of 2,3,7,8-substituted congener concentrations account for 83 percent of the total CDD/CDF concentrations in rural background soil and 91 percent in urban background soil. Profiles based on the ratio of 2,3,7,8-substituted congeners to total CDD/CDFs in rural background soil indicate that OCDD and 1,2,3,4,6,7,8-HpCDD account for the highest percentages of total CDD/CDFs, followed by OCDF and 1,2,3,4,6,7,8-HpCDF (Reed et al., 1990; BC Environment, 1995; U.S. EPA, 1996; Tewhey Assoc., 1997; MRI, 1992; Rogowski et al., 1999; and Rogowski and Yake, 1999) (Figure 3-3). For urban background soils, profiles were similar to those observed in rural background soils, based on data from NIH (1995), U.S. EPA (1996), and Rogowski et al. (1999) (Figure 3-4).

Based on several of the studies described in this chapter, mean TEQ_{DF}-WHO_{98} levels were calculated (Table 3-15), based on the available data, to represent "typical" background conditions in the North America. The mean rural background TEQ_{DF}-WHO_{98}

level was estimated to be 2.6 ppt, and the "typical" urban background TEQ_{DF}-WHO_{98} level was estimated to be 8.8 ppt, assuming that nondetects equal zero. The mean rural background concentration is based on data from eleven studies in seven U.S. States (i.e., Ohio, Minnesota, Illinois, Maine, Connecticut, Colorado, and Washington) and two areas in Canada (i.e., British Columbia and Ontario) (n = 319; BC Environment, 1995; Birmingham, 1990; MRI, 1992; Pearson et al., 1990; Reed et al., 1990; Tewhey Associates, 1997; U.S. EPA, 1985; U.S. EPA, 1996; Rogowski et al., 1999; Rogowski and Yake, 1999; U.S. EPA Region 8, 2000b). The mean urban background concentration is based on data from five U.S. States (i.e., Michigan, Maryland, Ohio, Colorado, and Washington) and Ontario, Canada (n = 305; Birmingham, 1990; Nestrick et al., 1986; NIH, 1995; Pearson et al., 1990; U.S. EPA, 1985; U.S. EPA, 1996; Rogowski et al., 1999; U.S. EPA Region 8, 2000b). The TEQ_{P}-WHO_{98} was 0.31 ppt (n = 27) for rural soil and 2.0 ppt (n = 134) for urban soil, based on soil data from U.S. EPA Region 8 (2000b) which were collected in and around Denver, Colorado. In calculating the mean concentrations, each site was weighted equally (i.e., the means are based on the average of the mean concentrations from each location). In contrast, the weighted means in Table 3-15 represent average concentrations for rural and urban sites that have been weighted according to the number of samples at each site; all soil samples are treated individually regardless of location. Thus, more heavily sampled locations have a greater impact on the weighted mean than those sampled less frequently. Therefore, means, not weighted means, were used to depict typical rural and urban background concentrations in North America. It should be noted, however, that the means and weighted means in Table 3-15 are quite similar.

Background TEQ_{DF}-WHO_{98} levels for soils were estimated by setting nondetects to zero instead of one-half the detection limit, because congener-specific detection limits were not available for some of the early studies. If one-half the detection limits had been used to represent nondetected congeners, the estimated background TEQ_{DF}-WHO_{98} levels may have been slightly higher. Based on the results of European studies, it appears that background TEQ_{DF}-WHO_{98} concentrations in European soil are similar to those of the United States. The TEQ_{DF}-WHO_{98} concentration in urban background soil is used in Chapter 4 to calculate background exposures. Urban soils are used because the majority of the population lives in urban areas. Thus, using these concentrations would represent typical exposure levels.

3.4. CONCENTRATIONS IN WATER

Tables B-6 and B-7 (Appendix B) contain summaries of data from the limited number of published studies regarding concentrations of CDDs and CDFs in water. Data on dioxin-like PCB congener concentrations in water were not found in the literature. Several of the CDD/CDF studies are discussed below.

3.4.1. North American Data

A survey of 49 drinking water supplies in Ontario, including supplies in the vicinity of chemical industries and pulp and paper mills, was initiated in 1983 (Jobb et al., 1990). As of February 1989, 4,347 congener analyses had been performed on 399 raw and treated water samples. OCDD was detected in 36 of 37 positive results and ranged from 9 to 175 ppq in raw samples (33 positive samples) and 19 to 46 ppq in treated samples (4 positive samples). These low concentrations were found primarily in water obtained downstream of industrialized areas in the St. Clair/Detroit River system. No samples contained detectable levels of 2,3,7,8-TCDD. Because CDDs and CDFs are hydrophobic compounds, and consequently, have a tendency to sorb onto particulate matter in water, conventional water treatment processes are expected to be effective in removing the contaminants along with the particulates. This is substantiated by the fact that 33 of the 37 positive results were raw water samples. Because of the relatively low levels of CDDs detected in the samples, it is difficult to ascertain whether the CDDs were particulate-associated or dissolved.

A survey of 20 community water systems throughout New York State was conducted in 1986 (Meyer et al., 1989). The sampling sites were representative of the major surface source waters in New York. They included sources receiving industrial discharges or known to contain dioxin-contaminated fish, as well as waters in more remote areas. TCDFs were detected in the finished water at the Lockport facility (duplicate samples had concentrations of 2.1 and 2.6 ppq). Except for a trace of OCDF detected at one location, no other CDDs/CDFs were detected in finished water at any of the other 19 community water systems surveyed. Raw water sampled at the Lockport facility contained concentrations of TCDDs (1.7 ppq), as well as TCDFs to OCDF (18, 27, 85, 210, and 230 ppq, respectively). As can be seen from the data, the CDF congener group concentrations increased with increasing chlorine number.

3.4.2. European and Japanese Data

CDDs in surface water samples collected from the Eman River in southern Sweden generally increased in concentration from the TCDDs to OCDD; whereas, the CDF levels showed very little variation between the congener groups (Rappe et al., 1989a). In general, however, the levels of CDFs were higher than the levels of CDDs. Concentrations of 2,3,7,8-TCDF were 0.022 ppq in Jarnsjon and 0.026 ppq in Fliseryd. The filtered water, before chlorination and distribution as drinking water, had no detectable tetra-, penta-, or hexa-chlorinated congeners of CDDs or CDFs, but the HpCDDs and OCDD were detected at 120 and 170 ppq, respectively.

A survey was conducted at the Venice lagoon in the north of Italy by the Ministry of Justice and the Ministry of Works to assess the CDD/CDFs contamination produced by industrial and municipal waste water discharges (Ramacci et al., 1998). The results showed that four out of seven waste water samples were characterized by a prevalence of OCDF; two had an almost equal distribution between OCDD and OCDF; and only one collected from a septic tank of the city of Venice presented a prevalence of OCDD.

In Japan, water samples were collected from a coastal area, river, and pond in Matsuyama between October 1996 and September 1997 (Seike et al., 1998). The total concentrations of CDD/CDFs ranged from 15 to 170 pg/L (n = 3) in coastal waster with an average of 51 pg/L, from under the detection limit to 1500 pg/L (n = 22) in river water with an average of 180 pg/L, and from 44 to 530 pg/L (n = 3) in pond water with an average of 260 pg/L. CDD/CDFs in coastal water were relatively lower than from other sources, and were thought to be diluted with seawater and/or deposited to the coastal sediment.

Raw and treated tapwater samples from Japanese water supplies were analyzed by Magara et al. (2000) for CDD/CDFs and PCBs 77, 81, 126, 169, 105, 114, 118, 123, 156, 157, 167, and 189. The average TEQ_{DFP}-WHO_{98} was 0.148 pg/L (ppq) for raw water and 0.019 pg/L (ppq) for treated water. CDFs accounted for about 60 percent of the total TEQ in the treated samples.

3.4.3. Water Observations and Trends

Some general observations for CDD and CDF levels are possible from the limited data available from the various water studies described above:

- CDD/CDFs are seldom detected in drinking water at ppq levels or higher.
- Raw water samples generally have higher concentrations of CDD/CDFs than finished water samples.
- The concentration of CDDs and CDFs in surface water generally increases from the tetra-chlorinated to the octa-chlorinated congener groups.

3.4.4. Water CDD/CDF Profiles and Background TEQ Concentrations

CDD/CDF congener profiles could not be generated for water because of the lack of congener-specific data for treated drinking water. For the background studies reviewed here, only data for OCDD and OCDF were available.

Based on the above studies, a total of 236 samples from Ontario, Canada, and Lockport, New York, were selected as representing background conditions in North America. The "typical" TEQ_{DF}-WHO_{98} level was computed as 0.00056 ppq, assuming that nondetects equal half the detection limit (Jobb et al., 1990). This value is used in Chapter 4 to estimate background exposures to the U.S. population from drinking water consumption. It should be noted, however, that OCDD and OCDF were the only congeners for which background data were available. Of the 214 samples analyzed for OCDD, only 4 were positive, and only 2 out of 22 samples analyzed for OCDF were positive. No appropriate data on drinking water concentrations could be found for Europe, and only one study was available for Japan.

3.5. CONCENTRATIONS IN SEDIMENT

Tables B-8 through B-10 (Appendix B) contain summaries of data from several of the numerous studies in the published literature regarding concentrations of CDDs, CDFs, and dioxin-like PCB congeners in sediment. Several of these studies are discussed in the following paragraphs. It should be noted that the review of sediment data presented here is not based on a comprehensive review of the published studies on CDD/CDFs in sediment. Instead, it is intended to provide a brief overview of sediment levels of CDD/CDFs from a sampling of representative studies. In addition, because the levels of CDD/CDFs and PCBs in sediment layers may be indicative of the cumulative history of contamination at a site (i.e., reservoir sources), the studies presented here represent only

those that analyzed surficial (i.e., recently deposited) sediment samples or the uppermost layers from sediment cores, and not deep sediment core samples.

3.5.1. North American Data

In sediment samples collected from estuaries adjacent to an industrial site in Newark, New Jersey, where chlorinated phenols had been produced, the level of OCDD was many times higher than that of 2,3,7,8-TCDD (Bopp et al., 1991). Studies conducted by Wenning et al. (1992; 1993) in Newark Bay also indicated that OCDD was found in higher concentrations than the lower-chlorinated congeners in this water body. Based on 19 sediment samples, OCDD levels ranged from 310 ppt to 17,000 ppt, and 2,3,7,8-TCDD levels ranged from 2.8 pt to 480 ppt. Observed congener patterns for this area were similar to those found in sediments from several other U.S. and European water bodies. The authors suggest that these similarities are a result of similar municipal and industrial sources in heavily industrialized and populated areas. Based on the results of principal components analyses, the congener profiles for sediments from Newark Bay are closely related to those of several different potential sources, including chemical manufacturing processes and municipal activities. Hudson River sediment samples contained primarily the higher chlorinated (Cl_6 to Cl_8) CDD and CDF congeners (Petty et al., 1982). Concentrations of the HpCDD and OCDD homologues ranged from 5 to 15 ppb, and the OCDD homologue in most instances accounted for more than half of the total CDD residue. Likewise, the HpCDFs and OCDF occurred at the highest levels (ca. 1 ppb).

Surface sediment samples were collected from several estuaries in the United States (Norwood et al., 1989). Sampling sites included Black Rock Harbor in Bridgeport, Connecticut, (an industrialized urban estuary); central Long Island Sound (a relatively clean reference site); Narragansett Bay, Rhode Island, (where chemical industries may have contributed to the input); New Bedford Harbor, Massachusetts, (a section of which is a National Superfund Site because of PCB contamination); and Eagle Harbor, Washington, (the site of a creosote wood treatment facility). Sediments in New Bedford Harbor were reported to be more heavily contaminated with CDFs than sediments from the other sites. In particular, HxCDF congeners were greater by a factor of 40 (although individual data points were not presented) at one of the more contaminated New Bedford Harbor sites. In

contrast, sediments from Eagle Harbor were practically devoid of CDFs and showed a large increase in the HpCDD and OCDD congeners closer to the treatment facility. Narragansett Bay and Black Rock Harbor were similar in both concentration and distribution of CDDs and CDFs, and Black Rock Harbor contained slightly higher levels of the tetra- to hepta-CDD and CDF congeners. Sediment from Long Island Sound was cleaner and had a distribution of CDFs between that of Narragansett Bay and Black Rock Harbor. Sediment with the least contamination was collected in New Bedford Harbor, up-river from the PCB facilities; the highest OCDD concentration (1,400 ppt) was detected in Eagle Harbor.

Sediment samples from Siskiwit Lake, on Isle Royale, Lake Superior, were examined to evaluate the atmospheric input of CDDs and CDFs to the lake (Czuczwa et al., 1984). The water level in Siskiwit Lake is 17 meters higher than that in Lake Superior, and in addition, there are no anthropogenic inputs in the drainage basin of Siskiwit Lake. Consequently, the atmosphere is the only source of anthropogenic chemicals in that lake. OCDD was most predominant, and the HpCDD and HpCDF congeners also were abundant. The study indicated a considerable decrease in concentration of all CDDs and CDFs between 6 and 8 cm of the sediment core depth (i.e., sediment believed to have been deposited about 1940).

Surficial sediments collected from Jackfish Bay on the north shore of Lake Superior contained moderate concentrations of the TCDF and OCDD congeners, with trace concentrations of other congeners (Sherman et al., 1990). The concentration of OCDD was similar to that found in the Siskiwit Lake sediment samples. The OCDF and OCDD profile for a sediment core collected from Moberly Bay was similar to the surficial sediment pattern. These congener groups predominated at all depths where detectable concentrations occurred. In addition, low concentrations of the HpCDD and PeCDF and HpCDF congeners were detected. The concentration profile of the HpCDF congener group showed a relatively high value that dropped abruptly to nondetectable (<60 ppt) below a depth of 10 cm. This abrupt change corresponded to a section date 1973 that reflects an operational change at the pulp mill.

A survey of surficial harbor sediments collected near a wood preserving plant in Thunder Bay, Ontario, Canada, on the north shore of Lake Superior, found the highest concentrations of CDD/CDFs at stations closest to the plant dock, and lower

concentrations at locations further from the source (McKee et al., 1990). No CDDs or CDFs were detected below the surficial layer. TCDD and PeCDD congeners were below analytical detection limits in all samples. However, the concentrations of the HxCDDs to OCDD congeners increased with the degree of chlorination. The maximum concentrations of the HxCDDs to OCDD ranged from 5,700 ppt for the HxCDDs to 980,000 ppt for OCDD. As with the CDD distribution profile, the HxCDFs to OCDF increased with the degree of chlorination.

Sediment levels of CDD/CDFs in British Columbia were found to be higher in samples collected from sites in the receiving environment adjacent to a suspected source (secondary sites) than in areas not expected to be contaminated (background) (Table 3-16) (BC Environment, 1995). These observations are based on a 2-year study conducted during 1990/91 and 1991/92 by British Columbia's Ministry of Environment. Secondary sites were identified as being associated with chemical or combustion sources. Background samples did not contain detectable levels of 2,3,7,8-TCDD, and the mean 2,3,7,8-TCDF concentration was 1.4 ppt. For the purposes of calculating I-TEQ_{DF} values for this study, nondetects were set to zero. Mean I-TEQ_{DF} levels were 32.5 ppt for secondary sites (all sources) and 3.9 ppt for background sites (Table 3-16).

Bottom surficial sediments (0-3 cm) were collected from the sedimentation basins of Lake Ontario to assess the levels of the various PCB congeners (Oliver and Niimi, 1988). Concentrations of 2,3',4,4',5-PeCB (PCB 118); 2,3,3',4,4'-PeCB (PCB 105); and 2,3,3',4,4',5-HxCB (PCB 156) in the sediment were 15, 10, and 2.1 ppb, respectively. A baseline assessment of CDDs and CDFs was performed on the Elk River, a semi-rural area located about 25 miles northwest of Minneapolis-St. Paul, Minnesota (Reed et al., 1990). Sediment samples were collected from Lake Orono, a reservoir on the Elk River, and from an abandoned gravel pit. Although none of the sediment samples contained 2,3,7,8-TCDD, the gravel pit sediments contained measurable concentrations of TCDFs. Only one Lake Orono sample contained measurable concentrations of 2,3,7,8-TCDF (0.31 ppt) and total TCDF (0.54 ppt). Gravel pit samples also contained HpCDDs to OCDD and PeCDFs to OCDF. Lake Orono samples contained HpCDDs, OCDD, and HpCDF congeners. HpCDDs ranged from 7.3 ppt in the lake inlet to 110 ppt in the gravel pit and in the lake near the dam. OCDD concentration ranged from 450 ppt in the gravel pit to 600 ppt in the middle of Lake Orono. The sediment profiles reflected combustion source influences.

The Sheboygan River, a Wisconsin tributary to Lake Michigan, is polluted with PCBs from the mouth to about 14 miles upstream (Sonzogni et al., 1991). That portion of the river is a Superfund site, as well as one of the Great Lakes "Areas of Concern." Sediment cores were collected at Rochester Park, near the original source of the PCBs, about 14 miles upstream from the mouth. The PCB congeners 2,3',4,4',5-PeCB (PCB 118); 2,3,3',4,4'-PeCB (PCB 105); and 3,3',4,4'-TCB (PCB 77) were detected in all samples and ranged from about 5 to 1,500 ppb. Remaining dioxin-like PCB congeners were detected less frequently and ranged from nondetectable to slightly over 100 ppb. The PCB congener 2,3',4,4',5-PeCB (PCB 118) appears to be the most common dioxin-like PCB in environmental samples and was found in the Sheboygan River sediments in the highest weight percent. The eight toxic PCBs detected in this study were present in relatively low concentrations compared to total PCBs or other more abundant congeners.

Sediments collected from Waukegan Harbor in Lake Michigan contained the dioxin-like PCB congeners 3,3',4,4'-TCB (PCB 77) and 2,3,3',4,4'-PeCB (PCB 105) (Huckins et al., 1988). The percentage of 3,3',4,4'-TCB (PCB 77) in the samples averaged 0.16 percent ± 0.15, with concentrations ranging from 13 to 27,500 ppb. The percentage of 2,3,3',4,4'-PeCB (PCB 105) averaged 0.66 percent ± 0.37, with concentrations ranging from 102 to 131,000 ppb. In another Lake Michigan study, sediment samples collected from Green Bay contained concentrations of all 11 dioxin-like PCB congeners (Smith et al., 1990b). The dominant congeners were 2,3,4,4',5-PeCB (PCB 114) and 2,3,3',4,4'-PeCB (PCB 105), with concentrations of 11 and 5.8 ppb, respectively.

Fiedler et al. (1995b) and Rappe et al. (1995b) analyzed sediments samples from a river system in southern Mississippi to determine if the concentrations of CDDs and CDFs in the sediments were influenced by a local pulp and paper mill. The pulp mill, which is located adjacent to the Leaf River and currently uses chlorine dioxide in its bleaching process (elemental chlorine was used from 1984 through 1989), was suspected of contributing to CDD and CDF contamination in the region (Fitzpatrick, 1995). A total of 61 sediment samples were collected from sites located upstream and downstream from the mill. Study results indicated that most CDD and CDF congeners were present in all sediment samples collected, but the predominant congeners were the HpCDDs and OCDD (Rappe et al., 1995b). Congener profiles were generally similar for samples collected from both populated, potentially polluted areas and pristine areas. In addition, for the majority

of sampling sites in the study, the ratio of the sum of CDDs to CDFs ranged from 43 to 1,200. Rappe et al. (1995b) stated that this observation "is notable because, with the exception of sewage sludge, no environmentally significant source has been identified with such a dominance of CDDs." The mean I-TEQ_{DF} concentration observed in this study was 10.6 ng/kg dry weight, and the median I-TEQ_{DF} concentration was 9.90 ng/kg dry weight (Fiedler et al., 1995b). Median values reported in this study were consistent with those of an earlier study conducted by the Mississippi Department of Environmental Quality in 1992 in the same river system.

Rappe et al. (1997a) analyzed sediment core samples from five lakes in southern Mississippi. The sediment cores were collected from five man-made recreational lakes with no known industrial point source of CDD/CDFs and low atmospheric deposition rates. Cores were subdivided into sections to evaluate temporal trends in deposition of CDD/CDFs. I-TEQ_{DF} values for the lake cores ranged from 0.38 to 9.52 ppt (dry weight). 2,3,7,8-TCDD was present at levels below the detection limit in all of the sediment core samples. The higher chlorinated congeners (hexa to octa CDD/CDFs) predominated. OCDD levels ranged from 150 ppt dry weight to 5,500 ppt dry weight, while total CDD levels ranged from 176 to 7,577 ppt dry weight. CDF levels ranged from nondetectable to 14.4 ppt dry weight. As observed in another analysis of sediment cores from the region (Rappe et al., 1997b), the CDD to CDF ratios were very high, ranging from 79.1 to 9,920. The CDD and CDF congener patterns were similar to those observed by Rappe et al. (1995b) in previous sediment studies in the region. No observable trend for levels of CDDs, homologues, or I-TEQ_{DF}s correlating to the age of the strata could be identified.

Rappe et al. (1997b) also studied sediment samples from 15 manmade lakes in the same region of southern Mississippi. Lakes were selected from pristine areas, areas not known to be impacted by industrial point sources of CDDs and CDFs. As in previous studies from this region (Rappe et al., 1995b and Fiedler et al., 1995b), HpCDDs and OCDD were the predominant congeners in these deep lake and sedimentation area samples. OCDD levels ranges from 1,400 to 43,000 ppt dry weight (median 7,700 ppt). The concentration of HpCDDs ranged from 63 ppt to 2,000 ppt dry weight (median 430 ppt). 2,3,7,8-TCDD was detected in 20 of the 27 sediment samples at levels not exceeding 1.0 ppt dry weight. CDDs dominated, and the ratio of CDDs to CDFs ranged from 19 to 764 (79 percent had ratios >100). The I-TEQ_{DF} concentration in the sediment

samples ranged from 2 ppt dry weight to 63.7 ppt dry weight. Rappe et al. (1997b) postulated that the high levels of OCDD found in this region of the United States are due to natural formation. The authors base this theory on the fact that the sediment samples were collected in pristine areas with no known industrial sources of CDD/CDFs and low atmospheric deposition rates. However, they have observed consistently higher than expected OCDD levels and high CDD/CDF ratios in this region, which do not correspond with other levels in the published literature.

In an effort to determine whether incineration of municipal waste influenced CDD/CDF levels in the immediate area of waste incineration facilities, sediment samples were collected from surface water near cities with, and without, operating incinerators throughout Connecticut. A total of 344 sediment samples were collected between 1987 and 1990. The mean total CDD/CDF concentrations for pre-operational and operational status were 3,590 pg/g and 4,523 pg/g, respectively, when nondetects were assumed to be one-half the detection limit (MRI, 1992). Based on the concentration data reported in MRI (1992), mean I-TEQ_{DF} values for pre-operational and operational sediments were 21 pg/g and 24 pg/g, respectively.

Sediment samples collected at the lowermost Tennessee River (Kentucky Dam Tailwater) and Kentucky Lake at the depth of 0-5 cm had total PCB concentrations ranging from the detection limit (1.0 ng/g dry weight) to 26.36 ng/g dry weight (Loganathan et al., 1998). The total PCB concentrations sampled from the lowermost Tennessee River were generally higher that those from Kentucky Lake. The PCB congeners found in the sediment samples included PCB-8, 29, 50, 28, 52, 44, 101, 87, 154, 118, 153, 105, 138, 187, 128, 200, 180, and 170; the dominant congeners were PCB-44 and PCB-101. Of these congeners, only PCBs 118 and 105 are considered to be dioxin-like.

Recently, EPA conducted a time-trend study of dioxin-like compounds in sediment cores (Versar, 1996a; Cleverly et al., 1996). Cores from 11 lakes/reservoirs were collected, sectioned and dated, and analyzed for CDD/CDFs and PCBs 77, 105, 118, 126, 156, 157, and 169. The lakes were located in various geographic locations throughout the United States and were selected to represent background conditions (i.e., no known CDD/CDF sources). Based on the most recently deposited sediments (i.e., the uppermost core sections), total I-TEQ_{DF} concentrations ranged from 0.11 ppt to 15.6 ppt with a mean of 5.3 (TEQ_{DF}-WHO_{98} concentrations ranged from 0.12 ppt to 16.3 ppt, with a mean of

5.3 ppt) when nondetects were set to one-half the detection limit, and from 0.11 ppt to 14.3 ppt with a mean of 4.6 ppt (TEQ_{DF}-WHO_{98} concentrations ranged from 0.12 ppt to 15.6 ppt, with a mean of 4.7 ppt) when nondetects were set to zero (Table 3-17). Chandler Lake, an Arctic lake located in North Slope, Alaska, had the lowest TEQ_{DF} concentration, and Canandaigua Lake in New York and Santeetlah Reservoir in North Carolina, both eastern lakes, had the highest TEQ_{DF}s. In general, the higher chlorinated CDD/CDFs accounted for the largest proportion of total TEQ concentrations. PCB TEQ_P-WHO_{98} and TEQ_P-WHO_{94} ranged from 0.07 ppt for Chandler Lake to 2.2 ppt for Canandaigua Lake, with a mean TEQ_P-WHO_{98} of 0.53 ppt when nondetects were set to either zero or one-half the detection limit. Total CDD/CDF concentrations for these 11 lakes are presented in Table 3-18. Total CDD/CDFs ranged from 9.1 ppt for Chandler Lake, Alaska, to 2,916 ppt for Santeetlah Reservoir, North Carolina, with a mean of 926 ppt. Total PCBs ranged from 34 ppt for Chandler Lake, Alaska, to 2,116 ppt for Canandaigua Lake, new York, with a mean of 489 ppt. Table 3-18 also presents the estimated annual flux of CDD/CDFs to these lakes. Flux was calculated by multiplying sediment concentrations by lake-specific sedimentation rates (g/cm^2-yr), and dividing by lake-specific sediment focusing (redistribution) factors. CDD/CDF Flux ranged from 0.05 pg/cm^2-yr for Chandler Lake to 190 pg/cm^2-yr for Santeetlah Reservoir. PCB flux ranged from 0.19 pg/cm^2-yr for Chandler Lake to 103 pg/cm^2-yr for Santeetlah Reservoir. These data are considered to be the best available data for characterizing sediment CDD/CDF and dioxin-like PCB background concentrations in the United States because they are representative of sites not expected to be impacted from within several geographic regions.

3.5.2. European Data

This section presents a brief overview of some data on European sediments. It is not intended to be a comprehensive review of all available studies on European sediments. No attempt was made to characterize background levels of CDD/CDFs for Europe because of the variability and limited scope of this review.

Sediment samples from the vicinity of a magnesium production plant in Norway were analyzed for CDDs and CDFs (Oehme et al., 1989). The concentration distribution of CDD and CDF congeners was rather homogeneous, except for a slight decrease at a

sampling station downstream of the plant and higher levels in deeper sediments (4-6 and 11-13 cm depth) at that site. TCDF congener profiles were the same as those for magnesium production. In addition, the PeCDF congener profiles were very similar to those found in the wastewater.

Trapped sediments from the archipelago of Stockholm, Sweden, displayed CDD and CDF congener distribution patterns that were very similar to those exhibited in total air and air particulates (Rappe and Kjeller, 1987). HpCDDs, OCDD, and HpCDF were the dominant congener groups in the sediment.

Bottom surface sediment samples collected from the Baltic Sea showed interesting CDD and CDF distribution patterns (Rappe et al., 1989b). Background samples, one between the Swedish and Soviet coasts and the other between the Swedish and Finnish coasts, contained similar levels and distribution profiles. The study indicated that the pattern of the TCDF congeners at these sites was typical of the "incineration pattern" (i.e., patterns resulting from MSW incineration, car exhausts, steel mills, etc.), which also had been found in samples of air and air particulates. However, sediment samples collected at a distance of 4 to 30 km from a pulp mill revealed a congener distribution pattern typical of bleaching mills. TCDFs found in the sediment 4 km from the pulp mill contained only two major congeners. The sediment collected 30 km from the mill displayed the same pattern.

Evaluation of sediments in Hamburg Harbor in Germany revealed high concentrations of the TCDDs through OCDD (mean concentrations of 564, 1112, 2744, 4040, and 7560 ppt, respectively) and the TCDFs through OCDF (mean concentrations of 526, 2980, 4106, 2358, and 2712 ppt) (Gotz and Schumacher, 1990). The average concentration of 2,3,7,8-TCDD was 375.3 ppt. High concentrations of 2,3,7,8-TCDD, especially in the Moorfleeter Canal and the Auserer Vering Canal, were attributed to discharges from an organochlorine pesticide manufacturing plant. Patterns of 2,3,7,8-TCDD and the other HpCDD congeners are characteristic of the patterns resulting from the production of 2,4,5-T and 2,4,6-trichlorophenol. In addition, the pattern of the HpCDF congeners can be linked to emissions from thermal processes employed by chemical industries in the production of chlorinated organic chemicals. High concentrations of hepta- and octa-CDDs/CDFs may also be the result of other industrial combustion processes in the Hamburg area.

The Venice lagoon in the north of Italy, covering a surface of approximately 500 km^2 with a depth of <2 m, has a limited water exchange with its surrounding area. The pollution loading sources includes the effluent of water streams and industrial and municipal waste water discharges, agricultural runoff, and an intense traffic of motorboats. Two sediment studies were conducted at this lagoon. Ramacci et al. (1998) used the data collected by the Ministry of Justice and the Ministry of Works to assess the CDD/CDFs contamination. The sediment samples were collected from various depths, including surficial to 60 cm. The dry weight I-TEQ_{DF} concentrations for various depth were 16.0 pg/g for surficial sediment, 14.3 pg/g and 19.8 pg/g for sediment samples from a depth of 0-20 cm, 6.2 pg/g and 0.5 pg/g for sediment samples from a depth of 20-40 cm, and 6.0 pg/g for the sediment at the depth of 40-60 cm. Di Domenico et al. (1998) collected the data from the top 10-30 cm thick sediment layer of the Venice lagoon bottom in 1992 and 1995. For the area under industrial or prevailing industrial exposure, the concentrations of total CDD/CDFs ranged from 840 pg/g to 29,000 pg/g; the I-TEQ_{DF} concentrations ranged from 12 pg/g to 570 pg/g; and the total PCB concentrations ranged from 53 ng/g to 720 ng/g. For the area exposed to municipal waste water discharges, the concentrations of total CDD/CDFs ranged from 210 pg/g to 1,400 pg/g; the I-TEQ_{DF} concentrations ranged from 4.8 pg/g to 23 pg/g; and the total PCB concentrations ranged from 71 ng/g to 610 ng/g. The CDD/CDF congener profile for sediments from the Venice lagoon appeared to be strongly influenced by the waste water discharges. A prevalence of OCDD and OCDF over other congeners was observed (Ramacci et al., 1998).

Masahide et al. (1998b) examined sediment samples collected from a depth of 0-10 cm in the Districts of Gdansk, Szczecin, and Katowice in Poland in 1993-1994. The dry weight total PCB concentrations sampled in Northern Poland ranged from 1.7 ng/g to 630 ng/g with an average of 110 ng/g. The dry weight total PCB concentrations were 1.7-2.2 ng/g at the area without industrial activity, 78-99 ng/g at the places receiving untreated municipal effluents, and 46-630 ng/g at the sites under the influence of human activities. The dry weight PCB concentrations sampled in Southern Poland ranged from 46 ng/g to 1,300 ng/g with an average of 540 ng/g. This highest concentration was sampled from a pond receiving effluent water from a coal mine in Katowice.

3.5.3. Vietnamese and Japanese Data

Schecter et al. (1989a) collected sediment samples from three rivers in Vietnam and analyzed them for CDD/CDF residues. Rivers included the Red River in the nonindustrialized North, the Saigon River in the industrialized South, and the Dong Nai River in an area sprayed with Agent Orange, a TCDD-contaminated herbicide. Results of these analyses are presented in Table 3-19. The average total concentrations of CDD/CDFs were 240 pg/g dry weight for the Red River, 6,800 pg/g dry weight for the Saigon River, and 1,200 pg/g dry weight for the Dong Nai River. Schecter et al. (1989a) suggested that the total CDD/CDF levels in these Vietnamese rivers is comparable to the total CDD/CDF levels observed in the lake sediments in the United States and Europe (Table 3-19).

In Japan, sediment samples were collected from a coastal area, river, and pond in Matsuyama between April 1995 and December 1997 (Seike et al., 1998). The dry weight total concentrations of CDD/CDFs ranged from 2.0 to 16 ng/g (n = 3) in the coastal area with an average of 8.1 ng/g, from 0.95 to 4.3 ng/g (n = 22) in river water with an average of 2.0 ng/g, and from 0.77 to 3.1 ng/g (n = 3) in pond water with an average of 2.3 ng/g. TCDD and OCDD were the main contributors to total CDD concentrations in all sediment samples, while CDF homologue compositions varied with the samples. Sediment samples were also collected in June-July 1993 at eight sites from upper, mid- and downstream of the Tama River, Japan, which was polluted by industrial and domestic wastewater (Onodera et al., 1998). Total CDD/CDF dry weight concentrations ranged from 27.0 to 231.6 pg/g with an average of 90.7 pg/g. The total I-TEQ_{DF} concentrations ranged from 0.05 to 2.8 pg/g with an average of 1.2 pg/g.

3.5.4. Sediment Observations and Trends

Some general observations for CDD and CDF levels in the United States are possible from the data presented in the various sediment studies above:

- CDD and CDF congener distribution patterns in sediment generally follow those exhibited by the contaminant source.

- The concentration of CDD and CDF congeners in sediment generally increases with the degree of chlorination, but decreases uniformly with distance from the source.

3.5.5. Sediment CDD/CDF Profiles and Background TEQ Concentrations

CDD/CDF homologue group profiles for sediment were calculated as the mean homologue group concentrations divided by the mean total CDD/CDF concentrations. Congener profiles are the ratio of 2,3,7,8-substituted congeners to total CDD/CDFs in sediment. These congener profiles for sediment are presented in Figure 3-5. They are based on data from the recent EPA sediment core study, which evaluated sediment data from 11 non-source-impacted sites throughout the United States (i.e., 1 Alaska site, 3 New York sites, 1 North Carolina site, 1 Georgia site, 3 Utah sites, and 2 Washington sites) (Cleverly et al., 1996; Versar, 1996a). Only the uppermost sediment core samples (i.e., the most recently dated samples) were used in this analysis. The congener that accounts for the highest proportion of total CDD/CDFs is OCDD, with 1,2,3,4,6,7,8-HpCDD and OCDF also accounting for significant portions of total CDD/CDFs (Table 3-20). For the homologue group profile for sediment, OCDD and HpCDD account for the highest proportion of total CDD/CDFs.

Based on data from the uppermost sediment samples from EPA's recent sediment core study (Cleverly et al., 1996; Versar, 1996a) ($n = 11$), the mean background TEQ_{DF}-WHO_{98} level was 5.3 ppt, assuming that nondetects equal half the detection limit (Table 3-21). When nondetects were set to zero, the mean TEQ was 4.7 ppt. These data were considered to be the most appropriate data set for characterizing background CDD/CDF TEQ concentrations, because they are representative of sites not expected to be impacted from various geographic locations in the United States. Thus, the "typical" background concentration in sediment is assumed to be 5.3 ppt TEQ_{DF}-WHO_{98}.

3.6. CONCENTRATIONS IN FISH AND SHELLFISH

Tables B-11 through B-13 (Appendix B) contain summaries of data from the numerous studies in the published literature regarding concentrations of CDDs, CDFs, and dioxin-like PCB congeners in fish and shellfish. It should be noted that some studies reported fish concentrations on a whole weight basis and others reported concentrations

for fish fillets. In the appendix tables and in the data used for calculation of background fish levels, whole weight concentrations were converted to fillet concentrations, assuming that the fillet contained one-half the concentration of the whole fish (U.S. EPA, 1990; Branson et al., 1985). This was necessary for estimating human exposures, because it is assumed that fish fillets, and not whole fish, are ingested by humans. In the following studies, summaries of CDD/CDF and PCB concentrations are presented as reported by the authors.

3.6.1. North American Data

A large quantity of fish data were collected as part of EPA's National Study of Chemical Residues of Fish (NSCRF), more commonly referred to as the National Bioaccumulation Study, during the period of 1986 to 1989 (U.S. EPA, 1992). Based on these data, several summaries were prepared and are presented here. Tables B-11 and B-12 include the dioxin and furan data collected as part of the National Bioaccumulation Study. Samples were collected from a wide variety of sites across the United States, including 314 sites thought to be influenced by point or nonpoint sources and over 30 sites identified as relatively free of influence from point and nonpoint sources. This latter group of sites can be characterized as background per the definition used in this document. Background data are presented in Table 3-22. Using the maximum concentration from each site, the mean I-TEQ_{DF} concentration was 0.59 ppt for the background sites, when nondetects were set at zero, and 1.2 ppt when non-detects were set to one-half the detection limit. For other sites, I-TEQ_{DF} concentrations ranged from 0.7 ppt (POTWs) to 33.9 ppt (Superfund sites). Table B-13 includes similar data for the various PCB congener groups from 362 National Bioaccumulation Study sites. EPA recalculated the background TEQ_{DF}-WHO_{98} concentrations for the background sites using the mean concentration from each site instead of the maximum value for each site. Additional adjustments were included to account for the fact that some samples were analyzed on a whole body basis while others were analyzed on a fillet basis. All concentrations were expressed on a wet weight basis. The background TEQ_{DF}-WHO_{98} concentrations were 0.29 ppt when non-detects were set to zero and 1.3 ppt when non-detects were set to one-half the detection limit. Because the specific PCB congeners could not be identified, it is not known what percentage of these concentrations represent

the PCBs identified as dioxin-like. Of these sites, 20 were identified as background sites. The total PCB (all 209 congeners) mean concentration for these background sites was 46,900 ppt. Because the dioxin-like PCBs consist of only 11 of the 209 possible PCB congeners, it may be that they are a small percentage of the total; however, only congener specific analysis can ultimately confirm this. As discussed at the end of this section (Section 3.6.4), this study was selected as the best basis for estimating background fish levels in the United States.

Fish muscle and hepatopancreas samples of striped bass, blue crabs, and lobsters collected from Newark Bay and the New York Bight all contained high levels (up to 6,200 ppt) of 2,3,7,8-chlorine substituted tetra- and penta-CDDs and CDFs (Rappe et al., 1991). Levels of 2,3,7,8-TCDD were higher than any other New Jersey samples, and the highest sample in this study (found in crab hepatopancreas) may be the highest level of 2,3,7,8-TCDD ever reported for aquatic animals. Crustaceans resembled one another in congener pattern. Specifically, they all contained both a large number and large amounts of CDD and CDF congeners in addition to the 2,3,7,8-chlorine substituted compounds. The striped bass samples, on the other hand, contained primarily the 2,3,7,8-chlorine substituted congeners.

Carp, catfish, striped bass, large mouth bass, and lake trout were collected from sites in the Hudson River and the Great Lakes Basin that were contaminated with industrial chemicals or contained known or suspected levels of PCBs (Gardner and White, 1990). The congener 2,3,7,8-TCDF was detected in 12 fish fillets at levels that ranged from 3 to 93 ppt. A 2,3,7,8-chlorine substituted PeCDF was detected in 14 fish fillets at levels ranging from 4 to 113 ppt. An interesting observation in this study was that 2,4,6-chlorine substituted CDFs were detected in four fish samples, suggesting that those fish may have been exposed to chlorinated phenols. The study indicated that the 2,4,6-chlorine substituted CDFs occurred in the fish at levels similar to those of the 2,3,7,8-chlorine substituted CDFs, but with less frequency.

Composited whole fish samples of lake trout or walleye collected from each of the Great Lakes and Lake St. Clair were analyzed for CDDs and CDFs (De Vault et al., 1989). CDF and CDD concentrations in lake trout were substantially different for each lake and between sites in Lake Michigan, probably reflecting differences in types and amounts of loadings to the lakes. In all of the sampling sites (except Lake Ontario), 2,3,7,8-TCDF

was the dominant CDF congener in lake trout and ranged from 14.8 ppt in Lake Superior to 42.3 ppt in the whole fish samples of Lake Michigan. In Lake Ontario, the dominant congener in lake trout was a 2,3,7,8-chlorine substituted PeCDF. The distribution of CDF congeners in the Lake Erie walleye was very similar to that of the lake trout from Lake Superior. With regard to CDDs, the concentrations of 2,3,7,8-TCDD in the whole fish samples ranged from 1 ppt in Lake Superior to 48.9 ppt in Lake Ontario. With the exception of Lake Ontario, the dominant CDD congener was a 2,3,7,8-chlorine substituted PeCDD. A 2,3,7,8-chlorine substituted HxCDD also contributed significantly to the total CDD concentrations. As with CDFs, the distribution of CDD congeners in the Lake Erie walleye was very similar to that of the lake trout from Lake Superior. Total I-TEQ_{DF}s for these samples ranged from 5.3 ppt to 67.0 ppt on a whole weight basis when nondetected congeners were set to one-half the detection limit.

In another study, CDDs and CDFs were measured in four species of salmonids (lake trout, coho salmon, rainbow trout, and brown trout) collected from Lake Ontario (Niimi and Oliver, 1989a). Levels of 2,3,7,8-TCDD in whole fish ranged from 6 to 20 ppt, and the HxCDD congener group was most dominant in all fish. High levels of OCDD also were detected in lake trout and coho salmon, but not in rainbow trout or brown trout. Although total CDF levels were about 25 percent lower than the total CDD concentrations, the levels of 2,3,7,8-TCDF (which was the dominant component of the TCDF congener group) were the same range as 2,3,7,8-TCDD (6 to 20 ppt). I-TEQ_{DF} concentrations ranged from 7.3 ppt to 22.3 ppt on a whole weight basis, when nondetects were set to zero. The study suggested that, although collection sites can influence chemical levels and congener composition, comparisons of chemical levels and congener frequencies may not be suitable because of differences resulting from localized factors. The study also indicated that the importance of the various CDD and CDF congeners can differ with location (i.e., the same species of fish collected at different locations in a study area may reveal that the most common congener is different at each site).

Travis and Hattemer-Frey (1991) evaluated data generated as part of the National Dioxin Study regarding 2,3,7,8-TCDD concentrations in fish. Fish were collected from 304 urban sites in the vicinity of population centers or areas with known commercial fishing activity, including sites from the Great Lakes Region. Data from that study indicated that concentrations of 2,3,7,8-TCDD in whole fish from urban sites ranged from

nondetectable to 85 ppt. In addition, only 29 percent of the fillets from urban sites had detectable levels of 2,3,7,8-TCDD, with a geometric mean concentration of 0.3 ppt. Whole fish samples from the Great Lakes Region had higher 2,3,7,8-TCDD levels than fish from urban areas (e.g., 80 percent vs. 35 percent detectable levels). In the Great Lakes Region, 2,3,7,8-TCDD concentrations in whole fish samples ranged from nondetectable to 24 ppt, with a geometric mean of 3.8 ppt. These levels were 10 times higher than the concentrations in whole fish from urban areas. Likewise, the mean concentration of 2,3,7,8-TCDD in Great Lakes Region fish fillets (2.3 ppt) was about seven times higher than the levels in the fillets from urban areas (0.3 ppt). As with the whole fish samples, fish fillet samples from the Great Lakes Region had higher 2,3,7,8-TCDD levels than fillets from background urban areas (e.g., 67 percent vs. 29 percent detectable levels). Comparable levels of 2,3,7,8-TCDD were detected in whole bottom feeders and predators from the Great Lakes Region.

In an effort to determine whether incineration of municipal waste influenced CDD/CDF levels in the immediate area of waste incineration facilities, fish samples were collected from surface water near cities with, and without, operating incinerators throughout Connecticut. A total of 550 fish samples were collected between the years of 1987 and 1990. The total CDD/CDF concentrations for pre-operational and operational status were 28.44 pg/g and 58.38 pg/g, respectively, when nondetects were assumed to be one-half the detection limit (MRI, 1992).

Cooper et al. (1995) and Fiedler et al. (1997c) collected fish samples from grocery stores and local fish markets in southern Mississippi. All samples had detectable concentrations of CDD/CDFs. High I-TEQ_{DF} concentrations were observed in farm-raised catfish nuggets (mean = 2.1 ppt/sample I-TEQ_{DF}) and in the parts of the crustacea containing the digestive gland (Cooper et al., 1995). The congener profile for the shellfish samples was similar to that observed for sediments collected in the same area and, reported sewage sludge patterns. For marine fish fillets (i.e., Spanish mackerel and mullet), the mean I-TEQ_{DF} concentration was 0.27 ppt. The meat of marine shellfish (i.e., claw and body of blue crab and whole American oysters) had I-TEQ_{DF} concentrations averaging 0.63 ppt, and freshwater shellfish (i.e., crawfish) had concentrations averaging 1.0 ppt. I-TEQ_{DF} concentrations in fish and shellfish are presented in Table 3-23.

To further examine the high TEQ_{DF} concentrations of the farm-raised catfish from southern Mississippi, Cooper et al. (1997) and Fiedler et al. (1998) performed a follow up to their 1995 study examining catfish feed and pond sediment along with catfish samples from the previously tested facility and other sites in the southeastern United States. The follow-up study also tested for PCB levels. Samples included three catfish fillets and three catfish nugget (i.e., small pieces of fillet) samples from the same store and distribution supplier as sampled in the previous study (Cooper et al., 1995), one catfish fillet from an Alabama supplier, three catfish fillets and one feed and pond sediment sample from a different catfish farm in Mississippi, and two catfish and one catfish feed samples from a site in Arkansas. A summary of the results is presented in Table 3-24. Three farm-raised catfish fillet samples and three catfish nugget samples from Mississippi had lipid-based 2,3,7,8-TCDD levels ranging from 2.1 to 4.7 ppt and total lipid-based TEQ_{DFP}-WHO_{94} ranging from 10.9 to 30.2 ppt. Catfish samples from Arkansas had lipid-based 2,3,7,8-TCDD levels ranging from 27 to 32 ppt and total lipid-based TEQ_{DFP}-WHO_{94} ranging from 41.9 to 44.9 ppt. Similar results were observed in the feed samples. The feed from the Mississippi aquaculture facility, which supplied the food for the Mississippi catfish fillet and nugget samples, contained 2.7 ppt lipid 2,3,7,8-TCDD and a total lipid-based TEQ_{DFP}-WHO_{94} concentration of 10.5 ppt, compared with feed levels from the Arkansas facility that contained 44 ppt lipid 2,3,7,8-TCDD, and a total lipid-based TEQ_{DFP}-WHO_{94} concentration of 61. CDD/CDF congener profiles are also consistent between the catfish and the respective feed suppliers' products with the exception of OCDD and 1,2,3,4,6,7,8-HpCDD. Pond sediment congener profiles were not consistent with the profiles exhibited in the catfish samples, demonstrating significantly lower levels of most 2,3,7,8-substituted CDDs, and higher levels of 2,3,7,8-substituted CDFs. PCB analysis of these same catfish samples demonstrated that for all but one sample, the highest concentrations of PCBs were observed for congeners 153 and 138, respectively. PCB TEQ_{P}-WHO_{94} in the catfish samples (both fillet and nuggets) ranged from 0.45 to 4.9 ppt lipid, with the PCB fraction of the total TEQ_{P}-WHO_{94} ranging from 4 to 16 percent. The feed sample TEQ_{P}-WHO_{94} level from the Mississippi site was 3.31 ppt lipid, while the level from the Arkansas site was 0.19 ppt lipid, and the pond sediment level contained a TEQ_{P}-WHO_{94} level of 0.04 ppt lipid. Rappe et al. (1997c) continued this investigation by evaluating one combined catfish feed sample from Arkansas and its eight ingredients (i.e.,

soybean meal, meat and bone meal, wheat, corn, fish meal, cottonseed meal, and midds). The soybean meal had the highest I-TEQ_{DF} concentration (i.e., 576 pg/g lipid). The 2,3,7,8-TCDD concentration in this ingredient was 370 pg/g lipid. The combined catfish feed sample had a I-TEQ_{DF} concentration of 101 pg/g lipid and a 2,3,7,8-TCDD concentration of 67 pg/g lipid. Rappe et al. (1997c) suggested the ball clay anticaking agent in the soybean meal as the source of CDD/CDFs in this ingredient.

Schecter et al. (1997) analyzed samples of freshwater (n = 10) and marine fish (n = 13) collected from grocery stores in five U.S. cities (Binghamton, New York; Chicago, Illinois; Louisville, Kentucky; Atlanta, Georgia; and San Diego, California). Whole weight mean I-TEQ_{DF} values were 0.69 ppt for composites of freshwater fish and 0.25 ppt for composites of ocean fish, when nondetects were set to one-half the detection limit. Total mean CDD/CDF concentrations were 16.2 ppt (whole weight) for freshwater fish and 3.4 ppt (whole weight) for ocean fish, when nondetects were set to one-half the detection limit. Schecter et al. (2001) reported mean whole weight TEQ_{DFP}-WHO_{98} concentrations for the same fish samples as 1.7 ppt for freshwater fish and 0.39 ppt for ocean fish when nodetects were set to one-half the detection limit, and 1.6 ppt for freshwater fish and 0.16 ppt for ocean fish when nondects were set to zero. Additional detail on the Schecter et al. (1997) study are presented in the section on concentrations in food products (Section 3.7). Schecter et al. (1993a) analyzed five fish collected from a supermarket and found an average of 0.05 ppt of I-TEQ_{DF}.

FDA analyzed fish and shellfish samples collected in 1996 through 1999 as part of a market basket survey. The samples were collected from grocery stores from locations around the country and were analyzed for CDD/CDFs. The results of these analyses have been reported by Jensen and Bolger (2000) and Jensen et al. (2000). The combined results from these two publications are presented in Table 3-25. TEQ_{DF}-WHO_{98}s ranged from 0.22 ppt for pollack to 2.0 ppt for catfish.

Samples from all trophic levels in the Lake Ontario ecosystem were analyzed for PCB congeners (Oliver and Niimi, 1988). Analysis revealed that the PCB concentration increased from water to lower organisms to small fish to salmonids, demonstrating the classical biomagnification process. In addition, the chlorine content of the PCBs increased at the higher trophic levels. PCBs with the highest chlorine content (57 percent) were found in sculpin, small bottom-living fish that feed on benthic invertebrates. TrCBs and

TCBs comprised a much higher percentage of the PCBs in the lower trophic levels than in salmonids and small fish. The percentage of PeCBs and OCPB in all samples was fairly uniform, but the HxCBs and HpCBs comprised a much larger fraction of the PCBs in the small fish and salmonids than in the lower trophic levels.

A study regarding the distribution of PCBs in Lake Ontario salmonids (brown trout, lake trout, rainbow trout, and coho salmon) showed that the PeCBs and HxCBs were dominant in all species (Niimi and Oliver, 1989b). The 10 most common PCB congeners represented about 52 percent of the total content and did not appear to be influenced by species or total concentration. Homologues observed averaged approximately 56 percent chlorine by weight in whole fish and muscle. The analysis of the chlorine content suggested that the more persistent congeners tend to behave as a homogeneous mixture instead of as individual congeners.

Petreas (1991) conducted a study to assess the influence of a bleached pulp and paper mill and other industrial facilities on the PCB congener levels in aquatic species and sediment in northern California. Petreas (1991) collected samples of local fish species, bivalves (freshwater clams that had been transplanted 2 months earlier), and sediment samples at sites upstream, downstream, and within the vicinity of a pulp and paper mill plant. Whole body fish samples were composited, or analyzed individually, based on size. These samples were analyzed for PCBs 77, 126, and 169. Results of an analysis of the raw data from these samples are presented in Table 3-26. Levels of PCBs in fish tissue ranged from 1.2 pg/g for PCB congener 169 to 1,095 pg/g for PCB congener 77. Results of the fish tissue analysis according to sampling location indicated that "no special impact could be attributed to the pulp mill discharge" (Petreas, 1991). Bivalve concentrations ranged from 0.7 pg/g for PCB congener 169 to 102 pg/g for PCB congener 77. Concentrations of PCB congeners 77 and 126 were at least an order of magnitude higher in bivalves than in sediments from the same sampling location, indicating that these congeners bioconcentrate in the aquatic bivalve species evaluated. Bivalve and sediment impacts that could be attributed to facility discharges were not observed in this study.

Krahn et al. (1995) analyzed marine fish and invertebrates collected from several coastal sites of the northeastern United States for dioxin-like PCBs. Samples of winter flounder (muscle tissue), northern lobster (muscle tissue and hepatopancreas), and blue mussel (whole bodies) were analyzed for dioxin-like PCBs. Total mean PCB concentration

ranged from 4 ppt to 351 ppt in muscle tissue from flounder and lobster, and blue mussel whole bodies. Total PCB concentrations in lobster hepatopancreas ranged from 764 to 32,800 ppt. Total mean TEQ_P-WHO_{94} for these PCBs ranged from 0.1 ppt to 6.9 ppt for muscle tissue samples of winter flounder, 0.1 ppt to 3.7 ppt for whole blue mussels, and 0.1 ppt to 5.4 ppt for lobster muscle. Hepatopancreas tissue from lobster showed considerably higher TEQ_P-WHO_{94} concentrations, ranging from 5.2 ppt to 1,820 ppt.

Mes and Weber (1989) analyzed a freshwater fish composite sample and a canned fish composite sample for PCBs 77, 126, and 169. The number of samples included in these composites was not reported. Respective wet weight concentrations of these three PCBs were 36 ppt, 8 ppt, and <1 ppt for freshwater fish, and 8 ppt, 3 ppt, and <1 ppt for canned fish samples. In a later study, Mes et al. (1991) evaluated numerous PCB congeners including dioxin-like PCBs 105, 114, 118, 156, 157, and 189 in foods. A total of five composite freshwater fish, marine fish, and shellfish samples, each composite taken from major Canadian city, were analyzed for these PCBs. The number of samples included in these composites was not reported. Total PCB congener residues for freshwater fish, marine fish, and shellfish were 31.9 ppt, 4.6 ppt, and 0.9 ng/g, respectively, on a wet weight basis, based only on congeners observed in three out of five composites. Schecter et al. (1997) also analyzed freshwater and marine fish samples for dioxin-like PCBs 77, 105, 114, 118, 126, 169, and 180. Concentrations of these congeners ranged from not detected to 1,800 ppt on a whole weight basis in fresh fish, and from 0.20 ppt to 320 ppt in ocean fish. The total whole weight TEQ_P-WHO_{94} was 0.7 ppt for fresh fish and 0.2 for ocean fish, when nondetects were set to one-half the detection limit (Schecter et al., 1997).

3.6.2. European Data

Evaluation of fish in the Baltic Sea (Gulf of Bothnia) and northern Atlantic Ocean in the vicinity of Sweden revealed that concentrations of CDDs and CDFs in composited whole fish herring samples from the Atlantic Ocean were lower than those in the Gulf of Bothnia (Rappe et al., 1989b). Detectable levels of 2,3,7,8-TCDD in salmon muscle were found in both wild homing (4.6 to 19 ppt) and hatchery-reared (0.2 to 0.3 ppt) varieties in the Gulf of Bothnia. In addition, concentrations of the same representative congeners of the Cl_5 to Cl_8 CDD and CDF congener groups found in herring were found in both varieties

of salmon. Levels of those congeners in the muscle of wild salmon, however, were five to ten times higher than the herring levels, while the levels in the hatched salmon essentially were the same as in the herring samples. Perch collected at a distance of 1-6 km from a pulp mill in the southern part of the Gulf of Bothnia contained 2,3,7,8-TCDD and 2,3,7,8-TCDF; the levels were higher in the samples collected closer to the pulp mill. These two compounds have been identified in bleaching effluents from pulp mills, as well as in bleached pulp. Arctic char collected from Lake Vattern, a popular fishing lake in southern Sweden, contained levels of 2,3,7,8-TCDD (6.5 to 25 ppt whole weight), 2,3,7,8-TCDF (21 to 75 ppt whole weight), and representative congeners of the PeCDD and PeCDF homologues. There was a good correlation between the weight of the fish and the levels of CDDs and CDFs. The main general pollution sources of the long, deep, narrow lake are two pulp mills.

Fish (cod, haddock, pole flounder, plaice, flounder, and eel), mussels, and edible shrimp from a fjord area contaminated by wastewater from a magnesium factory in Norway were analyzed for CDDs and CDFs (Oehme et al., 1989). Certain magnesium production processes can result in the formation of substantial amounts of CDDs and CDFs as byproducts. The congener pattern of tetra- and penta-chlorinated CDDs and CDFs released in wastewater during the magnesium production process is very characteristic and is dominated by congeners with chlorine in the positions 1,2,3,7 and/or 8. Fish and shellfish differ in their ability to bioconcentrate CDD and CDF congeners. For example, fish generally only concentrate the most toxic 2,3,7,8-substituted congeners; whereas, shellfish can usually concentrate most of the congeners. Nearly all congeners were present in the shrimp and mussel samples. Although these organisms displayed the very characteristic PeCDF congener pattern of the magnesium production process, some deviations were found in the TCDF congener distribution within those species. For fish, the concentrations of CDDs and CDFs are dependent on the exposure level, fat content, living habit, and the species degree of movement. The highest CDD and CDF levels were found in comparatively high fat-content bottom fish collected close to the source. Cod and haddock (lower fat-content nonstationary fish) had much lower concentrations, even in the vicinity of the magnesium production factory. An interesting note is that the main stream of the fjord follows the west coast; subsequently, cod and eel samples collected along the west coast of the fjord had considerably higher levels of CDDs and CDFs than

those collected from the eastern fjord entrance. Similarly, the level of 2,3,7,8-TCDD in mussels decreased by one order of magnitude from the vicinity of the magnesium production factory to the outer region of the fjord system.

Brown trout, grayling, barbel, carp, and chub collected in the Neckar River in southwest Germany contained much higher levels of 2,3,7,8-TCDF than in eels collected from the same river and the Rhine River (Frommberger, 1991). In addition, eels from both rivers showed very similar patterns for CDD and CDF congener distribution; whereas, the patterns of CDD and CDF distribution generally showed some degree of difference among the other fish collected from the Neckar River. Perch and bream collected from various locations in the vicinity of Hamburg Harbor, however, showed similar patterns in the distribution of the Cl_4 to Cl_8 CDD and CDF congener groups (Gotz and Schumacher, 1990). In general, the levels of CDFs were higher than the level of CDDs in these fish, especially with regard to the TCDFs to HxCDFs. Pooled samples of eels, collected at six different localities in The Netherlands, contained low levels of CDDs and CDFs, the major congeners of which were 2,3,7,8-chlorine substituted (Van den Berg, 1987). Concentrations of the various congeners identified in the eel samples ranged from 0.1 to 9.1 ppt. The sample with the highest concentration of 2,3,7,8-TCDD (9.1 ppt) was collected from Broekervaart in a location that was not far from a chemical waste dump that contained high concentrations of the same congener.

In 1992, Falandysx et al. (1997) examined congener-specific PCB data in fish from the southern part of the Baltic Sea. Eight fish species were collected from the Gulf of Gdańsk near Gdynia. Total PCB levels were high in whole fish samples from this area, ranging from 1.4-million ppt lipid to 11-million ppt lipid. Measurements were performed for 94 PCB congeners. Predominant homologue groups were PeCBs and HxCBs, which constituted 33 to 46 percent and 36 to 46 percent of the total PCB concentrations, respectively. Of the five dioxin-like PCBs examined, levels were highest for PCB 118, and ranged from 160,000 ppt lipid in whole cod samples to 2-million ppt lipid in whole eelpout specimens. Also detected, but in lesser quantities, were TrCBs (0 to 0.9 percent), TCBs (5.5 to 11 percent), HpCBs (7.4 to 13 percent), OCBs (0.23 to 0.53 percent), nonachlorobiphenyls (0 to 0.5 percent), and aldo decachlorobiphenyl (<0.01 to 0.01 percent). A large degree of variability in total PCB levels between species of fish was observed. Total PCB levels in the whole fish samples ranged from 1,400 ng/g lipid weight

(47.6 ng/g wet weight) in cod to 11,000 ng/g lipid weight (48 ng/g wet weight) in pikeperch; 11,000 ng/g lipid weight (332.2 ng/g wet weight) in eelpout. The authors observed that with the relatively similar lipid content of the fish, which varies from 3.02 to 6.26 percent, the interspecies variability in the PCB congener pattern could possibly be attributed to variabilities in "enzyme activity, feeding behavior and trophic niche" (Falandysx et al., 1997).

Lulek et al. (1997) examined five random freshwater fish samples from five different Swiss and French lakes and rivers for 13 dioxin-like PCBs. The sampling locations included two from Lake Geneva, one each from the upper and lower Maggia River in Switzerland, and one from the Saône River in France. The analyzed fish included one each of three different species (i.e., bream, burbot, and arctic char) and two each of a fourth species (i.e., trout). Total PCB levels in the whole fish samples ranged from 1,137,000 ppt lipid (65,980 ppt wet weight) in the trout from the upper Maggia River to 3,235,000 ppt lipid (237,460 ppt wet weight) in the trout from the bottom of the Maggia River to 1,594,000 ppt lipid (254,430 wet weight) in the arctic char, to 2,179,000 ppt lipid (101,970 wet weight) in the burbot of Lake Geneva to 10,590,000 ppt lipid (402,420 ppt wet weight) in the bream of the Saône River. Congener profiles were similar in all species. Total TEQ_P-WHO_{94} concentrations in the whole fish ranged from 104 ppt lipid in the burbot to 523 ppt lipid in the bream (Lulek et al., 1997).

In 1995, the Ministry of Agriculture, Fisheries and Food (MAFF, 1998) sampled trout farms throughout England and Wales. Forty samples, each consisting of several fillets of muscle, were analyzed. When setting nondetects to the limit of detection, lipid-based CDD/CDF concentrations ranged from 2.1 to 13 ppt I-TEQ_{DF} (mean 5.1). Wet weight concentrations ranged from 0.06 to 0.67 ppg I-TEQ_{DF} (mean 0.24). Lipid based PCB concentrations varied from 8.9 to 51 ppt TEQ_P-WHO_{94} (mean 19.0), and wet weight levels ranged from 0.22 to 2.4 ppt TEQ_P-WHO_{94} (mean 0.87). Fat content in the samples ranged from 1.8 to 8.6 percent.

Robinson et al. (2000) analyzed over 100 samples of uncooked marine fish and fish fingers (i.e., fish coated with bread crumbs) for CDD/CDFs and numerous dioxin-like PCB congeners (e.g., 77, 81, 126, 169, 105, 114, 118, 156, 157, 167, 180, 189). Some of these fish were caught in United Kingdom waters; others were imported. The concentration of these compounds varied with fish species, fat content (i.e., fat weight

concentrations were higher in oily fish than in fish with lower fat contents), and sampling month (i.e., lower fat weight concentrations were seen in samples collected during February than in those collected in November and May). The lipid-weight TEQ-WHO_{98} concentrations are shown in Table 3-27. The method used for treating non-detected values in calculating TEQs was not reported. Jacobs et al. (2000) collected 10 samples of farmed Atlantic Salmon from several sites in Scotland and a site in Norway. The samples were analyzed for CDD/CDFs and seven PCB congeners (i.e., 77, 105, 118, 126, 156, 157, 169). TEQ_{DF}-WHO_{98}s ranged from 5 to 18 ppt, on a lipid basis, when non-detects were set to either one-half the detection limit or zero. TEQ_{P}-WHO_{98}s ranged from 9 to 25 ppt on a lipid basis. Lipid contents ranged from 3 to 15 percent. In general, the highest levels were observed in the oldest fish.

3.6.3. Fish Observations and Trends

Some general observations for CDD and CDF levels are possible from the data presented in the various fish and shellfish studies above:

- For fish, the concentrations of CDDs and CDFs are dependent on the exposure level, fat content, living habits, and the degree of movement of the species. Comparatively high fat-content bottom fish, collected close to the contaminant source, generally have the highest CDD/CDF levels; whereas, lower fat content, nonstationary fish have much lower concentrations, even in the vicinity of the contaminant source.

- The National Dioxin Study indicated that the levels of 2,3,7,8-TCDD in fish from the Great Lakes Region were higher than those from urban areas. Comparable levels were detected in whole bottom feeders and predators from the Great Lakes Region.

- With regard to PCBs, concentrations increase from water to lower organisms to small fish to salmonids, and the chlorine content of the PCBs increase at the higher trophic levels.

3.6.4. Fish CDD/CDF Profiles and Background TEQ Concentrations

Example CDD/CDF congener profiles for freshwater fish were generated using data for 10 freshwater fish samples collected from five U.S. States (i.e., New York, Illinois, Kentucky, California, and Georgia), as reported by Schecter et al. (1997). These profiles do not include all of the data used to estimate the background TEQ_{DF}-WHO_{98} concentration

in freshwater fish because congener-specific data were not available for all of the fish data used in calculating the background TEQ concentrations. The CDD/CDF profile for freshwater fish, based on Schecter et al. (1997), was generated by setting nondetects to zero and calculating the ratio of individual congener concentrations to total 2,3,7,8-substituted CDD/CDFs. This was done for consistency with other food profiles presented in this chapter. For marine fish, congener-specific data for mackerel from Mississippi, as reported in Fiedler et al. (1997c), were used to provide an example profile. The example profile for marine fish was based on one mackerel sample. An example shellfish profile was developed using data from Fiedler et al. (1997c), and is based on 13 samples, all presumed to be freshwater species (i.e., crab (n = 6), oyster (n = 3), crayfish (n = 4). Profiles were generated in the same manner as for freshwater fish. Profiles for freshwater fish, marine fish, and shellfish are presented in Table 3-28 and Figure 3-6. In general, CDDs account for a higher percentage of the total 2,3,7,8-substituted CDD/CDFs than CDFs. OCDD is the dominant congener for all three fish groups with 1,2,3,4,6,7,8-HpCDD accounting for the second highest percentage.

Although a comprehensive market basket survey representing the most commonly eaten fish species by the general population would probably provide the best information on background concentrations of CDD/CDFs in fish and corresponding background exposures from fish ingestion, these data are not available from a single source. Thus, the background CDD/CDF TEQ concentrations for freshwater and marine finfish and shellfish were estimated based on data from a variety of studies. These studies included EPA's National Bioaccumulation Study (U.S. EPA, 1992), Fiedler et al. (1997), Jensen and Bolger (2000), and Jensen et al. (2000). These studies were selected because they are based on sampling from grocery stores and/or are based on a National sampling strategy. It should be noted, however, that although the National Bioaccumulation Study data are based on a National sampling, they may be more representative of wild caught fish (i.e., recreational fishing) than fish obtained by the general population at grocery stores. For example, a large percentage of the trout consumed by the general population is likely to be farm-raised. However, because no data were available on farm-raised (or grocery store) trout, the concentration of CDD/CDFs in wild caught trout were used in estimating background fresh and estuarine finfish concentrations. For catfish, which is also primarily farm-raised, grocery store data from FDA's market surveys were used. Concentrations for

several other species (i.e., mullet and mackerel) were based entirely on data collected in the Mississippi area; and may not be entirely representative of levels seen in other locations. Finally, concentrations for some species were averaged over several data sets. In most cases, similar concentrations for these species were observed in the various studies. Species-specific mean concentrations represent the average of the mean concentrations for the various sites where samples were collected, and not the mean of all individual samples. The mean is used to ensure that each site is weighted equally (i.e., heavily sampled sites do not have any greater impact on the overall mean that sites with fewer samples).

Average background concentrations were estimated for freshwater fin- and shellfish, and marine fin- and shellfish by weighting the species-specific fish concentrations according to their species-specific fish consumption rates for the U.S. population (U.S. EPA, 2000). The consumption data are based on an analysis of the USDA's 1994-96 Continuing Survey of Food Intake Among Individuals (CSFII). Weighting was accomplished by multiplying the consumption rates in g/day by the TEQ_{DF}-WHO_{98} concentrations in pg/g. The resulting TEQ intakes in pg/day were then summed by category. Finally, the total TEQ intake (g/day) for the category was divided by the total TEQ consumption rate (g/day) to estimate the weighted average background concentration (pg/g) (Table 3-29).

For consumption categories for which no species-specific concentration data were available, default values were selected to represent that fish category. For example, for freshwater and estuarine finfish, the average TEQ_{DF}-WHO_{98} concentration from U.S. EPA (1992) was used in conjunction with the total consumption rate for those species with no corresponding concentration data. For freshwater/estuarine shellfish, the default value used for the "other" category represents the average concentration for the freshwater/estuarine shellfish species for which concentration data were available. Likewise for marine finfish and shellfish, the default concentration used is the average concentration for species with specific concentration data. This adds a degree of uncertainty to the estimates. Based on this analysis of the available species-specific fish data that are most representative of consumption among the U.S. population, the average background TEQ_{DF}-WHO_{98} concentration in freshwater fish and shellfish was estimated to be 1.0 ppt, assuming non-detects are equal to one-half the detection limit. The

background value for marine fish and shellfish was estimated to be 0.26 ppt TEQ_{DF}-WHO_{98}, when non-detects were set to one-half the detection limit.

The background TEQ_P-WHO_{98} concentration in freshwater fish and shellfish was estimated to be 1.2 ppt, when nondetects were set to one-half the detection limit, based on data from Schecter et al. (1997), Mes and Weber (1989), and Mes et al. (1991). TEQ_P-WHO_{98} for marine fish and shellfish was estimated to be 0.25 ppt when nondetects were set to one-half the detection limit, based on Mes and Weber (1989), Mes et al. (1991), and supermarket data from Schecter et al. (1997), as presented in Section 3.7.2.

3.7. CONCENTRATIONS IN FOOD PRODUCTS

Dietary intake is generally recognized as the primary source of human exposure to CDD/CDFs (Rappe, 1992). Several studies estimated that over 90 percent of the average daily exposure to CDD/CDFs are derived from foods (Rappe, 1992; Henry et al., 1992; Fürst et al., 1991). CDD/CDFs in fatty foods such as dairy, fish, and meat products are believed to be the major contributors to dietary exposures (Rappe, 1992; Henry et al., 1992). Travis and Hattemer-Frey (1991), using a fugacity model, estimated that the food chain, especially meat and dairy products, accounts for 99 percent of human exposure to 2,3,7,8-TCDD.

Analysis of trace levels of CDD and CDF congeners in food has been hindered in the past by lack of sensitive analytical detection methods, extraction difficulties from the high-lipid content food products in which these chemicals are most often found, and the presence of other potentially interfering organochlorine compounds. However, as the analytical difficulties associated with detecting CDD and CDF congeners at ppt levels or lower (Firestone, 1991) were overcome, more food data began to be generated. In recent years, EPA, in association with the U.S. Department of Agriculture (USDA), has conducted several studies of dioxin-like compounds in foods. The results of these studies are presented in the following sections.

Tables B-14 and B-15 (Appendix B) contain summaries of data from the recent published literature regarding concentrations of CDDs and CDFs in food products. Most of the selected studies investigated "background" levels of CDDs and CDFs rather than studies targeted at areas of known contamination. Table B-16 contains a summary of PCB congener concentrations in food products.

Studies summarized in Tables B-14 and B-15 primarily examined CDD and CDF levels in products of animal origin (i.e., fish, meat, eggs, and dairy products). Because of their lipophilic nature, CDDs and CDFs are expected to accumulate in these food groups. Data in the tables indicate that CDDs and CDFs are found at levels ranging from the intermediate ppq up to the low ppt range. As expected, the highest levels reported are those measured in foods with high animal fat content. The highest reported congener concentrations are for the HpCDDs and OCDD. In general, for the less-chlorinated congener groups (i.e., Cl_4 - Cl_6), the CDD and CDF levels are both low and of similar magnitude. However, for the Cl_7 and Cl_8 congener groups, CDDs are higher than CDFs.

3.7.1. Migration of CDD/CDF from Paper Packaging Into Food

In the past, low levels of CDDs and CDFs have been detected in bleached paper. (See discussion in Volume 1.) Because bleached paper is sometimes used for food packaging, concern has been expressed that CDD/CDFs may migrate from the paper into the food.

Using refined and highly sensitive analytical methods, LaFleur et al. (1990) observed the migration of 2,3,7,8-TCDD, 2,3,7,8-TCDF, and 1,2,7,8-TCDF from bleached paper milk cartons into whole milk. After 12 days of exposure, 6.7 percent of the 2,3,7,8-TCDD; 18 percent of the 2,3,7,8-TCDF; and 13 percent of the 1,2,7,8-TCDF in the milk carton leached into the milk. The concentrations of the three congeners in milk were 8.5, 110, and 49 pg/kg for 2,3,7,8-TCDD; 2,3,7,8-TCDF; and 1,2,7,8-TCDF, respectively. [Note: These data are not reported in Appendix B; only data for raw milk are reported.] LaFleur et al. (1990) also analyzed a single background milk sample for 2,3,7,8-TCDD and 2,3,7,8-TCDF. The sample contained 2,3,7,8-TCDD at a concentration of 1.8 pg/kg and nondetectable concentrations of 2,3,7,8-TCDF.

Study results reported by LaFleur et al. (1990) were performed by the National Council of the Paper Industry for Air and Stream Improvement (NCASI) at the request of the U.S. Food and Drug Administration (FDA) as part of a cooperative Federal agency effort to assess the risks posed by dioxin contamination of paper products (i.e., the Federal Interagency Working Group on Dioxin-in-Paper). In addition to assessing the migration of CDDs and CDFs from milk cartons, studies were also conducted to assess the extent of CDD/CDF migration into food from coffee filters, cream cartons, orange juice

cartons, paper cups for hot beverages, paper cups for soup, paper plates for hot foods, dual ovenable trays, and microwave popcorn bags. Migration of CDD/CDFs from the paper into food was observed in all studies. Results of these migration studies and an assessment of the risks to the general population posed by migration from paper are addressed in detail in U.S. EPA (1990). CDD/CDF levels currently found in food due to any leaching of dioxin-like compounds from paperboard containers are expected to be significantly lower than those reported in U.S. EPA (1990) because of process changes implemented by the pulp and paper industry to reduce formation of CDDs and CDFs (59 FR 17384).

In 1990, EPA referred the issue of potential CDD/CDF contamination from bleached food-contact paper products to FDA, because the risks were considered to be unreasonable in accordance with Section 9(a) of TSCA (55 FR 53047). In a 1994 Federal Register notice (59 FR 17384), FDA outlined various options being considered to address this issue, including the voluntary industry program to reduce TCDD in food-contact bleached paper products that had been in effect since 1990. As discussed in Volume 1, the paper industry has made process changes that they expect have generally reduced dioxin levels in bleached paper pulp to less than 2 ppt of I-TEQ_{DF}. Similar or lower levels could be expected in final paper products. NCASI reports that essentially no detectable migration of dioxin to milk occurs from cartons at these levels. According to an industry-wide survey conducted in 1993 by the American Forest and Paper Association, the voluntary specification for 2 ppt or less TCDD has been met by industry (59 FR 17384). This standard was still being met in 1995 (personal communication between G. Schweer, Versar, Inc. and E. Machuga, FDA, October 5, 1995).

3.7.2. North American Food

Until recently, data on measured levels of CDDs, CDFs, and dioxin-like compounds in U.S. food products have generally come from studies of a specific food product(s) in a specific location(s) rather than from large survey studies designed to allow estimation of daily intake of the chemicals for a population. For example, CDD/CDFs have not been routinely monitored for in the U.S. FDA Surveillance Monitoring Program for domestic and imported foods (conversation between Dr. S. Page, FDA, and G. Huse, Versar, Inc., February 8, 1993) nor have they been routinely monitored for by the U.S. Department of

Agriculture (USDA) in the National Meat and Poultry Residue Monitoring Program (conversation between Dr. E. A. Brown, USDA-FSIS, and G. Schweer, Versar, Inc., February 8, 1993).

However, USDA has developed some site-specific, though dated (late 1970s), CDD monitoring data, and recently, EPA and USDA conducted joint statistically-based national studies to evaluate the amount of CDD/CDF residues in animal products. Earlier efforts by USDA to examine CDD/CDFs in animal products were in response to a decline in general health noted by inspectors in several cattle herds in Michigan. Wood products in the local barns and other cattle holding premises, presumed to be treated with pentachlorophenol (PCP), were suspected as the cause of this health decline (Buttrill et al., 1978; Tiernan and Taylor, 1978). PCP was suspected to contain trace CDD and CDF levels as manufacturing contaminants at that time. In response to this incident, USDA performed two national investigations. The first study analyzed peritoneal adipose and liver samples collected from beef cattle in 23 States (Tiernan and Taylor, 1978), while the second study analyzed adipose tissue samples (body region not specified) collected from dairy cattle in 30 States (Buttrill et al., 1978)--neither study specified the cattle breeds for any sample. HxCDD, HpCDD, and OCDD were screened for in the analyses of samples from each study. In the beef cattle study (Tiernan and Taylor, 1978), 220 samples were analyzed: 189 peritoneal adipose samples and 31 liver samples. No residues were detected in any liver samples. A total of 19 (i.e., 10 percent) of the 189 adipose samples were found to contain HxCDD, HpCDD, or OCDD at levels >0.10 ppb (assumed to be on a whole weight basis), while 56 (i.e., 30 percent) contained levels <0.10 ppb (assumed to be on a whole weight basis) that were detectable based on the signal-to-noise ratio of the analytical instrumentation. OCDD accounted for the majority of the samples that positively contained CDDs (i.e., 17 or 9.0 percent), while only 3 samples contained HxCDD and 2 samples contained HpCDD residues. In the dairy cattle study, 358 adipose samples were analyzed (Buttrill et al., 1978). Nine samples (i.e., 2.5 percent) positively contained CDD levels >0.19 ppb or the "level of reliable measurement," while another 30 samples (i.e., 8.4 percent) contained identifiable CDD levels that were below the "level of reliable measurement" (i.e., not positively identified due to low concentration levels). As with the beef cattle study results, OCDD accounted for the majority (eight) of positive samples. HpCDD was identified in only a single sample that also contained OCDD.

HxCDD was also identified in only a single sample. Data from the USDA studies are not useful for estimating CDD/CDF exposure for two reasons. First, the samples were analyzed for only 3 of the 17 CDD/CDF congeners with dioxin-like toxicity, and these were reported on a homolog basis rather than a congener-specific basis. Second, the limit of detection was at or above 0.1 ppb or 100 ppt. Background levels for individual congeners appear to be much less than 100 ppt. For example, the highest congener levels in beef fat analyzed by Fürst et al. (1990) were 5.4 ppt for OCDD.

FDA has also conducted some limited analyses for the higher-chlorinated dioxins in market basket samples collected under FDA's Total Diet Program (Firestone et al., 1986). Food samples found to contain PCP residues >0.05 µg/g were analyzed for 1,2,3,4,6,7,8-HpCDD and OCDD. Also, selected samples of ground beef, chicken, pork, and eggs from the market basket survey were analyzed for these dioxin congeners, regardless of the results of PCP residue analysis. Between 1979 and 1984, 16 ground beef samples, 18 pork samples, 16 chicken samples, and 17 eggs samples with no PCP contamination were collected at various locations throughout the United States and analyzed for 1,2,3,4,6,7,8-HpCDD and OCDD. No dioxin residues were detected in any of the ground beef or egg samples. OCDD was observed at detectable concentrations in only 2 of the 18 pork samples (27 ppt 53 ppt) and 2 of the 16 chicken samples (29 ppt, 76 ppt). One chicken sample with PCP residues >0.05 µg/g had detectable residues of both 1,2,3,4,6,7,8-HpCDD (28 ppt) and OCDD (252 ppt). Egg samples from Houston, Texas, and Mesa, Arizona, with PCP residues >0.05 μg/g, had detectable 1,2,3,4,6,7,8-HpCDD levels ranging from 21 ppt to 588 ppt, and OCDD levels ranging 80 ppt to 1,610 ppt. These levels were attributed to local PCP contamination (Firestone et al., 1986). Milk samples, contaminated with PCP at levels ranging from 0.01 µg/g to 0.05 µg/g PCP, contained no detectable dioxins. It should be noted that these food residue data were not used in this assessment of dioxin exposures in the United States, because the reported limits of detection (10 to 40 ppt) for the FDA analyses were considerably higher than the levels of dioxins observed in foods from more recent studies. Also, the study only analyzed for residues of 2 of the 17 toxic CDD/CDF congeners. Finally, the study focused on samples with PCP contamination and, therefore, was not generally representative of background exposures.

FDA conducted a market basket survey of dairy products and commercial fish and shellfish in 1995/96 (Bolger and Jensen, 1998). Analysis of the foods for CDD/CDFs demonstrated that, other than the catfish samples, few of the food products had quantifiable levels of CDD/CDFs below 1 ppt. Samples containing detectable levels below 1 ppt yielded uncertain results, highly dependent on what value nondetects were set to (i.e., zero, one-half the detection limit, or the detection limit). Consequently, the market basket survey results were not used in calculation of background estimates of CDD/CDFs. Catfish fillet samples did, however, show quantifiable results. Twelve of the 19 catfish samples were suspected of being linked to the use of ball clay as a feed additive. CDD/CDF levels in these fillets ranged from 1.20 to 5.66 ppt I-TEQ_{DF} (mean = 3.11), when nondetects were set to one-half the detection limit and also when nondetects were set to the limit of detection. The seven uncontaminated catfish samples had levels ranging from 0.03 to 0.70 ppt I-TEQ_{DF} (mean = 0.29), when nondetects were set to one-half the detection limit, and 0.05 to 0.71 ppt I-TEQ_{DF} (mean = 0.31), when nondetects were set to the limit of detection.

Jensen and Bolger (2000) and Jensen et al. (2000) reported on additional FDA market basket dairy samples collected during 1996 through 1999. These data are shown in Table 3-30. FDA also analyzed 15 composite egg samples collected in 1997 from California, Ohio, Georgia, New York, Pennsylvania, Oregon, Minnesota, and Wisconsin (two composite samples were collected from each state except Oregion, which had only one composite) (Hayward and Bolger, 2000). Each composite contained 24 eggs. The TEQ_{DF}-WHO_{98} for these samples was 0.07 pg/g whole weight when only the positive samples were included in the TEQ calculation. When all sample results were included in the analysis, the mean TEQ_{DF}-WHO_{98} concentration was 0.013 when non-detects were set to zero and 0.081 when non-detects were setto one-half the detection limit.

Cooper et al. (1995) collected 38 samples of various food items from grocery stores and local fish markets in southern Mississippi during the spring of 1994. Food items "were selected based on their suspected high levels of CDD/CDF to the dietary intake." Thus, locally consumed dairy products, meat, egg, and seafood samples were collected, but items such as vegetables, fruit, grain, and cereal products were not sampled. All 38 samples collected had detectable levels of CDD/CDFs. I-TEQ_{DF} concentrations for each sample are reported in Table 3-31. In general, the levels of

CDD/CDFs in fish and shellfish were higher than the levels in meat and dairy products, and farm-raised catfish had the highest I-TEQ_{DF} concentrations of all the food types analyzed. I-TEQ_{DF} concentrations in meat and dairy products were slightly lower than those reported in other U.S. and European studies (Cooper et al., 1995).

As an extension of previous studies of food samples collected in southern Mississippi, Fiedler et al. (1997d) examined the CDD/CDF I-TEQ_{DF} concentrations of seven restaurant-prepared food dishes. Samples included: a veal chop, chicken strips and fries, blackened amberjack fish fillet, seafood soup, pasta with cheese and cream sauce, cheese sticks, and cheese cake. I-TEQ_{DF} values of CDD/CDFs ranged from 0.0197 ppt to 0.173 ppt on a fresh weight basis and from 0.128 ppt to 1.67 ppt on a lipid basis. The veal chop contained the highest I-TEQ_{DF} levels with 1.67 ppt I-TEQ_{DF} (lipid) and 0.173 ppt (whole weight), and also had measurable quantities of all the analyzed CDD/CDF congeners with the exception of 2,3,7,8-TCDD. 2,3,7,8-TCDD was not detected in quantifiable amounts in any of the restaurant samples. The major fraction of the total I-TEQ_{DF} came from PeCDDs and HxCDDs in most of the samples. The authors observed similar congener patterns in the dairy-based dishes (cheese sticks, pasta with cream sauce, and cheese cake) and in the veal chop sample. Specifically, the ratios between the HxCDDs (1,2,3,4,7,8-, 1,2,3,6,7,8-, and 1,2,3,7,8,9-) were approximately 1:4:1, and the concentration of 1,2,3,7,8-PeCDD and 2,3,4,7,8-PeCDF was approximately the same in dairy-based and veal chop dishes. The authors speculated that a dairy diet for the source cattle would possibly explain the similar pattern in the veal chop and dairy-based dishes. I-TEQ_{DF} levels in the restaurant-prepared seafood dishes were lower than I-TEQ_{DF} levels of store purchased seafood items and farm-raised catfish items from southern Mississippi studied by Cooper et al. (1995). An I-TEQ_{DF} level of 0.5 ppt (lipid) was found by Fiedler et al. (1997d) in restaurant-prepared fish fillet samples, while a mean I-TEQ_{DF} level of 20.5 ppt (lipid) was observed in commercially bought fresh farm-raised catfish nuggets by Cooper et al. (1995) in the same area of southern Mississippi. The restaurant-prepared seafood soup had an I-TEQ_{DF} of 0.646 ppt (lipid), while the I-TEQ_{DF} levels of store purchased fresh crab and crawfish ranged from 5.23 to 40.1 ppt (lipid). Fiedler et al. (1997d) calculated the contribution of the seven restaurant food items to the percentage of daily intake. Based on an assumed average daily dietary CDD/CDF intake of 100 pg I-TEQ_{DF}/person, the veal chop would contribute 46 percent of the daily intake, the chicken

strips 6.7 percent, the fish fillet 7.7 percent, the seafood soup 18 percent, the pasta with cream sauce 51 percent, the cheese sticks 13 percent, and the cheese cake 15 percent.

The California Air Resources Board (CARB) collected multiple samples of seven types of foods from commercial food sources in two urban areas of California (Stanley and Bauer, 1989). Foods were collected randomly, but an emphasis was placed on food stuffs of California origin (Stanley and Bauer, 1989). The types of food stuffs included saltwater fish, freshwater fish, beef, chicken, pork, milk, and eggs. A total of 210 samples were collected in Los Angeles (30 individual samples of each of the 7 types of foods), and 140 samples were collected in San Francisco (20 individual samples of each of the 7 types of foods). Food items were composited before chemical analysis to obtain a sample that was representative of average levels of CDDs and CDFs in the food stuffs, increase the probability of detection, and reduce the cost of chemical analysis. Samples were composited separately for each type of food stuff within each geographical area. Each composite sample contained 6 to 10 individual food samples, and 5 to 8 composite samples were analyzed for each food type. CARB data are summarized in Table 3-32. Beef (ground beef), pork (bacon), chicken, fish, and milk samples were analyzed on a lipid weight basis; however, for the purposes of this report, they were subsequently converted to a wet weight basis by multiplying the lipid weight concentration of CDD/CDFs by the fraction of fat contained in the food product of interest. Assumed lipid contents of 19, 15, and 4 percent for beef, pork and chicken, and milk were used. When nondetects were set to one-half the detection limit, the mean I-TEQ_{DF}s were 0.29 ppt, 0.24 ppt, 0.21 ppt, and 0.06 ppt for beef, pork, chicken, and milk, respectively. When nondetects were set to zero, I-TEQ_{DF}s were 0.03, 0.05, 0.08, and 0.02, respectively. Egg samples were analyzed for CDD/CDFs on a wet weight basis. I-TEQ_{DF}s for eggs were 0.14 ppt, when nondetects were set to one-half the detection limit and 0.004 when nondetects were set to zero.

The NCASI study (as described by LaFleur et al., 1990; and Henry et al., 1992) collected random food samples directly from the shelves of grocery stores located in the southern, midwestern, and northwestern regions of the United States. The samples were analyzed for 2,3,7,8-TCDD and 2,3,7,8-TCDF. These data are summarized in Table 3-33.

Schecter et al. (1993a) conducted complete congener analyses of 18 food samples collected from a supermarket in Binghamton, New York, in early 1990. Samples included

five fish, three types of beef (ground beef, beef sirloin tip, and beef rib steak), one chicken drumstick, one porkchop, one lamb, one ham, one bologna, one heavy cream, and four types of cheese. The following ranges of I-TEQ_{DF} levels on a whole weight basis were found: fish: 0.02 - 0.24 ppt; meat: 0.03 - 1.5 ppt; and dairy products: 0.04 - 0.7 ppt. These data are summarized in Table 3-34.

In a more recent study, Schecter et al. (1997) analyzed food samples collected directly from supermarkets in five U.S. cities: Binghamton, New York; Chicago, Illinois; Louisville, Kentucky; Atlanta, Georgia; and San Diego, California. The types of foods collected included: beef, chicken, ocean fish, fresh fish, and pork. Samples of each food type from the five geographic regions were pooled and analyzed for CDD/CDFs and selected PCBs. Ranges of CDD/CDF I-TEQ_{DF} values were calculated for each food group by assigning either zero or the detection limit to undetected congeners. The following ranges of CDD/CDF I-TEQ_{DF} levels on a lipid weight basis were found: beef: 0.89 - 2.86 ppt; chicken: 0.10 - 5.17 ppt; ocean fish: 2.45 - 21.14 ppt; fresh fish: 12.51 - 16.07 ppt; and pork: 0.64 - 3.97 ppt. These data are summarized in Table 3-35. Using the reported lipid content of these pooled samples to calculate the whole weight concentrations, the whole weight equivalents for these ranges are estimated to be: beef: 0.12 - 0.38 ppt; chicken: 0.005 - 0.28 ppt; ocean fish: 0.035 - 0.30 ppt; fresh fish: 0.60 - 0.78 ppt; and pork: 0.06 -0.36 ppt. PCB concentrations are also presented in Table 3-35. Schecter et al. (2001) reported again on the data collected from supermarkets in five U.S. cites. In this paper, mean TEQ_{DEP}-WHO_{98} concentrations for the same foods as described previously in Schecter et al. (1997) were presented. The whole weight mean TEQ_{DFP}-WHO_{98} concentrations were as follows when non-detects were set to one-half the detection limit: beef: 0.40 ppt; chicken: 0.33 ppt; pork: 0.39 ppt; ocean fish: 0.39 ppt; and fresh fish: 1.7 ppt. When non detects were set to zero, the mean whole weight TEQ_{DFP}-WHO_{98} concentrations were: beef: 0.16 ppt; chicken: 0.14 ppt; pork: 0.12 ppt; ocean fish: 0.16 ppt; fresh fish: 1.6 ppt.

Schecter and Li (1997) also analyzed four kinds of U.S. fast foods (i.e., hamburger, pizza, fried chicken, and ice cream) for CDD/CDFs and dioxin-like PCBs (105, 108, 156, 180). The I-TEQ_{DF} concentrations were similar for hamburger, pizza, and chicken, ranging from approximately 0.01 ppt wet weight, when a value of zero was used for nondetected congeners, to 0.3 ppt wet weight, when the detection limit was used for nondetected

congeners to calculate the total I-TEQ_{DF} value. These values are similar to those observed for other raw food groups and may indicate that cooking does not have a significant effect on the levels of CDD/CDFs in foods. (Further discussion on the effects of cooking can be found in Section 3.7.5.) The I-TEQ_{DF} concentrations for ice cream ranged from 0.03 to 0.49 ppt. Only PCB 180 was detected in hamburger at a concentration of 126 ppt. In pizza, PCB 118 (189 ppt) and PCB 180 (152 ppt) were detected, and in fried chicken, only PCB 118 (250 ppt) was detected. None of the PCB congeners evaluated were quantifiable in ice cream.

Schecter et al. (1989b) compared the levels of CDD/CDFs in cow's milk and infant formulas from Thailand and the United States. Samples of cow's milk and infant formulas were obtained from grocery stores in the Binghamton, New York, area in 1987. Thai formulas were purchased in Bangkok, Thailand, in 1986. In general, the I-TEQ_{DF} levels, on a lipid basis, were lower in infant formula than in cow's milk (Table 3-36). In addition, the formulas that were purchased in the United States had lower I-TEQ_{DF} levels than those purchased in Thailand. On a sample weight basis, the I-TEQ_{DF} level for whole cow's milk was 0.04 ppt (i.e., 1.2 lipid based ppt x 3.4 percent fat). This is similar to I-TEQ_{DF} levels observed for cow's milk in other parts of the United States and in Europe. Using a Nordic model for calculating TEQs, the data for cow's milk and infant formulas were compared to the Nordic-TEQ levels found in human milk samples from various countries. Human milk from industrialized areas (i.e., United States, Germany, and South Vietnam) had higher CDD/CDF Nordic-TEQ levels than either cow's milk or soy-based infant formulas.

U.S. EPA (1991) collected milk samples from several sites in the vicinity of a municipal waste incinerator in Rutland, Vermont, and two background samples from a dairy farm 123 kilometers from the incinerator, where no obvious industrial sources of CDD/CDF were present. All samples were taken from bulk storage tanks at the farms. The report indicated that facility emissions could not be correlated with the levels of CDD/CDF and other contaminants measured in various environmental media. For all milk samples, the majority of the congeners were not detected. It was reported that only OCDD was consistently detected at levels from 0.2 to 2.4 pg/g in the farms near the facility. The levels in milk from the three farms near the facility ranged from about 0.2 to 0.4 pg of I-TEQ_{DF}/g whole milk, and the I-TEQ_{DF} for the background samples collected from the distant farm was 0.12 pg/g. I-TEQ_{DF}s were calculated by U.S. EPA (1991) by

setting the nondetects equal to the detection limit. The 0.12 ppt I-TEQ_{DF} background value estimated by EPA is nearly 2 orders of magnitude higher than the I-TEQ_{DF} for milk based on the NCASI data. (This is probably due largely to the incomplete congener analysis conducted by LaFleur et al., 1990.) Examination of the raw data supporting this study indicated that all of the CDD/CDF congeners in the background sample were nondetectable. Consequently, if nondetects are set to zero, the total background I-TEQ_{DF} for milk would be zero. If half the detection limits are used to calculate the total I-TEQ_{DF} level, the estimated value is 0.07.

Birmingham et al. (1989) analyzed CDD/CDF residues in food collected in Ontario, Canada. Most of the food was grown in Canada, although some was from the United States. They reported analyzing 25 composite samples from 10 food groups. The precise number of samples in each food group was not reported. No TCDD, PeCDD, HxCDD, TCDF, or PeCDF were found at detection limits of 0.1 to 7 ppt. Low ppt levels of some of the higher chlorinated CDD/CDFs were detected in some foods. I-TEQ_{DF} levels were also estimated for the major food groups. However, as shown in Table 3-36, these data were reported on a homolog basis. It is unclear what procedure was used to convert the homolog data to I-TEQ_{DF}. The text implies that nondetects were treated as zero for purposes of estimating I-TEQ_{DF}. In addition to the animal food data shown in Table 3-37, measurements were also made in potatoes, apples, tomatoes, peaches, and wheat. Only OCDD was detected at levels ranging from 0.6 to 8 pg/g fresh weight. The I-TEQ_{DF} totals for vegetables were reported as 0.004 ppt for fruit, 0.002 ppt for vegetables, and 0.0007 ppt for wheat- based products. The procedure used to develop these I-TEQ_{DF} estimates was not clear.

Canada has a food safety program that analyzes total diet samples (i.e., representative food samples of the general population) for chemical substances, The analyses are run on commercially bought and prepared foods. As a part of that program, Ryan et al. (1997) analyzed CDD/CDFs and non-ortho PCBs in 44 food composites from Toronto and also in 44 composite samples from Montreal during the summers of 1992 and 1993, respectively. To optimize specific congener detection, samples of primarily animal origin were analyzed. Food groups included beef (ground beef, beef steak, beef roast), cured pork, organ meat, and poultry, dairy products of varying lipid content (whole milk, 1 percent milk, cream, cheddar cheese, and butter), fish (fresh water and marine),

and cooking fats and salad oils. Congener-specific data were not presented in this report. I-TEQ_{DF} levels and TEQ_{P}-WHO_{94} levels were calculated by setting nondetects to one-half the detection limit. These data were reported on a whole weight basis. TEQ values for each city are summarized in Table 3-38. The highest concentrations of total TEQ_{DFP}-WHO_{94} were found in butter (0.93 ppt in Toronto and 0.62 ppt in Montreal), fresh water fish (0.62 ppt in Toronto and 0.48 ppt in Montreal), oils (0.44 ppt in Toronto and 0.31 ppt in Montreal), and in ground beef (0.39 ppt in Toronto and 0.37 ppt in Montreal). TEQs for dairy products increased with increasing lipid content. Butter (lipid content approximately 70 percent) had a total TEQ_{DFP}-WHO_{94} of 0.93 ppt in Toronto and 0.62 in Montreal, while 1 percent milk (lipid content approximately 0.48 percent) had a TEQ_{DFP}-WHO_{94} of 0.036 ppt in Toronto and 0.025 ppt in Montreal. Fresh water fish, with a total TEQ_{DFP}-WHO_{94} of 0.62 ppt (Toronto) and 0.48 ppt (Montreal), were found to have higher total TEQ_{DFP}-WHO_{94} levels than marine fish (0.28 ppt in Toronto, and 0.12 ppt in Montreal). PCBs constituted 58 percent of the total TEQ_{DFP}-WHO_{94} value in Toronto (0.36 ppt) and 67 percent in Montreal (0.32 ppt). In the meat food group, more of the total TEQ_{DFP}-WHO_{94} was attributable to the CDD/CDF portion than the non-ortho PCB portion. The proportion of total TEQ_{DFP}-WHO_{94} attributable to non-ortho PCBs was greater in the dairy products and fish than in the meat samples.

Mes and Weber (1989) analyzed one composite sample each of beef, butter, cheese, eggs, organ meats, and poultry for PCBs 77, 126, and 169. The number of individual samples included in these composites was not reported. Whole weight concentrations of total PCBs (i.e., the sum of PCB 77, 126, and 169) were as follows: beef - 2 ppt, butter - 24 ppt, cheese - 11 ppt, eggs - 3 ppt, organ meats - 4 ppt, and poultry - 2 ppt. In a later study, Mes et al. (1991) evaluated numerous PCB congeners including dioxin-like PCBs 105, 114, 118, 156, 157, and 189 in foods. Five composite samples of the following food types were collected: milk, various dairy products, various cuts of beef and pork, lamb, organ meats, fish, eggs, luncheon meats, cooking fats, and soup. The number of individual samples included in each of these composites was not reported. Each composite sample was taken from one of five major Canadian cities. Among these foods, total whole weight PCB concentrations were highest for freshwater (31.9 ng/g), canned (9.9 ng/g), and marine (4.6 ng/g) fish, followed by butter (3.0 ng/g)

and cheese (1.7 ng/g). Concentrations were lowest (i.e., <0.1 to 0.1 ng/g) in canned meat soup, margarine, milk, yogurt, and lamb.

Recently, EPA has worked in cooperation with USDA to estimate the levels of CDD/CDFs and dioxin-like PCBs in U.S. food products. Analyses have been conducted for beef, pork, poultry, and milk products. A study of CDD/CDFs in vegetable oils has also been conducted. Data from the completed EPA/USDA studies are used in this Chapter to estimate background levels of CDD/CDFs and dioxin-like PCBs in foods. These studies were designed to be representative of the animal products used in the United States, and are believed to be suitable for calculating national averages.

Beef

EPA conducted a joint study with USDA to evaluate the amount of CDD/CDF residues in beef animals from federally inspected establishments (Winters et al., 1996a). Using a statistically-based sampling plan, 63 back fat samples were collected. Back fat was selected for sampling because: (1) it was assumed to be representative of fat people consume, because it is an extension of the fat reservoir, which, at another point, is the fat that is on rib cuts; (2) it was obtainable with little disruption by the USDA Federal inspectors who collected the samples; and (3) it has high fat content, which would optimize the analytical capability of measuring dioxins in the matrix. The average fat content of the samples was 80 percent. The sampling plan was designed to provide samples representative of the slaughtering establishments, cattle class (i.e., bulls, steer, heifers, beef cows, and dairy cows) and region of the United States in order to provide a national estimate of CDD/CDFs in beef. Tissue samples were analyzed for the residues of the 17 toxic CDD/CDF congeners and for percent lipid content. Limits of detection for the study were 0.05 ppt for the tetra-CDD/CDFs, 0.5 ppt for the penta-, hexa-, and hepta-CDD/CDFs, and 3.0 ppt for OCDD/CDF, on a whole weight basis. Because the samples were 80 percent fat, these whole weight detection limits translate to average lipid-based detection limits of 0.0625 ppt for the tetra-CDD/CDFs, 0.625 ppt for the penta-, hexa-, and hepta-CDD/CDFs, and 3.75 ppt for OCDD/OCDF.

Based on the analytical results, the most frequently detected CDD/CDF congener was 1,2,3,4,6,7,8-HpCDD. This congener was detected in over 70 percent of the samples and most frequently had the highest concentration of all the CDD/CDF congeners.

The second most frequently detected congener was 1,2,3,6,7,8-HxCDD, which was detected in approximately 32 percent of the samples. The most toxic congener, 2,3,7,8-TCDD, occurred in 11 of the 63 samples. Congeners not detected in any of the 63 beef samples included 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, 1,2,3,7,8,9-HxCDF, 1,2,3,4,7,8,9,-HpCDF, and OCDF. Of the 17 congeners, 1,2,3,4,6,7,8-HpCDD and OCDD had the highest mean concentrations for the 63 beef samples. Overall, total CDD concentrations were higher than CDF concentrations in 44 of the 45 samples that had detectable CDD/CDF concentrations. Of the 63 samples, 18 (i.e., 28.6 percent) had no detectable CDD/CDFs. When nondetects were set to zero, the mean total CDD concentration accounted for approximately 88 percent of the mean total CDD/CDF concentration, while total CDFs accounted for only 12 percent. When nondetects were set to one-half the detection limit, the mean total CDD concentration accounted for 70 percent of total CDD/CDF concentrations, and CDFs accounted for 30 percent. Based on the cattle classes, both I-TEQ_{DF} and TEQ_{DF}-WHO_{98} concentrations were highest in bulls and lowest in dairy cows.

The mean lipid-based TEQ_{DF}-WHO_{98} value for the 63 beef samples was estimated to be 0.36 ppt (I-TEQ_{DF} = 0.35 ppt), when nondetects were set to zero, and 1.06 ppt (I-TEQ_{DF} = 0.89 ppt), when nondetects were set to one-half the detection limit. These mean values were calculated by statistically extrapolating the sample size for each cattle class to the percentage of the U.S. food supply that they represent. CDDs made up almost 76 percent of the total TEQ_{DF}-WHO_{98}, while CDFs accounted for only about 24 percent, when nondetects were set to zero. When nondetects were set to one-half the detection limit, CDD concentrations accounted for 65 percent of the total TEQ_{DF}-WHO_{98} and CDFs accounted for 35 percent of the TEQ_{DF}-WHO_{98}.

Assuming that the TEQ_{DF}-WHO_{98} concentration in the lipid portion of the back fat samples is equivalent to the TEQ_{DF}-WHO_{98} concentration in the lipid portion of edible cuts of beef, the lipid-based results from this study may be used to estimate the TEQ_{DF}-WHO_{98} concentration of CDD/CDFs in beef that is consumed by the general population. For example, if it is assumed that the average fat content of edible cuts of beef is 17 percent, then the TEQ_{DF}-WHO_{98} concentration in beef consumed by the general population is 0.18 ppt (i.e., 0.17 times 1.06 ppt), when nondetects are set to one-half the detection limit, and 0.06 ppt (i.e., 0.17 times 0.36), when nondetects are set to zero.

The percentage of fat in beef was estimated using food consumption data and fat content data for various beef products provided by David Haytowitz, USDA, to Linda Phillips, Versar, Inc., by personal communication, January 2001. USDA obtained food consumption data from the 1994-96 Continuing Survey of Food Intake Among Individuals (CSFII). The total quantity (in grams) of each food item eaten by the survey population in one survey day was tabulated and weighted to represent the quantity eaten by the entire U.S. population in one day. The fat content of each of these food items was also reported. To estimate the weighted mean percent of fat in beef products that are typically consumed by the U.S. population, the total amount of each beef item was first multiplied by the fraction of fat reported for that item to calculate the amount of beef fat consumed from each beef item. Next, the total amount of beef fat consumed (in grams) was calculated by summing the beef fat intakes for the individual beef items. The total amount of beef consumed was also estimated by summing the beef intake for the individual beef items. Finally, the weighted fraction of beef was estimated by dividing the total beef fat intake by the total beef intake. An abbreviated (i.e., the total number of beef items included in the analysis was 146; only a few beef items were included in the example to demonstrate the methodology) example of this calculation is provided in Table 3-39.

EPA, in cooperation with USDA, also recently analyzed beef samples for dioxin-like PCBs (Winters et al., 1996b; Saunders, 1997). The same samples that were analyzed for CDD/CDFs, as described above, were analyzed for PCBs 77, 118, 105, 126, 156, 157, and 169. Results of these analyses are presented in Table 3-40. Dioxin-like PCB congeners were found to be present in beef fat at an occurrence of greater than 85 percent; however, PCB 77 was found in only 19 percent of the samples. Using a statistical extrapolation of the data to account for the percentage of the different cattle classes in the U.S. food supply, the mean lipid-based total TEQ_P-WHO_{98} concentration for these dioxin-like PCBs was estimated to be 0.49 ppt (TEQ_P-WHO_{98} is also 0.49 ppt), when nondetects were set to either zero or the detection limit. PCB 126 contributed the most to the total TEQ_P-WHO_{98}. Assuming that the average fat content of edible cuts of beef is 17 percent, the PCB concentration in beef consumed by the general population was estimated to be 0.084 ppt TEQ_P-WHO_{98} (i.e., 0.49 times 0.17).

To ensure the relationship between lipid concentrations of dioxin-like compounds in the back fat of cattle is comparable to the level in edible meat products, EPA and USDA collaborated on an additional beef study examining the CDD/CDF/PCB concentrations in various cattle fat reservoirs (Lorber et al., 1997a). Fat matrices under examination included back fat (60 to 90 percent lipid), perirenal (i.e., kidney) fat (70 to 90 percent lipid), muscle tissue (less than 5 percent lipid), and liver (less than 5 percent lipid). Three data sets, cited in Lorber et al. (1997a), were analyzed in the study. The first data set came from a 1995 study in which the 17 dioxin and furan congeners and 6 coplanar PCBs were measured in 5 tissue samples (i.e., back fat, muscle, liver, serum) from animals at 3 research facilities around the United States (Feil et al., 1995). The five selected animals came from research facilities at Pennsylvania State University (PSU), North Dakota State University (NDSU), and Oregon State University (OSU). These animals were raised under the same conditions as cattle raised in routine U.S. feedlot operations, and were slaughtered after about 1-1/2 years. The second data set came from a 1996 dosing study in which four animals were fed high amounts of several, but not all, of the dioxin and furan congeners (Feil et al., 1996). Dosed animals experienced unanticipated exposure to some higher chlorinated congeners that exceeded the dosing levels. The likely source of this exposure comes from the PCP-treated wood in the feeding facilities. Feil et al. (1996) reported the homologue group concentrations in back fat, perirenal fat, muscle tissue, serum, and liver. Lorber et al. (1997a) analyzed the unpublished congener-specific data from this study. The third data set came from a 1995 depletion study of CDD/CDFs in five animals from a herd in Bolsover, Derbyshire, England (Startin et al., 1994). The animals in this herd had very high CDD/CDF concentrations in milk, which was traced to locally contaminated feed.

Results reported below are based solely on analyses of the five animals in the first data set, because they were believed to be representative of a typical food source (i.e., raised under routine feedlot conditions). The animals in the other two studies were not used in the analysis because they experienced high levels of exposure. Examination of total and TEQ_{DF}-WHO_{98} lipid-based concentrations in back fat compared with intramuscular fat concentrations, demonstrated that sampling for CDD/CDFs in back fat can be assumed to be representative of the levels found in edible fat. Assumptions used in this document to estimate CDD/CDF and PCB concentrations in edible beef from back fat are, therefore,

believed valid. This finding is based on examination of the ratios derived by dividing TEQ and total CDD/CDF/PCB concentrations in back fat by the same levels in intramuscular fat as shown in Table 3-41. A ratio of 1.0 indicates that muscle and back fat concentrations are equal. The ratio of total CDD/CDF concentrations in intramuscular fat (ppt lipid) to the same level in back fat (ppt lipid) mostly ranged from 0.5 to 1.5 for the individual CDD/CDF congeners, and the TEQ_{DF}-WHO_{98} ratios ranged from 0.6 to 1.7 (average of 0.9) (Lorber et al., 1997a). PCB comparisons are less straightforward. PCBs 77, 118, and 106 contain total and TEQ_{P}-WHO_{98} concentrations up to 16 times higher in muscle than in back fat. The ratios for PCBs 126, 156, 157, and 169, which ranged from 0.3 to 1.5, however, indicate that back fat levels are comparable to edible fat concentrations.

Pork

In addition to a national survey of CDD/CDFs and dioxin-like PCB residues in beef animals, EPA and USDA recently reported on the completion of a second survey of these compounds in pork (Lorber et al., 1997b). Using a statistically-based sampling plan, 78 belly fat samples were collected from 46 slaughtering establishments. The same justification for collection of back fat samples from beef animals applies to the collection of belly fat samples from the pork animals. These samples averaged 60 percent lipid (standard deviation of 12 percent), similar to the 80 percent lipid of the beef back fat samples. Tissue samples were analyzed for the 17 toxic CDD/CDF congeners and 7 coplanar PCBs, including PCBs 77, 118, 105, 126, 156, 157, and 169. Procedures for analysis were similar to the procedures for beef fat reported in Ferrario et al. (1996a) for CDD/CDFs and for PCBs in Ferrario et al. (1996b). Limits of detection for CDD/CDFs for the study were: 0.1 ppt for the tetras; 0.5 for the pentas, hexas, and hepta; and 1.0 ppt for the octas. Detection limits for the PCBs were: 1.5 ppt for PCB 77, 50.0 ppt for PCB 118, 26.0 for PCB 126, 10.0 for PCB 156, 2.5 ppt for PCB 157, and 0.1 ppt for PCB 169. These were detection limits for the sample matrix, and because the pork samples were about 60 percent lipid, the lipid-based detection limits can be estimated by dividing these detection limits by 0.60.

The sampling plan was designed to be representative of the pork class as a whole, and its three major subclasses: barrows/gilts, sows, and boars/stags. These classes are referred to by their common names: market hogs, sows, and boars, respectively. One

major difference in the pork survey design as compared to the beef survey design was that the two minor classes of pork animal (i.e., the sows and boars) were oversampled in relation to their prevalence in the national slaughter of pork animals as a whole. In the beef survey, the number of animals sampled from each cattle class (which included bulls, steers, heifers, beef cows, and dairy cows) were proportional to their prevalence in the national slaughter, with one exception. The exception was the sampling of two bulls; whereas, sampling in accordance to their prevalence in the class would have required only one sample. Results of the beef survey showed that the concentrations of CDD/CDFs in the bull were 3 to 10 times higher than the other four cattle classes (Winters et al., 1996b). However, it was difficult to draw conclusions and determine the variability in this class because of the small sample size. Based on this experience, an alternate strategy of oversampling the minor swine classes was adopted. This oversampling optimized the ability to distinguish concentration patterns among the three classes, and allowed for an estimate of the variability of the slaughter class estimates. Nationally, market hogs comprise about 95 percent of the total slaughter, with sows comprising about 4 percent and boars 1 percent of the slaughter. In the final sample of 78 animals, 56 were market hogs, 11 were sows, and 11 were boars. These classes represent 71.8 percent, 14.1 percent, 14.1 percent of the total sample size, respectively.

The most toxic congener, 2,3,7,8-TCDD, occurred in only 3 of the 78 samples. Congeners not detected in any of the 78 pork samples included 1,2,3,7,8-PeCDF; 1,2,3,7,8,9-HxCDF; and 1,2,3,4,7,8,9-HpCDF. Overall, CDD concentrations were higher than CDF concentrations. The four most frequently detected congeners were 1,2,3,4,6,7,8-HpCDD; OCDD; 1,2,3,4,6,7,8-HpCDF; and OCDF, all at a frequency of 50 to 60 percent detected. Results also indicated important differences among the swine classes. The TEQ_{DF}-WHO_{98} concentration in sows appeared higher than market hogs: 1.85 ppt (I-TEQ_{DF} = 1.72 ppt) for sows versus 1.44 ppt (I-TEQ_{DF} = 1.26 ppt) for market hogs. This may be due to a longer life span for sows (i.e., >2 years) than for market hogs (i.e., <1 yr). With a longer life, sows accumulate more dioxins and have greater body burdens than market hogs, despite also having the dissipation route of milk excretion. Perhaps the most striking result, however, was for the boar class. While a very small class in terms of exposure (only 1 percent of the pork food supply), older boars were significantly different from all other classes, while younger boars were similar to the

other pork classes. The older boars' lipid concentrations of 6.32 ppt TEQ_{DF}-WHO_{98} (I-TEQ_{DF} = 6.48 ppt) for CDD/CDFs and 0.54 ppt TEQ_{DF}-WHO_{98} (TEQ_{P}-WHO_{94} = 0.54 ppt) for coplanar PCBs were about 5 and 10 times higher than the overall averages for CDD/CDFs and coplanar PCBs, respectively. Like the sows, age is the principal factor that likely explains the higher concentrations. The average age of slaughter for market hogs is less than 1 year, while the old boars live longer than 2 years.

As shown in Table 3-42, the mean lipid-based TEQ_{DF}-WHO_{98} value for the 78 pork fat samples was 1.48 ppt (I-TEQ_{DF} = 1.30 ppt), when nondetects were set equal to one-half the detection limit, and 0.42 ppt (I-TEQ_{DF} = 0.46 ppt), when nondetects were set to zero (Lorber et al., 1997b). Assuming the TEQ_{DF}-WHO_{98} concentration in the lipid portion of belly fat samples is equivalent to the TEQ_{DF}-WHO_{98} concentration in the lipid portion of edible cuts of pork, the lipid-based results of this study can be used to estimate the TEQ_{DF}-WHO_{98} concentrations people are exposed to by eating pork. The average fat content of edible cuts of pork is assumed to be 19 percent (estimated using food consumption data and fat content data for various pork products provided by David Haytowitz, USDA, to Linda Phillips, Versar, Inc., by personal communication, January 2001). Thus, the average TEQ_{DF}-WHO_{98} content of pork consumed by the general population would be 0.28 ppt (i.e., 1.48 ppt times 0.19), when nondetects are set to one-half the detection limit, and 0.080, when nondetects are set to zero. For PCBs, the mean lipid-based TEQ_{P}-WHO_{98} was 0.06 ppt, when nondetects were set to one-half the detection limit, and 0.04 ppt, when nondetects were set to zero (the TEQ_{P}-WHO_{94} are the same as the TEQ_{P}-WHO_{98} for pork) (Table 3-36) (Lorber et al., 1997b). Assuming the average fat content of edible pork cuts is 19 percent, the TEQ_{P}-WHO_{98} concentration in pork consumed by the general population is estimated to be 0.012 ppt (i.e., 0.06 ppt times 0.19), when nondetects are set to one-half the detection limit, and 0.0074 ppt (i.e., 0.04 ppt times 0.19), when nondetects are set to zero.

Poultry and Eggs

EPA and USDA jointly participated in a study of dioxin-like compounds in the U.S. poultry supply (Ferrario et al., 1997). The study is a companion report to the cooperative studies on beef and pork (Winters et al., 1996a; Winters et al., 1996b; and Lorber et al., 1997b), and is the basis for the background TEQ concentrations for poultry. Using a

statistically based sampling plan, 80 abdominal samples were collected from 70 U.S. slaughtering establishments. Abdominal fat was selected for sampling because it has a very high lipid content, thereby optimizing the analytic capability of detecting and quantifying dioxins in the samples. The average fat content of the samples was 80 percent. The sampling plan was designed to be representative of the four poultry classes: young chickens, light fowl, heavy fowl, and young turkeys. Nationally, young chickens account for about 95 percent of total poultry slaughter. In the final sample of 80 animals, 41 (51 percent) were young chickens, 12 (15 percent) were light fowl, 12 (15 percent) were heavy fowl, and 15 (19 percent) were young turkeys. Samples were analyzed for percentage lipid, the same 17 toxic CDD/CDF congeners, and the same coplanar PCBs as the beef and pork samples, as discussed previously. Procedures for analysis of CDD/CDFs are described in Ferrario et al. (1996a) and for analysis of coplanar PCBs in Ferrario et al. (1996b). The detection limits for the study were 0.05 ppt for the tetra-CDD/CDFs; 0.25 ppt for the penta-, hexa-, and hepta-CDD/CDFs; and 0.5 ppt for the OCDD/CDF, on a whole weight basis. The detection limits for PCBs were: 0.80 ppt for PCB 77, 30.0 ppt for PCB 118, 10.0 ppt for PCB 105, 0.10 ppt for PCB 126, 4.0 ppt for PCB 156, 1.0 ppt for PCB 157, and 0.08 ppt for PCB 169. These were detection limits for the sample matrix, and because the poultry samples were about 80 percent lipid, the lipid-based detection limits can be estimated by dividing these detection limits by 0.80.

Laboratory analyses of the samples revealed that two young chicken samples could be classified as outliers by the Dixon and Grubs outlier tests. These two samples demonstrated significantly higher concentration levels of all the dioxin congeners, but CDF and PCB levels were comparable to the results from the other young chickens and other poultry classes. The results are reported below and also used to calculate national background levels; they do not include the data from these two young chicken samples.

The most toxic congener, 2,3,7,8-TCDD, occurred in 67 percent of the young chickens (mean 0.16 ppt lipid-based), 25 percent of the light fowl (mean 0.05 ppt lipid-based), 92 percent of the heavy fowl (mean 0.43 ppt lipid-based), and 73 percent of the young turkeys (mean 0.24 ppt lipid-based). No samples had detectable concentrations of 1,2,3,7,8,9-HxCDF. Ten percent of the young chicken samples had detectable levels of 1,2,3,4,7,8,9-HpCDF; none was detected in the other poultry classes. Overall, CDD concentrations were higher than CDF concentrations, and a larger percentage of the

samples had detectable levels of CDDs than CDFs. The most frequently detected congeners were 1,2,3,4,6,7,8-HpCDD; OCDD; and 2,3,7,8-TCDF, at a detection frequency of 94, 73, and 84 percent, respectively.

The mean lipid-based TEQ_{DF}-WHO_{98} value for the 78 poultry fat samples was 0.77 ppt (I-TEQ_{DF} = 0.65 ppt), when nondetects were set to one-half the detection limit, and 0.48 ppt (I-TEQ_{DF} = 0.42 ppt), when nondetects were set to zero. For PCBs, the mean lipid-based TEQ_{P}-WHO_{98} (and TEQ_{P}-WHO_{94}) value for the same samples was 0.29 ppt, when nondetects were set to either one-half the detection limit or when nondetects were set to zero. Table 3-43 presents a summary of the lipid-based TEQ_{DF}-WHO_{98} results on the basis of poultry class.

Assuming the TEQ_{DFP}-WHO_{98} concentration in the lipid portion of the abdominal fat samples is equivalent to the TEQ_{DFP}-WHO_{98} concentration in the lipid portion of generally consumed poultry, the lipid-based results from this study may be used to estimate the TEQ_{DFP}-WHO_{98} concentration in poultry consumed by the general population. For example, if it is assumed that the average fat content of poultry is 9 percent, then the TEQ_{DF}-WHO_{98} concentration in poultry consumed by the general population would be 0.070 ppt (i.e., 0.09 times 0.77 ppt), when nondetects are set to one-half the detection limit, and 0.043 ppt (i.e., 0.09 times 0.48 ppt), when nondetects are set to zero. The percentage of fat in poultry was estimated using food consumption data and fat content data for various food products provided by David Haytowitz, USDA, to Linda Phillips, Versar, Inc., by personal communication, January 2001). Using the same assumptions, the TEQ_{P}-WHO_{98} concentration in poultry consumed by the general population is estimated to be 0.026 ppt (i.e., 0.09 times 0.29 ppt), when nondetects are set to zero and to one-half the detection limit.

Background TEQ_{DF}-WHO_{98}s for eggs are based on whole weight data for 15 composite egg samples, each containing 24 eggs that were collected in 1997 by FDA from sites in California, Ohio, Georgia, New York, Pennsylvania, Oregon, Minnesota, and Wisconsin as part of a market basket survey (Hayward and Bolger (2000). The estimated total TEQ_{DF}-WHO_{98} for these eggs was 0.081 ppg whole weight, using one-half the detection limit and 0.013 ppt whole weight, when non-detects were set to zero (Table 3-44). Cooper et al. (1995) and Fiedler et al. (1997c) obtained similar results for three egg samples that were analyzed for CDD/CDFs. The estimated total TEQ_{DF}-WHO_{98} for

these eggs was 0.032 ppt (I-TEQ_{DF} = 0.026 ppt), using one-half the detection limit for nondetectable concentrations, and 0.023 ppt (I-TEQ_{DF} = 0.017 ppt), using zero to represent nondetectable concentrations. Schecter et al. (1997) also analyzed eggs. However, many of the congeners were not detected at higher detection limits than those in the Cooper et al. (1995) and Fiedler et al. (1997c) studies. The whole weight I-TEQ_{DF} concentration reported by Schecter et al. (1997) was 0.31 ppt, four to ten times higher than that reported in the other studies. Thus, the Schecter et al. (1997) data were not used in calculating the background estimate for CDD/CDFs. Background TEQ_P-WHO_{98} concentrations were estimated to be 0.1 ppt in eggs (TEQ_P-WHO_{98} was also 0.1 ppt), based on U.S. data from Schecter et al. (1997) and Canadian data from Mes and Weber (1989) and Mes et al. (1991). Schecter et al. (1997) analyzed egg samples (n = 18) for PCBs 118, 126, and 169. Mes and Weber (1989) analyzed one composite egg sample for PCBs 77, 126, and 169, and Mes et al. (1991) analyzed five composite egg samples for PCBs 105, 114, 118, 156, and 157.

Milk and Milk Products

Background TEQ_{DF}-WHO_{98} concentrations in milk were based on data from a recent study conducted by EPA that utilized the Environmental Radiation Ambient Monitoring System (ERAMS) for collecting milk samples (Lorber et al., 1998b). ERAMS has 51 sampling stations in 41 of the 50 U.S. States, and Panama and Puerto Rico. Milk samples from these ERAMS stations collected during four time periods (i.e., April, July, and October 1996, and January 1997) were composited into duplicate composites samples (n = 8) and analyzed for the 2,3,7,8-CDD/CDF congeners and dioxin-like coplanar PCBs 77, 105, 118, 126, 156, 157, and 169 to generate national estimates of the CDD/CDF content of milk. In addition, samples from individual ERAMS stations, collected over the same time period, were analyzed to evaluate geographic or temporal variability in CDD/CDF/PCB concentrations. Composite samples had a mean TEQ_{DF}-WHO_{98} content of 0.98 ppt (I-TEQ_{DF} = 0.82 ppt), when nondetects were set to one-half the detection limit, and 0.97 ppt (I-TEQ_{DF} = 0.81 ppt), when nondetects were set to zero. For PCBs, the lipid-based TEQ_P-WHO_{98} concentration was 0.49 ppt (TEQ_P-WHO_{94} was also 0.49 ppt), when nondetects were set to either one-half the detection limit or zero. These whole milk samples had a mean lipid content of 3.19 percent. However, not all of the milk consumed

is whole milk. Therefore, a weighted mean lipid content was calculated, based on the fat content of whole milk, low fat milk (1.3 percent), and skim milk (0.7 percent), as reported by U.S. EPA (1997), and the proportion of total milk intake accounted for by these milk types (USDA, 1995). Based on adult milk intake rates, the weighted milk fat percentage is 1.8 percent (Table 3-45). Using this weighted lipid content, the whole-weight TEQ_{DF}-WHO_{98} concentration in milk, as consumed, would be 0.018 ppt (i.e., 0.018 times 0.98 ppt) and the TEQ_{P}-WHO_{98} concentration in milk, as consumed, would be 0.0088 ppt (i.e., 0.018 times 0.49 ppt). Congener-specific data for the eight composite samples are presented in Table 3-46. Little evidence of a temporal trend in TEQ_{DF}-WHO_{98} concentrations was observed, based on the results of individual station samples. Results did, however, suggest a geographic trend with CDD/CDF concentrations in milk being highest in the southeastern United States and lowest in the southwestern United States. The TEQ_{DF}-WHO_{98} estimates for U.S. milk obtained by this study are consistent with the levels observed in previous, more limited milk studies (Schecter et al., 1989b; U.S. EPA, 1991).

Additionally, some idea of the total TEQ_{DF} level in milk samples can be gained by assuming that levels in beef fat are similar to levels in milk fat. This assumption implies that the differences in feeding/raising practices of dairy cattle vs. beef cattle do not cause substantial differences in CDD/CDF exposure. Beef contains approximately 20 percent fat, and whole milk is about 4 percent fat. Thus, on a whole food basis, CDD/CDF levels in beef should be about five times higher than in milk. Support for this concept can be seen in the German data presented by Fürst et al. (1990, 1991). These data show that the I-TEQ_{DF} level is 1.35 ppt in milk fat and 1.08 ppt in beef fat. On this basis, the North American data for beef (0.20 ppt of TEQ_{DF}-WHO_{98}) suggest that milk would be about 0.04 ppt of TEQ_{DF}-WHO_{98}. This value is consistent with the TEQ_{DF}-WHO_{98} value obtained from the recent EPA study that utilized the ERAMS for sampling U.S. milk.

Whole weight TEQ_{DFP}-WHO_{98} concentrations for dairy products (other than milk) were derived from the TEQ_{DFP}-WHO_{98} concentrations in milk fat by assuming that the concentration of CDD/CDFs is the same in fat of dairy products as in milk fat. Whole weight TEQ_{DFP}-WHO_{98} concentrations were calculated by multiplying the milk fat TEQ_{DFP}-WHO_{98} concentrations by the fractional fat content of dairy products. However, because the dairy products category included a variety of food types (i.e., cheese, yogurt, milk-

based desserts, etc.), it was first necessary to calculate a fractional fat content value that is representative of the percentage of fat in the diet, on average, that originates from dairy products other than milk. This composite fractional dairy fat value was based on dietary intake data from USDA's 1989-1991 Continuing Survey of Food Intake Among Individuals (CSFII) (USDA, 1995), and fat content data from USDA's Agricultural Handbook Number 8 (USDA, 1979-1984), as reported in EPA's Exposure Factors Handbook (U.S. EPA, 1997), as shown in Table 3-47. The composite percent of fat in dairy products was estimated to be approximately 12 percent (i.e., 11.84 percent). Thus, the whole weight TEQ_{DF}-WHO_{98} concentration in dairy products was estimated to be 0.12 ppt (i.e., 0.98 ppt [milk fat concentration] times 0.12). The whole weight TEQ_{P}-WHO_{98} concentration was estimated to be 0.058 ppt (i.e., 0.49 ppt [milk fat concentration] times 0.12).

These values are similar to I-TEQ concentration estimates for dairy products based on data from Schecter et al. (1992a), Jensen and Bolger (2000), Cooper et al. (1995), Fiedler et al. (1997c) and Schecter et al. (2001). Schecter et al. (1992a) reported on the analysis of 2,3,7,8-substituted CDD/CDFs in U.S. dairy products. Cottage cheese, soft cream cheese, and American cheese samples were selected randomly from New York supermarkets and analyzed on a wet-weight basis. All dairy products sampled had at least 13 detectable congeners out of the 17 evaluated, and only one congener (1,2,3,7,8,9-HxCDF) was not detectable in any of the five dairy products. Whole weight I-TEQ_{DF}s ranged from 0.04 to 0.72 ppt, when nondetects were set to one-half the detection limit. Assuming a fat content of 25 percent for these cheeses, the lipid weight I-TEQ_{DF} content would be 0.16 to 2.9 ppt. This lipid-based concentration range brackets the mean milk fat concentration observed by Lorber et al. (1998b). Jensen et al. (2000) reported whole weight TEQ_{DF}-WHO_{98} values ranging from 0.082 to 0.38 ppt in various dairy products when non-detects were set to one-half the detection limit (Table 3-30). When non-detects were set to zero, TEQ_{DF}-WHO_{98} values ranged from 0.0069 to 0.22 ppt (Table 3-30). Cooper et al. (1995) and Fiedler et al. (1997c) also reported on CDD/CDFs in three samples of cheddar cheese and three samples of butter. Lipid-based I-TEQ_{DF} concentrations ranged from 0.70 to 0.97 ppt in butter and 0.74 to 0.86 ppt in cheddar cheese. Schecter et al. (2001) reported whole weight mean TEQ_{DFP} - WHO_{98} concentrations of 0.47 ppt in cheese, 0.16 ppt in milk, and 1.1 ppt in butter when non-detects were set to one-half the detection limit and 0.022 ppt in milk, 0.17 ppt in cheese,

and 0.82 ppt in butter when nondetects were set to zero. In view of the similarities between the milk fat I-TEQ_{DF} concentrations observed by Lorber et al. (1998b) and the lipid-based I-TEQ_{DF} concentrations observed in dairy products, the use of the national milk fat data to estimate CDD/CDF concentrations in dairy products from various studies is a reasonable approach for estimating background concentrations of dioxin-like compounds for this food group.

Fruits and Vegetables

Data on CDDs and CDFs in U.S. fruit and vegetable products are extremely limited. The Ministry of the Environment, Ontario, conducted a study of CDDs and CDFs in locally produced and imported fruits and vegetables, some of which originated in the United States (Ministry of the Environment, 1988; Birmingham et al., 1989). Samples of fresh apples, peaches, potatoes, tomatoes, and wheat products were analyzed. In general, the minimum detection limits for these analyses were less than 1 ppt. The report indicated that "fruit and vegetable samples were substantially free of PCDD and PCDF residues, especially the more toxic tetra, penta, and hexachlorinated forms" (Ministry of the Environment, 1988). OCDD was the only congener detected in any of the samples. One apple and one peach sample contained detectable OCDD concentrations (8 ppt and 0.6 ppt, respectively). Detectable OCDD concentrations were found at concentrations ranging from 1 to 3 ppt in potatoes and 0.6 to 0.7 ppt in wheat samples. None of the tomato samples contained detectable levels of any CDD or CDF congeners. Based on these results, Birmingham et al. (1989) estimated the I-TEQ_{DF}s for fruits, vegetables, and wheat products to be 0.004 ppt, 0.002 ppt, and 0.0007 ppt, respectively.

As discussed in Volume 3, dioxin contamination of fruits and vegetables is thought to occur primarily via particle deposition or vapor adsorption onto outer layers with little penetration to inner portions. Plant uptake from the soil via the roots is generally considered negligible. However, the work of Hülster and Marschner (1993) indicates that zucchini and pumpkins were exceptions. For these plant species, it appears that root uptake occurs and leads to a uniform concentration within the fruit. The concentration of CDDs and CDFs in zucchini squash grown on "uncontaminated" soil (0.4 ppt I-TEQ_{DF} soil concentration) ranged from 0.5 to 0.7 ppt I-TEQ_{DF} dry weight. These reported values may be converted to whole weight I-TEQ_{DF} concentrations by using an assumed moisture

content of 93.7 percent (USDA, 1979-1984). The resulting range of whole weight concentrations for zucchini is 0.03 to 0.04 ppt I-TEQ_{DF}. Müller et al. (1993) also evaluated CDDs and CDFs in vegetables (carrots, lettuce, and peas) grown at both contaminated plots and control plots. For the control plots, the highest levels of CDDs and CDFs were observed in carrot peels: 0.55 ppt I-TEQ_{DF} dry weight, or 0.07 ppt I-TEQ_{DF} whole weight, assuming a moisture content for carrots of 87.8 percent (USDA, 1979-1984). Lower concentrations were observed in samples from the cortex of the carrots, indicating that the "contamination source for the peel of carrots is the soil" (Müller et al., 1993). Lettuce concentrations ranged from 0.1 to 0.4 ppt I-TEQ_{DF} dry weight. This is equivalent to a whole weight concentration range of 0.005 to 0.018 ppt I-TEQ_{DF}, assuming a moisture content of 95.4 percent for lettuce (USDA, 1979-1984). Concentrations in peas from contaminated plots ranged from 0.04 to 0.12 ppt I-TEQ_{DF} dry weight (0.004 to 0.013 ppt I-TEQ_{DF} whole weight, assuming a moisture content of 88.9 percent). Lower concentrations in peas (i.e., close to the detection limit; exact value not given) were reported for control plots. Similar data for vegetables grown in the United States were not available.

Recently, Tomoaki et al. (2000) reported on the levels of CDD/CDFs and coplanar PCBs in leafy vegetables in Japan. Whole weight TEQ_{DF}-WHO_{98} concentrations were 0.196 pg/g for spinach (n = 7) and 0.094 pg/g for komatsuna (n = 7). Washing followed by boiling reduced the total concentrations to 21 percent, 31 to 38 percent, and 60 to 61 percent of the original concentrations for CDDs, CDFs, and PCBs, respectively. Non-detects were set to zero in the calculations. Kim et al. (2000a) analyzed cabbages and radishes purchased in Korean markets fro CDD/CDFs. TEQ_{DF}-WHO_{98}s were 0.082 ppt for cabbage (n = 15) and 0.0013 ppt for radishes (n = 15) when non-detects were set to zero. Kim et al. (2000b) also evaluated cabbages and radishes, and observed similar results. TEQ_{DF}-WHO_{98}s were 0.042 ppt for cabbages and 0.007 ppt for radishes. Kim et al. (2000b) also analyzed pooled fruit samples (i.e., apples, oranges, and tangerines) and observed an average whole weight TEQ_{DF}-WHO_{98} of 0.006 ppt. The TEQ_{DF}-WHO_{98} was 0.006 ppt for potatoes and 0.012 ppt for rice.

Vegetable Oil

High fat levels in vegetable oil suggest that it may be important to consider as a source of human exposure. Vegetable oils can be made from a variety of plants, including soybeans, corn, olives, peanuts, sunflower seeds, safflower seeds, linseed, and cotton seed. Many of these items are protected from atmospheric deposition, which implies that their CDD/CDF levels would be low. However, Theelen (1991) estimated that vegetable oil could contribute about 10 percent of a person's total daily intake in The Netherlands (14 of 120 pg I-TEQ/d). This estimate was based on the Fürst et al. (1990) study that found nondetects for most congeners, except some of the higher chlorinated congeners of CDD and CDF (detection limit = 0.5 ppt). Half the detection limit was used for the nondetects, and most of the congeners were not detected. Consequently, the actual value could be much lower.

Recently, EPA conducted a study to evaluate the levels of CDD/CDFs in vegetable fats and oils using an adaptation of EPA Method 8290 (Versar, 1996b; Schrock et al., 1996). A total of 30 oil samples collected from various geographical regions of the United States were analyzed for CDD/CDFs. Samples included soybean, corn, peanut, canola, olive, safflower, and sunflower oils, in addition to margarine, solid shortening, and canola oil spray. OCDD was the only analyte detected in all 30 oil samples above background levels found in method blanks. Concentrations of OCDD detected in the oil samples ranged from 3.6 to 33.1 pg/g compared to OCDD method blank levels of 2.8 to 4.4 pg/g. When subtracting out the appropriate method blank concentrations of OCDD from the vegetable oil samples, the range of concentrations was 0.2 to 30.3 ppt, with a mean of 5.6 ppt. Detection limits were generally near 1 pg/g for all analytes and ranged from 0.1 to >2 pg/g. None of the oil samples or blanks with detection limits ranging from 0.2 to 1.8 ppt showed 2,3,7,8-TCDD. Other than OCDD, all detections were at or near the detection limits. Because the occurrences of the CDD/CDFs in vegetable oil were near detection limits and there was only a small percentage of occurrences overall (not including OCDD), an average TEQ_{DF}-WHO_{98} concentration calculated for the case where nondetects were set equal to 0 is evaluated as more meaningful than a TEQ_{DF}-WHO_{98} concentration calculated for nondetects set equal to one-half detection limit. The mean TEQ_{DF}-WHO_{98} calculated at ND = 0 was 0.056 ppt, and this value was used in calculating background exposures. By way of comparison, the mean TEQ_{DF}-WHO_{98} calculated at ND

= ½ detection limit was 1.5 ppt. The difference between the mean concentration calculated both ways is much larger than the difference seen for other food products. This suggests that the detection limits for the vegetable oil were too high to render a calculation of a mean at one-half the detection limit meaningful; for this reason, the mean calculated this way is not used in Chapter 4 for calculating background exposures.

TEQ_P-WHO_{98} concentrations for PCBs were based on data from Mes et al. (1991). A total of five composite samples of cooking fats and salad oils were analyzed for PCBs. The total TEQ_P-WHO_{98} concentration for these samples was 0.037 ppt, whole weight, based on the geometric mean of positive samples.

3.7.3. European Food

One of the most extensive investigations reported to date that involve testing of a variety of randomly selected food samples collected within the framework of official food control have been performed in the Federal Republic of Germany (Beck et al. 1989; Fürst et al., 1990; Malisch, 1998). Detailed results of these studies are included in Appendix B. Fürst et al. (1990) analyzed 107 food samples collected in Germany. The results of this study are presented in Table 3-48. All samples, except some of the milk, were randomly collected during official food monitoring programs. The authors speculated that a source may have been near the areas where the milk samples were collected, because they appeared higher than other milk tested in Germany, which showed levels around 1 ppt I-TEQ_{DF}. In a later report, Fürst et al. (1991) reported that a much larger survey of dairies in Germany had been completed. This survey analyzed 168 samples of milk and milk products collected at dairies prior to bottling in 1990. They found an arithmetic mean of 1.35 pg of I-TEQ_{DF}/g of fat. I-TEQ_{DF}s in these studies were estimated by assuming that nondetects equaled half the detection limits. Except for 1,2,3,7,8,9-HxCDF and 1,2,3,4,7,8,9-HpCDF, the 2,3,7,8-substituted congeners were detected at a frequency of greater than 99 percent in these samples (Fürst, 1995). In a more recent study, Fürst and Wilmers (1995) compared the levels of CDD/CDFs found in dairy products from 1990 to the levels in 120 dairy samples collected in 1994. Over the 4-year period, mean I-TEQ_{DF} concentration in milk fat decreased by almost 25 percent from 1.35 ppt to 1.02 ppt. Similar reductions were noted in human milk fat (Fürst and Wilmers, 1995). Fürst et al. (1991) also provided a summary of the results of several European studies. The data

summaries relevant to background levels in meat and dairy products from Fürst et al. (1991) are presented in Table 3-49. Fürst et al. (1991) report that information on CDD and CDF levels in vegetables and fruits is scarce and that the available data indicate a background of below 1 ppt.

Beck et al. (1989) analyzed 12 food samples collected randomly from food markets in West Berlin, Germany. Chicken, eggs, butter, pork, ocean perch, cod, herring, vegetable oil, cauliflower, lettuce, cherries, and apples were analyzed for CDD/CDFs. CDD/CDFs were detected in samples of animal origin in the ppq to ppt range (fat weight basis). No CDD/CDF congeners were detected at a detection limit of 0.01 ppt (whole weight basis) in samples of plant origin. Mayer (1995) analyzed 27 bulk milk samples (i.e., background) collected from large dairies in Bavaria, Germany, and 160 milk samples from farms in the vicinity of suspected dioxin sources between 1989 and 1993. Background I-TEQ_{DF} concentrations ranged from 0.69 ppt to 1.12 ppt, with a mean of 0.9 ppt on a lipid basis. Nondetected congeners were assumed to equal one-half the detection limit. Few of the potentially impacted samples had I-TEQ_{DF} concentrations exceeding 5 ppt. Malisch et al. (1994) analyzed one background egg sample and one egg sample from a contaminated site in Germany. The mean I-TEQ_{DF} concentrations were 1.2 pg/g fat for the background site and 12.7 pg/g fat for the contaminated site. These results are based on analyses using four different analytical methods, which showed similar results.

Malisch (1998) followed up with a more recent study of intake of food in Germany. In this study, CDD/CDF levels in food from the southwestern part of Germany were measured between 1993 and 1996. Malisch (1998) analyzed 1,414 food samples for CDD/CDF concentrations. The results indicated that the more recent I-TEQ_{DF} concentrations are lower than those previously observed by Fürst et al. (1991) and Fürst et al. (1990) (Table 4-50).

Schmid and Schlatter (1992) found low background levels of CDD/CDFs in milk samples from Switzerland. A total of 28 cow's milk samples and 1 goat's milk sample were collected during 1990 and 1991 from industrial dairies and from both rural alpine sites and potentially impacted sites (i.e., highly industrialized areas, and areas with waste incineration and metal recycling). Due to insufficient analytical sensitivity, 2,3,7,8-TCDD was not detected; thus, an assumed concentration was used for 2,3,7,8-TCDD in

calculating I-TEQ_{DF}s. The lowest I-TEQ_{DF} concentrations were observed in samples from rural and alpine areas. The mean lipid-based I-TEQ_{DF} for these seven milk samples ranged from 0.70 ppt to 3.28 ppt. The goat milk sample had a I-TEQ_{DF} concentration of 0.88 ppt. Based on pooled milk samples from nine industrial dairies in Switzerland, the average lipid-based I-TEQ_{DF} was 1.31 ppt. This is approximately equivalent to a whole weight I-TEQ_{DF} concentration of 0.05 ppt, assuming a lipid content of 4 percent for these samples. No significant differences were observed between samples stored in cardboard containers and those stored in glass bottles. Higher I-TEQ_{DF} concentrations were observed in samples collected from potentially impacted sites (2.02 ppt to 4.85 ppt on a lipid basis).

In 1996, the French Ministry of Agriculture, Fisheries and Food Products (FMAFFP) (1997) undertook a study to investigate "background" levels of CDD/CDFs in the French Republic (FMAFFP, 1997; Defour et al., 1997). This followed a 1993/94 FMAFFP study examining dioxin levels found in French milk samples collected from areas near known polluting industries. In this 1996 study, 40 dairy products, including cheese, butter, milk-based desserts, and cream, were sampled from 34 regions of France. Also, 12 cow's milk samples were collected from different locations in two regions (i.e., Seine-Maritime and Pas-de-Calais). These two regions had shown elevated levels over other regions of the country in the previous study, which targeted areas near pollution sources. The seven milk samples from the Seine-Maritime region had a mean lipid-based I-TEQ_{DF} of 1.77 ppt. The five milk samples from the Pas-de-Calais region had a mean I-TEQ_{DF} of 2.13 ppt. Each of these regions had one sample with a I-TEQ_{DF} greater than 3.0 ppt; whereas, the remaining samples clustered together at levels around 1.5 ppt and 1.9 ppt, respectively. The congener profiles of the milk samples showed a predominance of OCDD, and the furans typically were higher than the dioxins. Table 3-51 presents the mean I-TEQ_{DF} levels of the dairy products tested by the FMAFFP. The lipid-based I-TEQ_{DF} values of the eight butter samples ranged from 0.51 ppt to 2.10 ppt (mean of 1.01 ppt). The lipid-based I-TEQ_{DF} values of the 20 cheese samples ranged from 0.54 ppt to 1.44 ppt (mean of 1.11 ppt). The 12 fresh cream and milk-based desserts had lipid-based I-TEQ_{DF} values ranging from 0.78 ppt to 3.15 ppt (mean of 1.34 ppt). The sample from the Nord region had an I-TEQ_{DF} value of 3.15 ppt, which was significantly higher than the other cream or milk-based dessert samples, possibly reflecting industrial sources in the region. The mean value of the remaining 11 samples was 1.18 ppt I-TEQ_{DF}.

Theelen et al. (1993) collected food products from various locations in The Netherlands and analyzed them for 2,3,7,8-chlorine substituted dioxins, furans, and planar PCBs. Meat samples were collected from slaughter houses throughout The Netherlands. Fish, mixed meats, and cheeses were gathered at various grocery stores. Mixtures of foods in these categories were prepared based on the proportion of the average annual consumption rate that different food items in these categories represented. The food industry provided purified oils and fats. Mixtures of these items were also prepared in proportion to their annual use in The Netherlands. The concentrations of CDD/CDFs in these food products are presented in Table 3-52.

Food samples were collected in 1996 from both local markets and supermarkets from Catalonia, Spain (Domingo et al., 1999). A total of 35 food samples were collected and analyzed for CDD/CDF concentrations. The food samples included various types of beef, pork, chicken, lamb, fish, seafood, canned fish, milk and dairy products, vegetables, cereals, fruits, fats and oils, and eggs. The lipid-based and wet-weight I-TEQ_{DF} concentrations in these foods are presented in Table 4-53. As shown in Table 4-53, both the lipid-weight and wet-weight I-TEQ_{DF} concentrations were highest in fish and seafood. It is interesting to note that reported concentrations of CDD/CDFs in fruits, vegetables, and cereals were similar to those observed for meat and dairy products. However, the number of samples collected from each food group was not reported, and the method used for treating non-detects in calculating total I-TEQ_{DF}s was not reported.

CDDs and CDFs have been studied in dairy products in Spain. Ramos et al. (1999) analyzed butter samples for CDD/CDFs/PCBs and estimated TEQ_{DFP}-WHO_{94}s. Eight of the best known brands of butter were purchased from Spanish supermarkets. A total of 21 samples were analyzed. The results of the study indicated that the I-TEQ averages were 0.41 ppt for CDDs, 0.70 ppt for CDFs, and the TEQ_{P}-WHO_{94} average was 0.09 ppt for PCBs. The most toxic CDD congener, 2,3,7,8-TCDD, was found at detectable levels in 15 of the 21 samples analyzed and the most toxic CDF congener, 2,3,7,8-TCDF, was found in all samples. Ramos et al. (1999) did not report whether non-detects were set to zero or one-half the detection limit in calculating TEQs.

In the early 1990s, the United Kingdom's Ministry of Agriculture, Fisheries, and Food (MAFF) conducted a survey of CDD/CDFs in foods collected as part of their Total Diet Study (MAFF, 1992). Food samples were collected in 1988 from two UK locations:

Port Talbot and Stonehaven, selected to represent an urban/industrial site and a rural site, respectively. Additional samples were collected in Norwich. Selected food items included: meat and meat products, milk products, fish, fats and oils, eggs, and fruits and vegetables. I-TEQ_{DF}s were calculated by setting nondetects to either zero or to the limit of detection to provide a range of possible I-TEQ_{DF} values for each food item. Results of these analyses are presented in Table 3-54 in terms of total I-TEQ_{DF}s. Higher I-TEQ_{DF} concentrations were found in fatty food products, such as fish, meats, and fats and oils, than in food items with lower fat contents, such as fruits and vegetables. For some food items, higher I-TEQ_{DF} concentrations were observed at the urban/industrial area than at the rural site. Milk samples were collected from farms in rural/remote areas that were not expected to be impacted and from farms closer to urban/industrialized areas. In addition, retail milk samples were collected in 1990 from several UK locations during both winter and summer months. The results of these analyses are presented in Table 3-55. After laboratory procedures were developed for the fractionation of ortho and nonortho substituted chlorobiphenyls, Kroskos et al. (1996) analyzed frozen aliquots of the same 1990 milk samples for PCB congeners. The mean concentration for seven congeners (PCBs 28, 52, 101, 118, 138, 153, and 180) was 0.26 μg/kg whole milk or 6.7 μg/kg on a lipid basis assuming a typical fat content of 3.9 percent for cow's milk. The mean TEQ_P-WHO_{94} concentration of PCBs 77, 118, 126, 169, and 180 in the milk samples was 0.06 ppt whole milk. PCB 118 and 126 accounted for 98 percent of the total PCB TEQ (Kroskos et al., 1996). Additional MAFF analyses of Total Diet Study samples examining temporal trends in dietary intake are summarized in Chapter 6.

Foxall et al. (1995) analyzed samples of fruits and vegetables from urban and rural areas in Wales and England for CDD/CDF and PCB residues. The study was initiated as a result of concerns over elevated CDD/CDF and PCB concentrations in the air and soil in the vicinity of a chemical waste incinerator. Samples were collected from gardens at five sites within a 1.5-mile radius of the incinerator and from five similar sites in three rural areas for comparison. The produce evaluated included apples, courgettes, lettuce, and potatoes. Median I-TEQ_{DF} concentrations ranged from 0.3 ppt to 0.4 ppt for the four fruit and vegetable products, when nondetects were set to the limit of detection. In addition, no significant differences were observed between CDD/CDF and PCB concentrations in produce taken from urban and rural sites. The authors noted that CDD/CDF

concentrations in produce directly exposed to atmospheric deposition (i.e., apples and lettuces) are not significantly different from root vegetables (Foxall et al., 1995).

The Ministry of Agriculture, Fisheries, and Food (MAFF) also analyzed commercially available cow's milk for dioxins and PCBs in samples collected in 1995 from 12 locations in England (MAFF, 1997a). The locations were chosen to be representative of the different regions. Full fat milk purchased in glass bottles was tested. Lipid-based CDD/CDF concentrations ranged from 0.67 to 1.4 ppt I-TEQ_{DF}. Lipid-based PCB levels ranged from 0.75 to 2.3 ppt TEQ_P-WHO_{94}. Concentration levels of dioxins found in the 1995 samples were lower than those found in a comparable MAFF survey conducted on milk collected during 1990 (MAFF, 1992). (See Section 6.5, Temporal Trends in Food Products, for details.)

In a Lancaster University study, Stewart and Jones (1996) also examined PCBs in cow's milk from rural and urban dairy farms in the northwest of England. Sites were chosen to be representative of farms providing milk for human consumption. Stewart and Jones (1996) sampled pooled milk taken from 10 herds between 1993 and 1994. The sum of the lipid based levels of PCBs 77, 105, 118, 126, 156, 169, 170, and 180 ranged from 1.2 to 2.1 ppt TEQ_P-WHO_{94}.

The Ministry (MAFF) has also studied dioxin levels in samples of cow's milk from individual farms located around known emission sources in the United Kingdom annually since 1993. Additionally, beginning in 1994, the samples were analyzed for PCBs. Between 1993 and 1995, MAFF collected samples from 93 farms in the vicinity of 29 industrial sites (MAFF, 1997b). The concentration of dioxins in the cow's milk (for sample years 1993-1995) ranged from 0.87 to 11 ppt TEQ milk fat. In all but two of the samples, dioxin levels were within or below the normal range of 1.1 to 7.1 ppt I-TEQ milk fat previously described for the United Kingdom (MAFF, 1992). Two samples with slightly elevated results were obtained from farms in the vicinity of a municipal waste incinerator, which closed in 1996 due to noncompliance of plant emission standards. PCB levels (sample years 1994-1995) ranged from 1.1 to 9.3 ppt TEQ_P-WHO_{94} lipid. In 1996, the Ministry sampled 26 farms in the vicinity of 7 industrial sites and found dioxin levels ranging from 0.81 to 8.6 ppt TEQ_P-WHO_{94} milk fat. PCB concentrations ranged from 1.2 to 8.0 ppt TEQ_P-WHO_{94} milk fat (MAFF, 1997c).

The Ministry (MAFF) also analyzed 40 samples of cow's milk obtained from 20 dairies and farms in Northern Ireland during 1993 and 1994 (MAFF, 1997d). Sites were chosen to be representative of all the regions of Northern Ireland, and the samples were collected in polypropylene containers. Lipid-based dioxin concentrations in the retail samples from dairies ranged from 0.74 to 2.7 ppt I-TEQ_{DF} lipid (mean = 1.2 ppt I-TEQ_{DF}), and the concentrations in individual farm samples ranged from 0.84 to 3.0 ppt I-TEQ_{DF} lipid (mean = 1.2 ppt I-TEQ_{DF}). I-TEQ_{DF}s were calculated by setting nondetects to the limit of detection.

Vartiainen and Hallikainen (1994) conducted a survey of CDD/CDFs in cow's milk from Finland's largest dairies, eggs from major Finnish producers, and meat (pork and bovine) from major Finnish slaughter houses. Twenty samples in each food category were analyzed for CDD/CDFs. Low levels of CDD/CDFs were observed in cow's milk. Based on Nordic TEF_{DF}s (N-TEF_{DF}s), the mean lipid-based Nordic TEQ_{DF} (N-TEQ_{DF}) concentrations were 0.83 ppt for milk stored in glass bottles, 1.17 ppt for milk stored in paper milk cartons, and <0.5 ppt for meats. Whole-weight N-TEQ_{DF} concentrations in eggs averaged 0.12 ppt. The method used for treating nondetects in calculating these mean N-TEQ_{DF}s was not described in the paper. Also, use of N-TEQ_{DF}s instead of I-TEQ_{DF}s adds uncertainty to the interpretation of these data.

Himberg (1993) analyzed Finnish food samples for dioxin-like PCBs 77, 105, 126, and 169 to estimate the average daily intake of these PCBs. A total of 34 food samples were collected from food stores in the city of Helsinki. Concentrations of these PCBs in foods are presented in Table 3-56. Concentrations were higher in fish than meat by approximately one order of magnitude. Van Rhijr et al. (1993) analyzed 39 cow's milk samples from various agricultural, industrial, and impacted sites in The Netherlands for dioxin-like PCBs 77, 126, and 169 and CDD/CDFs. Mean lipid-based I-TEQ_{DF}s ranged from 0.8 to 1.8 for agricultural sites, 2.7 ppt for an industrial site, and 3.6 ppt to 7.7 ppt for sites near municipal waste incinerators. Lipid-based average TEQ_{P}-WHO_{94} ranged from 1.1 ppt to 1.9 ppt for agricultural sites, 2.1 ppt for the industrial site, and 1.8 pt to 4.5 ppt for sites near municipal waste incinerators.

3.7.4. Eastern European and Asian Food

Schecter et al. (1990, 1992b) analyzed foods collected from sites within the former Soviet Union between 1988 and 1990 for CDD/CDF residues. A total of 31 samples were collected from markets and restaurants in four cities (i.e., Moscow, Irkutsk, Novosibirsk, and Baikalsk). Fish samples were collected from local rivers in these areas. The study compared CDD/CDF levels from Moscow, which represented an area that had been industrialized for a long period of time, and Siberian cities, where industrialization had occurred more recently. Fathead minnow samples were collected from Lake Baikal in Baikalsk, because it was believed that they may have been impacted by a nearby pulp and papermill. Results of these analyses are presented in Table 3-57. I-TEQ_{DF}s ranged from 0.02 to 0.7 ppt wet weight for samples from Moscow, 0.04 to 0.8 ppt wet weight for samples from Irkutsk, 0.005 to 0.8 ppt wet weight for samples from Novosibirsk, and 0.9 to 1.4 ppt wet weight for samples from Baikalsk. Schecter et al. (1993b) analyzed foods from the same cities within the former Soviet Union for PCBs and organochlorine pesticides. PCB 180 was the only PCB congener analyzed for which a TEF_P-WHO_{94} had been developed. Foods analyzed included pork, poultry, fish, beef, lamb, and cheese. PCB 180 in these samples ranged from less than 0.001 to 0.007 ppm on a lipid basis.

Amirova et al. (1997) reported on the results of a 1996 examination of I-TEQ_{DF} levels in 17 foods purchased from food stores in Ufa, a town in the agricultural region of Bashkortostan in Russia. Foods were selected that contained high fat contents, such as dairy products, fish, beef, port, poultry, and vegetable oil (Amirova et al., 1997). The highest I-TEQ_{DF} concentrations, on a lipid basis, were found in freshwater fish (9.2 ppt), cream (5.45 ppt), and milk (3.32 ppt). Using data on the food consumption patterns of both rural and urban regions of the Republic of Bashkortostan, the dietary intake of I-TEQ_{DF}s for the urban population of Bashkortostan was calculated to be 2.31 pg/kg/day, while the rural population was estimated to have a lower level of 1.15 pg/kg/day.

Olie et al. (1989) analyzed food and wildlife samples from North and South Vietnam for CDD/CDF residues. Samples were collected between 1985 and 1987 from markets, fishermen, and women in the fields. The collection protocol used non-random sampling and did not provide a statistically representative sample of foods in these regions of the country. However, based on the limited number of samples collected, the study results suggest that food samples collected in the South contain higher levels of

CDD/CDFs than samples collected in the North. The authors suggest that these differences may be due, in part, to differences in the level of industrialization in these regions (i.e., the South is more industrialized than the North), and the spraying of South Vietnam with Agent Orange during the Vietnamese War (Olie et al., 1989). Concentrations of CDD/CDF in North Vietnamese food and wildlife samples ranged from 0.26 ppt I-TEQ_{DF} wet weight (catfish) to 3.30 ppt I-TEQ_{DF} wet weight (chicken fat) and 3.51 ppt I-TEQ_{DF} wet weight (cow fat) (Olie et al., 1989). For these same food products (i.e., catfish and chicken fat; cow fat was not analyzed), I-TEQ_{DF} concentrations in South Vietnamese food samples were higher (i.e., 5.68 and 31.54 ppt I-TEQ_{DF} wet weight, respectively) than those observed in samples collected from North Vietnam. The highest I-TEQ_{DF} concentrations in South Vietnamese wildlife were observed in turtle ovaries (85.71 ppt I-TEQ_{DF} wet weight). Schecter et al. (1990) reported the levels of PCBs in samples of pork and chicken collected in Vietnam. PCB 180 was the only PCB congener analyzed for which a TEF_P-WHO_{94} had been developed. PCB 180 ranged from less than 2.0 to 2.0 ppb on a lipid basis in pork and 3.0 to 4.0 ppb on a lipid basis in chicken.

3.7.5. Effects of Cooking and Trimming, or Processing on Residue Levels in Foods

Data on the effects of cooking on the levels of dioxin-like compounds in food products are limited, and the available data on this subject are somewhat contradictory. Cooking losses of dioxin-like compounds are reported in the literature in two ways. One method calculates losses by comparing total residues in a sample before cooking to total residues after cooking (i.e., by comparing total micrograms of dioxin-like compounds in raw and cooked foods). The other method calculates losses on the basis of the sample weight (i.e., by comparing the concentrations of residues in raw and cooked food). Losses of total residues are often accompanied by similar losses of water and/or fats. Thus, although total residues are reduced by cooking, concentrations based on the uncooked and cooked sample weights show little difference. Because dietary doses of dioxin-like compounds are calculated on the basis of dioxin residues in uncooked foods and intake rates of as-eaten (i.e., cooked) foods, changes in the concentrations of dioxin-like compounds from cooking would be relevant to these calculations. In contrast, losses of total residues, although an interesting phenomena, would have less effect on the

results of these estimates. This section summarizes some of the data on the effects of cooking on dioxin-like residues in foods, as reported in the scientific literature.

Stachiw et al. (1988) evaluated changes in the residue levels of 2,3,7,8-TCDD in fish from cooking. Restructured carp fillets (i.e., fabricated fish products that use mechanically deboned fish) from Saginaw Bay, Michigan, measuring either 7.5-cm or 10-cm diameters, with a uniform thickness of 1 cm, were roasted (covered or uncovered) or charbroiled to internal end temperatures of 60°C, 70°C, or 80°C. Both spiked samples (i.e., spiked to levels approximating 100 ppt) and control samples (i.e., unspiked, containing levels ranging from 37 to 45 ppt) were tested for residues of 2,3,7,8-TCDD before and after cooking. Samples were also tested for total cooking losses (i.e., losses of fat and moisture). Cooking losses ranged from approximately 5 to 20 percent, depending on the cooking method. Results of the TCDD residue analyses indicated that both cooking methods resulted in significant reductions of total 2,3,7,8-TCDD residues (Table 3-58). Reductions of total TCDD residues by cooking ranged from 34.2 percent to 67.5 percent for control samples and 44.2 percent to 70.6 percent for spiked samples (Stachiw et al., 1988). These percentage reductions were not significantly different for control vs. spiked samples. Thus, the concentration of TCDD in the raw samples did not appear to have a significant impact on the percent reduction by cooking. However, increasing the end point temperature and surface area of the sample resulted in significantly increased losses. Also, TCDD losses were two to eight times greater than total cooking losses (i.e., fat and moisture losses) (Stachiw et al., 1988). When TCDD levels were evaluated on a ppt whole weight concentration basis, reductions ranged from 24 to 60 percent for control samples and 38 to 65 percent for spiked samples.

In a similar study, Zabik et al. (1979) compared the reductions in PCBs in lake trout achieved by various cooking methods. Samples of fat trout from Lake Superior, Michigan, were analyzed before and after broiling, roasting, or microwave cooking. Significant total residue losses of xenobiotics were observed for all cooking methods (i.e., 26 to 53 percent for PCBs). However, when PCB losses were calculated on a wet weight concentration (ppm) basis, losses ranged from 5 to 16 percent, depending on the cooking method. On a fat weight concentration basis (ppm), PCB losses ranged from 16 to 40 percent, depending on the cooking method. In a later study, Zabik et al. (1982) found

that cooking was not an effective means of reducing the total residues or concentrations of xenobiotics in the edible tissue of carp from Saginaw Bay.

Poston et al. (1994) and Moya et al. (1997) found that total PCB levels in winter flounder from New Bedford Bay, Massachusetts, were reduced by one cooking method, but not others. Significant reductions in total PCB residues was observed in deep fried fish, but not in fillets pan fried or broiled. Similar results were obtained on an individual congener basis. Deep frying reduced total PCB levels 47 percent. However, deep-fried fillets also showed a weight loss of approximately 40 percent. Pan fried fillets showed a much lower percent reduction in total PCB residues. Water losses were also significantly lower for these two cooking methods (i.e., 7 percent and 15 percent, respectively) (Moya et al., 1997).

Smith et al. (1973) reported that the total residue levels of PCBs (Aroclor 1248 and 1254) in chinook and coho salmon steaks from Lake Michigan were reduced only slightly by baking and poaching; however, Cichy et al. (1979) observed significant losses (38 to 43 percent) of PCBs in Michigan lake trout that were irradiated and broiled. Losses were calculated by comparing the total micrograms of PCBs in raw and cooked fish. Pan-frying of white croaker fillets from Santa Monica Bay and Orange County, California, resulted in total PCB (Aroclor 1242 and 1254) losses of 65 percent and 28 percent, respectively (Puffer and Gossett, 1983). Trotter et al. (1989) found that, on the basis of concentration, PCB levels in cooked and uncooked bluefish were similar. However, when the results of cooked samples were corrected for moisture losses and compared to raw samples based on total residue levels, PCBs were found to be reduced by 27 percent.

Based on a study of Atlantic bluefish collected near Long Island, New York, Armbruster et al. (1989) concluded that trimming resulted in the largest reductions in PCB residues in fish. Armbruster et al. (1989) reported that trimming bluefish fillets resulted in an average total PCB residue reduction of 59.4 percent and that baking, broiling, frying, or poaching resulted in further losses averaging only 7.5 percent. The magnitude of reduction observed for the various cooking methods (combined with trimming) did not differ significantly. In addition, Armbruster et al. (1989) analyzed oil drippings released during cooking, and found that the total PCB residues in the oil did not account for the total losses of PCBs that occurred during cooking. Based on these results, Armbruster et al. (1989) concluded that "PCB losses by vaporization during the various cooking

procedures may have constituted the major portion of the mean total (7.5 percent) loss from cooking." Skea et al. (1979) also reported that trimming resulted in significantly greater reductions in PCB concentrations in fish than cooking. Skea et al. (1979) evaluated the effects of trimming and various cooking methods on the residue levels of PCB, Mirex, and DDT in brown trout and smallmouth bass collected from Lake Ontario. PCB results from this study are summarized in Table 3-59 according to the percent reduction in concentration (μg/g) and total reduction of PCB residues (i.e., calculated by comparing the total micrograms of PCBs in raw and cooked fish). Trimming alone resulted in total percent reductions of approximately 80 percent. Of the cooking methods, deep fat frying resulted in the greatest additional reductions in PCB residues Skea et al. (1979).

Zabik (1974) found that cooked chicken pieces had significantly lower concentrations of PCBs than raw pieces. Ten hens that had been fed PCB Aroclor 1254 were slaughtered, split in half, and cut into several pieces (i.e., drumsticks, breasts, thigh, etc.). Pieces obtained from one-half of the chicken were analyzed raw, and pieces from the other half were analyzed after stewing or pressure cooking. The two cooking methods resulted in similar losses of PCBs (Table 3-60). Cooking resulted in greater losses from abdominal adipose tissue and thigh skin. These pieces also had the highest fat content. Recovery of PCBs was calculated by comparing the levels of Aroclor in cooked chicken and broth to the levels in raw chicken. Percentage recoveries ranged from 60 to 95 percent.

Schecter et al. (1996) studied the effects of cooking on CDD/CDF levels in hamburger. Ground beef was purchased from a supermarket in Binghamton, New York, and divided into eight samples. Four samples were analyzed for CDD/CDFs uncooked, and the other four samples were broiled and then analyzed for CDD/CDFs. Cooking produced a 42 to 49 percent decrease in I-TEQ$_{DF}$s per hamburger. However, this decrease was identical to the decrease in weight due to cooking. Thus, reduction in CDD/CDFs in hamburger are due to loss of fat and water during cooking. The I-TEQ$_{DF}$s calculated on a whole weight concentration basis were 0.128 to 0.134 ppt for uncooked samples and 0.116 to 0.145 ppt for cooked samples. These results indicated little change in total I-TEQ$_{DF}$ concentrations from cooking, despite the significant losses observed on the basis of total residue level.

Schecter et al. (1999) recently extended their studies to examine the effect of broiling on CDD, CDF, and co-planar PCB levels in hamburger, bacon, and catfish. The samples were again purchased from a supermarket in Binghamton, New York, and each food type was divided into nine samples. Five samples of each food type were broiled in an electric oven (one of each cooked food type sample was consumed to guarantee edibility), and the other four samples were analyzed uncooked. Reductions of approximately 50 percent in the total CDD/CDF/PCB TEQ levels (using I-TEFs for CDD/CDFs and TEF_P-WHO_{94} for PCBs) were observed in the broiled samples. However, after adjusting for moisture losses due to broiling (i.e., looking at concentration on a weight basis), the following TEQ concentrations of CDD/CDF/PCBs were observed: (1) TEQ concentrations in the hamburger remained the same (about 0.155 ppt); (2) TEQ concentrations in the bacon increased 84 percent (from 0.079 ppt uncooked to 0.145 ppt cooked); and (3) TEQ concentrations in the catfish decreased by 34 percent (from 0.577 ppt uncooked to 0.378 ppt cooked).

Petroske et al. (1997) studied the effect of pan frying on CDD/CDF concentrations in ground beef. Samples were collected from four control animals and four dosed (16 congeners) cattle in a dioxin/furan feeding experiment. Muscle tissue (rib eye) and back fat from the cattle were blended into patties containing approximately 20 percent fat. The patties were then cooked in a stainless steel frying pan to an internal temperature of 74°C. During the cooking process, the fats, juices, and volatiles that formed were collected on an inverted funnel placed over the frying pan, draining back into the pan. These volatiles were analyzed along with the cooked patties. Analysis of the samples showed significant reductions in total congener residue levels (pg/patty) after pan frying (assuming the fats and juices are not consumed). Decreases after cooking ranged from approximately 21 to 50 percent for the control samples and approximately 31 to 50 percent for the dosed animals. The majority of reductions after pan frying, for both types of sample, were in the 40 to 50 percent range, which is similar to the reductions observed by Schecter et al. (1996; 1999) after broiling. The findings were not analyzed on a concentration (i.e., ppt per unit weight) basis, however. Consistent with the findings of Stachiw et al. (1988), the concentration of CDDs and CDFs in the raw samples did not appear to have a significant impact on the percent reduction by pan frying. Taking into consideration the CDD/CDFs found in the volatiles and juices released during the cooking

process, between 6 and 16 percent of the dosed CDD/CDF congeners were unaccounted for after cooking. Unaccounted losses were greater for the lower chlorinated dioxin congeners than for the more highly chlorinated congeners, while the opposite was observed with the furans. Petroske et al. (1997) hypothesized that "pan frying of ground beef patties, and likely non-patty ground beef significantly reduces the quantity of dioxin and furan congeners consumed if the fat and juices are discarded, while congeners releases as volatiles may pose a secondary mode of human exposure."

As indicated previously, Tomoaki et al. (2000) found that washing followed by boiling significantly reduced the concentrations of CDD/CDFs and PCBs on leafy vegetables. Concentrations were reduced to approximately 20 percent, 30 to 40 percent, and 60 percent of the original concentrations of CDDs, CDFs, and PCBs, respectively.

To evaluate the potential for contamination of foods with CDD/CDFs during the curing process, Mayer (1998) examined CDD/CDFs levels in 41 smoked ham samples produced in southern Germany, and compared the results to CDD/CDFs in 21 untreated pork samples. Only the results from samples of the outer layer of the smoked ham, about 1 cm thickness, were included in the comparison because it was assumed that CDD/CDFs derived from the curing smoke would be concentrated in this surface. I-TEQ_{DF} concentrations ranged from 0.08 pg/g fat to 85 pg/g fat, with an average of 6.2 pg/g fat in the smoked ham samples. In comparison, the I-TEQ_{DF} concentrations in the untreated pork samples were between 0.09 pg/g fat and 1.2 pg/g fat, with an average of 0.31 pg/g fat. The median I-TEQ_{DF} levels for these two groups were approximately the same; 0.33 pg/g fat for the outer parts of smoked ham samples and 0.31 pg/g fat for the untreated pork samples. Most pork samples had lipid-based I-TEQ_{DF} concentrations below 0.5 pg/g. A total of 61 percent of the smoked ham samples, compared to 90 percent of the untreated pork samples, had I-TEQ_{DF} concentrations lower than 0.5 pg/g fat. Mayer (1998) also presented I-TEQ_{DF} levels based on all edible parts of the smoked ham samples. The results indicated that 30 samples had I-TEQ_{DF} concentrations lower than 0.04 pg/g; 8 samples showed levels between 0.06 and 0.35 pg/g; and 3 samples were highly contaminated with I-TEQ_{DF}s ranging from 1.7 to 3.7 pg/g. CDD/CDF homologue group profiles illustrated that smoked ham with low CDD/CDF contamination had a similar profile to that of untreated pork. Smoked ham with elevated levels of CDD/CDFs had a similar profile to that of highly contaminated ham, but a quite different profile to that of untreated

pork. Mayer (1998) indicated that the curing process may be a source of CDD/CDFs in smoked ham.

Results of the preceding studies suggest that processes such as smoke curing may increase CDD/CDFs in foods. Cooking may significantly reduce total residues of dioxin-like compounds in foods. However, the data reported on the basis of concentration are somewhat contradictory. Schecter et al. (1996, 1999) observed that concentrations of dioxin-like compounds in beef were not significantly affected by cooking, but the effects of cooking were more significant in bacon and fish. Skea et al. (1979) also observed significant concentration changes of PCBs in fish. In contrast, the Zabik et al. (1979, 1982) studies did not show significant losses of PCB concentrations in fish from cooking. Therefore, based on the existing data, it is not possible to draw conclusions with regard to reductions in food concentrations of dioxin-like compounds from cooking. As a result, potential reductions in concentrations from cooking are not accounted for in Chapter 4 for the purpose of estimating dietary intake of dioxin-like compounds.

3.7.6. Food Observations and Trends

Some general observations for CDD/CDF levels are possible from the data presented in the various food product studies above:

- TEQ concentrations of CDD/CDFs and PCBs are similar in the studies from the United States and Europe.
- CDD/CDF levels in the higher chlorinated congeners (i.e., HpCDDs and OCDD) are present in higher concentrations than the lower chlorinated congeners. In the higher chlorinated congeners, CDD levels are present in greater concentrations than the CDFs.
- PeCDD is frequently the highest contributors to total TEQs in foods.
- Food products of animal origin (i.e., fish, meat, eggs, and dairy products), which have a high fat content, have a higher concentration of CDD/CDFs than those food products that have lower lipid contents.
- Generally, of all the food products, fish and shellfish contain the highest levels of CDD/CDFs.

3.7.7. Food CDD/CDF Congener Profiles and Background TEQ Concentrations

The 2,3,7,8-substituted congener profile for various foods are presented in Table 3-61 and Figures 3-7 through 3-10. These profiles are calculated as the ratio of individual congener concentrations to the sum of concentrations for all of the 2,3,7,8-substituted congeners and are based on data from the studies discussed previously and footnoted on Table 3-53. Profiles for beef, milk, and dairy products are similar, with 1,2,3,4,6,7,8-HpCDD and OCDD dominating the profiles in nearly equal proportions. In contrast, OCDD is the single dominant congener in both chicken, eggs, and pork.

U.S. food data on CDD/CDFs are summarized in Table 3-62. Background TEQ_{DF}-WHO_{98} estimates are presented first assuming that nondetects equal half the detection limits and second assuming that nondetects equal zero. Large national surveys conducted by EPA/USDA (i.e., beef, pork, poultry, and milk) provide an adequate basis for estimating the concentrations of dioxin-like compounds believed to be representative of background levels in U.S. foods. For some food groups, however, the small sample size and high number of nondetects provide an uncertain basis for estimating national background levels. Overall, the general agreement between the national U.S. estimates and the food level estimates for Canada and Europe provides some reassurance that the U.S. values are reasonable. For the purposes of calculating background exposures to CDD/CDFs via dietary intake, the upper-range background TEQ_{DF}-WHO_{98} (i.e., those calculated using one-half the detection limit for the nondetects) were used, except for vegetable oil. (See Chapter 4.)

North American food data on PCBs are summarized in Table 3-63. These data are used in Chapter 4 to estimate background dietary exposures to PCBs.

3.8. SUMMARY OF CDD/CDF AND PCB LEVELS IN ENVIRONMENTAL MEDIA AND FOOD

This chapter summarizes data on CDD/CDF and PCB levels in environmental media and food with emphasis on "background levels." Data representative of background conditions in environmental media are considered to be those collected in rural, pristine, and urban (soil and air only) areas not believed to be impacted by any local sources (e.g., incinerators).

The mean background levels for the various environmental media and foods presented in this chapter are summarized in Table 3-64. These total background level TEQ_{DFP}-WHO_{98} are used in Chapter 4 to estimate typical exposure levels in the United States. Standard deviations of the total mean TEQ_{DF}-WHO_{98} for each media were also calculated to depict the "range" of probable CDD/CDF levels in various media. For media for which complete congener-specific data for multiple samples from the same study (i.e., beef, pork, poultry, milk, dairy, and sediments) were available, means and standard deviations were calculated by conventional methods. However, for media for which mean total TEQ_{DF}-WHO_{98} were calculated by summing congener-specific TEQ_{DF}-WHO_{98} from multiple studies (e.g., soil, air), the use of typical methods for calculating standard deviations was not possible. Therefore, standard deviations were based on the standard deviation of the congener that contributed most to the total TEQ_{DF}-WHO_{98}. The percentage deviation from the mean for that congener was applied to the total mean TEQ_{DF}-WHO_{98} for all congeners combined. The congeners selected for use in the standard deviation estimates are presented in Table 3-65. The data in this table indicate that the pentachlorinated dioxins and furans were frequently the highest contributors to total TEQ_{DF}-WHO_{98} in foods and other environmental media in the United States. Standard deviations for fish could not be calculated because of the weighing method used in developing the average background concentration for fish. Media levels presented in Table 3-61 are shown graphically in Figure 3-11. Table 3-61 illustrates that of all the food products, levels (whole weight basis) of CDD/CDF/PCBs are highest in freshwater fish.

Secondary Soil (combustion sources) • 2,3,7,8-TCDD • 2,3,7,8-TCDF	 ND - 5.6 ND - 180.0	 0.09 (90) 6.5 (90)	0.0 - 472.6	18.7 (90)

[a] Background samples were believed to be indicative of ambient levels of dioxins and furans in the environment. Primary samples were collected immediately at a potential source of contamination. Secondary samples were collected from areas directly impacted by the primary source and could be used to indicate movement of contaminants.

[b] Concentrations in picograms/gram (pg/g) dry weight.

[c] I-TEQ_{DF}s are the sum of seventeen 2,3,7,8-substituted dioxins and furans after the concentration of each individual dioxin or furan is multiplied by its International Toxicity Equivalency Factor (I-TEF_{DF}). For samples with nondetected levels of a dioxin or furan, zero was used as the concentration for the I-TEQ_{DF} calculation.

[d] Numbers in parentheses indicate the number of samples (n) used to calculate mean.

[e] ND = Not Detected.

[f] When the total TEQ was recalculated using TEF_{DF}-WHO_{98}s, the TEQ_{DF}-WHO_{98} was 4.4 pg/g.

[a] Background samples were believed to be indicative of ambient levels of dioxins and furans in the environment. Secondary samples were collected from areas directly impacted by the primary source, and could be used to indicate movement of contaminants.

[b] Concentrations in picograms/gram (pg/g) dry weight.

[c] I-TEQ_{DF}s are the sum of 17 2,3,7,8-substituted dioxins and furans after the concentration of each individual dioxin or furan is multiplied by its International Toxicity Equivalency Factor (I-TEF_{DF}). For samples with nondetected levels of a dioxin or furan, zero was used as the concentration for the I-TEQ_{DF} calculation.

[d] Numbers in parentheses indicate the number of samples (n) used to calculate mean.

[e] ND = Not Detected.

Table 3-22. Background Data for Fish from the National Bioaccumulation Study

Congener	No. of Background Sites	Concentration Range[a] (pg/g)	Mean Conc.[a] (pg/g)	Standard Deviation[a] (pg/g)	Median Conc.[a] (pg/g)
2,3,7,8-TCDD	34	0.06 - 2.26	0.56	0.38	0.50
2,3,7,8-TCDF	34	0.10 - 13.73	1.61	2.51	0.90
1,2,3,7,8-PeCDD	33	0.15 - 2.67	0.77	0.54	0.54
1,2,3,7,8-PeCDF	34	0.10 - 1.90	0.43	0.31	0.39
2,3,4,7,8-PeCDF	34	0.10 - 1.39	0.50	0.36	0.42
Total HxCDDs	30	ND - 3.57	0.39	0.8	ND
Total HxCDFs	29	ND - 2.59	0.22	0.66	ND

Source: U.S. EPA (1992).

[a] Concentrations are picograms per gram (pg/g) wet weight. The mean, median, and standard deviation were calculated using one-half the detection limit for samples that were below the detection limit. In cases where multiple samples were analyzed per site, the value used represents the highest concentration.

Note: ND = nondetect.

Table 3-23. Levels of CDD and CDF I-TEQ_{DF}s in Fish From the Southern Mississippi Region

Food Sample	Number of Observations	I-TEQ_{DF} pg/g sample[a]
Catfish (farm-raised) Nuggets[b]	3	1.19, 2.64, 2.57
Mullet Fillet	2	0.089, 0.027
Spanish Mackerel Fillet	1	0.72
American Oyster Meat	3	0.62, 0.53, 0.60
Blue Crab		
Claw Meat	3	0.06, 0.10, 0.09
Body (soft-shell)	3	1.09, 1.14, 1.44
Crawfish		
Tail Muscle	2	0.033, 0.087
Head and Digestive Gland	2	2.34, 1.55

[a] One-half the detection limit was used in calculating the I-TEQ_{DF}s.

[b] Nuggets are small pieces of fillet.

Source: Cooper et al. (1995).

Table 3-24. Summary of CDD, CDF, and PCB Analyses in Farm Raised Catfish from the Southeastern United States[a]

Sample Type	Number of Observations	I-TEQ_{DF} (mean) pg/g lipid	TEQ_{P}-WHO_{98} (mean) pg/g lipid [b]	TEQ_{DFP}-WHO_{98} (mean) pg/g lipid

(a) Fiedler et al., 1997
(b) Jensen and Bolger, 2000
(c) Jensen (2000); personal communication by facsimile
(d) Jensen et al., 2000, with additional clarification by personal communication with FDA
(e) U.S. EPA, 1992
(f) Classified as marine by U.S. EPA, 1992
(g) Assumed to be marine, based on recommendation by EPA, Office of Water
(h) Catfish and trout were assumed to be entirely farm-raised
(i) Calculated as the average over all locations assuming that Jensen et al. (2000) and Jensen and Bolger (2000) collected samples at different locations and Fiedler et al. (1992) collected samples from one location.
(j) Total N does not equal the sum of Ns of total freshwater/estuarine fish and total marine fish because the same data are used in both categories for salmon, scallop, and crab. Thus, the N for these data were not double counted.
* For freshwater/estuarine species for which species-specific concentration data were not available, the average value from U.S. EPA, 1992 was used
** For freshwater/estuarine shellfish species for which species-specific data were not available, the average value from the species with known concentrations was used.
*** For unclassified fish, 39% of the consumption was assumed to be freshwater/estuarine and 61% was assumed to be marine, based on recommendations by EPA, Office of Water.
**** This concentration is a species-specific ingestion-weighted average value.
***** For marine species for which species-specific concentration data were not available, the average value for the available species shown here was used.

NOTE: Data from U.S. EPA, 1992 for the following species were not used here, except in the average freshwater/estuarine fish concentration, because corresponding consumption data were not available: freshwater bass, crappie, dolly varden, redhorse, rockbass, sucker, and sunfish.

Table 3-39. Example of Method for Estimating Fat Content (percent) of Beef

Item Number	Beef Item Description	Fat Fraction	Beef Intake[a] (g)	Fat Intake from Beef[b] (g)
1	Beef, ground, regular, cooked, broiled, medium	0.2069	5372916272	1111656377
2	Beef, ground, lean, cooked, broiled, medium	0.1846	1804281336	333070335
3	Beef, short loin, top serloin, choice	0.1097	791973251	86879466
4-146	–	–	17855973824	2775999294
SUM	–	–	2.58E+10	4.31E+9
Weighted Average[c]				**0.167**

a Total beef intake for the U.S. population in a day based on survey data weighted to the U.S. population.
b Fat intake from beef calculated as the beef intake multiplied by the fat fraction.
c Calculated as the sum of fat intake from beef (g) divided by the sum of beef intake (g).

Table 3-47 Calculation of Fractional Fat Content of Dairy Products Category

Milk or Dairy Product[a]	Mean Whole Weight Dietary Dairy Intake (g/day)[b]	Mean Fat Content (%)	Total Dairy Fat Intake (g/day)	Mean Whole Weight Dietary Intake of Dairy Other Than Milk (g/day)	Percent Dietary Intake of Dairy Other Than Milk (%)	Dairy Product Fat (%)
Whole milk	56	3.16	1.77	--	--	--
Lowfat milk	83	1.33	1.10	--	--	--
Skim milk	33	0.17	0.06	--	--	--
Yogurt	4.5	1.47	0.07	4.5	7.76	0.11
Cheese	14	25.3	3.54	14	24.14	6.11
Milk desserts and other[c]	39.5	8.25(d)	3.26(d)	39.5	68.10	5.62
TOTAL	230		9.80	58	100	11.84(e)

a CSFII food categories taken from USDA (1995).

b USDA (1995).

c Milk desserts = 21 g/day. Because total dairy = 230 g/day and total dairy minus milk desserts and other = 190.5; other is assumed to = 18.5 g/day (i.e., 230 minus 190.5 minus 21 = 18.5).

d No fat content data available for milk desserts and other dairy products. Total dietary fat intake for milk desserts and other calculated as the total dietary fat intake (i.e., 9.8 g/day, based on adult total fat intake of 81.39 g/day [CDC, 1994; as cited in U.S. EPA, 1997]), times the fraction of fat that comes from dairy products (i.e., 0.12, based on NLMB, 1993; as cited in U.S. EPA, 1997), minus the dairy fat intake of the other milk and dairy foods [i.e., (81.39 g/day * 0.12) - (6.54 g/day) = 3.26 g/day]. The mean fat content of milk desserts and other was calculated as the dairy fat intake (3.26 g fat/day) divided by the dietary intake (39.5 g/day).

e The overall fractional fat content of dairy products other than milk (11.84%) is calculated as the sum of the products of the fractions of dairy intake other than milk times the fractional fat contents, on the various non-milk dairy products [i.e., (0.0776 * 0.0147) + (0.2414 * 0.253) + (0.6810 * 0.0825) = 0.1184].

Table 3-48 CDD/CDF Levels in German Food

	Mean I-TEQ_{DF}[a] (pg/g fat)	Number of Samples

[e] Based on data from Lorber et al. (1998b).
[f] Based on data from Lorber et al. (1998b).

Table 3-62. Summary of CDD/CDF Levels in U.S. Food (pg/g fresh weight)

	Mean TEQ_{DF}-WHO_{98} Assuming ND = 0.5 DL	Mean TEQ_{DF}-WHO_{98} Assuming ND = zero	Number of Samples	Reference
Beef	0.18	0.061	63	Winters et al. (1996a)
Pork	0.28	0.080	78	Lorber et al. (1997b)
Poultry	0.068	0.043	78	Ferrario et al. (1997)
Eggs	0.081	0.013	15 composites	Hayward and Bolger (2000)
Dairy Products	0.12	0.12	8 composites	Based on data from Lorber et al. (1998b)
Milk	0.018	0.017	8 composites	Lorber et al. (1998b)
Freshwater Fish and Shellfish	1.0[b]	--[c]	222	Fiedler et al. (1997); Jensen and Bolger (2000); Jensen et al.(2000); U.S. EPA (1992)
Marine Fish and Shellfish	0.26[b]	--[c]	158	Fiedler et al. (1997) Jensen et al. (2000)
Vegetable Fat	NA[a]	0.056	30	Versar (1996b)

[a] High detection limits led to a calculation of the mean with ND = 0.5 DL that was judged to be misleading. See text for more detail.
[b] This concentration is a species-specific ingestion-weighted average value.
[c] Not calculated because of lack of congener-specific data for all species.

ND = Nondetect; DL = Detection Limit
NA = Not available

Table 3-63. Summary of TEQ_P-WHO_{98} Levels in North American Food (pg/g fresh weight)

	Mean TEQ_P-WHO_{98} Assuming ND = 0.5DL	Mean TEQ_P-WHO_{98} Assuming ND = Zero	Number of Samples	Reference
Beef	0.084	0.084	63	Winters et al. (1996b)
Pork	0.012	0.0074	78	Lorber et al. (1997b)
Poultry	0.026	0.026	78	Ferrario et al. (1997)
Eggs	0.1	NR	18 1 composite 5 composites	Schecter et al. (1997) Mes and Weber (1989) Mes et al. (1991)
Dairy Products	0.058	0.058	8 composites	Based on data from Lorber et al. (1998b)
Milk	0.0088	0.0088	8 composites	Lorber et al. (1998b)
Freshwater Fish	1.2	NR	1 composite of 10 samples 1 composite 5 composites	Schecter et al. (1997) Mes and Weber (1989) Mes et al. (1991)
Marine Fish	0.25	NR	1 composite of 13 samples 5 composites	Schecter et al. (1997) Mes et al. (1991)
Vegetable Fat	0.037	NR	5 composites	Mes et al. (1991)

NOTE: Schecter et al. (1997) and Mes and Weber (1989) values based on one-half the limit of detection for nondetects and Mes et al. (1991) data based on positive composite samples only. Five additional composite samples labeled "shellfish" from Mes et al. (1991) were not used in estimating background levels because information on the source of the shellfish (i.e., freshwater or marine) needed to categorize the data were not available. It is therefore assumed that the species included in the freshwater and marine categories are representative of both finfish and shellfish from those sources.

Table 3-64. Summary of North American CDD/CDF and PCB TEQ-WHO_{98} Levels in Environmental Media and Food (whole weight basis)

Media	CDD/CDFs[a]	References	PCBs[a]	References	Mean Total CDD/CDF/PCBs

Table 3-64. Summary of North American CDD/CDF and PCB TEQ-WHO_{98} Levels in Environmental Media and Food (whole weight basis) (continued)

Media	CDD/CDFs[a]	References	PCBs[a]	References	Mean Total CDD/CDF/PCBs
Pork, ppt	n = 78 0.28 ± 0.28 Range = 0.15 - 1.8	Lorber et al. (1997b)	n = 78 0.012	Lorber et al. (1997b)	0.29
Poultry, ppt	n = 78 0.068 ± 0.070 Range = 0.03 - 0.43	Ferrario et al. (1997)	n = 78 0.026	Ferrario et al. (1997)	0.094
Vegetable Fats, ppt	n = 30 0.056 ± 0.24[g]	Versar (1996b)	n = 5 composites 0.037[e]	Mes et al. (1991)	0.093

[a] Values are the arithmetic mean TEQs, in ppt, and standard deviations. Nondetects were set to one-half the limit of detection, except for soil and CDD/CDFs in vegetable fats for which nondetects were set to zero.

[b] The values for environmental media are means of the data, but lack the spatial representativeness to be considered true national means.

[c] Congener-specific PCB data are limited.

[d] The values for fish lack the statistical significance to be considered true means; the values for the other food groups were derived from statistically-based surveys and can be considered true national means. The CDD/CDF concentrations are species-specific ingestion weighted average values.

[e] Standard deviations could not be calculated due to limitations associated with the data (i.e., composite analyses).

[f] Based on data from Canadian air, as reported by Hoff et al. (1992). Not used in U.S. background exposure estimates in Chapter 4.

[g] TEQ calculated from Versar (1996b) by setting nondetects to zero.

Table 3-65. CDD/CDF Congeners that Contribute the Highest Percentage of TEQ_{DF}-WHO_{98} to the Total TEQ_{DF}-WHO_{98} for All Congeners Combined

Media	North America	Percentage of Total TEQ_{DF}-WHO_{98}
Urban Soil	1,2,3,7.8-PeCDD	22.0
Sediment[a]	1,2,3,4,6,7,8-HpCDD	18.9
Freshwater Fish and Shellfish	--[b]	
Marine Fish and Shellfish	--[b]	
Urban Air	1,2,3,7,8-PeCDD	22.5
Water[c]	OCDD	56.3
Milk[a]	1,2,3,7,8-PeCDD	32.7
Dairy[a]	1,2,3,7,8-PeCDD	32.7
Eggs[a]	1,2,3,7,8-PeCDD	24.6
Beef[a]	1,2,3,7,8-PeCDD	32.8
Pork[a]	1,2,3,7,8-PeCDD	30.5
Poultry[a]	1,2,3,7,8-PeCDD	31.5
Vegetable Fats[a,d]	1,2,3,7,8-PeCDD	44.0

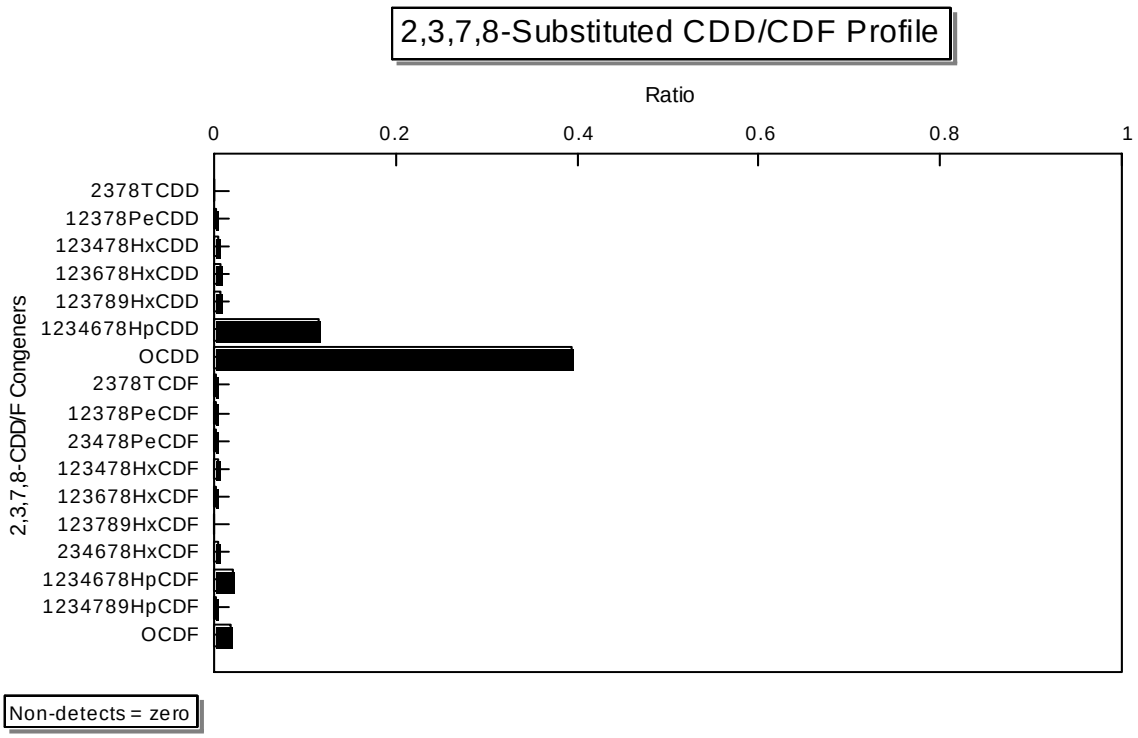
NOTE: Data were not available for all congeners in all media.

[a] Not used in calculation of the standard deviation because adequate congener-specific data were available for all samples allowing for the calculation of means and standard deviations by traditional methods.

[b] Not calculated due to lack of congener-specific data for all species.

[c] Data available for OCDD and OCDF only.

[d] Due to the large number of nondetects, zero was used to represent nondetects in determining the congener that contributed the most to the total TEQ_{DF}-WHO_{98}.



Note: Based on data from OEPA (1995), CDEP (1998), and Cleverly et al. (2000).
