feed is assumed to be analogous to the vegetation in cattle diet; therefore, the experimental BCFs can be directly applied to vegetation in cattle diets. However, Fries and Paustenbach also hypothesized that soil is less bioavailable than feed, based on some rat feeding studies, and therefore the BCF developed from feed cannot directly be used on a soil concentration - it should be reduced. Information in Fries and Paustenbach led to an assignment of 0.65 for the soil bioavailability factor, $\mathbf{B_s}$. This was reduced to 0.30 and increased to 0.90 in sensitivity testing. Three parameters describe the proportion of the dry matter in the diet of beef cattle that is soil, **BCSDF**, grass, **BCGDF**, and feed, **BCFDF**. The sum of these three terms, by definition, equals 1.00. Beef cattle are principally pastured (where incidental soil ingestion occurs), with supplemental feeds including hay, silages, and grain, particularly in cooler climates where they are housed during the winter. Values of 0.04 for BCSDF, 0.48 for BCGDF, and 0.48 for BCFDF were used in the demonstration scenarios. A final set of two parameters describes the proportion of these dietary intakes that are contaminated. One is defined as the fraction of grazing land that is contaminated, **BCGRA** for beef cattle. The initial assumption of 1.00 for this parameter meant that all the grass as well as all the soil in which the cattle grazed was contaminated (since soil was assumed to be ingested during grazing). The last one similarly is defined as the proportion of feed that is contaminated, **BCFOD** for beef cattle. It were also set at 1.00, perhaps indicating that feed was grown on-site. Rather than change these diet fraction assumptions and extent of contamination assumptions individually or in tandem (if necessary), what is done instead is to model four different scenarios relating to cattle exposures. These four scenarios and the parameter changes made are:

1) *High and low soil ingestion*	Low: BCSDF = 0.01 BCGDF = 0.50 BCFDF = 0.49
No changes to BCGRA or BCFOD; diet assumptions changed to reflect high and low soil ingestion patterns	High: BCSDF = 0.15 BCGDF = 0.43 BCFDF = 0.42
2) *Low exposure conditions* Grazing is under lush conditions, so soil ingestion and diet pattern is modeled as "low" soil ingestion above; also, most feed is purchased externally and uncontaminated; BCFOD reduced from 1.00 to 0.25	BCSDF = 0.01 BCGDF = 0.50 BCFDF = 0.49 BCFOD = 0.25

3) *Low extent of contamination* Diet assumptions are unchanged from initial assumptions; only it is assumed that 25% instead of 100% of dry matter in cattle diet is contaminated	BCGRA = 0.25 BCFOD = 0.25
4) *High/low lifetime pasturing* Tests for beef cattle only assuming heavy lifetime pasturing, 90% grass, and light lifetime pasturing, 08% grass	Low: BCSDF = 0.02 BCGDF = 0.08 BCFDF = 0.90 High: BCSDF = 0.08 BCGDF = 0.90 BCFDF = 0.02

● Effluent Discharge Source Category: Section 4.6, Chapter 4, discusses briefly how data from the 104-mill pulp and paper mill study (EPA, 1990) were used to develop initial parameters required for this source category in its demonstration in Chapter 5. The use of the 104-mill data in a model evaluation exercise is expanded upon in Chapter 7, Section 7.3.6. The data is also used here to assign high and low values for four of the seven required parameters for this source category. Two have to do with flow rates: $\mathbf{Q_e}$ which is the effluent flow rate, and $\mathbf{Q_u}$ which is the receiving water flow rate. The range of Q_e is from 10^5 to 10^7 L/hr, which are the low and high surrounding the $4.1x10^6$ rate used in the demonstration scenario in Chapter 5. The range of Q_u is 10^7 to 10^9 L/hr (excluding the top ten receiving water bodies, which were in the 10^{10} L/hr range and for which model did not appear to perform adequately), and these were the low and high around the $4.7x10^9$ L/hr rate used in Chapter 5. Two parameters describe the suspended solids content of the effluent, $\mathbf{TSS_e}$, and the suspended solids content of the receiving water body, $\mathbf{TSS_u}$. TSS_e ranged from 10 to 250 mg/L in the 104-mill study, so this was the range around the 70 mg/L used as the initial value. Data from STORET used to develop TSS_u led to an average of 9.5 mg/L and a range of less than 1 to 50 mg/L; a range of 2 (a reasonable value for a stationary water body such as a pond or lake) to 50 mg/L was tested. One required parameter was, of course, the rate of contaminant discharge, **LD**, in units of mg/hr. The assumed value was 0.0315 mg/hr, and this decreased and increased an order of magnitude for low and high testing. The remaining two parameters are the organic carbon contents of effluent solids, $\mathbf{OC_e}$, and upstream river suspended solids, $\mathbf{OC_u}$. A range based on data was not available for these parameters. OC_e was assigned a value of 0.36 based on the fact that solids in effluent discharges are primarily biosolids, and this value was one cited for surface water algae; values of 0.15 and 0.50 were tested. The value of 0.05 for OC_u was the value assumed for demonstration of other

source categories, where the parameter was called OC_{ssed}. The same range of 0.02 to 0.10 for OC_{ssed} was used for OC_u.

● Stack Emission Source Category: The parameters in this category listed in Table 6-1 are the only ones which are unique to this source category. As seen, there are only a very few unique parameters. Most of these are associated with surface water impact, and one series of tests evaluated the impact of parameter changes to surface water concentrations and fish concentrations. These include the contaminant deposition rates, $\mathbf{RDEP_{wat}}$ and $\mathbf{RDEP_{sw}}$, which are depositions onto the watershed draining into the surface water body and the surface water body itself (units are $\mu g/m^2$-yr). The initial values for these were those modeled to occur 5000 meters from the stack. This assignment for the stack emission demonstration scenarios, #4 and #5 in Chapter 5, assumes that the stack is located reasonably distant from the impacted water body. These depositions rates are specific to 2,3,7,8-TCDD. Rates of 2,3,7,8-TCDD deposition at 200 meters and at 10,000 meters were used as high and low values, respectively. It should be noted that depositions are higher at 200 meters and lower at 10,000 meters as compared to 5,000 meters, but air concentrations are lower at 200 meters as compared to 5,000 meters. This trend occurs because wet deposition is highest nearest the stack. Total depositions are driven by these high wet deposition totals; hence total depositions at 200 meters exceed those at 5,000 meters. However, dispersion modeling shows that ambient air concentrations of contaminants in the vapor phase (given the wind data and all other parameters and assumptions in using the ISCST3 model for the demonstration scenarios) are highest 500-1000 meters from the stack. For sensitivity testing, differences in model performance as a function of distance from the stack will be evaluated. $\mathbf{RDEP_p}$ is the deposition of particles themselves and was supplied in order to maintain a mass balance of solid materials entering the water body. The default value of 0.03 g/m^2-yr was taken from Goeden and Smith (1989) for a study on the impacts of a resource recovery facility on a lake. They estimated a total deposition of particles to the lake from all sources was 74.4 g/m^2-yr. Assuming the stack is unlikely to contribute all sources of particles to a water body, a high value was chosen as 3 g/m^2-yr, and a low value was given as 0.003. The fraction of depositing particles remaining in suspension, $\mathbf{f_{sd}}$, was initialized as 1.00 (meaning that all directly depositing particles remain in suspension) based on an argument that the small particles emitted from the stack and transported directly to the surface water body would settle to surface water bottoms much more slowly than other solids entering water bodies. A low value of 0.00 was tested (meaning that all solids directly depositing within a year settle quickly to become bottom sediments). The average watershed mixing zone depth, $\mathbf{d_{wmx}}$, was initialized at 0.10 m

(10 cm) which is midway between the 2 cm assumed for non-tilled conditions and 20 cm assumed for tilled conditions. This assumption might translate to a rural watershed comprised equally of farmed and unfarmed land. It was reduced to 1 cm and increased to 20 cm in sensitivity testing. A second series of tests evaluated biota impacts at the site of exposure, vegetables/fruits and beef/milk. Parameter inputs for these tests include the ambient air concentration and depositions at the site of exposure, $\mathbf{C_{va}}$ and $\mathbf{RDEP_e}$, and the no-till depth of mixing, $\mathbf{d_{not}}$. The no-till depth of mixing was increased from 2 to 5 cm. Concentrations and depositions of 2,3,7,8-TCDD at 200 and 10,000 meters were tested. The baseline quantities at 5,000 meters were varied to reflect different vapor/particle partitioning assumptions. Currently, the assumption is that 2,3,7,8-TCDD emissions are 51% in the vapor phase and 49% in the particle phase. Linear adjustments to the emissions in vapor and in particle form can be made to stack emissions. Concentrations and depositions at specific locations are then adjusted in the same linear manner to reflect different vapor/particle partitioning assumptions. Two assumptions tested include 10% vapor/90% particle and 90% vapor/10% particle.

● Contaminant Physical and Chemical Properties: The initial values for testing of this category of parameters were the ones used for 2,3,7,8-TCDD. Generally, the high and low values tested are those which may represent a range for this contaminant only, not all dioxin-like compounds. However, several of the ranges also encompass values that could be pertinent to other compounds. It should be remembered that this is simply a model performance exercise and nothing else. Also, it could be argued that some of the parameters should be changed in tandem - that there may be a relationship between soil/water adsorption, as modeled by Koc, and bioconcentration. Such relationships were not explored in these exercises. Notes on the parameters are as follows:

1. **Henry's Constant, H** - The value of 3.29×10^{-5} atm-m^3/mole was used for 2,3,7,8-TCDD. Except for a heptachloro-PCB, Henry's Constants for the dioxin-like compounds ranged from 10^{-6} to 10^{-4}. Because of this, the initial value was reduced and then increased an order of magnitude for this test.

2. **Molecular Diffusivity in Air, $\mathbf{D_a}$** - This parameter is needed for the volatilization flux algorithm. Because no values were available for the dioxin-like compounds, values were estimated based on the ratios of molecular between a dioxin-like compound of interest and a compound for which a D_a was available - in this case, diphenyl. The range of values tested are 0.005 cm^2/s as a low and 0.10 cm^2/s around the initial value of 0.047 cm^2/sec.

3. **Organic Carbon Partition Coefficient, Koc**: The Koc is perhaps the single most influential parameter governing the fate and transport of the dioxins from contaminated soils in this assessment, impacting surface water concentrations, vapor phase air concentrations, and directly or indirectly, all biomass concentrations (fish, vegetation, beef/milk). The literature for 2,3,7,8-TCDD shows a range of Koc under 10^6 (from Schroy, et al., 1985) to over $2x10^7$ L/kg (Jackson, et al., 1986). The value selected for 2,3,7,8-TCDD was $3.98*10^6$, based on an examination of available literature on the subject. The values tested were one order of magnitude less ($4*10^5$) and one order of magnitude more ($4*10^7$) than the value initially assumed for 2,3,7,8-TCDD.

4. **Air-to-Leaf Vapor Phase Transfer Factor, B_{vpa}**: The initial value for 2,3,7,8-TCDD was developed in a calibration exercise using field data which included air concentrations and grass concentrations which corresponded to these air concentrations. Details of this calibration are provided in Chapter 4, and will not be repeated here. Plus or minus an order of magnitude will be tested as a high and low value for B_{vpa}.

5. **Particle-Phase Fraction, ϕ:** This fraction was used in the stack emission source category for determining the portion of emitted contaminant that was and remained in the particle phase from stack to exposure site. Details on the measured and theoretical partitioning is given in Chapter 3 of this Volume. As discussed there, measured partitioning of 2,3,7,8-TCDD in ambient air showed a very small amount in the particle phase, 13%. However, speculation was that the monitoring method itself could lead to an underestimate in the particle phase, and for that reason, a theoretical approach was used to partition the dioxin. This led to a ϕ of 0.49 for 2,3,7,8-TCDD. The stack emission demonstration will be used to evaluate the impact of assuming 0.20 or 0.80 for 2,3,7,8-TCDD ϕ.

6. **Root Bioconcentration Factor, RCF:** The initial value for 2,3,7,8-TCDD was estimated as a function of octanol water partition coefficient, Kow. Assuming a log Kow of 6.8, RCF was solved as 5,200. Different assumptions for log Kow were used to estimate high and low values of RCF for this exercise. Examining literature Kow for the dioxin-like compounds, no log Kow are less than 6.0 (the lowest at 6.2) and only one value estimated to exceed log Kow equal 8.5. A high and low RCF were estimated, therefore, using log Kow of 6 and 8.5. This led to tested values of RCF of 1,260 and 106,000.

7. **Beef/milk Bioconcentration Factor, BCF:** Unlike the RCF (but like the BSAF and BSSAF as noted blow), there are no empirical formulas developed for BCF as a function of more common parameters such as Kow. The literature summary and interpretation of 2,3,7,8-TCDD cattle feeding studies by Fries and Paustenbach (1990) led them to assign a value of 5.0 for

2,3,7,8-TCDD. The study by McLachlan, et al. (1990) allowed for generation of BCF values for 16 of the 17 dioxin and furan congeners of dioxin toxicity equivalency, and the results from that study are used for this assessment. Fries, et al. (1999) presented another set of field-derived BCFs for 14 of the 17 dioxin-like dioxins and furans, and the BCF he calculated for 2,3,7,8-TCDD was 7.1. The 2,3,7,8-TCDD BCF used in this assessment was 5.76, which is close to the value of 5.0 promoted by Fries and Paustenbach (1990). Their summary, included in Table 4-5 in Chapter 4, showed BCF less than 1.0 for higher chlorinated dioxin-like compounds. For sensitivity testing, values of 1.0 and 10.0 were used as low and high values for BCF.

8. **Biota Sediment and Biota Suspended Solids Accumulation Factors, BSAF and BSSAF**: EPA (1993; 1995) summarizes several water column based and sediment (both suspended and bottom) based empirical parameters used to estimate fish concentrations given a water or sediment concentration. Two of these are the BSAF and BSSAF, which are used in this assessment. Although no data exists to determine values of the suspended solids factor, BSSAF, EPA (1993) suggests that BSAF values could be used. The range of BSAF values for 2,3,7,8-TCDD discussed in EPA (1993; 1995) is 0.03 to 0.30, and this was the low and high values selected for both BSAF and BSSAF. The literature summary on BSAF included in Chapter 4 of this assessment does include studies which imply higher BSAF for 2,3,7,8-TCDD. One study, which focused on bottom feeders (carp, catfish, etc.), found a BSAF for 2,3,7,8-TCDD (CDEP, 1992) of 0.76, whereas the range of 0.03 to 0.30 focused on column feeders. A high value of 2.94 (Kjeller, et al., 1990) was found in a lake in Sweden speculated to be impacted by an active pulp and paper mill. This high value appears to be an outlier not found in other field data sets.

9. **First-order Plant Weathering Factor, kw**: This is used to simulate the weathering of contaminated particulates which have settled on plant matter via dry and wet deposition. Several modeling efforts have used the same kw as used in this effort; that kw is 18.01 yr^{-1}, which corresponds to a half-life of 14 days. Values of 51 (half-life of 5 days) and 8.4 (half-life of 60 days) yr^{-1} were used to test the impact of this parameter.

10. **Dissipation Rate Constant for Eroding or Depositing Contaminants, k**: Evidence for soil degradation of the dioxin-like compounds indicates that residues even millimeters below the soil surface degrade at a very slow rate, if at all (see Chapter 2, Volume 2 of this assessment). This was the basis for not considering degradation of soil sources of dioxin-like compounds in this assessment. However, when residues migrate to impact only a thin layer of soil at a distant site, the processes of volatilization or photolysis (the one degradation process which appears to transform dioxin-like compounds in the environment) are likely to impact delivered residues. A rate constant of 0.0277 yr^{-1}, which corresponds to a 25-year half-life, was

used in two instances for this methodology - for erosion of off-site soils onto exposure site soils, and for deposition of stack emissions onto exposure site soils. This value was changed to 0.277 yr^{-1} (half-life of 2.5 years) and 0.00277 yr^{-1} (half-life of 250 years) in sensitivity testing.

6.3.3. Results

The results of the sensitivity analysis are principally described in a series of high/low bar graphs. The Y-axis is on a log scale and shows changes in media concentration estimation when the high and low parameter substitutions are made. The Y=1 line is the value of the media concentration with all baseline parameter selections; the precise value of that media concentration is noted on each graph. Other y-axis values are arrived at as the ratio of the pertinent media concentration estimated with the altered parameter over the baseline concentration; a y-axis value of 0.1, for example, means that the concentration with the parameter substitution was one-tenth the concentration under baseline conditions. Also noted on each graph is the pertinent source strength term - for air concentration sensitivities, soil concentrations are noted, and so on. The parameters tested are named on the x-axis, and these names correspond to the names in Table 6.1. The definition and baseline value of these key parameters are noted below each graph. The high and low values tested are appropriately placed either above (when the concentration increases with the parameter change) or below the bar graphs. These parameters are the only ones which impact the tested media concentration. Of course, the soil concentration also impacts the media concentration, but as noted in the previous section, soil concentrations have a direct and linear impact in all cases, and so are not displayed on the figures. Observations from each figure now follow.

6.3.3.1. *Estimation of Vapor-Phase and Particle-phase Air Concentrations Distant from a Site of Soil Contamination*

Results for this test are shown in Figures 6-1 and 6-2. For the test of the vapor-phase algorithm, Figure 6-1, no single change resulted in estimations over an order of magnitude different from that made with baseline parameters. The model is insensitive to porosity and particle bulk density parameters, E_{slp} and P_{soil}. The results are also reasonably insensitive to ranges for organic carbon content of soil, OC_{sl}, and windspeed, U_m. For all other parameters, there appears to be roughly an order of magnitude spread over the range of parameters tested. Increasing the exposure duration to 70 years would decrease air concentration predictions by about 35% and decreasing the duration to 1 year would roughly double concentrations. As discussed earlier in Section 6.2, the volatilization algorithm assumes that contamination begins at

the soil surface at time zero, and residues available for volatilization originate from deeper in the profile over time. The result of this assumption is that the flux decreases as time increases. This is the only algorithm of this assessment where an assumption of a decreasing source strength over time is made.

Results from the test of the particle phase flux and dispersion algorithm are shown in Figure 6-2. The y-axis in this test spans two orders of magnitude since changes in the parameters describing the inherent wind erodibility of the soil, U_t and F(x), results in over an order of magnitude higher and lower than concentration estimations as compared to estimations using the selected values of U_t and F(x). The assumption of bare soil conditions at the site of contamination led to a value of 0.0 for V, the vegetative cover parameter. If the contaminated site had a reasonably dense vegetative cover leading to a V of 0.9, air concentrations at the nearby site of exposure would be about an order of magnitude less. The impact of area (ASC), distance (DL_e), and frequency (FREQ) on exposure site concentrations mirror those for vapor-phase air concentrations. That is because these three are used in the same far-field dispersion algorithm. Another parameter used for the far-field dispersion algorithm is windspeed, U_m. However, interestingly, the impact of that parameter is reversed between the vapor and particulate phase algorithms. For the particulate phase, the windspeed has more of an impact in increasing wind erosion and hence the reservoir of airborne contaminant - increasing windspeed increases air concentrations. For the vapor phase, windspeed does not play a role in estimating volatilization flux, but only a role in the far-field dispersion model. In that role, increasing wind speed increases dispersion and decreases concentrations.

Noteworthy for the particle phase algorithm is that estimated concentrations are independent of any chemical-specific parameters; wind erosion suspending the particles is only a function of climate, ground cover, and soil erodibility. Also noteworthy is that the baseline air concentration of contaminants on particles is over an order of magnitude lower than the baseline air concentration of contaminants in the vapor phase. Besides having implications for particle phase and vapor phase inhalation exposures, this difference also has implications for impacts to vegetation concentrations and subsequently to beef and milk concentrations.

The results shown in Figure 6-1 and 6-2 are specific to algorithms estimating emissions from soil, volatilization and wind erosion, and dispersion of those emissions to calculate an air concentration at a distant site. Chapter 4 also described an algorithm to estimate “near-field” dispersions, which can be used to estimate air concentrations above a site of soil contamination. Brief tests were conducted to evaluate the difference in impacts when the near field dispersion model is used instead of the far field dispersion model. One observation was that all parameters

associated with flux calculations had identical impacts to near-field air concentrations as compared to far-field concentrations. Included in this group were: for the volatilization algorithm - the exposure duration, ED, the organic carbon content, OC_{sl}, soil porosity, E_{slp}, particle bulk density, P_{soil}, and the three chemical-specific parameters, Henry's Constant, H, organic carbon partition coefficient, Koc, and molecular diffusivity, D_a, and for the wind erosion algorithm - fraction of vegetative cover, V, average windspeeds, U_m, and the parameters associated with the erodibility of the soil, U_t and F(x). The impact of area is different for concentrations calculated with the near-field algorithm compared to the far-field algorithm. This is because the area term, ASC, has a different role for the near field as compared to the far field algorithms. For the far field algorithm, ASC in effect impacts the source strength, with an order of magnitude increase in ASC increasing exposure site air concentrations by a little over 2 times (>200%). For the near field dispersion, ASC impacts the dispersion algorithm, and the same order of magnitude increase in area only increases concentrations by around 30%.

6.3.3.2. *Estimation of Soil Erosion Impacts to Nearby Sites of Exposure*

Results from this test are shown in Figure 6-3. This model shows little sensitivity to two parameters, the bulk density of soil at the site of exposure, B_{soil}, and the amount of "clean" soil (that which is between the contaminated and exposure site) which erodes onto the exposure site, SL_{ec}, along with the contaminated soil. These will not be discussed further. In contrast to SL_{ec}, the model has a direct linear impact with the amount of soil eroding from the contaminated site, SL_s. Decreasing that amount by a factor of 10 decreases exposure site soil concentrations by the same amount, and doubling contaminated site erosion also doubles exposure site soil concentrations.

The model appears to show insensitivity to the distance between the exposure and contaminated site, DL_e. However, this result should be viewed cautiously. The sediment delivery ratio equation was developed to estimate sediment loads from construction sites to nearby surface water bodies, and from distances up to 250 m. Its application to distances beyond that are questionable, and applications from one land area to another land area rather than from one land area to surface water, should also be questioned. At the model baseline distance of 150 m, the SD_s (sediment delivery ratio) is 0.26. At 1000 m, it is 0.17, which is a marginal dropoff for what appears to be a significant increase in distance. The distance becomes increasingly important when there are obstructions between the contaminated and the exposure site such as ditches, roads, and so on. When using this methodology, one should consider not relying on the sediment delivery ratio equation for: 1) transport of soils beyond 250 meters, 2) when the

exposure site is upgradient from the site of contamination (in its development for construction sites, the assumption that a water body is downgradient soil concentration at the exposure site only doubled; it did not increase by an order of magnitude. It is unreasonable to assume that all the eroded soil would crowd into the smaller exposure site. When the contaminated site decreased an order of magnitude to 4,000 m^2, the exposure site soil concentration likewise decreased by an order of magnitude. In this case, like the case when the contaminated and exposure site were of the same size, all the contaminated soil eroding in the direction of the exposure site mixes into exposure site soil, so the resulting average soil concentration at the exposure site is linearly related to the concentration at the contaminated site. A similar trend is noted with changes in the exposure site area term..

The impact to changes in depth of tillage is nearly, but not quite, linear. Decreasing the no till depth of mixing, d_{not}, from 0.02 m to 0.01 m increased soil concentrations by a factor of 1.4 roughly, while increasing d_{not} to 0.10 decreased concentrations by 70%. A similar, nearly linear, impact is noted with the changes tested for tillage depth, d_t. For figure clarity, these results were left off Figure 6-3, but decreasing the depth from an initial 0.20 m to 0.10 m increased concentrations by just under a factor 2, and decreasing it to 0.30 m decreased concentrations by just under 33%.

The impact of changing the dissipation rate is not linear. Decreasing the rate by an order of magnitude, which is equal to increasing the half-life from 25 to 250 years, only about doubles the predicted soil concentrations, while increasing the dissipation rate by an order of magnitude, or reducing the half-life to 2.5 years, reduces the soil concentration by a factor of 5.

It is interesting that some of the tested model parameter changes, including manipulation of the areas of contamination and exposure sites, and the dissipation rate, result in increasing the exposure site soil concentration to nearly the same concentration as the contaminated site. This is a somewhat counterintuitive result; it seems unlikely that an off-site location would have concentrations close to the contaminated site. If, in fact, the model has a tendency to overpredict exposure site concentrations, there are several reasons why this might occur: 1) overestimation of the sediment delivery ratio, which was discussed above, 2) a shallow mixing depth for untilled situations, 3) a low dissipation rate (which translates to a long half-life), 4) high estimates of erosion from the contaminated site, and/or 5) use of a steady state solution.

Regarding this latter point, a steady state solution means that if erosion continues indefinitely and the contaminated site soil concentrations do not lessen during this time, than the exposure site soil concentrations reaches the level predicted by the model. This could lead to a significant overestimation if the soil contamination was relatively recent. For example, if the

erosion from a contaminated site to an exposure site has been occurring for 25 years, it can easily be shown that the full solution to the soil concentration, Equation (4-16) in Chapter 4, will result in a soil concentration that is 72% of the concentration estimated using the steady state simplification, Equation (4-17) in Chapter 4. At 50 years, the modeled soil concentration will be 92% of the steady state solution. These calculations assumed the half-life of 25 years. Therefore, if the soil contamination occurred within 20 years or so, assessors may wish to model a lower and perhaps more accurate soil concentration by using the full solution rather than the steady state solution to estimate exposure site soil concentrations and impacts.

6.3.3.3. *Estimation of Soil Erosion Impacts to Nearby Surface Water Bodies*

Results from this test are shown in Figure 6-4. One immediate point to make about this bar graph is that the results displayed are essentially identical for water, bottom sediment, and fish concentrations, with the exception of two trends which will be described below. Also, since bottom and suspended sediment concentrations are assumed to be linearly related by the equation: $C_{ssed} = (OC_{ssed}/OC_{sed}) * C_{sed}$, where C_{ssed} and C_{sed} are suspended and bottom sediment concentrations, respectively, and OC_{ssed} and OC_{sed} are suspended and bottom organic carbon fractions, than the relationships in Figure 6-4 apply to suspended sediment concentrations as well.

One of the exceptions has to with trends regarding partitioning of dioxins between sediments and water. The parameters involved in this algorithm are the organic carbon content parameters, OC_{ssed} and OC_{sed}, and the organic carbon partition coefficient, Koc. First, the direction of the change is not the same. The sorption, and hence concentration, of dioxin-like compounds onto sediments can be increased by increasing the organic carbon content of the sediments or increasing the Koc. However, doing either decreases the concentration in water. For the "low organics" test, water concentration increases by a factor of 2.7 rather than slightly decreases as in Figure 6-4, which for this case, displays only the impact to bottom sediments. For the "high organics" test, water concentrations decrease to 0.60 of what they were in baseline conditions. The high Koc decreases water concentrations to 0.1, and the low Koc increases water concentrations 7 times. Both these trends are distinctly different than the sediment trends; they were left out of the graph in order not to crowd the graph (or require another one be drafted), and also because water concentrations in the sub-ppq range are of minimal concern for exposure. The other exception has to do with the impact of changes to the organic carbon content of bottom and suspended sediments in the calculation of fish concentrations. Fish tissue concentrations for three of the four source categories of this assessment are a direct function of bottom sediment

concentrations; the one source category where this is not true is the effluent discharge source category, where fish tissue concentrations are a function of suspended sediment concentrations. As laid out in Chapter 4, whole fish tissue concentrations are estimated as: (C_{sed}/OC_{sed}) * BSAF * f(lipid), when fish tissue concentrations are a function of bottom sediment concentrations, and for the effluent source category, fish tissue concentrations are estimated as: (C_{ssed}/OC_{ssed}) * BSSAF * f(lipid). It is seen from Figure 6-4 that the concentration on bottom sediments, C_{sed}, is impacted by the value assigned to OC_{sed}. However, the impact to C_{sed} with changes to OC_{sed} is marginal and in the same direction. For example, reducing OC_{sed} from its baseline of 0.03 to 0.01, reduces C_{sed} by a small amount. The impact to fish tissue from changes in OC_{sed} is more pronounced and essentially in an inverse linear manner, as shown by the formulation above.

Other than these two exceptions, a principal message from Figure 6-4 is that all surface water impacts are identically impacted by surface soil and erosion parameters. The comments in the above section concerning the distance between the contaminated soil and the target site, which in the above section was the exposure site, but for here it is the surface water body, also pertains to this algorithm. Specifically, it was noted that the sediment delivery ratio equation seemed relatively insensitive to changes in distance. In Figure 6-4, this also seems to be the case, as little change in predicted water impacts occurs between the tested values of 50 and 1000 meters. However, if clear impediments such as roads or ditches are between the site and the target area as the distance increases, than it is quite possible that the sediment delivery ratio equation is not appropriate to use when predicting the delivery of contaminated soil to the water body. On the other hand, if a site is near a surface water body, it seems that the origins of the sediment delivery ratio equation - developed from data on construction sites near surface water bodies - are more appropriate.

The key source strength terms tested, the area of contamination, ASC, and the soil loss rate from the site of contamination, SL_s, both have a direct linear impact on the both sediment and surface water concentrations. The other soil loss term, the erosion rate for the watershed, SL_w, also has a direct linear impact. Somewhat less critical in this algorithm is the size of the watershed. The reduction of watershed size by about an order of magnitude increased water concentrations by about a factor of 2, and an increase in size by an order of magnitude reduced impacts by about 70%.

The algorithm seemed fairly insensitive to the remaining five parameters tested. The average watershed concentration, initialized at 0.0 in order to just show the incremental impact from the contaminated site, was increased to 1 ppt. This approximates a background concentration of 2,3,7,8-TCDD and was an order of magnitude lower than the contaminated site

concentration of 1 ppb. It is seen in Figure 6-4 that background soils have a marginal impact on a water body which is impacted from a site of elevated soil concentrations located near the water body. The impact of the organic carbon partition coefficient, Koc, on bottom sediments appears small despite the fact that the Koc range spans two orders of magnitude. This is an indication that it is so high for the dioxin-like compounds, that (at least in the algorithm of this assessment), its assignment is not critical for sediment concentration estimations. The same lack of impact appears to be the case for the organic carbon content of water body sediments, and the level of suspended solids in the water column. The range of enrichment ratios tested, 1 to 5, represents the appropriate high and low value this parameter would take, based on literature studies of this phenemona. As will be discussed in Chapter 7, a site in Connecticut had sediment concentrations in background settings about 2.8 times higher than surface soil concentrations. In this tested range, only a small impact to surface water is noted.

6.3.3.4. Vapor-Phase Transfers and Particle-Phase Depositions to Above Ground Vegetation

Concentrations in above ground vegetation are a function of vapor-phase transfers and particle phase depositions. Vapor and particle reservoirs originate from contaminated soils as volatilization and wind erosion, respectively. Atmospheric dispersion and deposition modeling delivers concentrations and depositions, respectively, from a stack to a site of exposure. The principal difference in the soil and stack emission source categories is in the relative proportions of the contaminant which are in the vapor and particle phases. As discussed below, more contaminant is delivered via particle depositions for the stack emission source category as compared to the soil contamination source category.

Vapor transfers and particle depositions for the soil contamination source category are evaluated in Figures 6-5 and 6-6. The same general trends shown in these figures also occurs in the stack emission source category. Three types of vegetation are modeled for this assessment, including vegetables/fruit, grass, and animal feeds. The latter two are for the terrestrial animal bioconcentration algorithms, the first for human exposure via consumption of unprotected fruits or vegetables.

For vapor-phase impacts shown in Figure 6-5, it would appear that changes to total vegetation concentrations are critically a function of parameters specific to the vapor transfer algorithm. There is between one and two orders of magnitude range of plant concentrations predicted over the range of the vapor phase transfer coefficient, B_{vpa}, tested. This parameter is uncertain as well as very influential in this methodology. There is about a one order of magnitude range for the vegetable/fruit category and a two order of magnitude range for the grass

and feed categories. The reason there is a difference in the influence of B_{vpa} in the vegetative categories has to do with the use of a second and also influential and uncertain parameter, the VG parameter. This parameter was introduced to model the difference between the leaves of the experiment for which B_{vpa} was developed an the bulky vegetation to which the B_{vpa} is applied, the VG parameters (VG_{veg}, VG_{gr}, and VG_{fod}). The need for such a correction factor is justified given the evidence that dioxin-like compounds to do not translocate into vegetation. The grass leaf concentrations in the experiments for which B_{vpa} was derived are likely to be analogous only to the outer layer concentrations in bulky vegetation, not the whole plant (or whole fruit/vegetable) concentrations. This empirical parameter was set to 0.01 for bulky fruits/vegetables, but was set at 1.00 for grass, under the assumption that grass is similar to leaves, and 0.50 for cattle fodder, which is assumed to contain some bulky (grains) and leafy (hay) vegetation. Relatively speaking, therefore, the impact of grass concentrations to vapor phase concentrations are 100 times higher than the impact of vegetable/fruit concentrations to vapor phase concentrations because of this VG parameter. There is a linear impact for grass and feed to changes in VG - halving VG for grass halves the grass concentration, for example. The impact of changes to VG is less for vegetables/fruits, again because its influence is minimized due to its low initial value of 0.01.

A dry weight to fresh weight conversion factor, FDW, is required for estimating above ground concentrations of vegetable/fruits. This is because the algorithms estimate above ground vegetative concentrations on a dry weight basis, and the concentrations need to be diluted since fruit and vegetable consumption are given in this assessment on a fresh weight basis. The impact to concentrations is direct and linear, and since the range of likely FDW is small, the impact is small as well. This parameter is also required for the particle deposition algorithm, but is. left out of Figure 6-6 for clarity. In fact, FDW is applied once vapor phase and particulate phase contributions to vegetable/fruit concentrations are already summed; in other words, it is not tied to either the vapor or particle phase algorithms.

The impact of all the particle phase parameters to overall plant concentrations is less than that of vapor transfers, as seen in a comparison between Figures 6-5 and 6-6. For the parameters including rainfall amount (R), washout factor (W_p), denseness of vegetation (as modeled by yield, Y, and intercept fraction, INT), velocity of particle deposition (V_p), and plant weather dissipation rate, kw, results in Figure 6-6 are for vegetable/fruits and not grass or fodder. Vegetables/fruits are more impacted by particle depositions than grass/fodder, and as seen, there is less than half an order of magnitude impact from the range of values for these parameters tested. As noted above, the impact of depositions on vegetable/fruit concentrations occurs because the correction factor for vegetables, VG_{veg}, is equal to 0.01, which minimizes the vapor-

phase contributions to vegetable concentrations in comparison to the contributions of the vapor phase concentrations for grass and fodder concentrations, which have correction factors of 1.00 (for grass) and 0.50 (for fodder).

This trend is quantified in Table 6-2. Model results on the proportion of above ground plant concentrations that are due to air-to-leaf transfer and particulate deposition were examined for the soil contamination and stack emission source categories for 2,3,7,8-TCDD, and results are summarized in Table 6-2. Results show that vapor phase transfers tend to dominate vegetative concentrations, although particle phase concentrations are important for bulky fruits and vegetables. Results also show that the relative impact of vapors and particles is a function of distance for the stack emission source category. For the central stack emission Scenario, #4, where the site of exposure is 5000 meters from the stack, vapor transfers generally have more of an impact to vegetation as compared to the high end Scenario, #5, where the site of exposure is 500 meters away.

It is possible that the impact of particle depositions is being underestimated, for at least four reasons:

- The wind erosion algorithm estimating air-borne contaminant concentrations for the soil contamination source category only estimates concentrations of PM-10, or inhalable size particulates, those 1 0 μm size diameter and less, while the ISCST3 model considers all size particulates emitted from stacks. Larger size air-borne particulates, while not inhalable, would deposit onto vegetation.
- For the demonstration of the soil contamination source category which involves soil contamination distant from the site of exposure, only the off-site locations provide the source of air-borne particulates. Meanwhile, algorithms are in place estimating exposure site contamination, albeit to thin surface levels. Certainly, the reservoir of air-borne particulates depositing onto vegetation would also include contributions from where the vegetation is located and the surrounding land, not only from the area of soil contamination.
- For the stack emission source category, resuspension of deposited particles and deposition onto plants is not considered. This omission is similar to the omission noted in the bullet above.
- The modeling does not consider the splash effect of rainfall, which would deposit soil onto the lower parts of plants. This would make the most impact for grass and for vegetables near the ground surface such as lettuce.

- For the soil contamination source category, an additional factor is on the way the model does not reapportion volatilized residues onto airborne particles. As was discussed in Chapter 5, the 2,3,7,8-TCDD vapor phase dominates the total air concentration and is about 95% of the total concentration. Residues which volatilize from the soil are assumed to remain in the vapor phase. In contrast, the 2,3,7,8-TCDD vapor phase is 51% of total air concentrations in the stack emission source category, because this is the fraction developed from the equilibrium vapor/particle partitioning algorithm. If dioxins were reapportioned after volatilizing, the vapor/particle partitioning for the soil contamination source category would shift over to the particle phase and the particle phase impacts to vegetation would be increased.

The precise impact of these factors might be investigated more fully in a later assessment with additional models. Tests were run for this sensitivity analysis by increasing the amount of particulate phase contaminants depositing onto vegetation by an order of magnitude to the soil contamination demonstration scenario, without changing the vapor phase contributions. The vapor phase/particulate phase contributions to above ground fruits and vegetables, originally 56%/44% (from Table 6-2), changed to 11%/89% with an order of magnitude increase in particulate phase contributions. Vegetable concentrations increased by a factor of 6. The impact was less for grass and fodder, with concentrations increasing by a factor of 1.7.

The impact of partitioning of airborne dioxins between a vapor and a particle phase was more fully investigated using results from the high end demonstration of the stack emission source, Scenario 5. The results from this analysis are shown in Figure 6-7. For this test, the partitioning of 2,3,7,8-TCDD was altered from the originally assigned values of 51% vapor/ 49% particle. The vegetation examined include above and below ground vegetable concentrations, and above ground grass and cattle feed.

The obvious trend to note from this figure is that the impact of this repartitioning is the opposite for vegetables/fruits, both above and below ground, as compared to grass and cattle feed. For above ground vegetation, this is the result of the use of the empirical correction factor, VG. As discussed above, assignment of the value of 0.01 for vegetable/fruit VG minimizes the impact of vapors on above ground vegetables/fruits. Therefore, when particle phase depositions are increased, as in the right-hand side of Figure 6-7, vegetable/fruit concentrations increase, and likewise, decreases in particle phase depositions decrease the concentrations. The reason that the trend is the same for below ground vegetables is that changes in particle depositions lead to concurrent changes in soil concentrations. Since the leafy vegetation of grass and cattle feed are

dominated by vapor phase transfers, reductions and increases in the vapor phase concentration lead to reductions and increases in the concentrations of these vegetation. Even at the lower vapor fraction, 20% in the right-hand side of Figure 6-7, vapor impacts still dominate the predicted concentrations for these vegetation.

6.3.3.5. *Estimation of Below Ground Vegetation Concentrations*

One important factor to note up front about below ground vegetable concentrations as compared to above ground vegetable concentrations (no underground fruits are assumed in this assessment) is that below ground vegetable concentrations of 2,3,7,8-TCDD are about four orders of magnitude higher than above ground vegetable concentrations for the soil contamination demonstration scenario. For the stack emission scenario, above and below ground concentrations of 2,3,7,8-TCDD are comparable. Also, the below ground vegetable ingestion rate of 1.16 g/kg-day is quite comparable to the above ground vegetable ingestion rate of 1.52 g/kg-day. Given the difference in concentration estimations in the soil contamination demonstration, below ground vegetables explain over 99% of the total exposure via ingestion of impacted vegetables in that demonstration. Again, they are about half the total vegetable exposure for the stack emission source category. Sensitivity of underground vegetable concentrations to parameter changes for the soil contamination source category becomes important from this perspective.

The reason for this dichotomy in performance between the soil contamination and stack emission source categories has been examined in other parts of this document, including the examination of vegetable results in Chapter 5, and the soil-to-air model testing in Chapter 7. To review these discussions, it was found that when soil is assumed to be source for air concentrations, as in the soil contamination source category, then a ratio of air to soil concentrations will be very low compared to an air to soil concentration ratio when the air is assumed to be source for soil concentrations, as in the stack emission source category. This air to soil ratio does not have any important meaning except in the context of this discussion. Two possible explanations were offered for this trend: 1) the models predicting volatilization and dispersion were underpredicting air concentrations, and/or 2) the soil to air models are not unpredicting air concentrations - the tendency for dioxins to escape soil (i.e., the fugacity of dioxins in soil to air transfers) is very low compared to the tendency for dioxins to move towards soil.

This question now is whether this dichotomy in performance is reasonable. A model exercise in Chapter 7 evaluated the air-to-soil algorithm and the soil-to-air algorithm using air

and soil data from the same rural site. It was shown that the air to soil model very reasonably was able to duplicate the soil concentrations, but that the predictions of air concentrations above the soil were much lower than observed, by about an order of magnitude. Again, this could be due to the fact that the models may be underpredicting air concentrations above them. Also, it could be due to the fact that air concentrations measured in the rural setting are due to long range transport from distant sources and not the soil concentrations. Given that the model appeared to perform well in air-to-soil modeling, it is expected that the observation that above, and below ground vegetable concentrations in the stack emission are comparable, is supportable. The same confidence cannot immediately be placed on the difference in modeling between above and below ground vegetables for the soil contamination source category.

In any case, the impacts of parameter changes for the algorithm predicting concentrations in underground vegetables are shown in Figure 6-8. These results were generated by the soil contamination source category, although analogous results would result for the stack emission, source category. All results are essentially linear, which is not surprising since below ground vegetable concentrations are a linear function of all the parameters tested: $C_{veg} = (C_{soil} * RCF * VG_{bg}) / (Koc * OC_{sl})$. The two orders of magnitude range for the root concentration factor, RCF, translates to a two order of magnitude range of concentration estimation. The same is true for the empirical correction factor applied to below ground vegetables, VG_{bg} , and the organic carbon partition coefficient, Koc. A smaller impact is noted for the organic carbon fraction of soil, OC_{sl}. Koc and OC_{sl} are required for this algorithm because vegetable concentrations are a function of soluble phase concentrations, not soil concentrations. Increasing Koc and/or increasing OC_{sl} results in decreasing the water concentrations, explaining why the high values for these parameters reduce vegetable concentrations. The smallest range in Figure 6-8 is the depth of tillage parameter, which directly influences the soil concentration, C_{soil}. Reducing the depth of tillage by 2 increases the soil concentration by about this same amount, as seen in Figure 6-8.

One final note is that the dry to fresh weight ratio, FDW, is not on this figure, while it does appear on Figure 6-7. This is because the RCF was developed on a fresh weight basis already, so no conversion to a fresh weight is required.

6.3.3.6. *Beef Fat Concentration Estimation in the Soil Contamination and Stack Emission Source Categories*

The impacts of parameter changes to beef fat concentration estimation for the soil contamination and stack emission source categories are shown in Figures 6-9 and 6-1 0. These sensitivity runs were both run on 2,3,7,8-TCDD, the only dioxin congener demonstrated for the

soil source category in Chapter 5, but 1 of the 17 dioxin-like congeners evaluated in the demonstration of the stack emission source in Chapter 5.

The overriding difference in the way the two source categories predict beef fat concentrations is that, in the soil contamination source category, the soil-to-cattle pathway dominates the prediction of beef fat concentration, whereas in the stack emission source category, the air-to-plant-to-cattle dominates. In Figure 6-9 showing results for the soil contamination source, there is essentially a linear relationship between changes in soil concentration and the beef impact, whereas in Figure 6-10 showing the stack emission relationships, a nearly linear impact is noted instead for changes in the grass and fodder concentrations. This overall trend is principally due to trends that have previously been discussed - that is, when soil is the source of contamination, the impact to air and above ground vegetation is proportionally smaller as compared to when air is the source of contamination.

This trend is further elucidated in the impact of two other soil related tests - one on the soil bioavailability factor, Bs, and one on the proportion of soil ingested in the cattle diet. In both cases, changes to these parameters have a significant impact in the soil source category but a minor impact in the stack emission category. Actually, the importance of soil exposure in the soil source category and the importance of vegetation in the stack ,emission category influences most of the other results on Figures 6-9 and 6-10. In the "low" exposure conditions, the reduction in soil intake from 4% of the diet to 1% of the diet influenced the results for the soil source category, but the influence was minor for the stack emission category because intake of contaminated grass was essentially unchanged and the "lower" exposure was mainly reflected in a reduction of intake of contaminated cattle feed. In the "extent of pasturing" test, the increase in soil intake from 4% to 8% resulted in a significant impact for the "high" condition in the soil source category, but less of an impact in the stack emission category, because again the vegetative intakes were not significantly changed for this test.

In addition to the sensitivity analysis shown in Figures 6-10 and 6-1 1, this trend can be described simply by displaying the following results from the demonstration of the soil source and stack emission source categories from Chapter 5:

	Percent impact due to ingestion of:		
Description	Soil	Grass	Feed
Soil contamination, beef	98	< 1	> 1
Soil contamination, milk	97	< 1	> 2
Stack emission, beef	11	61	28
Stack emission, milk	7	14	79

As seen here, soil only accounts for 11 and 7% of beef and milk concentration impacts from stack emissions in the example scenario, but overwhelms the soil source category.

The only parameter which was equally influential for both categories, was the bioconcentration factor, BCF. To estimate beef fat concentrations, the concentrations in the soil and vegetation of the cattle diet are multiplied by this factor, so logically, its influence is separate from the modeling of concentrations in soil or vegetation. Also, the response to changes in this parameter are linear.

As seen in the above results, the relative impacts of soil and vegetation to milk fat is similar to that of beef fat in the two source categories. The baseline scenario for a dairy cow's exposure has a significantly greater amount in cattle feed, 90%, as compared to the beef cattle, 45%. That is why the percent of impact for milk is more driven by feed than grass as compared to beef in the stack omission source.

The free range chicken scenario is driven by soil in both the stack emission and the soil contamination scenario. The following results display this trend:

	Percent impact due to ingestion of:		
Description	Soil	Grass	Feed
Soil contamination, chicken and eggs	> 99.9	< 0. 1	0
Stack emission, chicken and eggs	79	21	0

The reason for this trend is that the free range chicken exposure scenario has the chicken diet comprised of 10% soil, 5% incidental leafy vegetation while scavenging, and 85% residue free chicken feed. The justification for assuming that 85% of the chicken diet was residue free came

from Stephens, et al. (1995), who did not detect dioxins in the analysis of a standard chicken feed. They also developed the chicken/egg bioconcentration factors used in this assessment and assumed a 10% soil percent in the diet of the free range chicken. Further detail on the use of the Stephens, et al. (1995) data can be found in Chapter 4. In any case, it is expected that the chicken and egg models will respond to parameter changes in the same manner as the beef fat sensitivities as displayed in Figure 6-9, showing sensitivities in the soil contamination source category, rather than Figure 6-10, which shows the stack emission source sensitivities.

6.3.3.7. *Impact of Distance from the Stack Emission Source on Concentrations in Soil, Vegetables, and Beef Fat*

For this test, the high end scenario for the stack emission demonstration, Scenario 5, was used as the baseline. The exposure site was located 500 meters from the stack in the downwind direction. Two other locations, 200 and 5000 meters, were, evaluated, and predictions for soil, below and above ground vegetables, and beef fat were examined. The results of this examination are shown in Figure 6-11.

In the high end stack emission demonstration scenario, the farm was assumed to be 500 meters from the stack. Nearer to the stack at 200 meters, ambient air concentrations and dry deposition amounts were lower, but wet deposition was at its maximum. One effect of this was that vegetable concentrations increased. Below ground vegetables increased by about a factor of about 4, due to the same increase in soil concentration as a result of much higher wet deposition. Above ground vegetation increased by about 50%. As was described earlier, particle depositions dominated above ground vegetable/fruit concentrations. Therefore, an increase in overall particle depositions due to an increase in wet depositions led to increased above ground vegetable/fruit concentrations. However, the trend was not the same for beef fat. As discussed in earlier sections, vapor contributions dominated grass and feed concentrations for the stack emission source category. Therefore, a drop in ambient air vapor phase concentrations at 200 meters as compared to 500 meters dominated the result, and the net impact was to reduce beef fat concentrations. From Figure 6-11, it is seen that beef fat concentrations were reduced by about 30% when using ISCST3 output from 200 m instead of 500 m. Further from the stack at 5000 meters, all biota concentrations were lower. Vapor phase air concentrations were roughly halved as compared to what they were at 500 m, and dry and wet deposition were lower by 60 and 80% respectively compared to levels at 500 m. This led to substantial reductions in vegetable concentrations. Beef fat concentrations were also lower at 5000 meters as compared to 200 m

and the baseline distance of 500 m. Overall, beef fat concentrations were about 70% less at 5000 meters as compared to 500 m.

Trends for milk fat concentration are not exactly the same, but very similar to those of beef fat. Trends for chicken and egg are similar to that of soil and below ground vegetables, because these tissues are modeled primarily as a function of the free-range chicken exposure to soil - this was discussed in the previous section to this one.

6.3.3.8. *Water and Fish Concentrations Resulting from Effluent Discharges*

The impacts of parameter changes for algorithms estimating water and fish concentrations are shown in Figure 6-12. First, it should be noted that fish and water impacts are included in the same graph because the impacts to both concentrations are exactly the same with the noted changes in parameters, with one exception. This exception is the partition coefficient, Koc. Increases in Koc result in higher suspended sediment concentrations, which lead to higher fish tissue concentration estimations, but lower water concentration estimations. Increasing Koc by an order of magnitude actually decreases water concentrations to 14% of its baseline value, or 0.14 on the y-axis of Figure 6-12. Decreasing Koc by an order of magnitude increases water concentrations by a factor of 2.4. Roughly, the location of the high and low Koc points on Figure 6-12 should be reversed for water concentration impacts. Also, the biota to suspended solids accumulation factor, BSSAF, and the fish lipid content, f_{lipid}, are specific to fish tissue estimations.

Clearly, both concentrations are mostly impacted by the loading rate - the impact is linear and direct. Of all the parameters describing the effluent stream and the receiving water body, only the two order of magnitude change in receiving water body flow rate seems to have about an order of magnitude range of predictions. The effluent flow rate is ultimately low in comparison to the receiving water body, so its impact is limited. The range of organic carbon contents of the effluent and of the suspended solids in the receiving water are reasonably assigned and appear to have a small impact.

Higher suspended solids content in the receiving water body can result in lower fish and water concentrations. This might be termed a "solids dilution effect". Few studies are available in the literature which support this result, but two studies were found which are consistent with a solids dilution effect. One “simulated field experiment" conducted by Isensee and Jones (1975) maintained a constant water concentration of 239 ppb, but reported a decrease in 2,3,7,8-TCDD concentrations in both mosquite fish (2200 ppb to 90 ppb) and catfish (720 to 90 ppb) as the amount of sediment increased from 20 to 440 g. Sherman (1992), in a review of this and other

simulated field experiments and laboratory flow through experiments, points out that a bioconcentration factor for these simulated field experiments would decrease as the sediment increases. He speculates that, in comparing water flow through experiments with field simulated data, the bioconcentration factors tend to be less in field simulated experiments because 2,3,7,8-TCDD may sorb to sediments and be less bioavailable. A second study supporting a solids dilution effect was conducted by Larsson, et al. (1992). They studied uptake of PCBs and p,p'-DDE in 341 northern pike in 61 lakes in southern Scandinavia. They found that the levels of these persistent pollutants in the fish decreased as productivity increased. Productivity was measured by total phosphorus, chlorophyll a, and lake water transparency, which was mainly influenced by phytoplankton biomass. Their hypothesis was that the levels decreased because humus adsorbs persistent pollutants, rendering them less available for uptake in fish.

The two order of magnitude range in Koc translates to about a one order of magnitude range in estimated fish and water concentration estimations. Fish tissue concentrations are linearly and directly related to the BSSAF and f_{lipid}. About an order of magnitude of concentration estimation is noted with about the same order of magnitude in likely values.

6.3.3.9. *Water and Fish Concentrations Resulting from Stack Emissions*

Results of sensitivity analysis of algorithms estimating surface water and fish concentrations resulting from stack emissions are shown in Figure 6-13. First, it is noted that the impact to both these media is the same with impacts to all parameters. The impact with changes in the deposition of particles onto the water body, $RDEP_p$, and with the fraction of deposited particles remaining in suspension, f_{sd}, is negligible. The assigned values to these parameters for the demonstration are, therefore, sufficient for any purpose. It is importantly noted the ISCST3 model or other atmospheric transport models do not need to estimate the concentration of contaminants on emitted particles - all that is required are mass emissions of contaminants (in g/sec units) and the delineation of size fractions of particles emitted. The ISCST3 model does not require a particle emission rate. An assumption of a greater deposition of particles directly into surface waters might translate back to an assumption of particle emissions. The $RDEP_p$ is only required to maintain a mass balance of solids entering the surface water body, and as it turns out, particles entering surface waters by this route are only a miniscule part of the total solids entering the body. There are no impacts to water or fish concentration estimations with reasonable values for this parameter. The same appears true for f_{sd}, which determines the extent to which directly depositing contaminants remain in suspension. The assigned value of 1.00 (meaning that all directly depositing contaminants remain in suspension), based on the argument

that particles emitted from stack are likely to be lighter than eroding soil particles, appears sufficient for general purposes.

Water body impacts are essentially linearly related to the average watershed depth of mixing. The value assigned for the demonstration scenario was 0.1 m, which is midway between the value assumed for non-tilled conditions, 0.02 m, and tilled conditions, 0.20. The value of 0.10 m suggests that half the watershed is tilled. The linear relationship underscores the importance of this uncertain parameter, and also suggests that erosion drives water body impacts rather than direct deposition. This trend is also apparent for the tests on depositions to the watershed, the RDEPwat, input, versus depositions directly onto the surface of the water body, the $RDEP_{sw}$ input. The impact to changes in $RDEP_{wat}$ are roughly linear - an increase in watershed depositions (but not depositions directly onto the water body) by about a factor of 13 leads to an increase in the water body impacts by a factor of 11 . There was less but still a noteworthy change when depositions directly onto the water body increased or decreased - a 13-f old increase led to a 2.5 fold increase in water body impacts.

Changing the size of the watershed did not have much of an impact to water body impacts. In changing the size, the four parameters as noted on Figure 6-13 were changed simultaneously. Intuitively, increasing the size of watershed should increase water body impacts, since more land impacted by depositions would be draining into the water body. However, two factors counter this intuition: 1) the water body volume also changes concurrently, tending to dilute any additional soil inputs, and 2) soil inputs are not proportionally increased because the sediment delivery ratio decreases as the size of the watershed increases - from 0.06 in the baseline setting to 0.01 in the test for the large watershed. In fact, water body impacts dropped slightly for the large watershed and increased only very slightly for the smaller watershed. This increase was due also to the change in the sediment delivery ratio, which increased from 0.06 to 0.25.

6.3.4. Key Trends from the Sensitivity Analysis Testing

These are as follows:

1) Source terms are the most critical for exposure media impacts. Source terms include soil concentrations, stack emissions, and effluent discharges. In nearly all cases, the impact to exposure media is linear with changes to source terms. Proximity to the source term can be important as well, as demonstrated with differences in distance from the stack emission source.

2) Chemical-specific parameters, particularly the bioconcentration/biotransfer parameters, are the second most critical model inputs. Some of these have lesser impacts,

such as the organic carbon partition coefficient, Koc, for surface water impacts. Generally, at least an order of magnitude in range in possible media concentrations is noted with the range of chemical-specific parameter ranges tested. The impact of changes to bioconcentration/biotransfer parameters is mostly linear. This is because these transfer factors estimate media concentrations as a linear transfer from one media to another - fish lipid concentrations are a linear function of the concentration of contaminants in sediments. These transfer parameters are also identified as uncertain parameters. Tested ranges sometimes spanned over an order of magnitude for 2,3,7,8-TCDD.

3) All other parameters had less of an impact as compared to source strength and chemical specific parameters; nearly all impacts were within an order of magnitude for the range of tested values. Part of the reason for this trend is that there is a reasonably narrow range for many of the parameters in this range - soil properties, wind speeds, vegetation yields, and others. It is important, nonetheless, to carefully consider all the model parameters. While impacts were generally within an order of magnitude of the values selected for the demonstration scenarios, there was often an order of magnitude or more difference between plausible high and low values for individual parameters.

4) A principle trend of note concerns the air to soil algorithm for the stack emission source category compared to the soil to air algorithm of the soil source category. Several tests in this chapter demonstrated the difference in model performance when soil is the source of contamination compared to when air is the source of contamination. The relationship between air and soil concentrations is distinctly different for the soil contamination source category as compared to the stack emission source category. It is found that the "air/soil" concentration ratio is much smaller in the soil source category as compared to that same ratio in the stack emission source category. This air to soil ratio does not have any important meaning except in the context of this discussion. An air-to-soil model validation exercise in Chapter 7 showed that the deposition modeling appeared to very reasonably predict soil concentrations. This exercise relied on concurrent measurements of air concentrations and soil concentrations in an actual rural background setting. The air concentrations became the independent variable used to model soil concentrations. The reasonable validation was the result of predicted soil concentrations matching observed soil concentrations. However, when the same exercise was turned around - i.e., the observed soil concentration was used to predict air concentration, it was found that the predicted air concentration was much lower than the observed air concentration. Two possible explanations were offered for this trend: 1) the models predicting volatilization and dispersion were underpredicting air concentrations, and/or 2) the soil to air models are not underpredicting

air concentrations - air concentrations over a soil are perhaps more a function of atmospheric transport from distant sources than volatilization or wind erosion from soils. In any case, this dichotomy in air/soil model performance had several cascading impacts as were found in this chapter as well as Chapter 5 demonstrating the methodologies. Results include, for example: 1) soil concentrations drive terrestrial animal food concentrations for the soil source category, since vegetation concentrations are so low as not to be a large influence in comparison to soil. On the other hand, the vegetation concentrations drive the terrestrial animal food concentrations in the stack emission source category - the air-to-plant pathway is most important here, and 2) below ground vegetable concentrations are four orders of magnitude higher than above ground vegetables for the soil contamination source category while they are roughly comparable for the stack emission source category.

6.4. MASS BALANCE CONSIDERATIONS

As has been discussed in this document more than once is the characterization of this methodology as a screening level methodology. Steady state, equilibrium partitioning, and assumptions of nondegradation of source strengths are key assumptions which lead to this qualification. Stacks are assumed to emit a constant amount of contaminant over a duration of exposure for the stack emission source category. Effluent discharges are assumed to continue unabated over a duration of exposure. These are both reasonable assumptions for evaluating the long-term impacts of these sources where no change in practices occur. Any violation of mass balance principals will, therefore, not be examined for these sources. The same assumption of unabated and c6nstant releases might be questioned, however, for the soil contamination source category. Soil concentrations are assumed to remain constant, despite mechanisms which would dissipate concentrations over time. Volatilization and transport off-site, and wind erosion and transport off-site, are two mechanisms which dissipate residues into the air and deplete the source strength. Soil erosion off the site to a nearby exposure site and to nearby water bodies also is a mechanism of release. A key dissipation mechanism is soil degradation. There is evidence that photolysis is a mechanism of degradation of dioxin-like compounds, as discussed in Chapter 2 of Volume 11 of this assessment. However, this would only apply to those residues directly on the soil surface and, as such, it may be reasonable to make an assumption of nondegradation if a concurrent assumption is that residues exist below the soil surface. In any case, releases for a bounded area of soil contamination including volatilization, wind erosion, and soil erosion, which are estimated for purposes of estimating off-site impacts, are not also used to

estimate dissipation of the reservoir of contaminant in the soil. Said another way, the amount lost via these pathways is not a function of a soil reservoir which decreases over time.

The purpose of this section is to examine this assumption for the case of a bounded area of hig.h soil concentration. The demonstration of the soil contamination source category will be the focus of discussions below. First, an estimate of the "reservoir" of 2,3,7,8-TCDD that is implied with the default parameters will be made. Then, an estimate of the rate at which this reservoir dissipates using the solution algorithms for dissipation: volatilization and wind erosion flux from soils, and soil erosion, will be made. Other routes of dissipation that will be examined are the soil ingestion by cattle and children, the loss via dermal contact, and the removal via harvest of below ground vegetation. These will be shown to be minuscule in comparison to air and soil erosion. The loss of soluble residues via surface runoff or leaching will be evaluated. Surface water bodies and above ground vegetation are sinks for dioxin-like compounds and therefore are not mechanisms of soil dissipation. If it can be shown, for example, that it takes several hundred years to dissipate a given reservoir, then it may be fair to conclude that exposures assuming non-dissipation over a 20 or even a 70 year exposure period are not significant overestimates. On the other hand, complete dissipation within a time period less than or even near to the period of exposure would mean that exposures and risks are being overestimated.

As will be shown, the rates of reservoir dissipation are very important considerations for soil contamination. Users of this-methodology should consider dissipation of available residues and the discussions below when determining the duration of exposure for site-specific assessments. A recommended rule of thumb for users of this methodology is to evaluate the time to dissipation using the methodology below, and if it is less than or even near the assumed period of exposure (2 years to dissipate versus 20 years of assumed exposure, e.g.), then it may be appropriate to assign a duration of exposure equal or less than the calculated time to residue dissipation.

One of the key parameters in determining how rapidly residues will dissipate is one which is not required for this methodology. This is the depth of contamination. This depth, plus the initial concentration and the areal extent of contamination, describe the full extent of the source strength. The exercises below have assumed a shallow depth of 0.15 meters, or 6 inches, in soil. The impact of this assumption is demonstrated below. Also, the exercises below are specific to 2,3,7,8-TCDD.

The demonstration of the off-site soil contamination source category. were as follows: 40,000 m2 soil contaminated with an initial concentration of 1 ug/kg (ppb). It is assumed that the contamination extends to 0. 1 5 meters (6 inches).

Step 1. Estimate the amount bound to soil:

(total volume of contaminated site = 40,000 m^2 * 10,000 cm^2/m^2 * 15 cm =		6×10^9 cm^3
(soil bulk density)	x	1.5 gm/cm^3
(unitless 2,3,7,8-TCDD soil con., g/g)	x	$(1/10^9)$
= grams 2,3,7,8-TCDD in soil		9 gms

Note: at a soil concentration of 1 µg/kg, there will also be some 2,3,7,8-TCDD in soil pore water. This amount is insignificant in comparison to the amount bound to soil, and will be neglected.

Step 2. Now estimate the amounts lost by various routes of dissipation

- Volatilization -Volatilization flux is a function of exposure duration, with less average flux calculated over longer durations - this is, in fact, the only model algorithm which accounts for reservoir depletion over time. The durations of exposure for the high end scenarios was 20 years. The release rate via volatilization is given as the term FLUX and is shown in Equation (4-22) in Chapter 4. Plugging in baseline parameter values for 2,3,7,8-TCDD and a duration of 20 years results in a calculated flux of 1.06×10^{-18} g/cm^2-sec. Over a year and over the 40,000 m^2 contaminated area, this translates to an annual dissipation rate of 0.013 g/yr of 2,3,7,8-TCDD.

- Wind erosion: Unlike the volatilization algorithm, the flux due to wind erosion is not dependent on the duration of exposure. The wind erosion algorithm is described in Section 4.3.3 in Chapter 4. Plugging in baseline parameter values results in a flux of 2,3,7,8-TCDD of 5.74×10^{-20} g/cm^2-sec, or an annual flux over the 40,000 m^2 contaminated area of 0.0007 g/yr.

- Soil erosion: The annual erosion rate off the contaminated site was 21515 kg/hayr. This rate was assumed to erode towards the exposure site as well as towards the impacted surface water body. However, it would not be appropriate to double that quantity since it is used in two

different algorithms - the exposure site could be in the direction of the water body, for example. Or, if applied to a specific site, one could ascertain that the exposure site is upgradient from the contaminated site, and so on. In any case, 21515 kg/ha-yr can be translated to a cm/yr of soil erosion as follows:

volume per 1-cm hectare slice = 10,000 m^2/ha * 10,000 cm^2/m^2 * 1 cm =
$1x10^8$ cm^3
X 0.015 kg/cm^3 (soil bulk density)
kilograms per 1-cm hectare slice = 150,000 kg/cm-hectare

Therefore, 21515 kg/ha-yr translates to a loss of soil equal to 0.14 cm/yr. Given that 9 g 2,3,7,8-TCDD are estimated to occur in 15 cm, the annual loss of 2,3,7,8-TCDD is 0.084 g/yr.

- Runoff and Leaching: Transport via water is not considered in this methodology since the dioxin-like compounds are so tightly sorbed that these are expected io be negligible. An estimate of loss via water will nonetheless be made for this exercise. Surface water body volume was estimated assuming a runoff rate of 15 in/yr, which was defined as all surface water contributions (surface runoff, interflow, and ground water recharge). This is a reasonable estimate for water-borne losses for this exercise. The annual amount of 2,3,7,8-TCDD lost in this water can be estimated using the soil partition coefficient, Kd_s, relationship, which is C_s/C_w. Kd_s is equal to 39,800 for 2,3,7,8-TCDD (organic carbon partition coefficient, Koc of $3.98x10^6$ * soil organic carbon, OC_{sl} of 0.01), so the concentration in water, C_w, given a soil concentration, C_s, of 1 µg/kg, is $2.5x10^{-5}$ µg/L, or $2.5xl0^{-11}$ g/L. Translated to a 40,000 m^2 area, 15 in/yr equals $1.524xl0^7$ L, so the total annual loss in water equals 0.00038 g/yr 2,3,7,8-TCDD.

Except for soil degradation, these are the dissipation routes that would be considered for a site of soil contamination that is not used for any purpose - residence, agriculture, and so on. For the sake of completeness, other routes that will be looked at now include soil ingestion, soil dermal contact, and harvesting of underground vegetation.

- Soil Ingestion: Soil ingestion by children in the high end scenario is 600 mg/day, or 0.22 kg/yr. Soil ingestion by cattle will also be considered. First, an assumption of how many cattle would be feeding on a 40,000 m^2 area should be made. A daily cattle dry matter ingestion rate is 19 kg/day. For beef cattle that are assumed to principally graze, for 90% of their dry matter intake, the daily ingestion of grass would be 17.1 kg/day, and their daily intake of soil

while grazing, 8% of total dry matter intake, is 1.52 kg/day. With this daily ingestion of grass, their annual need for grass would be 6200+ kg/yr. The yield of grass assumed for other purposes in this assessment was 0.15 kg/m^2-yr dry weight, or 6000 kg/40,000 m^2-yr. Therefore, it appears that one grazing cow requires the 40,000 m^2 to himself (as a rough approximation). The annual intake of soil by this cow equals 555 kg/yr, which as expected, is much higher than child soil ingestion. The annual removal of 2,3,7,8-TCDD by cattle soil ingestion is 555 µg/yr, or 0.0006 g/yr.

- Dermal Contact: The dissipation of 2,3,7,8-TCDD residues via dermal contact is estimated as, EV*CA*CR*C_s, where EV = event frequency in terms of number of dermal contact events per year, which equals 365 in the high end scenario, CA = contact area, which ranges from 1000-10,000 cm^2, CR = contact rate, which ranges from 0.005-0.1 mg/cm^2-event, and Cs = 2,3,7,8-TCDD concentration, which is 1 µg/kg, or in more convenient units, 10^{-12} g/mg. Using the higher values, the annual loss via dermal contact is negligible at $3.7xl0^{-7}$ g/yr.

- Underground Vegetation Harvests: The yield of vegetables required for other algorithms of this assessment, is 7.8 kg/m^2 fresh weight. The vegetable concentration/soil concentration ratio for tilled soils is about 0.033 (from results of the demonstration scenario). Therefore, for a 1 µg/kg soil concentration, the fresh weight vegetable concentration would be 0.033 µg/kg fresh weight. Therefore, the removal per m^2 is 0.26 µg/m^2, and the removal over 40,000 m^2 in g/yr is 0.01 g/yr if all the 40,000 m^2 were devoted to underground vegetables.

This exercise has shown that the principal mechanism of removal is soil erosion at 0.084 g/yr 2,3,7,8-TCDD, with volatilization explaining 0.013 g/yr removal. The sum of these two routes is 0.097 g/yr, and the sum of all the other routes examined briefly above is 0.01 g/yr, leading to a round total estimate of 0.11 g/yr. With an initial reservoir of 9 gr, it would take 82 years to dissipate the available reservoir, not including degradation and assuming that surface concentrations remain constant. The limited field data that is available on the loss of dioxins from surface soils suggested anywhere from 10 to 100 years for surface and subsurface residues. These losses would include degradation and transport. This assessment assumes a 25-year half-life for residues arriving at exposure sites from distant sources of contamination such as soils or stack emissions. As a rough estimate, half of the 9 gram reservoir would be dissipated at 25 years; 4.5 grams loss per 25 years translates to 0.18 g/yr lost. The algorithms of this assessment already lead to 0.11 g/yr lost, and therefore the observation that it would take about 80 years to

dissipate the reservoir appears sound. In other words, this simple exercise suggests that transport from a site, rather than degradation, could dominate the dissipation rates of 10 to 100 years that have been observed in the field.

This was not a definitive exercise, by any means, but it does lend some confidence that a principal of mass balance may not have been violated for the soil source categories, and for the assumption of 30 years exposure duration. As this section began, the algorithms of this assessment are characterized as screening level methodologies. Users of this methodology should be cognizant, nonetheless, of the possibility of depleting a reservoir of soil contamination prior to an assumed duration of exposure.

Notes:

[1] "Selected" is the value chosen for the demonstration scenarios. The "Low" and "High" values were selected for the sensitivity analysis.

[2] "Ratings" are qualitative judgements pertaining to the use of the selected values for use in other assessments - see text for more detail.

[3] "----" means that low and high values were not selected because these parameters were not tested in the sensitivity analysis exercises. Trends with these parameters were demonstrated with related parameters.

Table 6-2. Contribution of above ground vegetation concentrations of 2,3,7,8-TCDD from air-to-leaf transfers and particulate depositions.[1]

Description[2]	Air-to-leaf vapor transfers	Particle depositions
Scenario 3: Soil contamination		
vegetables/fruit	56	44
grass	96	4
feed	97	3
Scenario 4: Stack emissions, central		
vegetables/fruit	35	65
grass	91	9
feed	92	8
Scenario 5: Stack emissions, high		
vegetables/fruit	20	80
grass	82	18
feed	87	13

[1] Results are in percent of total contribution.

[2] Scenario 3 demonstrated the soil contamination source category, where soil at a contaminated site 150meters away was initialized at 1 μg/kg (ppb) 2,3,7,8-TCDD; Scenarios 4 and 5 demonstrated the stack emission source category - in Scenario 4, the exposure site was 5000 meters from the emitting stack, and in Scenario 5, the exposure site was 500 meters from the stack.

7. MODEL COMPARISONS AND MODEL VALIDATIONS

7.1. INTRODUCTION

This chapter is comprised of two principle sets of exercises aimed at lending credibility to the models selected for use in this site-specific methodology. One set compares alternate approaches to modeling the fate and transport of dioxins, which users can consider in place of the models selected. The comparisons involve generating results with both sets of models, and then seeing how the results compare. Assuming the models selected in this document and the alternates have some inherent credibility, the model results should compare favorably. In most cases, they do compare well, but there are a few where model comparisons are not satisfactory. If the two sets of models compare favorably, one would expect that this lends credibility to both sets of models, and hopefully some confidence in the use of the models selected for this document.

The fate, transport, and transfer models presented in this document can also attain a measure of credibility if it can be shown that estimations of environmental and exposure media concentrations are consistent with those found in the literature. Some of those comparisons can use the exposure media concentrations generated in the demonstration scenarios because the source strength terms of the demonstrations were crafted to be meaningful. Specifically, the background scenario was demonstrated with both air concentrations and soil concentrations that are from an actual rural background setting that is justified as being generally typical for rural settings. The soil contamination source category was demonstrated with a bounded area of high soil concentrations of 1 ppb. This was also supported by literature showing this that sites of high soil contamination contained dioxin-like compounds in the ppb range. Other comparisons are more site-specific: for a specific site, the source strength is known and input into the model, and the model predictions of environmental media concentrations are compared with site-specific measurements of these concentrations.

Tests of this latter case can be termed “validation” exercises. In this document, the word “validation” refers to an exercise in which the following holds true:

1. An impacted media concentration is known. A concentration of a contaminant in a media that can be predicted by the fate models, such as a concentration in soil, vegetation, water, sediment, biota, or ambient air, is known through a site-specific monitoring program. Model predictions of these concentrations have often been termed the “dependent” model results in a validation exercise.

2. The source causing this impact is known. The source term information has often been called the "independent" model input in a validation exercise. For example, if the concentration of a contaminant in ambient air represents the known dependent quantity, than the independent, or source, term could be the emissions from one or more tall stacks nearby. Specifically, source term information would translate to the level of emissions (in units of mass/time such as g/sec) of the particular contaminant from the identified stacks. The model validation exercise would take these known emissions, put them into an air dispersion model along with other parameters (i.e., stack heights, exit velocities, site-specific meteorological data, etc.), and predict ambient air concentrations. In other model validation exercises, however, the source is likely not going to be the incinerator emissions. For example, if underground vegetables were the impacted media, than the independent source term could be the concentration in the soil in which the vegetables were growing. One could also start with ambient air concentrations in a model validation exercise involving underground vegetables. In this case, the air concentrations would be used to predict the soil concentrations, and these soil concentrations would be used to predict the vegetable concentrations. In any case, the source term needs to be known and the model user needs to be reasonably certain, or at the very least, the model user needs to assume, that the source directly impacts the effected media.

3. All other model parameters are assigned values using the best available information. Site-specific information is the most appropriate to use, if it is available. Chemical-specific parameters, such as the bioconcentration/biotransfer parameters, can either rely on site-specific information or are inherent properties of the chemical. An example of the former are the soil (or sediment)/water partition coefficients: Kd, Kdsed, and Kdssed. These parameters are calculated as the product of the organic carbon partition, Koc, which is an inherent chemical property, and the organic carbon content of the sorbing media (soil, sediment, or suspended sediment), which is site-specific. Examples of inherent properties are the bioconcentration parameters which are used to predict, for example, biota concentrations (vegetation, animal fat) as a function of the concentration in the contacting media (soil, vegetation).

4. Model predictions of the impacted media are compared with observations. Once all the parameters are assigned values, the model is run and model predictions of the dependent media concentration are compared to the real world observations of this concentration. This is the final step in a model validation exercise.

Model validation needs to be distinguished from model "calibration". Calibration exercises require real world measurements of independent source terms and dependent media impacts, as do validation exercises. What distinguishes the two exercises is that a calibration exercise is conducted in order to determine values for one or more key model input parameters by "forcing" the model to duplicate the observed data by adjusting the value of this key input parameter until this duplication is reached. As described in step 3 above, all model parameters are assigned values in a validation exercise; none are adjusted in order for model predictions to fit the observed data. An example of a model calibration exercise is the calibration of the air-to-leaf transfer factor for the vapor phase, B_{vpa}. The exercise is described in detail in Chapter 4. Briefly, air concentrations of these compounds in experimental conditions were known, as were the final concentrations in grass harvested after three weeks of growth. All other model parameters necessary for the prediction of the concentration of the dioxins and furans in the grass, including the physical parameters (mass of grass harvested, fresh to dry weight conversion, etc.), vapor/particle partitioning in the air, and particle deposition algorithm parameters, were assigned values based on site-specific measurements or the literature. The B_{vpa} was then adjusted until the model predictions of grass concentrations matched the observed grass concentrations.

Finally, it should be understood that model testing is an ongoing process. The model comparisons and validations described in this chapter are, by no means, expected to establish model validity beyond any doubt. Users of this methodology are encouraged to subject the models to any number of tests, validation or otherwise, as they use the models described in this document to conduct site-specific assessments for dioxin-like compounds

7.2. MODEL COMPARISON EXERCISES

7.2.1. Evaluation of Alternative Air-to-Leaf Modeling Approaches

The first section below describes the field data that was used in this model testing exercise. The second section describes the two alternative empirical models of air-to-plant impacts of the dioxin-like compounds. One was developed only for the impact of vapor phase dioxins, and does not have an explicit particle phase impact model. It will be compared to the vapor transfer model of this methodology. The other model assumes that plants "scavange" a fixed volume of air of dioxins; grass concentrations are very simply modeled as the total (vapor+particle) air concentration times a "scavenging" coefficient. The third section presents the results of this exercise. These first three section are paraphrased from Lorber and Pinsky (1999), where further details on this exercise can be found. Finally, the fourth section reviews a

very similar model comparison exercise published in the literature in which the model of this methodology, along with these same two alternative models, are applied to different field data.

7.2.1.1. The Field Data

Jones and Duarte-Davidson (1997) present the results of an extensive monitoring study of dioxin concentrations in air and grass, as well as deposition fluxes, from three sites over three time periods between 1992 and 1993 in the United Kingdom. The three sites include a rural background site, an urban site, and an industrial site. The study was originally funded as a monitoring program to evaluate the environmental levels of dioxin-like compounds in a contaminated industrial area in Bolsover, UK (Sandalls, et al, 1996). By also including an urban site and a rural background site in their study, the authors were able to use the data to better understand the processes of air-to-plant transfer of the dioxins. The regional background site was located about 6 km upwind of the industrial complex in Bolsover, the urban site was about 2 km in the town of Bolsover, and the industrial sampling location was located just outside the industrial complex, about 100 m away.

Jones and Duarte-Davidson (1997) present two sets of data which are appropriate for air-to-plant model validation and model comparison purposes. Specifically, they presented concurrently measured concentrations of dioxin and furan congeners, and homologue groups, for air and grass sampled for two of the sites, the industrial and rural background site, for one of the sampling periods, Sep. 14 - Oct. 30, 1993. They also presented the results of their deposition collection for those two sites/sampling periods. Although other data sets of this kind were collected during the program, only these two sets were presented. Specifically, the following observed data were available for one sampling period each at the rural background and industrial sites: 1) average total air concentrations of 17 dioxin congeners and 8 homologue groups for a 6+-week period (9/14/93-10/30/93), 2) average concentrations of these compounds in grass grown during this period, 3) average deposition rates, in units of pg/m^2-day for these compounds, and 4) grass yields, in g/m^2. The air, grass, and deposition data are provided in Table 7-1. Further details on the sampling design, monitoring program, analytical methods, and other aspects of the study can be found in Jones and Duarte-Davidson (1997).

7.2.1.2. Model Descriptions and Application to the Field Data

The vapor transfer approach was parameterized and applied to 2,3,7,8-TCDD by Smith, et al. (1995a) and Trapp and Matthies (1995). The steady state solution for their vapor transfer velocity approach is given as:

$$C_{vpa} = \frac{F_v}{k_v \; Y_j} \qquad (7\text{-}1)$$

where:

C_{vpa} = plant concentration due to vapor-phase transfer, pg/g dry weight
F_v = deposition of vapor-phase congener, pg/m^2-day
k_v = first-order dissipation constant, day^{-1}
Y_j = yield of crop j, g/m^2

The non-steady state solution has an additional term in the numerator, $1\text{-}e^{(-kv\ t)}$, where t is the time to harvest. This non-steady state term was used for the particle phase solution in the model validation exercise. However, given that the k_v was assigned a relatively large value by both researchers for 2,3,7,8-TCDD vapors depositing onto plants (a large k_v corresponds to a short half-life), and the growing period for grasses is 45+ days in the field data set applied, this additional term approaches 1.0, and it can therefore be neglected in the vapor phase solution.

The two articles evaluated diverge at this point. The Trapp and Matthies (1995) approach is actually a comprehensive approach involving root uptake impacts. They summarize the literature to conclude that vapor phase impacts for lipophilic compound such as dioxin dominate the plant contamination and hence, they do not model particle phase impacts. They also present their solution in a more generalized fashion by having a volume term in the denominator of Equation (7-1) above instead of a plant yield term; the volume term is easily converted to a mass (or yield) term with a plant density factor. Their solution for F_v is:

$$F_v = A \; g \; C_{va} \; 86400 \qquad (7\text{-}2)$$

where:

F_v = deposition of vapor-phase congener, pg/m^2-day
A = leaf area index, m^2 leaf area/m^2 ground area
g = conductance, m/sec
C_{va} = vapor phase air concentration, pg/m^3
86400 = converts sec to days

Trapp and Matthies (1995) state that g has a range of 0.0001 m/sec to 0.005 m/sec, where the upper boundary conductance is appropriate for a plant species with relatively permeable cuticles and the compounds are very lipophilic, and the lower boundary conductance is where uptake is mainly via stomata and the compounds are less lipophilic. For 2,3,7,8-TCDD, Trapp and Matthies (1995) assume a g of 0.001 m/sec. For the leaf area term, they have assumed a value of 5 for the condition they describe as "meadow". Without further information on refinement of these terms for the experimental conditions of the Jones and Duarte-Davidson (1997) settings, a g of 0.001 m/sec and an A of 5 will be assumed for this exercise.

Smith, et al. (1995a) estimate the F_v as a multiplication of the vapor phase air concentration, C_{va} (pg/m^3), the transfer velocity, V_t, (cm/sec), and the plant interception (fraction, unitless). They state that the transfer velocity is represented as the inverse of the sum of the resistances to transfer to the plant surface as:

$$V_t = \frac{1}{R_a + R_b + R_c} \qquad (7\text{-}3)$$

where:

V_t = transfer velocity, cm/sec

R_a = atmospheric resistance, sec/cm, a function of vertical turbulent transport

R_b = surface boundary layer resistance, sec/cm, a function of molecular diffusivity

R_c = plant canopy/leaf resistance, sec/cm, a function of vegetative density, stomatal uptake, surface effects, humidity, and so on

They have assigned values of R_a = 0.4 sec/cm, R_b = 0.38 sec/cm, and R_c = 0.5 sec/cm, leading to an overall V_t of 0.78 cm/sec. They assumed a crop interception fraction of 1.00.

Both research efforts have, therefore, arrived at fairly similar quantities in front of the air concentration term (C_{va}), despite having slightly different theoretical frameworks. Trapp and Matthies (1995) arrive at the quantity of 0.005 m/sec (A g = 5 * 0.001 m/sec), and Smith, et al. (1995a) arrive at 0.0078 m/sec (INT * V_t = 1 * 0.0078 m/sec).

Both also have used the same experimental work of McCrady and Maggard (1993) as part of their derivation of the k_v. Trapp and Matthies (1995) assumed that the overall k term was a function of losses by photodegradation, volatilization, and dilution from plant growth. They used the photodegradation k term of 0.3744 day^{-1} taken from McCrady and Maggard (1993), but then multiplied it by 0.30 assuming that the plant was in full sunlight only 30% of the time. They

calculated a volatilization rate term of 0.012 day^{-1}, and assumed a dilution term of 0.035 day^{-1}, leading to an overall k_v term of 0.159 day^{-1}. Smith, et al. (1995a) took the full photodegradation plus volatilization rates determined by McCrady and Maggard (1993), without any correction for time in sunlight, to arrive at a k of 0.495 day^{-1}. They did not consider dilution by plant growth.

McLachlan (1995) developed a simple "scavenging" approach to predict grass concentrations of dioxins from air concentrations of dioxins. He suggests that grass scavenges the equivalent of 9 m^3 or air per gram of grass, and that corn scavenges 4.5 m^3 of air. The important assumption in this approach is that plants can scavenge vapors and particles equivalently; therefore, vapor/particle partitioning is unnecessary, and grass concentrations are very simply modeled as:

$$C_{gi} = SC\ C_{ai} \qquad (7\text{-}4)$$

where:

C_{gi} = grass concentration of congener i, pg/g dry weight basis
SC = scavenging coefficient, m^3/g
C_{ai} = total (vapor + particle) phase air concentration of congener i, pg/m^3

With this as background, it is now possible to describe how the three models will be applied to the field data. For simplicity, the three models will be referred to as the EPA model, the scavenging model, and the vapor deposition model. In applying the EPA model, total dioxin concentrations were first partitioned into a vapor and a particle phase following the procedures outlined in Chapter 3. In that chapter, particle fractions, ϕ (the vapor fractions are solved as, 1 - ϕ), are developed for an ambient air temperature of 20 °C for airsheds described as, "clean continental", "background", "background plus local conditions", and "urban". For this application, these ϕ were rederived for 10 °C, the air temperature more typical of September and October in the UK, and the "average background" and "urban" ϕ were used for the rural and industrial sites, respectively. According to the modeling procedures of this assessment, described in detail in Chapter 4, vapor dioxins "transfer" to the grass; grass concentrations due to air-borne vapors are modeled simply as the air concentration times an air-to-leaf transfer factor, B_{vpa}. Chapter 4 describes the derivation of this empirical transfer factor. Particle-phase dioxins deposit onto grass, under both wet and dry conditions. Jones and Duarte-Davidson (1997) do not provide the rainfall data for the sampling period necessary to estimate wet deposition. For

simplicity, wet deposition will not be modeled. Dry deposition, as outlined in Chapter 4, Section 4.3.4, will be modeled as a function of the particle phase concentration times a deposition velocity, which will be assumed to be 0.20 cm/sec. This deposition mixes in a reservoir of grass, described by the grass yields, which were provided in Jones and Duarte-Davidson (1997) as 89 and 42 g dry weight/m^2 for the rural and industrial sites, respectively. As outlined in Chapter 4, Section 4.3.4, interception fractions for grasses corresponding to these yields are solved for as 0.23 (for 89 g/m^2) and 0.11 (42 g/m^2). The first-order weathering constant will be assigned a value of 0.0495 day^{-1}, corresponding to a half-life of 14 days. This value has also been used in the literature and otherwise in this document.

For testing of the scavenging model, the measured air concentrations in the rural and industrial site will be multiplied by the scavenging coefficient of 9.0. For testing of the vapor deposition model, the total air concentration of 2,3,7,8-TCDD will be partitioned into the particle and vapor phase for these field data, again assuming "average background" for the rural site and "urban" for the industrial site. The vapor portion of the air concentration will be used in the vapor deposition model. The model predictions of the vapor component of the grass concentration will be compared against the vapor component of grass concentration as predicted by the models of this assessment and the measured grass concentration.

There were 25 modeled/measured concentration pairs in the rural site data set, including the 17 individual congeners and the 8 homologue groups. In order to obtain independent data points for model testing, the measured air and grass concentrations of the individual congeners were subtracted from the homologue group concentrations; individual congener concentrations are, by definition, contained within the homologue group concentrations. Doing this subtraction should have resulted in 25 independent measured/modeled pairs for model testing. However, it was found that, for HpCDD, HxCDF, and HpCDF, subtraction of the congener air concentrations from these homologue group air concentrations resulted in negative concentrations. There was obviously some measurement error in this data set. The air:grass pairs for these three homologue groups were, therefore, not considered for further model testing. Without these three readings, the air and grass data at the rural site were quite correlated; the correlation coefficient of the remaining 22 data pairs was 0.92.

Similar measurement error resulted in the deletion of 4 air:grass pairs in the industrial data set. The air concentrations of the homologue groups HpCDD and HpCDF also were lower than the sum of the individual congener concentrations. The grass concentrations of 1,2,3,7,8-PCDD and 1,2,3,7,8-PCDF were given as non-detected, but the air concentrations of these

congeners in the urban settings were similar to the air concentrations in the rural settings, and significant grass concentrations were noted in the rural setting.

Even with these four pairs deleted, the industrial site data was not as consistent as the rural data. The correlation coefficient for the remaining 21 data pairs was 0.66. An examination of the data highlights some of the differences between the two data sets. In some instances, air concentrations that were similar in the rural and industrial sites led to grass concentrations that were more impacted in the industrial site. For example, the air concentration of 2,3,7,8-TCDD in the rural setting was 0.01 pg/m^3, while it was 70% higher than that in the industrial setting at 0.017 pg/m^3. However, the grass concentration in the industrial site was about 4 times as high as in the rural setting, 2.8 pg/g in the industrial site versus 0.72 pg/g in the rural site. Similar observations can be made for 4 other congeners. On the other hand, there were several instances where similar rural and industrial air concentrations resulted in lower grass concentrations in the industrial as compared to the rural setting. Similar OCDD concentrations of 2.5 pg/m^3 in the two settings resulted in a grass concentration of 94 pg/g in the rural setting but only 43 pg/g in the industrial site setting. This trend can be found in 13 other instances. Also, the industrial data contained three data points that appeared to be flawed.

In summary, then, 22 air:grass pairs for the rural data set and 21 air:grass pairs for the industrial site were retained for model testing

Model goodness-of-fit tests were run for the rural site only, not on the industrial site, simply because the rural site data was better correlated. The absolute and signed difference between the natural logs of the measured and modeled grass concentrations provided the goodness-of-fit measure. The signed error, or bias, measures the systematic tendency of the model to under or overpredict; a bias near 0 suggests that the model underpredicts and overpredicts by about the same amount. The absolute error calculation describes model variation; how close the model predictions come to the observations, regardless of whether the model over or underpredicted. A value close to 0 suggests a very good match between predictions and observations. Log concentrations were used because there were a wide range in grass concentrations, from sub-ppt concentrations for the lower chlorinated dioxins to concentrations near 100 ppt for the homologue groups.

7.2.1.3. Results and Discussion of the Air-to-Leaf Model Comparison Exercise

Results of this model comparison are shown in Figures 7-1 through 7-4, and Table 7-2.

Figures 7-1 and 7-2 compare the measured grass concentrations with the EPA and the Scavenging Model for the rural and urban site, respectively. The natural log of the observed

concentrations are shown on the x-axis and the predicted concentrations on the y-axis. The dashed line shows where predicted equals observed; points above the line show overpredictions by the models while points below the line show model underpredictions. As seen in Figure 7-1, model predictions of rural grass concentrations using the EPA Model matched the observed concentrations better than the Scavenging model, but both models underpredicted concentrations. The predicted total toxic equivalent (I-TEQ) concentration of the EPA model was 3.7 pg/g, compared to the observed I-TEQ concentration of 6.0 pg/g. The bias was -0.66, giving a bias factor of exp [-0.66] = 0.51 and suggesting that the EPA model underpredicted by about a factor of 2.0. The absolute error was close to the bias at 0.68, again indicating that the EPA model mostly underpredicted plant concentrations; of 22 observation:prediction pairs, the EPA model underpredicted concentrations 21 times.

Figure 7-1 shows that the Scavenging Model underpredicted grass concentration at the rural site more than the EPA model. The modeled I-TEQ concentration was 1.85 pg/g, less than one-third the measured I-TEQ concentration of 6.0 pg/g. The absolute error was 1.325, and the bias was its negative counterpart, -1.325. This means that the model underpredicted concentrations in all instances, and that this underprediction was by an average factor of 3.8 ($e^{1.325}$) .

Figure 7-2 shows the EPA and the Scavenging Model predicting essentially the same concentration for nearly every data point, and both underpredicted grass concentrations significantly. The TEQ concentrations predicted by the EPA and the Scavenging Models were 3.26 and 2.94 pg/g, respectively, while the observed TEQ concentration was 7.35 pg/g. The bias and absolute differences for both models on this data set also mirrored each other. For the EPA Model, the bias and absolute differences were -1.01 and 1.09, and for the Scavenging Model, the bias and absolute difference were nearly the same at -1.07 and 1.15. These results indicate that both models underpredicted by about the same factor of 3.

One reason for this similarity in performance is that the EPA model reduced to principally a particle-phase deposition model; nearly all the dioxin was in the particle phase for the “urban” setting at 10 °C. Like the Scavenging Model, therefore, plant concentrations were mostly a linear function of total air concentrations for the application of the EPA Model at the industrial site.

As described earlier, the data at the industrial site was not nearly as well correlated as the data at the rural site - the correlation between air and grass data at the industrial site was 0.66 compared to 0.92 at the rural site. One factor likely to have influenced this is the fact that the soil at the industrial site was much higher for some of the dioxins as compared to the rural site. While the soil concentrations were not reported by Jones and Duarte-Davidson (1997), Sandalls

(1996) reported exceedingly high concentrations of TCDD (up to 9400 ppt, and several hundred ppt even 4-5 km from the major air source identified in the Bolsover area), and elevations in 2,3,7,8-TCDD, PCDD and TCDF in soils near the industrial site. Not ironically, these same four compounds, along with 1,2,3,6,7,8-HxCDD, were identified earlier as the compounds which had high grass concentrations at the industrial site despite air concentrations that were comparable to air concentrations of the same compounds at the rural site. If these five air:grass pairs are subtracted from the industrial site data set, the correlation between air and grass data now is much improved: it is at 0.80, up from 0.66. Also, the absolute error for both the Scavenging and the EPA Model for this smaller observed:predicted test improve to 0.61, indicating that modeled grass concentrations are now within exp [0.61] = 1.85 of measurements concentrations, rather than within a factor of 3.0. Obviously, the grass concentrations of these five compounds appear to have been influenced by high soil concentrations, and the ability of the models to reproduce these concentrations is limited because they are air-to-grass models and not air/soil-to-grass models. While it has been demonstrated that there is essentially no translocation from soil to above-ground plants (although pumpkins, cucumbers, squash, and other members of the cucumber family have been shown to translocate dioxins for an unknown reason (Hulster, et al., 1994)), there may have been some rainsplash impact or soil-to-air-to-plant impacts such as from wind erosion or soil volatilization for these compounds at the industrial site.

On the other hand, it was also true that air concentrations reasonably similar at the industrial and rural site led to lower grass concentrations at the industrial site for all the other dioxin and furan compounds. This is a trend that can possibly be explained and modeled by the EPA Model of this evaluation. For an urban setting, more of the dioxins are modeled to partition into the particle phase. As will be described below when discussing the calibration of the Scavenging Model, vapor phase dioxins have been shown to have a greater impact to plants compared to particle phase dioxins. Therefore, equivalent total air concentrations in a rural and an urban setting would lead to higher vegetation concentrations in the rural setting, because dioxins partition more into the vapor phase in such a setting, both in reality and as modeled by the EPA Model.

Table 7-2 shows the comparison of the measured grass concentration of 2,3,7,8-TCDD with the modeled vapor transfer concentration using the EPA vapor transfer model and the two Vapor Deposition Models. It is clear from this table that the vapor deposition algorithm, as parameterized by Smith et al. (1995) and Trapp and Mattheis (1995), predicts concentrations that are 2 to 4 times lower than predictions made by the vapor transfer algorithms of the EPA Model, and even lower still than observed grass concentrations. As will be described below, vapor phase

deposition velocity and the decay rate of the dioxins on the plant are two parameters likely to have been assigned inappropriate values for this exercise, and also likely to be difficult to assign in any application of the vapor deposition approach.

Whereas the scavenging ratio of 9.0 may have been appropriate for the field data used by McLachlan (1995) in the development of this approach, it is by far too low for this particular data set. A calibration exercise was performed on the 22 rural air/grass data points. In this exercise, the least squares fit of the difference between predicted and measured log grass concentrations was sought. The best fit was found at the constant scavenging coefficient of 36.4. With this value, the goodness-of-fit measures improve substantially: the bias goes to 0 (by definition of the least squares fit) from -1.325, and an absolute error goes to 0.417 (predictions are within a factor of 1.5, sometimes higher, sometimes lower) from 1.325 (predictions are always lower by about a factor of 4.0).

A critical assumption of the scavenging approach is that vapor and particle-phase dioxins are scavenged equivalently from the air. Therefore, a constant scavenging coefficient can be applied to total air concentration to predict total grass concentration. The error terms for the best-fit scavenging ratio suggest this might be reasonable. However, this assumption is not supported by the data in this field site. Figure 7-3 shows the scavenging ratios calculated for the 22 air:grass data points of the rural field site graphed as a function of the degree of chlorination. For example, there are four data points plotted for 4 on the x-axis: 2,3,7,8-TCDD, 2,3,7,8-TCDF, the TCDD homologue group, and the TCDF homologue group. The scavenging ratios are simply calculated as the grass concentration (in pg/g dry weight) divided by the air concentration (in pg/m^3) at the rural field site (with subtractions of congener concentrations from homologue group concentrations). As seen in the figure, there is a clear trend in that the scavenging ratio appears to generally decrease from the tetra to the hepta degrees of chlorination, with perhaps an increase at the octa degree of chlorination. It also suggests more of a trend for the dioxins as compared to the furans: there may be a higher scavenging ratio, in general, for the dioxins.

The experiments on Welsh Ray Grass (Welsch-Pausch, et al., 1995) used to calibrate the EPA's air-to-leaf transfer factor (Lorber, 1995) provided a reason for this trend: when blocking out the particle deposition impacts to potted grass, the authors found that the grass concentrations of the tetra through hexa chlorinated dioxins and furans were similar to concentrations in potted grass where particle depositions were not blocked out. The authors concluded that the plant concentrations for these dioxin/furan homologue groups were dominated by vapor-phase dioxins, even though the total air concentration itself was not necessarily dominated by the vapor phase. Therefore, given these experimental results, it follows that the lower chlorinated congeners

would have a larger overall scavenging coefficient. The field data certainly shows that trend; Figure 7-3 shows larger scavenging coefficients for the lower chlorinated dioxins and furans.

Figure 7-4 compares measured and modeled deposition amounts for the rural and industrial site combined. It is clear that the modeled rates of deposition were consistently higher than the measured rates. There was a high degree of correlation between measured and modeled rates, however, with a correlation coefficient of 0.99. The absolute error and bias were 1.16 and 1.11, respectively, suggesting that the model predictions were about 3.2 times higher than observed. This would indicate a systematic bias, either that the model tended to overpredict depositions or that the measurements tended to under-represent depositions.

If the model tended to overpredict deposition, this may have been due to inappropriate parameter assignment: too rapid a velocity of deposition, or too much dioxins assumed to be in particle phase. Measured deposition velocities can be calculated from the data of Jones and Duarte-Davidson (1997) in Table 7-1 simply as the deposition flux divided by the air concentration (with proper conversions). Average velocities calculated this way were 0.06 cm/s for the rural site and 0.08 cm/s for the industrial site and only one calculated deposition velocity was greater than the 0.20 cm/s velocity assigned for this modeling exercise. The predicted depositions would be lower still if measured particle phase fractions were used instead of modeled fractions since, measured particle-particle fractions of dioxins tend to be lower than modeled using the Junge model for vapor/particle partitioning. For this particular field site, measured vapor/particle fractions were not available to evaluate this possibility.

On the other hand, it could be the case that the deposition collectors are underestimating depositions. Jones and Duarte-Davidson (1997) suggest two possible causes for the upturned frisbees to be underestimating deposition: 1) they are smooth and therefore less efficient at capturing particles as compared to leafy vegetation or ground surfaces, and 2) dioxins in wet deposition can be adsorbed onto the sampler surface and presumably, not be available to be measured.

In any case, it can be concluded that the deposition model, which was the simple product of the particle-phase reservoir times a deposition velocity of 0.20 cm/s, resulted in the deposition amounts that about 3 times higher than were measured in the rural and industrial sites of this data set.

In the introduction to Section 7.2.1, this exercise was described as both a model validation and model comparison exercise. It can be concluded that the EPA model was reasonably successful in this validation with the rural site field data, but less successful on the industrial site data. On the other hand, both the vapor transfer and scavenging models could not

be successfully validated on this field data. In the case of the vapor transfer model, the likely shortcoming was in the assignment of the parameters, vapor deposition velocity and degradation of vapor phase 2,3,7,8-TCDD deposited on the grass. In the case of the scavenging coefficient, the value of 9.0 suggested in its development (McLachlan, 1995) was too low. One can calibrate both models such that the fit between observed and predicted grass concentrations is favorable. These calibrated models can then be applied to other field data sets in order to see if the calibrated values are "valid". The deposition portion of the EPA model was found to consistently overpredict deposition, which could be due to either inappropriate parameter assignments, or the tendency of the upturned frisbee to underestimate deposition amounts.

7.2.1.4. Literature Comparisons of Air-to-Plant Modeling Approaches

Douben, et al. (1997) presents an exercise comparing the three air-to-plant approaches that were compared in the previous section: the approach in this document, the scavenging approach, and the vapor deposition approach. Their exercise used, as observed air data, concentrations from a semi-rural site in the United Kingdom (UK). This was not the same as the rural site in the Jones and Duarte-Davidson (1977) study. Since this data set had several non-detects, the authors supplemented it with data from a rural site showing similar detected concentrations in Germany; the final observed air concentrations were crafted from these two data sets. The observed grass data came from a different site in the UK. Comparing model performance on a set of data from a single site, as was done in the previous section, is preferable to "crafting" observed air and grass data. Still, if the data can be considered representative, than using data from different sites may not be invalid; developing representative air and beef profiles was done for the air-to-plant-to-beef model validation described in Section 7.3.11 below. The application of the approach of this document used an earlier vapor transfer factor, from Lorber (1995), which also had an earlier vapor/particle partitioning scheme. They used the vapor deposition approach described and parameterized by Smith, et al. (1995) for all dioxin congeners, not just 2,3,7,8-TCDD - the vapor deposition velocity (0.78 cm/sec) and plant degradation (0.495 day^{-1}, corresponding to a half-life of 1.4 days) parameters were assigned the same the same for all congeners. For the vapor deposition algorithm, they used measured vapor fractions (from the site in Germany) as compared to use of the modeled vapor fractions in the exercise above. Finally, they used the scavenging approach promoted by McLachlan (1995) including the assignment of a scavenging coefficient of 9 for all congeners.

In general, they showed some of the similar trends that were described above. The models of this assessment had the highest predicted grass concentration; this was also the trend

in the exercise described above. However, these predictions were higher than the grass observations of the crafted air/grass data set in Douben, et al. (1997), sometimes by upwards of a factor of 10. The vapor transfer approach was the lowest predictor, but in their case, predictions were usually within an order of magnitude, sometimes within a factor of 2. The scavenging approach performed the best on their data set. Similar to the conclusion in Jones and Duarte-Davidson (1997), Douben, et al. (1997) concludes the following regarding vapor and particle atmospheric scavenging (p. 342 in Douben, et al. (1997)): "However, an implication of the good predictions obtained across the range of PCDD/Fs with the scavenging model is that airborne PCDD/Fs which may be present either in the vapour- or particulate-phase appear to transfer with similar efficiencies to pasture grass and may remain associated with the grass after deposition." However, even in the crafted air and grass profile, there is similar evidence as described above in that the scavenging coefficient increases as the degree of chlorination decreases, at least clearly so for the tetra congeners. From their data, calculated scavenging coefficients are: 57 for TCDD/Fs (n=2), 9 for PCDD/Fs (n=3), 5 for HxCDD/Fs (n=7), 11 for HpCDD (n=3), and 11 for OCDD/Fs (n=2).

Currado and Harrad (1998) evaluated two of the three modeling approaches described in the previous section to a data set including air concentrations, deposition amounts, and grass concentrations of 20 individual PCB congeners from an urban site in Birmingham, UK. The two models they tested were the EPA air-to-leaf model (which they further developed for CDD/Fs to include a soil-to-plant algorithm as described in Harrad and Smith (1997), although they only used the air-to-plant algorithm for this application to PCBs), and the Scavenging Model. For the EPA model, they partitioned the PCBs into particle and vapor phases using the Junge-Pankow model advocated in this assessment, corrected for air temperature, and then transferred the vapor-phase and deposited the particle-phase PCBs onto the grass. The vapor phase transfer factors were determined as a function of the PCB log Kow and H, as described in Lorber, et al. (1994), including an empirical reduction factor of 40. For the test of the Scavenging Model, they simply plotted total (vapor + particle) air concentrations against measured air concentrations, and investigated the correlation between the two. According to the Scavenging Model approach, the total air concentration times a constant (equal to the volume of air being "scavenged" of PCB to produce the grass concentration), which is the same constant for all PCBs, should equal the grass concentration.

Using the EPA framework, they found very good agreement between predicted and measured grass concentration for the PCBs: observed/predicted ratios ranged from 0.34 to 1.97, with a mean of 0.93 and a correlation coefficient of 0.46. They also found good agreement

observed and predicted vapor/particle partitioning (observed/predicted particle fraction ratios ranged from 0.17 to 2.15, mean of 0.89 and correlation coefficient of 0.59) and observed and predicted particle deposition fluxes (observed/predicted ratios from 0.33 to 4.19, mean of 1.33, and correlation coefficient of 1.09).

On the other hand, they did not get as good results with the Scavenging Coefficient model. They did find that this would work for the penta- and hexachlorobiphenyls - their grass scavenged the PeCBs and HxCBs present in 22 m^3 of air, but there was not a similar relationship found for tri- and tetrachlorobiphenyls. Although the authors didn't investigate further, there may be a relationship between portion of the PCBs in the particle-phase, there would be more in the particle phase as the degree of chlorination increases (as it is with CDD/Fs), and the capabilities of the Scavenging Approach.

7.2.2. An Alternate Modeling Approach for Estimating Water Concentrations Given a Steady Input Load from Overland Sources

A study to evaluate the bioaccumulation of 2,3,7,8-TCDD in fish in Lake Ontario included an extensive modeling exercise (EPA, 1990a). The model used was WASP4 (Ambrose, et al., 1988). This is a substantially more complicated model than used in this assessment. The underlying principal for the WASP4 model is a conservation of mass. Contaminant source terms, described in mass/time units, enter what are termed control volumes, or segments. The contaminant partitions between sorbed, bound, and dissolved phases; it is not required to specify whether the contaminant enters via soil erosion, water runoff, surface deposition, or otherwise. Contaminants are, however, assumed to enter via the surface or as part of inflows to the water body, in contrast to ground water recharge. The mass transported into a segment is either transported out of the segment, accumulates in the segment, or is transformed by chemical or biological reactions.

As noted, 2,3,7,8-TCDD input into the Lake Ontario application partitions within the water column into a sorbed compartment, a dissolved compartment, and a bound compartment. This bound compartment is further described as non-settling organic matter. Three analogous compartments receive 2,3,7,8-TCDD in the bottom sediment layer. Several exchanges between the six compartments and contaminant losses within each compartment are modeled. For example, losses from water column compartments include downstream transport, volatilization and photolysis; the loss mechanism from the bottom sediment layer is sedimentation. Exchanges between compartments consider partitioning, diffusion, and sediment settling and resuspension.

This model requires substantial parameterization. Once values were selected for the Lake Ontario application, an evaluation was made on the impact of different levels of 2,3,7,8-TCDD input. Dynamic and steady state results were discussed. Principally examined for the steady state results were the concentrations of bottom sediment sorbed 2,3,7,8-TCDD and water column dissolved (soluble) phase 2,3,7,8-TCDD. A given level of steady 2,3,7,8-TCDD input, in kg/yr, resulted in a steady state concentration sorbed to bottom sediment and dissolved in the water column.

The premise in both the Lake Ontario steady state application of WASP4 and the water concentration algorithms in this assessment is that contaminants continue to enter water bodies over time unabated. Ground water entry of contaminants is not considered in either approach. Although a direct modeling comparison cannot be done, it is possible to slightly adjust the algorithms of this assessment to evaluate how results from a simple partitioning approach would compare with results from the complex fate and transport approach of the WASP4 steady state application.

Assume a surface water body is initially free of contaminant and at time t equals 1 day, a strongly hydrophobic contaminant, such as the dioxin-like compounds of this assessment, begins to enter a lake. Assuming the contaminant enters via soil particles, as in the approach of this assessment, it will then partition between those soil particles and surrounding water. The soil particles will slowly move toward the bottom of the lake at a rate described by a particle settling velocity. A settling velocity of 1 m/day is assumed in the Lake Ontario simulations. The amount of time it takes to settle to the bottom once entering from the surface equals the lake depth divided by this settling time. The Lake Ontario depth was 86 m. Therefore, it might take 86 days to settle. This, of course, neglects resuspension of settled particulates. With this simplistic framework, a steady state amount coming into the lake after 86 days is matched by an amount depositing onto the lake bottom; the amount of contaminant within the water column has reached steady state. Water concentrations can then be estimated assuming equilibrium partitioning.

Results of sediment and water column steady state concentrations are described for any loading of 2,3,7,8-TCDD in the WASP4 steady state application; those loadings are described in kg/yr. Loadings in kg/yr are easily correlated to a steady state water column amount, given the above analysis. For example, a loading of 1.0 kg/yr could translate to a within water column steady state amount of 0.24 kg (1.0 kg/yr * (86 d)/(365 d/yr)).

This steady water column amount partitions between suspended sediment and surrounding water. First, the total concentration (sorbed + soluble) simply equals:

$$C_{tot} = 1000 \frac{LD}{VOL} \quad (7\text{-}5)$$

where:

C_{tot} = total concentration, mg/L
LD = water column steady state amount of contaminant, kg
VOL = lake volume, m^3
1000 = converts kg to mg and m^3 to L

The dissolved phase portion of total is given by:

$$C_{wat} = \frac{C_{tot}}{1 + (Kd_{ssed}\ TSS\ 10^{-6})} \quad (7\text{-}6)$$

where:

C_{wat} = soluble phase water concentration, mg/L
C_{tot} = total concentration, mg/L
Kd_{ssed} = partition coefficient between suspended sediment and surrounding water, L/kg
= $Koc*OC_{ssed}$
Koc = organic carbon partition coefficient, L/kg
OC_{ssed} = fraction organic carbon of suspended sediments
TSS = total suspended sediments, mg/L
10^{-6} = converts mg/kg to mg/mg

Parameters in this equation for the Lake Ontario WASP4 application include VOL, Koc, OC_{ssed}, and TSS. Lake Ontario volume was given as 1.68×10^{12} m^3, Koc was estimated for the WASP4 application as 3,162,000, OC_{ssed} was estimated at 0.03, and TSS was estimated 1.2 mg/L. For a steady load of 1 kg/yr and a resulting LD of 0.24 kg, the steady state water column 2,3,7,8-TCDD concentration, using the simplistic approach described above, is estimated as 0.13 pg/L (ppq). The steady state water column concentration estimated by WASP4 given the same parameters and a load of 1 kg/yr is roughly 0.20 pg/L. An uncertainty analysis done with these WASP4 results concluded that 95% confidence limits around this prediction are 0.03 and 0.40 pg/L.

This would seem to imply that the simple partitioning approach used in this assessment compares favorably with the more complex fate and transport modeling assessment using WASP4, for Lake Ontario.

7.2.3. Estimating Fish Tissue Concentrations Based on Water Column Concentrations Rather than Bottom Sediment Concentrations

EPA prepared a document titled, "Interim Report on Data and Methods for Assessment of 2,3,7,8-Tetrachlorodibenzo-p-Dioxin Risks to Aquatic Life and Associated Wildlife" (EPA, 1993). That document provides details on the two key bioaccumulation parameters used for the methodologies of this document, the Biota Sediment Accumulation Factor, BSAF, used for the soil and stack emission source categories, and the Biota Suspended Solids Accumulation Factor, BSSAF, used for the effluent discharge source category. That document also discussed several water column based bioaccumulation factors, which are the focus of this section. A later publication prepared by the same group at EPA titled, “Great Lakes Water Quality Initiative Technical Support Document for the Procedure to Determine Bioaccumulation Factors” (EPA, 1995a), also describes water and sediment based bioaccumulation factors.

Before discussing these factors, it is noted that food chain modeling is a well developed alternate approach for estimating fish tissue concentrations of bioaccumulating contaminants (Thomann, 1989), which has also been applied to 2,3,7,8-TCDD (Parkerton, 1991). This approach is significantly more complex than the bioaccumulation/biotransfer approach of this methodology. It involves detailed site-specific characterizations, specifically the identification and transfer modeling between trophic levels of a food chain in a water body. Food chain modeling is a mechanistic approach, while the transfer approaches of this methodology are empirical. No judgement is rendered as to the relative merit of food chain models versus use of bioaccumulation coefficients. If detailed site-specific data is available, and given time and resources, assessors should consider food chain modeling for estimating fish tissue concentrations.

One water column measure which has been classically used is termed the Bioconcentration Factor, or BCF. Bioconcentration refers to the net accumulation of a chemical from exposure via water only, and BCFs are most often obtained in laboratory conditions. BCFs are defined as the ratio of the chemical concentration in organism (mass of chemical divided by wet weight of organism tissue) to that in water.

Another water column measure of the potential for a contaminant to accumulate in fish tissue is termed the Bioaccumulation Factor, or BAF. Bioaccumulation refers to the net

accumulation of a chemical from exposure via food and sediments as well as water. Similar to the BCF, BAFs are defined as the ratio of the chemical concentration in the organism to that in the water.

For chemicals that are not strongly hydrophobic (unlike the dioxin-like compounds), the distinction between bioconcentration and bioaccumulation is small. Whereas food intake is generally a few percent of body weight per day, water passing over gills will equal hundreds to thousands times the organism weight per day, depending on species, activity, temperature, and other factors. Given this, the concentration of chemical in food must be 3 or more orders of magnitude greater than that in water before food can substantially contribute to uptake. EPA (1993) estimates that food intake becomes a critical contributor to the accumulation of contaminants in fish tissue for contaminants with log Kow of 5 and greater.

Since the dioxin-like compounds fall into this category, the remainder of this section will focus on the Bioaccumulation Factor. EPA (1993) defines steady-state lipid-based BAFs for total chemical in water and freely dissolved chemical in water (i.e., chemical which is truly in a dissolved phase and not bound to dissolved or suspended particulate organic materials) as:

$$ssBAF_l^t = \frac{C_{lipid}}{C_w^t} \quad (7\text{-}7a)$$

$$ssBAF_l^d = \frac{C_{lipid}}{C_w^d} \quad (7\text{-}7b)$$

where:

$ssBAF_l^t$ = steady-state lipid-based BAF for total chemical in water, unitless

C_{lipid} = the mass of contaminant in fish lipid tissue divided by the mass of fish lipid tissue, mg/kg

C_w^t = the mass of total contaminant in water divided by the mass of water in the water body, mg/kg (note: 1 L water nearly equals 1 kg, therefore, 1 mg/L can be assumed to equal 1 mg/kg)

$ssBAF_l^d$ = steady-state lipid-based BAF for freely dissolved chemical in water, unitless

C_w^d = the mass of freely dissolved contaminant in water divided by the mass of water in the water body, mg/kg

EPA (1993) then develops relationships between $ssBAF_l^d$ and $ssBAF_l^t$, based on dissolved and particulate organic carbon reservoirs in the water column, and partition coefficients for these reservoirs. This is meaningful in complex modeling where these two reservoirs of organic carbon can be accounted for, such as in the WASP4 model. Alternately, EPA (1993) defines the TBF_{oc}, a total binding factor to organic carbon, which empirically considers the reservoir of dissolved organic material (i.e., increases total binding and reduces truly dissolved phase concentrations) when such a reservoir is not explicitly modeled. The modeling frameworks in this assessment have only one compartment of suspended material to which contaminants sorb, with one associated organic carbon content. A second reservoir to which contaminants bind, the reservoir of dissolved organic material, is not modeled.

EPA (1993) developed a $ssBAF_l^t$ and a $ssBAF_l^d$ for lake trout, 2,3,7,8-TCDD, and for Lake Ontario 1987 contamination conditions. The WASP4 model was used to model three hypothetical loading conditions that might have resulted in fish tissue concentrations observed in 1987: steady state loading, a steady state loading followed by a 90% reduction in annual loads for 20 years (i.e., 1968-1987), a steady state loading followed by a 100% reduction (i.e., no loading) for 20 years. The BSAF for lake trout estimated for 1987 data is given in EPA (1990a) as 0.07. The BSAF is determined from measured bottom sediment concentrations and fish tissue concentrations; an assumption of historical loading is not necessary for BSAF development. Details of the Lake Ontario study, including initial modeling efforts with the WASP4 model can be found in EPA (1990a). Slight refinements to the WASP4 runs were later made (cited in EPA, 1993 as an unpublished report: Endicott, D.D., W.L. Richardson, T.F. Parkerton, and D.M. DiToro. 1990. A steady-state mass balance and bioaccumulation model for toxic chemicals in Lake Ontario: Report to the Lake Ontario Fate of Toxics Committee. U.S. EPA, Environmental Research Laboratory, Duluth, MN: 121 pp). The BAFs determined in these later runs will be tested using the models of this assessment.

In order to do this exercise, all critical model parameters used to develop the BAFs for this WASP4 modeling exercise will be used in the model framework of this assessment. The most critical parameter is the organic carbon partition coefficients, Koc, assumed for 2,3,7,8-TCDD. BAFs were determined assuming Koc of 10^7 and 10^8. Since the models of this assessment assume steady loading into water bodies, only the BAFs developed under "steady state" loading conditions will be used. As noted, the WASP4 model considers binding to more than one suspended compartment. The increased binding can be modeled using a TBF_{oc}, which was assumed to be 1.5 for Lake Ontario by Cook. For the models of this assessment, this factor will be applied to Koc - it effectively increases Koc by 50%. The concentration of suspended

solids in Lake Ontario and used in the WASP4 modeling exercise was 1.2 mg/L. The other critical parameters are the fraction organic carbon contents of the suspended solids and the bottom sediments, OC_{ssed} and OC_{sed}, respectively. Assigned values to these parameters, based on Lake Ontario data, in the WASP4 exercise and in this exercise were 0.15 (15%) and 0.03 (3%), respectively.

Since the purpose of this exercise is to evaluate how the modeling approaches of this document perform using the BSAF or the alternate BAF approach, duplicating the source strength terms used in the WASP4 modeling exercise is not necessary. The pertinent question is, with a given source strength, how would both approaches predict fish tissue concentrations. For simplicity, the background demonstration scenario described in Chapter 5 will be adopted for use here. In this scenario, the soil within the watershed is assumed to at a uniform concentration. For the exercise here, a uniform concentration of 1.0 ppt for 2,3,7,8-TCDD will be assumed.

In summary, the parameters for this exercise including the steady state BAFs are:

Test 1: Koc = $1.5*10^7$; $ssBAF_l^d = 1.9x10^6$; $ssBAF_l^t = 5.16x10^5$; BSAF = 0.07

Test 2: Koc = $1.5*10^8$; $ssBAF_l^d = 1.9x10^7$; $ssBAF_l^t = 6.78x10^5$; BSAF = 0.07

The 1.5 in the Kocs was the TBF_{oc} noted above. The BAFs specific to each Koc were the ones developed also specific to those Koc in the WASP4 modeling exercises. For both tests: soil concentration of 2,3,7,8-TCDD = 1.0 ng/kg (ppt), total suspended solids (TSS) = 1.2 mg/L, the organic carbon content of suspended sediments (OC_{ssed}) = 0.15, and the organic carbon content of bottom sediments (OC_{sed}) = 0.03. Whole fish tissue concentrations are estimated as $C_{lipid} * f_{lipid}$, where f_{lipid} is 0.07.

The whole fish tissue concentration for the BSAF approach in Test 1 was estimated to be 0.61 ppt. Using the $ssBAF_l^t$ and $ssBAF_l^d$, the whole fish tissue concentrations were estimated very nearly to be the same at 0.867 ppt for $ssBAF_l^t$ and 0.863 ppt for $ssBAF_l^d$. The test results did not change substantially for Test 2. The BSAF approach led to a fish tissue concentration of 0.62 ppt, and the concentration was identical for BAFs at 0.869 ppt.

While it appears that the water column based approaches estimate fish tissue concentrations identical to each other and very close to estimates made based on bottom sediment concentrations, in fact the performance of the models differ when parameters are changed in these tests. More incoming 2,3,7,8-TCDD can be modeled to remain in the water column with an increase in the reservoir of total suspended solids, the TSS parameter initialized in above tests at 1.2 mg/L. Continuing with Test 1 parameters above, increasing TSS from 1.2 mg/L to 10 mg/L has the following changes to fish tissue concentrations: 0.54 ppt for the BSAF test, 4.85 ppt for the $ssBAF_{lt}$ test and 0.76 ppt for the $ssBAF_l^d$ test. Decreasing the organic

carbon content of the suspended solids will have the effect of reducing the amount of incoming 2,3,7,8-TCDD simulated to remain in the water column, while increasing the amount modeled to reside in bottom sediments (because a mass balance of 2,3,7,8-TCDD is maintained), and also increases the dissolved phase concentration. Changing the TSS back to 1.2 mg/L and reducing the organic carbon content of suspended solids from 0.15 to 0.05 results in the following changes to fish concentrations: 0.62 ppt for the BSAF test, 0.45 ppt for the $ssBAF_l^t$ test and 0.88 ppt for the $ssBAF_l^d$ test. These two tests have demonstrated the variability in fish tissue concentrations when key water column parameters are altered. Fish concentrations would also differ if the key bottom sediment parameter, the organic carbon content of bottom sediments, was different. Returning to original Test 1 parameters and reducing the organic carbon content of bottom sediments from 0.03 to 0.01 results in the following changes to fish concentrations: 1.73 ppt for the BSAF test, 2.45 ppt for the $ssBAF_l^t$ test and 2.44 ppt for the $ssBAF_l^d$ test.

The predictions for all tests might be considered reasonably close, given the uncertainties in the bioaccumulation and water modeling parameters. The one test described above where the BSAF and BAF approaches led to the most differences was the one which increased suspended material contents from 1.2 mg/L to 10 mg/L. In that case, nearly a ten-fold difference was noted in fish concentrations with the $ssBAF_l^t$ as compared to the BSAF or the $ssBAF_l^d$.

An important consideration in using the water column based approaches is that the BAFs developed by Cook (or that could be developed otherwise) are based on modeled rather than measured water column concentrations, and measured lake trout tissue concentrations. In that sense, the BAFs were calibrated for Lake Ontario conditions and specific to the WASP4 modeling exercise. Therefore, using these BAFs in the modeling framework of this assessment is, strictly speaking, invalid. Further, the values of the BAFs varied depending on the assumptions on historical loadings into Lake Ontario. As noted above, three loading conditions were tested. The steady state BAFs were given above. For the 20 year - 90% reduction tests, the following BAFs were determined: BAF_l^d was 3.03×10^6 for Koc = 10^7 and 2.86×10^7 for Koc = 10^8, and BAF_l^t was 8.26×10^5 for Koc = 10^7 and 1.02×10^6 for Koc = 10^8. For the 20 year - 100% reduction tests, the following BAFs were determined: BAF_l^d was 3.86×10^6 for Koc = 10^7 and 3.40×10^7 for Koc = 10^8, and BAF_l^t was 1.05×10^6 for Koc = 10^7 and 1.21×10^6 for Koc = 10^8. The BSAF developed for lake trout for Lake Ontario was developed using measurements of both fish tissue and bottom sediment concentrations.

Both the BSAF and BAF are most appropriately developed using site specific data (coupled with a modeling exercise for BAF). Inasmuch as that can be impractical or difficult for many sites, efforts are underway to determine the general applicability of BSAFs and BAFs

determined for one site to other sites. EPA (1993) proposes that BAF_ls for different congeners can be roughly estimated as the BAF_l for 2,3,7,8-TCDD multiplied by the ratio of the BSAF for the congener and the BSAF for 2,3,7,8-TCDD. Such an estimate will incorporate differences in uptake, metabolism and chemical partitioning but not differences caused by chemical loss processes such as volatilization and photolysis. This approach for estimating BAF_ls for other congeners does allow for some generality since sediment and fish tissue data for other congeners and water bodies is available.

Another bioaccumulation term discussed in one literature article for dioxin is termed the Regulatory Bioaccumulation Multiplier, or RBM (Sherman, et al., 1992). Multiplication of this term and a "nominal water concentration" estimates a 3% lipid fish concentration. A nominal water concentration equals an amount of a contaminant, 2,3,7,8-TCDD in this application, added or entering a water body over time, divided by a flow volume over that same time. Assuming a fish lipid content of 3%, an RBM of 5000 was recommended based on examination of laboratory flow through data, simulated field data, and actual field data (EPA's Lake Ontario study and data downstream of pulp and paper mills). Dividing the 5000 by 0.03 gives $1.67*10^5$, and this number is now analogous to the $ssBAF_l^t$ developed by EPA (1993) described above, and in the same range as the $5.2\text{-}6.8*10^5$ range for $ssBAF_l^t$.

7.2.4. Other Modeling Approaches and Considerations for Air Concentrations Resulting from Soil Volatilization

Volatilization was modeled for the soil contamination source category, using an approach given in Hwang, et al. (1986), developed for PCB flux from soils. Another model often used to estimate volatilization from soil was presented by Jury and coworkers in a series of papers in the early 1980s (Jury, et al., 1983, 1984a,b). The full solution to Jury's model is complex and not amenable to spreadsheet programming structure. It was available for use in this exercise in an EPA model known as EMSOFT (EPA, 1997a). There is a steady state, simplified solution to the Jury model which is used in EPA's Superfund Soil Screening Methodology (EPA, 1996). Both of these Jury approaches account for movement of the organic contaminant in the vapor phase via diffusion and the dissolved phase via solute movement, and they also account for changes in volatilization rate over time: volatilization decreases with time after an initially assumed soil concentration in the surface soil depletes and deeper residues volatilize to a lesser extent (the Hwang model also accounts for a decrease in the volatilization rate over time).

If one assumes that the contaminant moves through the soil column in only the vapor phase, a simplification of the fundamental equations used by Jury offers another option for

modeling soil volatilization. The steady-state vapor diffusion equation was used by Farmer, et al. (1980a) in modeling hexachlorobenzene vapor diffusion in a laboratory soil column, and also by Johnson and Lindberg (1995) in modeling mercury volatilization from soil. It will be applied here to 2,3,7,8-TCDD.

The two Jury models and the vapor phase diffusion model are compared with the Hwang approach, as applied in this document for 2,3,7,8-TCDD. Following now are more complete descriptions of the Hwang model, the Jury models and the vapor diffusion model. The parameters used for all models are shown in Table 1.

I. Hwang Model: Farmer, et al. (1980b) applied a basic diffusion equation to the problem of soil volatilization of pesticides. This diffusion equation does not consider movement of the contaminant with soil water or degradation in the soil column:

$$\frac{\partial^2 C_T}{\partial z^2} - \frac{1}{D}\frac{\partial C_T}{\partial t} = 0 \qquad (7\text{-}8)$$

where:

C_T = mass of chemical per unit soil volume, g/cm^3
z = soil depth, cm
D = apparent diffusion coefficient for contaminant in soil, cm^2/sec
t = time, sec

Hwang, et al. (1986) redefined this basic equation to consider instead the gas phase, C_G, which they assumed was in local equilibrium with soil concentration, Cs. Their steady state equation was:

$$\frac{\partial^2 C_G}{\partial z^2} - \left[1 + \frac{BD\ Kd}{\Phi\ K_H}\right]\frac{1}{Dei}\frac{\partial C_G}{\partial t} = 0 \qquad (7\text{-}9)$$

where:

C_G = concentration of chemical in the gas phase, g/cm^3
BD = soil bulk density, g/cm^3

Kd	=	soil/water partition coefficient, cm^3/g
	=	Koc * foc
Koc	=	organic carbon partition coefficient, cm^3/g
foc	=	fraction organic carbon in soil, unitless
ϕ	=	soil porosity, cm^3/cm^3, or unitless
K_H	=	dimensionless Henry's Constant
	=	H/RT (= 41 H, substituting R and T below)
H	=	Henry's Constant, atm-m^3/mol
R	=	universal gas constant, $8.21*10^{-5}$ atm-m^3/mol-°K
T	=	standard temperature, 20 °K
Dei	=	effective diffusivity of contaminant in soil, cm^2/sec
z	=	distance from surface soil, cm
t	=	time, sec

Hwang, et al.(1986) assumed that PCBs in soil were in equilibrium between the sorbed and the gaseous phase as follows:

$$C_G = \frac{K_H \, Cs}{Kd} \qquad (7\text{-}10)$$

where:

C_G	=	concentration of chemical in the gas phase, g/cm^3
K_H	=	dimensionless Henry's Constant (= 41H, as defined above)
Cs	=	soil concentration, g/g (unitless form here for units consistency)
Kd	=	soil/water partition coefficient, cm^3/g (= foc*Koc, as defined above)

They also assumed that the effective diffusion was related to the diffusion coefficient of the contaminant in air as:

$$Dei = D_G^{air} \, \Phi^{1/3} \qquad (7\text{-}11)$$

where:

Dei	=	effective diffusion coefficient, cm^2/sec
D_g^{air}	=	diffusion coefficient for contaminant in air, cm^2/sec
ϕ	=	soil porosity, cm^3/cm^3, or unitless

Hwang, et al. (1986) solved this equation for two cases: when the contaminated soil was bare to the atmosphere and where the contaminated soil was covered with a layer of clean soil. Obviously, the option chosen for this methodology, and for this examination of alternate volatilization methods, was the bare soil contamination. Their initial and boundary conditions were: 1) the concentration of the contaminant in the air at the soil surface is 0 continually, and 2) the concentration in the soil air just below the surface and at an infinite depth remains constant and is a function of the soil concentration and contaminant properties - this function is given as Equation (7-10) above.

The flux rate that occurs after a time period t is given as:

$$J_s\ (t) \;=\; \frac{(\Phi)\ (D_{ei})\ (Cs)\ (H)\ (41)\ (10^{-6})}{Kds\ [\ (\pi)\ (I)\ (t)\ ]^{0.5}} \qquad (7\text{-}12)$$

where:

J_s	=	average volatilization flux rate of contaminant from soil, g/cm^2-s
ϕ	=	soil porosity, cm^3/cm^3, unitless
D_{ei}	=	effective diffusivity of contaminant in air, cm^2/s
Cs	=	contaminant concentration in soil, ppm or mg/kg
H	=	Henry's Constant of contaminant, atm-m^3/mol
Kds	=	soil/water partition coefficient, cm^3/g
t	=	time, sec
I	=	interim undefined term for calculation, cm^2/s
	=	$[\ D_{ei}\ \phi\ ]\ /\ [\ \phi + P_{soil}\ (1\text{-}\phi)\ [Kds/(41\ H)]\ ]$
P_{soil}	=	particle bulk density of soil, g/cm^3

The average flux rate during the exposure period is given as $2 * J_s(ED)$, where ED is the exposure duration in seconds.

It is noted in Hwang, et al. (1986) that this procedure would tend to overestimate emissions and resulting exposures in situations involving small spills which would not involve deep contamination. It is also noted that the average flux rate is inversely proportional to the square root of the duration of exposure - the longer the duration of exposure, the lower will be the average flux rate. Whereas this solution assumes an unlimited reservoir of contaminant, it is an unsteady state solution (unlike most other solution strategies) and is essentially an average flux rate over an amount of time defined by the exposure duration. Inherent in the solution was the consideration that residues dissipate by volatilization at the surface layers, resulting in contaminants diffusing upwards from deeper soil layers over time. With this longer path of diffusion, volatilized amounts decrease, and hence the average flux over time also decreases.

The parameters required for the Hwang model are provided in Table 7-3, and these include the initial soil concentration of 2,3,7,8-TCDD, C_0, the soil parameters P_{soil}, foc, ϕ, and BD, the exposure duration (or total time during which volatilization occurs starting from time t = 0 at the initial soil concentration, C_0), and the chemical-specific parameters D_g^{air}, Koc, and H.

II. Jury Model: This model assumes: 1) uniform soil properties throughout the soil column to an infinite depth, 2) there is a stagnant air boundary layer at the soil surface across which diffusion occurs and the chemical concentration at the top of this boundary layer is zero, 3) linear equilibrium liquid-solid and liquid-air partitioning is valid, and 4) degradation follows first-order kinetics. With these conditions, the mass conservation equation is:

$$\frac{\partial C_T}{\partial t} + \frac{\partial J_s}{\partial z} + \mu C_T = 0 \qquad (7\text{-}13)$$

where:

C_T	=	mass of chemical per unit soil volume, g/cm^3
J_s	=	chemical mass flux per unit soil are per unit time, g/cm^2-sec
μ	=	net degradation rate, 1/sec
t	=	time, sec
z	=	soil depth, cm

The volumetric total soil concentration, C_T, is given as:

$$C_T = BD\ Cs + \theta\ C_L + a\ C_G \quad (7\text{-}14)$$

where:

C_T	=	mass of chemical per unit soil volume, g/cm^3
Cs	=	concentration of chemical on soil, g/g (expressed in unitless form here for units consistency)
BD	=	soil bulk density, g/cm^3
C_L	=	concentration of chemical in the liquid phase, g/cm^3
θ	=	volumetric soil water content, cm^3/cm^3, or unitless
C_G	=	concentration of chemical in the gas phase, g/cm^3
a	=	volumetric soil air content, cm^3/cm^3, or unitless

The terms BD, θ, and a are in front of the concentration terms to convert them to volumetric units, to be consistent with the volumetric definition of C_T. It should be noted that for 2,3,7,8-TCDD, which is very tightly sorbed to soil, C_G and C_L become very small and C_T can be calculated as Cs BD. The mass flux, J_s, can be written as:

$$J_s = -D_G \frac{\partial C_G}{\partial z} - D_L \frac{\partial C_L}{\partial z} + J_w C_L \quad (7\text{-}15)$$

where:

J_s	=	chemical mass flux per unit soil are per unit time, g/cm^2-sec
D_G	=	soil-gas diffusion coefficient, cm^2/sec
C_G	=	concentration of chemical in the gas phase, g/cm^3
D_L	=	soil-liquid diffusion coefficient, cm^2/sec
C_L	=	concentration of chemical in the liquid phase, g/cm^3
J_w	=	water flux, cm/sec
z	=	soil depth, cm

D_G and D_L are given by appropriate forms of the Millington-Quirk equations:

$$D_G = \frac{a^{10/3}}{\Phi^2} D_G^{air} \quad (7\text{-}16a)$$

$$D_L = \frac{\theta^{10/3}}{\Phi^2} D_L^{water} \quad (7\text{-}16b)$$

where:

D_G	=	soil-gas diffusion coefficient, cm^2/sec
a	=	volumetric soil air content, cm^3/cm^3, or unitless
ϕ	=	soil porosity, cm^3/cm^3, or unitless
D_g^{air}	=	chemical gaseous diffusion coefficient in air, cm^2/sec
D_L	=	soil-liquid diffusion coefficient, cm^2/sec
D_L^{water}	=	chemical liquid diffusion coefficient in water, cm^2/sec
θ	=	volumetric soil water content, cm^3/cm^3, or unitless

Soil porosity is defined as the amount of void space in the soil, and can be calculated as, 1 - (soil bulk density)/(soil particle density). A common value used for soil bulk density, in the absence of site-specific data, is 1.5 g/cm^3. Soil particle density is not site-specific, rather it is an inherent soil property. It has been estimated to be between 2.6 and 2.7 g/cm^3, and is often assigned a value of 2.65 g/cm^3. Therefore, soil porosity is calculated at 0.434 (ie., 1 - 1.5/2.65). This porosity is comprised of air and water; that is, soil porosity, ϕ = volumetric soil water content, θ + volumetric soil air content, a, using the terms defined above. For a soil that is sometimes wet and sometimes dry, an average soil water content would range between field capacity, around 0.30 for typical soils, and wilting point, around 0.15. This exercise will assume a water content of 0.23 and a porosity of 0.43, leaving air content to be calculated at 0.20.

This solution requires the partitioning of the chemical into sorbed (Cs), liquid (Cl) , and gas (Cg) phases. The soil concentration is initially given, and liquid and gas phases are then solved as:

$$C_L = \frac{Cs}{Kds} \quad (7\text{-}17)$$

where:

C_L	=	liquid phase concentration, g/cm^3 soil water
Cs	=	soil concentration, g/g (unitless form here for units consistency)
Kds	=	soil/water partition coefficient, cm^3/g (= Koc*foc, as above)
C_G	=	concentration of chemical in the gas phase, g/cm^3
K_H	=	dimensionless Henry's Constant (= 41 H, as above)

Like the Hwang model, initial and boundary conditions are required for the solution to this model. The key initial condition is that the total concentration is constant to some depth, and that below this depth, the concentration is zero. The upper boundary condition is represented by a stagnant boundary layer condition, and the lower boundary conditions is that the total concentration is 0 at infinite depth. With these initial and boundary conditions, Equation (7-13) is solved using the Laplace transform method. This is not amenable to spreadsheet calculations. The EPA model, EMSOFT, was coded in fortran using original code supplied by Jury for his equations, and it performs this transformation. EMSOFT calculates water flux under user-specified water flux conditions, entering a positive flux amount (meaning a net leaching rate at that amount), 0 (no net leaching or evapotranspiration), or a negative flux amount (meaning a net evapotransiration rate) in units of cm/day. For this exercise, the solution at water flux = 0 will be assumed.

The parameters required for EMSOFT are provided in Table 7-3, and these include the initial soil concentration of 2,3,7,8-TCDD, C_0, the soil parameters foc, θ, ϕ, a, and BD, the water flux assumption, the depth of constant soil concentration, the exposure duration (or total time during which volatilization occurs starting from time t = 0 at the initial soil concentration, C_0), the boundary layer thickness, and the chemical-specific parameters D_g^{air}, D_l^{water}, Koc, H, and the 2,3,7,8-TCDD soil half-life. Of various output options in EMSOFT, average volatilization rate was selected.

$$C_G = K_H C_L \qquad (7\text{-}18)$$

III. Steady-State Solution to the Jury Model: This steady-state, simplified solution to the Jury model was used in Superfund's soil screening model. The simplifying assumptions (in addition to other assumptions of the Jury approach) which allowed for this solution were: 1) there is no stagnant boundary layer, 2) there is no water evapotranspiration or leaching

(equivalent to the selection of 0 water flux in the full Jury model described above), 3) the chemical is at a uniform concentration from the soil surface until depth d_z, and 4) there is no degradation of the chemical over time. The volatilization flux rate, J_s, at any given time after t=0 when the uniform soil concentration is C_{T0}, is given by:

$$J_s(t) = C_{T0} \left(\frac{D_E}{\pi t} \right)^{1/2} \left(1 - \exp \left(\frac{-d_z^2}{4 D_E t} \right) \right) \quad (7\text{-}19)$$

where:

J_s	=	volatilization flux, g/cm^2-sec
C_{T0}	=	initial total concentration on a volumetric basis, g/cm^3
D_E	=	effective soil diffusion coefficient, cm^2/sec
d_z	=	depth of uniform soil concentration at t=0
t	=	time, sec

Equation (7-19) was derived specifically for the case where there is a finite reservoir of contaminant to volatilize; i.e., where the depth of contamination, d_z, is meaningful. At infinite depth, this term drops out. With a combination of large enough d_z and small enough D_E, the exponential term quickly approaches 0, so the parenthetical approaches 1 and can be neglected in the solution. Mayer, et al. (1974) suggests that the infinite reservoir solution is violated for a finite reservoir when t (time) exceeds $(d_z^2)/(14.4*D_E)$. With dioxin parameters, D_E is calculated to be $2*10^{-10}$. Therefore, time t calculates out to over 1000 years with d_z equal to 10 cm before the infinite solution becomes violated. Needless to say, the infinite reservoir steady state solution can be used for dioxin, and the exponential term can be neglected. The total soil concentration, or concentration expressed as mass divided by a volume of (soil+soil pore space), is required for this solution, rather than just the soil concentration expressed as mass of contaminant divided by mass of soil to which it is adsorbed. As discussed above, total soil concentration is the sum of the concentrations in soil, soil air, and soil water, and for 2,3,7,8-TCDD and similarly very tightly sorbed contaminants, the total volumetric soil concentration can be estimated as BD * Cs. The effective soil diffusion is given by:

$$D_E = \frac{D_G^{air} K_H a^{10/3}/\Phi^2 + D_L^{water} \theta^{10/3}/\Phi^2}{BD\ Kds + \theta + aK_H} \quad (7\text{-}20)$$

where:

D_E	=	effective soil diffusion coefficient, cm^2/sec
D_g^{air}	=	chemical air-gas diffusion coefficient, cm^2/sec
D_l^{water}	=	chemical liquid diffusion coefficient in water, cm^2/sec
θ	=	volumetric water content, cm^3/cm^3, or unitless
a	=	soil air content, cm^3/cm^3, or unitless
ϕ	=	soil porosity, cm^3/cm^3, or unitless
BD	=	soil bulk density, g/cm^3
Kd	=	soil/water partition coefficient, cm^3/g (= Koc * foc, as above)
K_H	=	dimensionless form of the Henry's Constant (= 41H, as above)

As can be seen in this formulation, Equation (7-19), the maximum volatilization flux decreases as time increases. Again, the Jury algorithm considers the depletion of the surface residues as a function of time. The Superfund Soil Screening Guidance document (EPA, 1996) suggests that this formulation, Equation (7-19), be run several times over the exposure duration in order to determine the average flux. However, assuming the infinite reservoir solution which neglects the exponential term in Equation (7-19) (and like the Hwang model), the average flux can more easily be calculated as, 2 * J_s (t), where t is the full duration of volatilization flux. That is what is assumed for this exercise.

The parameters required for this simplified solution to the Jury model are provided in Table 7-3, and these include the initial soil concentration of 2,3,7,8-TCDD, C_0 , the soil parameters foc, θ, ϕ, a, and BD, the exposure duration, and the chemical-specific parameters D_g^{air}, D_l^{water}, Koc, and H.

IV. State-State, Infinite Reservoir, Vapor-Phase Diffusion Only: If the liquid phase in the mass flux Equation (7-15) above is neglected, than the flux through soil can be very simply calculated as:

$$J_s = -D_G \frac{C_{G1} - C_{G0}}{d_z} \quad (7\text{-}21)$$

where:

J_s	=	chemical mass flux per unit soil are per unit time, g/cm^2-sec
D_G	=	effective soil diffusion coefficient, cm^2/sec
	=	$(a^{10/3}/\phi^2)\ D_g^{air}$; a, ϕ, and D_g^{air} defined as above
C_{G1}	=	concentration of the contaminant in soil air-filled pore space, g/cm^3
C_{G0}	=	concentration of the contaminant in air at the soil-air interface, g/cm^3
d_z	=	depth over which a constant concentration is assumed, cm

Maximum vapor phase diffusion occurs when C_{G0}, the concentration of the contaminant in air at the soil-air interface (essentially just above the soil surface), is set to 0.0, which is done for this solution. This assumes, essentially, that wind is sufficiently high to cause a 0 concentration directly above the soil. The concentration in air-filled pore space, C_{G1}, is simply solved as, (K_H Cs)/Kds, as described above. The depth of the soil column will be assumed to be 10 cm in this example.

The parameters required for this simplified vapor diffusion solution are provided in Table 1, and these include the initial soil concentration of 2,3,7,8-TCDD, C_0, the soil parameters foc, ϕ, a, and BD, and the chemical-specific parameters D_g^{air}, Koc, and H.

V. Results of Alternate Soil Volatilization Model Testing: The results of this simple test are shown in Table 7-4. This model comparison test showed that the Hwang model predicted an average flux over 30 years roughly four times higher than the average flux predicted by the full Jury model, and about three times higher than the simplified Jury model used in the Superfund Soil Screening methodology. The close match between the full Jury model coded in Fortran in EMSOFT and the simplified Jury solution coded into the spreadsheet was evidence that both models were correctly coded and used (or that they were both incorrect in the same way, which is unlikely). The exact reason for this three- to four-fold difference in the Jury versus the Hwang models was not investigated, and could lie in differences in assumed boundary conditions (Hwang, et al. (1986) discusses differences in boundary conditions between his and Jury's models). In any case, it is judged that both models predict comparable volatilization fluxes. On

the other hand, the vapor diffusion model predicted volatilization rates that were 100 times less than the Jury models and about 250 times lower than the Hwang models. The reason for this discrepancy could not be ascertained.

The Jury model was run altering the boundary layer assumption and the half-life assumption. The simplified Jury solution assumes no boundary layer to offer resistence to volatilization. That was one key reason that the simplified model predicted higher concentrations than the full Jury model. When the boundary layer assumption was reduced from 0.5 cm to 0.01 cm, the volatilization rate predicted by EMSOFT increased slightly from $2.8*10^{-19}$ to $3.0*10^{-19}$ g/cm^2-sec. Another simplification of the Soil Screening Methodology solution was that no soil degradation was assumed. The full Jury model in EMSOFT does allow for consideration of soil degradation. When the half-life was assigned a value of 25 years, which was what has been assumed for dioxins which had deposited in soils from distant sources in this document (depositing by air from incinerators or overland by erosion from contaminated soil sites), the average volatilization dropped slightly from $2.8*10^{-19}$ to $2.2*10^{-19}$ g/cm^2-sec.

These differences between the Hwang and Jury models are insignificant considering that the compounds modeled by this methodology - the dioxins, furans, and PCBs, are all relatively tightly bound and resist degradation in soil, so that losses in the 10^{-19} g/cm^2-sec range represent a minisicule part of the entire soil reservoir.

VI. Alternate Approaches for Dispersion of Soil-Emitted Dioxins: Near-field and far-field dispersion models are used to estimate air concentrations resulting from soil emissions, including volatilization and wind erosion, for the soil contamination source category. The near-field model can be used to estimate concentrations which occur on-site whereas the far-field model can be used to estimate off-site air concentrations. An alternate approach to estimating on-site dispersion given a volatilization flux is the "box-model" approach. This simple approach can be visualized as follows: air above soil is contained within a structure which has two walls, say a north and south wall, and a ceiling - wind blows through the building in an east-west direction mixing the volatilized flux. This is expressed mathematically as:

$$C_{air} = \frac{FLUX\ AREA\ 10^6}{b\ U_{mix}\ Z} \qquad (7\text{-}22)$$

where:

C_{air}	=	total concentration of contaminant in air, $\mu g/m^3$
FLUX	=	average volatilization + wind erosion flux rate of contaminant from soil, g/cm^2-sec
AREA	=	area over which flux occurs, cm^2
b	=	side length perpendicular to wind direction, m
U_{mix}	=	mean annual wind speed corresponding to mixing zone height, m/sec; estimated as ½*Um, where Um is average wind speed
z	=	mixing zone height, m
10^6	=	converts g to µg

Before testing the box-model equation, results for the approach used in this assessment are summarized. The key factors impacting air concentration calculations for the soil contamination source category include characteristics of the contaminant (Henry's Constant, etc.), the duration of exposure, the area over which contamination occurs, and whether the near field or far field dispersion algorithms are used. For the demonstration of the soil contamination scenario, Scenario 3, the contaminated soil area was 40,000 m^2 (10 acres). The exposure duration was 30 years. The flux of 2,3,7,8-TCDD was $1.11x10^{-18}$ g/cm^2-sec. The air concentration estimated for Scenario 3 where the exposure site was 150 meters from the site of soil contamination was 0.0043 pg/m^3. This calculation used the far field dispersion algorithm. When the flux rate is input into the near field algorithms, the air concentrations is a little over ten times higher at 0.045 pg/m^3.

The values used to evaluate the box model approach were the fluxes, as given above, the mixing zone wind speed, 2 m/sec, which is half the average wind speed assumed in this assessment, the areas noted above, the side length, estimated as the square root of the area, and a mixing zone height estimated initially at 2 m. The box-model air concentration is estimated at 0.55 pg/m^3. This is 10 times higher than the near-field dispersion modeling and 100 times higher than the far-field solution.

An uncertain parameter for both modeling approaches is the area of soil contamination. The mixing zone height for the box model is also a parameter of uncertainty. Users of the box model approach have often assumed a conservative 2 m height approximating the height of exposed individuals. However, others have claimed this is far too low a mixing height, suggesting 10 meters or even an atmospheric height closer to 100 meters. Higher mixing zone heights would have brought the box model estimations more in line with estimations made in this

assessment. The closest analogous parameter in the dispersion model to the mixing zone height is the height of exposed individual, which is more unambiguously the breathing zone height of 2 m.

One key assumption concerning the exposure site air concentrations resulting from a distant area of soil contamination should be questioned. The current approach assumes that air-borne contaminates originate at the site of contamination and are transported to the site of exposure. On the other hand, this assessment also assumes that exposure site soil becomes contaminated over time due to erosion. It is at least plausible that volatilization and wind erosion from soils other than the area of elevated contamination would contribute to air-borne contamination, and concentrations to which individuals are exposed to at sites of exposure near sites of contamination.

This was tested by using the near field algorithms and assuming soil concentrations predicted to occur at the exposure site. In more detail, the soil contamination demonstration scenario included a 10 ha field at 1 ppb 150 m from the exposure site, also at 10 ha. The soil concentrations estimated to occur at the exposure site were 0.39 ppb for a 2-cm no-till depth and 0.06 ppb for a 20 cm tilled depth. The near field algorithms for volatilization, wind erosion, and dispersion were run starting with these concentrations, and resulting concentrations were compared with those estimated to occur only from volatilization and wind erosion from the contaminated site followed by transport to the exposure site. The air concentration estimated to occur from untilled soil is about 4.3 times higher than that estimated to occur from the off-site area and transported; the air concentration estimated to occur from tilled soil is 25% less than estimated to occur from volatilization and transport.

This might imply that exposure site air concentrations are being underestimated if air concentrations at the site of exposure are assumed to only originate at the site of contamination, and not also at the site of exposure, or even from other areas. This exercise implies that the underestimation might be less than a factor of 5.0. Of course, this conclusion is contingent on the off-site impact algorithms which have estimated that a 0.39 or a 0.07 ppb soil concentration will result 150 meters from an area whose concentration is 1.00 ppb.

7.2.5. Alternate Models for Estimating Plant Concentrations from Soil Concentrations

The models of this assessment separate above and below ground vegetation for estimating concentrations. Root concentrations (roots are below ground vegetation) are a function of soil water concentrations and a Root Concentration Factor, RCF. Above ground vegetation, which in this assessment include above ground fruits and vegetables, pasture grass, and cattle feed, are

modeled as a function of vapor phase transfers and wet plus dry particle depositions. This section examines one alternate approach for above ground vegetation; alternate approaches for below ground vegetation could not be found.

One approach to modeling plant concentrations would be with passive uptake via evapotranspiration. The assumption here is that soluble phase contaminants move passively with transpiring water. This approach has been applied for contaminants which are soluble in water. However, nearly all the evidence suggests that this would not be appropriate for the dioxin-like compounds. Specifically, the evidence suggests that residues do not translocate to within portions of either above or below ground vegetation. Such would be case for soluble contaminants moving passively with transpiring water. This conventional wisdom was, however, challenged with recent experiments by Hulster, et al. (1994) on vegetation of the cucumber family. Their results were most striking for zucchini, which showed uniform plant concentrations from inner to outer portions of the zucchini fruit, and the highest whole fruit concentrations they had ever measured, despite careful experimental conditions which physically isolated the fruit from the soil. Pumpkins also showed high plant contamination, with more expected plant concentrations measured for the cucumber. Assuming the vegetation of this assessment - fruit/vegetables for human consumption and vegetation of the beef/dairy food chain - do not behave as in the Hulster, et al. (1994) experiments, than translocation to inner plant parts is not expected.

The specific issue of uptake and translocation via transpiration was investigated using soybean and corn plants grown hydroponically in carefully constructed growth chambers (McCrady, et al., 1990). Roots and the hydroponic growth solution were separated from the shoots and leaves of these plants using two separate chambers, one inverted over the other. Separate air-flow systems for each chamber included traps for volatile organics. Mass balance on the tritiated TCDD experiments was able to recover 98% in the soybean experiment and 86% for the corn experiment. Most of the recovered material was found in the roots; 75% for soybeans and 67% for corn, with the second highest recovery was on the inside surface of the root chamber, around 15% for both experiments. Recovered TCDD was also found, in order of decreasing percentage, in the growth solution, root chamber air, shoot chamber air, and shoots. The recovery from the shoots was negligible at 0.004% and 0.001% of the total TCDD for the soybean and corn, respectively. McCrady, et al. (1990) concluded that transpiration stream transport of 2,3,7,8-TCDD to plant shoots is an insignificant mechanism of plant contamination, and that volatilization of TCDD is an important transport mechanism that can result in significant quantities of airborne TCDD being absorbed by plant shoots.

Briggs, et al. (1982) provide another way to evaluate the translocation of contaminants from roots to above ground vegetation. Experiments with barley roots in growth solution led to the development of an empirical parameter describing the efficiency of transport of organic chemicals to plant shoots from root uptake. This parameter is called the Transpiration Stream Concentration Factor (TSCF) and is defined as (concentration in transpiration stream)/(concentration in external solution). The empirical formula presented for this factor is:

$$TSCF = 0.784\ e^{-[\log Kow - 1.78]^2 / 2.44} \quad (7\text{-}23)$$

Given a log Kow for 2,3,7,8-TCDD of 6.8, TSCF is solved for as roughly $2 * 10^{-5}$. Assuming that the concentration of external solution concentration for the experimental conditions of Briggs' experiments is equivalent to the concentration in soil water in a field situation, then the TSCF for 2,3,7,8-TCDD implies that the transpiration stream water of a plant is over 5 orders of magnitude lower than the soil water concentration. Like McCrady's experiments, this also shows the insignificance of translocation of residues from roots to shoots.

The one approach that was found that might have been used in the place of the algorithms for above ground vegetation, is simpler and more general in nature. It was developed from field data on above ground vegetation concentrations correlated to soil concentrations of contaminants and the octanol water partition coefficient (Travis and Arms, 1988). This correlation led to an empirical bioconcentration factor for vegetation, B_v, regressed against the contaminant log Kow, and defined by the authors as the concentration in above ground plant parts divided by the concentration in soil:

$$\log B_v = 1.588 - 0.578 \log K_{ow} \qquad n = 29,\ r = 0.73 \quad (7\text{-}24)$$

With 2,3,7,8-TCDD log Kow equal to 6.8, the B_v translates to a value of 0.0041. Note that this B_v is defined identically to the plant:soil contaminant concentration ratios that are discussed in Section 7.3.10 below which compares the model's estimations of these ratios with those found under experimental conditions. As discussed in that section, plant:soil ratios calculated using the soil contamination algorithms were in the range of 10^{-5} for bulky vegetables and 10^{-3} for leafy vegetation. It is not clear how to compare the B_v of 0.0041 to these ratios without retrieving the studies which Travis and Arms (1988) used, although this value is clearly

higher than the fruit/vegetable ratio and consistent with the grass/feed ratios. The studies used by Travis and Arms were not retrieved. An examination of the chemicals used by Travis and Arms show that 25 of 29 used are pesticides, which suggests that plant concentrations may be those of agricultural crops, which might make it a closer kin to bulky vegetables rather than leafy vegetation. If so, a comparison of the above-ground vegetable 10^{-5} ratio with this 0.0056 ratio would be appropriate. An examination of the chemicals also reveals that 10 of the 29 are moderately to very soluble (log Kow less than 4.00), while others are similarly insoluble as the dioxin-like compounds (including DDT, TCDD, Aroclor 1254, and others; 15 with log Kow greater than 5.0). Developing such an empirical relationship which mixes chemicals whose mode of action is passively with water (which would be the case with aldicarb and simazine, among others on the list) with those whose mode is through vapor transfers or particle depositions (TCDD, and so on) does not appear to be technically valid. Nonetheless, the fact that the Travis and Arms B_v is much higher than the plant:soil ratio for vegetables generated for the soil contamination source category demonstration is noted. Also, there is no provision in the Travis and Arms approach to distinguish between bulky and leafy vegetation, and this appears to be an important consideration for the dioxin-like compounds.

7.2.6. Alternate Modeling Approaches for Estimating Beef and Milk Concentrations

Webster and Connett (1990) compared five models which estimated the 2,3,7,8-TCDD content of cow's milk from 2,3,7,8-TCDD air contamination. The five models were described in Michaels (1989), Connett and Webster (1987), Stevens and Gerbec (1988), Travis and Hattemer-Frey (1987), and McKone and Ryan (1989). Ironically, a sixth model by Fries and Paustenbach (1990), noted by Webster and Connett as available but received too late for inclusion in their article, formed the basis for the approach taken in this assessment.

All five models compared by Webster and Connett have the same basic framework. Particulate-bound 2,3,7,8-TCDD deposits onto the ground and vegetation (cattle feed and pasture grass). Algorithms to estimate resulting vegetation and soil concentrations in these models are the same ones used in this approach, although parameter assignments are different. A daily dosage of 2,3,7,8-TCDD to the cattle is calculated and converted to a concentration in whole milk using a "biotransfer factor". This same structure was used to estimate concentrations in beef, using a beef biotransfer factor different than the milk biotransfer factor. Mathematically, this is expressed as:

$$C_{m,b} = F_{m,b} \; Dose \qquad (7\text{-}25)$$

where:

$C_{m,b}$	=	concentration in whole milk/beef, mg/kg
$F_{m,b}$	=	milk/beef biotransfer factor, day/kg
	=	$(BCF_{mf,bf} * f_{m,b})/Q$
$BCF_{mf,bf}$	=	experimentally-derived unitless bioconcentration factor defined as the concentration in milk fat/beef fat divided by the concentration in the experimental vehicle (cattle feed, e.g.); similar to BCF of this assessment
$f_{m,b}$	=	fat content of milk/beef, unitless
Q	=	daily mass intake of cattle in experiment, kg
Dose	=	total daily dose of 2,3,7,8-TCDD, mg/day
	=	sum $(a_j * c_j * Q_j)$
a_j	=	relative bioavailability on intake vehicle j (soil, air, vegetation, etc)
c_j	=	concentration of 2,3,7,8-TCDD in vehicle j, mg/kg (or equivalent units)
Q_j	=	mass of vehicle j intake, kg (or equivalent units)

Further details on the models can be found in their primary references and in Webster and Connett's comparison. Some highlights, including comparisons of the five approaches to the approach taken in this assessment, are:

1) Two of the approaches, that of Stevens and Gerbec (1988), and McKone and Ryan (1989), consider inhalation of contaminated air by cattle to contribute to their daily dose of 2,3,7,8-TCDD. One of the approaches, that of Travis and Hattemer-Frey (1987), considers ingestion of contaminated water by cattle. A later assessment by Travis and Hattemer-Frey (1991) has all the components of their earlier assessment, and adds cattle inhalation exposures. This assessment does not consider cattle inhalation of contaminated air nor ingestion of contaminated water in estimating beef and milk concentrations. However, these intakes were shown to be insignificant when estimated by these researchers. Stevens and Gerbec estimate inhalation contributions to be less than 0.05% (0.0005 in fractional terms) of total daily dose, or an essentially insignificant amount. Travis and Hattemer-Frey (1991) estimate inhalation to contribute between 0.3 and 1.0% to milk and beef concentrations, respectively. McKone and Ryan (1989) did not provide sufficient information to easily determine the relative contribution

of inhalation on estimation of cattle beef and milk concentrations by their estimations. Travis and Hattemer-Frey (1987, 1991) estimate water contributions to be less than 0.01% (0.0001) of total daily cattle dose of 2,3,7,8-TCDD.

2) None of the approaches considered vapor phase transfers from air to plant, although Webster and Connett recommended its inclusion in their article. The later assessment by Travis and Hattemer-Frey (1991) on 2,3,7,8-TCDD did include vapor phase transfers into vegetation consumed by cattle. According to results of the example scenarios in this assessment, these transfers appear to be particularly critical, and this was also the conclusion of Travis and Hattemer-Frey based on their modeling results.

3) Two of the assessments, that of Stevens and Gerbec (1988) and Fries and Paustenbach (1990) considered a period of residue-free grain only diet for a period of time before slaughter for purposes of fattening the cattle. Stevens and Gerbec (1988) assumed that the residues in cattle would depurate during the last 130 days of their lives on this regime. Assuming a half-life of 2,3,7,8-TCDD in cattle of 115 days, they showed a 54% reduction in beef concentrations due to this practice. Fries and Paustenbach (1990) note that cattle can gain as much as 60-70% in body weight, so dilution can also result in lower beef concentrations at slaughter. Based on these findings, a "feedlot fattening" factor of 0.50 was used in the air-to-beef model validation exercise that is described in Section 7.3.12. The procedures to estimate a reduction in concentration used by these researchers is straightforward. Assuming first order kinetics sufficiently describes reduction in concentrations during a period prior to slaughter, the fractional reduction during such a period is given as, $1 - \exp(-k_d t)$, where k_d is the depuration rate constant, in $days^{-1}$, and t is the depuration period, in days. The rate constant can be estimated from the depuration half-life, HL, as 0.693/HL. The 115 day half-life assumed by Stevens and Gerbec (1988) corresponds to a rate constant of 0.006 day^{-1}, and assuming a 130 day depuration period, the fractional reduction is easily calculated as 0.54 (i.e., $1 - \exp(-k_d t)$). The amount remaining after 130 days is estimated as the initial amount multiplied by 0.46 (i.e., $\exp(-k_d t)$).

4) Two of the assessments did not assume any cattle ingestion of contaminated soil, and two of the assessments estimated the contribution to milk concentrations due to ingestion of contaminated soil was minor at 1 and 2%. Only one of the assessments, Travis and Hattemer-Frey (1987), estimated any significant impact due to soil ingestion, attributing 19% of the concentration due to ingestion of contaminated soil. Their later assessment (Travis and Hattemer-Frey (1991)) estimated soil to contribute 29 and 20% of beef and milk concentration estimations, respectively. They estimated this high a contribution by contaminated soil even though they assumed that contaminated soil comprised 1% of the total dry matter intake by cattle.

Fries and Paustenbach (1990) recognized the importance of cattle soil ingestion, evaluating scenarios where cattle soil ingestion ranged from 1 to 8% of total cattle dry matter intake.

The example scenarios in Chapter 5 assumed that beef cattle ingestion of contaminated soil was 4% of their total dry matter intake, and 2% of a dairy cattle's intake was contaminated soil. The percentage of beef and milk concentrations of 2,3,7,8-TCDD attributed to soil, feed, and pasture grass, when soil contamination is the source and when stack emissions are the source, was examined in Section 6.3.3.6 in Chapter 6. It is noted there that soil ingestion appears significantly more critical for soil contamination as compared to stack emissions. Soil ingestion by beef and dairy cattle explain around 90% of final beef and milk concentration for soil sources. On the other hand, soil ingestion explained only around 5% of final beef and milk concentration for the stack emission source.

The earlier literature noting only 1-2% impact by soil ingestion were more analogous to the stack emission source category than the soil source category, in that impacts were estimated starting from air-borne contaminants depositing onto soils and vegetation. One difference in the assessments estimating the 1-2% impact with this assessment indicating about 5% impact was that the other assessments assumed less soil ingestion, 0.5% in Stevens and Gerbec (1988) and 1-3% in Travis and Hattemer-Frey (1987) and McKone and Ryan (1989).

The critical focus of the Webster and Connett (1990) comparison, is the milk fat bioconcentration factor, BCF_{mf}. As shown in Equation (7-25), the biotransfer factor, F_m, is estimated using experimental data which yields a milk fat bioconcentration factor, BCF_{mf}. Experiments most relied upon by these modelers are those described in Jensen, et al. (1981), and Jensen and Hummel (1982). A key difference in the early modeling approaches is the interpretation of these two and other studies and the resulting assignment of BCF_{mf}, with values ranging from 5 to 25. Webster and Connett (1990) discuss issues of experimental interpretation.

Parameter assignments and assumptions (cattle soil ingestion versus no ingestion, etc.) obviously all impact estimations and can be a critical source of variation and uncertainty in estimates of beef and milk concentrations. The uncertainty associated with the modeling framework described above was explored by McKone and Ryan (1989) using Monte Carlo techniques. They found that the 90% confidence range for human exposure to 2,3,7,8-TCDD, where the source was air contamination and the human exposure route was through milk, spanned two to three orders of magnitude.

The approach taken by all five researchers centers on the milk biotransfer factor, abbreviated F_m in Webster and Connett (1990) and in units of day/kg. Beef bioaccumulation was modeled in the same way using a beef biotransfer factor, F_b. Travis and Arms (1988) developed

this concept to the fullest, taking several data sets from the literature on a variety of contaminants and animals, to derive empirical formulas for F_b and F_m, which they termed B_b and B_m, as a function of contaminant octanol water partition coefficient, Kow:

$$\log B_b = \log Kow - 7.6 \quad (7\text{-}26a)$$

$$\log B_m = \log Kow - 8.1 \quad (7\text{-}26b)$$

Given a log Kow of 6.8 for 2,3,7,8-TCDD (assumed in this assessment), B_b is solved for as 0.16 and B_m is solved for as 0.05. Travis and Hattemer-Frey (1991) used 0.80 and 0.03 for 2,3,7,8-TCDD B_b and B_m.

Simple transformations can show how the earlier approaches, summarized above in Equation (7-25), and the approach of Fries and Paustenbach (1990) (which is the approach used in this assessment), are the same. First, the concentration of dioxin-like compounds in the fat of beef and milk is given in this assessment by (also see Chapter 4):

$$C_{fat} = BCF\ DF_s\ B_s\ AC_s + BCF\ DF_g\ AC_g + BCF\ DF_f\ AC_f \quad (7\text{-}27)$$

where:

C_{fat} = concentration in beef fat or milk fat, mg/kg
BCF = bioconcentration ratio of contaminant as determined from cattle vegetative intake (pasture grass or feed), unitless
DF_s = fraction of cattle diet that is soil, unitless
B_s = bioavailability of contaminant on the soil vehicle relative to the vegetative vehicle, unitless
AC_s = average contaminant soil concentration, mg/kg
DF_g = fraction of cattle diet that is pasture grass, unitless
AC_g = average concentration of contaminant on pasture grass, mg/kg
DF_f = fraction of cattle diet that is feed, unitless
AC_f = average concentration of contaminant in feed, mg/kg.

Transformation steps are: 1) factor out the BCF from Equation (7-27) , 2) multiply Equation (7-27) by unity expressed as Q/Q, where Q equals total dry matter intake by cattle; 3) the multiplication of Q by the diet fraction terms, DF_s, DF_g, and DF_f, gives the values for soil dry matter intake, Q_s, grass - Q_g, and feed - Q_f, 4) with BCF factored out, and Q*DFs replaced by Q_s, etc., the parenthetical now reads, (Qs*Bs*ACs + Qg*ACg + Qf*ACf) - this is the "Dose" term defined earlier in Equation (7-25), 5) finally, multiply the right hand side of Equation (7-27) by fat content, say f_m for milk, which would transform the right and hence left hand side of that equation to whole product concentration. Transformed Equation (7-27) is analogous to Equation (7-25):

$$C = \frac{BCF\ f_m}{Q} \left[Q_s\ B_s\ AC_s + Q_g\ AC_g + Q_f\ AC_f \right] \qquad (7\text{-}28)$$

While this analysis has shown how the biotransfer approach can be transformed into the bioconcentration approach of this methodology, one has to be careful with the assignment of the biotransfer and bioconcentration parameters. The following analysis shows why the Travis and Arms (1988) empirical algorithms shown above in Equations (7-26a) and (7-26b) are not appropriate for dioxin-like compounds.

McLachlan, et al. (1990) kept an inventory of the dioxins ingested by a lactating cow as well as the dioxins being emitted through the milk. This was the data used to develop the bioconcentration factors for the dioxins used in this assessment. The volume of milk generated by the cow was also given, allowing for the calculation of the biotransfer factor. The experimental biotransfer factor for milk derived from McLachlan's data is compared against the factor which can be estimated using the log Kow of the individual dioxin congeners (the congener log Kow are listed below in the issue regarding TEQ parameters) combined with the Travis and Arms (1988) biotransfer equation:

Congener	Travis and Arms B_m	McLachlan B_m
2378-TCDD	0.03	0.01
12378-PCDD	0.03	0.01
123478-HxCDD	0.49	0.006
123678-HxCDD	0.16	0.005
123789-HxCDD	0.16	0.005
1234678-HpCDD	1.26	0.001
OCDD	0.31	0.001

2378-TCDF	0.03	0.003
23478-PCDF	0.07	0.009
12378-PCDF	0.05	0.002
123478-HxCDF	0.16	0.007
123678-HxCDF	0.16	0.006
123789-HxCDF	0.16	0.006
234678-HxCDF	0.16	0.005
1234678-HpCDF	0.63	0.001
1234678-HpCDF	0.63	0.003
OCDF	5.00	0.001

It is clear that the Travis and Arms' biotransfer relationship will greatly overestimate the transfer of dioxins into milk, given the data of McLachlan. It would appear from McLachlan's data that as the log Kow increases, the biotransfer decreases, which is the opposite of the trend implied from the Travis and Arms' relationship.

The Travis and Arms trend is explainable, however, given the data from which Travis and Arms developed their relationship. In their literature article, they supplied the log Kow and the experimentally derived biotransfer factor for all the data points they used to derive their empirical relationship. For determining a milk biotransfer factor, they had 28 data points, and only 6 of them were for chemicals with log Kow greater than 6.00. The range of log Kows for data they had was 2.8 to 6.5. The dioxin-like compounds, on the other hand, have log Kow that range from 6.5 to 8.0. In this 2.8-6.5 log Kow range, it would appear that as log Kow increases, the tendency to bioaccumulate in milk increases. Interestingly, of the 6 data points Travis and Arms had for chemicals with log Kow over 6.00, their actual data point leads to a higher biotransfer point than is calculated with their derived empirical relationships:

Chemical	log Kow[1]	B_m from the data[2]	B_m calculated[3]
Aroclor 1254	6.47	0.01	0.02
Chlordane	6.00	0.0004	0.008
DDD	6.02	0.003	0.008
fenvalerate	6.20	0.0008	0.01
mirex	6.89	0.009	0.06
TCDD	6.15	0.01	0.01

[1] as used by Travis and Arms
[2] the actual data point claimed by Travis and Arms (1988)
[3] as calculated with Equation (7-26b)

As discussed above, it would appear that the trend of higher bioaccumulation with higher log Kow is true for the range of log Kow used by Travis and Arms - 2.8 to 6.5. However, for the dioxin congeners where log Kow is higher at 6.5 to 8.0, the trend is the opposite - the biotransfer decreases as the log Kow increases. This could be due to greater rates of metabolism for organic compounds of higher log Kow, or just for the dioxins, leading to lower concentrations in the animal food products. In any case, it is clear that the Travis and Arms' biotransfer factor equations for beef and milk are not appropriate for the dioxin-like compounds, and perhaps as a general rule, for other organic compounds with log Kow 6.5 or higher.

Douben, et al. (1997) compares three approaches for air-to-plant-to-milk modeling. One of the approaches is the one of this document. The second employs the "carryover" factor, which is very similar to the biotransfer factor defined above. Whereas the biotransfer factor is defined as the concentration in milk (mg/L, e.g.) divided by the mass of dioxin ingested (mg/day), the carryover factor is defined as the mass of compound excreted in milk (mg/day) divided by the mass of dioxin ingested (mg/day). Douben, et al. (1997) assigns values to the carryover factor based on the data of McLachlan, et al. (1990). The third approach is the "scavenging" approach developed by McLachlan (1995) and described above for the transfer of dioxins from air to grass. McLachlan (1995) developed the concept further to show that the concentration in milk can be estimated as a function of the total mass of dioxins ingested by the dairy cow (equal to the dry weight of vegetation consumed times the scavenging coefficient times the air concentration) times the absorption fraction (the amount absorbed by the dairy cow) divided by the mass of milk excreted each day:

$$C_{milk} = \frac{CA_j \left(SC_g M_g + SC_s M_s \right) ABS_j}{LAC} \qquad (7\text{-}29)$$

where:

C_{milk} = milk concentration, ng/kg (ppt; 1 liter = 1kg)
CA_j = concentration of congener j in air, ng/m^3
SC_g = scavenging coefficient for grass, m^3/g
M_g = mass of grass ingested, g/day
SC_{cs} = scavenging coefficient for corn silage, m^3/g
M_{cs} = mass of corn silage ingested, g/day
ABS_j = absorption fraction for congener j

LAC = lactation rate, kg/day

Assuming 9 kg dry weight of grass and 4 kg dry weight of corn silage ingested per day, and scavenging coefficients for grass and silage to be 9 and 4.5 m^3/g, respectively, Douben, et al (1997) reduced the parenthetical above to a constant of 100,000 m^3/day (actually calculates to 99,000). They were able to test the model assuming a lactation rate of 0.6 kg/day and using absorption efficiencies provided in McLachlan (1995). While differences in specific congener/model predictions were noted, Douben, et al. (1997) generally found comparable predictions for milk TEQ concentrations - all were within a factor of 5 of observed concentrations.

One critical theoretical assumption not explored in these modeling comparison exercises is whether 2,3,7,8-TCDD and other congeners bioaccumulate equally in beef fat and milk fat - are the BCF_{mf} and BCF_{bf} equal? Fries and Paustenbach (1990) emphasize that differences in observed concentrations in beef and milk are critically a function of the differences in the diets of cattle raised for beef versus those raised for milk. They assumed that the beef and milk bioconcentration factor was equal for their example calculations. The key difference Fries and Paustenbach cite is the tendency for beef cattle to graze while lactating cattle are more often barn fed. Grazing cattle intake more contaminated soil than barn fed cattle. Fries and Paustenbach derived F for higher chlorinated dioxin-like compounds from experimental data, noting that the F value is less with higher chlorination. Webster and Connett (1990) made the analogous observation, saying that 2,3,7,8-TCDD equivalents transferred from air to milk less efficiently than 2,3,7,8-TCDD. This is also consistent with the data of McLachlan, et al (1990), which is used in this assessment for assignment of BCFs to dioxin-like compounds.

Besides different diets between beef cattle and lactating cows is that lactation provides a mechanism for dioxin excretion from the body, which theoretically would lead to body fat concentrations in lactating cows being less than body fat concentrations in non-lactating cattle which don't have this excretion mechanism. However, researchers have observed that the dioxin concentrations in the fat of milk and of body fat in non-lactating cattle are similar. McLachlan (1994) attributes this to the fact that cattle are most often slaughtered while they are still growing and increasing their body fat reservoir. Therefore, dioxins appear to reach steady state in the fat of non-lactating cattle at concentrations similar to those found in cow's milk.

Some conclusions from this analysis of these efforts for estimating bioconcentration in beef and milk are:

- Although the biotransfer and carryover frameworks look different than the framework used in this assessment, they are actually the same with a simple mathematical transformation;
- All of these approaches are empirical; that is, values for the critical dioxin-specific parameters (scavenging coefficients, carryover factors, bioconcentration factors, biotransfer factors) are developed from field data. When they are developed by different researchers on different field data, they will (of course) not predict equally. However, and as evidenced by the results of Douben, et al. (1997), they all appear to predict milk TEQ concentrations about equally.
- A caution is noted, nonetheless, with the use of the Travis and Arms (1988) empirical algorithm for the assignment of biotransfer factors for the dioxin compounds: as described above, this empirical relationship does not hold for the dioxin-like compounds, which have higher log Kow than the log Kow of the compounds used by Travis and Arms (1988) to develop their relationship. Provided above are biotransfer factors for dioxins developed from the same data used to develop the bioconcentration factors of this methodology.
- The possible dosage to cattle of 2,3,7,8-TCDD via contaminated air or water was considered in earlier assessments, but was not found to be a significant pathway, and was not considered in this assessment;
- Earlier assessments (before 1990) did not consider vapor phase transfers to vegetation consumed by cattle; key studies in the literature as well as the results of the demonstration scenarios suggest that this transfer is particularly critical;
- Even though the structure of the analysis has been consistent from the earlier to the current approaches, different assumptions on parameter values greatly impacts modeling results. The critical bioconcentration factor, earlier termed BCF_m (for milk) and termed simply BCF in this assessment, has been estimated to be between 5 and 25 for 2,3,7,8-TCDD in different assessments. This assessment uses a BCF value of 5.76 for 2,3,7,8-TCDD. Using Monte Carlo techniques on this model structure for estimating human exposure to milk resulting from air contamination of 2,3,7,8-TCDD, McKone and Ryan (1989) showed a 90% confidence interval spanning 2 to 3 orders of magnitude.

7.2.7. An Alternate Approach to Vapor/Particle Partitioning in the Air

Chapter 3 described the application of the Junge (1977) and Pankow (1987) model for partitioning air-borne dioxin-like compounds into vapor and particle phases. The governing equation for this model is:

$$\phi = \frac{c\,\Theta}{p^{\circ}_{L} + c\,\Theta} \qquad (7\text{-}30)$$

where:

ϕ = fraction of the compound adsorbed to aerosol particles

p°_{L} = saturation liquid phase vapor pressure of the pure compound at ambient temperature, Pa

Θ = the particle surface area per unit volume of air, cm^2 aerosol/cm^3 air

c = a constant which is related to the difference between the heat of desorption from the particle surface, Q_d, and the heat of vaporization of the compound, Q_v. The value of c is often estimated at 17.2 Pa-cm

A disadvantage to using this model is that the parameters Θ and c in this equation must be estimated as they cannot be measured directly. There is also uncertainty is the saturation liquid vapor pressure, p°_{L}, which must be estimated from the solid-phase vapor pressure, p^{o}_{S}. Assignment of these parameters and the development of the vapor/particle partitioning algorithm is provided in Chapter 3.

A second model was developed in the latter part of the 1990s and is now widely used to characterize the partitioning of semivolatile organic compounds to aerosol particles (Finizio et al. 1997, Harner and Bidelman, 1998; Pankow, 1998). The derivation of this model begins with this alternate equation for the particle fraction, ϕ:

$$\phi = \frac{C_p\,(TSP)}{C_g + C_p\,(TSP)} \qquad (7\text{-}31)$$

where:

ϕ = fraction of the compound adsorbed to aerosol particles

C_p = the concentration of semivolatile compounds associated with aerosols, ng/μg particles
C_g = the gas-phase concentration, ng/m^3
TSP = the total suspended particle concentration, μg/m^3

Defining the ratio of the particle phase to the gas phase (C_p/C_g) as K_p, a particle-gas partition coefficient, and dividing all terms on the right side of the equation by C_g, Equation (7-31) can be rewritten as:

$$\phi = \frac{K_p\ (\ TSP\ )}{1\ +\ K_p\ (\ TSP\ )} \qquad (7\text{-}32)$$

Once deriving K_p, ϕ can be solved for in this equation. K_p can be measured in the field, but alternately it has been related to the octanol air partition coefficient, Koa (Finizio et al., 1997):

$$K_p = 10^{-9}\ K_{oa}\ f_{om}\ (\gamma_{oct}/\gamma_{om})(M_{oct}/M_{om})/\rho_{oct} \qquad (7\text{-}33)$$

where:

K_p = particle-gas partition coefficient, m^3/ng
K_{oa} = octanol air partition coefficient, dimensionless
f_{om} = fraction of organic matter in the aerosol involved in partitioning
$\gamma_{oct,\ om}$ = activity coefficients in octanol and aerosol organic matter
$M_{oct,\ om}$ = molecular weights of octanol (130 g/mol) and the organic matter
ρ_{oct} = density of octanol, 820 kg/m^3

Simplifying assumptions that have been made for this formulation include that γ_{oct}/γ_{om} and M_{oct}/M_{om} are equal to 1 (Bidleman and Harner, 2000), leading to:

$$Log\ K_p = Log\ K_{oa} + Log\ f_{om} - 11.91 \qquad (7\text{-}34)$$

Bidleman and Harner (2000) make the further simplification that urban aerosols contain 15% carbon, present as compounds with the average molecular formula of octanol (74% carbon), thus leading to an assignment of 0.20 for f_{om}, and this equation:

$$Log\ K_p = Log\ K_{oa} - 12.61 \quad (7\text{-}35)$$

The octanol air partition coefficient is directly measurable at ambient temperatures and has been reported for several classes of semivolatile organic compounds, including PCBs (Harner and Bidleman, 1996; Komp and McLachlan, 1997), PAHs (Harner and Bidleman, 1998), polychloronaphthalenes (Harner and Bidleman, 1998), and other compounds (Harner and MacKay, 1995). However, measurements of K_{oa} for dioxin-like dioxin, furan, and PCB congeners could not be found in the literature. Alternately, K_{oa} can be estimated from the ratio of the octanol water partition coefficient and the Henry's Constant, as:

$$K_{oa} = \frac{K_{ow}\ R\ T}{H} \quad (7\text{-}36)$$

where:

K_{oa}	=	octanol air partition coefficient, dimensionless
K_{ow}	=	octanol water partition coefficient, dimensionless
R	=	universal gas constant, $8.2*10^{-5}$ atm-m^3/mole-K
T	=	ambient temperature, K
H	=	Henry's Constant, atm-m^3/mole

Lee and Jones (1999) discuss the difference between the K_{oa} calculated in this manner and measured values. For PCBs, they cite literature showing that measurements of K_{oa} were 1.4 to 4.7 times higher than modeled K_{oa}. Using a relationship derived for PCBs, they attempted a correction for the dioxin-like compounds. For this section, Equation (7-36) will be used to model the K_{oa} for dioxin-like compounds.

Another approach taken by some to develop a more site-specific relationship between K_{oa} and K_p is to measure the gas and particle fractions for a given site and compound, and then directly assign values for K_p (as C_p/C_g). Then, these site-specific K_p can be correlated to reported or estimated K_{oa} using the general formula:

$$Log\ K_p = m\ Log\ K_{oa} + b \quad (7\text{-}37)$$

Kaupp and McLachlan (1999) took measurements of polychlorinated dibenzo-p-dioxins (PCDDs), dibenzofurans (PCDFs), polychlorinated biphenyls (PCBs), napthalenes (PCNs), and polycyclic aromatic hydrocarbons (PAHs) over the course of a year in southern Bavaria. They investigated the relationship between K_p and the saturation liquid vapor pressure, $p°_L$, as well as the relationship between K_p and K_{oa}, using the generalized logarithmic equation shown above. They found a good correlation between K_p and $p°_L$ when they grouped PCDD/Fs and PCBs (r^2 = 0.93) and separately when they grouped PAHs and PCNs (r^2 = 0.98), but not when they grouped all four sets of compounds together. On the other hand, they found a reasonable correlation existed for the whole group of four compound classes when they correlated K_p and K_{oa} (r^2 = 0.76). The linear relationship they found was:

$$Log\ K_p = 0.6368\ Log\ K_{oa} - 8.9111 \quad (7\text{-}38)$$

Given values of K_{oa}, K_p can be solved for using Equations (7-38) or (7-35). In order to compare this approach for assigning vapor/particle partitioning with the one chosen for this document (the Junge-Pankow model based on the saturation liquid vapor pressure), these two versions of the particle-gas partition coefficient, K_p, will be generated from K_{oa}. In both cases, the octanol air partition coefficient, K_{oa}, will be assigned values based on Equation (7-36) since measured values the dioxin-like compounds could not be found in the literature. Then, the two sets of K_ps will be used to predict values of the particle phase fraction, ϕ, as given in Equation (7-32). As described in Chapter 3, four values for the atmospheric particle concentration, the parameter TSP of Equation (7-32), describe four conditions termed, "clean continental", "background", "background plus local sources", and "urban". For this exercise, the value selected for urban conditions, 98 $\mu g/m^3$, will be used. Finally, the two sets of ϕ for the 17 dioxin and furan congeners generated here using K_{oa} will be compared with the ϕ generated in this methodology document using the Junge-Pankow model. This comparison is shown in Table 7-5.

As shown there, while the trend is generally similar between the two models (higher particle fraction as the degree of chlorination increases), there is a large discrepancy between the predictive methods. The calculation of the particulate fraction, ϕ, using the Junge-Pankow model, results in much larger values as compared to the procedure described in this section using

the octanol air partition coefficient. A similar discrepancy is found when calculating ϕ for other atmospheric conditions and lower values of the particle density term, TSP - background plus local conditions, background, and clean continental. There is not much difference in using a theoretical relationship between K_{oa} and K_p given above in Equation (7-35) or the empirical relationship shown as Equation (7-38).

The same discrepancy between the Junge-Pankow model and the K_{oa} model was found in two studies which both measured the concentration and partitioning of dioxin-like compounds in air and then tried to predict the particulate fraction using the same two models described in this section (Lee and Jones, 1999; Oh et al., 2001). Not only did both studies find that the octanol air partition coefficient method predicted a much smaller fraction to occur in the particulate phase for all congeners and homologue groups modeled, but they also both concluded that the octanol air partition coefficient method fit the measured data better. Chapter 3 discussed the general trend that the Junge-Pankow model based on $p°_L$ would lead to greater particulate fractions than measured, but it also discussed issues identified for the measurement of dioxin-like compounds - that "blow-off" and other causes could cause the filter-PUF derived measurements to be overestimates of the vapor phase fraction (equivalently, they would underestimate the particle phase).

In any case, this methodology document recommends use of the Junge-Pankow model for vapor/particle partitioning and, in particular, derives a set of particle-phase fractions for four atmospheric conditions for the dioxin-like compounds. The results of this analysis are shown in Table 3-7 of Chapter 3. Further, these results are used in several model validation exercises in this chapter, including air-to-leaf modeling, air-to-soil modeling, and air-to-leaf-to-beef modeling. Users may, of course, use other modeling approaches for the dioxin-like compounds, including the alternate vapor/particle model based on the octanol air partition coefficient described in this section.

7.3. MODEL VALIDATION EXERCISES

7.3.1. The Impact of Dioxin Soil Contamination to Nearby Soils

Contaminated soils from a bounded area of soil contamination are assumed to migrate via erosion and impact the soils of a nearby exposure site. This section examines the model algorithms for estimating impacts to nearby soils from a contaminated soil source.

Contaminated soils erode onto a nearby site of exposure and mix into a depth of either 2 cm for untilled conditions or 20 cm for tilled conditions. The 2-cm depth was chosen as the mixing depth for both depositing residues in the stack emission source category and for residues

migrating from a contaminated site to a nearby impacted site in the soil contamination source category. This 2-cm depth replaced the 1-cm depth which was the value selected for earlier versions of this dioxin exposure reassessment (EPA, 1992a; EPA, 1994). Principal justification for this assumption came from a report showing soil concentration profiles taken at 2 cm increments to be generally uniform for background undisturbed soils to a depth of 5 cm, with dropoffs in concentrations below this (Brzuzy and Hites, 1995). For two sandy profiles, the peaks were found at greater than 30 cm. The authors speculated that their findings are the result of depositions corresponding to the rise of dioxins in the environment starting 50 or so years ago. A mixing depth of 5 cm may be more appropriate for the algorithms of this assessment if a source being evaluated has been emitting for that length of time. However, exposure durations and source emissions for the categories of this assessment are likely to be emitting for substantially less than the past 50 years, justifying the selection of 2 cm for the untilled mixing depth.

A *contaminant concentration ratio* is defined for purposes of this discussion as the ratio of soil concentration at the site of exposure to the soil concentration at the site of contamination. For example Scenario 3, soil eroded from a 40,000 m^2 (10-acre) contaminated site was assumed to partially deposit onto a 40,000 m^2 exposure site. The contaminant concentration ratio was 0.39 for the 2-cm depth of mixing at the site of exposure and 0.06 for the 20-cm mixing depth**.**

Data to rigorously validate the approach taken in this assessment to model the impacts of soil erosion from a site of contamination to a nearby site is unavailable. However, there have been documented evidence of migration of 2,3,7,8-TCDD away from industrial sites with soil contamination of 2,3,7,8-TCDD, resulting in off-site soil contamination. Off-site soil concentrations of concern were identified in 7 of 100 Tier 1 and Tier 2 sites of the National Dioxin Study (EPA, 1987). The study noted that in most cases, 2,3,7,8-TCDD had not migrated off-site. Most, but not all, Tier 1 and 2 sites did have some off-site soil sampling without detection. It should be noted, however, that soil detection limits for most of these 100 Tier 1 and 2 sites were at 1 ppb; this would have precluded finding concentrations less than 1 ppb in some of the off-site soil sampling, particularly important for many of the sites where on-site detections were in the low ppb range. Summary data from the 7 sites noted above is provided in Table 7-6. Contaminant concentration ratios cannot be evaluated by this summary because of lack of detail provided in the National Dioxin Study.

Further detail on the 1984 sampling at the Dow Chemical site in Midland is provided in Nestrick, et al. (1986). An evaluation of the information in that reference is more informative than the Dow Chemical summary in Table 7-6. The entire site is 607 hectares. On-site sampling

included areas identified as chlorophenolic production areas, a waste incinerator area, and "background" areas. Background areas were within the 607 ha site but away from production areas. Two of the on-site areas were further identified as areas with Localized Elevated Levels (LELs). These two areas comprise less than 0.5% of the total site area, but had the three highest occurrences of 2,3,7,8-TCDD at 25, 34, and 52 ppb. Including these three high occurrences in the total of 33 samples taken on-site at sites of concern (i.e., not including the background sites) leads to an average concentration of 4.3 ppb; excluding them leads to an average of 1.0 ppb. The average of 11 background samples (including two ND assumed to be 0.0) was 0.15 ppb. A contaminant concentration ratio of 0.035 is calculated assuming an average concentration for contaminated soil of 4.3 ppb (0.15/4.3 = 0.035), and a ratio of 0.15 is calculated if the average soil contamination concentration is more like 1.0 ppb rather than 4.3 ppb.

This ratio of 0.035 is about one-tenth as much as the 0.39 ratio estimated assuming the shallow 2-cm depth of contamination, although the ratio of 0.15 is similar to the 0.39 ratio of Scenario 3. The depth of 20 cm led to a modeled ratio of 0.06, which is more in line with the Dow contaminant ratio of 0.035. The 2-cm depth ratios are probably more pertinent for comparison, however, since it is unlikely that there were tillage operations (or other soil practices which would distribute residues) in background areas of the 607 ha Dow site.

It appears reasonable that the no-till contaminant ratio of 0.39 is higher than the Dow ratios for several reasons. First, the contaminated areas sampled were those likely to be of concern and comprising only a small percentage of the total 607 hectare site. That might question the representativeness of 4.3 ppb as average soil contamination in impacted areas; the three highest concentrations came from specifically identified LELs comprising only 0.5% of the 607 ha site area. Second, a map provided in Nestrick, et al. (1986) including a distance scale clearly shows that all of the background samples were much further than 150 meters from the contaminated sample points, with several sample points hundreds to over a thousand meters from the contaminated sample points. The contaminant concentration ratio of example Scenario 3, 0.39, was estimated with a distance of 150 meters. Third, the example scenarios had specific assumptions about erosion which may or may not have been appropriate for application to the Dow site.

Ideally validation of the soil erosion model would involve direct application at the Dow site and comparison of predicted values to measured values. This was not feasible due to lack of information regarding the Dow site. Instead, this analysis has shown that the model predictions of contaminant concentration ratios differ logically from observed ratios at the Dow site.

7.3.2. Soil Concentrations and Concurrent Concentrations in Bottom Sediments and Fish

The Connecticut Department of Environmental Protection (CDEP, 1992; MRI, 1992) established a program in 1986 for monitoring TCDD, TCDF, and other dioxin-like isomers of comparable toxicity in several environmental matrices near resource recovery facilities (RRFs). Matrices monitored include ambient air, residues and leachate from the ash disposal sites, surficial soils, surface water surficial bottom sediments, and whole fish. The purpose of the program is to evaluate the impact of RRFs. Eight locations were evaluated through 1990, with one location serving as a baseline or reference site. Of the seven remaining locations, RRFs began operation in 1983 (1 RRF), 1987 (3), 1988 (1), and 1990 (2). This section will examine the soil, sediment, and fish data from that program.

The soil concentrations throughout all eight sites might be characterized as typical of background concentrations mainly because the concentrations of 2,3,7,8-TCDD measured through 1990 averaged 0.56 ppt (n = 77; assuming non-detects were ½ detection limit), with roughly a 50% non-detect rate (at a detection limit which has varied by data set, but has been around 0.1 ppt). In studies measuring soil concentrations of 2,3,7,8-TCDD in background or rural settings, either none was found, or concentrations were found in the low ppt range - this seems to also characterize the Connecticut data. For example, the soil concentration of 2,3,7,8-TCDD of 0.37 used in the background demonstration scenarios in Chapter 5 was measured at a rural background site located 28 miles from Columbus, Ohio. In a statistical analysis of the Connecticut data collected through 1988, the average soil concentration for 2,3,7,8-TCDD as 0.44 ppt (n = 42; CDEP, 1992; same procedures for estimating average concentrations), which is lower than the 0.56 ppt concentration for all samples through 1990. Concentrations of 2,3,7,8-TCDF taken after 1988, however, are lower than those taken in 1987 and 1988: the average including samples through 1988 was 8.20 ppt (n = 41; CDEP, 1992); while through 1990 was 6.77 (n = 77; CDEP, 1992). (Unlike the concentrations for 2,3,7,8-TCDD, this 2,3,7,8-TCDF concentration in the Connecticut data is higher than the background site near Columbus, Ohio: 0.64 ppt in Columbus versus 6.8-8.2 ppt in Connecticut.) This simple examination of averages over time does not seem to indicate statistically significant change, if any. As well, in a statistical analysis of the data (principal component analysis of the concentration levels of all isomers in soil, fish, and sediment to attempt to identify stratification of the data by year) for four of the RRFs through 1990, MRI (1992) concluded that the RRFs had no apparent effect on the levels of the dioxin-like compounds in the three matrices.

The purpose of developing the argument that levels in soil are low and perhaps typical of background conditions, although that is questionable for 2,3,7,8-TCDF, is to be able to compare

the soil to sediment, and sediment to fish ratios that arise from this data with those that were generated in example Scenarios 1 and 2 in Chapter 5. Those scenarios were crafted to be typical of “background” settings. It is noted that the comparison of soil-to-sediment ratios and the sediment-to-fish ratios in this exercise is not, strictly speaking, a validation exercise since the Connecticut circumstances were not duplicated.

Information and results from the CDEP program for the soil, sediment, and fish matrices are presented in Tables 7-7 through 7-9. The data and supporting documentation was supplied by CDEP (1992). Table 7-7 provides a summary of the eight sites in the CDEP program for which data was available. One "reference" or "control" site includes two areas, which for 1988 was at Union, Connecticut, and for 1990 was at Stafford, Connecticut. No nearby potential sources of dioxin release (industrial, commercial) were identified for these two reference sites. One of the sites, the Hartford site, is near the Connecticut River. All water bodies sampled were coves with direct links to the river. Industrial and commercial enterprises which use the river are speculated to have resulted in the generally higher fish concentrations noted in the Hartford site, as compared to the other sites. Twenty-one water bodies have been sampled, including harbors, channels, impoundments, reservoirs, coves, ponds, rivers, and lakes. Six species of fish have been sampled, including carp, channel and white catfish, white sucker, brown bullhead, and yellow perch. All but the yellow perch are bottom feeders. The yellow perch was sampled mostly when a sufficient sample of bottom feeder could not be obtained. Samples of bottom feeders were sought because it was felt that they would have the highest tissue concentrations due to their association with bottom sediments, and therefore be the best markers for impact and change over time (C. Fredette, CDEP, personal communication). The soil sampling program was not extensive; samples were only taken near ambient air monitoring stations, and only 77 samples were taken through 1990. It certainly cannot be claimed that the samples are statistically representative of soils which drain into the water bodies. However, given the consistency in concentrations noted and their low values, the supposition is made that concentrations are adequately representative of soils which impact the water bodies. Maps of the sites were obtained from CDEP to evaluate the distance from the soil sampling sites to the nearest water bodies. Nearly all soil sampling sites were within 3 miles of the nearest water body, and most were near to and less than one mile away.

Table 7-8 lists the frequency of non-detects for all data through 1990, and incomplete information on detection limits. For determining average concentrations in sampled matrices, non-detects were assumed to equal ½ the detection limit. The detection limits for these matrices varied over time with different data sets. The detection limits noted were those cited for 1987

and 1988 data (from a draft Monitoring Progress Report supplied by CDEP). That report did not list detection limits for three matrices noted. In parenthesis is noted the lowest concentration in the data sets, which would correspond to ½ the detection limit at the time the non-detect was measured. The purpose of presenting this data is simply to argue that assuming ½ the detection limit for computing averages will not greatly impact the averages. This can be demonstrated for the one matrix where this is most likely to be a concern - soil concentrations of 2,3,7,8-TCDD where a 50% non-detect rate was noted. If half the samples were assigned a value of 0.0 instead of perhaps 0.07 ppt (half the noted detection limit of 0.13 ppt), than the overall average would drop from 0.56 ppt to 0.52 ppt.

Table 7-9 summarizes the key results from the CDEP data. The C_{sed}:C_{soil} ratio is the ratio of sediment concentration to soil concentration for the eight sites for 2,3,7,8-TCDD - these are not organic carbon normalized concentration ratios. The second ratio noted is called the BSAF, because it is defined in the same way that the Biota Sediment Accumulation Factor is defined: the ratio of the lipid-normalized whole fish tissue concentration over the organic carbon normalized bottom sediment concentration. The BSAF is used to estimate fish tissue concentrations from bottom sediment concentrations in this assessment. The fish lipid contents and organic carbon contents for each site were supplied by CDEP (1992). The BSAFs for the entire data set and the four concentrations are based on averages of fish lipid and organic carbon contents from the entire data set.

Key observations from the demonstration scenarios and the results of the CDEP program are:

1) Demonstration scenarios 1 and 2 in Chapter 5 estimated the impact from basin-wide soil concentrations of the 17 dioxin congeners that have been found in a typical background setting. The difference in the scenarios was in exposure patterns and exposure site characteristics - the impacts to surface water sediments and fish were the same in both scenarios. The estimated concentrations of 2,3,7,8-TCDD, 2,3,7,8-TCDF, and 2,3,4,7,8-PCDF in bottom sediments were 0.99, 1.22, and 0.51, respectively, and the sediment to soil ratios for these three compounds were 2.55, 1.82, and 2.43. The differences in the sediment:soil ratios of these congeners is due to slightly different organic carbon partition coefficients assumed for the three congeners. These ratios compare to the overall 3.86, 2.59, and 1.58 estimated in the Connecticut data set for 2,3,7,8-TCDD, 2,3,7,8-TCDF, and 2,3,4,7,8-PCDF, respectively. The ratio for total toxic equivalents was 2.69, compared to the modeled 2.64. These ratios tend to support the model's approach.

One of the key model parameters in the soil to sediment algorithm which is uncertain is the soil enrichment ratio. It was assigned a value of 3.0, which means that concentrations in soil eroding from the field are three times higher than concentrations on the field. If the soil enrichment ratio is set to 1.0, it would lead to sediment:soil ratios less than 1.00. The close match of sediment:soil ratios with an enrichment ratio of 3.0 does not necessarily validate the model's approach to evaluating surface water impacts from low basin-wide soil concentrations, however. The model assumes that all surface water impacts are from erosion of basin soils. However, sediment concentrations in water bodies are also a function of direct atmospheric depositions onto water bodies and other direct, industrial related, discharges into water bodies. Such depositions may originate from sources other than soil contamination, such as air emissions from cars or industry. The impact of industrial sources to the sediments in the CDEP data is unclear. As noted, evidence collected so far does not indicate an impact from incinerator emissions. The Hartford site has been cited as being impacted with industrial use of the nearby Connecticut River. However, the sediment concentrations of the water bodies at this site are not higher than other sites - in fact, the sediment concentrations from the Bridgeport, Bristol, Preston, and even the background Union/Stafford sites are comparable or higher. In any case, deposition of air-borne contaminants are likely to impact bottom sediments to some degree, and the soil contamination models of this assessment do not include such an impact (the stack emission source category does include this impact for emissions reaching water bodies).

In summary, the CDEP data appears to indicate that bottom sediment concentrations exceed surface soil concentrations by more than a factor of 2.0 in environmental settings that mostly do not appear to be impacted by industrial activities. The models also predict a similar enrichment of sediment concentrations, mainly due to the use of soil enrichment ratio of 3.0

2) The overall BSAF ratios for the three dioxin compounds and the I-TEQ ratio, ranging from 0.24-0.86, are higher than the BSAF used in the demonstration scenario of 0.09 for 2,3,7,8-TCDD and 0.144 for 2,3,4,7,8-PCDF. Higher BSAF in the CDEP data are expected because the fish species sampled were bottom feeders, except for the yellow perch. The selected BSAF of 0.09 is mainly supported by Lake Ontario data (EPA, 1990a), which was on brown and lake trout, smallmouth bass, and white and yellow perch, all column feeders. Bottom feeders are expected to have more exposure to the contaminants because of their direct contact with sediments. This implies that use of the BSAF for site-specific assessments should consider the dietary pattern of exposed individuals. If a significant portion of local fish consumption includes bottom feeders (such as catfish), then perhaps a BSAF greater the 0.09 used for the demonstration scenarios is warranted.

3) Of the six sites for which BSAFs were individually determined for 2,3,7,8-TCDD, the highest BSAF was from the Hartford site at 0.97. The claim is not made that it is substantially or significantly different from BSAFs at the other sites - it is simply a point of interest for comment. The Hartford site has been previously identified as likely to have been impacted by activity on Connecticut River - all the fish are taken from coves directly connected to the river. Although the bottom sediment concentrations at this site are not different from other sites, one hypothesis is that the water column is more impacted for this site as compared to other sites.

In Chapter 4, Section 4.3.4, a key issue identified for the validity of the BSAF approach is the issue of past versus ongoing contamination. Generally, the hypothesis offered was that fish are likely to be more exposed with ongoing impacts to the water body as compared to a situation where impacts were principally historical. The effluent discharge source category is a case of ongoing impacts. The argument presented in Section 4.6. of Chapter 4 was that the BSSAF (biota suspended sediment accumulation factor) should be greater in numerical value than a BSAF whose value is derived from data on a water body whose impacts have been primarily historical. This was the case for the assignment of a 0.09 for the BSAF, which was based on data on column feeders in Lake Ontario, a lake whose impact has been speculated as primarily historical. Although the numerical difference between the Hartford BSAF, at 0.97, and the next largest BSAF at Bristol, at 0.78, is not that large, perhaps that difference is due to the fact that the fish are more exposed at Hartford due to ongoing impacts from the Connecticut River.

In summary, this section has evaluated data supplied by the Connecticut Department of Environmental Protection on fish, sediment, and soil data. It is the only data set that could be found where soil and sediment data were concurrently taken in areas evaluated as (mostly) not impacted by industrial activity. An examination of the sediment to surface soil concentration ratios, showing them generally to be in the range of 1.6 to 3.9, supports the soil contamination model of this assessment for estimating sediment impacts from uniform basin-wide soil concentrations, which showed sediment to surface soil concentration ratios ranging from 1.8 to 2.6. The BSAFs determined from the CDEP data are higher than the BSAFs used in the demonstration scenarios of this assessment. This was likely due to use of bottom feeders for fish concentration of the CDEP - bottom feeders are likely to have more exposure to dioxin-like compounds in water bodies than column feeders due to their association with contaminated bottom sediments.

7.3.3. Other Bottom Sediment Concentration Data

Assuming elevated sediment concentrations are a function of elevated surface soil concentrations is reasonable when the only source of water body contamination is soil contamination. However, comparing soil and sediment concentrations would not be appropriate if sediments and water were impacted by industrial discharges, which has often been cited as the cause for sediment and water impacts (see Bopp, et al., 1991; Norwood, et al., 1989; e.g.). Sediment concentrations of note have also been found in surface water bodies near urban settings, with car and industrial stack emissions cited as likely causes (Gotz and Schumacher, 1990; Rappe and Kjeller, 1987). Rappe, et al. (1989) collected samples from the Baltic Sea, which were described as background samples. They note that the pattern of tetra-CDF congener concentrations found in the Baltic Sea were typical of what they termed the "incineration patterns" - air and air particulate concentrations that were attributed to sources such as incineration, car exhausts, steel mills, etc. On the other hand, sediment samples collected between 4 and 30 km downstream from a pulp mill revealed a congener pattern typical of bleaching mills. The stack emission and effluent discharge source categories provide separate models for water body impacts. The capability of the effluent discharge model is estimating fish tissue concentrations is examined in Section 7.3.6 below. The remainder of this section examines some of the data available which is not attributed to industrial or urban sources.

Smith, et al. (1995b) evaluated sediment core data from the Hudson River National Estuary Research Reserve system located on the lower (southern) Hudson River. They also took soil cores near the estuaries studied. Using principal component analysis, as well as a mass balance approach, they concluded that the CDD/CDF concentrations in the river sediments were dominated by soil erosion (76% of total influx) and sewage-containing effluents (19%). In doing their mass balance exercise, they used an “organic enrichment factor” of 1.6. Their data was on homologue groups, not on individual congeners, so their data is not directly amenable to comparison to model simulations or other data discussed in this section.

Except for the CDEP data described in Section 7.3.2 above, and possibly this data on Hudson River sediments (Smith, et al., 1995b), data was not found linking sediment concentrations to soil concentrations, in an urban or more pertinent to this assessment, a rural setting. Some sampling has occurred in areas described as rural or background. Sediment sampling in Lake Orono in Central Minnesota in such a setting found no tetra- and penta-CDDs, although occurrences of total hexa-CDDs were found in the low ng/kg (ppt) level, occurrences of hepta-CDDs to a high of 110 ppt, and total OCDD concentrations ranged from 490-600 ppt for three samples (Reed, et al., 1990). A report on sampling of several estuaries in Eastern United States included a "reference" or relatively clean site, central Long Island Sound. There were no

occurrences of 2,3,7,8-TCDD, although 2,3,7,8-TCDF was found at 15 ppt in this clean site. Other sites had identified industrial source inputs and higher noted concentrations (Norwood, et al., 1989). 2,3,7,8-TCDD was extensively found in sediments of Lake Ontario (EPA, 1990a). The average of samples from all depths of sediment collection from 49 stations including 55 samples was 68 ppt. The average of 30 surficial sediment samples was 110 ppt. A modeling exercise implied that an annual load of 2.1 kg/year into Lake Ontario corresponds to a concentration of 110 ppt. One identified source was the Hyde Park Landfill, located about 2000 feet from the Niagara River, which drains into Lake Ontario. Between 1954 and 1975, an estimated 0.7 to 1.6 tons of 2,3,7,8-TCDD were deposited in the landfill. A principal conclusion from the modeling exercise, however, was that a characterization of historical loadings of 2,3,7,8-TCDD into the lake was not available and would be necessary to evaluate the contributions by the Hyde Park Landfill.

7.3.4. Data on Water Concentrations of Dioxin-Like Compounds

Chapter 3 of Volume II summarizes available data on surface water concentrations of the PCDDs and PCDFs. Results summarized there are not directly amenable to comparison because the sources of contamination were unspecified except to note that, in some studies, a portion of the sampling occurred for water bodies known to be impacted by industrial discharges. The 104-mill pulp and paper mill study, which measured discharges of 2,3,7,8-TCDD and 2,3,7,8-TCDF into surface water bodies, was the only such study currently available which measured impacts to surface water bodies. Section 7.3.6 below discusses the use of this data to evaluate the effluent discharge source category. However, this study did not measure water concentrations, and no other studies could be found which measured both source strength and resulting surface water concentrations.

Nonetheless, the data on water concentrations of dioxin-like compounds does indicate that occurrences of PCDDs and PCDFs are generally not-detected or in the low pg/L (ppq) range; detection limits were generally at or near 1 pg/L. The one exception to this is occurrences in tens to hundreds of pg/L range for PCDFs in one of twenty community water systems sampled in New York (Meyer, et al., 1989). Concentrations exceeding 200 pg/L were found in the hepta- and octa-CDFs; concentrations between 2 and 85 pg/L were found in the tetra to hexa-CDFs for this impacted water system.

The highest water concentrations estimated in the demonstration scenarios in this assessment were the concentrations associated with the soil contamination demonstration. There, soil concentrations in a bounded area of soil contamination were 1 ppb for the three example

compounds. Also, watershed soils were assumed to be at 0.00 in order to demonstrate the incremental impact from the bounded area only. Water concentrations for 2,3,7,8-TCDD, 2,3,4,7,8-PCDF, and 2,3,3',4,4',5,5'-HPCB were 0.012, 0.091 and 0.0016 pg/L, respectively. Water concentrations for the effluent discharge scenario, #6, were comparable to these at 0.018, 0.029, and 0.0029 pg/L for the three example compounds, respectively. For Scenarios 1 and 2, where watershed soil concentrations of 2,3,7,8-TCDD and 2,3,4,7,8-PCDF were set at 0.39 and 0.67 ng/kg (ppt), respectively, surface water concentrations were lower $8*10^{-3}$ pg/L (ppq) for 2,3,7,8-TCDD and $9*10^{-3}$ pg/L for 2,3,4,7,8-PCDF. For Scenarios 4 and 5 demonstrating stack emission depositions and where watershed soil concentrations of toxic equivalents, WHO_{98}-TEQ_{DF}, were estimated to be in the10^{-3} ppt range, surface water concentrations were in the 10^{-5} ppq range.

7.3.5. Data on Fish Concentrations in the Literature

This assessment estimated fish lipid concentrations of 2,3,7,8-TCDD for the various source categories to be: 1) background conditions - 3.0 ppt, 2) soil contamination - 4.3 ppt, 3) stack emission source category - 0.0003 ppt, and 4) effluent discharge source category - 6.4 ppt. The fish lipid content assumed was 0.07. Therefore, whole fish tissue concentrations are estimated at about one order of magnitude lower than these lipid concentrations. Data was not found to appropriately compare the stack emission source category results, and data on the effluent discharge source category is examined in the next section below. This section will examine some available data on fish concentrations in order to compare results from the first two categories with measured results.

The most appropriate study with which to make comparisons is the National Study of Chemical Residues in Fish (EPA, 1992b; hereafter abbreviated NSCRF). Fish tissue data on a variety of species and contaminants of concern in aquatic environments and fish from around the country were developed. Most important for current purposes, the sites were carefully characterized in terms of potential sources of fish contamination. There were 353 sites from which fish tissue data were available, of which 347 had data on 2,3,7,8-TCDD. Results from four site categories might be appropriate for comparison with concentrations estimated to occur from low, possibly background, soil concentrations of 2,3,7,8-TCDD. The four categories and number of sites per category were: the USGS water quality network NASQAN - 40 sites; Background (B) - 34 sites, Agricultural (A) - 17 sites, and Publicly Owned Treatment Works (POTW) - 8 sites. The average 2,3,7,8-TCDD whole fish tissue concentrations (lipid contents not provided) measured for these four categories were: NASQAN - 1.02 ppt; B - 0.56 ppt; A -

0.75 ppt, and POTW - 0.90 ppt. Background conditions were demonstrated in Chapter 5 using a soil concentration of 2,3,7,8-TCDD that was found in an actual background conditions - 0.37 ng/kg (ppt). The resulting fish tissue concentrations estimated for this soil concentration was 0.2 ppt (on a whole tissue basis assuming a fish lipid fraction of 0.07). Four of the site categories of the NSCRF might be considered representative of sources characterized as land areas of high soil concentrations of 2,3,7,8-TCDD. These were: Industrial/Urban site (IND/URB) - 105 sites, Refinery/Other Industry (R/I) - 20 sites, Wood Preservers (WP) - 11 sites, and Superfund Sites (NPL) - 7 sites. Average fish tissue concentrations measured for these site categories were: IND/URB - 4.04 ppt, R/I - 4.38 ppt, WP - 1.40 ppt, and NPL - 30.02 ppt. The source category of this assessment most similarly characterized to these would the category of soil contamination, where a bounded area of contaminated soil had 2,3,7,8-TCDD concentrations at 1.00 ppb. The resulting fish tissue concentration predicted was 0.3 ppt (assuming a fish lipid fraction of 0.07). The two remaining site categories of the NSCRF were Paper Mills Using Chlorine (PPC), and Other Paper Mills (PPNC). These data served as the basis for the comparison discussed below in the effluent discharge source category.

In general, the range of fish tissue concentrations measured for (perhaps) background conditions, 0.56 - 1.02 ppt, were comparable to the 0.21 ppt fish tissue concentration estimated assuming the background soil concentration of 0.37 ppt. The same may not be true, however, in the comparison of fish tissue concentrations ranging from 1 to 30 ppt associated with urban/industrial contamination. The fish tissue concentration modeled in the demonstration of the soil contamination source category was much lower at 0.3 ppt. However, it may not be entirely appropriate to compare the demonstration of the soil contamination source category with the urban/industrial sites of the NSCRF. For the demonstration scenario, the contaminated site was 4 ha within a 100,000 ha watershed which had concentrations of 2,3,7,8-TCDD set to 0.0. The fact that the background demonstration predicted a fish concentration 0.2 ppt, which was within a factor of 3 to 5 of observations from the NSCRF (or closer to values in the NSCRF if the fish lipid content was higher than 0.07), might be considered a limited validation of the models. This is not a validation exercise, strictly speaking, since specific field data were not input and compared.

One data point from that study of interest is the 30.02 ppt concentration found for the NPL site. This is two orders of magnitude higher than the 0.3 ppt estimated for the soil contamination source category. No insights can be gained from this difference because information was unavailable on the seven sites which were characterized as Superfund sites and which were expected to have been the cause of the 30.02 ppt fish concentration. It would be

interesting to know the surface soil concentrations of the 7 NPL sites, the size of these sites including the receiving water body, and their proximity to the receiving water body - that information may be sufficient to conduct a partial model validation exercise.

Another comprehensive data base of fish concentrations of 2,3,7,8-TCDD is from EPA's National Dioxin Study (EPA, 1987; abbreviated NDS), which actually provided the motivation for the NSCRF when significant residues of 2,3,7,8-TCDD were found in fish in the NDS. Fish concentrations from the NDS are also listed and discussed in Kuehl, et al. (1989). Travis and Hattemer-Frey (1991) summarized the fish data from the NDS. Their summary is as follows. Data collected from 304 urban sites in the vicinity of population centers or areas with known commercial fishing activity, including the Great Lakes Region, showed concentrations to range from non-detected to 85 ng/kg (ppt). The geometric mean concentration was 0.3 ppt, and only 29% had detectable levels of 2,3,7,8-TCDD. The Great Lakes data had more contamination, with 80% detection rate and a geometric mean concentration of 3.8 ppt.

The NSCRF also collected data on 2,3,4,7,8-PCDF, the second example compound demonstrated. Briefly, the range of average fish tissue concentrations noted for the site categories evaluated as background above is 0.42-0.78 ppt, very similar to the 2,3,7,8-TCDD range of 0.56-1.02 ppt. The modeled fish tissue concentration of 2,3,4,7,8-PCDF for background conditions was about the same as that for 2,3,7,8-TCDD at 0.17 ppt. The range of 2,3,4,7,8-PCDF average fish concentrations for the sites of elevated soil concentration was 1.86-5.44 ppt, which, like the comparison above for 2,3,7,8-TCDD, is higher than the modeled 2,3,4,7,8-PCDF concentrations of 0.18 for the soil contamination source category with initial soil concentrations of 1.0 ppb.

The NSCRF also collected data on PCB concentrations in fish, although the results were expressed in terms of total tetra-, hepta-, and so on. The data indicates concentrations well into the part per billion range for this breakout, and even higher considering total PCBs. The average concentration of total heptachlorobiphenyls over all study sites was 96.7 µg/kg (ppb). The average concentration of total PCBs over all sites was estimated as 1897.88 ppb, and the average concentration of total PCBs for background sites was 46.9 ppb. The modeled concentration of the example heptachlorobiphenyl, 2,3,3',4,4',5,5'-HPCB, for the soil contamination source scenario, where the soil concentration was 1 ppb, was 7.6 ppt.

Data from the Great Lakes region indicate that PCB concentrations are significantly higher than CDD/F concentrations in this area. PCB concentrations from fish in Lake Ontario are in the tens to hundreds of ppb level (Niimi and Oliver, 1989), while 2,3,7,8-TCDD contamination in Lake Ontario was in the tens of ppt level (EPA, 1990a) - a three order of

magnitude difference. Other data in Table B.10, Appendix B, Volume II, where concentrations were similarly in the tens to hundreds of ppb level were from Lake Michigan (Smith, et al. 1990) and Waukegan Harbor in Illinois (Huckins, et al., 1988). The single data point from that table for 2,3,3',4,4',5,5'-HPCB, the example PCB congener in Chapter 5, was for carp in Lake Michigan, and was 29 ppb (29,000 ppt).

While the modeled CDD/F fish concentrations for background settings seem reasonably in line with measured concentrations from similar settings, this assessment may have underestimated concentrations of 2,3,3',4,4',5,5'-HPCB. As noted, concentrations for fish in the Great Lakes Region were in the tens to hundreds of ppb range, while this assessment derived estimates in the low ppt range. It is inappropriate to make direct comparisons without also comparing source strengths. Concentrations of PCBs in bottom sediments ranged from the low ppb for the tri-PCBs, to the tens of ppb for the tetra through hexa-PCBs, back to the low ppb for the hepta and octa-PCBs, in Lake Ontario (Oliver and Niimi, 1988). Another literature source showing fish concentrations in Waukegan Harbor, IL, in the hundreds of ppb range, had sediment concentrations of specific congeners as low as 5 ppb to as high as 131 ppm. The concentration of 2,3,3',4,4',5,5'-HPCB in bottom sediments was estimated to be 1.6 ppt in the soil contamination scenario. Therefore, one reason PCB concentrations in fish estimated in this assessment are as much as four orders of magnitude lower than noted in the literature is because sediment concentrations estimated for the source categories in this assessment are also about four orders of magnitude lower. The BSAF for PCBs also was noted to be variable, with values below 1.0 to values over 20.0 (see Chapter 4, Section 4.3.4). The BSAF for the example PCB congener in this assessment was 2.0. Higher BSAFs would also increase PCB concentrations estimated for fish.

The fish concentration of 2,3,7,8-TCDD estimated for the stack emission source category was lowest at 0.00002 ppt. Data was unavailable to place this in any comparative framework. This is because the incinerator modeled was a well-controlled incinerator and the impacts modeled were incremental - they did not include a background load into the water body which would undoubtably drive fish concentrations in an area where there is a well-controlled incinerator.

7.3.6. Impact of Pulp and Paper Mill Effluent Discharges on Fish Tissue Concentrations

a. Description of Exercise and Model Parameters

This section describes a validation exercise of the effluent discharge algorithm. The description of this exercise as a "validation" exercise tentative, since much of the data used is of uncertain quality. Discharge rates of 2,3,7,8-TCDD (mass/time units) into surface water bodies

from a subset of 104 pulp and paper mills, which were sampled on a one-time basis in 1988 for such discharges and other parameters (EPA, 1990b; hereafter referred to as the 104-mill study), represent the key observed source term for this exercise. Fish concentrations of 2,3,7,8-TCDD for fish sampled downstream of these sources as part of the National Study of Chemical Residues in Fish (EPA, 1992b; abbreviated NSCRF hereafter) represent the key predicted model result for this exercise.

The National Council of the Paper Industry for Air and Stream Improvement (abbreviated NCASI hereafter) has already performed this exercise, and a brief description of their efforts and results can be found in Sherman, et al. (1992). NCASI carefully matched NSCRF data to appropriate mills of the 104-mill study. In many cases, they found more than one fish sample to correspond to a given discharge. Also, they considered circumstances where more than one mill effluent discharge can be considered to have impacted the environment where fish were sampled. In these cases, discharge rates from the contributing mills were fed into the model as source terms.

In NCASI's careful examination of the available data, they only considered 47 of the 104 mills as appropriate for this type of model testing. From these 47 mills, 95 fish samples with detectable residues of 2,3,7,8-TCDD were identified. Some mills had only one fish sample corresponding to it while others had up to four fish samples. The following explains why 57 of the remaining mills were not considered for this exercise:

1. Downstream of 10 pulp and paper mills was an estuary. NCASI considered the model appropriate for riverine situations only and did not calculate fish concentrations for estuarine settings.

2. The measurement for 2,3,7,8-TCDD in the effluent was listed as non-detect, and no further data examination and modeling occurred. There were 13 mills in this category.

3. NCASI could not identify appropriate fish measurements in the NCSRF downstream of the mill, and did not model further. Seven mills were in this category.

4. Some of the mills in NCASI's exercise were only considered "proximate" mills adding to the source term associated with another mill and one or more fish concentrations. Five mills were described in this manner.

5. For the remaining 22 mills, no explanation was provided for their lack of inclusion in the validation exercise.

Details of the NCASI modeling assumptions were supplied to EPA by NCASI (personal communication, Steven Hinton, PhD., P.E., NCASI, Inc.; Department of Civil Engineering, Tufts University, Medford, MA, 02155) and adopted for this exercise. Several other source materials

were used to develop the parameters for this exercise. First, Figure 7-5 shows the effluent discharge model and all the numerical quantities required, including the source term and the observed fish concentration, and model parameters associated with the mill discharge and the aquatic environment. Further description of the effluent discharge model can be found in Chapter 4. The model parameters and their source materials are now listed.

1) **Mill parameters including the 2,3,7,8-TCDD discharge rate, the effluent flow rate, the suspended solids content of the effluent flow, and the organic carbon content of the suspended solids in the effluent flow:** The 104-mill pulp and paper mill study (EPA, 1990b), a cooperative study between EPA and the paper industry, measured mass releases of 2,3,7,8-TCDD (actually effluent flow and concentrations, from which mass releases can be estimated), effluent flow, and total suspended solids content of the effluent flow (and other information such as releases of 2,3,7,8-TCDF, which were not needed for this exercise). For purposes of this validation exercise, actually only the total suspended solids content of effluent discharges was used from the primary reference of this study (EPA, 1990b). Data from the 104-mill study was also used in a modeling study, described more fully below, and in that reference, it was more conveniently organized and compiled. As such, effluent flow and 2,3,7,8-TCDD discharge rates came from a secondary reference. The organic carbon content of the solids in the effluent was assumed to be 0.36. This was the value used in the example scenario of Chapter 5, and was based on the fact that effluent solids are principally biosolids).

2) Receiving water body parameters including flow rate, suspended solids content, and organic carbon content of suspended solids. A modeling study conducted by EPA (EPA, 1990c) used a simple dilution and the EXAMS model to evaluate the impact from discharges of 2,3,7,8-TCDD and 2,3,7,8-TCDF from chlorine bleaching mills. Mills from the 104-mill study were the ones evaluated in this report. This study developed key receiving water parameters for these mills which are pertinent to the dilution model of this assessment, including harmonic mean flows at the point of effluent discharges, which were based on the nearest STORET sampling point, and suspended solids concentration of the receiving water body at this point. Details on how these key quantities were developed are included in that report and will not be discussed here. The organic carbon content of the suspended solids was assumed to be 0.05, which was also the content assumed for the example scenarios in Chapter 5.

3) Parameters associated with 2,3,7,8-TCDD, including the organic carbon partition coefficient, Koc, and the biota suspended sediment accumulation factor (abbreviated BSSAF). The Koc for 2,3,7,8-TCDD was the same 3.98×10^6 otherwise assumed in this

assessment, and the BSSAF value was assumed to be 0.09, which is the same value as the BSAF, Biota (bottom) Sediment Accumulation Factor. Sections in Chapter 4 further discuss the Koc, BSAF, and BSSAF.

4) Fish data including the fraction lipid and the observed fish concentrations: The core reference for this information is the National Study of Chemical Residues in Fish (EPA, 1992b), as noted above. NCASI compiled the fish concentrations and associated lipid content of the samples as part of their modeling exercise, and these were used here as well.

Table 7-10 lists the parameters used for each identified mill and receiving water body, as well as the modeled and observed fish concentrations. Not included in this table are the parameters assumed for all model runs, including the organic carbon contents of the suspended solids terms, and the 2,3,7,-TCDD Koc and BSSAF.

b. Results and Discussion

One important point to discuss up front is that 38 of the 47 eligible mills discharged into surface water bodies that were characterized as "low", while the remaining 9 mills discharged into "high" receiving water bodies. This characterization refers to the flow rates of the receiving water bodies. The average harmonic mean flow rate of the 38 low water bodies was $5.3 * 10^8$ L/hr, with a range of 10^7 to 10^9 L/hr, while for the other nine, the average flow was $2.6 * 10^{10}$ L/hr, with a narrow range of 1 to $4 * 10^{10}$ L/hr.

This distinction appears to be non-trivial for a few reasons. One, model predictions appear to more closely match observations for the smaller water bodies. The average of 38 mills and 74 fish for modeled and observed fish concentrations is 7 ppt and 15 ppt, respectively. The average of 9 mills and 21 fish associated with large receiving water bodies for modeled and observed fish concentrations is 0.1 and 5.3 ppt, respectively. However, some paired data (predicted versus observed fish concentration) showed over 3 orders of magnitude difference - 0.001 pg/g TCDD predicted versus 1.4 pg/g TCDD observed, for example. As evaluated by NCASI, another important feature of the larger receiving water bodies that they were the ones principally considered to have multiple discharges.

A final observation concerning the large receiving water bodies is that the suspended solids data is also significantly different than the low receiving water bodies. For the 38 water bodies associated with the small water bodies, the receiving water body solids content averaged 9 mg/L, while for the nine high receiving water bodies, the suspended solids content averaged 73 mg/L. This importance of the suspended solids content is principally seen for mills 39-42. The solids content of these water bodies ranged from 107 to 221 mg/L. The average modeled fish

concentration for these mills was 0.005 ppt, while the average observed fish concentrations was 3.0 ppt. The impact is one of "dilution": discharged 2,3,7,8-TCDD mixes into a larger reservoir of suspended particles, leading to a low 2,3,7,8-TCDD concentration on suspended solids concentration and lower predicted fish tissue concentrations. This dilution effect may also be real, as the average observed fish concentrations for these circumstances of 3.0 ppt may indicate a significant difference with the average 15.0 ppt observed for the smaller receiving water bodies. Nonetheless, these high suspended solids data must be considered suspect; if the suspended solids concentration were, in fact, lower on average, than model predictions would have closer than 3 orders of magnitude away from measurements.

Considering all 47 mills and 95 fish observations, it was found that 73 and 87% of predictions within a factor of 10 and 20 of observed concentrations, respectively. The predicted and observed results of this exercise for these 47 mills is shown graphically in Figure 7-6, which also shows the bounds of + or - a factor of 10 difference in predictions and observations Of note and perhaps not ironically, the highest observed fish concentration of 143.3 ppt is matched by the highest predicted fish concentration of 89.2 ppt. .

While Figure 7-6 appears to show a poor match in predictions and observations, the data available must be carefully considered. Only one discharge measurement is made, and a limited number of fish at various points downstream were available for this exercise. It would certainly be more meaningful if several discharge measurements per mill were made and several fish measurements were made downstream of the discharge. To be more rigorous, several measurements of discharge would have to be made over time to best reflect an average discharge. Likewise, other mill-specific parameters are uncertain, such as receiving water body flow, suspended solids in the water body, and so on. Finally, and perhaps most importantly, the assumption of this exercise is that the mill discharges of 2,3,7,8-TCDD represent the only sources impacting the fish. This is most unlikely to be the case for the large receiving water bodies, which may be receiving other industrial point discharges or non-point sources (runoff, atmospheric deposition). Given the factor of 2 difference in average predicted and observed fish concentrations for the low receiving water bodies, one might cautiously conclude that the effluent discharge model of this assessment is generally valid for, at least, receiving rivers with flows in the range of 10^8 L/hr.

Given this last cautious statement, one can continue this exercise by attempting a calibration on an appropriate parameter(s) so that predictions better match observations. The appropriate parameter for calibration is the BSSAF. The choice of 0.09 for the 2,3,7,8-TCDD BSSAF was based on data from Lake Ontario (EPA, 1990a). Specifically, 0.09 was the BSAF -

lake bottom sediment to fish lipid accumulation factor - for measured fish and bottom sediments of Lake Ontario. As this is a lake and not a riverine situation, and inasmuch as 2,3,7,8-TCDD contamination of Lake Ontario sediments have been attributed to historical impacts and not ongoing causes, the 0.09 may be inappropriate. As well, a range of BSAFs for 2,3,7,8-TCDD were noted in the literature in Chapter 4 of this assessment, ranging from less than 0.05 to greater than 1.00. EPA (1993) suggests that data collection methods limit the usefulness of some of the available literature, particularly those showing very high BSAF, and in a similar examination of BSAF data, suggests a range of 2,3,7,8-TCDD BSAF from 0.03 to 0.3. In any case, this suggests that the BSSAF is a reasonable candidate for calibration in this exercise.

A different selection for BSSAF significantly improves model performance. If the BSSAF is increased to 0.20 (up from 0.09), the average predicted fish tissue concentration for the 38 mills discharging into the smaller water bodies increases as expected from 7.0 to 15.6 ppt, comparing better now to the average observed concentration of 15.0 ppt.

Conclusions from this exercise include:

1. For at least smaller receiving water bodies, those with harmonic mean flows on the order of 10^7 to 10^9 L/hr, the effluent discharge model is appropriate for assessing effluent discharge impacts to fish for 2,3,7,8-TCDD and perhaps other dioxin-like compounds.

2. There appears to be a distinction in model performance for the large and small receiving water bodies. The high suspended solids concentrations generated in an earlier modeling exercise for the larger water bodies is one cause for model underprediction; these solids concentrations should be further reviewed. Also, these water bodies were evaluated by NCASI as ones with multiple sources. Other sources not identified by NCASI could also have been the cause for higher measured fish concentrations as compared to model predictions. The NSCRF report (EPA, 1992b) contains an appendix giving a matrix indicating point source categories of discharges which may have affected fish concentration results. Pulp and paper mills with and without chlorine were listed as point sources for 125 episodes (an episode is a fish sampling site). In 37 of these episodes, other point sources were identified, including one or more of the following: refinery (refinery using the catalytic reforming process), NPL site (a Superfund site), or other industry (an industrial discharge other than a paper mill or refinery). Given other sources, it is in fact a benefit to the exercise that predictions were lower than observations.

3. The model more closely predicts fish concentrations for the smaller receiving water bodies when the BSSAF is calibrated from 0.09 to 0.20. Considering that 0.09 was a value for 2,3,7,8-TCDD developed with data from Lake Ontario, a standing water body with principally

historic and not ongoing 2,3,7,8-TCDD impacts, this setting is probably an inappropriate surrogate for ongoing discharges to a riverine situation. This would argue that a calibration is warranted.

7.3.7. Air Dispersion and Soil Concentration Modeling Around an Incinerator Known to be Emitting Large Amounts of Dioxins

The Columbus Municipal Solid Waste-to-Energy (CMSWTE) Incinerator in Columbus, OH, operated between June 1983 and December 1994, and processed an average of 1600 metric tons of solid waste per day during its operation. A stack test taken in 1992 (EERC, 1992) indicated that the annual emission rate of dioxin I-TEQs was 984 g. Measures were taken to reduce dioxin emissions by the operators of CMSWTE. A second stack test was taken in 1994 (EMC, 1994) to evaluate the effectiveness of these dioxin reduction measures. The rate of emission from this test was calculated at 267 g TEQ/yr, indicating about a 75% reduction in dioxin emissions. These rates of emission can be compared against United States estimates of total annual emissions from all known sources of dioxin release of 12 kg TEQ in 1987 and 3 kg in 1995; see Volume I of these Dioxin Exposure Reassessment documents.

An ambient air monitoring study undertaken by the Ohio Environmental Protection Agency (OEPA) included two rounds of sampling in 1994, one during a concurrent stack test, and one round in 1995 after the incinerator had shut down (OEPA, 1994; 1995). For both sampling events in 1994, the concentration was highest in the air monitor (1 of 6 total monitors; 5 operational for each sampling event) located in the downwind direction (southeast) from the CMSWTE. Also, the profile of dioxins in the air matched the stack emission profile much more closely than the other air samples, which had lower and more typical urban air concentrations. A soil monitoring study conducted during 1995 and 1996 included 34 soil samples taken on-site and up to 8 km in all directions from the plant (Lorber, et al., 1998). An evaluation of these soil data clearly showed an imprint from the CMSWTE, with concentrations decreasing as a function of distance from the stack, approaching a local background after about 3 km.

Complete descriptions of the stack, air, and soil measurements conducted around the CMSWTE are available in previous papers (EERC, 1992; EMC, 1994; Ohio EPA, 1994, 1995; Lorber, et al., 1998) and only summarized here.

The ISCST3 was run twice, once to obtain predicted concentrations over the 48-hour period corresponding to the two ambient air monitoring events in 1994, and once to obtain annual average wet and dry deposition of sorbed dioxins to input into a simple soil reservoir mixing model to predict dioxin concentrations. The objective of this exercise was to use current

EPA guidance on the use of ISCST3 for air dispersion/deposition modeling of dioxins (EPA, 1994;1995b), coupled with a soil concentration model, and after doing so, determine how well the model was able to reproduce observed air and soil concentrations. This might be described as a "model validation" exercise because it has these characteristics: 1) all available site-specific information - stack emission rates, meteorological data, stack parameters, and others - are input into the model, 2) all other parameters for which no site-specific data is available - soil half-lives, atmospheric particle densities and mass fractions, and others - are input into the model using best available information with no attempts at "calibration" in order to make the model results best match observations, and 3) model results including predicted air and soil concentrations are compared against corresponding monitored concentrations.

On the other hand, it is recognized that this exercise falls short of a rigorous model validation exercise for ISCST3. The observed ambient air data set includes only two monitoring dates, with five ambient measurements for one date and four for the other date. Actual stack measurements of emissions are available for one of those dates, so a comparison of measured and predicted air concentrations for the second date does not qualify as a "validation" exercise. It must be assumed that emissions were the same for this second air sampling date. This is admittedly a small data set and a resulting rigorous test for ISCST3 dispersion model testing. Also, ISCST3 (and similar gaussian dispersion models) is expected to perform better for longer averaging periods (e.g., annual) than for short term events. Expectations for the "success" or characterization of the "failure" of the ISCST3 dispersion algorithms have to be tempered by these considerations.

The input of the average predicted depositions of dioxins into a simple soil mixing model to predict soil concentrations, and then comparing those to observed soil concentrations, is an exercise that may come closer to being a "model validation" exercise. In that case, the ISCST3 is applied in an hourly short-term mode over one year's worth of meteorological data to predict average long-term depositions to soil. These depositions are input into a soil mixing model to predict soil concentrations, and then the model results are compared with observations of soil concentrations. Unlike 48-hour air measurements, soil impacts are "long-term", particularly since dioxins are known to accumulate in soils over time and not undergo very meaningful dissipation. Also, there are 34 soil measurements around the CMSWTE available, and this number allowed for a reasonable characterization of the elevation of dioxin concentrations near the facility and the decline of concentration with distance.

In any case, discrepancies between predictions and observations in both the air and soil model comparison exercises were examined in order to gain insight on the capability of the

ISCST3 model to predict ambient air and soil impacts of emitted dioxins, and to gain insight on potential issues for further study of atmospheric and soil fate for dioxins.

7.3.7.1. *Modeling Procedures*

ISCST3 Modeling: ISCST3 is a Gaussian plume model, which accepts a variety of source geometries and emissions schedules in order to compute ambient air concentrations and surface deposition fluxes at specified receptor points. Two applications of ISCST3 were conducted for this effort. In one, the air dispersion algorithms alone were run, and meteorological data requirements included hourly wind speed, wind direction and stability for describing dispersion. These runs were conducted for the purpose of predicting 48-hr air concentrations, to compare with the 48-hr ambient air measurements. For the other, the particle-phase deposition algorithms were employed and dioxins were depleted from the plume by an amount equal to that depositing as the plume moved outward from the CMSWTE. The key output from these runs were long-term average dry and wet deposition of particle-bound dioxins, which were used for predicting soil concentrations of dioxins, to compare with the soil measurements.

For the dispersion model test, there were, in fact, two separate tests of the air dispersion algorithm - each test had a different meteorological data set: an “airport” set and an “on-site” meteorological data set. The airport set includes surface data (wind speed, wind direction and atmospheric stability) from the Columbus, OH, airport and upper air data for the mixing height from Dayton, OH. airport (BEEline Software, Inc. ISCST3 driver diskette 1998). The airport data was applied only for the first of two air monitoring events. On-site data for both of the 1994 measurement periods include wind speed and wind direction (Ohio Environmental Protection Agency. private communication 1998). The Columbus stability and Dayton mixing height were used in the on-site set. The purpose of obtaining and testing two meteorological data sets was to be able to evaluate the importance and uncertainty associated with key input stream. Besides meteorological data, other required inputs for modeling dispersion alone included: (1) building configuration data, (2) emissions data, and (3) receptor data. These dispersion model runs omitted particle-phase deposition, plume depletion, and chemical decay in the air. The dioxins were modeled as if the entire emission were in the form of a conservative pollutant, with no differentiation in fate of the individual compounds as a function of vapor/particle partitioning behavior, or atmospheric degradation or transformations.

For the deposition application of ISCST3, wet and dry deposition of particle-bound dioxins were modeled and then input to a separate soil mixing model to predict soil

concentrations. Therefore, additional meteorological data required were precipitation data. The prediction of depositions of particle-bound CDD/Fs with ISCST3 relies on particle-specific (particle diameter, e.g.) and dioxin-specific (vapor/particle partitioning, e.g.) parameters which are not required for dispersion modeling. The ISCST3 model estimates deposition flux values by multiplying the pollutant concentration in airborne particles by a deposition velocity. The deposition velocity is calculated considering gravitational settling velocities and atmospheric resistance. Annual average depositions were predicted using a single year of meteorological data from 1989; modeling from 1983 to 1994 would obviously have been preferable, but only one year of data was available. Meteorological data was provided by the National Climatic Data Center and from EPA's Support Center for Regulatory Air Modeling internet page (www.epa.gov/ttn/scram). The surface and precipitation data was collected at the Columbus, Ohio Weather Service Office. Atmospheric mixing heights were determined using upper air data collected at the Dayton, Ohio Weather Service Station. An examination of the meteorological data from 1989 compared with historical averages showed that the wind speed and direction were very similar to historical means, and the precipitation was slightly above normal for 1989 (111 cm for 1989 compared to an historical average for Columbus, OH, of 96 cm/yr). The ISCST3 was run in plume depletion mode, meaning that dioxins were depleted from the plume moving away from the incinerator by an amount equal to the dioxins depositing by dry and wet particle-phase deposition.

Like the air dispersion tests of ISCST3, two sets of outputs were generated for soil concentration modeling. There were two stack tests available, and it was unclear as to which would better characterize long term emissions of dioxins from CMSWTE. Both were used to predict soil concentrations. This is described in more detail in the next section below on Source Characterization.

The ISCST3 model was run on a "unitized" basis for both dispersion and deposition simulations, meaning that ambient air concentrations and deposition results were generated for an emission rate of 1 g/sec. For the dispersion-only runs, the individual total emission rates of all 25 CDD/Fs (17 congeners on non-zero toxicity and 8 homologue groups) were multiplied by the predicted unit concentration to give the predicted ambient concentrations at the receptor points. Deposition predictions for the CDD/Fs were generated using this two-step procedure: 1) the total amount of the CDD/F emitted was assumed to partition into vapor and particle fractions according to ambient conditions at 20 °C (in contrast to partitioning assuming conditions at the stack exit); this step allowed for an estimation of dioxin-specific particle-bound emission rates in g/sec, 2) then, these particle-bound mass emission rates were multiplied by the unitized dry and

wet deposition rates predicted to occur at the receptor point to provide the compound-specific deposition rates.

All model parameters for both runs, with the exception of the details on receptor locations (air and soil monitoring locations around the CMSWTE) are provided in Table 7-11. Further detail on modeling algorithms for the ISCST3 can be found in EPA (1995b).

Source Term Characterization: Two stack tests were available to supply the critical source term for this exercise (EERC, 1992; EMC, 1994). The first was conducted in 1992 by the Ohio Environmental Protection Agency (OEPA) for purposes of permit renewal. High dioxin emissions at 6799 ng total/dscm concentration (total = sum of the homologue group concentrations; dscm = dry standard cubic meter) and 976 g TEQ/yr (when extrapolating the results from 1 stack to the 3 stacks at CMSWTE and assuming historical average operation times for the CMSWTE) mass emissions were found, leading to regulatory actions by the state and federal environmental agencies. Process modifications were undertaken for purposes of reducing dioxin emissions, and the CMSWTE was retested in March of 1994. Total concentrations were reduced to 3685 ng/dscm and the mass TEQ emissions were reduced by about 75% to 267 g TEQ/yr (estimated using the same historical CMSWTE operation practices).

This second stack test occurred during March 16-18 of 1994. This corresponds closely to the time that the OEPA was sampling the air for dioxins - on the 15-17th of March. Therefore, the air dispersion model tests for March used the March stack test results. Unfortunately, the CMSWTE was not stack-tested during the April air sampling events. It was necessary to use the March stack test results for the April dispersion model tests, and then, of course, to assume that the April emissions were similar to the March stack test emissions.

For deposition modeling, a decision also needed to be made regarding characterization of long-term emission rates. Rather than select either the 1992 or the 1994 stack emission test for this evaluation, or an average of the two, to represent long-term dioxin emission rates, results were generated for both emission tests to demonstrate the importance of this critical and uncertain term in the modeling procedure.

Soil Concentration Modeling: Wet and dry depositions are summed and become the source term for a simple reservoir mixing model for predicting soil concentration C_s, as:

$$C_s = \frac{F\,(1 - e^{-kt})}{k\,M} \qquad (7\text{-}39)$$

where:

Cs	=	the soil concentration, pg/g
F	=	the annual total (wet + dry) deposition of dioxins as predicted by ISCST3, pg/m^2-yr
k	=	the first order annual soil dissipation rate, yr^{-1}
t	=	the time during which deposition occurs, yr
M	=	the soil mixing mass, g/m^2

The dissipation rate assumed here for all dioxin compounds was 0.02772 yr^{-1} (half-life of 25 years), a mid-range value selected to be between a value of 0.0693 (half-life of 10 years) often assumed for surficial dioxin residues (EPA, 1994) and 0.00693 (half-life of 100 years) speculated to be an upper range for subsurface dioxin residues (Paustenbach, et al., 1992). The best validation of this choice of half-lives for all dioxin congeners comes from McLachlan, et al. (1996), who reported on an analysis of soil taken from experimental plots which had been amended with sewage sludge in 1968 and sampled in 1972, 76, 81, 85, and 90. These archived samples were analyzed for all 17 dioxin-like CDD/Fs, and based on an analysis of results, McLachlan and coworkers concluded that half-lives were on the order of 20 years, with dioxin removal from the plots being mainly physical removal processes (overland runoff, wind erosion). Furthermore, their results suggested that all congeners had been removed at roughly the same rate, which is why they concluded that removal processes were mainly physical and very little in-situ degradation appeared to be occurring. A time of operation, t, of 11.5 years was used, corresponding to the time of operation of the CMSWTE. The soil mixing mass, M, equaled 112,500 g/m^2, which assumes a mid-range soil bulk density of 1.5 g/cm^3 and the soil sampling depth of 7.5 cm.

Description of the Measured Air and Soil Concentrations: Ambient air monitoring was conducted by the Ohio Environmental Protection Agency (OEPA) in 1994 to evaluate ambient air concentrations after process modifications reduced dioxin emissions from the CMSWTE. General Metal Works model PS-1 high volume samplers were used to collect 48-hr samples. Concentrations were, therefore, the sum of vapor + particle phase concentrations. Six monitors

were in the city of Columbus between 1.8 and 3.0 km from the site, mostly in the historical downwind direction, northeast, but one in the upwind southwest direction. Two of the samplers were co-located (for purposes of quality control), so results from these two samplers were averaged to represent one sampling point A seventh sampler was located 45 km southwest of the facility in a rural "background" setting; results from this sampler were not used in this modeling study. Five samples (4 sampling locations; the co-located samples were averaged) were taken in March and 6 samples (5 locations) were taken in April, 1994. The March set, taken on the 15-17th of the month, occurred at nearly the precise time that the March 1994 stack testing occurred, on the 16-18th. The April sampling event occurred during April 19-21. Exact starting and stopping times of the air monitors were not available for this test. For purposes of air dispersion modeling, the starting and stopping times were assumed to be the mid-day of the beginning and ending days of each sampling periods. In all, there were 9 urban air sampling events taken during 1994 that comprise the "observed" air concentration data set used in this modeling study. Wind rose data for the March and April sampling periods were also available, and the provided insights into the expected impact patterns. A final round of air samples from the seven air monitors was taken in 1995 after the CMSWTE had shut down. The purpose of this data set was to evaluate the air quality now that the CMSWTE was no longer operating. Full details on the air monitoring studies, including analytical methodologies, quality control, and final results, are described in OEPA (1994, 1995).

A first phase of soil sampling was conducted by the United States Environmental Protection Agency (EPA) in December of 1995. Sampling in this round included 4 samples on the site of the incinerator, 18 samples within about 3 km of the incinerator in the city of Columbus, and 3 samples at a background site 45 km from the CMSWTE. This background site was the same as the air monitoring background site. The study design for this phase employed a stratified random selection process, involving sites in the four major quadrants around the incinerator (northeast, southwest, etc.) with an emphasis of sampling in the quadrant which was historically downwind from the incinerator, the northeast quadrant. The following conditions were sought during site selection: 1) level, undisturbed soils, 2) away from trees, 3) not adjacent to roads, 4) not near pressure treated wood, and 5) not known or suspected to have high dioxin concentrations for any other reason. All samples were collected using pre-cleaned equipment dedicated to each sampling location. Each sample site consisted of an area of 1.5 m x 1.5 m. A grid of 25 sections was established at each site and used for random selection of aliquot sample sites. Four random aliquots were collected for each sample. A "sample" for this study was, therefore, a composite of four aliquots. Aliquots were collected using a stainless steel tulip bulb

planting device. This device removed a plug approximately 7.5 cm in diameter to a depth of about 7.5 cm.

A second phase of soil sampling was undertaken in August of 1996. Thirteen samples were taken from about 2 km away from the incinerator to about 8 km distant. The purpose of this second phase was to ascertain whether a background concentration for the city of Columbus could be determined. A similar selection criteria for sample sites was employed in this second phase.

Altogether, there were 4 soil samples on the incinerator property, 31 samples in the city of Columbus taken from right outside the incinerator to upwards of 8 km away, and 3 background samples taken 45 km away, for a total of 38 soil samples. This modeling used 34 of the samples - it did not have use for the 3 background samples, and 1 of the remaining samples was found to be contaminated by a local source not associated with the CMSWTE. Full details of the soil monitoring study can be found in Lorber, et al. (1998).

Figure 7-7 shows the location of the CMSWTE in relation to the 32 soil samples in Columbus and the 5 urban air sampling locations. Not shown in this figure are 3 of the 4 soil samples taken on the site of the incinerator, and the background site in which 3 soil samples were taken and the 1 background air sampler was located. This figure identifies the groupings of the soil samples, as described in the results section below.

Subtracting Local Background Concentrations From Measured Concentrations:

The ISCST3 will predict only the increments of dioxin concentration in the air and soil that are due to emissions from the CMSWTE. Therefore, a procedure had to be developed to subtract a local "background" of dioxins from both the air and soil observed data.

The average of 6 air measurements taken in 1995 after the CMSWTE shut down was assumed to represent the background dioxin air concentrations for this site. The average total concentration from 1995 was 2870 fg/m^3, with a range of 2030 to 4760 fg/m^3. The 1995 average concentrations of each dioxin-like congener as well as those of the homologue groups were subtracted from each of the March and April 1994 corresponding measurements. When such a subtraction resulted in a concentration less than 0, the concentration was assumed to be 0 for purposes of this exercise.

An analysis of the observed soil data in Lorber, et al. (1998) showed that concentrations decrease to the local soil background at about 3 km from the CMSWTE, at a TEQ soil concentrations of 4.0 pg/g (ppt). The soil profile of CDD/Fs for this background provided in

Lorber, et al. (1998) was subtracted from each of the 34 observed soil measurements; when this subtraction resulted in a concentration less than 0, the concentration was set to 0.

Procedures for Evaluating the Performance of the Models: The paucity of the observed data, particularly the air measurements, makes a rigorous "goodness-of-fit" statistical comparison of predicted versus observed inappropriate. Rather, tabular summaries of predicted and observed concentrations are utilized, and simple qualitative discussions address the goodness-of-fit. For the air dispersion comparisons, predicted air concentration quantities associated with a 48-hour air monitoring event are compared with the appropriate observed quantities. For the deposition comparisons, soil samples are "clustered" and simple mean concentrations are generated for both modeled and observed concentrations. Four clusters which are displayed include: 1) "on-site" - 3 soil samples taken on the site on the CMSWTE, 2) "off-site" - 5 samples just off-site and in the historical downwind direction, northeast, within 500 meters of the incinerator, 3) "urban" - 14 samples taken from about 500 meters to about 3 kilometers, and 4) "urban background" - 12 samples taken from about 3 to about 8 kilometers. As discussed in Lorber, et al (1998), the high soil concentrations found in the on-site cluster were speculated to have resulted in ash drift from piles or trucks transporting the ash to nearby landfills rather than deposition. Therefore, a comparison of predicted and observed concentrations for this on-site cluster are displayed for information purposes only, not to be considered in the context of model testing. Otherwise, all observed soil samples, and clusters, can be considered to represent long-term deposition trends as the monitoring study protocols insured that they were in relatively flat, undisturbed locations away from any nearby potential dioxin sources (roadways, PCP treated wood, etc.). The predicted and observed concentration quantities which are displayed include: 1) homologue group concentrations, 2) total concentrations, which are sum of the 10 homologue group concentrations, and 3) TEQ concentrations. These terms were defined above.

In addition to tabular summaries, isoline figures were generated. These are lines of equal concentration around the CMSWTE, either air or soil concentrations, that were generated using ArcView® - a desktop GIS package. First the point data, measured or modeled concentrations, are brought into ArcView® as point coverages. Then, using the ArcView® kriging routing, surfaces of the concentrations are generated using the exponential function to estimate the semivariogram. For the air and soil concentration isoline generation, modeled concentrations were generated for 250 meter intervals to about 3 km in all directions, and these were input as point coverages into ArcView®. There were too few observed air concentration measurements,

so isolines could not be generated for these. Instead, measured air concentrations were overlain on the predicted isolines. For soil concentration, there was judged to be sufficient coverage with 34 soil samples to generate "observed" isolines to compare with predicted isolines.

Finally, it is reiterated that all "observed" concentrations, both soil and air, were generated by subtracting out background concentrations in the procedure described above. Therefore, all tabular or figure notations of a "0" observed concentration means that, if subtracting out the background concentrations from the measured concentrations resulted in a negative concentration, the measured concentration was set to zero for purposes here.

7.3.7.2. *Results and Discussions*

Air Dispersion Modeling: Even before air dispersion modeling was undertaken, examination of the data revealed clear trends. Analyses of on-site wind roses for the March and April 1994 sampling dates reveal that there is one dioxin monitoring station likely to have been influenced by the CMSWTE. This station, termed SE-3 by the Ohio Environmental Protection Agency (OEPA) was about 2 km east of the source and was downwind from the source approximately 53% of the time during the sampling period in March 1994 and 78% of the time in April 1994 (OEPA, 1994). In contrast, none of the other 5 stations was downwind for time fractions approaching those of SE-3. The measurements confirmed that SE-3 was the most impacted of the samplers, with TEQ measurements of 168 fg TEQ/m^3 in March and 353 fg TEQ/m^3 in April. The average of the measurements from the other 5 samplers over the two dates (a total of 8 samples; one sampler was not operational for both events) was 52 fg TEQ/m^3, with a range of 10 to 98 fg TEQ/m^3 (note: background not subtracted out for these observations). Lorber, et al (1998) examined this trend further, showing also that the profile of CDD/Fs found in March and April in SE-3 matched the stack emission profile of CDD/Fs more closely than the other ambient air samples, which displayed profiles more typical of background air.

Table 7-12 compares the observed total concentrations at each reporting monitoring station with the model predictions for both meteorological data sets, the "on-site" and "airport" sets. As noted earlier, two important considerations for evaluating the comparison of predicted and measured air concentrations are: 1) having 4 and 5 air measurements for sample dates in March and April, respectively, is a small sample size, and 2) one can expect the ISCST3 to perform better for longer averaging times as compared to shorter averaging times. It would be fair to conclude that the paired comparisons of predicted and observed 48-hr air concentrations are severe tests of model performance, and Table 7-12 shows the large scatter expected from this test.

Still, some meaningful observations might be possible from Table 7-12. First, it does not appear that either of the meteorological data sets provides a superior fit to the data for the March sampling event. The on-site runs appeared to better identify SE-3 as the monitor of most impact, and also to identify the sampler SN-2 as having some impact, but not as much impact as SE-3. The airport meteorological set appeared to show a significant impact to SN-2, but not as much of an impact for SE-3. On the other hand, the simulations using on-site meteorological data identified SNW-1 as having the highest concentrations, while the simulations using the airport data correctly modeled this site perhaps more correctly as having little impact. Both meteorological data sets correctly identified SSW-4 as the monitor which showed no impact.

For the April sampling date, the on-site meteorological data correctly identified SE-3 and SSW-4 as monitors having some impact, with little or no impact for the other three monitors. However, SE-3 was not simulated to have the most impact, as was found.

The difference between using the on-site and air meteorological data was further examined using isoline figures. Six such isoline drawings, with observed concentrations overlain, are shown in Figure 7-8. These include TCDD, OCDD, and TEQ predicted/observed results from March for the on-site data and the airport data set. Observations from this figure include:

1) ISCST3 modeling runs using both meteorological data sets appear to have correctly identified the western quadrants (northwest and southwest) as being areas of little impact. The observed “0" concentration in the southwest quadrant (sampler SSW-4) is consistent with this trend, as are wind rose that are displayed and discussed in OEPA (1994). Both figures appear to have identified the northeast and southeast as areas of principal impact, with little impact due east. The two observed air measurements in the northeast quadrant (samplers SN-2 and SNW-1) do, in fact, suggest low impact due north with increasing impact as one moves in the northeast direction. The observed air measurement in the southeast quadrant (sampler SE-3) may, in fact, have missed areas of higher impact during the two days, which the model runs suggest are either further north or further south.

2) The discussion above comparing the measured point estimates with the modeled point estimates suggests that there may be significant differences in the way the two meteorological data sets simulated impacts. More specifically, the “airport” data simulation showed three times as much impact for sampler SN-2 compared to the “on-site” simulation: 20,833 fg/m ^{3} total (airport) vs. 6,606 fg/m^3 (on-site). On the other hand, the “on-site” simulation showed 7 times more impact for sampler SNW-1: 8943 fg/m ^{3} (on-site) vs. 1270 fg/m ^{3} (airport). Looking at Figure 7-8, however, the differences do not appear that meaningful. The on-site simulations

seemed to push the plume a little more northeast and southeast compared to the airport runs, which showed more impact due north and south. Sampler SN-2 was simulated to be in a zone of important impact according to the airport meteorological data set, while sampler SNW-1 was simulated to approach this zone more so with the on-site meteorological data set. These types of trends emphasize the potential problems and misinterpretations that can occur when one attempts a validation exercise with ISCST3 with short-term data and a limited number of air measurements.

3) The biggest discrepancy for the three dioxin quantities compared in Figure 2 is for OCDD. It appears as though much higher concentrations, ranging from 1 to almost 5 pg/m^3 in the northeast and southeast were modeled, while measurements of 0.5 pg/m^3 and less were observed. These high modeled OCDD concentrations were the main reason that the ISCST3 modeled much higher observed total concentrations than were measured (see Table 7-12). For the other quantities, TCDD and TEQ, while the location of high impacts may not have been perfectly identified, at least the magnitude of the high measurements were in the range of the high modeled concentrations. This important trend is discussed in more detail below.

As mentioned above, station SE-3 stands out in both the March and April sampling as having the highest impact of all stations. Thus, the data from this station have the best chance of avoiding the uncertainties introduced by background fluctuations. Predicted and observed homologue group concentrations for SE-3 for the both sampling dates are compared in Table 7-13. These results were generated using on-site meteorological data. Table 7-13 also shows the CMSWTE stack emission rate of these homologue groups.

Being only an exercise in air dispersion modeling (no wet/dry deposition; no stack speciation; no atmospheric chemical reactions), there is a perfect correlation between the homologue profile of the emissions and air concentration predictions for both March and April. The observed air concentrations clearly do not have this stack emission profile, however. Specifically, the speciation pattern from source to receptor has shifted in these ways: 1) the lower chlorinated tetra and penta CDD/Fs have greatly magnified in importance in the ambient air profile as compared to the stack profile, and 2) conversely, the hexa through octa homologues, with the exception of OCDF, have been reduced in importance in the ambient air profile as compared to the stack profile. Said another way, the model predicted lower concentrations for the lower chlorinated CDD/Fs than were measured, and higher concentrations for the higher chlorinated CDD/Fs. The total concentration predictions were, however, within about a factor of two of observations. Not that it has meaning with regard to fate and transport considerations, but

the TEQ concentrations were comparable: 125 and 309 fg TEQ/m^3 measured during March and April compared with 142 and 156 fg TEQ/m^3 modeled for SE-3.

Three possible explanations are offered to explain why the model did not predict the measured shift in homologue profile between the stack and field:

1) It is known that CDD/Fs with fewer chlorines have higher vapor to particle (V/P) ratios; indeed, high temperatures in the stack could generate even higher V/P ratios (Eschenroeder, 1994). If stack sampling methods underestimate the amount of vapor pollutant being emitted, than the lower chlorinated dioxin emission rates are being underestimated - an error that would be exacerbated by the even higher V/P ratios in the high temperature stack gas. The PS-1 samplers capturing both vapor and particle-phase CDD/Fs in ambient air are well tested and not expected to have caused error in the characterization of total ambient air concentrations of dioxins. There has been some speculation that PS-1 samplers may overestimate the vapor fraction of dioxins, but this would not affect their characterization total concentrations (sum of vapor and particle phase concentrations; see Chapter 3 for a complete discussion of vapor/particle partitioning).

2) Running the air dispersion algorithms of ISCST3 alone did not account for particle deposition, yet some of the higher chlorinated CDD/Fs, expected to be sorbed to ambient air particles or fly ash, may have deposited by dry deposition prior to the air sampling locations. The results for the deposition modeling described below support this hypothesis, at least for the dioxins. It compares model predictions of soil concentration with measured soil concentrations. One clear trend was that the model consistently underpredicted the soil concentration of the hepta and octa dioxin homologue groups. This result, combined with the observation that the higher chlorinated dioxins were the most overpredicted in air concentrations in this paper, suggests that the plume is being depleted of higher chlorinated dioxins by deposition. However, this trend was not duplicated by the higher chlorinated furans. There, modeled soil concentrations were more nearly consistent with measured soil concentrations, with a small degree of overprediction.

3) Another possible physical explanation is that dechlorination may occur between the emission point and the ambient measuring station a kilometer or two downwind. Workers at Monsanto Laboratories (Orth, et. al., 1987) and at the Agro-Environmental Science Institute in Japan (Koshioka, et al., 1989) have observed photolysis of TCDD. Generally, polychlorinated organic compounds easily experience photochemical loss of chlorine atoms. If the higher chlorinated CDD/Fs dechlorinated to form lower chlorinated CDD/Fs in the atmosphere, than more lower chlorinated CDD/Fs would have arrived at the ambient air monitoring stations to cause the distinct ambient air profile.

Deposition and Soil Concentration Modeling: Table 7-14 provides results from this exercise, which are observed and predicted homologue and TEQ concentrations for 4 clusters of soil samples. These clusters were developed for purposes of displaying results from the soil monitoring study conducted around the CMSWTE (Lorber, et al., 1998), and generally correspond to increasing distance in all directions from the incinerator. As discussed above, the observed and predicted soil concentrations for soil samples taken on-site, the first cluster of Table 7-14, are shown for informational purposes only; it is not expected that the on-site soil samples represented long-term deposition trends. Some trends that may be observed from the results in Table 7-14 include:

1) Since emission rates between the 1994 and 1992 stack tests differed by about a factor of 4, subsequent predictions of soil concentration made with each stack emission rate also differed by this factor of 4. Generally, the 1994 stack test predictions appear to better match the observed soil concentrations compared to the 1992 stack test with all homologue groups except TCDD; the TCDD predictions using the 1992 stack test are a better match. Most of the time, however, both sets of predicted homologue group soil concentrations were higher than observed soil concentrations, sometimes by more than a factor of 10 when using the 1992 stack test.

The question that this study is unable to answer is which stack test is more likely to have been representative of long term emission trends from the CMSWTE. The 1994 test occurred specifically after measures had been taken to reduce dioxin emissions. Because of process changes made to the CMSWTE, it would be reasonable to assume that the 1994 test is not representative of long term emissions. On the other hand, the 1992 test was occurring during heavy rainfall, which soaked the refuse to be burned. Data on the refuse moisture content showed that the average moisture content of the refuse burned in 1992 was about 10% higher than in 1994 - it was about 38% during the 1992 test compared to 28% in 1994. Some have suggested that wetter refuse may result in higher dioxin emissions (personal Communication, K. Jones, Zephyr Consulting, Seattle, WA.), although this hypothesis is unproven and the moisture content of feed materials is not considered to be a principal factor in predicting dioxin emissions - factors such as feedstock content, combustion efficiency, pollution control device, and pollution control inlet gas temperature are more often cited as the critical factors.

2) Noteworthy for results with both stack tests is that much more OCDD is found in the soil than predicted, and the same is true but to a lesser, although still noticeable, extent with HpCDD; in other words, the model under-predicted the soil concentrations of these homologue groups. As noted above in the description of air dispersion results, the ISCST3 was found to greatly over-predicted OCDD and HpCDD ambient air concentrations. Taken together, these

trends suggest that OCDD and HpCDD deposited near the incinerator to a much greater extent than was modeled. Since both dioxin homologue groups exist in the atmosphere principally sorbed to particles, this may reflect inappropriate parameter assignments relating to particle phase deposition algorithms, or possibly inappropriate deposition algorithms in general. However, the model appears to *overpredict* OCDF and HpCDF, and like OCDD/HpCDD, OCDF and HpCDF are also tightly sorbed to airborne particles, so perhaps the model's treatment of particle fate may not be the cause of significant underprediction of OCDD.

3) With both stack test results, the model would appear to proportionally overpredict most congeners (not OCDD/HpCDD) to a greater degree the further downwind one gets. This suggests that more dioxin mass is being removed from the plume as it disperses downwind than ISCST3 is able to simulate. Removal mechanisms include particle and vapor phase deposition, plant capture, and atmospheric degradation (photolysis and photooxidation).

Figure 7-9 shows a series of 9 isoline maps crafted to additionally display the trends of the measured versus the modeled soil concentration. Each group of three isoline maps pertains to one CDD/F compound; there are three isoline figures each for TCDD, OCDD, and TEQ concentrations. The first in the sequence of three are isoline maps drawn from the measured data, and the next two are maps drawn from using the 1992 and then the 1994 stack test. Observations from Figure 7-9 include:

1) The shape of the isoline figures developed using the 1992 stack emission test will be the same as those developed using the 1994 stack emission test, because they were all developed from the same unitized simulation - the only difference will be the mass of particle-bound emissions as a function of the compound and stack test.

2) The observed maximum soil concentration appears to occur in the northeast quadrant about a kilometer away. The predicted maximum soil concentrations are also found in the northeast quadrant, but they are a bit closer, at about ½ kilometer away. Also, the isolines drawn from model simulations seem to suggest that the maximum will occur more due north of the CMSWTE as compared to isolines drawn from measured data.

3) As was noted above, these isolines suggest much higher OCDD concentrations, in the thousands of parts per trillion (or equivalently, parts per billion), are found near the CMSWTE, as compared to modeled OCDD concentrations, which are in the hundreds of parts per trillion. It is noted that smooth isolines could not be drawn from the observed OCDD data because of the inhomogeniety of the results. Specifically, of the 8 highest soil samples nearest the CMSWTE, 5 had observed concentrations of OCDD above 1900 pg/g, ranging from 1930 to 6651 pg/g, but the

other 3 measurements were less than 1000 pg/g, ranging from 309 to 731 pg/g. The observation that OCDD was elevated in soils well above 1000 pg/g is supported by the data, despite oddly shaped isolines. The observed TCDD concentrations in the vicinity of the CMSWTE appear in range from 40 to a peak of 160 ppt, which is close to the range of 50 - 200 ppt modeled when using the 1992 stack emission test. However, when using the 1994 stack emission, the elevation in TCDD is only suggested to be in the 5 - 20 ppt range. Although not meaningful with regard to fate and transport, per se, the 1994 stack test appears to better duplicate the observed range of elevated TEQ concentrations - between 20 and 50 ppt, while the 1992 stack test simulations suggest elevations as high as 200 ppt TEQ.

7.3.7.3. *Discussion and Concluding Remarks*

Caution was expressed in the opening paragraphs that this exercise should not be characterized as a "model validation" exercise, mainly because of the weaknesses and uncertainties in the data and model parameters. To reiterate, some of those weaknesses/uncertainties include: a) a very small number of observed air monitoring data points (and the lack of precise information on when the air monitors were turned on and off, which can be important for short term air dispersion testing), and a relatively small number of soil measurements, b) the lack of consideration of all possible plume depletion mechanisms in the dispersion and deposition modeling. For the deposition modeling, the plume depletion by particle-phase deposition was considered, but other plume depletion mechanisms include atmospheric degradation of either vapor or particle phase dioxins, vapor phase deposition, and vapor- and particle-phase vegetative capture, c) a reasonable but still possibly flawed means to subtract "background" from measured air and soil concentrations. It is possible, for example, that air monitoring locations have their own, very localized, "background". Therefore, averaging all 5 air concentration measurements from 1995 to represent "background" to subtract equally from all measurements in 1994 may not be appropriate, d) uncertainties in dioxin-specific fate parameters including vapor/particle partitioning of the CDD/Fs and soil half-lives, and e) uncertainties and/or lack of representativeness in the important source term, the rate of dioxin emissions from the stack, and the equally important meteorological data used to drive the model simulations.

These latter uncertainties in source term and meteorological data were evaluated by using different data sets. Specifically, two meteorological data sets were used in the dispersion modeling exercise - an "on-site" meteorological data set supplied by Ohio EPA (who took the air samples), and a publicly available data set from a nearby airport. Two possible stack tests were

used to characterize long term emission rates for deposition and soil concentration modeling. As discussed above, there were no clear "superior" choices in either meterological data set or stack emission test. While it was clear that air concentration and soil concentration results differed when by using both data sets, in fact it was also clear that both data sets seemed to predict some quantities better than the counterpart data set.

With these cautions, it may be fair nonetheless, to make these statements regarding the ability of the ISCST3 to model the impact of dioxin emissions from the CMWSTE:

1) Elevations of dioxins in air and soil were clearly identified in the sampling programs, and they were also clearly modeled by ISCST3. Predicted and measured dioxin elevations in air and soil appear to generally be within a factor of 10 of each other, with both under and over predictions identified above. These elevations appear to be restricted to only within a few kilometers, 2-3 kilometers, and this was also found in the dispersion and deposition modeling. From the soil modeling exercise, it appears as though the model overpredicted soil concentrations to a greater degree the further downwind one went. This suggests that the plume was being depleted by dioxins in a manner that was not duplicated by the ISCST3 modeling.

2) It is clear from the analysis in this paper that the stack emission profile of CDD/Fs is very different from the profiles measured in the soil and in the air. This could be explained by "changes" in the profile at some point between the stack and both air and soil measurement sites, or it could be that there were problems in the measurement of CDD/Fs in either the stack or the environmental media. Assuming no major problems with measurement, it can be said that these trends cannot be duplicated in ISCST3 without the input of congener-specific atmospheric degradation rates, and/or congener-specific soil dissipation rates. Also, one hypothesis offered to explain the change in the dioxin profile from stack emission to air measurement was that some dechlorination might be occurring - the higher chlorinated CDD/Fs may be dechlorinating to form lower chlorinated CDD/Fs. If so, and if attempting to duplicate this trend, the ISCST3 model would need additional algorithms to model these transformations.

While admittedly a limited field test of deposition and soil concentration models, the data used here had these important features, which are not readily (if at all) available for similar model testing of ISCST3 with CDD/Fs: multiple stack tests offering a full suite of dioxin homologue and congener data; a historically high emission rate and over 11 years of emissions such that a signal is left behind in the soil and an imprint in the ambient air while monitoring was occurring, and a reasonable approach to determining the local background of dioxin soil and air

concentrations that could be subtracted from the total measured soil and air concentrations to characterize a "signal" of higher dioxin concentrations found near the incinerator.

7.3.8. Air-to-Soil and Soil-to-Air Modeling

The observed air and soil data used in the background demonstration scenarios in Chapter 5 were from the rural background site of the Columbus site described above. These rural data also allow for an opportunity to test the air-to-soil modeling and the soil-to-air modeling algorithms. To summarize those scenarios, actual air concentrations and soil concentrations of the 17 dioxin-like congeners from the rural background site in Ohio were used as source terms. The I-TEQ air and soil concentrations from this site were 0.019 pg/m^3 and 1.37 pg/g, respectively. The individual congener concentrations in air and soil were used to predict concentrations in terrestrial foods (vegetables/fruits, animal food products) and the aquatic environment (water, fish, and sediments). Soil concentrations were not predicted from air concentrations and likewise, air concentrations were not modeled from soil emissions. For this model validation exercise, however, the opportunity presents itself to model air-to-soil impacts and soil-to-air impacts, and then to compare model predictions with observations.

Chapter 4 describes the models for estimating soil concentrations based on dry and wet deposition of particle-bound dioxins. The models were used in the stack emission source category, and in that context, dry and wet deposition amounts are modeled using the ISC3 air dispersion and deposition model. The full amounts of dry and wet deposition (i.e., no subtraction for plant interception) are mixed into a reservoir of soil and dissipated according to a defined dissipation rate. The reservoir of soil for this exercise will be that defined by a 7.5-cm depth, which was the depth of the soil sampling at the rural site in Ohio, and the assumed soil bulk density will be 1.50 g/cm^3. The dissipation rate is 0.0277 yr^{-1}, which corresponds to a half-life of 25 years. Since deposition was not monitored at the rural site, it will be estimated as the particle bound air-borne reservoir times a velocity of deposition. Koester and Hites (1992) measured a dry deposition rate of 0.002 m/sec for dioxins in Indiana. They also measured wet deposition and found it be roughly comparable for two sites. On this basis, dry deposition in this exercise will be modeled using the 0.002 m/sec velocity of deposition and wet deposition will be assumed to be equal to dry deposition.

Chapter 4 also described models for estimating air concentrations given soil concentrations. These algorithms were for the soil source category. The algorithms for volatilization were developed for PCBs and made simplifying assumptions such as no degradation, an infinite source of contaminant, and so on. An "unlimited reservoir" approach

was used to estimate the flux of particle bound dioxins from soils due to wind erosion. A near-field dispersion algorithm estimated air borne concentrations given flux estimates of vapor and particle-bound dioxins. Despite using an "unlimited reservoir" approach, it was observed in Chapter 5 that the particle-bound air-borne concentrations were about an order of magnitude less than the vapor-phase concentrations for the demonstration of the soil contamination source category.

The results of this validation exercise are shown in Table 7-1. There is a clear dichotomy in the results. The air-to-soil model appears to model soil impacts reasonably well, with modeled soil concentrations somewhat lower but within the realm of field observations. On the other hand, the soil-to-air modeling did not show a good match. All predicted congener concentrations were 2-3 orders of magnitude lower than observed congener concentrations, and there was a 500-fold difference in observed and predicted TEQ air concentrations.

Regarding the air-to-soil modeling, 11 of the 17 observed soil concentrations were higher than model predictions. All but three congeners were modeled to within a factor of five of observations, and the three other congeners were about a factor of 10 from observations (i.e., either observations were 5 to 10 times higher than predictions, or predictions were 5 to 10 times higher than observations) . The four highest observations are matched with the four highest predictions as follows: 17.7 ppt observed 1,2,3,4,6,7,8-HpCDD versus 9.1 ppt modeled, 161.0 versus 36.2 ppt for OCDD, 4.06 versus 2.74 ppt 1,2,3,4,6,7,8-HpCDF, and 10.7 versus 2.70 ppt OCDF. The observed I-TEQ soil concentration of 1.37 ppt matches well with the predicted TEQ concentration of 0.70 ppt.

While the soil model appears to work reasonably well based only on impact of particle depositions, vapor impacts are not considered, and consideration of such would increase predictions of soil concentrations. As noted above, it does appear that soil concentrations may generally be underpredicted, although for six congeners, the model predictions were higher than observations. Direct vapor deposition could impact soils, but for the soil observations in the rural site in Ohio, all samples were taken in grassy areas, and with a vegetative cover, it is speculated that there would little direct vapor deposition. Therefore, detritus production would be a mechanism for vapor impacts to soils. Barbour, et al. (1980) list a detritus production rate for a setting described as "tallgrass prairie" as 520 g/m^2-yr. Given the concentrations predicted to occur in grass due to vapor transfers, one can estimate the loadings of dioxin corresponding to a detritus production of this magnitude. The predicted TEQ concentration in leafy vegetation due to vapor transfers was 0.27 pg/g dry weight given the rural air concentrations at this site in Ohio. This concentration times the detritus rate leads to a loading of 112 pg TEQ/yr. In contrast, the

dry and wet deposition loading estimated by dry and wet deposition of particle-bound dioxins (as described above) is 2130 pg TEQ/yr. Therefore, on a TEQ basis, vapor impacts via detritus production would only be about 5% of loadings by dry and wet deposition of particle bound dioxins. There was also a reasonably narrow range for individual congeners, where detritus loadings were about 5-15% of atmospheric deposition of particle-bound dioxins. Particle-bound dioxins also impact vegetation, and detritus production might be considered as an additional loading due to particle bound dioxins. However, since 100% of atmospheric depositions are loaded into the soil model, detritus production is inherently handled, and considering detritus production would double-count the impact of particle-bound dioxins.

Another factor to consider is the representativeness of the air concentrations. The air concentration profile was generated as the average of 3 samples, one taken in March, 1994, one in April, 1994, and one in June, 1995. It has been observed that air concentrations are higher during winter months (Reed, et al., 1990), and perhaps the inclusion of additional winter samples from the site in Ohio would lead to a higher air concentration profile and higher predicted soil impacts.

Regarding soil-to-air modeling, it is not that clear that emissions and resulting air concentrations above soils at background levels should be lower by up to 2 orders of magnitude than what would occur in background setting. The argument has been made in Volume II, Chapter 2 of this assessment that emissions from tall industrial stacks, followed by long range transport, are principal sources of these compounds in rural environments where the food supply is produced. The question remains as to how much of the contaminant in rural air is due to urban emissions followed by long range transport versus emissions from the soil reservoir source. If the modeling of this assessment is correct, than soils contribute very little to rural air concentrations. However, other evidence developed in this assessment suggests that the soil release and dispersion algorithms of this assessment may be underestimating air concentrations. One piece of that evidence is discussed in the next section below. Plant:soil ratios, defined as the ratio of 2,3,7,8-TCDD concentration in plants divided by that in the soil, were found to be lower in model predictions as compared to literature values. Two possible hypotheses were offered below: 1) the model is underpredicting air concentrations resulting from soil releases, and/or 2) plant:soil ratios derived in experiments are not only the result of soil related impacts, but also from distant sources of air-borne release and long range transport - i.e., the air reservoir is not solely explained by soil releases. This is the same issue that is discussed for the soil-to-air model exercise here. One other possibility for the difference in the inability of the model to duplicate plant:soil ratios would be that the algorithms estimating air to plant transfers are modeling too

low a transfer rate. However, the air to plant transfer algorithms were examined in Section 7.2.1 above and in Section 7.3.12 below, which describes a broader air-to-beef food chain validation exercise. In both sections, concentrations of the dioxin congeners in leafy vegetation were compared with model predictions for leafy vegetation, and predicted concentrations were found to be in line with observations. Also, the vapor-phase air-to-leaf transfer coefficient was calibrated with field data, and since it is shown that vapor phase transfers tend to dominate plant concentrations, air-to-plant transfers should, by definition, be modeled adequately.

In summary, this section has shown that the air-to-soil model based on deposition of particle-bound dioxins appears to work well. Vapor impacts would occur primarily by die-back of vegetative materials, but the additional increment to soil concentrations are estimated to be less than 10% by this route. Inclusion of winter-time air concentrations in the average air profile used to predict soil concentrations could lead to higher predictions of soil concentrations and a superior match of predicted and observed soil concentrations in this exercise. The soil-to-air models may be underpredicting air concentrations. The observed air concentrations are 2-3 orders of magnitude higher than predicted to occur by soil emissions alone. This is due, in part, by the fact that some fraction of the observed air concentration is due to long range transport from distant sources. It is not known what fraction this is, but other evidence has suggested that dioxins in rural settings distant from known sources of dioxin release originate, in fact, from those distant sources. Other evidence suggests that the soil-to-air models may still be underestimating the impacts to air from contaminated soils. The only way to truly test the soil-to-air models would be to have air concentrations measured above soils, where it is known that there are no other sources to measured air concentrations. Unfortunately, this data would be hard to develop for the ubiquitous dioxins and none was available for testing.

7.3.9. Transfer of Dioxins From Soils to Below Ground Vegetables

This section describes a validation of the transfer algorithm from soils to below ground vegetables. The equation for calculating the concentration of dioxins in below ground vegetables is:

$$C_{bgv} = \frac{C_s \; RCF \; VG_{bg}}{Kd_s} \qquad (7\text{-}40)$$

where:

C_{bgv} = fresh weight concentration of below ground vegetables, pg/g

C_s	=	contaminant concentration in soil, ppt or pg/g
Kd_s	=	soil-water partition coefficient, L/kg
	=	$Koc*OC_{sl}$
Koc	=	contaminant organic partition coefficient, L/kg
OC_{sl}	=	fraction organic carbon in soil, unitless.
RCF	=	root concentration factor equaling the ratio of the contaminant concentration in roots (fresh weight basis) and the concentration in soil water, unitless
VG_{bg}	=	empirical correction factor for below ground vegetation which accounts for the differences in the barley roots for which the RCF was derived and bulky below ground vegetables, unitless

The key contaminant-specific parameter, RCF, was developed from data developed by Briggs, et al. (1982) on the transfer of organic contaminants from solution into barley roots. The soil concentration, C_s, is divided by the soil partition coefficient, Kd_s, so as to convert it to a soil water concentration. The VG_{bg} is an empirical factor introduced to describe the difference between the thin barley roots of the Briggs experiments and the bulky below ground vegetation to which it is applied for the dioxin documents. Evidence shows that dioxins translocate only to a small degree into bulky below ground vegetables (see next section). The assignment of values to VG_{bg} in this assessment also considers other factors pertinent for estimating concentrations for human exposures, including factors which would further reduce whole vegetable concentrations including washing or peeling. Further detail on the algorithm can be found in Chapter 4.

Data from Muller, et al. (1994) was used to validate this model. Specifically, carrots were grown in pots with soil of two concentrations, a control soil and a contaminated soil. Muller, et al. (1994) provided graphs showing the congener group concentrations for soil, and for three parts of the carrot: peel, cortex, and stele. The precise concentrations from these graphs was unavailable. However, the graphs were digitized by Cambridge, Environmental (58 Charles Street, Cambridge, MA; concentration values contained in discussions in a public comment provided to EPA), and their concentrations were used in this exercise. Data in this article also included the soil organic carbon content, 8.1% (OC_{sl} = 0.081).

Part of this data set was used in conjunction with the model displayed above. The VG_{bg} was taken out of the equation and the soil concentration data was input into the model to predict the peel concentrations. The cortex and stele concentrations were not used in the validation exercise. These predicted peel concentrations were compared with the observed peel

concentrations. Since the data was available in congener groups and not individual congeners, the values for the parameters RCF and Koc were estimated as the congener-specific value if only one dioxin-like congener was in the congener group (2,3,7,8-TCDD, e.g.), or as the average of the congener-specific values of the multiple dioxin-like congeners in the congener group (the three HxCDDs, e.g.). Finally, the data in Muller, et al (1994) was only given in dry weight terms without discussion of the dry weight fraction, and the model predicts a fresh weight. For this exercise, it was assumed that carrots are 15% dry weight; the fresh weight was divided by 0.15 to estimate the dry weight concentration.

Table 7-16 shows the data that went into this validation exercise and the results. It would appear that the model works reasonably well. The difference in peel concentrations due to soil concentrations is apparent in both the data and the model predictions, and the magnitude of the difference appears to be captured. With one exception, the predictions and observations are within a factor of 4 of each other, with the exception being a factor of 5. Thirteen of 20 predictions/observations are within a factor of 2 of each other. The biggest discrepancies are the HpCDF and OCDF congener groups, with predictions exceeding observations by a factor of about 4 for both the control and contaminated soils. This data is further examined in Chapter 4 to determine the VG_{bg} parameter. Generally, it is concluded from this validation exercise that this data supports the use of the Briggs, et al. (1982) RCF empirical formulation to predict the peel concentration in underground bulky vegetation.

7.3.10. Impacts of Contaminated Soils to Vegetation

There have been several studies in addition to the carrot study described above which have measured plant concentrations of 2,3,7,8-TCDD for plants grown in soils with known concentrations of 2,3,7,8-TCDD or dioxin Toxic Equivalents (TEQs) or dioxin congener groups. One quantity that can be estimated from these studies is a *plant:soil contaminant concentration ratio*. The plant:soil ratio equals the concentration in the plant divided by the concentration in soil in which the plant is growing. Concentration ratios predicted to have occurred in the demonstration scenarios can be compared against those that have been measured in the various studies.

These ratio comparisons cannot strictly be considered model validations. Only the exercise described in the previous section, where experimental data were duplicated with modeling, can be considered a model validation. Still, trends ascertained from the literature will be compared with concentration ratios from the demonstration scenarios. The literature articles measuring soil and resulting plant concentrations of dioxin-like compounds are summarized in

Table 7-17. This table also includes concentration ratios, and separates sections for above and below ground vegetation.

In measuring both the soil and the plant concentration, several of the early literature articles, particularly those from Seveso (Wipf, et al., 1982; and Coccusi, et al., 1979) presumed that the soil in which the plant was growing was the ultimate source for the 2,3,7,8-TCDD contamination of above ground plant parts, if not from direct uptake than from deposition of suspended particles. However, recent research has concluded that the contamination of above ground plant parts is due principally to air-to-plant transfers (Hulster and Marschner, 1993; Muller, et al, 1993; Muller, et al., 1994; Welsch-Pausch, et al, 1995; and others). These cited research efforts have concluded that there is no consistent relationship between soil concentrations of dioxin-like compounds and above ground vegetative concentrations of these compounds, which has led the researchers to conclude that air-to-plant transfers explain plant concentrations (one study did strongly imply a direct soil/plant for dioxin-like compounds for at least one family of above ground vegetables, the cucumber family (Hulster, et al., 1994); this will be discussed below). This fact, coupled with the fact that sources of airborne contamination by dioxins include both distant sources and soil releases, make it difficult to compare literature reports of plant:soil contamination concentrations with those predicted by the soil contamination modeling of this assessment.

Recall that for the soil contamination source category, the presumption is that air concentrations and depositions to which the plant are exposed originate only from the contaminated soil. One would expect that the modeled plant:soil ratio for above ground plant parts would be lower than plant:soil ratios measured in actual field settings, since the field measured ratios are influenced by more than just the soil releases into the air.

What is more pertinent in the demonstration scenarios for comparing plant:soil ratios for above ground vegetation are the results for the “background” scenarios. Here, air concentrations from an actual setting provide the source of dioxins for above ground plants. Simultaneously, soil concentrations which correspond to the actual setting where air concentrations were measured are input into the scenario. Therefore, plant:soil ratios from this demonstration should be analogous, at least, to plant:soil ratios derived from other actual field settings.

Unlike above ground vegetation, the literature is consistent in concluding that soil provides the source for underground soil to root transfers. For this reason, Table 7-17 and the following discussions distinguish between above and below-ground vegetation.

The following plant:soil contaminant concentration ratios for TEQs were estimated for the two scenarios demonstrating background conditions in Chapter 5, Scenarios 1 and 2: below

ground vegetables - 0.19 (dry weight basis, assuming vegetables are 15% dry matter, and using tilled soil concentrations which are 50% of untilled soil concentrations), above ground vegetables/fruit - 0.10 (dry weight basis, 15% dry matter, tilled soil concentrations), grass - 0.33 (dry weight, untilled soil concentrations), and feed 0.16 (dry weight, untilled soil concentrations). Some observations from experimental results found in the literature, and comparison with the results of the model, are:

1) The largest body of consistently developed experimental data on soil-plant relationships of dioxin-like compounds comes from a research group in Germany who have published numerous articles for different vegetation and experimental conditions in the 1990s (Hulster and Marschner, 1991; Hulster and Marschner, 1993; Hulster, et al., 1994; Muller, et al., 1993; Muller, et al, 1994). Some of the earlier literature showed much higher impacts to vegetation than measured by these German researchers (Coccusi, et al., 1979; Facchetti, et al., 1986; Young, 1983), which, in the judgement of the authors of this assessment, renders them suspect. One early report, that of Wipf, et al. (1982), does show results consistent with the German research. The observations following will focus mainly on this research from Germany.

2) Experimental results for both above and below ground vegetation suggest that plant:soil ratios decrease as soil concentration increases. For below ground vegetation, this suggests that the movement into plants is not a passive and unimpeded process occurring with transpiration water, for if it were, plant:soil ratios would be constant as concentration increases. For above ground vegetation, the observations given above that air-to-plant transfers and not soil-to-plant transfers better explain plant concentrations, and that air concentrations include soil releases as well as long term transport, leads one to conclude that a consistent relationship between soil concentrations and plant concentrations is not to be expected. An explanation for this trend for below ground vegetative trends could not be found.

The models of this assessment - soil to below ground vegetation, soil to air to above ground vegetation, and air to above ground vegetation - cannot duplicate these observed trends, that is, the models will not show a decrease in plant:soil ratios as soil concentration increases. When soil is the only source of contamination, as in the soil contamination source category, above and below ground vegetation concentrations are a linear function of a biotransfer factor and an appropriate media concentration - air, soil, water. For particle depositions, no transfer parameters are used, but plant concentrations are a linear function of model inputs, including deposition rates, plant interceptions and yield, and a plant washoff factor. Therefore, plant concentrations will be a linear function of soil concentrations for the soil contamination source category.

3) Plant:soil ratios for below ground vegetables for soil concentrations in the low ppt range would appear to be in the 10^{-1} to 10^{-2} range (Muller, et al, 1993; Hulster and Marschner, 1991), which may be a little lower than the 0.19 predicted by the model. Much higher ratios were found in the earlier studies (Coccusi, et al., 1979; Facchetti, et al., 1986; Young, 1983), which earlier had been speculated as being questionable. One earlier study, that of Wipf, et al. (1982), does report ratios similar to these later studies, as noted above. At higher soil concentrations in the sub to low ppb range, plant soil ratios are more in the 10^{-4} to 10^{-3} range (Hulster and Marschner, 1993; Hulster and Marschner, 1991).

4) The results for above ground bulky vegetation, fruits and vegetables, indicate plant:soil ratios that are lower than plant:soil ratios for bulky below ground vegetation, for comparable soil concentrations. The data of Muller, et al. (1994) can be used to demonstrate this point. This data was used over others because the soil concentrations, at 5 and 56 ppt TEQ, are nearer to the background soil concentration of 1.37 ppt TEQ used in the background demonstration scenarios than any of the other studies found. First, their results include total crop dry weight concentrations of TEQs for carrots, lettuce, and peas (including pods) in soils with TEQ concentrations of 5 and 56 ppt. At these two soil concentrations, the carrot:soil ratios were 0.07 (at 5 ppt TEQ soil concentration, dry weight of the carrot) and 0.017 (at 56 ppt). Their lettuce and pea pod:soil ratios for the control and contaminated plots ranged from 0.0016 to 0.016 (total crop, dry weight basis). The modeled plant:soil ratio of 0.10 for vegetables/fruits in the background scenarios is higher than the 0.0016 to 0.016 for lettuce and peas in the Muller, et al. (1994) experiments. This could suggest an overestimation of the modeling of air-to-plant impacts.

5) Several of the articles, both from the German work and the earlier work, noted that most of the concentration was in the outer portions of the below and above-ground vegetation, and not the inner portions. Despite significant increases in soil concentration from the ppt to the ppb range, inner potato tuber concentrations remained constant (Hulster and Marschner, 1991, 1993). This evidence was the principal justification for the use of the empirical adjustment factors termed VG for soil to below ground transfers, VG_{bg}, and vapor-phase air transfers to bulky above ground vegetation, VG_{ag}. The chemical-specific empirical transfers factors for both of these transfers were developed in laboratory experiments with several chemicals using thin vegetation - solution phase transfers to barley roots for below ground vegetation concentrations, and vapor phase transfers to azalea leaves and grass leaves for vapor phase transfers. For the dioxin-like compounds, direct use of these transfer factors would be most appropriate for the outer few millimeters, perhaps, of below and above ground bulky vegetation. The assignment of

a VG of 0.01 for bulky above and below ground vegetation was based on an outer surface volume to whole plant volume ratio for a common vegetation such as a carrot or an apple. A VG of 1.00 was used for grass, since that is a thin vegetation.

Further evidence for the above ground VG came from a study by McCrady (1994), who measured the uptake rate constants of vapor-phase 2,3,7,8-TCDD to several vegetation including grass and azalea leaves, kale, pepper, spruce needles, apple, and tomato. The uptake rate for the apple divided by the uptake rate for the grass leaf was 0.02 (where uptake rates were from air to whole vegetation on a dry weight basis). For the tomato and pepper, the same ratios were 0.03 and 0.08. The VG_{ag} was 0.01 for fruits and vegetables in this assessment. McCrady (1994) then went on to normalize his uptake rates on a surface area basis instead of a mass basis; i.e., air to vegetative surface area uptake rate instead of an air to vegetative mass uptake rate. Then, the uptake rates were substantially more similar, with the ratio of the apple uptake rate to the grass being 1.6 instead of 0.02; i.e., the apple uptake rate was 1.6 times higher than that of grass, instead of 1/50 as much when estimated on an air to dry weight mass basis. The ratios for tomato and pepper were 1.2 and 2.2, respectively. Therefore, since the B_{vpa} in this assessment is an air to plant mass transfer, the McCrady experiments would appear to justify the use of an above-ground VG of a magnitude less than 0.10.

6) An experiment by the Hulster, et al. (1994) on vegetation of the cucumber family contradicted the conventional wisdom that direct soil to root to above ground plant impact would not occur for the dioxin-like compounds. Their results were most striking for zucchini, which showed uniform plant concentrations from inner to outer portions of the zucchini fruit, and the highest whole fruit concentrations and plant:soil ratios they had ever measured, despite careful experimental conditions which physically isolated the fruit from the soil. Pumpkins also showed high plant contamination and plant:soil ratios, with more expected plant concentrations measured for the cucumber. No explanation was offered for these results. It was assumed for this exposure assessment that the fruits and vegetables for human consumption, and the grasses, hay, and other vegetation animals consume, would not follow this pattern.

A principal observation that can be drawn from this examination is that the plant:soil contaminant concentration ratios from the background scenario may be higher than observed in experiments, although this conclusion must be tempered by the fact that the soil concentrations in the experiments were always higher than the 1.29 ppt WHO_{98}-TEQ_{DF} soil concentrations used in the background scenario. One other important observation made above was that, as the soil concentration increased, the plant:soil concentrations decreased. For the experiment where soil

concentrations were closest to background, the 5 and 56 ppt TEQ concentrations in the experiments of Muller, et al. (1994), the overprediction by the model was on the order of 10.

The same story is not necessarily told, however, when comparing results from the demonstration of the soil contamination demonstration with these literature ratios. The plant:soil ratios for the background scenarios ranged from 0.10 to 0.33. The following plant:soil contaminant concentration ratios were estimated for the soil contamination scenario. Again, tilled soil concentrations and dry weight vegetative concentrations were used: below ground vegetables - 0.22, above ground vegetables/fruit - 0.00005, grass - 0.003, and feed 0.002. These ratios were calculated using the soil concentrations predicted to occur at the site of exposure, which is valid for the below ground vegetables, but not quite for the above ground vegetation. Ratios calculated by using the near field dispersion models and assuming plants are grown on the impacted soils would result in slightly higher ratios, by about a factor of three. Below ground vegetables still show a clear relationship with soil concentrations, as in the background scenarios. However, now it appears that plant:soil ratios for above ground vegetation are much lower for this demonstration scenario as compared to the background scenarios.

In fact, in a slight variation to this exercise, one could use near background soil concentrations for the soil contamination algorithms and show similarly low plant:soil ratios. In this instance, one can observe that at low background soil concentrations, the soil-to-plant algorithms of the soil contamination source category underestimate above ground plant concentrations.

This observation that plant:soil ratios for above ground vegetation are higher in the literature as compared to modeled ratios for the soil contamination algorithm has to be carefully considered. Two explanations are offered. For experiments conducted outdoors, the source of air reservoirs of dioxin-like compounds are the soil in which the plant is growing as well as from distant sources and long-term transport. Also, it is possible that the model is underpredicting air concentrations and hence underpredicting soil-to-air-to-plant transfers. The same issue arose in Section 7.3.8 earlier, where it was noted that the soil contamination model predicted very low air concentrations given background soil concentrations, much lower than observed background air concentrations. In that section, like in this section, it was unclear whether long range transport explained most of background air concentrations and/or the model was underpredicting air concentrations.

7.3.11. Comparison of Measured and Modeled Vapor/Particle Distributions for Semivolatile Compounds Other Than Dioxin

In Chapter 3, the Junge-Pankow model was described and applied to the dioxin-like compounds in order to partition air-borne dioxins into a vapor and a particle phase. These modelled particle percentages were then compared to measured particle percentages, and a consistent pattern among several field measurements versus model predictions emerged: the model tended to predict that more of the dioxin would be in the particle phase compared to what was measured. Whether the model is "correct" or the measurements are "correct" is a matter of ongoing debate, as described in Chapter 3. This section will compare measured and modelled particle percentages for semivolatile organic compounds (SOCs) other than the dioxins. These include PAHs, PCBs, and organochlorine pesticides.

Table 7-18 presents a summary of the analysis of monitoring data on SOCs from several cities and rural locations. The parameters in this table come from the following empirical correlation, which is described in more detail in Chapter 3:

$$Log\ K_p = m\ Log\ p^\circ_L + b \qquad (7\text{-}41)$$

where:

K_p = particle/gas partition coefficient, $m^3/\mu g$, defined as: Cp (ng/μg)/C_g (ng/m^3), where C_p is the concentration associated with aerosols, and C_g is the gas-phase concentration

p°_L = liquid sub-cooled vapor pressure, Pa

m, b = empirically derived slope and intercept from the data sets

The sub-cooled liquid vapor pressures for the SOCs were taken from reports in the literature including values for PAHs (Yamasaki et al., 1984), PCBs (Falconer and Bidleman, 1994), and OC pesticides (Hinckley et al., 1990). The particle-bound fraction, ϕ, is related to K_p, as follows:

$$\phi = \frac{K_p\ [\ TSP\ ]}{1 + K_p\ [\ TSP\ ]} \qquad (7\text{-}42)$$

where:

ϕ = particle bound fraction, unitless (not the same as the particle bound concentration, C_p)

K_p = particle/gas partition coefficient, $m^3/\mu g$

TSP = total suspended particulates, $\mu g/m^3$

If TSP was not reported in the original paper (in most cases), it was assumed that TSP = 98 $\mu g/m^3$ for urban air and 10-42 $\mu g/m^3$ for non-urban air of varying cleanliness.

The two equations above, in combination with the data reported in the literature article, were used to develop the dotted line "observed" particle percentages shown in Figures 7-10 and 7-11. The modeled particle fractions were determined for these sites using the Junge-Pankow model detailed in Chapter 3. According to that model, the particulate fraction is estimated as:

$$\phi = \frac{c\,\Theta}{p^{\circ}_{L} + c\,\Theta} \qquad (7\text{-}43)$$

where:

ϕ = fraction of the compound adsorbed to aerosol particles

p°_{L} = saturation liquid phase vapor pressure of the pure compound at ambient temperature, Pa

Θ = the particle surface area per unit volume of air, cm^2 aerosol/cm^3 air

c = a constant which is related to the difference between the heat of desorption from the particle surface, Q_d, and the heat of vaporization of the compound, Q_v, estimated at 17.2 Pa-cm

In applying this model, values of Θ assumed include $4.2*10^{-7}$ for "clean continental", $3.5*10^{-6}$ for "background plus local sources" and $1.1*10^{-5}$ for "urban" conditions. Further detail on this model can be found in Chapter 3.

The agreement between the measured and predicted aerosol-bound fractions of PAHs is remarkably good, as seen in Figure 7-10. Two model curves are shown for rural air in Figure 7-10b, representing "clean continental background" and "background plus local sources" regimes. Experimental PAH distributions fall reasonably close to the range of particulate values predicted by the model, although the fraction of aerosol-bound PAHs at rural sites (e.g., Lake Superior) is greater than expected for the more volatile compounds. This may be due to a portion of these PAHs being "non-exchangeable" (Pankow, 1988).

Fewer data are available for non-dioxin organochlorine compounds. Figure 7-11 shows the measured particulate percentages of PCB congeners and chlorinated pesticides in comparison to predictions. Again, the two depictions of model predictions for rural conditions, Figure 7-11b,

show a range from clean continental to background plus local sources. The monitored data fall below the model values, but the discrepancy is generally not as great as for the PCDD/Fs.

Overall, it can be concluded the Junge-Pankow model appears to predict vapor/particle partitioning very similar to measurements for PAHs, but not as similar for PCBs and chlorinated pesticides, although the match there is still superior to that of PCDD/Fs. This exercise does lend additional credibility, in general, to the Junge-Pankow Model. However, the model and the measurements for PCDD/Fs do diverge, as described at length in Chapter 3, and the debate remains as to which is "correct" for the PCDD/Fs - the model or the measurements.

7.3.12. An Update of the Air-to-Beef Model Validation Exercise

In the previous version of this dioxin exposure document (EPA, 1994) as well as in a journal article (Lorber, et al., 1994), a validation of the air-to-beef food chain model used in this assessment was presented. As a result of public comments received on the review of the dioxin exposure document, that exercise has been refined and updated. This section will review the principal comments made and these updates. Except for a brief overview, this section will not describe the previous air-to-beef model validation exercise.

Figure 7-12 presents an overview of the air-to-beef food chain model. The premise of this modeling exercise to test the beef food chain model for dioxin-like compounds is that air-borne reservoirs of these compounds in rural environments are the "source term" explaining concentrations found in beef. The principal assumption in the validation exercise is that one can define an "average" rural air profile of dioxins, route this profile through the food chain model, and predict an "average" beef concentration. This exercise probably would not qualify as a validation exercise in the traditional sense. Most environmental model validation exercises rely on data obtained from a single site. For a traditional model validation of the air-to-beef model, one would need the following: a representative air concentration profile, including all the dioxin-like congeners, during the lifetime of the cattle, information on the cattle diet during his lifetime, a set of vegetation congener-specific concentrations typical of the cattle diet (and the cattle should be fed from vegetation grown in the area corresponding to the air concentration), and a set of congener-specific concentrations from beef from the slaughtered cattle. As this information was unavailable, the model validation exercise proceeded by attempting to define these "average" air profiles, vegetative profiles, and beef concentration profiles.

The key components of the previous model validation exercise were:

1. The representative air profile was crafted based on a representative profile of urban air concentrations generated as the average of 85 data points of air concentrations from urban settings, coupled with information suggesting that rural air profiles were lower than urban air profiles, by about a factor of 5. The rural air profile was crafted, therefore, by dividing each congener concentration in the urban air profile by 5.
2. Each congener was separated into a vapor fraction and a particle fraction. The vapor/particle partitioning model is described in Chapter 3.
3. The vapor fraction "transfers" into cattle vegetation, including categories described in Chapter 4 as "grass" and "hay/silage". The particle bound fraction is assumed to deposit onto these vegetation. Dry deposition was modeled as a product of the concentration times a deposition velocity of 0.002 m/sec, based on the findings of Koester and Hites (1992). Also, wet deposition was assumed to equal dry deposition, based on measurements of Koester and Hites (1992) showing these two components to be roughly comparable for settings in Illinois and Indiana.
4. Forty-eight percent of the cattle diet was assumed to be in grass, 48% was assumed to be in hay/silage, and 4% was assumed to be in soil. The concentration in the fat of beef was modeled as a function of the concentrations in these media times a bioconcentration factor.
5. The cattle were assumed to undergo a period of feedlot fattening prior to slaughter. This is a predominant practice in the United States, and it was felt that the observed beef concentrations were from cattle which went through feedlot fattening. Based on previous modeling efforts, the impact of this fattening regime was to reduce concentrations in the body fat by about a factor of 2 compared to body fat concentrations prior to entry into the feedlot. Therefore, concentrations predicted to occur without this feedlot consideration were reduced by 50% to model the impact of feedlot fattening.
6. The "observed" beef concentration profile was crafted as the average of 14 samples from 3 "grab bag" studies measuring the concentration in beef and veal from grocery stores.

Four principal comments received on the air-to-beef model validation exercise following the release of the 1994 dioxin exposure document were:
1. Although the final predicted TEQ beef concentration was reasonably close to the observed beef TEQ concentration, there was not a good match in the concentrations of the individual congeners not a good match of total concentrations (i.e., the sum of the concentrations of all congeners).
2. The air-to-leaf transfer factor was overestimating the impact of vapor-phase dioxins to vegetation.

3. A simple division of the crafted urban profile by 5 to arrive a crafted rural profile would not appropriately consider changes in the profile from urban to rural centers that have been studied and are believed to occur.
4. The results of the USDA/EPA beef study that is described in Volume I of this Exposure Reassessment and in Winters, et al. (1996) is preferable as an observed data set to the grab sample of 14 data points.

The first comment was addressed by revising the air-to-beef model validation exercise based on the next three comments. The discussion of the revised model exercise will now proceed by first reviewing the model changes made, then reviewing the revised air and the new beef concentration profiles used, and how the revised model validation exercise compares with the original validation exercise.

a. Revisions to the air-to-beef model parameters: Table 7-19 compares the four key changes made to the model validation exercise. Following are brief notes on each:
1. B_{vpa}: Chapter 4 describes how this version of the air-to-leaf transfer factor was derived from experiments conducted by Welsch-Pausch, et al. (1995). As seen in Table 7-19, this procedure resulted in a lowering of the transfer factor for all congeners by an order of magnitude and less, except the octa congeners which were lowered by 2-3 orders of magnitude and the hepta furan congeners, which were slightly higher in their current form. It is noted that these B_{vpa} are slightly different than a set of B_{vpa} published as proceedings of the 15th International Symposium on Chlorinated Dioxins and Related Compounds (Lorber, 1995). The procedure to derive the B_{vpa} in this assessment is the same as in that publication. However, this assessment uses a different set of vapor/particle fractions based on a reassignment of dioxin fate parameters. With different v/p fractions, the calibrated B_{vpa} was slightly different.
2. As just noted, the vapor/particle partitioning changed slightly in the current version, due to the reassignment of critical parameters required for the calculation of the vapor/particle percentages. These parameters include the Henry's Constants and the liquid sub-cooled vapor pressures. In their current form, there is generally less concentration predicted to occur in the vapor form, particularly for the penta dioxin, the tetra furan, and the two penta furans. It is noted that the 1994 vapor percentages for the octa congeners were assigned a value of 0.00. In fact, if the percentages were calculated to two decimal places with the 1994 parameters, they would equal 0.02% (or, on a fraction basis, 0.0002) instead of 0.00 as noted. Although a small percentage, it is seen that the air-to-leaf transfer factors for the octa congeners were on the order 10^8 to 10^9. As

discussed in the prior air-to-beef model validation (EPA, 1994; Lorber, et al., 1994), this became critical as assignment of the very small vapor fraction did make a significant difference to octa vegetation predictions, and hence octa beef concentration predictions. For the current exercise, there was no rounding to 0.00; the values calculated and used are 0.2% for both octa congeners with the revised fate parameters.

3. The bioconcentration factors for each congener were uniformly increased by about 30% as compared to the 1994 version. This was due to a recalculation using the same data as was used for the 1994 version. Based on a personal communication with the study author, it was determined that the total dry matter intake by the lactating cow was miscalculated for the 1994 version. Instead of 15 kg/day, the correct total dry matter intake was 21 kg/day. Therefore, intake concentrations decreased by about one-third, and so calculated bioconcentration factors increased by about one-third.

4. The soil concentrations used in the current version were the actual measured soil concentrations corresponding to the site where the air concentrations were taken. As will be described below, the air concentration profile was taken from an actual rural site near Columbus, Ohio. These were the same air profile and soil profile used in the demonstration background scenario in Chapter 5. The soil concentrations used in the 1994 model validation exercise were not model inputs, but were rather predicted by the deposition of particle-bound dioxins. There does not appear to be substantial differences in the two profiles, and as soil is a small part of the cattle diet, these changes were not meaningful to final predictions of beef concentrations.

b. New air profile: While a straight division of an urban profile by a factor of 5 may recognize overall reductions in air concentrations when going from an urban to a rural location, and concurrent reductions in TEQ air concentrations, they may not recognize a key trend observed by researchers concurrently studying urban and rural air profiles. The trend was best stated by Eitzer and Hites (1989), who studied such profiles including a statistical analysis of profiles. As they stated, "The geographic variability suggests the following atmospheric transport scenario. Urban air is contaminated with PCDD/F by proximity to the combustion sources of these compounds. As the air mass moves away from the urban area, it is diluted with cleaner air, lowering the PCDD/F concentrations. As the air is transported, transformations occur changing the profile. One transformation is photodegradation of vapor-phase PCDD/F. The less chlorinated PCDD/F have greater proportions of their total concentration in the vapor phase. Thus, vapor-phase photodegradation during the transport process would have a greater effect on the less chlorinated PCDD/F. Like the washout process, these degradation processes

would favor an ultimate PCDD/F profile with enhanced concentrations of the more chlorinated compounds." Simply dividing an urban profile by a factor of 5 did not account for these changes. It should be noted that photodegradation has not been definitely proven to occur and explain the trends noted by Eitzer and Hites (1989). Most importantly, they identified a trend that appears to be true, not only for their profiles, but for air concentration profiles from the Columbus area, as will be described shortly.

Ideally, one would want several rural profiles representing beef production areas in the United States. Lacking that information, what was available was a profile derived from a study of ambient air in the city of Columbus undertaken by the Ohio EPA (OEPA, 1994;1995), and described above in Section 7.3.7 on a model validation exercise of the ISCST3 model. That study included two sampling events of urban air in 1994 and one sampling in 1995. Concurrent with the urban samples were two background rural samples in 1994 and a third in 1995. The rural sampling site was located 28 miles in the upwind direction from Columbus (i.e., it was least likely to be impacted by urban sources in the nearest largest city, Columbus). The sampling program was undertaken to evaluate air quality in the vicinity of a municipal solid waste incinerator. There were six samplers in the city of Columbus, 5 operating for each of the 1994 sampling events (not the same 5), and 6 operating in 1995. Therefore, there were a total of 16 urban air samples. This incinerator was operating in 1994, but was shut down in 1995. Therefore, the 1995 sampling was undertaken to evaluate the air quality in the absence of the incinerator. During the sampling in 1994, OEPA (1994) identified a clear trend in the data: that the measurements were highest in the air samplers which were located in the predominant wind direction, from the incinerator to the air sampler, during the sampling. The 1995 did show a reduction in the measured air concentrations (OEPA, 1995). There was one rural air sampler, so the sampling program included three rural air samples. The three rural air samples did not show any trend related to the incinerator, and as will be seen, were lower in magnitude than the urban samples. Chapter 5 describes how the rural air profile for the background scenario was crafted from these three rural samples.

This revised air-to-beef model validation exercise will use the rural air profile that was crafted for the background scenario. Table 7-20 compares the air concentration profiles discussed above, including the crafted 1994 urban and rural air profiles compared against the Columbus urban air profile and the Columbus rural air profile. The Columbus urban air profile was developed as the average of the 16 data points from the three air sampling, including the assumption that the air concentration was ½ detection limit for all non-detects. The final

column shows the ratio of the Columbus urban air concentration with the Columbus rural air concentration.

The Columbus urban air concentration looks substantially like the crafted urban air profile with notable differences only for 1234678-HpCDD, OCDD, and 2378-TCDF. In each of these cases, the Columbus air profile is smaller than the crafted urban profile. The Columbus 2378-TCDF concentration is more than a factor of 5 lower than the crafted urban concentration of 2378-TCDF. OCDD in Columbus is almost a factor of 3 lower than the crafted urban profile, and the absolute difference in the OCDD concentrations of nearly 2.0 pg/m^3 explains most of the difference of about 2.2 pg/m^3 of total dioxin in the profiles (with "total" being defined as the sum of the 17 dioxin-like congeners). The I-TEQ concentrations in the urban profiles are similar - the Columbus urban air I-TEQ concentration of 0.070 pg/m^3 is about 75% of the crafted urban profiles of 0.095 pg/m^3.

The two rural air profiles have the same I-TEQ concentration of 0.019 pg/m^3, but the Columbus rural total concentration is about 50% higher than the crafted rural profile. This is due principally to the higher OCDD and 1234678-HpCDD concentrations in the Columbus profile. Most importantly, it would appear that the Columbus urban and rural profiles conform to the expectations as laid out earlier in the quote from Eitzer and Hites (1989). Specifically, it does appear that the lower chlorinated congeners undergo more of a loss, proportionally speaking, as compared to the higher chlorinated congeners. The ratio of the urban hepta and octa dioxin and furan congeners to their rural counterparts ranges from 1.2 to 3.8; while the range for the tetra through hexa dioxin and furan congeners is 1.0-6.3. The 1.0 ratio is for a congener which has a very low concentration to start with, 0.003 pg/m^3, and whose rural concentration is driven by detection limits. Without this congener, the second lowest ratio is 2.4. In other words, it would appear that a more appropriate range for the tetra through hexa congeners is 2.4-6.3. Of note are the very low changes in the hepta dioxin congener and octa dioxin congener, whose ratios are 1.2. Also of note is the very lower tetra furan congener, which dropped by a factor of 6.3 and is also 6 times lower than the concentration for this congener in the crafted rural profile of the 1994 exercise. These trends for the OCDD and tetra furan congener will later be important in explaining improvements in beef concentration predictions for the current model validation exercise.

c. New beef profile:

The EPA/USDA study on dioxins in beef is described in Chapter 3, Volume II of this assessment and also in Winters, et al. (1996). The congener profile for this study is compared

with the congener profile for the 14 grab samples from three studies in the next section on results. It is noted that the EPA/USDA study shows lower congener concentrations for all but one congener, and total and TEQ concentrations that are 2-3 times lower that the 14 grab samples. The precise reason for this difference in profiles is not known, but some possible reasons could be:

1) The three studies from which the 14 samples originated were not statistically designed studies, and may have simply taken samples with higher concentrations.

2) There may, in fact, be a trend of reduced concentrations in the beef because of the time periods in which the data was obtained. Two of the three studies took samples prior to 1990, the other one taking samples in 1992. The EPA/USDA study took samples in 1994. Furst and Wilmers (1995) did note nearly a 25% reduction in cow milk concentrations of I-TEQs taken in 1994 as compared to 1990. This is a much smaller reduction than the 60-70% reduction noted in the two groups of beef samples.

3) There was no detailed examination of the quality assurance programs for the three studies taking grab samples from the grocery stores. There may have been laboratory problems.

4) There has been some data suggesting the leaching of dioxins into milk from milk cartons. The packaging and handling of beef may also introduce dioxins into beef. Since the EPA/USDA beef study obtained samples directly from the slaughterhouse, such introductions by packaging and handling would not occur. However, this explanation was contradicted by three additional grocery store grab samples of ground beef taken in Mississippi in 1995 (Cooper, et al., 1995), which showed concentrations quite comparable to the EPA/USDA beef sampling program. If packaging and handling did effect the 14 grab bag samples, they did not affect the Mississippi sampling.

5) The EPA/USDA samples were from back fat. The back fat samples were from a reservoir in the cow, which at a point nearby, is the fat which is the outer part of meat cuts from the cattle rib area. Back fat itself is not used or consumed. There is very little data on the differences in concentrations of dioxin-like compounds in the different edible and non-edible fat reservoirs of cattle. A recent study showed that there are not significant differences in dioxin and dioxin-like coplanar PCBs among fat reservoirs except a much higher concentration in the lipid of liver (Lorber, et al., 1997). Nonetheless, the grocery store samples were from different reservoirs of fat than the back fat of the EPA/USDA study.

If it is true that the fat concentrations of dioxins are similar across different body reservoirs of fat (with the exception of the lipid in liver), than it is certainly appropriate to conclude that the results of the EPA/USDA statistical monitoring study are a more appropriate

representation of edible fat in beef as compared to the compilation of 14 grab samples used in the prior air-to-beef model validation exercise.

d. Results of the revised validation exercise: Table 7-21 shows the 1994 and 1996 model predictions for leafy vegetation, and compares then against five available data sets for leafy vegetation. The data on hay in the US (Reed, et al., 1990) seems to conflict the other available data on the table - it has significantly higher concentrations of the congeners it does have available, particularly the value for 285 ppt concentration of OCDD. This data could have been influenced by a local source, or because of the particular type of hay it was, it may have had much higher particulate dioxin contributions as compared to other grass data sets. One set from a rural setting in the UK (Jones and Duarte-Davidson, 1997), however, also has somewhat high OCDD concentrations at 94 ppt. All other sets had OCDD concentrations less than 25 ppt OCDD. This site in the UK also had relatively high air concentrations at 0.21 pg I-TEQ/m^3 compared to the rural air profile of 0.019 pg I-TEQ/m^3 from the Columbus site used in the exercise here. As described in Section 7.2.1. above, the modeling framework of this assessment used this data set to model a grass concentration of 3.7 pg I-TEQ/g, which is reasonably close to the measured 6.0 pg I-TEQ/g. The other two data sets from the UK are reasonably similar, with the more recent data set (Kjeller, et al., 1996) showing lower concentrations, and in fact, this data was used by the authors (among other data) to suggest that emissions of dioxins are being reduced in the UK. The data set on alfalfa is consistent with this data on grass in the UK.

It is easily seen that the current set of model predictions of dioxins in grass is much more in line with these two UK observations and the US alfalfa observation as compared to the predictions in the 1994 data set. There was a general reduction in the concentrations predicted between 1994 and the current predictions, due primarily to the reductions in the air-to-leaf vapor transfer factor, B_{vpa}. There were noticeable improvements in some of the congeners, particularly the predictions for 2378-TCDF and 12378-PCDF, and to a lesser extent but still noticeable, improvements in 12378-PCDD, 123478-HxCDD, 23478-PCDF, 123478-HxCDF, 123678-HxCDF, 234678-HxCDF, and OCDF. There was also an improvement to OCDD. It was noted above that the vapor fraction assumed for OCDD was 0.00 in the 1994 exercise, but in a detailed examination in Lorber, et al. (1994) and EPA (1994), use of a vapor fraction of 0.0002 for OCDD, which is what the V/P model calculated for the vapor fraction for OCDD, actually resulted in grass concentration approaching the hay concentration found in Reed, et al. (1990). Given the other leafy concentrations, it would appear that an OCDD grass concentration in the 10-30 ppt range is more appropriate than one greater than 100 ppt.

As a final and simple test of the current model predictions for leafy vegetation, the two data sets from the UK were averaged with the one set from alfalfa in the United States and correlated against the two sets of model predictions. The best fit regression line for the 1994 model predictions and this average of three observations had a slope of 0.26, an intercept of 0.84, and importantly a rather poor r^2 of 0.14. In contrast, the best fit regression line for the 1996 model predictions had a slope of 1.13, an intercept of 0.007, and a much improved r^2 of 0.98.

Table 7-22 compares the final predicted and observed beef data sets from the 1994 and the current validation exercise. There are reductions in both the observed and predicted beef concentrations from the 1994 results to the current results. However, given the conclusion stated above regarding the superiority of the EPA/USDA beef data set for this validation exercise, it is most appropriate to compare the predictions made in 1994 and those made in the current exercise with this observed data set. Just by visual inspection, it is seen that notable improvements in model predictions are noted for the following congeners: 12378-PCDD, OCDD, and 2378-TCDF. There are some congener predictions for which the 1994 validation exercise appears to result in a superior match, including 123478-HxCDD, 12378-PCDF, 123789-HxCDF, and 234678-HxCDF. Overall, the TEQ concentration in the current validation is closer to the observed TEQ concentration, although the total concentration appears more favorable for the 1994 validation exercise.

A simple correlation test suggests that the current model validation is superior to the 1994 model predictions. The following shows the results of linear regressions of the 1994 and 1996 model predictions with the EPA/USDA monitoring results assuming ND = ½ detection limit and ND = 0.0:

	Slope	Intercept	r^2
1994 model/ND = ½ detection	0.70	0.58	0.11
1994 model/ND = 0	0.74	0.13	0.16
1996 model/ND = ½ detection	1.02	0.55	0.57
1996 model/ND = 0	0.76	0.25	0.41

As seen, there is a better regression with the current modeling exercise as compared to the 1994 model exercise, with current r^2 of 0.57 and 0.41 compared against r^2 of 0.11 and 0.16.

It is also easy to see why individuals commenting on the air-to-beef model validation exercise of 1994 would note a poor correlation between observed and predicted concentrations. Very poor matches between predicted and observed are seen for 123678-HxCDD, 1234678-

HpCDD, OCDD, 2378-TCDF, 123478-HxCDF, 1234678-HpCDF, 1234789-HpCDF, and OCDF. Overall, the r^2 for the 1994 predictions against the observations from the 14 grocery store samples was 0.16. Also, the slope for this test was the highest of all the tests so far at 2.4, indicating that, for the best fit regression line, observations were higher than predictions by a greater margin than when testing against the EPA/USDA data set. For these tests, the slopes ranged from 0.74 to 1.02.

e. Remaining uncertainties in the validation exercise and in air-to-beef modeling in general: Following is a summary of the key uncertainties of this exercise and of food chain modeling in general:

1. A characteristic rural air environment: A profile of air concentrations of dioxin-like congeners in a rural environment would be better achieved as the average of several profiles in appropriate environments instead of just one.

2. A better understanding of the differences in the EPA/USDA sampling program and the grocery store samples taken earlier: There were 5 possible explanations listed as to why the earlier beef samplings appeared to have uniformly higher concentration profile as compared to the USDA/EPA beef profile. Before fully relying on the EPA/USDA sampling of cattle back fat, it would be appropriate to understand how the concentrations may differ, if any, with fat in beef purchased at grocery stores.

3. Vapor/particle partitioning: A theoretical modeling approach was used to partition the total reservoir of congeners into particle and vapor phases. Monitoring data suggests a different partitioning regime. This dichotomy was discussed in Chapter 3 and further in this Chapter in Section 7.3.11. A carefully designed monitoring experiment could shed some light on vapor/particle partitioning for dioxin-like compounds. This is obviously critical given the major conclusion of the dominance of vapor phase concentrations in explaining beef concentrations.

4. Vapor transfers to vegetation: Like the partitioning issue, the quantification of transfers onto vegetation is critical. There is some suggestion that the Welsch-Pausch experiments for which the air-to-leaf vapor transfer factor was developed may be unrealistic for field situations. Factors which make it unrealistic includes pots raised off the ground, and the grass being a dense monoculture. More typical field situations - at ground level with varied vegetation of lesser density may lead to lower transfers of vapors from the atmosphere to the canopy (M. McLachlan, Bayreuth University, FRG, personal communication). A data set including both field level pasture measurements coupled with a corresponding air profile would

be preferable to the data set of Welsch-Pausch for calibrating a vapor transfer factor, but none could be found for this assessment.

5. Particle depositions onto vegetation: The impact of wet deposition needs to be further investigated. A literature article suggesting that about 30% of particles depositing in rain are retained on the canopy after the rainfall justified the assignment of 0.30 to the parameter, R_w (fraction retained on vegetation from wet deposition). The weathering half-life of 14 days, while often used for dioxins, is also identified as uncertain. This half-life was based on studies on particle depositions on plants. It is possible that the dioxins would preferentially sorb onto the plants. Therefore, while particles themselves may have a 14-day half-life on the plants, the dioxins on the particles may remain behind on the plants and have a much longer half-life. Umlauf and McLachlan (1994) modeled the deposition of particle bound semi-volatile organic compounds (SOCs) to spruce leaves and assumed that the SOCs were fully retained on the leaves. In their publication, they did discuss the transfer of the SOCs from the particles to the leaves. Finally, the deposition velocity of 0.2 cm/sec should be considered further.

6. The bioconcentration factor: Only one study was found from which congener-specific bioconcentration factors for the suite of congeners could be developed, and this was for one cow, for one lactating period, and was for milk and not beef. The differences in bioconcentration between beef and milk need to be further investigated and quantified.

7. Cattle diet and the impact of feedlot fattening: A cattle diet was simplistically assumed to consist of 4% soil and equal parts of grass and non-grass feeds. Perhaps a more representative diet could be crafted, which would lead to a different exposure pattern by the beef cow prior to feedlot fattening. Equally if not more important is the impact of this feedlot fattening. It is clear that commercial beef cattle in the United States undergo a period of feedlot fattening. However, before and after monitoring quantifying the impact of this practice could not be found. Two modeling studies, which assumed that dilution and depuration were occurring during feedlot fattening, estimated that concentrations were halved due to this process. This was the assumption also made in this paper, and it needs to be further evaluated.

7.3.13. *Expansion of the Terrestrial Food Chain Model for Dioxins and Applications to other Foodstuffs in the United Kingdom*

Harrad and Smith (1997) adopted the food chain model developed initially in the first draft of the Dioxin Reassessment (EPA, 1994), expanded it to include soil-to-above ground plant transfers, and applied it to UK data in very much the same manner as in the air-to-plant-to-beef exercise described just above in Section 7.3.12. Soil-to-above ground impacts are assumed not

to occur in this assessment, and in Harrad and Smith (1997), they found that soil-to-above ground translocations explained very little of the predicted grass concentrations. They also expanded the initial development of this approach in EPA (1994) to include poultry and eggs, both of which are now modeled in this current assessment.

Although they didn't exactly state where the air data come from in their exercise, it is surmised that they selected a rural air concentration profile of the 17 dioxin-like CDD/Fs they deemed to be typical of UK conditions. Then they routed this concentration through the food chain models to predict the dioxin concentrations in various kinds of animal feeds, and then the concentration in animal meats. They compared predictions of dioxins in grass (one of the animal feeds) to those reported for a bulk herbage representing the years 1979-1988 reported in Kjeller, et al. (1991). They found the ability of the air-to-grass model to predict grass concentration to be "reasonably satisfactory" with predictions falling within an order of magnitude of observations, and I-TEQ predicted and observed concentrations to be close at 1.3 pg/g (predicted) and 0.86 pg/g (observed). They did note more variability in congener-by-congener predictions for the other food products but found that I-TEQ concentrations were reasonably well predicted, including: 1) retail meat products (assumed to be beef, but not identified as such), pg/g fresh weight: predicted - 0.252, observed - 0.254; 2) milk, pg/g fresh weight: predicted - 0.090, observed - 0.057; 3) poultry, pg/g fresh weight: predicted - 0.630, observed - 0.399; 4) eggs, pg/g fresh: predicted - 0.262, observed - 0.194; and 5) potatoes, pg/g fresh: predicted - 0.0072, observed - 0.037.

7.3.14. *Beef and Milk Fat Concentrations when Soil is the Source of Contamination*

Sampling of beef and milk near areas of elevated soil concentrations, or where cattle were raised on soils with known high concentrations of 2,3,7,8-TCDD, were not found in the literature. Therefore, the beef fat concentration of 60 ppt estimated to occur near an area where the soil concentrations of 2,3,7,8-TCDD was 1 ppb cannot easily be evaluated. There are some studies on other animals indicating high tissue concentrations in areas of high soil contamination of 2,3,7,8-TCDD. Lower, et al. (1989) studied animal tissues for wild animals in the abandoned town of Times Beach, Missouri, and compared their results for similar wild animals tissue concentrations found in Eglin Air Force Base in Florida; Seveso, Italy; and Volgermeerpolder, Holland. With 2,3,7,8-TCDD soil levels in these areas in the hundreds to thousands of ppt, tissue levels for earthworm, mouse, prairie vole, rabbit, snake, and liver samples from some of these animals, were in the tens to thousands of ppt.

There is an episode of beef and dairy cows being raised on lots where the soil was heavily contaminated with polybrominated biphenyls (PBB; details can be found in Fries and Jacobs, 1986; and Fries, 1985). Soil concentrations to which dairy and beef cows were exposed were 830 and 350 μg/kg (ppb), respectively. Body fat of the dairy cows had PBB concentrations of 305, 222, and 79 ppt (dairy heifers, primiparous dairy, and multiparous dairy, respectively). Body fat for the beef cows exposed to 350 ppb soil levels were 95 (cows) and 137 ppt (calves). Milk fat concentrations from the primiparous dairy and multiparous dairy cows exposed to 830 ppb soil levels were 48 and 18 ppt.

Fries (1985) estimated a quantity which is useful for purposes of comparison - this quantity is the ratio of concentration in animal fat to concentration in soil to which the animal is exposed. His justification for deriving this ratio is that soil was speculated as the principal source of body burdens of PBB in the data listed above. This is also the case for the soil contamination source category of this assessment. Ratios he derived for body fat of dairy heifers ranged from 0.10 to 0.37, while it was 0.02 and 0.06 for milk fat. For body fat of beef cows, these ratios were 0.27 and 0.39. Fries also measured a ratio of 1.86 for sows and gilts. He attributes much higher sow ratios to their tendencies to ingest more soil.

Analogous ratios can be derived for the demonstration of the soil contamination source category for beef and milk fat. For the demonstration in Chapter 5, the soil concentration predicted to occur at the farm was 0.36 ppb, and the beef fat and milk fat concentrations were predicted to be 0.06 and 0.03 ppb, respectively. These correspond to ratios of 0.17 for beef fat and 0.08 for milk fat. The milk fat ratio compares favorably with PBB ratios derived by Fries (1985), but the beef fat ratio appears generally lower. The beef fat concentrations in the demonstration scenarios were driven by the fraction of soil in the diet of the beef cattle, as were the concentrations in the milk fat. It may be possible that the cattle slaughtered for beef raised in the lots with high PBB concentrations were exposed to more soil than was assumed in the demonstration scenarios. There, soil was 4% of the diet. If this value were increased to 8%, than predicted beef fat concentrations would also double, and the beef fat:soil ratio would be 0.34 instead of 0.17.

* Units: air - pg/m^3; deposition - pg/m^2-day; grass - pg/g dry weight of dioxin in the grass. Grass yield for rural = 89 g/m^2 dry weight, for industrial = 42 g/m^2 dry weight.

Table 7-2. Model results comparing the EPA vapor transfer model and the Vapor Deposition Model with the field data for 2,3,7,8-TCDD (concentrations in pg/g dry weight).

Description	2,3,7,8-TCDD grass concentrations, pg/g dry	
	Rural	Industrial
Observed data	0.72	2.8
EPA vapor transfer model	0.25	0.21
Smith et al. (1995) model	0.06	0.05
Trapp & Mattheis (1995) model	0.13	0.1

Table 7-3. Model parameters used in the Hwang and the alternate volatilization models tested in this comparison exercise.

Description	Jury model	Simplified Jury model	Hwang model	Vapor diffusion
I. Soil Parameters				
C_0, initial soil concentration, mg/kg	0.001	0.001	0.001	0.001
θ, volumetric water content, cm^3/cm^3, or unitless	0.23	0.23	NR	NR
a, soil air content, cm^3/cm^3, or unitless	NR	0.2	NR	0.2
ϕ, soil porosity, cm^3/cm^3, or unitless	0.43	0.43	0.43	0.43
BD, soil bulk density, g/cm^3	1.5	1.5	NR	NR
Psoil, soil particle bulk density, g/cm^3	NR	NR	2.65	NR
J_w, water flux, cm/sec	0	NR	NR	NR
foc, fraction organic carbon	0.01	0.01	0.01	0.01
d_z, soil depth of constant concentration, cm	10	NR	NR	10
II. Chemical Properties				
D_g^{air}, chemical gaseous diffusion coefficient in air, cm^2/sec	$4.7*10^{-2}$	$4.7*10^{-2}$	$4.7*10^{-2}$	$4.7*10^{-2}$
D_l^{water}, chemical liquid diffusion coefficient in water, cm^2/sec	$5.6*10^{-6}$	$5.6*10^{-6}$	NR	NR
Koc, organic carbon partition coefficient, cm^3/g	$3.98*10^{6}$	$3.98*10^{6}$	$3.98*10^{6}$	$3.98*10^{6}$
H, Henry's Constant, atm-m^3/mole	$3.2*10^{-5}$	$3.2*10^{-5}$	$3.2*10^{-5}$	$3.2*10^{-5}$
μ, soil degradation rate, 1/sec	0	NR	NR	NR
III. Model Solution Parameters				
BL, boundary layer thickness, cm	0.5	NR	NR	NR
Time of Volatilization, days	10950	10950	10950	NR

NR = Not required for solution

Table 7-4. Results of model volatilization comparison exercise.

Description	Volatilization, g/cm^2-sec
Hwang model	$1.03 * 10^{-18}$
Full Jury model as coded in EMSOFT	$2.81 * 10^{-19}$
Simplified Jury Model as used in Superfund Soil Screening	$3.89 * 10^{-19}$
Vapor diffusion solution only	$4.03 * 10^{-21}$
Full Jury model, boundary layer = 0.01 cm	$3.02 * 10^{-19}$
Full Jury model, half-life = 25 years	$2.16 * 10^{-19}$

Table 7-5. Comparison of the derivation of the fraction of sorbed dioxin congener based on the octanol air partition coefficient, K_{oa}, or based on the sub-cooled liquid vapor pressure, as done for this document as described in Chapter 3.

Congener	Solving for K_{oa} [1]			ϕ for urban conditions[2]		ϕ for urban conditions as in Chapter 3
	log K_{ow}	H	log K_{oa}	theoretical	empirical	
2378-TCDD	6.81	$3.95*10^{-5}$	9.63	0.09	0.14	0.75
12378-PCDD	6.64	$2.60*10^{-6}$	10.58	0.48	0.40	0.95
123478-HxCDD	7.80	$1.05*10^{-5}$	11.13	0.76	0.60	0.99
123678-HxCDD	7.30	$1.10*10^{-5}$	10.61	0.49	0.41	0.99
123789-HxCDD	7.30	$1.10*10^{-5}$	10.61	0.49	0.41	0.99
1234678-HpCDD	8.00	$1.26*10^{-5}$	11.25	0.81	0.64	0.997
OCDD	8.20	$6.75*10^{-6}$	11.72	0.92	0.78	0.999
2378-TCDF	6.10	$1.44*10^{-5}$	9.29	0.05	0.09	0.73
12378-PCDF	6.79	$5.00*10^{-6}$	10.44	0.40	0.35	0.91
23478-PCDF	6.50	$4.98*10^{-6}$	10.15	0.26	0.26	0.94
123478-HxCDF	7.00	$1.43*10^{-5}$	10.19	0.27	0.27	0.98
123678-HxCDF	7.00	$7.31*10^{-6}$	10.49	0.42	0.36	0.98
123789-HxCDF	7.00	$1.10*10^{-5}$	10.31	0.33	0.31	0.99
234678-HxCDF	7.00	$1.10*10^{-5}$	10.31	0.33	0.31	0.99
1234678-HpCDF	7.40	$1.41*10^{-5}$	10.60	0.49	0.40	0.99
1234789-HpCDF	8.00	$1.40*10^{-5}$	11.20	0.79	0.62	0.997
OCDF	8.80	$1.88*10^{-5}$	11.88	0.95	0.82	0.999

[1] K_{oa}, the octanol air partition coefficient, is solved as, [Kow*R*T]/[H], where K_{ow} is the octanol water partition coefficient, dimensionless; R is the universal gas constant, $8.2*10^{-5}$ atm-m^3/mole-K;T is ambient temperature, 273 °K, H is the Henry's Constant, atm-m^3/mole.

[2] ϕ, the fraction of sorbed particle, is solved as $[K_p (TSP)]/[1 + K_p (TSP)]$. K_p is solved for either "theoretically", where log K_p = log K_{oa} -12.61, or "empirically" based on field data, as done by Kaupp and McLachlan (1999) as, log K_p = 0.6368 log K_{oa} -8.9111. See Section 7.2.7 for more detail on these algorithms.

Table 7-6. Summary of off-site soil contamination from Tier 1 and 2 sites of the National Dioxin Study.

Site name	On-site # samples/range (ppb)	Off-site # samples/range (ppb)	Comments
Diamond Alkali Newark, NJ	9/60-51,000	537/ND-725	Facility involved in the manufacture of 2,4,5-T; off-site sampling covered a 4000-ft radius including public areas such as a public housing unit, park, streets, and river. Two of 11 samples from a park were positive at 1-3.1 ppb; detection limit was 1 ppb. Other off-site positives were from streets and river sediments.
Brady Metals Newark, NJ	10/1.9-3500	30/1.7-1156	Site directly associated with the Diamond Alkali site summarized above; text did not provide any further detail on off-site soil sampling.
Love Canal Niagara, NY	NA/NA-6.7	20/3-263	Love Canal contamination well documented elsewhere; few details provided in reference for soil sampling programs; it was noted that 3,000 cubic yards of fly ash and BHC cake were taken from Love Canal in 1954 and used as fill at the nearby 93rd Street School, a subsurface sample 3+ ft deep showed a concentration of 6.7 ppb. The off-site summary provided here was from an area identified as Hyde Park.
Vertac Jacksonville, AR	45/<1-1,200	320/<1-33.4	A site manufacturing 2,4,5-T; it is not clear than any of the off-site sampling was for surface soil - summary tables identified it as "various"; text description did not mention off-site soil contamination and indicated that solid and liquid waste were buried on-site in a series of landfills. 2,3,7,8-TCDD was found in fish as far away as 100 miles.
Hooker Chemical Niagara, NY	17/ND-18,600	4/ND-430	A site manufacturing 2,4,5-TCP; subsurface soil sampling ranged from ND to 18.6 parts per million; one off-site surface soil detection noted at 1.1 ppb.
Bliss Tank Property Rosat, MO	NA/ND-430	NA-ND-430	No summary text provided in primary reference; tabular summary identified soil sampling as on/off-site soil; non-detects were noted in 13 off-site dust sampling.
Dow Chemical Midland, MI	#1: 43/0.041-52 #2: 106/ND-1500	11/0.0006-0.45 42/0.003-2.03	Site most extensively studied of those in National Dioxin Study; data identified as #1 was a summary of 1984 data supplied in NDS; #2 was a summary of 1985 data; the 1984 data was further detailed in Nestrick, et al. 1986; see text for further discussions on this site.

Table 7-17. Summary of plant concentration versus soil concentration data for 2,3,7,8-TCDD.

Plant:soil Concentrations	Contaminant Ratio	Reference and Comments
I. Below-Ground Vegetation		
54-167 ppt/ 1-5 ppb	0.01-0.17	Wipf, et al., 1982; results are for 2,3,7,8-TCDD and greenhouse carrots grown in Seveso contaminated soil; the 54 ppt concentration listed was for carrot peels and inner portions; the 167 ppt listed includes the 54 ppt plus additional residues found in wash water and can be described as "unwashed" concentration; 96% of 167 ppt unwashed concentration includes that found in wash water (67%) and peels (29%).
0.8-9.2 ppb/ 2.7-8.3 ppb	0.24-1.73	Coccusi, et al., 1979; results are for 2,3,7,8-TCDD and carrots, potatoes, narcissus, and onions grown on contaminated soil the spring following the Seveso contamination; aerial plant part ratios were 0.25-0.40 - underground part ratios were 0.23-1.73; residues in contaminated plants were found to dissipate when contaminated plants transplanted to unpolluted soils; results show higher ratios than the Wipf, et al. (1982) noted above; results were expressed in fresh plant weight and fresh soil basis; very high ratios and plant impacts render these data suspect.
156-1807 ppt/ 160-752 ppt	1.00-2.40	Facchetti, et al., 1986; results are for 2,3,7,8-TCDD and bean and maize roots grown in indoor greenhouse pots and outdoor pots; unclear whether plant concentrations are fresh or dry weights. Data considered highly suspect due to very high ratios found and also reporting 16 and 37 ppt in roots when "blank" soil had 1.5 ppt (ratios of 10.7 and 24.7).
735 ppt/ 411 ppt	1.8	Young, 1983; results are for 2,3,7,8-TCDD and roots of grass and broadleaf plants at Eglin Air Force Base; unclear whether root concentrations are fresh or dry weight.
0.5-40.2 ppt/ 2-6000	0.001-0.3	Hulster and Marschner, 1991; results at right are for unpeeled potato tubers, in TEQ and dry weight basis. Plant:soil ratio decreased as soil concentrations increased; highest ratios were at the 2.4 ppt low soil concentration. Peeled tuber concentration stayed below 0.5 ppt over all soil concentrations, indicating insignificant within plant translocation. Plant concentrations given in dry weight basis.
0.1-15 ppt/ 6-690 ppt	0.001-0.5	Muller, et al. 1994; results at right describe the range of concentrations and ratios for data on ten congener groups, in two soils (a control and a contaminated soil), and for carrots. For the control soil, which had a TEQ concentration of 5 ppt, typical of background soils, the average plant:soil ratio was 0.10; for the contaminated soil with a TEQ concentration of 56 ppt, the plant:soil ratio was 0.02.

Table 7-17. (cont'd).

Plant:soil Concentrations	Contaminant Ratio	Reference and Comments
I. Below-Ground Vegetation (cont'd)		
0.2-6.0 ppt/ 328-12,800 ppt	0.00001-0.009	Hulster and Marschner, 1993. Results are for potato tubers, peeled and unpeeled, and for potato shoots, results for TEQ and in dry matter terms. Concentrations for peeled potato tubers stayed consistently less than 0.5 ppt, despite soil concentrations, while shoots and unpeeled tubers increased as concentration increased. Plant:soil ratios remained relatively constant for tubers and shoots with soil concentration increases, leading authors to conclude that a soil/plant relationship exists for plants growing in the soil. Less transfer was noted for higher chlorination.
II. Above-Ground Vegetations		
9-42 ppt/ 10 ppb	0.0009-0.0042	Wipf, et al., 1982; analysis of apples, pears, plums, figs, peaches, and apricots grown in Seveso, Italy year following contamination; apples, pears, and peaches showed >95% of whole fruit concentrations listed here was in the peels; analysis of vegetative samples in less contaminated areas showed non-detections at 1 ppt detection limit; reference was unclear as to whether reported concentrations in fruit was based on fresh or dry weight.
8-9 ppt/ 10 ppb	0.0008	Wipf, et al., 1982; concentrations listed were those found in sheaths of corn grown year following Seveso contamination; none found in cobs and kernels at 1 ppt detection limit.
1-63 ppt/ 12-3300 ppt	0.003-0.35	Sacchi, et al., 1986; data was for: "aerial parts" of bean and maize plants, tritiated TCDD amended soil with concentrations ranging as noted, taken at different intervals including 7, 34 and 57 days (one test), 17, 34, and 57 days (another test), 8 and 77 days, and 8 and 49 days, and in tests where soil was and was not amended with peat. Results showed increasing plant concentrations with increasing soil concentrations, but the ratio of plant to soil concentrations was inversely related to increasing soil concentrations (lowest ratios at highest soil concentrations). Soils without peat had higher ratios than soils with peat. Plant concentrations were fresh weight basis; high plant impact and trend for increasing impact over time renders these results suspect.

Table 7-17. (cont'd).

Plant:soil Concentrations	Contaminant Ratio	Reference and Comments
I. Above-Ground Vegetation (cont'd)		
ND (DL=1 ppb)/60 ppt	<0.017	Isensee and Jones, 1971; results are for mature oat and soybean tops, and oat grain and the bean of soybean, in soil treated with [^{14}C]TCDD to achieve a concentration of 60 ppb - no residues of TCDD were found; ratios of 0.14 and 0.28 were found for 2,4,-dichlorophenol (DCP) in oat and soybean tops, and 0.20 for 2,7-dichlorodibenzo-p-dioxin (DCDD) in oat tops; trace amounts of DCP and DCDD were found in the bean of soybean.
10-270 ppt/ 411 ppt	0.02-0.66	Young, 1983; data was for 2,3,7,8-TCDD and above ground plant parts of perennial grasses and broadleaf plants grown on 2,4,5,-T treated soils. Unclear whether plant concentrations are fresh or dry weight basis. Soil concentration was average over 3 depth increments to 15 cm. Crown near soil surface at 270 ppt and 0.66 ratio was highest; plant tops had ratios of 0.02-0.17.
0.3, 0.1 ppt/ 8750,5215 ppt	0.00003, 0.00002	Muller, et al, 1993. Result at right are for whole pear (0.3) and whole apple (0.1) dry weight concentrations (article presented TEQs for two pears from one tree which were averaged, and one apple, and for fresh weight; dry weight was estimated assuming 12% dry matter in pears/apples) and the average concentration over 70 cm (article supplied concentrations for the 0-30 and 30-70 cm depths). Article also provided peel and pulp results and results for congener groups. Article concluded: soil levels were not correlated to fruit concentrations and therefore fruits were impacted by airborne contamination, and that concentrations were higher in peel than in pulp.
0.1-0.6 ppt/ 326-5752 ppt	0.00002-0.0008	Hulster and Marschner, 1993. Results are for inner and outer leaves of lettuce, expressed as dry matter, and in TEQs. Results indicate a drop in ratio as soil concentration increases, and unexpected small differences between inner and outer leaves.
4-38 ppt/ 326-12,800 ppt	0.001-0.01	Hulster and Marschner, 1993. Results are for hay, dry matter, and TEQs. Results indicate a drop in ratio as soil concentrations increase.

Table 7-17. (cont'd).

Plant:soil Concentrations	Contaminant Ratio	Reference and Comments
I. Above-Ground Vegetation (cont'd)		
< 1 ppt/ 326-5752 ppt	0.0001-0.0003	Hulster and Marschner, 1993. Results are for grass and herbs, dry matter, and TEQs. Results indicate a drop in ratio as soil concentrations increase. For above three entries, results are also given for congener groups. Authors conclude that: little correlation between soil and above ground plant concentrations, and that contamination is by atmospheric deposition.
<0.01, 0.04/ 5, 56 ppt	<0.002	Muller, et al., 1994. Results are for peas at soil concentrations of 5 and 56 ppt; pea concentrations in TEQ and dry weight. Results for pods indicated more impact with ratios at 0.002-0.026. Ratios decreased as soil concentration increased.
0.32, 0.21 ppt/5, 56 ppt	0.004-0.064	Muller, et al., 1994. Results are for lettuce at soil concentrations of 5 and 56 ppt; lettuce concentrations in TEQ and dry weight. Little difference seen between inner and outer leaves, which was unexpected - outer leaves expected to be more impacted. Ratios decreased as soil concentration increased.
0.5-22.6 ppt/ 0.4, 148	0.14-2.5	Hulster, et al., 1994. Results are for zucchini fruit at two soil concentrations of 0.4 and 148 ppt TEQ, fruit results are TEQ and dry weight. Results contradict conventional wisdom that above ground vegetation impact is from air only and mainly an outer surface phenomena; zucchini contamination was uniform throughout plant and plant:soil ratios highest ever found for above ground bulky fruits.
0.6 ppt/ 148 ppt	0.004	Hulster, et al., 1994 Results are for cucumber grown in soil at 147 ppt TEQ; cucumber results in TEQ and dry weight. Results are more in line with most other studies for above ground bulky fruit plant:soil ratios.
7.5 ppt/ 148 ppt	0.05	Hulster, et al., 1994. Results are for pumpkin grown in soil at 148 ppt TEQ; pumpkin results in TEQ and dry weight. Results not as dramatic as for zucchini, but plant concentrations are ratio are still high.
0.4-1.9 ppt/ 2.4-6000 ppt	0.0003-0.3	Hulster and Marschner, 1991. Results are for lettuce, in TEQ and dry weight. Experiments were conducted outdoors with soil covered by a water permeable polypropylene fleece. Plant concentrations showed little variation with large increases in soil concentration, and given the soil covering, this would strongly indicate little root to shoot translocation and that lettuce concentrations were the result of air to plant transfers

8. UNCERTAINTY

8.1. INTRODUCTION

This chapter addresses uncertainty in dioxin exposure assessment performed with the methodologies presented in this document. Some discussion of the issues commonly lumped into the term "uncertainty" is needed at the outset. The following questions capture the range of issues typically involved in uncertainty evaluations:

(1) How certain are site specific exposure predictions that can be made with the methods?
(2) How variable are the levels of exposure among different members of an exposed local population?
(3) How variable are exposures associated with different sources of contamination?

The emphasis in this document is in providing the technical tools needed to perform site-specific exposure assessments. For the assessor focusing on a particular site, question (1) will be of preeminent importance. Therefore, the emphasis of this Chapter is to elucidate those uncertainties inherent to the exposure assessment tools presented in this document. This chapter examines the uncertainties associated with estimating exposure media concentrations of the dioxin-like compounds using the fate, transport, and transfer algorithms, and also identifies and discusses uncertain parameters associated with human exposure patterns (contact rates and fractions, exposure durations, etc.).

Section 8.2 focuses on uncertainty issues associated with the use of the ISCST3 model for air transport modeling for the stack emission source category. The ISCST3 model and its application in this assessment are presented in detail in Chapter 3. Section 8.3 discusses the variability and uncertainty with chemical-specific parameters which are required for all source categories of this assessment methodology. Section 8.4 provides a general overview of all key uncertainties with each pathway.

A site specific assessment will also need to address the variability of risks among different members of the exposed population, the second key question above. The level of detail with which this can be done depends on the assessors knowledge about the actual or likely activities of these residents. In this document, one approach to evaluating this variability is demonstrated. Separate "central" and "high end" scenario calculations are presented to reflect different patterns of human activities within an exposed population. "Central" scenarios are constructed to represent typical behavior patterns for residential exposures in a hypothetical rural

setting. "High end" calculations focus on a farming scenario where individuals raise food for their own consumption, in the same rural area. It should be emphasized that high end calculations could also have been developed for residential exposures by making, for example, higher range assumptions about the duration of residence or contact rates with the contaminated media. Indeed, this would be recommended for an assessment where considerable emphasis was placed on residential exposures. The key issue with regard to intra-population variability is that it is best (if not only) addressed within the context of a specifically identified population. If such information is available, a powerful tool that can be used to evaluate the variability within a population is Monte Carlo Analysis. Section 8.5. reviews recent Monte Carlo studies which have been done for exposure to 2,3,7,8-TCDD. Assumptions on distributions of exposure patterns and fate and transport parameter distributions are described, as are the results of their analyses. Aside from this review, this chapter does not address question (2) in any further manner.

With regard to question (3), this document does not present a detailed evaluation of how exposure levels will vary between different sources of release of dioxin-like compounds into the environment. Volume I of this assessment examines sources of release of dioxin-like compounds into the environment. This document, Volume III, presents methodologies for three types of sources - soil, stack emissions, and effluent discharges into surface water bodies. While this document demonstrates the methodologies developed for these sources with source strengths and environments crafted to be plausible and meaningful, there is still a great deal of variability on both the source strengths and on the environments into which the releases occur. For example, the frequency with which farms and rural residences are near stack emissions of dioxin-like compounds is not addressed. The scenario calculations in Chapter 5 are intended to be illustrative; the exposure levels that are obtained there are not intended to be typical of actual exposures for the sources and pathways assessed.

Nonetheless, some readers might ideally wish information on both the magnitude of actual exposures and the variability of these exposures associated with different sources of dioxin-like compound releases into the environment. However, the analysis presented in this chapter cannot support so broad a goal. Representative data to address the variation of dioxin exposures are becoming available for sources as well as exposure media. Volume I discusses and quantifies releases from known sources in the US, and the compilation of environmental and exposure media concentrations presented in Chapter 3 of Volume II of this assessment displays the range of measured concentrations in the environment. The careful selection of certain literature reports on concentrations of dioxin-like compounds to represent background conditions, described in Chapter 4 of Volume II, is one way such environmental measurements

can be used. References to EPA and other assessments on dioxin-like compounds have been made throughout this document, such as those related to soil exposures (Paustenbach, et al., 1992a), exposures to contaminated fish (EPA, 1991a), exposures resulting from land disposal of sludges from pulp and paper mills (EPA, 1990), just to name a few. Still, studies comparing and ranking different sources and exposure patterns, and elaborations on ranges of source strengths and exposures, are generally not available. Information in Volumes I and II of this assessment, and procedures for source specific evaluations in Volume III, can provide others with information and tools to begin such analysis.

8.2. A DISCUSSION OF UNCERTAINTY ISSUES ASSOCIATED WITH THE USE OF ISCST3 FOR TRANSPORT AND DISPERSION OF STACK EMITTED CONTAMINANTS

Air dispersion and deposition analysis was performed using the ISCST3 Model. The model is intended to provide long term average air concentrations and wet and dry deposition flux. This section discusses some of the uncertainties and critical parameters associated with the general modeling approach used in ISCST3, and reviews some of the literature on model testing and validation.

Atmospheric dispersion in ISCST3 is modeled using the common Gaussian plume model. Downwind concentrations of the dioxin-like chemicals are calculated as a function of stack height, the mass emission rate, the wind speed, and general atmospheric conditions. The Gaussian model assumes that the emission concentrations predicted by the model will fit a normal distribution. The principal assumptions in the Gaussian model are (Kapahi, 1991):

- The air concentration of the chemical at a fixed distance from the source is directly proportional to the emission rate from the source;
- The air concentration of a given chemical is inversely proportional to the wind speed corresponding to the effective height of release of the chemical into the air;
- The predicted ground-level concentration of the chemical approaches zero at large distances from the initial point of release.
- The model is steady-state.
- The model assumes constant wind speed, wind direction, and atmospheric stability over time and space for a given time period.

In general, the Gaussian plume model has been shown to predict annual average ambient air concentrations of a chemical emission from an industrial source to within a factor of one-order of magnitude of measured values, and in some cases, within a factor of 3 to 4-fold of field

measurements (Cohrssen and Covello, 1989). This modeling error spans both sides of the predicted concentration, that is, the actual concentration may be plus or minus this amount of the predicted value. Even more assertive, an early position paper on the application of gaussian short-term dispersion models claimed an approximate factor-of-two accuracy in the absence of complicating factors (complex terrain, building wake effects) (AMS, 1978).

The most sensitive aspects to variability in modeled predictions of ambient air impacts, if emissions are held constant, are stack height (height of the release), and terrain (flat verses complex topography). To investigate modeling variability, EPA placed a prototype hypothetical hazardous waste incinerator in flat terrain and elevated terrain in geographical areas around the U.S. (EPA, 1991b; analysis conducted with the Industrial Source Complex, or ISC, model). Then the stack height was varied at these particular locations. Numerous runs were made at twelve specific sites to compare and contrast the influence of stack height and terrain on predicted ambient air concentrations of various mass emission rates of specific inorganic pollutants. A series of tables were developed from this sensitivity analysis from which the numerical estimation of the variability as a function of stack height and terrain can be inferred. When the hypothetical hazardous waste incinerator was modeled in flat terrain, e.g., topography within a distance of 5 km is not above the height of the stack, and the stack height was varied from 4 meters to 120 meters, the variability in the predicted ambient air concentration spanned two orders of magnitude (100). The lower stack height resulted in a predicted ambient air concentration that was 100 times greater than the concentration predicted using the tallest stack height. When the hypothetical hazardous waste incinerator was located in complex terrain over the same range of physical stack heights, the variability in estimated groundlevel concentration of the subject pollutant spanned two orders of magnitude (100-fold). In the latter case the stack height was computed as the terrain-adjusted stack height by subtracting from the physical stack height the influence of terrain on plume rise. From the limited sensitivity analysis of hazardous waste incinerators, it can be assumed that the predictions of spacial ground-level ambient air concentrations of dioxin-like compounds could differ from values in Tables 3-17 and 3-18 by two-orders of magnitude in consideration of changes in stack height or changes in terrain. For example, Tables 3-17 and 3-18 show that the maximum annual average ambient air concentration of 2,3,7,8-TCDD predicted near the hypothetical incinerator is approximately 10^{-11} $\mu g/m^3$ for the stack height of 30.5 meters, and assuming flat terrain. If only the stack height is varied from 20 meters to 120 meters, and all other modeling parameters are held constant, then the predicted ambient air concentration would be approximately 10 times greater and 10 times less than the estimated concentration, respectively. The uncertainty is broader when considering the influence

of topography on predictability of the ground-level concentrations from the model. If only terrain elevation is varied at a distance of 5 km from the hypothetical incinerator from zero elevation to 30.5 meters, e.g., the height of the stack, then the predicted ambient air concentration of 2,3,7,8-TCDD would be approximately ten times greater. The tables derived in the hazardous waste incineration analysis have a limitation of elevation of terrain to the height of the stack.

The most uncertain aspect to the modeling is the estimation of dry and wet deposition flux of dioxin-like compounds on the vicinity of a hypothetical incinerator. Contributing most to this uncertainty seems to be the settling velocities and scavenging coefficients estimated for specific particle size diameters (Cohrssen and Covello, 1989; Doran and Horst, 1985). Seinfeld (1986) found that particles over 20 microns in diameter settle primarily by gravity, whereas smaller particles deposit primarily by atmospheric turbulence and molecular diffusion. Considerable, but non-quantifiable, uncertainty exists with respect to deposition velocities of particles 0.1 to 1.0 microns in diameter (Seinfeld, 1986). The uncertainty is difficult to define. The wide variation of predicted deposition velocities as a function of particle size, atmospheric turbulence and terrain adds to this uncertainty (Sehmel, 1980). However, Gaussian plume dispersion models have been field validated for their ability to spatially predict dry deposition flux over some specified distance (Doran and Horst, 1985). In a series of field experiments conducted by Pacific Northwest Laboratory (Doran and Horst, 1985), zinc sulfide was used as a depositing tracer gas, and sulfur hexafluoride was used as a non-depositing tracer gas to compare and contrast modeling results with field measurements of dry deposition and atmospheric diffusion of the gases. The tracer was released from a height of 2 meters, and all releases were made under relatively stable atmospheric conditions. Five sampling stations were located downwind of the release from 100 to 3200 meters. The results of these experiments showed good agreement with the predicted verses the measured deposition of the tracer ZnS. The overall correlation coefficient between predicted and measured deposition concentration was found to be 0.82 (Doran and Horst, 1985), but the models marginally over-predicted deposition flux near the source of release, and under-predicted deposition flux at 3200 meters.

Travis and Yambert (1991) have evaluated the uncertainty in modeling the dry deposition flux of particulates using four standard Gaussian plume dispersion models. Since deposition flux is dependent on deposition velocity for a given particle mass and diameter, comparisons were made between model-generated deposition velocities and measured values found in the open literature for particles ranging from 0.01 to 30 microns in diameter. It was found that measured deposition velocities for a given particle size in the scientific literature exhibit variability spanning roughly two orders of magnitude. The analysis of the mean predicted deposition

velocities to mean measured values showed that most measured data exceeded the predicted data for all four models. Moreover, the models underestimated the mean deposition velocities for particles in the range of diameters from 0.05 to 1.0 microns.

Similar uncertainty probably exists with regard to scavenging of various diameter particles by various intensity of rainfall. Seinfeld (1986) has calculated scavenging coefficients in terms of the removal efficiency of particles of a given size by rain droplets having a given momentum. Seinfeld (1986) found that the scavenging coefficient of a given particle diameter corresponding to a given rainfall intensity can be calculated based on physical laws, but there is a complete absence of research data to verify these calculations. Hence it is not possible to address the accuracy nor uncertainty of the wet deposition flux estimated in Table 3-19.

There have been some limited validation work done with ISCST3 and its ISC predecessors. Chapter 7 described a model validation exercise for air dispersion and deposition/soil concentration modeling done for dioxins in the vicinity of a municipal solid waste incinerator known to be emitting large amounts of dioxins. The predicted concentrations were mostly within a factor of 10 of observations, higher or lower, for both air and soil. There was evidence that the profile of dioxins in both the air and the soil were distinct from the profile of dioxins being emitted from the incinerator. This observation suggests transformations in the dioxin profile in either, or both, the air and soil environments. In clearly impacted ambient air samples that were downwind of the incinerator during sampling events, for example, the measured profile suggested a more predominance of lower chlorinated dioxins than was seen in the stack emission. Two explanations were offered to explain this observation: the higher chlorinated dioxins deposited much more so than the lower chlorinated dioxins, which lessened their predominance in the profile and/or higher chlorinated dioxins dechlorinated to form lower chlorinated dioxins. When testing air dispersion alone (no deposition, no atmospheric decay or transformation of emitted dioxins), the air concentration profile perfectly matched the stack emission profile, as it should, so neither of these possibilities could be tested. However, when testing the deposition/soil concentration capabilities of ISCST3, evidence did strongly suggest that the model was underpredicting the deposition rate of OCDD, at least. Even with this possible finding, the disparity between the soil concentration profile and the stack emission profile continued to suggest that transformations may be taking place in soils and/or the air which were not captured in the model testing at this site. In general, the model was able to duplicate the trend of elevations in both air and soil near the facility, to within a factor of 10 of these elevations.

Early ISC (the predecessor to ISCST3) model validation work was conducted by Bowers, et al. (1981). They tested the gravitational dry particle deposition algorithms, new at that time, and showed that the model predicted deposition rates generally within a factor of two of measured depositions of glass microspheres of 50 to 200 μm measured in an experimental setting. They also tested the capabilities of building wake effects using data from diffusion experiments conducted at a Nuclear Power Station in which the tracer SF_6 was released from the reactor building main vent and the tracer Freon 12B2 was simultaneously released from three vents on the adjacent turbine building. They then predicted concentrations of these tracers with and without building wake effects, and found that the inclusion of building wake effects improved the average correspondence between modeled and observed concentrations by almost a factor of 2.

8.3. UNCERTAINTIES AND VARIABILITIES WITH CHEMICAL-SPECIFIC MODEL PARAMETERS AND ASSUMPTIONS

This assessment assumed that levels of dioxin-like compounds in soil and sediment were constant over the period of exposure, with two exceptions. One circumstance was when contaminated soil eroded from one site and deposited on a site of exposure nearby - the soil contamination source category. The other was when stack emitted particulates deposited onto a site of exposure - the stack emission source category. In both these instances, it is assumed that only a relatively thin layer of surface soil at the site of exposure would be impacted, and that this thin layer is subject to dissipation processes - erosion, volatilization, possibly degradation. Data in Young (1983) implied a soil half-life of 10 years for surficial 2,3,7,8-TCDD residues, although the circumstances of the soil contamination were not analogous. Specifically, a 37 ha test area at the site had received an estimated 2.6 kg of 2,3,7,8-TCDD over a two year period. Soil sampling which occurred over 9 years from the last application suggested that less than 1 percent remained at the test area. Although Young hypothesized that photodegradation at the time of application was principally responsible for the dissipation of residues, other mechanisms of dissipation including volatilization, erosion, and biological removal may also have contributed to the loss of residues. Soil sampling over time after application implied a dissipation half-life of 10 years for soil residues of 2,3,7,8-TCDD. Mclachlan, et al. (1996) reported on an analysis of soil taken from experimental plots which had been amended with sewage sludge in 1968 and sampled in 1972, 76, 81, 85, and 90. These archived samples were analyzed for all 17 dioxin-like CDD/Fs, and based on an analysis of results, McLachlan and coworkers concluded that half-lives were on the order of 20 years, with dioxin removal from the plots being mainly physical removal

processes (overland runoff, wind erosion). Furthermore, their results suggested that all congeners had been removed at roughly the same rate, which is why they concluded that removal processes were mainly physical and very little in-situ degradation appeared to be occurring. Paustenbach, et al. (1992a) reviewed several reports of the soil dissipation of 2,3,7,8-TCDD, including Young (1983), and concluded that the half-life of 2,3,7,8-TCDD residues below the surface varied from 25-100 years. A half-life of 25 years ($k = 0.0277\ yr^{-1}$) was assumed to apply to all dioxin-like compounds in this assessment.

Section 2.6.1, Chapter 2 in Volume II of this assessment, reviewed the literature on degradation of dioxin-like compounds. As discussed, biological transformations as well as chemical processes (oxidation, hydrolysis, and reduction) do not appear to result in substantial degradation of these compounds. There is evidence of photolysis, particularly when dissolved in solution and when organic solvents are present. Most of these data are specific to 2,3,7,8-TCDD. Uncertainty is introduced into parameter assignment when information specific to one congener is assumed to apply to all dioxin-like congeners. However, it is judged that there is no good data available to assign different soil dissipation rates to different dioxin congeners in this assessment, and McLachlan's (1996) data is judged to be reasonably strong to support an assumption that all dioxin congeners dissipate with roughly the same half-life.

Dissipation of surficial residues could translate to lower soil-related exposures including particulate inhalations, soil ingestion, and soil dermal contact. However, it is not clear that reductions in exposure would, in fact, occur, particularly if the soil is contaminated below the surface. Processes such as wind erosion, soil erosion, or volatilization originating from deeper in the soil profile, could serve, in a sense, to replenish reservoirs at the soil surface. Depositions back onto soils from other soils, or depositions from distant sources, also replenish soils. Given very low rates of degradation (for all degradation processes except photolysis), the assumption of no degradation for the soil contamination source category is reasonable with moderate, but unquantifiable uncertainty.

In evaluating an assumption of no degradation, another issue to consider is the depletion of the original source of contamination. For the stack emission and effluent discharge source categories, the assumption is made that steady releases occur while the source is active. Therefore, depletion of the original source is not an issue. For the soil contamination source category, it is assumed that the reservoir of contaminant is constant throughout the duration of exposure. If such a duration is assumed to be very long, then degradation or dissipation of soil residues would be more critical than if the duration were relatively short. Uncertainties associated with the duration of exposure are discussed in Section 8.4 below. Also, Section 6.4 in

Chapter 6 evaluated the assumption of a constant soil concentration by estimating the time it would take for a 15-cm reservoir of soil contamination to be depleted, using the dissipation algorithms of this assessment. These algorithms include volatilization, soil erosion, and wind erosion, with lesser releases due to biological uptake, and leaching and runoff. It was found that it would take over 90 years to deplete a 15-cm reservoir, lending some credibility to a non-degradation assumption if the exposure duration were in the range assumed for the demonstration scenarios of this assessment, 30 years.

A critical contaminant parameter required for the procedures in this assessment is the octanol water partition coefficient, Kow, although none of the fate and transport algorithms directly require a Kow. One of the empirical biota transfer parameters is, however, a function of Kow. This is the RCF, or Root Concentration Factor, which estimates the transfer of contaminant from soil water to root. Log Kow estimates for dioxin-like compounds range from 6.00 to 8.5, with higher log Kow associated with higher chlorination. However, this is not a certain parameter. Estimates in literature for 2,3,7,8-TCDD, for example, range from 6.15 to 8.5. The uncertainty of the RCF is addressed in Chapter 7, Section 7.3.9, where experimental data on the transfer of dioxins from soil to carrots was used in a validation exercise. It was found that the RCF allowed for the reasonably accurate simulation of the transfer of dioxins to the carrot peel, with the model able to predict peel concentrations within a factor of 2 for 15 of 20 observations, and for the other five observations, predictions and observations differed by a factor of 5 or less.

Two biota transfer coefficients are used to estimate fish tissue concentrations based on water body sediment concentrations: the Biota Sediment Accumulation Factor, BSAF, and the Biota Suspended Solids Accumulation Factor, BSSAF. There are no empirical relationships which estimate these as a function of the more common Kow for dioxin-like compounds. Rather, values were assigned based only on experimental and field data. Needless to say, most of the data available was for 2,3,7,8-TCDD, leaving large gaps for other compounds. Also, there is no data available for estimating the BSSAF, a parameter proposed in EPA (1993) which was used in the effluent discharge source category. The BSSAF was set equal to the BSAF for this assessment. Field data including bottom sediment concentrations and concurrent fish concentrations were used to determine values for BSAF. The limited field data available for BSAF suggests values in the range of 0.03 to 0.30 for 2,3,7,8-TCDD, with higher values approaching 1.00 indicated for bottom feeders (catfish, carp, etc.), and decreasing values as the degree of chlorination increases - limited information suggests values in the 10^{-3} to 10^{-2} range for hexa- through octa- CDDs and CDFs. EPA (1995) used available data to develop the "bioequivalency factors", BEFs, or multipliers to the BSAF or BSSAF to assign values for

congeners other than 2,3,7,8-TCDD, when data on only 2,3,7,8-TCDD is available. The BEF concept and the BEFs are described further in Chapter 4. They were used to assign values for the BSAF/BSSAF for other dioxin-like congeners assuming a BSAF/BSSAF of 0.09 for 2,3,7,8-TCDD. Data on PCBs suggest that BSAFs are higher than those of CDDs and CDFs by an order of magnitude and more, and that the trend with increasing degrees of chlorination is not the same. The data indicates that BSAFs for PCBs increase from dichloro- through hexa- or perhaps hepta-chloro PCBs, and decrease thereafter.

A bioconcentration factor, BCF, translates the average contaminant in the diet of the cattle into a beef or milk fat concentration. Experimental rather than field data was available for estimates of BCF for dioxin-like compounds. Farm animals were fed known quantities of these compounds and their body tissues and milk were monitored over time to arrive at BCFs. Data showed that the BCF decreased to below 1.0 as the degree of chlorination increased. An experimental data set, including analysis of 16 of the 17 dioxin-like congeners, described in McLachlan, et al (1990), was used to assign BCF values for this assessment. A more recent study, by Fries, et al. (1999), developed BCFs for 14 of 17 congeners in a feeding experiment where four cows were fed PCP-contaminated wood. Results showed a good agreement between these BCFs and those developed from the data of McLachlan, et al. (1990), although the BCF for 2,3,7,8-TCDD was highest in this experiment at 7.1 as compared to the BCF of 5.76 developed from McLachlan's data and used in this assessment. Limited data showed PCB BCFs to be the same order of magnitude, although trend data for increasing degrees of chlorination was not available.

Similar bioconcentration factors, also termed BCF in Chapter 4, were described for chicken fat. Like the beef/milk fat BCF, they were developed from experimental data on chickens and eggs (Stephens, et al., 1995). The transfer of vapor-phase dioxins from air to plant is also modeled with a simple biotransfer factor, termed B_{vpa}, is also developed from field data.

Obviously, a degree of uncertainty is introduced when relying on these empirical bioconcentration or biotransfer coefficients to estimate concentrations in fish, beef, milk, chicken, eggs, and terrestrial vegetation. The variability in the data suggests up to an order of magnitude range of variation may result from use of these parameters. All but one of these factors (the RCF) were developed from field or experimental data on dioxin-like congeners or homolog groups. This, by definition, will lend a degree of credibility to their assignment. Also, a validation exercise described in Chapter 7 testing the air-to-beef algorithm is a test of two of these biotransfer/bioconcentration factors, the B_{vpa} and the BCF, and both appear to be supported by this exercise. It appears likely, therefore, that the actual variation in these

biotransfer/bioconcentration factors, is less than an order of magnitude, perhaps less than a factor of five.

Another important chemical-specific parameter that can be estimated from Kow or estimated experimentally is the organic carbon partition coefficient, Koc. Koc describes the steady state partitioning between soil or sediment organic carbon and water; it impacts the volatilization flux from soils, and the partitioning between suspended sediment and water in the water column. Koc is used to estimate in-situ partitioning using a fraction organic carbon in the soil or sediment, OC_{sl}, OC_{sed}, and OC_{ssed}, as $Koc*OC_{sl}$, etc. The resulting chemical-specific parameter is termed the soil (or sediment) partition coefficient, Kd_s (or Kd_{sed}, Kd_{ssed}). The empirical equation used to estimate Koc from Kow in this assessment was derived by Karickhoff (1979). This equation was chosen over others available (Lyman, 1982) because it was derived from laboratory testing of 10 hydrophobic contaminants. Others available would have led to lower estimates of Koc. The Koc for 2,3,7,8-TCDD estimated for this assessment using Karickhoff's relationship was 3,980,000. Some data implies that this estimate itself may be low for 2,3,7,8-TCDD. Studies reviewed in Section 2.4.5., Chapter 2 of Volume II of this assessment, particularly those Jackson, et al. (1986) and Lodge (1989), indicate 2,3,7,8-TCDD Koc estimates in the range of 20,000,000 to greater than 30,000,000.

Another contaminant parameter is the Henry's Constant. Volume II, Chapter 2, provides the values of the Henry's Constants, H, for dioxin-like compounds, some of which were estimated given vapor pressure and water solubility data. The CDD/F Henry's Constants were in the 10^{-6} to 10^{-5} atm-m^3/mol range, while coplanar PCBs were in the 10^{-5} to 10^{-4} range, with one high value at $3x10^{-3}$ atm-m^3/mol.

Finally, the contaminant molecular diffusivity in air is required for estimates of volatilization flux from soils. The molecular diffusivity in air is set at 0.05 cm^2/sec for all dioxin-like compounds. Molecular diffusivity is a property of both the chemical and the medium. It represents the propensity of a chemical to move through a medium. It is recognized to be largely a function of molecular weight. The values selected are evaluated as reasonable for all dioxin-like compounds, since the molecular weight for these compounds are similar.

8.4. UNCERTAINTIES ASSOCIATED WITH EXPOSURE PATHWAYS

The purpose of this section is to qualitatively describe the uncertainties associated with exposure estimates for the exposure pathways that are included in this methodology. The principal focus is on the exposure parameters - the contact rates and fractions, exposure durations, and so on. A brief summary is also presented on some of the findings pertaining to the

fate, transport, and transfer algorithms used to estimate the exposure media concentrations. This summary will highlight findings that have been included in other sections of this chapter, Chapter 7 on model comparisons and model validations, as well as a section in Chapter 6 on User Considerations. Each section below includes a table summarizing key points of uncertainty. Section 8.4.1 looks at three key exposure parameters which are common among all pathways - lifetime, body weights, and exposure durations. Sections 8.4.2. to 8.4.11 are pathway-by-pathway discussions.

8.4.1. Lifetime, Body Weights, and Exposure Durations

Values for lifetime of 70 years and adult body weight of 70 kg are traditionally used for risk assessment purposes, although data in the Exposure Factors Handbook (EPA, 1997) suggest that the current average body weights may be lower and the lifetime may be longer. The deviations are small and more precise numbers would not change exposure estimates by a meaningful amount. The uncertainty regarding body weight is reduced in the ingestion pathways of fruit/vegetables and the terrestrial animal food products including beef, milk, chicken, and eggs. This is because the consumption rates used in these pathways for the demonstration does in this assessment are in units of g/kg/day and were derived from survey data which incorporated the amount consumed with the individual body weight. Specifically, these rates originated from the household portion of the National Food Consumption Survey conducted by USDA (USDA, 1992). Chapter 2 describes the use of this survey data in detail and Section 8.4.7 below summarizes some of the uncertainties in using it. The assumed child body weight of 17 kg (for ages 2-6) is well founded and not expected to introduce uncertainty into soil ingestion exposure estimates.

Assumptions on exposure durations are the most uncertain of the three parameters discussed here. A value of 9 years assumed for central exposure scenarios was the 50th percentile of time living at one residence derived from census survey data (EPA, 1997). Such mobility surveys typically ask respondents how much time they are living at one residence, so a result such as this one will likely be an underestimate because respondents are likely to continue to live at their residence beyond the time they answered the survey question. The estimate of 30 years for the average residence time of farming families (used to define high end exposure scenarios) was also based on survey data which showed that the 90th percentile time spent in one residence was 32.7 years. For the high end scenarios of this assessment, this 90th percentile is justified based on the definition of high end. Also, however, it is supported based on a

qualitative judgement that farming families may tend to live longer in one spot as compared to non-farming families.

Exposure durations are also tied to assumptions about source strength over time. Assuming 30 years of exposure to stack emissions, for example, assumes that the source of stack emissions will be (or has been) in operation for this length of time with the same stack emission controls in place. The same is noted for the effluent discharge source category. If the source is contaminated soil, assumptions include whether or not the soil will be removed, the site will be capped, and so on. Another consideration is the dissipation of soil residues. Section 8.3 discussed uncertainties with the assumption of non-degradation of dioxin-like compounds in soil when the soil itself is contaminated. A 25-year dissipation half-life is applied to residues which migrate to an exposure site to impact only a thin layer of surface soil. Specifically, a simple soil mixing model incorporating the 25-year dissipation half-life is used to calculate steady state soil concentrations of dioxin in a thin surface layer resulting from atmospheric depositing dioxins, from the stack emission source, or from soil eroding from a nearby site of soil contamination. As discussed above in Section 8.3., an assumption of non-degradation during periods of exposure in the range of 30 years is reasonable, since degradation/dissipation pathways lead to very slow decline of dioxin concentrations in soil.

Exposure estimates are linearly related to all three exposure parameters - increasing body weight and lifetime decreases exposures in an inverse linear fashion, while increasing exposure durations increase estimates in a direct linear fashion.

Uncertainties associated with body weight, lifetime, and exposure durations are summarized in Table 8-1.

8.4.2. Soil Ingestion Exposure

This exposure is directly a function of the concentration of contaminants in surface soil layers. For example Scenarios 1 and 2, demonstrating background conditions, soil concentrations at the site of exposure were set at levels corresponding to an actual setting which can described as, “background”. For example Scenario 3, demonstrating the soil contamination source category, erosion onto the site of exposure deposited residues into a thin, no-till, surface layer of 2 cm, and a thicker, 20-cm, till layer of soil. Soil ingestion exposures were based on concentrations in the 2-cm layer. In Scenarios 4 and 5 demonstrating the stack emission source category, contaminated particles deposited onto the exposure site, also creating a till and a no-till concentration. The no-till depth for this category was also 2 cm.

Discussions on the methodology to estimate exposure site soil concentrations resulting from erosion of contaminated soil from a nearby site are contained in Section 6.3.3.2, Chapter 6, which was on sensitivity analysis and the impact of different parameter values on estimated exposure site soil concentrations, and in Chapter 7, Section 7.3. discussing literature reports of off-site impacts from soil contamination. While off-site impacts were noted in the literature, no data could be found that was directly amenable to comparison with the scenarios of Chapter 5. The closest site for which data was available was the Dow Site in Midland, Michigan. The ratio of soil concentrations of 2,3,7,8-TCDD in areas described as "background" in the 600 ha site to soil concentrations in the contaminated areas was 1/8 to ½ as much (depending on how the contaminated area soil concentration was interpreted) as the ratio modeled in the off-site demonstration scenario. This might imply that the model overpredicts off-site soil impacts, except that the "background" areas in the Dow Site appear substantially further away than the 150 meters in the off-site demonstration scenario. Also, data was unavailable to determine the erodibility of soil at the Dow Site. Had this and other site-specific information been available, a more precise test of the off-site soil impact algorithms of this assessment may have been possible. Still, a key finding in the sensitivity analysis exercises was that the erosion algorithms may be overestimating off-site impacts. No information is available on estimating how much of an overestimation may have resulted, and this finding is not a definite conclusion.

If, in fact, an overestimation is occurring, it could be due to a few different factors: 1) an uncertain dissipation rate - increasing it could reduce soil concentrations, 2) assumed depth of mixing for untilled situations - increasing it could also reduce soil concentrations, and 3) the steady state simplification. These factors were examined in the sensitivity analyses conducted in Chapter 6.

In contrast to the possible overprediction of soil concentrations for the soil contamination source category, an exercise described in Chapter 7, Section 7.3.8 suggested that the stack emission source category may be underpredicting soil concentrations. Measured air concentration in an actual rural setting were used in a model validation exercise which attempted to duplicate measured soil concentrations at that same setting. It was seen that modeled soil concentrations were slightly lower than measured soil concentrations. Two possible causes for this underprediction were offered: 1) the model does not account for deposition of vapor-phase dioxins, either through direct deposition or by detritus production, and 2) the representative air profile was derived from samples in March, April, and June, and the average may not have represented typically higher wintertime air concentrations.

In the stack emission source category and the soil contamination source category where the site of exposure is distant from the site of contamination, the two key uncertain parameters are the depth of mixing and the soil half-life for dioxins depositing onto the site of exposure. The mixing depth is a theoretical parameter for which little data is available. The data of Brzuzy and Hites (1995) on soil profiles of dioxins for undisturbed soils does show that dioxins migrate below the surface, in some cases under sandy conditions, to depths greater than 30 cm. However, their non-sandy soil profiles showed most of the dioxins within 5 cm of the surface, and considering that their undisturbed soil cores reflect depositions of dioxins which were speculated to have occurred 50 years or more, the assumption of 2 cm is felt to be reasonably justified. Others have assumed depths of mixing of 1 cm for analogous applications. Evidence from radioactive fallout suggests depths no deeper than 5 cm. Sensitivity analysis on the erosion algorithms showed that assuming a depth of 1 cm instead of 2 cm would have increased soil concentrations by a factor of 2.5, while decreasing the mixing depth to 10 cm decreases soil concentrations by 60%. Very little data is available on dioxin soil half-lives, but the assumption of a half-life of 25 years is within the range of 25-100 years hypothesized by Paustenbach, et al. (1992a) for surface and buried residues based on their survey of the available literature. The analysis by McLachlan, et al. (1996) on data on dioxin concentrations in a plot of soil amended with sewage sludge over 20 years earlier showed half-lives consistently around 20 years for the suite of dioxin congeners, and this is probably the best support for the use of a constant half-life for all dioxin congeners.

Another issue is whether children should be assumed to be exposed to tilled soils - tilled by home gardening, farming, etc. - or untilled soils. It is feasible that children would be exposed to tilled soils in farming or home garden settings. If the soil was impacted by stack emission depositions or erosion from a nearby site of soil contamination, then tilling would reduce soil concentrations. However, it is more reasonable to assume that they generally play outside in areas that are not mechanically tilled.

The estimated soil ingestion quantity is based on field measurements, using trace elements, of soil ingested by relatively small groups of children over brief periods. Methodological issues in these studies remain to be addressed. In particular, ingestion estimates may have been lower if dietary intake of the trace elements was taken into account. Research is underway to refine soil ingestion estimates obtained through trace element measurements. Given the available data, EPA (1997) suggests that 100 mg/day is a reasonable central estimate for children under 6 years of age, and that value is used in this assessment in the central scenarios. Due to the behavior known as pica, some children are known to ingest high amounts of various

non-food materials. Estimates of pica ingestion of soil by children have ranged as high as 5000 mg/day. The high end estimate of 600 mg/day is not characterized as pica. It was determined from studies evaluated in EPA (1997) which showed upper percentile estimates ranging from 106 mg/day to 1,432 mg/day with an average of 587 mg/day for soil and dust ingestion.

Soil ingestion exposure estimates also depend on the duration of the period over which children are assumed to ingest soil. Data on soil ingestion by age are not available, and the estimate that significant ingestion occurs between ages 2 and 6 is broadly supportable on behavioral grounds.

No measurement data are available on soil ingestion in infants (0-2 yrs. old) or in older children or adults, and no ingestion is assumed for these groups. While some soil ingestion will occur in these groups, e.g., through contact of soiled hands with food, it is plausible that such ingestion is of a lesser degree than occurs in early childhood. If Hawley's (1985) estimate that an adult ingests an average 60 mg/d of soil is used, after accounting for differences in exposure duration (9-20 yrs versus 5 yr) and body weight (70 kg versus 17 kg), the adult soil ingestion exposure is close to the estimated exposure for children (at 200 mg/d). The high end example scenarios in Chapter 5 assumed that the exposed family was involved in farming operations. One implication is that individuals on the farm would be working closely with the soil, which may result in some soil or dust ingestion (dust ingestion is distinct from the particulate inhalation exposure pathway). The other implication is that, should this be the case, they might be in contact with tilled or otherwise well mixed soil, whose concentration could be as much as 10 times less than the no-till soil for which children are assumed to be exposed.

Considering these uncertainties, the soil ingestion exposure estimates presented for children are plausible. Further consideration may be warranted for considering adult soil ingestion, particularly in farming situations. Uncertainties associated with the soil ingestion pathway are summarized in Table 8-2.

8.4.3. Soil Dermal Contact Pathway

Estimates of dermal exposure to soil rely largely on four factors unique to this pathway: exposed skin area, soil adherence (also termed soil contact), frequency of soil contact and fraction of contaminant absorbed. The uncertainty in these three terms are discussed below.

Before that discussion, a brief note is made on uncertainties associated with soil concentrations. Discussions above on the soil ingestion pathway addressed uncertainties associated with soil concentrations which result from migration of residues from a distant source to the site of exposure. Distant sources in this assessment include off-site soil contamination and

stack emissions. Discussions in the soil ingestion pathway section above pertain to this exposure pathway and are not repeated here. However, there is one key difference in the soil dermal and soil ingestion pathways. Soil ingestion exposures are assumed to occur only from surficial soil layers and from untilled soils, which translates to the 2-cm mixing depth for both the "central" (residential) and "high end" (farming properties) scenarios. Soil dermal contact, on the other hand, is assumed to occur in association with both tilled and untilled soils . "Indoor" soil is assumed to have concentrations equal to that of untilled soils, while "outdoor" dermal contact events are assumed to occur in association with gardening or farming activities, where the concentrations are the more dilute tilled concentrations.

The range of possible estimates of exposure via dermal contact is probably more a function of variability in the population than uncertainty in the dermal contact methodology and assignment of exposure parameters. Relatively accurate measurements have yielded a good data base on total skin area. Thus the uncertainty in this factor is derived more from the assumptions of how much of the total skin area is exposed. EPA (1992b) recommends approaching this issue by determining the coverage of normal apparel in the exposed population and assuming exposure is limited to the uncovered skin. As discussed in EPA (1992b), this assumption could lead to underestimates of exposure since studies have shown that some exposure can occur under clothing, especially in the case of vapors or fine particulates. Assignment of skin surface areas in this assessment have assumed estimates for various combination of areas for hands, arms, and legs. The extent to which individuals where short or long sleeve shirts and trousers is part of the variability in skin surface area assignment.

The potential for soil contact and subsequent adherence probably varies little across the population, but few actual measurements have been made. A wide range of from <0.002 to >20 mg/cm^2-event has been identified in EPA (1997). The very high adherence rates were found for the scenario described as, "kids-in-mud", and was from data on children playing by a lakeshore. The lower range was found for an indoor Tae Kwon Do setting. Adherences for a day-care setting ranged from 0.03 for arms and legs to 0.1 for hands. Outdoor adherences for gardeners ranged from 0.005 for legs to 0.02 for arms to 0.2 for hands. The uncertainty in these estimates reflect primarily the lack of measurement data rather than population variability. Site variability is probably important as well since soil properties such as moisture content, clay content and particle size distribution are likely to affect adherence.

Exposure frequency to soil reflects largely personal habits and thus the range in values for this parameter is primarily based on population variability. Seasonal and climate conditions can also affect this behavior introducing site variability as well. Indoor contact events were assumed

to occur daily, gardening events were assumed to occur 100 times per year and farming events 350 times per year. These values were assigned based on judgement, and not any particular studies.

The dermal absorption fraction of compounds varies widely across chemicals, whereas skin properties that affect absorption, i.e. thickness and composition vary little across the population. Thus the uncertainty in this factor is derived primarily from measurement error rather than population variability. Soil properties, such as organic carbon content, can also affect the extent of dermal absorption and thus create site variability as well. EPA (1992b) reports two studies which measured dermal absorption of 2,3,7,8-TCDD from soil. Testing included human skin in vitro, rat skin in vitro and rat skin in vivo. On the basis of these tests, a range of 0.1 - 3.0% was recommended in EPA (1992b). Dermal absorption testing, especially for soils, is a relatively new field and many uncertainty issues are involved. These include extrapolation of animal tests to humans, extrapolation of in vitro to in vivo conditions, and extrapolation of experimental conditions to expected exposure conditions. Extrapolation of the tests on 2,3,7,8-TCDD to the other dioxin like compounds (which have not been tested) introduces further uncertainties. A dermal absorption fraction of 3.0% was adopted here for application to all the dioxin like compounds. Based on the observed range of values for 2,3,7,8-TCDD this assumption may lead to overestimates of a factor of 30. Considering all possible uncertainties, under estimates are also possible, though judged less likely.

In summary, dermal exposure estimations rely on a number of parameters whose values are not well established. The range of possible dermal contact estimations is judged to be mainly a function of population variability, rather than parameter uncertainty. One parameter that is uncertain is the absorption fraction. The value selected for this assessment. 0.03 (3% absorption) is on the upper end of the range of suggested values, so its selection is likely to result in overestimating, rather than underestimating, the exposure due to this pathway. Although it is difficult to estimate the overall variability and uncertainty with this pathway, it is judged to be plus or minus one to two orders of magnitude. A summary of the uncertainties associated with the dermal absorption pathway is given in Table 8-3.

8.4.4 Water Ingestion

The strong sorptive tendencies of the dioxin-like compounds result in very low water concentrations. Monitoring for CDD/Fs mostly have not found these compounds at a detection limit around 1 pg/L (ppq), and when found, have generally been very near this concentration. The one exception is an upstate New York community water system, where tetra through octa-

CDFs were found at concentrations ranging from 2 pg/L (tetra) to over 200 pg/L (octa). The surface water concentrations predicted by the algorithms of this assessment for all source categories are 10^{-2} pg/L and lower, which is consistent with the sparse monitoring data. Although there was no data found that could be directly applicable to the source categories, it does not appear that the models estimating water concentrations will introduce significant uncertainty into water ingestion exposure estimates.

The classically assumed water ingestion rate of 2.0 L/day was examined in EPA (1997). The conclusion was that this estimate is more appropriately described as an upper percentile consumption rate for adults, and recommended 1.4 L/day for use as an average. This value was used for water ingestion in the central scenarios. EPA (1997) cautions that data on consumption rate for sensitive subpopulations such as manual laborers are unavailable. As such, the 1.4 L/day rate for individuals in farming families who work the field may be low. For this reason, a 2.0 L/day was assumed in the high end, farming, scenarios.

The contact fraction is defined as the fraction of total contact with an exposure media that is contact with contaminated media. For drinking water, this translates to the fraction of water ingestion that comes from the contaminated water source. In the example scenarios, it was assumed that the impacted water was a river which supplied water to the exposed individuals, perhaps through a public water system. The contact fraction of 0.70 for central scenarios is based on time use surveys which showed roughly this fraction of time spent in and around the home environment on the average (EPA, 1997). The upper limit is, by definition, 1.00; this was felt to be unrealistic even for high end scenarios. EPA (1997) recommends an upper end value for time at residence at 0.90, and this value was used for the high end scenarios.

The uncertainties associated with the water ingestion pathway are summarized in Table 8-4.

8.4.5. Fish Ingestion Exposure

Chapter 7, Sections 7.3.5 and 7.3.6 addressed the capabilities of the models of this assessment to estimate fish tissue concentrations, by comparing measured fish concentrations with modeled concentrations. In general, it was concluded that modeled fish tissue concentrations in background settings are consistent with those found in the literature for similar settings. Also, impacts of point source discharges into surface water appear to have been appropriately modeled.

Chapter 7, Section 7.3.2. looked at a comprehensive data set developed and supplied by the Connecticut Department of Environmental Protection which included soil concentrations,

sediment concentrations of water bodies near where soil samples were taken, and fish concentrations from the same water bodies. Data on 2,3,7,8-TCDD, 2,3,7,8-TCDF, 2,3,4,7,8-PCDF, and total TEQ were examined. Soil concentrations of 2,3,7,8-TCDD were found to be in the low ppt range, which has been described in various places in this document as a range for "background" soil conditions. Sediment concentrations of the three congeners and total TEQ were generally in range of 2-3 times higher than soil concentrations, which was consistent with the demonstration of background conditions. This demonstration scenario had a basin-wide 2,3,7,8-TCDD soil concentration of 0.37 ppt, and the sediment concentration was estimated at 0.99 ppt. The Biota Sediment Accumulation Factor, BSAF, from this field data was estimated to be 0.86 for 2,3,7,8-TCDD. This was higher than the assumed 0.09 in the demonstration scenarios. Two explanations were offered for this difference. One was that the fish sampled were bottom feeders, which would put them in more contact with contaminated sediments compared to column feeders, and the 0.09 value was based on data from column feeders; higher impact from contaminated sediments is expected from bottom feeders as compared to column feeders. Two, the 0.86 may have been skewed from two (of seven) sites in the Connecticut data which had high BSAFs at greater than 1 and 3. Although the soil sampling in this data set was generally sparse, the result that bottom sediment concentrations exceeded surface soil concentrations by 1.6-3.9 times generally supports the model's algorithms for estimating sediment concentrations in areas with low basin-wide concentrations.

Chapter 7, Section 7.3.5 looked at fish concentrations in background areas and where point source impacts to water bodies were identified. A principal source of information was EPA's National Study of Chemical Residues in Fish (EPA, 1992a; abbreviated NSCRF). The range of fish tissue concentrations of 2,3,7,8-TCDD measured for (perhaps) background conditions in this study, 0.56 - 1.02 ppt, were comparable to the fish tissue concentration estimated assuming the low (perhaps) background soil concentration of 0.37 ppt soil concentration, 0.2 ppt. It may not be appropriate, however, to make the same observation for the source categories assuming higher soil concentrations as compared to measured concentrations. In this case, the range of measured concentrations, 1.4 - 30.02 ppt, does not compare with the modeled 0.3 ppt. It was noted that the soil contamination source category was demonstrated with a setting that had four hectares of contaminated soil at 1 ppb surrounded by a watershed of 100,000 hectares with a 0.0 soil concentration, which may explain partly why the results did not compare with the concentrations in the NSCRF that were taken near contaminated sites. Specific field data were not available for more detailed analysis. In general, it would appear that the magnitude of concentrations appears to have been captured for background situations.

While the modeled PCDD/PCDF fish concentrations seem reasonably in line with measured concentrations, this assessment may have underestimated concentrations of 2,3,3',4,4',5,5'-HPCB in the demonstration scenarios. Concentrations for fish in the Great Lakes Region were in the tens to hundreds of ppb range, while this assessment derived estimates all under 1 ppb. However, an examination of bottom sediment concentrations of PCBs in the literature showed them to be roughly three orders of magnitude higher than estimated with the algorithms of this assessment. This mirrors the difference in observed versus estimated fish tissue concentrations. The Biota Sediment Accumulation Factors, BSAFs, for PCBs also was noted to be variable, with values below 1.0 to values over 20.0 (see Chapter 4, Section 4.3.4.1). The BSAF for the example PCB congener in this assessment was 2.0. Higher BSAFs would also increase PCB concentrations estimated for fish.

Chapter 7, Section 7.3.6 evaluated the model for estimating fish tissue concentrations for the effluent discharge source category, using data from the 104-mill study. Comparing model predictions of fish tissue concentrations with observed concentrations, it was found that there was generally an underprediction of observed fish tissue concentrations, although the average predicted concentration 7 ppt cannot be considered significantly different then the observed average concentration of 15 ppt. An important qualifier is that this exercise assumed that the effluent discharges were the sole source of contaminants which may have impacted the water bodies. Also, the maximum "observed" fish tissue concentration of 143 ppt was matched by a predicted concentration of 89 ppt, which was also the maximum predicted concentration. Finally, there was discussion that the BSSAF (biota suspended sediment accumulation factor) assigned value of 0.09 for 2,3,7,8-TCDD, the same value used for the BSAF, might be low for the effluent discharge source category. The justification for this hypothesis concerns the differences between past and ongoing water body impacts, and the fact that the 0.09 value was based on field data for a water body where impacts are speculated as principally occurring in the past (see Section 7.2.3.6 for a further discussion of this issue). When the BSSAF was "calibrated" to 0.20, the average predicted fish concentration of 15 ppt for 2,3,7,8-TCDD now matched the observed average fish tissue concentration.

The model did not perform as well for pulp and paper mills discharging into the largest receiving water bodies. The average fish tissue concentration observed for 21 fish was about 7 times higher than predicted concentration. No precise conclusion can be reached with this result, although modeling lower fish concentrations in a large receiving water body than are measured does not appear unexpected. Large water bodies are likely to be ones having multiple sources of dioxin release in comparison with small water bodies. Therefore, the assumption that one or

more proximate mills are solely responsible for observed fish concentrations is most likely to be flawed for large water bodies.

In summary, the evaluations for model performance regarding fish tissue concentration estimation seem to lend credibility to the approaches taken, despite the simplicity of the of dilution models chosen. The sensitivity analyses exercises on the algorithms to estimate fish tissue concentration discussed the variability and uncertainty with the parameters required for the algorithms. Generally, the most sensitive input was the source strength characteristics - soil concentrations, contaminant discharge rates in effluents, and so on. A single order of magnitude or less range in predicted concentrations would result with singular changes in all other model parameters.

An exposure parameter of paramount importance in estimating exposure to contaminated fish is the fish ingestion rate. Available fish consumption surveys are discussed in EPA (1997). They were divided into five subsets of surveys, one of which was titled, "freshwater recreational anglers". Three surveys in this subset were deemed appropriate for generation of consumption rates, and EPA (1997) recommended a mean and a 95^{th} percentile consumption rates of recreationally caught fish of 8 and 25 g/day, respectively. Another possible approach is described in EPA (1989) and was used in a previous version of this dioxin reassessment document (EPA, 1994). Briefly, this approach assumes a meal size and then determines, on a site-specific basis, the number of meals an individual would consume from fish obtained from the impacted water body. EPA (1994) assumed meal sizes of 150 g/meal, and 3 and 10 meals/year for the central and high end assumptions, respectively, which led to daily consumption rates of 1.2 and 4.1 g/day. Assessors should also be cognizant of situations where subsistence fishing can lead to much higher rates of fish consumption. EPA (1997) summarizes studies where subsistence patterns of fish consumption can lead to consumption rates in the hundreds of grams per day. Like other food consumption pathways, which have the highest exposure estimates for dioxin-like compounds, obtaining site-specific information for fish ingestion is critical for this pathway.

A summary of the uncertainties associated with the fish ingestion pathway is given in Table 8-5.

8.4.6. Vapor and Particle Phase Inhalation Exposures

This section will address the uncertainty associated with vapor and particulate phase inhalation exposures. Sources addressed in this assessment include stack emissions and contaminated soils; this section will only address contaminated soils. The fate and transport of

dioxin-like compounds from stack emissions to exposure sites, and the resulting air concentrations, are discussed in Chapter 3.

The respiration rates of 13 and 20 m^3/day used for inhalation exposures is based on data described in EPA (1997). The contact fraction is 0.70 for central scenarios and 0.90 for high end scenarios. Like the water ingestion contact fractions, these were based on time at home surveys. The inhalation rate and contact fractions are not expected to introduce much uncertainty into inhalation exposure estimates.

Another exposure parameter critical for the inhalation pathway is exposure durations, which is 9 years for central and 30 years for high end exposures. The uncertainties associated with this parameter in its use as an exposure parameter are discussed above in Section 8.4.1. However, exposure duration is additionally critical for the inhalation pathway for the soil contamination source category, as estimated volatilization flux is a function of the time during which volatilization is occurring. Essentially, the model assumes that contamination is at the soil surface at time zero, and over time, residues which volatilize originate from deeper in the profile leading to lower volatilization fluxes after time, and also lower average volatilization flux as the averaging time increases. The sensitivity analyses exercises in Chapter 6, Section 6.3.3.1., evaluated the sensitivity of air concentration predictions to changes in exposure duration. It was shown that there is roughly a factor of four difference between concentrations predicted over one year duration to a seventy year duration. Therefore, there is both a direct and an indirect impact from changing the exposure duration in these procedures. The direct impact from changing exposure duration is in the exposure equation - increasing the exposure duration increases the exposure estimate. What is seen also with increases in exposure, however, is a decrease in the estimated average air concentrations to which individuals are exposed. The impact in the exposure estimates is more driven by having more years of exposure rather than being exposed to a lower average air concentration, as expected.

Vapor-phase emissions from soils are estimated with a volatilization flux algorithm. The procedures were developed in Hwang, et al. (1986). A near-field dispersion model estimates air concentrations for the circumstance where the soil contamination is at the site of exposure. Where the site of contamination is located distant from the site of exposure, the same volatilization flux model is used, but exposure site concentrations for these sources are estimated using a far-field dispersion model.

Sensitivity analyses in Chapter 6 showed that the air concentration varied roughly over an order of magnitude with testing of key contaminant parameters, the organic carbon partition coefficient, Koc, and the Henry's Constant, H. Air concentration predictions are also sensitive to

other key parameters, including those associated with source strength (area of contamination, concentration), geometry, (distance to receptor in off-site source category), and climate (average windspeed). However, these might be expected to be known with a reasonable degree of certainty for a site-specific application. If they are, it can be concluded that the most uncertainty associated with the vapor phase algorithm is in the contaminant parameters, and it would appear that a range of about an order of magnitude difference in predicted air concentrations might be expected with different pairs of these parameters.

A model validation exercise described in Chapter 7, Section 7.3.8 tested the algorithms modeling air concentrations above a soil of known concentrations. Using measured soil concentrations at a site near Columbus, Ohio, and measured air concentrations at this same site, it was shown that the model predictions of air concentrations were orders of magnitude lower than measured air concentrations. While this suggests that the model is underpredicting the release of dioxins from soil into the air and/or underpredicting the dispersion of released residues, it may be true, on the other hand, that the measured air concentrations in the rural setting near Columbus are the result of long range transport of air-borne dioxins from distant sources of release.

Another piece of evidence came in an examination of above ground plant:soil ratios as generated by the models and found in experimental testing. The models underestimated these ratios by 1 to 2 orders of magnitude as compared to the literature when vegetation in the field studies described in the literature were grown in soils with concentrations in the ppt range, a range typical of background settings. Two explanations were offered for this trend: the experiments were impacted by sources of dioxins other than the soil in which the plant was growing, and/or, the soil-to-air models may be underestimating air concentrations. Like the model validation exercise described above, it is unclear which explanation dominates the observed trend.

An alternate model for volatilization flux and an alternate model for air dispersion were evaluated in Chapter 7, Section 7.2.4. It was found that the alternate volatilization model predicted about a third as much volatilization as the Hwang model, but that the alternate dispersion model predicted air concentrations that may be up to an order of magnitude higher than the models predicted in this assessment.

There was no data on concentrations of air-borne contaminants in the particle phase only. The procedures used to estimate the suspension of particles were developed from information on highly erodible soils. As such, fluxes and hence concentrations may be higher than expected. However, with no data to compare, this cannot be ascertained. It was seen that vapor phase concentrations exceeded particle phase concentrations by over an order of magnitude. The

sensitivity analysis exercises in Chapter 6 did indicate a two order of magnitude range in estimated concentrations depending on the assumptions concerning wind erodibility of the soil. Also, several issues of uncertainty concerning the suspension of contaminated particles and relationship between air-borne vapor and particle phases were examined. It was noted that the total reservoir of suspended contaminated particulates was likely to be underestimated because the algorithm for wind erosion was developed only for inhalable size, < 10 μm, particles, which is appropriate for inhalation exposures but would lead to an underestimate of the depositions onto vegetation, including fruits/vegetables for consumption and grass/feed for the beef/milk bioconcentration algorithm. Vegetation concentrations might also be low because the impact of rainsplash on transferring soil to the lower parts of vegetation was not considered.

A critical assumption made was that volatilized residues remained in the vapor phase and did not sorb to airborne particles. This led to a dominance of vapor phase contaminants - 90% and more of the total airborne reservoirs (vapor + particle phases) estimated for the on-site and off-site soil source categories were in the vapor phase. Even though only three contaminants were modeled for the soil source category, this trend would be repeated for essentially all the dioxins (except not as much for the octa dioxins since the models would predict much less vapor phase release than the other dioxins). Having much more vapor phase dioxins than particle phase dioxins is inconsistent with the vapor/particle partitioning models used to partition ambient air dioxins into vapor and particle phases, and also inconsistent with monitored vapor/particle partitioning. For example, the vapor/particle partitioning model resulted in a prediction that 51% of the total airborne 2,3,7,8-TCDD would exist in the vapor phase, not over 90%. For the other dioxins, the particle phase is predicted to dominate the air concentrations. This suggests that the soil models of this assessment are deficient in that they do not repartition soil emitted dioxins. Specifically, a portion of the vapor-emitted dioxins are unlikely to remain as vapor, but are likely to sorb to particles. Transferring portions of the vapor phase contaminants to the particulate reservoir to get balances suggested by the vapor/particle partitioning models of this assessment would not change total inhalation exposures, but would impact concentrations in above ground vegetation. Currently and even with transfers such as these, vapor phase transfers dominate plant concentrations. Because vapor phase reservoirs would be reduced after transferring a portion to the particle phase, such transfers translate to reductions in plant concentrations, and for grass and feed, subsequent reductions in beef and milk concentrations and exposure estimates.

Perhaps the most critical assumption which could be questioned is that airborne vapor and particle phase contaminants at the site of exposure originate only from the site of contamination when the site of contamination is distant from the site of exposure. Meanwhile,

soils at the exposure site are impacted - concentrations in the air at the exposure site do not consider possible fluxes from exposure site soils, or from soils between the contaminated and exposure sites.

A test was conducted for this assumption using the demonstration scenario for the soil contamination source category, which had a 4-ha site at 1 ppb 2,3,7,8-TCDD 150 meters from an exposure site of the same size. The soil concentrations at the exposure site were 0.36 ppb for a 2-cm notill mixing depth and 0.06 ppb for a 20-cm tilled mixing depth. These concentrations were then input as soil concentrations for the soil contamination source algorithms to determine what air concentrations would result above the soil. For this test, the "near field" dispersion algorithms described in Chapter 4 were used instead of the "far field" algorithms used in the demonstration of that source category in Chapter 5. These near field exposure site air concentrations, generated with a starting soil concentration of 0.36 ppb, were compared with exposure site air concentrations generated when using the far field dispersion algorithms, starting with the soil concentration of 1 ppb. It was found that on-site air concentrations with soil concentrations at 0.36 ppb exceeded exposure site vapor and particle air concentrations estimated for a 1 ppb contaminated site 150 meters away by a factor of about 5. When the same test was run using a tilled concentration of 0.06 ppb, concentrations predicted using the near field algorithms and this concentration were similar to the concentrations predicted using far field algorithms and a starting concentration of 1 ppb.

Several uncertainties were discussed, but a lack of data and a complete understanding of atmospheric processes for dioxin-like compounds precludes any final quantitative judgements on uncertainties in the air concentration algorithms. Some of the uncertainties imply that procedures and assumptions adopted overestimate pertinent environmental media, and others imply that such media concentrations were underestimated. The assumption that air-borne reservoirs of contaminant originate only at an off-site area of contamination and not from other soils should be examined further.

A summary of the uncertainties associated with the vapor and particle inhalation routes is given in Table 8-6.

8.4.7. Fruit and Vegetable Ingestion

Consumption rates of 1.49, 1.52, and 1.16 g/kg/day were derived in EPA (1997) from the household portion of the National Food Consumption Survey (NFCS; USDA, 1992). Contact fractions of 0.101 for fruits and 0.173 for vegetables were also obtained from an analysis of NFCS data. Briefly, the household portion of the NFCS was a survey filled out by the head of a

household and includes the amount of food product brought into the house for consumption. The data includes the number, age, and weight of all household members, in addition to critical questions concerning home production of foods. Further details on this survey and the use of the data is described in Chapter 2.

Use of this portion of the NFCS has its benefits and drawbacks. One major benefit is that it reduces uncertainty by the calculation of rates which include body weights. The earlier version of the dioxin reassessment document (EPA, 1994) had the consumption of all food items in terms of g/day. In this assessment, fish ingestion is still handled this way, but all other foods considered (vegetables/fruits, terrestrial animal food products) more appropriately consider the interaction between rate of consumption and body weight. Another major benefit is that it allows one to estimate how much of a food product is consumed in a household which was produced by the household, which is precisely what is desired for the demonstration scenarios of this assessment. This estimation includes a reported consumption rate and also a contact fraction ascertained from survey data. Another part of the NFCS was called the "1-day individual consumption survey". One cannot ascertain consumption rates for home-produced foods from the 1-day survey. However, the individual survey does ascertain the consumption rate for foods "as eaten" by the individual. In contrast, the household survey asked for total food product brought into the house for consumption that week. That necessitates assumptions on the meal size per individual in the household, and in addition to data on the weight of the household individuals, EPA (1997) derived estimates of g/kg/day consumption rates, which were used in this assessment. That also necessitates a consideration of the amount of the total food product brought into the house which is not eaten by individuals in the house, since the "total food product" is not a quantity analogous to, "as eaten". Reductions in this total would include losses such as from cooking, discarding part of the food product, such as bones or uneaten portions, or portions given to guests. This is one disadvantage to the household survey, in contrast to the "as eaten" data from the 1-day consumption survey. In Chapter 2, reduction factors are described and used in this assessment to describe cooking (weight reduction) and post cooking (bones, etc) for beef and chicken, as well as other meats not considered in this assessment.

EPA (1997) also ascertained, from questions on specific fruits/vegetables from the household survey, consumption rates for "exposed above ground vegetables/fruits" and "root vegetables". Protected vegetables/fruits, as opposed to exposed, were defined as vegetables/fruits which have outer protective coverings which are removed prior to consumption such as peas or oranges. No root vegetables were considered to be protected although, of course, it is common to consume some below ground vegetables such as carrots or potatoes after removal

of the skin. Consumption rates for exposed fruits and vegetables are desired because the evidence is fairly clear that dioxin-like compounds will not penetrate through thick skins which are peeled prior to consumption. This assessment does consider, however, the peeling of skins off exposed vegetables. This consideration is in the form of a "VG" parameter. The VG parameter, which includes separate assignments for above ground vegetables/fruits, VG_{ag}, and for below ground vegetables, VG_{bg}, considers the following: evidence that little translocation from the surface of bulky vegetation, below or above ground, to the inner portions of these vegetation, and any additional consideration of the peeling of the skin (carrots, potatoes, e.g) prior to consumption. In this assessment, values of 0.01 and 0.25 were assigned to VG_{ag} and VG_{bg}, respectively.

All these assumptions discussed: total consumption rates, protected or unprotected, above or below ground, and fraction home grown, are probably reasonable for general assessment purposes as long as exposures are to the broad categories of fruits or vegetables, and not for individual fruits or vegetables. For a site specific assessment, there will likely be wide variability on the types of produce grown at home, what percentage of that is unprotected, and so on. Finally, and as is also true for beef and milk exposures, this assessment only considers the impact of home-grown fruits and vegetables. In rural settings, it is plausible that a large percentage of an individual's total fruit and vegetable intake comes from nearby and impacted sources, more than the 10-20% assumed in this assessment. If all of the consumption of fruit and vegetables is from local sources, and adjustments are made to correctly predict concentrations in local fruits and vegetables, than contact fractions should be set at 1.0, and exposures could increase up to 10 times compared to the demonstration scenarios depending on concentration estimation.

Several issues of uncertainty pertinent to the estimation of concentrations in below and above ground vegetation have been examined in other parts of this document and are not repeated here. Key issues include: 1) the uncertainty associated with empirical parameters, VG_{ag} and VG_{bg}, 2) the assumption that residues which volatilize from contaminated soils remain in the vapor phase and not partially partition into the vapor phase, 3) the possible underestimation of total particle reservoirs of contaminant in the air resulting from wind erosion of contaminated soils because the wind erosion algorithm only estimated suspension of inhalable size and not all particulates, and also because the possible effect of rainsplash onto vegetables low to the ground such as lettuce, was not considered, 4) for the stack emission source, uncertainties associated with air dispersion and deposition modeling using the ISCST3 model as discussed earlier in Section 8.2, and therefore the subsequent impacts of air-to-plant and soil-to-plant transfers, 5) for the stack emission and off-site soil source categories, air borne concentrations in the vapor and

particle phases at the exposure site are assumed to only originate at the source of contamination (the off-site contaminated soil and stack emissions) and not on impacted soil at the exposure site - considering additional fluxes from impacted soils other than exposure site soils could lead to up to an order of magnitude higher concentrations in the vapor and particle phases, which in turn affect above ground vegetation, and 6) also for the stack emission and off-site soil source categories where garden soil concentrations are predicted and then used to predict concentrations in underground vegetables, there are uncertainties for the soil concentration algorithm, particularly in the assignment of half-life, mixing depths, and lack of consideration of detritus production and vapor impacts to soils.

Quantitative judgements as the uncertainties associated with these issues are difficult to make. An examination of experimental data in Chapter 7, Section 7.3.10, where most of the vegetation were grown in well characterized conditions implied that the soil contamination models may be underestimating concentrations in above ground vegetables. The evidence examined was plant:soil ratios for experimental conditions versus what the models would predict. This could be due to underestimation of air concentrations of dioxins originating from soils, and there was some suggestion of that. However, it could also be due to the fact that the residues affecting the plants in the experiments were not only from soil releases but from other sources leading to air-borne residues. The models of this assessment only consider air concentrations from the source in question. Therefore, it is hard to ascertain whether the models underpredict, overpredict, or adequately predict above ground vegetation concentrations resulting from soil contamination.

Chapter 7, Section 7.2.1 did look at three modeling approaches for the air-to-plant pathway for leafy vegetation (grass, in particular), including the EPA model. That did section did suggest that the EPA model led to reasonable matches between predictions and observations, with just about a factor of two separating predictions and observations. Also, the air-to-beef model exercise described in Chapter 7, Section 7.3.12 also included an examination of the capability of the air-to-plant model. Although there wasn't a good data set for validation - i.e., measured air concentrations above measured grass concentrations, the examination in that section did support the model's algorithms. In the same vein, it is noted that the vapor phase air-to-leaf transfer algorithm was developed from actual field data. By definition, therefore, it would appear that the air-to-plant modeling are going to predict reasonable plant concentrations. This discussion is put forth only to suggest that the air-to-plant modeling would not be an issue for uncertainty regarding the impact of contaminated soils on above ground plants.

A summary of uncertainties associated with the fruit and vegetable ingestion exposure pathway is provided in Table 8-7.

8.4.8. Ingestion of Terrestrial Animal Food Products Including Beef, Milk, Chicken, and Eggs

The algorithms for the calculation of dioxin concentrations in all these animal food products is the same: they are a function of the weighted average concentration in the diet of the cattle (dairy or beef) and chicken, which is a function of the proportion of the diet in soil and animal vegetation, and a bioconcentration factor. Therefore, previous sections on soil contamination, soil transport algorithms, and plant concentration estimation, are relevant to estimating terrestrial animal food concentrations.

The most critical and uncertain parameters in these algorithms are the bioconcentration factors. The multiplication of the weighted average dietary concentrations of the chicken and cattle by the bioconcentration factors yields a product fat concentration (beef fat, chicken meat fat, milk fat, and egg fat). A set of bioconcentration factors were developed from laboratory feeding experiments for chicken meat, specifically from data on chicken thighs, and a separate set from eggs. There is uncertainty in applying these laboratory derived BCFs to field situations. Data is being developed by these same researchers from chickens which are raised in the field. One purpose of these additional experiments is to verify the laboratory derived BCFs (M. Petreas, Department of Toxic Substances Control, California EPA, personal communication). The bioconcentration factors used for calculation of beef and milk fat were less certain. They were derived from one experiment on one cow and on milk. Besides the sparsity of data, there is obviously uncertainty in applying bioconcentration factors developed from milk fat to beef fat. However, researchers have noted that the dioxin concentrations in beef and milk fat tend to be similar, and this they attribute to the fact that most cattle are slaughtered within 2 years of life while they are still growing. Therefore, the body fat pool is expanding which provides dilution to dioxins taken in by the beef cattle, and as a result, body fat concentrations are found to be similar to milk fat concentrations.

What also strengthens the use of the milk fat BCF to beef fat is the air-to-beef model validation exercise described in Chapter 7, Section 7.3.12. That section described a validation exercise where air concentrations of dioxin-like compounds were routed through the food chain model to estimate concentrations in beef. Generally, that section showed that an air concentration of 0.019 pg I-TEQ/m^3, speculated to be an appropriate air concentration for rural environments where cattle are raised for beef, translates to a beef fat I-TEQ concentration of 0.61

ppt, using the models and parameters of this assessment. The observed beef fat concentration of 0.89 ppt I-TEQ (assuming non-detects were equal to ½ detection limit) was the average from a national, statistically design, monitoring study of dioxins in beef back fat conducted jointly by EPA and USDA. Besides a very reasonable match between observed and predicted I-TEQ beef fat concentration, Section 7.3.12 also describes a reasonable match in the concentrations of the individual congeners.

Other than the critical bioconcentration factors, there is uncertainty with the soil bioavailability factor, B_s, and the parameters describing the chicken and cattle diet which include dietary fractions in soil, grass, and feed (the sum of the three adding to 1.00). The B_s was assigned a value of 0.65 for the beef and chicken algorithms, and reflects an assumption that dioxins are less bioavailable to the animals when the vehicles are soil rather than vegetative feeds. This is a critical assumption for chickens, particularly, since the algorithm for free range chicken impact assumes 10% of the diet in soil, and no exposure through their other diet. This was based on analysis of the chicken feed showing non-detects for dioxins at low detection limits done by the researchers who developed the BCFs, who also developed the rationale for the 10% soil assumption (Stephens, et al., 1995b). The beef cattle diet differs from the dairy cattle diet in that the beef cattle diet is dominated by leafy vegetation (i.e., pasture grass) and partially protected vegetation (a combination category which would include barn feeds such as hay or silage), with 8% in soil. The dairy cattle diet is assumed to be dominated by grains, which are assumed to be protected and residue-free. Only 10% of the dairy cattle diet is assumed to originate from soil (4%) and leafy vegetation (6%).

Section 6.2.3., Chapter 6, described the results of sensitivity analysis of these parameters applied to the beef and milk algorithms. It was shown that there is a small range of possible values for B_s and a small impact on results, for beef and milk at least. The impact, as noted above, would be greater for chickens. Data indicates that range of values for BCF for 2,3,7,8-TCDD is 1 to 10, with a concurrent order of magnitude difference between the upper and lower values. The parameters describing cattle exposure to soils and vegetation at the site are also critical, with up to an order of magnitude difference in concentrations for the example exposure situations examined in Section 6.2.3. It is expected that cattle exposure assumptions can be reasonably described for a specific site. Therefore, the most uncertainty in the bioconcentration algorithm itself lies with the bioconcentration factor, BCF.

Besides the air-to-beef model validation exercise, there was one other literature comparison that was made was comparing beef fat:soil and milk fat:soil concentration ratios derived for PBBs with those estimated for 2,3,7,8-TCDD in the soil contamination demonstration

scenario. Such a comparison is thought to be valid since PBBs are similar in fate and bioconcentration tendencies to the dioxin-like compounds. The field data was from an experiment where the cattle were raised in soils very high in PBB concentration. This provided some evaluation of the beef bioconcentration algorithm as applied to soil contamination. In this comparison, differences in beef and milk bioconcentration tendencies appear to be captured. Fries (1985) found body fat:soil PPB and milk fat:soil PBB concentration ratios for dairy heifers to range from 0.10 to 0.37, and from 0.02 and 0.06, respectively. For body fat of beef cows, these ratios were 0.27 and 0.39. Analogous ratios were derived for the contaminated soil scenario, and for beef and milk fat. For the contaminated soil demonstration scenario, Scenarios 3, beef fat:soil and milk fat:soil ratios were 0.15 and 0.08, respectively. These appear a bit lower than the PBB ratios derived by Fries (1985). The interpretation of this result was that, again here was some evidence that models may be underestimating the impacts of soil contamination to air, and hence air to plants and plants to animals.

Chapter 7, Section 7.2.6 evaluated other beef and milk bioconcentration models; none were found for chickens. It was found that most efforts are quite similar to the model of this assessment, with simple mathematical transformations. Other efforts had considered cattle inhalation exposures and cattle ingestion of impacted water, and found them to be of minimal importance in estimating beef and milk concentrations. They were not considered in this assessment. Two efforts, that of Stevens and Gerbec (1988) and Fries and Paustenbach (1990), evaluated the practice of placing beef cattle on a grain-only diet for fattening prior to slaughter. Both assumed that the reduction in beef concentrations could be modeled as a first-order process with a half-life of around 115 days. With grain only diet periods of 120-130 days, they showed beef concentrations to be reduced by about 50%. The models of this assessment allow for the incorporation of an empirical reduction factor to account for a fattening program prior to slaughter. In the demonstration scenarios, it was assumed that the beef cattle slaughtered by the farmer for his home use were not fattened, and a value of 1.00 was assumed. For the air-to-beef model validation exercise, however, a value of 0.50 was applied, as suggested by these two research efforts.

The air-to-soil algorithms of the stack emission source category, and the soil-to-air algorithms of the soil contamination source categories have both been highlighted as algorithms which may have uncertainties. These uncertainties are detailed in Section 8.4.7. Generally, it was found that the air-to-soil algorithms may be slightly underestimating soil concentrations, while the soil-to-air algorithms may be underestimating air concentrations by an order of magnitude (although this speculation may not even be warranted, given that appropriate

experiments were not available to test the soil-to-air models). As a result, an examination of model trends show a key dichotomy in the way the stack emission source category performed as compared to the soil contamination source categories. Specifically, soil alone accounted for about 90% of the milk and beef impacts for the soil source category, whereas soil accounted for only about 5% of the milk and beef impacts for the stack emission source category. Refinements to the model algorithms or the model parameters which would increase air concentrations resulting from soils, and increase soil concentrations resulting from depositions would narrow this gap.

Data on rates of consumption of these food products, as well as the contact fractions used in the demonstration scenarios, were from the household component of the National Food Consumption Survey conducted by the USDA (USDA, 1992). A review of the uncertainties inherent in the use of this data is included in Section 8.4.7 above on fruit and vegetable ingestion, and will not be repeated here. One additional factor considered for meats of the terrestrial food pathways is the pre- and post-cooking losses, including factors such as weight loss by cooking, weight of bones, and so on. Based on data on such losses, consumption are reduced by about one-half based on these considerations.

A summary of uncertainties associated with the terrestrial animal food pathways is given in Table 8-8.

8.5. USE OF PROBABILISTIC TECHNIQUES FOR ASSESSING EXPOSURE TO DIOXIN-LIKE COMPOUNDS

The purpose of this discussion is to 1) briefly discuss how probabilistic techniques, such as Monte Carlo or Latin Hypercube simulations, work and could be applied in exposure assessments and 2) summarize recent efforts by five investigators to apply probabilistic procedures to assessments involving dioxin-like compounds.

Basically, Monte Carlo and Latin Hypercube assessments are generic statistical methods which generate a distribution for an output of a mathematical model using the distributions of the input variables. Computer simulations are used to repeatedly generate outputs based on parameter inputs, where values for parameters are selected from their distributions. The outputs are compiled and expressed as a frequency distribution. In the context of exposure assessment, for example, a Monte Carlo application could involve developing distributions for each of the parameters in the exposure equation and generating a distribution showing how the exposure levels vary in the exposed population. The final distribution can be interpreted as the probabilities of one individual (randomly selected from the exposed population) experiencing

various exposures. Since exposure levels are not only a function of the exposure parameters but also of the concentration in exposure media, another application of the Monte Carlo method would be to estimate the distribution of exposure media concentrations using mathematical models for fate and transport.

Probabilistic techniques can be a powerful tool for expressing variability and evaluating scenarios in exposure assessments. However, their use requires detailed input data which are frequently unavailable. Although the procedure may make an analysis look more elegant, it may actually yield misleading results if based on poor data. Accordingly, exposure assessors should be very cautious when trying to apply Monte Carlo techniques or interpreting the results.

Generally, Monte Carlo procedures should be applied only when credible distribution data are available for most of the key variables. Distribution data refers to empirical information on the statistical variation of the variable that is relevant to the site assessed. Usually this data should be obtained from surveys conducted at the site of interest. However, data on human behavioral characteristics could be obtained from survey information based on populations distant from the site, if comparability can be established.

Paustenbach et. al. (1992b) used Monte Carlo procedures to develop soil cleanup levels for 2,3,7,8-TCDD at residential and industrial sites. The following exposure pathways were included: dermal contact, soil ingestion, dust inhalation and fish ingestion. For each parameter a range of values was identified (on the basis of reported values in the literature) and a uniform distribution assumed. These assumptions are summarized in Table 8-9. For the residential scenario, the soil level corresponding to the 50th percentile (defined as 50% of the population being exposed below a risk of 10^{-5}) was 17 ppb and the 95th percentile was 7 ppb. For the industrial scenario (outdoors), the soil level corresponding to the 50th percentile was 160 ppb and the 95th percentile was 50 ppb.

Anderson et. al. (1992) used Monte Carlo procedures to describe the distribution of exposures to 2,3,7,8-TCDD occurring in various U.S. population segments as a result of ingesting fish caught near pulp and paper mills. The populations considered were all U.S. residents, all sport fishermen, U.S. residents living near (within 50 km) mills, and sport fishermen living near mills. The distributions for the various parameters were derived by either fitting idealized curves to empirical data or using personal judgement. These distributions are summarized in Table 8-10. The distribution of 2,3,7,8-TCDD concentrations in fish was derived from data collected in EPA's National Study of Chemical as exposure parameters. Distributions were developed for input factors and Monte Carlo Residues in Fish (EPA, 1992a). The following 50th and 95th percentile risks were estimated (using EPA cancer potency values):

all US residents - 1×10^{-9} & 3×10^{-7}
near mill residents - 4×10^{-8} & 2×10^{-6}
all sportfishermen - 2×10^{-8} & 3×10^{-6}
near mill sportfishermen - 6×10^{-7} & 2×10^{-5}

McKone and Ryan (1989) developed an exposure assessment procedure based on simple steady state transfer factors called PEFs or pathway exposure factors. These factors were applied to two paths: air/plant/food and soil/plant/food. This is an example of Monte Carlo techniques being applied to estimate exposure media concentrations as well as describe the variability in the distribution of exposure behaviors such as ingestion rates. The procedure was demonstrated using 2,3,7,8-TCDD and four pathways: ingestion of fruit/vegetables, grains, meat and dairy products. The distributions used for the various input parameters are summarized in Table 8-11.

Two recent assessments (Cullen, 1995; Keenen, et al., 1995) looked at the modeling of the impacts of dioxin-like compounds on indirect pathways from combustor emissions. Cullen (1995) looked the exposure to 2,3,7,8-TCDD through consumption of produce grown near a municipal solid waste incinerator. She included several parameters used to model the concentration of 2,3,7,8-TCDD in vegetables, and through a decomposition analysis, attempted to evaluate which parameters are most uncertain with regard to the modeling of vegetation concentration. Table 8-12 looks at the various parameters which Cullen (1995) evaluated to model vegetation concentrations.

Keenen, et al. (1995) evaluated another indirect pathway for 2,3,7,8-TCDD, also from an incinerator. The pathway they evaluated was the beef ingestion pathway, and the modeled incinerator type was a hazardous waste incinerator. They conducted a two-dimensional Monte Carlo exercise which separately characterized uncertainty and variation using a nested loop approach. They characterized the modeling of beef concentrations, including the modeling of the transfer of 2,3,7,8-TCDD from air to plant to animal, as uncertain, and characterized various exposure related quantities as variable. The “variable” considerations included locations of farms in relation to the incinerator (which was important because the air dispersion model predicted different concentrations and depositions of dioxins at sites of exposure), the individuals’ body weights, their beef consumption rates, and their exposure durations. In the nested approach, a beef concentration was estimated using the food chain model and parameter selections from probability density functions of the uncertain parameters. Then, a second nested procedure modeled a distribution of dose rates associated with the uncertainty calculation of the beef concentration. They results of their analysis suggest that exposures to 2,3,7,8-TCDD via

consumption of beef produced near a hazardous waste incinerator could have a total uncertainty spanning three orders of magnitude, and that the uncertainty was dominated by interindividual variability.

The five articles discussed above differ widely in how they have applied Monte Carlo methods, particularly in the selection of input parameter distributions. In some cases, it appears that uniform distributions were assumed due to the lack of data needed to support more complex distributions. The central values in these ranges probably occur more often than those near the ends, so the uniform distribution assumption probably underestimates the occurrence of central values and overestimates the occurrence of values near the ends of the distribution. Clearly more data are needed to better support input parameter distributions.

Also, the benefit of conducting Monte Carlo or other numerical methods to evaluate the uncertainty of model predictions of exposure media concentrations that result from a source of contamination is unclear. If attempting such an exercise, assessors must be aware of the following: 1) the relationship between contaminant fate parameters which are included in the same modeling exercise - high log Kow is associated with lower bioconcentration, lower volatility, etc.; and 2) the certainty in the range of parameters reported upon which a distribution is to be based - old literature, different and/or inappropriate experimental conditions, and so on. The authors of this assessment are of the opinion that the following exercises are far preferable in understanding and using fate and transport models for dioxins: 1) gaining confidence in a single set of dioxin fate parameters through model validation exercises, 2) checking the "validity" of predicted exposure media concentrations by comparing them with existing known concentrations, such as background concentrations or concentrations found in known settings of contamination, as a regular part of any fate modeling exercise, 3) understanding what optional models are available and, when possible, seeing if they result in a substantially different exposure media prediction, 4) identifying parameters of most uncertainty, and then determining how final predicted exposure media concentrations could vary as a result of varying that single parameters (as in the sensitivity analyses exercises in Chapter 6), and 5) compiling field data to assign and check on the all-important biotransfer/bioaccumulation parameters for the models of this assessment. These are exactly the exercises that have been undertaken in support of all the fate and transport models promoted in this document.

The five articles are just a small set of the growing body of literature on the topic of applying Monte Carlo methods to exposure and risk assessments. For example, the application of Monte Carlo methods to problems involving contaminated groundwater and related exposure pathways such as ingestion, indoor air inhalation and dermal contact with water has been

examined (McKone and Bogen, 1991). Although this work does not deal specifically with dioxin, it may be informative to readers generally interested in Monte Carlo procedures. Similarly, Paustenbach has published additional articles dealing with the application of Monte Carlo methods to exposure problems involving other chemicals (Paustenbach et al. 1991; Paustenbach, et al., 1992). Burmaster has also published numerous articles on this topic which may be of general interest to readers (ie. Burmaster and Stackelberg, 1991).

Table 8-1. Uncertainties associated with the lifetime, body weight, and exposure duration parameters.

Assumption/ Method	Approach	Rationale	Uncertainty	Comments
Lifetime	70 yrs	Standard EPA assumption.	Actuary data indicate that lifetime may be increasing	Not a major source of uncertainty
Body weight	70 kg	Standard EPA assumption. Not needed for food pathways of fruit/vegetables, beef, milk, chicken and eggs because consumption rates are units of g/kg/day and hence incorporate body weight	Not much uncertainty. Current data suggests average body weights are lower and are different for men or women - averages above 60 kg for both.	Not a major source of uncertainty.
Exposure duration	9 and 30 years	Assumptions for central and high end exposure scenarios. Estimates are 50th and 90th percentile mobility survey results; higher estimate also justified based on the assumption that rural farming families live in one location longer than non-farming families in rural settings.	Can vary for site-specific applications. Source strength dissipation not a consideration for effluent discharge or stack emission sources assuming discharges/emissions continue for duration of exposure. However, source strength dissipation may be a consideration for soil contamination source.	The 30 year duration for high end farming families assumes such families are less transient than non-farming families.
Overall: Of these three parameters, the exposure duration is the most uncertain. The values used in this assessment were from mobility studies and they also considered that farming families may tend to live in one location longer than non-farming families. Evidence in the literature and a sensitivity analysis exercise in Chapter 6 suggest that soil concentrations of dioxins dissipate slowly, such that the assumption of non-reduction of the soil concentration over the duration of exposure for the soil contamination source category is a reasonable assumption.				

Table 8-2. Uncertainties associated with the soil ingestion pathway.

Assumption/ Method	Approach	Rationale	Uncertainty	Comments
Exposure site soil concentrations estimated when source is not at exposure site	Air dispersion and deposition modeled for stack emission source category; erosion modeled for soil contamination source category; for both, soil mixing depths of 2 and 20 cm, and 25 year half-lives assumed	Algorithms assume steady state; limited research suggests that the selected parameters are reasonable estimates for dioxin-like compounds.	A model validation exercise suggests that the deposition model is underestimating soil concentrations, most likely due to lack of consideration of vapor deposition and detritus additions. On the other hand, the soil erosion algorithm may be overestimating off-site impacts.	Future refinements should focus on improvements to air-to-soil modeling which add vapor impacts and detritus production.
Soil ingestion exposure assumptions	Ingestion occurs between 2-6 years old; central and high end rates of 100 and 600 mg/day; adult ingestion not considered	Soil ingestion is most likely to occur for this age range; ingestion rates selected from a review of studies in EPA (1997).	Adult soil ingestion could be important for farming situations where soil contact is frequent. Proper soil ingestion rates is an ongoing issue of research.	Ingestion rates do not consider pica behavior, which could lead to ingestion rates significantly higher than selected here. Adult soil ingestion should be considered for site specific application.
Overall: The modeling algorithms which are used to predict soil concentrations at a site of exposure when the source is distant from the site of exposure can result, in one case, an overprediction of soil concentrations, and in the other case, an underprediction of soil concentrations. The air-to-soil algorithm of the stack emission may be underestimating soil concentrations because of a lack of consideration of vapor phase impacts and a lack of consideration of detritus production. On the other hand, the erosion algorithm may be overestimating soil concentrations, based on a comparison of off-site impacts noted at an industrial site in Midland, MI, with the modeled off-site impacts. Uncertain parameters identified for soil concentration modeling include the soil dissipation rate (half-life of 25 years), the soil erosion and transport algorithm, the mixing depths, and for the stack emission source category, the uncertainties associated with the ISCST3 model. Soil ingestion for older children and adults was not considered. Assessors may wish to consider these pathways if soil concentrations at a site (modeled or measured) are high. Otherwise, soil exposure parameters are expected to be reasonable for general assessment purposes.				

Table 8-3. Uncertainties associated with the dermal exposure pathway.

Assumption/ Method	Approach	Rationale	Uncertainty	Comments
Soil concentration modeling	See Section 8.4.2 and Table 8-2 for a summary of the uncertainties in soil concentration modeling.			
Use of tillled vs. untilled concentrations	used "tilled" concentration for all outdoor dermal exposures and "untilled" for indoor dermal exposures	Soil dermal contact assumed to occur while farming/gardening outdoors; indoor dust assumed to originate from untilled soils.	Tilled concentrations are lower than untilled concentrations; no data available to show relationship between outdoor and indoor dioxin concentrations in soil/dust.	Assessors should consider site-specific behaviors to determine patterns of behavior leading to soil dermal contact
Contact/ adherence rate	0.005 mg/cm^2-event for indoor contact; 0.03 and 0.1 mg/cm^2-event for residential gardening and farming, respectively.	Based on data suggesting a much larger range from <0.002 to >20 (for "kids-in-mud"); measurement data available described in EPA, 1997	measurement data may have uncertainties; variability expected due to behaviors, soil type, and so on.	Should be considered an uncertain parameter, but little data is available to make better parameter assignments.
Contact frequency	365 events/yr for indoor; 350 events/yr for farming; 100 events/yr for gardening.	based on judgement and assumption that farmers spend more time in soil than non-farmers; indoor events judged to occur daily.	uncertainty judged to be relatively small given assumptions for behaviors	climatic conditions, behaviors, other site-specific factors could be important
Surface area	1,000 cm^2 for indoor events; 10,000 for residential gardening (central scenario) and 3600 for farming (high end scenario)	Based on total body surface area data and clothing assumptions: bare hands indoors; hands and arms for farmers; hands, arms, and legs for gardeners	Good data and small variability on body surface area; clothing assumptions based on judgement and site-specific conditiosn.	Studies have shown that fine particulates can deposit under clothing. Different behaviors can lead to different assumptions regarding exposed body areas.
Absorption fraction	0.03 for all compounds	Data in EPA (1992c) suggested a range of 0.001 to 0.03 based on data for 2,3,7,8-TCDD.	Value chosen was upper end of range, so refinements would appear to lead to lower estimates of dermal exposure.	Soil properties may also affect absorption.
Overall: The uncertainties and variabilities in the soil contact/adherence and absorption fraction parameters make the overall exposure estimates highly uncertain; judged to be plus or minus 1 to 2 orders of magnitude. Assessors should also be aware of uncertainties associated with prediction of soil concentration if source is distant from site of exposure.				

Table 8-4. Uncertainties associated with the water ingestion pathway.

Assumption/ Method	Approach	Rationale	Uncertainty	Comments
Water Concentrations	See modeling approaches for the soil, stack emission, and effluent discharge source categories in Chapter 4		literature data show few occurrences of dioxin-like compounds at 1 pg/L detection; models estimate 0.01 pg/L range and lower; cannot therefore ascertain uncertainty due to modeling, although little uncertainty expected due to low concentrations both found and predicted; and suitability of model predictions of sediment concentrations.	No major uncertainty expected due to modeling of water concentrations
Water Ingestion Rate	1.4 L/day central; 2.0 L/day high end	The classically assumed 2.0 L/day was evaluated as upper end rather than central value; 1.4 L/day recommended instead for central value.	EPA (1997) also noted that information on sensitive subpopulations such as laborers was unavailable; still, their analysis indicated that 2 L/day corresponds to high end value; hence it is appropriate for high end settings	Not expected to be a critical factor for uncertainty.
Contact Rate	0.70 central; 0.90 high end	values correspond to central and high end values for time at residence from several time use studies reviewed in EPA (1997).	The major uncertainty has to do with the extent to which exposed individuals rely on impacted water body for drinking water consumption. By using contact rates based on time at home, the assumption is that 100% of drinking water at home comes from impacted water body (which is assumed to supply water to household).	Exposure could be less if exposed individuals rely on water supply for drinking water other than impacted water body.
Overall: Data in the literature suggests concentrations mostly below 1 pg/L, which is consistent with modeling of concentrations 0.01 pg/L and lower in demonstration of all source categories. With this evidence, uncertainty with modeling is unknown, but the uncertainty is expected to be low because there is evidence that sediment predictions are consistent with field information. In general, water exposure is essentially the lowest exposure pathway.				

Table 8-5. Uncertainties associated with the fish ingestion pathway.

Assumption/ Method	Approach	Rationale	Uncertainty	Comments
Bioaccumulation approaches for fish tissue concentration estimation	Modeled bottom and suspended concentrations multiplied by BSAF or BSSAF	Bioaccumulation approaches rather than bioconcentration approaches are appropriate for lipophilic persistent organic compounds; water-based rather than sediment based approaches could be used, but sediment based approaches offer two advantages: 1) sediment data can and has been measured to derive field-based BSAF/BSSAFs - water concentrations for dioxins are too low, and 2) models for predicting sediment concentrations can likewise be tested.	Strictly speaking, BSAFs developed from one set of data are not transportable to other water bodies, and/or to other fish species; uncertainty exists with sediment concentration modeling; range of measured BSAF from selected value of 0.09 to greater than 1.00.	Model validations and comparisons of predicted with measured fish concentrations speak well for fate and transport algorithms
Fish ingestion rate	8 and 25 g/day for central and high end	Based on a review of recreational angler surveys in EPA (1997)	Assignment of this parameter should be based on site-specific considerations; subsistence behaviors leading to much higher fish ingestion rates should be ascertained.	Example settings were defined as rural/agricultural, but with a major river used as drinking water supply and suitable for fishing; hence, freshwater recreational fishing data was used.
Overall: Comparison of fish concentrations generated in the demonstration scenarios with literature values of fish concentrations of dioxin-like compounds shows them to be comparable. The validation using 104-mill data and testing the effluent discharge algorithms showed that fish concentrations were low by about one-half, but two important considerations for that test include: the discharging mill was assumed to be the only source of 2,3,7,8-TCDD, and uncertainties with the field data and the BSSAF lead to a conclusion that the model behaves quite adequately. Fish concentrations of PCBs may have been underestimated, but this conclusion is tempered by the fact that the modeled PCB sediment concentrations are similarly lower than has been measured. Alternate modeling approaches based on water column factors show comparable fish concentrations than sediment-based methods. Assignment of the fish ingestion rates was based on data from “recreational angler surveys”; “general population” and “subsistence” ingestion rates would be lower and higher, respectively, than selected for this assessment.				

Table 8-6. Uncertainties and sensitivities associated with estimating vapor and particle-phase air concentrations from contaminated soils.

Assumption/ Method	Approach	Rationale	Uncertainty	Comments
Exposure parameters	13 and 20 m^3/day for central and high end; 0.70 and 0.90 contact fractions for central and high end.	Central and high end estimates as described in EPA (1997)	not much uncertainty or variability expected for inhalation rates and contact fractions	uncertainty introduced by exposure durations of 9 and 30 years because of their role in the volatilization algorithm; otherwise uncertainty more an issue for methodologies estimating air concentrations.
Volatilization followed by near or far field dispersion for vapor phase concentrations	Used model developed by Hwang, et al (1986) for volatilization of PCBs; standard area source modeling for dispersion	Like PCBs, dioxin-like compounds are highly sorbed and persistent. Hwang (1986) model also has the advantage that the solutions were simplified using assumptions deemed reasonable for soils contaminated with dioxins.	Chemical parameters H and Koc are most uncertain with an order of magnitude range in estimated concentrations; estimations also sensitive to area, distance, and frequency wind blows to receptor.	An analysis of model performance suggests that the soil to air algorithms may be underestimating air concentrations, although this cannot be ascertained for certain because measured air concentrations are due to distant sources as well as soils.
Wind erosion followed by same dispersion algorithms	Used model based on highly erodible soils for dust flux to estimate fluxes for particle sizes < 10 μm	Assuming highly erodible soils may tend to overestimate flux, but not considering particles of size >10 μm would underestimate total airborne reservoir.	Parameters associated with the erodibility of soils can lead to a 2 order of magnitude range for estimated concentrations; much less sensitivity noted for other parameters.	No data to evaluate model results; however, particle concentrations are over 1 order of magnitude lower than vapor concentrations. Considering that the model was based on erodible soils, dust flux concentrations may be generally unimportant.

Table 8-6. (cont'd).

Assumption/ Method	Approach	Rationale	Uncertainty	Comments
Volatilization or resuspension of eroded contaminants not considered	Contaminants eroding to exposure site assumed not to volatilize or resuspend to contribute to exposure site concentrations	Traditionally, evaluation of the off-site impacts from a site of soil contamination considered only the impacts from the contaminated site.	If delivered contaminants volatilize or resuspend at site of exposure, exposure site air concentrations would increase by a factor of 2 to over 10.	More consideration of the fate of delivered contaminants is warranted.
Overall: The results of a model validation exercise showed that model predictions of air concentrations of dioxins resulting only from soil emissions were less than observed air concentrations by 2-3 orders of magnitude. The fact that they are lower is to be expected, since observed air concentrations over soils in an actual setting are very likely to be due mostly to long range air-borne transport from distant sources. Still, an analysis of data of plants growing in soils of known concentrations also suggests that the air-to-soil model may be underpredicting air concentrations. Ultimately, no data could be found on air concentrations over soils where it is definitely known that the soil is the only source of the dioxin-like compounds, so a degree of underprediction, if that is in fact occurring, could not be ascertained. Sensitivity analysis showed estimations of vapor phase air concentrations to be sensitive to Koc and H, and also to key source strength and delivery terms such as areas of contamination and wind speed. Assuming these non-chemical specific parameters can be known with reasonable certainty for site-specific applications, the most uncertainty lies with chemical specific data. Alternate approaches for volatilization and air dispersion generally estimate comparable air concentrations (within an order of magnitude or lower). Approaches to estimate particulate phase concentrations are empirical and based on field data. They are based on highly erodible soils but are specific to inhalable size particles, those less than 10 μm. As such, they may overestimate inhalation exposures, but may underestimate the total reservoir of particulates, which becomes critical for the particle deposition to vegetation algorithms. Another area of uncertainty is the assumption that volatilized contaminants do not become sorbed to airborne particles - this is also critical because vapor phase transfers dominate plant concentration estimation. A final key area of uncertainty is that transported contaminants from a contaminated to an exposure site via erosion are assumed not to volatilize or resuspend at the exposure site - air borne exposure site concentrations may be underestimated as a result.				

Table 8-7. Uncertainties associated with vegetable/ fruit ingestion exposure algorithms.

Assumption/ Method	Approach	Rationale	Uncertainty	Comments
Ingestion Rates and Contact Fractions	1.16, 1.52, and 1.47 g/kg/day root/above veg, and fruit; 0.101 and 0.173 for fruit and veg contact fractions	Derived from National Food Consumption Survey (NFCS) of 1987-88; Household portion. Available data allows for most appropriate estimates of homegrown rates and contact fractions, and also ties body weight to ingestion rate by expression in terms of g/kg/day.	Household survey relies on head of household recall for week long food brought into home; whole food product do not include cooking losses, discarded amounts, etc.	All parameters evaluated as reasonable for general exposure to categories of fruit and vegetables; more refinement desired for specific assessments.
Below ground vegetable concentration	Used empirical RCF, root concentration factor, based on Kow, and VG_{bg}, below ground correction factor	Approach based on laboratory experiments; validation exercise on data for carrot peel concentrations grown in soils of known concentrations supports model capabilities.	VG_{bg} of 0.25 based on evidence of some translocation into carrots and potatoes; however, it remains most uncertain parameter; Kow is also uncertain, although validation exercise supports use of RCF	Further refinements to VG_{bg} may be warranted.
Above ground vegetable, fruit concentration	Air-to-leaf vapor phase transfer algorithm based on B_{vpa} (transfer factor) which was developed from field data; vapor phase impacts also include VG_{ag}; particle deposition algorithm for particle bound dioxins	Field experiments and modeling both show that vapor phase impacts dominate total plant concentrations; B_{vpa} calibrated from field data; particle deposition algorithm developed for radionuclide impacts to agriculture; VG_{ag} assignment of 0.01 considers both evidence of little within plant translocation for exposed bulky vegetations and reduction in plant concentrations due to peeling prior to consumption.	Model validation/comparison exercise showed the air-to-leaf model to work reasonably well in rural setting, but to underestimate grass concentrations when grass was grown in contaminated soils in an industrial setting; VG_{ag} still the most uncertain parameter.	Limited literature data and model validation exercise suggests that above ground vegetative impacts from contaminated soils may be underestimated; could be due to lack of consideration of rainsplash.
Overall: All ingestion parameters assumed are evaluated as reasonable for general exposure to broad categories of fruits and vegetables. However, great variability is expected if using these procedures on a specific site where home gardening practices can be more precisely ascertained. Validation exercises support both the soil to below ground vegetable and air-to-leaf algorithms. The most uncertain parameters for both algorithms are the "VG" parameters, VG_{ag} and VG_{bg}, which correct for evidence that there is little within plant translocation of dioxins in below as well as above ground bulky vegetations, and additionally considers peeling or washing of vegetations, which would further reduce whole plant concentrations.				

Table 8-8. Uncertainties associated with the terrestrial animal food pathways.

Assumption/ Method	Approach	Rationale	Uncertainty	Comments
Ingestion rates, contact fractions, food preparation consideration	Like for fruit/vegetables, ingestion rates and contact fractions developed from the household component of the National Food Consumption Survey (USDA, 1992; as interpreted in EPA, 1997). For meats, an additional pre- and post-cooking factor of about 0.50 further reduces consumption rates derived from this data to better relate food "brought into the house" to food "as eaten".			
Terrestrial animal bioconcentration models	Weighted average concentration in diet times BCF equals fat concentration; BCF for beef/milk developed from one experiment on one lactating cow.	Precedence and data support this approach. Two field studies collecting data to develop BCF for cow's milk arrive at very similar BCFs.	Uncertainty in applying milk-derived BCF to beef; chicken and egg BCFs separately derived in laboratory experiments; uncertainty in applying laboratory feeding experiments to field situations for chickens; dietary assumptions are variable and soil bioavailability correction factor, Bs, is uncertain and important for free range chicken scenario	Air-to-beef model validation exercise supports the use of milk-derived BCFs for beef, and approach in general. For predicting beef concentrations, site-specific consideration of fattening regime is important.
Related models	See previous sections for discussions on uncertainties in associated models including air dispersion and deposition modeling, soil-to-air and air-to-soil modeling, air-to-plant modeling, and soil concentration modeling.			
Overall: The demonstration scenarios showed that the terrestrial animal food pathways dominate human exposure. This was supported by similar findings in Volume II of this assessment, which estimated background exposures based on measured concentrations coupled with consumption rates. In site-specific applications, animal diet fractions in the various categories of animal feeds (leafy, partially protected, fully protected, soil) becomes important. The air-to-beef model validation exercise described earlier lends confidence to the use of the milk/beef bioconcentration algorithms.				

Table 8-9. Distributions for a Monte Carlo exercise which developed soil cleanup levels at residential and industrial sites.

Parameter	Range (Residential)	Range (Industrial)
Soil Contact μg/cm^2/d	200 - 1800	same
Dermal Bioavailability Fraction	0.01 - 0.025	same
Fraction soil from site	O-5 yr: 0.1 - 1.0 6-30 yr: 0.1 - 0.5	0.1 - 1.0
Fraction indoor dust contaminated	(not considered)	0.25 - 1.0
Indoor exposure duration	0-1.5 yr: 182-365 d/yr 1.5-30 yr: 200-365 d/yr	0 - 8 hr/d 220 - 260 d/yr
Outdoor exposure duration	0 - 1.5 yr 60-120 d/yr 1.5 - 30 yr 60-240 d/yr	0 - 8 hr/d 220 - 260 d/yr
Soil ingestion rate, μg/d	0 - 1.5 yr 100 - 10000 1.5 - 5 yr 9000 - 50000 6 - 12 yr 5000 - 50000 13 - 30 yr 100 - 50000	100 - 50000 (indoors) 100 - 10000 (outdoors)
Oral Bioavailability	0.38, 0.40, 0.47, 0.49	same
Air particulate concen., μg/m^3	25 - 45	same
Fraction outdoor dust contaminated	0.1 - 0.5	same
Inhalation rate m^3/hr	0-1.5 yr: 0.03 - 0.07 1.5-5 yr: 0.3 - 0.9 6-12 yr: 0.75 - 1.5 13-30 yr: 0.5 - 1.5	9 - 14.6 m^3/d
Lipid Content of Fish	0.01 - 0.05

1. DISPOSITION AND PHARMACOKINETICS

The disposition and pharmacokinetics of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and related compounds have been investigated in several species and under various exposure conditions. Several reviews on this subject focus on TCDD and related halogenated aromatic hydrocarbons (Neal et al., 1982; Gasiewicz et al., 1983a; Olson et al., 1983; Birnbaum, 1985; van den Berg et al., 1994). The relative biological and toxicological potency of TCDD and related compounds depends not only on the affinity of these compounds for the aryl hydrocarbon receptor (AhR), but on the species-, strain-, and congener-specific pharmacokinetics of these compounds (Neal et al., 1982; Gasiewicz et al., 1983a; Olson et al., 1983; Birnbaum, 1985; van den Berg et al., 1994, DeVito and Birnbaum, 1995).

2,3,7,8-TCDD and other similar compounds discussed here are rapidly absorbed into the body and slowly eliminated, making body burden (bioaccumulation) a reliable indicator of time-integrated exposure and absorbed dose. Because of the slow elimination kinetics, it will be shown in this section that lipid or blood concentrations, which are often measured, are in dynamic equilibrium with other tissue compartments in the body, making the overall body burden and tissue disposition relatively easy to estimate. Finally, it will be shown that body burdens can be correlated with adverse health effects (Hardell et al., 1995; Leonards et al., 1995), further leading to the choice of body burden as the optimal indicator of absorbed dose and potential effects.

1.1. ABSORPTION/BIOAVAILABILITY FOLLOWING EXPOSURE

Gastrointestinal, dermal, and transpulmonary absorptions represent potential routes for human exposure to this class of persistent environmental contaminants. Parenteral absorption is a route of exposure that has been used to generate disposition and pharmacokinetic data on these compounds.

1.1.1. Oral

1.1.1.1. *Gastrointestinal Absorption in Animals*

Much of human exposure to TCDD and related compounds is thought to be through the diet. Experimentally, these compounds are commonly administered in the diet or by gavage in an oil vehicle. Gastrointestinal absorption is usually estimated as the difference between the administered dose (100%) and the percent of the dose that was not absorbed. The unabsorbed fraction is estimated as the recovery of parent compound in feces within 24 to 48 hours of a single oral exposure by gavage. Table 1-1 summarizes gastrointestinal absorption data on TCDD and related compounds.

In Sprague-Dawley rats given a single oral dose of 1.0 μg [^{14}C]-2,3,7,8-TCDD/kg bw in acetone:corn oil (1:25, v/v), the fraction absorbed ranged from 66% to 93%, with a mean of ~84% (Rose et al., 1976). With repeated oral dosing of rats at 0.1 or 1.0 μg/kg/day (5 days/week for 7 weeks), gastrointestinal absorption of TCDD was observed to be approximately that observed for a single oral exposure (Rose et al., 1976). Oral exposure of Sprague-Dawley rats to a larger dose of TCDD in acetone:corn oil (50 μg/kg) resulted in an average absorption of 70% of the administered dose (Piper et al., 1973). More recently, Diliberto et al. (1996a) reported 88% absorption of TCDD in male Fischer 344 rats following oral exposure in Emulphor/95% ethanol/water (1:1:3). (Emulphor EL-620 is a polyoxyethylated vegetable oil preparation [GAF Corp., New York, NY]).

One study in the guinea pig reported that ~50% of a single oral dose of TCDD in acetone:corn oil was absorbed (Nolan et al., 1979). The gastrointestinal absorption of TCDD was also examined in the hamster, the species most resistant to the acute toxicity of this compound (Olson et al., 1980). Hamsters were given a single, sublethal, oral dose of [1,6-^{3}H]-2,3,7,8-TCDD in olive oil (650 μg/kg), and an average of 75% of the dose was absorbed. When TCDD was administered to rats in the diet at 7 or 20 ppb (0.5 or 1.4 μg/kg/day) for 42 days, 50% to 60% of the consumed dose was absorbed (Fries and Marrow, 1975). These findings indicate that oral exposure to TCDD in the diet or in an oil vehicle results in the absorption of >50% of the administered dose.

The intestinal absorption of [^{3}H]-2,3,7,8-TCDD has also been investigated in thoracic duct-cannulated rats (Lakshmanan et al., 1986). The investigators concluded that TCDD was absorbed into chylomicrons and transported through the lymphatic system before entering the systemic circulation.

The absorption of 2,3,7,8-TBDD in male Fischer 344 rats was studied after oral exposure by gavage at 5 μg/kg in Emulphor:ethanol:water (1:1:3) (Diliberto et al., 1990). The percent of the dose absorbed for this study was defined as 100% (% total oral dose in feces on days 1 and 2 minus % total intravenous dose in feces on days 1 and 2) using the intravenous pharmacokinetic data of Kedderis et al. (1991a).

The relative absorbed dose or bioavailability of 2,3,7,8-TBDD after oral exposure was estimated at 78%, 82%, 60%, and 47% at dose levels of 0.001, 0.01, 0.1, and 0.5 μmol/kg, respectively. These results suggest nonlinear absorption at the higher doses, with maximal oral absorption at an exposure of ≤0.01 μmol/kg (5 μg/kg).

The absorption of 2,3,7,8-TCDF has been investigated after oral exposure by gavage. Approximately 90% of the administered dose (0.1 and 1.0 μmol/kg) of 2,3,7,8-TCDF in Emulphor:ethanol (1:1) was absorbed in male Fischer 344 rats (Birnbaum et al., 1980). Similarly, >90% of the administered dose (0.2 μmol/kg, 6 μg/kg, and 1-15 μg/kg) of 2,3,7,8-

TCDF in Emulphor:ethanol:water (1:1:8) was absorbed in male Hartley guinea pigs (Decad et al., 1981a; Ioannou et al., 1983). Thus, 2,3,7,8-TCDF appears to be almost completely absorbed from the gastrointestinal tract. This absorption may be related to the greater relative solubility of 2,3,7,8-TCDF compared with that of 2,3,7,8-TCDD or 2,3,7,8-TBDD.

The oral bioavailability of 2,3,4,7,8-PeCDF and 3,3′,4,4′-TCB in corn oil was similar to that of 2,3,7,8-TCDD (Brewster and Birnbaum, 1987; Wehler et al., 1989; Clarke et al., 1984). Furthermore, 2,3,4,7,8-PeCDF absorption was independent of the dose (0.1, 0.5, or 1.0 μmol/kg). Incomplete and variable absorption of 1,2,3,7,8-PeCDD was reported in rats, with 19% to 71% of the dose absorbed within the first 2 days after oral exposure (Wacker et al., 1986).

Early studies on the pharmacokinetic behavior of OCDD by Williams et al. (1972) and Norback et al. (1975) demonstrated that OCDD was poorly absorbed after oral exposure. More recently, Birnbaum and Couture (1988) also found that the gastrointestinal absorption of OCDD in rats was very limited, ranging from 2% to 15% of the administered dose. Lower doses (50 μg/kg) in an o-dichlorobenzene:corn oil (1:1) vehicle were found to give the best oral bioavailability for this extremely insoluble compound.

Recently Mes et al. (1995) have reported PCBs in nondosed infants of dosed rhesus monkeys. Transfer to the infants was from both intrauterine and lactational exposure. Also, the infants showed a larger percentage of heptachorobiphenyls than did the dosed dams. Busbee and Zipring (1994) reported the direct absorption across the gastric mucosa of Aroclor 1232 (DCB) in an ovine. The absorption was rapid and the circulating DCB was not found to be associated with plasma lipid fractions. The researchers report no occurrence in the thoracic duct lymph prior to appearance in the circulating plasma. Also, the DCB did bind with plasma lipids in vitro. These data suggest that this DCB is transported similar to water soluble compounds.

1.1.1.2. *Gastrointestinal Absorption in Humans*

The above animal data indicate that gastrointestinal absorption of TCDD and related compounds is variable, incomplete, and congener- and vehicle-specific. More soluble congeners, such as 2,3,7,8-TCDF, are almost completely absorbed, whereas the extremely insoluble OCDD is poorly absorbed. In some cases, absorption has been found to be dose dependent, with increased absorption occurring at lower doses (2,3,7,8-TBDD, OCDD). The limited database in experimental animals also suggests that there are no major interspecies differences in the gastrointestinal absorption of these compounds.

Poiger and Schlatter (1986) investigated the absorption of TCDD in a 42-year-old man after ingestion of 105 ng [^{3}H]-2,3,7,8-TCDD (1.14 ng/kg bw) in 6 mL corn oil and found that >87% of the oral dose was absorbed from the gastrointestinal tract. Following absorption, the half-life for elimination was estimated to be 2,120 days.

Schlummer et al. (1998) used a mass balance approach to assess the gastrointestinal absorption of CDDs, CDFs, PCBs, and hexachlorobenzene (HCB) from food in seven individuals, 24 to 81 years of age, with different contaminant body burdens. The difference between the ingested (food concentration) and excreted (fecal concentration) amounts of each compound was defined as net absorption. Three types of net absorption were observed in this study: (1) nearly complete net absorption (e.g. 2,3,7,8-TCDF and 1,2,3,7,8-PeCDF); (2) incomplete net absorption (e.g., TCDD and 1,2,3,7,8-PeCDD in the younger subjects); and (3) net excretion (excretion to a greater extent than ingestion, e.g., 1,2,3,6,7,8-HxCDD and OCDD). In terms of TEQs, the maximum net absorption of CDDs and CDFs was 63% in one individual, while a net excretion of TEQs was found for the three oldest subjects, which also have the highest serum concentration of these congeners. When PCB 126 (3,3'4,4',5), with a TEF of 0.1, is included in the TEF calculation, the TEQ balance was dominated by this congener, resulting in a maximum net TEQ absorption of 80% and a net TEQ absorption in all but the oldest subject. Table 1-1 illustrates that compounds showing nearly complete net absorption had very low or nondetectable levels in the serum lipids, and for other congeners, there was a trend for decreasing net absorption/increasing net excretion with increasing congener concentration in serum lipids. Together, the data support the passive diffusion model for gastrointestinal absorption, where the concentration of the contaminant in the blood is the major factor determining absorption. However, the relatively high absorption levels of many congeners could not be explained on the basis of diffusive gradients estimated from the difference between the lipid-based food and serum concentrations, as the lipid-based food levels were always lower, favoring net excretion. The authors propose a fat-flush theory, which hypothesizes that the fat compartment of the absorbing tissue (gut wall) expands because of the uptake of dietary fat, resulting in a decrease in the lipid-based concentration of the gut wall below that of the food, thus facilitating absorption. Therefore, as food passes through the duodenum and the jejunum, CDDs, CDFs and PCBs experience a diffusion gradient and net absorption as a result of the fat-flush. As the gut contents reach the colon, dietary fat has been absorbed, causing a reduction in the concentration gradient favoring absorption of CDDs, CDFs, and PCBs. Thus, the fat-flush theory supports the hypothesis that absorption and excretion of CDDs, CDFs, and PCBs are distinct processes occurring at different locations in the digestive tract.

Duarte-Davidson and Jones (1994) report an average intake of a sum of several PCB congeners in the contemporary United Kingdom population of 0.53 micrograms/person/day. They estimate 97% of exposure can be accounted for by food consumption. This indicates that PCBs can likewise be absorbed through the gastrointestinal system.

Because CDDs, CDFs, and PCBs are present in human milk, McLachlan (1993) investigated the net absorption of these compounds in a nursing infant. The contaminant input,

through the ingestion of mother's milk, and the contaminant output in the feces were measured to estimate the digestive tract absorption of these compounds. For almost all congeners, more than 90% of the ingested compound was absorbed, indicating that the common assumption of 100% absorption of CDDs, CFFs, and PCBs in nursing infants is reasonable. Dahl et al. (1995) provide further evidence of this, as they report > 95% absorption in postpartum infants (1, 2, 3 months) in Sweden. Abraham et al. (1996) assessed the oral intake and fecal excretion of CDDs and CDFs in one formula-fed and two breast-fed infants at 1 and 5 months of age. The breast-fed infants had significantly more exposure to CDDs and CDFs, with >90% of the 2,3,7,8-TCDD, 2,3,4,7,8-PeCDF, 1,2,3,7,8-PeCDD, and 1,2,3,6,7,8-HxCDD (>93% of TEQs) being absorbed from mother's milk. Less complete bioavailability of higher CDDs was observed, with 62% to 88% of 1,2,3,4,6,7,8-HepCDD and 16% to 75% of OCDD absorbed from mother's milk (Abraham et al., 1996). Furst et al. (1994), Hong et al. (1994), Schecter et al. (1994a,b), Georgii et al. (1994), and others provide further evidence of the presence of dioxins, PCPs, and PCBs in human milk. This important route for excretion and exposure is discussed later in the chapter.

1.1.1.3. *Bioavailability Following Oral Exposure*

Oral exposure of humans to TCDD and related compounds usually occurs as a complex mixture of these contaminants in food, soil, dust, water, or other mixtures that would be expected to alter absorption.

The influence of dose and vehicle or adsorbent on gastrointestinal absorption has been investigated in rats by Poiger and Schlatter (1980), using hepatic concentrations 24 hours after dosing as an indicator of the amount absorbed (Table 1-2). Administration of TCDD in an aqueous suspension of soil resulted in a decrease in the hepatic levels of TCDD as compared with hepatic levels resulting from administration of TCDD in 50% ethanol. Likewise, Diliberto et al. (1996a) report 24.4% (+ 1.4) in the liver after dosing male Fischer 344 rats with TCDD in a solution of 1:1:3 ratio of Emulphor/95% ethanol/distilled water. The extent of the decrease was directly proportional to the length of time the TCDD had been in contact with the soil. When TCDD was mixed in an aqueous suspension of activated carbon, absorption was almost totally eliminated (<0.07% of the dose in hepatic tissues).

Philippi et al. (1981) and Huetter and Philippi (1982) have shown that radiolabeled TCDD becomes progressively more resistant with time to extraction from soil. Similarly, the feeding of fly ash, which contains CDDs, to rats in the diet for 19 days resulted in considerably lower hepatic levels of CDDs than did the feeding of an extract of the fly ash at comparable dietary concentrations of CDDs (van den Berg et al., 1987a). The CDDs were tentatively identified as 2,3,7,8-TCDD, 1,2,3,7,8-PeCDD, 1,2,3,6,7,8-HxCDD, and 1,2,3,7,8,9-HxCDD, and the difference in hepatic levels noted between fly ash-treated and extract-treated rats was greater

for the more highly chlorinated isomers than for 2,3,7,8-TCDD. These results indicate the importance of the formulation or vehicle containing the toxin(s) on the relative bioavailability of 2,3,7,8-TCDD, PeCDD, and HxCDDs after oral exposure.

Because TCDD in the environment is likely to be absorbed to soil, McConnell et al. (1984) and Lucier et al. (1986) compared the oral bioavailability of TCDD from environmentally contaminated soil with that from TCDD administered in corn oil in guinea pigs and rats, respectively. As indicated by biological effects and the amount of TCDD in the liver, the intestinal absorption from soil from Times Beach and Minker Stout, Missouri, was ~50% less than that from corn oil. Shu et al. (1988a) reported an oral bioavailability of ~43% in rats dosed with three environmentally contaminated soil samples from Times Beach, Missouri. This figure did not change significantly over a 500-fold dose range of 2-1,450 ng 2,3,7,8-TCDD/kg bw for soil contaminated with ~2, 30, or 600 ppb of TCDD TCDD. In studies of other soil types, Umbreit et al. (1986a,b) estimated an oral bioavailability in the rat of 0.5% for soil at a New Jersey manufacturing site and 21% for a Newark salvage yard. These results indicate that bioavailability of TCDD from soil varies between sites and that TCDD content alone may not be indicative of potential human hazard from contaminated environmental materials. Although these data indicate that substantial absorption may occur from contaminated soil, soil type and duration of contact, as suggested from the data that demonstrated decreased extraction efficiency with increasing contact time between soil and TCDD (Philippi et al., 1981; Huetter and Philippi, 1982), may substantially affect the absorption of TCDD from soils obtained from different contaminated sites.

1.1.2. Dermal Absorption

Brewster et al. (1989) examined the dermal absorption of TCDD and three CDFs in male Fischer 344 rats (10 weeks old; 200-250 g). The fur was clipped from the intrascapular region of the back of each animal. A single compound in 60 μL of acetone was then applied over a 1.8 cm^2 area of skin, which then was covered with a perforated stainless steel cap. Table 1-3 summarizes data on the absorption of each compound at 3 days after a single dermal exposure. At an exposure of 0.1 μmol/kg, the absorption of 2,3,7,8-TCDF (49% of administered dose) was greater than that of 2,3,4,7,8-PeCDF, 1,2,3,7,8-PeCDF, and 2,3,7,8-TCDD. For each compound, the relative absorption (percentage of administered dose) decreased with increasing dose, while the absolute absorption (μg/kg) increased nonlinearly with dose. Results also suggest that the majority of the compound remaining at the skin exposure site was associated with the stratum corneum and did not penetrate through to the dermis. In a subsequent study, Banks and Birnbaum (1991a) examined the rate of absorption of TCDD over 120 hours after the dermal application of 200 pmol (1 nmol/kg) to male Fischer 344 rats. The absorption kinetics appeared

to be first order, with an absorption rate constant of 0.005 $hour^{-1}$. With a similar exposure protocol, the dermal absorption of 2,3,7,8-TCDF was found to follow a first-order process, with a rate constant of 0.009 $hour^{-1}$ (Banks and Birnbaum, 1991b). Together, these results on dermal absorption indicate that at lower doses (≤0.1 μmol/kg), a greater percentage of this administered dose of TCDD and three CDFs was absorbed. Nonetheless, the rate of absorption of TCDD is still very slow (rate constant of 0.005 $hour^{-1}$), even following a low-dose dermal application of 200 pmol (1 nmol/kg). Results from Table 1-3 also suggest that the dermal absorption of 2,3,7,8-TCDF, 2,3,4,7,8-PeCDF, and 1,2,3,7,8-PeCDF occurs at a very slow rate. Using a similar exposure protocol, the dermal absorption of 2,3,7,8-TBDD was only 30% to 40% of that observed for TCDD (Diliberto et al., 1993a; 1996a).

The dermal absorption of several polyhalogenated aromatic hydrocarbons in male F344 rats was also compared with estimates of their respective octanol-water partition coefficients (Jackson et al., 1993). Inverse correlations were found between octanol-water partition coefficient estimates and the single-dose (~1.0 nmol/kg and ~0.1 μmol/kg) dermal absorption for most of the compounds studied. The differential dermal absorption of TCDD and 2,3,7,8-TBDD may result, in part, from the diminished ability of the more lipophilic 2,3,7,8-TBDD to partition out of the stratum corneum and into the underlying epidermal and dermal layers.

Rahman et al. (1992) and Gallo et al. (1992) compared the in vitro permeation of TCDD through hairless mouse and human skin. In both species, the amount of TCDD permeated increased with the dose, but the percentage of the dose permeated decreased with increasing dose. The permeability coefficient of TCDD in human skin was about one order of magnitude lower than that in mouse skin. The hairless mouse skin does not appear to be a suitable model for the permeation of TCDD through human skin because the viable tissues were major barriers to TCDD permeation in hairless mouse skin, while the stratum corneum layer provided the greater resistance in human skin. A significant increase in TCDD permeation through human skin was observed when the skin was damaged by tape-stripping. Gallo et al. (1992) suggested that washing and tape-stripping of the exposed area might remove most of the TCDD and reduce the potential for systemic exposure and toxicity because most of the TCDD remained within the horny layer of human skin even at 24 hours following exposure.

Weber et al. (1991) also investigated the penetration of TCDD into human cadaver skin at concentrations of 65-6.5 ng/cm^2. This study found that the stratum corneum acted as a protective barrier, as its removal increased the amount of TCDD absorbed into layers of the skin. With intact skin and acetone as the vehicle, the rate of penetration of TCDD into the dermis ranged from 6 to 170 $pg/hour/cm^2$, while penetration into the dermis and epidermis ranged from 100 to 800 $pg/hour/cm^2$. With mineral oil as the vehicle, there was about a five-to-tenfold reduction in the rate of penetration of TCDD into the intact skin.

Wester et al. (1993a) studied the dermal permeation potential of two PCBs, Aroclor 1242 and Aroclor 1254, from soil. Soil is the most common medium of contact for humans; hence any permeation potential is of great interest for risk assessment purposes. This study consisted of experiments conducted in rhesus monkeys (in vivo), in vitro human skin, and powdered human corneum. The monkeys were exposed topically for a 5-week period. Percutaneous absorption was determined by urinary and fecal [^{14}C]-PCB excretion. The percutaneous absorption in the monkey was 13.8% (±2.7%) for Aroclor 1242 and 14.1% (±1.0%) for Aroclor 1254. The authors report that these absorption rates for soil are similar to those from vehicles such mineral oil, trichlorobenzene, and acetone. These rates are somewhat higher than those for other compounds such as the pesticide butachlor, which was about 5.0% when applied to human skin (Ademola et al., 1993). On the other hand, Wester et al. (1993b) report a much higher absorption for pentachlorophenol (PCP) (24.4% from soil and 29.2% from acetone) in the rhesus monkey. The authors report that PCP is one of the more extensively absorbed compounds they have studied. Thus, at least for these two PCBs (Aroclor 1242 and Aroclor 1254), the absorption in the rhesus monkey appears to be intermediate between that of other compounds tested. In summary, these studies indicate that these two PCBs show significant partitioning into the stratum corneum from soil, a common environmental matrix.

1.1.2.1. *Bioavailability Following Dermal Exposure*

Dermal exposure of humans to TCDD and related compounds usually occurs as a complex mixture of these contaminants in soil, oils, or other mixtures, which would be expected to alter absorption. Poiger and Schlatter (1980) presented evidence that the presence of soil or lipophilic agents dramatically reduces dermal absorption of TCDD compared with absorption of pure compound dissolved in solvents. In a control experiment, 26 ng of TCDD in 50 μL methanol was administered to the skin of rats; 24 hours later the liver contained 14.8±2.6% of the dose. By comparing this value to the hepatic levels obtained after oral administration in 50% ethanol (in the same study), the amount absorbed from a dermal application can be estimated at ~40% of the amount absorbed from an equivalent oral dose. This comparison assumes that hepatic levels are valid estimates of the amount absorbed from both oral and dermal routes and that absorption from methanol is equivalent to absorption from 50% ethanol. The dose-dependent distribution of TCDD in the liver is another factor that may limit quantitative conclusions regarding bioavailability that are based solely on hepatic levels following exposure to 2,3,7,8-TCDD. As compared with dermal application in methanol, dermal application to rats of TCDD in vaseline or polyethylene glycol reduced the percentage of the dose in hepatic tissue to 1.4% and 9.3%, respectively, but had no observable effect on the dose of TCDD required to induce skin lesions (~1 μg/ear) in the rabbit ear assay. Application of TCDD in a soil/water

paste decreased hepatic TCDD to ~2% of the administered dose and increased the amount required to produce skin lesions to 2-3 μg in rats and rabbits, respectively. Application in an activated carbon/water paste essentially eliminated absorption, as measured by percent of dose in the liver, and increased the amount of TCDD required to produce skin lesions to ~160 μg. These results suggest that dermal absorption of TCDD depends on the formulation (vehicle or adsorbent) containing the toxin.

Shu et al. (1988b) investigated the dermal absorption of soil-bound TCDD in rats. Relative dermal bioavailability was estimated by comparing the level of TCDD in the liver of rats given soil-bound TCDD dermally to that of rats given oral doses of TCDD dissolved in corn oil. The level of TCDD in livers of rats dosed orally with TCDD in corn oil, following correction for unabsorbed TCDD TCDD, is assumed to represent 100% bioavailability. The dermal penetration of TCDD after 4 hours of contact with skin was ~60% of that after 24 hours of contact. After 24 hours of contact with the skin, the degree of dermal uptake from contaminated soil was ~1% of the administered dose. The authors observed that the degree of uptake does not appear to be influenced significantly by the concentration of TCDD in soil, by the presence of crankcase oil as a co-contaminant, or by environmentally versus laboratory-contaminated soil.

A major limitation of these studies is the uncertainty regarding the extrapolation of dermal absorption data on these compounds from the rat to the human. The in vitro dermal uptake of TCDD has been investigated in hairless mouse and human skin (Gallo et al., 1992; Rahman et al., 1992). In vitro dermal uptake of TCDD from laboratory-contaminated soil indicated that aging of soils (up to 4 weeks) and the presence of additives (2,4,5-trichlorophenol and motor oil) in the soil did not have any significant effect on dermal uptake (Gallo et al., 1992). Because most of the TCDD remained in the stratum corneum layer of human skin, the permeation of TCDD was significantly lower in human than in hairless mouse skin. There are no published quantitative in vivo data on the dermal absorption of TCDD and related compounds in the human, and data on the rhesus monkey are very limited. Brewster et al. (1988) found that 1,2,3,7,8-PeCDF was poorly absorbed in the monkey after dermal application, with <1% of the administered dose being absorbed in 6 hours. This provides further evidence for the very slow rate of dermal absorption of TCDD and related compounds.

1.1.3. Transpulmonary Absorption

The use of incineration as a means of solid and hazardous waste management results in the emission of contaminated particles that may contain TCDD and related compounds into the environment. Thus, significant exposure to TCDD and related compounds may result from inhalation of contaminated fly ash, dust, and soil. In an attempt to address the bioavailability and

potential health implications of inhaling contaminated particles, Nessel et al. (1990) examined the potential for transpulmonary absorption of TCDD in female Sprague-Dawley rats after intratracheal instillation of the compound in a corn oil vehicle or as a laboratory-prepared contaminant of gallium oxide particles. Several biomarkers of systemic absorption were measured, including the dose-dependent effects of TCDD on hepatic microsomal cytochrome P-450 content, AHH activity, and liver histopathology. Significant dose-related effects were observed at an exposure of $\geq$0.55 μg TCDD/kg. The authors found that induction was slightly higher when animals received TCDD in corn oil than when animals received TCDD-contaminated particles, and was comparable to induction after oral exposure. The results from Nessel et al. (1990) indicate that systemic effects occur after pulmonary exposure to TCDD, suggesting that transpulmonary absorption of TCDD does occur.

The pulmonary bioavailability of TCDD was also examined in female Sprague-Dawley rats following intratracheal instillation of PCDD-contaminated soil from a former 2,4,5-trichlorophenoxy-acetic acid manufacturing site (Nessel et al., 1992). A size-dependent enrichment of PCDDs and PCDFs was observed, with the smaller particles being more highly contaminated. TCDD was enriched up to 33-fold in small respirable particles as compared with unfractionated soil. Pulmonary bioavailability of TCDD was assessed by hepatic enzyme induction (AHH activity) and TCDD concentration. The data indicate that the relative pulmonary bioavailability of TCDD on respirable soil particles is 100% as compared with laboratory-recontaminated gallium oxide.

The transpulmonary absorption of TCDD was assessed in male Fischer 344 rats following intratracheal instillation of a 1 nmol/kg dose in Emulphor:ethanol:water (1:1:3) (Diliberto et al., 1996a). Transpulmonary absorption was 95%, suggesting that there was almost complete absorption of TCDD by inhalation under these conditions. Similar results also were observed for the transpulmonary absorption of 2,3,7,8-TBDD under similar exposure conditions (Diliberto et al., 1993a,b). Recent studies (Diliberto et al., 1996a) further show the importance of transpulmonary absorption for 2,3,7,8-TCDD. Tissue distributions were measured 3 days after administration via different routes. Comparisons show that the percentage of dose distributed to the liver after intratracheal (itr) injection is similar to that after intravenous administration (iv) (33% for itr, 37% for iv). Also, both the iv and itr routes show a preference for greater sequestration in the liver over fat when compared to the oral (po) route. These results suggest that the transpulmonary absorption of 2,3,7,8-TCDD and 2,3,7,8-TBDD was similar to that observed following oral exposure.

1.1.4. Parenteral Absorption

In an effort to obtain more reproducible and complete absorption of TCDD and related compounds for pharmacokinetic studies, Abraham et al. (1989a, b) used various vehicles to investigate the absorption of TCDD after parenteral application in rats. These investigators observed optimal results with the subcutaneous injection of TCDD with a mixture of toluene:DMSO (1:2) as the vehicle. At 3 and 5 days after treatment, the percentages of administered dose remaining at the injection site under the skin of the back were ~10% and 2%, respectively. The vehicle did not cause adverse effects at an applied volume of 0.2 mL/kg bw. The absorption of a defined mixture of CDDs and CDFs in the rat was also examined after subcutaneous injection with toluene:DMSO (1:2) as a vehicle. Of the 97 congeners analyzed, 70 were ≥95% absorbed 7 days after exposure; 21 were 90%-95% absorbed; and 1,2,3,9-TCDD, 1,2,3,6,7,9-/1,2,3,6,8,9-HxCDD, 1,2,3,4,6,7,9-HpCDD, OCDD, 1,2,4,6,8,9-HxCDF and 1,2,3,7,8,9-HxCDF were 84%-89% absorbed. Greater than 90% absorption of CDDs and CDFs also was observed under these conditions in the marmoset monkey, with the exception of 1,2,3,4,7,8,9-HpCDF, OCDF, and OCDD, which had ~50%-80% of the administered dose absorbed (Neubert et al., 1990; Abraham et al., 1989a). Although the absorption of CDDs and CDFs after subcutaneous administration in toluene:DMSO (1:2) is somewhat slow in rats and monkeys, absorption of most congeners was >90% within 7 days. Even for highly chlorinated insoluble congeners, such as OCDD and OCDF, subcutaneous absorption was >84% in the rat and >50% in the monkey.

Less complete and slower absorption of CDDs and CDFs was observed after subcutaneous injection of these compounds using an oil-containing vehicle (Brunner et al., 1989; Abraham et al., 1989a). Using a corn oil:acetone vehicle (24:1, v/v), Lakshmanan et al. (1986) observed that only 7% of the administered dose of TCDD was absorbed 24 hours after subcutaneous injection and that only 35% was absorbed after intraperitoneal injection. Brunner et al. (1989) also reported that intraperitoneal administration of CDDs and CDFs revealed a delayed absorption from the abdominal cavity that varied for the different congeners. Therefore, concentrations measured in abdominal adipose tissue after intraperitoneal administration may not represent average values of adipose tissue in the whole body, particularly at early time points following exposure. This may also be true following oral exposure because of different perfusion rates of different fat depots (McKinley et al., 1993).

1.2. DISTRIBUTION

1.2.1. Distribution in Blood and Lymph

Once a compound is absorbed, its distribution is regulated initially by its binding to components in blood and its ability to diffuse through blood vessels and tissue membranes.

Lakshmanan et al. (1986) investigated the absorption and distribution of TCDD in thoracic duct-cannulated rats. The results suggest that after gastrointestinal absorption, TCDD is absorbed primarily by the lymphatic route and is transported predominantly by chylomicrons. Ninety percent of the TCDD in lymph was associated with the chylomicron fraction. The plasma disappearance of TCDD-labeled chylomicrons followed first-order decay kinetics, with 67% of the compound leaving the blood compartment very rapidly ($t_{½}$=0.81 minutes), whereas the remainder of the TCDD had a $t_{½}$ of 30 minutes. TCDD was then found to distribute primarily to the adipose tissue and the liver.

In vitro studies have investigated the distribution of TCDD in human whole blood. Henderson and Patterson (1988) found ~80% of the compound associated with the lipoprotein fraction, 15% associated with protein (primarily human serum albumin), and 5% associated with cellular components. A subsequent in vivo investigation reported a similar distribution of TCDD in the various fractions of human whole blood (Patterson et al., 1989). Theoretical and limited experimental data also suggest that TCDD and related compounds may be associated with plasma prealbumin (McKinney et al., 1985; Pedersen et al., 1986). The distribution of [^{3}H]-2,3,7,8-TCDD among lipoprotein fractions from three fasting, normolipemic donors indicated a greater percentage associated with LDL (55.3% ± 9.03% SD) than with VLDL (17.4% ± 9.07% SD) or HDL (27.3% ± 10.08% SD). The distribution of TCDD among the lipoprotein fractions was similar to that reported earlier by Marinovich et al. (1983). When the binding of TCDD was calculated per mole of lipoprotein, it was suggested that the maximal binding capacity was exerted by VLDL, followed by LDL and HDL (Marinovich et al., 1983). The results also suggest that variations in the amounts of each lipoprotein class may alter the distribution of TCDD among lipoproteins in a given subject. Significant species differences also exist; in the case of the rat, which has markedly lower plasma lipids compared to humans, TCDD was distributed almost equally among the lipoprotein fractions (Marinovich et al., 1983).

Congener-specific differences have been observed for the in vivo binding of the 2,3,7,8-substituted PCDDs and PCDFs to different serum fractions in human blood (Patterson et al., 1989). Binding to the lipoproteins gradually decreased with increasing chlorine content, with about 75% of TCDD bound to lipoproteins while approximately 45% of OCDD was bound to this fraction. In contrast, binding to other serum proteins increased with chlorine content, from approximately 20% for TCDD to 50% for OCDD. The results indicate that the higher chlorinated PCDDs and PCDFs do not partition according to the lipid content of these blood fractions. However, Busbee and Zipring (1994) report that at least one lower chlorinated PCB, dichlorobiphenyl, absorbs and distributes with the nonlipid plasma fractions, rather than the lipid fractions as might be expected.

In addition, there is indirect evidence that suggests that the binding of TCDD to lipoproteins may alter the pharmacokinetics and toxic potency of the compound. Marinovich et al. (1983) found that experimentally induced hyperlipidemia in rats delayed the development of overt toxicity (lethality). However, the disposition of TCDD was not investigated under these conditions. These investigators suggest that the release of lipoprotein-bound TCDD is related to the metabolic turnover of lipoproteins. In hyperlipidemic rats, the turnover of VLDL and LDL is delayed significantly compared to that in normolipidemic animals, and this may contribute to the plasma lipoprotein binding modifying the toxicity of TCDD in hyperlipidemic rats.

The time- and temperature-dependent cellular uptake of lipoprotein-associated TCDD by cultured human fibroblasts was greatest from LDL, intermediate from HDL, and least from serum (Shireman and Wei, 1986). Decreased cellular uptake of LDL and TCDD was observed in mutant fibroblasts, which lack the normal cell membrane receptor for LDL. This provides some evidence that specific binding of LDL and the LDL receptor pathway may account for some of the rapid early uptake of TCDD with LDL entry. The results suggest that the entry of TCDD into cells may not be solely by simple diffusion. However, nonspecific binding of the LDL and transfer of TCDD from LDL to the cell membranes are probably also important, as significant time- and temperature-dependent uptake of TCDD and LDL occurred in the mutant fibroblasts.

Thus, upon absorption, TCDD and probably related compounds are bound to chylomicrons, lipoproteins, and other serum proteins that assist in distributing these uncharged, lipophilic compounds throughout the vascular system. These compounds then partition from blood components into cellular membranes and tissues, probably largely by passive diffusion. In addition, cellular uptake may be facilitated partly through the cell membrane LDL receptor, the hepatic receptor for albumin (Weisiger et al., 1981), and other systems.

1.2.2. Tissue Distribution

Once absorbed into blood, TCDD and related compounds readily distribute to all organs. Tissue distribution within the first hour after exposure parallels blood levels and reflects physiological parameters such as blood flow to a given tissue and relative tissue size. For example, high initial concentrations of TCDD, 1,2,3,7,8-PeCDF, and 3,3′,4,4′-TCB were observed in highly perfused tissue such as the adrenal glands during the 24-hour period after a single exposure (Birnbaum et al., 1980; Olson et al., 1980; Pohjanvirta et al., 1990; Brewster and Birnbaum, 1988; Durham and Brouwer, 1990). A high percentage of the dose of 2,3,7,8-TCDF and 1,2,3,7,8-PeCDF was also found in muscle within the first hour after intravenous exposure because of the large volume of this tissue (Birnbaum et al., 1980; Birnbaum, 1985; Brewster and Birnbaum, 1988). Nevertheless, within several hours the liver, adipose tissue, and skin become the primary sites of disposition, when expressed as percent of administered dose per gram tissue

and as percent of dose per organ. Liver, adipose tissue, skin, and thyroid were the only tissues to show an increase in the concentration of TCDD during the initial 4 days after a single intra peritoneal exposure of rats (Pohjanvirta et al., 1990). In this study, a similar general pattern of disposition was observed in Han/Wistar and Long-Evans rats, which are, respectively, most resistant and susceptible to the acute toxicity of TCDD (Pohjanvirta et al., 1990).

Table 1-4 illustrates the tissue distribution of TCDD in female Wistar rats 7 days after a single subcutaneous exposure (Abraham et al., 1988). This general pattern of distribution is similar to that observed in mice, rats, rhesus monkeys, hamsters, and guinea pigs, where liver and adipose tissue consistently have the highest concentrations of TCDD (Piper et al., 1973; Fries and Marrow, 1975; Rose et al., 1976; Allen et al., 1975; van Miller et al., 1976; Kociba et al., 1978a,b; Gasiewicz et al., 1983b; Manara et al., 1982; Olson et al., 1980; Gasiewicz and Neal, 1979; Birnbaum, 1986; Pohjanvirta et al., 1990; Abraham et al., 1988). A similar pattern of disposition also was observed for 2,3,7,8-TCDF in the guinea pig, rat, C57BL/6J and DBA/2J mouse, and rhesus monkey, with 2,3,7,8-TCDF concentrations highest in liver and adipose tissue (Decad et al., 1981b; Birnbaum et al., 1980, 1981). In summary, there do not appear to be major species or strain differences in the tissue distribution of TCDD and 2,3,7,8-TCDF, with the liver and adipose tissue being the primary disposition sites. For the PCBs, Ness et al. (1994) provide evidence of accumulation of PCB congeners in rat brain. Dams were dosed with Aroclor 1242 and pups from litters were euthanized at weaning. No differences in PCB concentrations between sexes or among brain regions were found, but the different congeners differed from each other in degree of bioaccumulation.

The tissue distribution of the coplanar PCBs and PBBs also appears to be similar to that of TCDD and 2,3,7,8-TCDF. Limited studies in rats and mice found that 3,3′,4,4′-TCB, 3,3′,4,4′-TBB, and 3,3′,4,4′,5,5′-HxBB distributed preferentially to adipose tissue and liver (Clarke et al., 1983, 1984; Millis et al., 1985; Wehler et al., 1989; Clevenger et al., 1989). Lindenau et al. (1994) studied the distribution of PCBs in the reproductive tissues of female rabbits after long-term low-dose exposures. Chlorinated hydrocarbons were found to accumulate especially in oviductal and uterine tissues and in follicular and uterine fluids.

Although the liver and adipose tissue contain the highest concentrations of TCDD and 2,3,7,8-TCDF, there are some congener-specific differences in the relative tissue distribution of related compounds. 2,3,7,8-TBDD and 1,2,3,7,8-PeCDD disposition in the rat was very similar to that of TCDD (Kedderis et al., 1991a; Wacker et al., 1986). The hepatic concentration of OCDD and 2,3,4,7,8-PeCDF in the rat, however, was approximately 10- to 20-fold greater than that in adipose tissue, which generally contains the second highest levels of these compounds (Birnbaum and Couture, 1988; Norback et al., 1975; Williams et al., 1972; Brewster and Birnbaum, 1987). The tissue distribution of a defined mixture of CDDs and CDFs (28.8 μg

CDDs+CDFs/kg bw containing 120 ng TCDD/kg bw) was measured in marmoset monkeys 7 days after a single subcutaneous exposure (Abraham et al., 1990). For most of the 2,3,7,8-substituted congeners, the highest concentrations were detected in hepatic and adipose tissue, with correspondingly lower values detected in kidney, brain, lung, heart, thymus, or testes. The hepatic and adipose tissue concentrations were similar for TCDD, 1,2,3,7,8-PeCDD, 2,3,7,8-TCDF, and 1,2,3,7,8-/1,2,3,4,8-PeCDF. Nonetheless, the hepatic concentrations were approximately tenfold or more greater than those of adipose tissue for 1,2,3,4,7,8-HxCDD, 1,2,3,6,7,8-HxCDD, 1,2,3,7,8,9-HxCDD, 1,2,3,4,6,7,8-HpCDD, OCDD, 2,3,4,7,8-PeCDF, 1,2,3,4,7,8-/1,2,3,4,7,9-HxCDF, 1,2,3,6,7,8-HxCDF, 1,2,3,7,8,9-HxCDF, 2,3,4,6,7,8-HxCDF, 1,2,3,4,6,7,8-HpCDF, 1,2,3,4,7,8,9-HpCDF, and OCDF. The lungs and thymus contained higher concentrations of all of these congeners than were detected in kidney, brain, heart, and testes. Unexpectedly, the concentrations of these HxCDDs, HpCDDs, OCDD, and HxCDFs were similar in the adipose tissue, lungs, and thymus. In the case of HpCDFs and OCDF, the concentrations were greater in the lungs than in the adipose tissue. The enhanced disposition of highly chlorinated congeners to the lungs and thymus is of interest and deserves further investigation. For example, it is possible that the high concentration in the lungs could be related to the insolubility of these compounds. Further, Diliberto et al. (1995) report that in mice, the ratio of liver to adipose tissue concentration of TCDD changes with dose. As the dose increases, the adipose (and other nonhepatic tissues) tissue dose/g decreases while it increases in the liver. Section 1.2.5 of this document discusses induction of hepatic cytochrome P-450 1A2 (CYP1A2) as the primary factor responsible for the hepatic sequestration of TCDD and related compounds.

It is also to be expected that exposure to a mixture of these compounds can cause effects in the uptake and distribution. Darnerud et al. (1993) report on the effects of pretreatment of various PCBs on the hepatic uptake of 2,3,7,8-TCDF in mice. After a 4-hour pretreatment, several mono- and di-ortho PCB congeners and Aroclor 1254 increased the hepatic uptake of TCDF. Non-ortho congeners decreased the uptake of TCDF. At longer pretreatment times (48 hours), both non-ortho and mono-ortho PCBs increased the hepatic uptake of TCDF. These studies illustrate the complexity of the pharmacokinetics of mixtures.

Whole-body autoradiography of mice and rats after intravenous administration of [^{14}C]-2,3,7,8-TCDD showed a selective localization of radioactivity in the liver and nasal olfactory mucosa (Appelgren et al., 1983; Gillner et al., 1987). The selective localization of TCDD in the nasal olfactory mucosa was apparently overlooked by other distribution studies that only examined selected organs. Gillner et al. (1987) found no TCDD-derived radioactivity in the olfactory mucosa after solvent extraction of sections, suggesting that TCDD was not covalently bound in this tissue. In addition, Gillner et al. (1987) reported induction of mRNA coding for P-4501A2 (CYP1A2) in the absence of P-4501A1(CYP1A1) induction in olfactory mucosa of rats.

The selective distribution of 2,3,7,8-TCDD in the liver and olfactory mucosa correlates with the tissue-specific localization of CYP1A2, which represents a potential sequestration (binding) protein (see Section 1.2.5). Increases in the incidence of squamous cell carcinoma of nasal turbinates and carcinoma of the liver were observed in rats after a 2-year exposure to TCDD in rat chow (Kociba et al., 1978a); however, this effect was not observed in nasal tissues of mice or rats intubated with TCDD.

Evidence has also been reported that suggests that TCDD uptake and retention by the liver is dependent on the cell type within the liver. Hakansson et al. (1989) found that at 4 days after exposure of rats to TCDD, 60% of the dose distributed to hepatocytes and 12% was retained by stellate cells. Half-lives for TCDD in hepatocytes and stellate cells were calculated to be 13 and 50 days, respectively, suggesting that TCDD is more persistent in nonparenchymal cells. The induction of CYP1A2 in hepatocytes is the primary factor responsible for the hepatic sequestration of TCDD and related compounds (see Section 1.2.5 of this document).

1.2.2.1. *Tissue Distribution in Humans*

Fachetti et al. (1980) reported tissue concentrations of TCDD at levels of 1-2 ng/g in adipose tissue and pancreas, 0.1-0.2 ng/g in the liver, and ≤0.1 ng/g in thyroid, brain, lung, kidney, and blood in a woman who died 7 months after potential exposure to TCDD from the Seveso accident. This pattern of TCDD distribution, however, may not be representative for humans because the woman at the time of death had an adenocarcinoma (which was not considered related to the accident) involving the pancreas, liver, and lung.

Ryan et al. (1985a) examined the distribution of TCDD in two humans at autopsy. They determined on a weight basis that TCDD distributed in descending order to fat (~6 ppt) and liver (~2 ppt), with levels in muscle and kidney below detection; however, TCDD levels compared on a per lipid basis were similar between tissues. These data should be interpreted with caution because only two subjects were examined and one of the subjects was suffering from fatty liver syndrome; therefore, the data cannot be generalized to the entire population.

Poiger and Schlatter (1986) estimated that ~90% of the body burden of TCDD was sequestered in the fat after a volunteer ingested [^{3}H]-2,3,7,8-TCDD in corn oil at a dose of 1.14 ng/kg. During this 135-day study, elevated radioactivity was detected in the blood only during the first 2 days after treatment. The data would be consistent with the high lipid bioconcentration potential of TCDD in humans, as calculated by Geyer et al. (1986) from daily intake assumptions, levels in human adipose tissue, and pharmacokinetic models. Geyer et al. (1986) estimated a BCF of between 104 and 206 for TCDD in human adipose tissue.

In human adipose tissue, levels of TCDD averaging 5-10 ppt have been reported for background populations in St. Louis, Missouri, by Graham et al. (1986), in Atlanta and Utah by

Patterson et al. (1986), and in Canada by Ryan et al. (1985b). Sielken (1987) evaluated these data and concluded that the levels of TCDD in human adipose are log-normally distributed and positively correlated with age. Among the observed U.S. background levels of TCDD in human adipose tissue, more than 10% were >12 ppt.

Patterson et al. (1987) developed a high-resolution gas chromatographic/high-resolution mass spectrometric analysis for TCDD in human serum. The arithmetic mean of the individual human serum samples was 47.9 ppt on a whole-weight basis and 7.6 ppt on a lipid-weight basis. Paired human serum and adipose tissue levels of TCDD have been compared by Patterson et al. (1988), Kahn et al. (1988), and Schecter et al. (1990a). All three laboratories reported a high correlation between adipose tissue and serum TCDD levels when the samples were adjusted for total lipid content. This correlation indicates that serum TCDD is a valid estimate of the TCDD concentration in adipose tissue.

Congener-specific partitioning of 2,3,7,8-substituted PCDDs and PCDFs between adipose tissue and plasma lipids has also been reported in a study of 20 Massachusetts Vietnam veterans (Schecter et al., 1990b). The distribution ratio between plasma lipid and adipose tissue increased with chlorine substitution on the PCDDs and PCDFs. Whereas 2,3,7,8-substituted TCDD, TCDF, PeCDD, PeCDF, HxCDD, and HxCDF had a plasma lipid-to-adipose tissue ratio of about 1.0, OCDD had a ratio of 2.0. On the other hand, whole blood PCDDs and PCDFs seem to be found at the same concentrations as in adipose tissue on a lipid basis (Schecter, 1991).

The disposition of 2,3,7,8-substituted PCDDs and PCDFs in human liver and adipose tissue was assessed in a study of 28 people from the Munich area (Thoma et al., 1989; 1990). Table 1-5 summarizes these results, which are expressed both on a lipid and wet-weight basis. The concentrations of PCDDs and PCDFs in adipose tissue and liver are not the same when calculated on a lipid basis. This is in contrast to the high correlation that was reported between adipose tissue and serum TCDD levels when expressed on a lipid-weight basis (Patterson et al., 1988; Kahn et al., 1988; Schecter et al., 1990a). Furthermore, the liver/adipose tissue ratio increased with the higher chlorinated PCDDs and PCDFs. The congener-specific hepatic disposition is also similar to that observed in rats and marmoset monkeys exposed to a complex mixture of PCDDs and PCDFs (Abraham et al., 1989b; Neighbored et al., 1990). Therefore, it is important to consider congener- and tissue-specific differences in disposition of PCDDs and PCDFs when blood levels are used to estimate tissue levels or body burdens.

Schecter et al. (1998a) assessed the disposition of PCDDS, CDFS, and coplanar PBS in the blood, milk, adipose tissue, placenta, and cord blood from five American women. When expressed on a pg/g lipid basis, the mean total TEQs were 11.6, 12.1, 10.5, 5.8, 10.0, and 10.2 in adipose tissue, predelivery blood, placenta, cord blood, postpartum blood, and breast milk, respectively. The results suggest that CDDs, CDFs, and PCBs, when expressed as total TEQs on

a lipid basis, partition to a similar extent between these tissues. Even though 2,3,4,7,8-PeCDF and PCB 126 were lower in cord blood than other tissues, the levels of TCDD were similar in these tissues.

In a study of potentially heavily exposed Vietnam veterans, MMWR (1988) reviewed an Air Force study of Ranch Hand veterans who were either herbicide loaders or herbicide specialists in Vietnam. The mean serum TCDD levels of 147 Ranch Hand personnel was 49 ppt in 1987, based on total lipid weight, while the mean serum level of the 49 controls was 5 ppt. In addition, 79% of the Ranch Hand personnel and 2% of the controls had TCDD levels $\geq$10 ppt. The distribution of TCDD levels in this phase of the Air Force health study indicates that only a small number of Ranch Hand personnel had unusually heavy TCDD exposure. Similar results were obtained by Kahn et al. (1988), who compared TCDD levels in blood and adipose tissue of Agent Orange-exposed Vietnam veterans and matched controls (Kahn et al., 1988). This study also examined moderately exposed Vietnam veterans who handled herbicides regularly while in Vietnam. Although this study can distinguish moderately exposed men from others, the data do not address the question of identifying persons whose exposures were relatively low and who constitute the bulk of the population, both military and civilian, that may have been exposed to greater than background levels of TCDD.

1.2.3. Time-Dependent Tissue Distribution

2,3,7,8-TCDD and related compounds exhibit congener-specific disposition, which depends on tissue, species, and time after a given exposure. In general, these compounds are cleared rapidly from the blood and distributed to liver, muscle, skin, adipose tissue, and other tissues within the first hour(s) after exposure. This is followed by redistribution to the liver and adipose tissue, which exhibit increasing tissue concentrations over several days after exposure. Elimination from tissues then occurs at rates that are congener-, tissue-, and species-specific. Thus, the ratio of the concentration of TCDD and related compounds in different tissues (i.e., liver/adipose) may not remain constant over an extended period after a single exposure. Abraham et al. (1988) examined the concentrations of TCDD in liver and adipose tissue of female Wistar rats over a 91-day period after a single subcutaneous exposure at a dose of 300 ng/kg bw (Figure 1-1). The maximum concentration of TCDD in the liver and adipose tissue was reached at 3 and 7 days after exposure, respectively. The liver/adipose tissue concentration ratio does not remain constant over time because the concentration of TCDD decreases more rapidly in the liver than in the adipose tissue. For example, the liver/adipose tissue concentration ratio (for TCDD) was 10.3 at 1 day after exposure and 0.5 at 91 days after exposure (Figure 1-1). Results from other disposition studies also indicate that the ratio of the concentration of TCDD and related compounds in liver, adipose tissue, and other tissues does not remain constant over

an extended period after a single exposure (Pohjanvirta et al., 1990; Birnbaum, 1986; Birnbaum et al., 1980; Decad et al., 1981a; Birnbaum and Couture, 1988; Olson et al., 1980; Kedderis et al., 1993a; Brewster and Birnbaum, 1987, 1988; Neubert et al., 1990). This relationship is important in attempting to correlate dose-response data with tissue concentrations of TCDD and related compounds.

In an attempt to maintain constant TCDD levels in tissues to study long-term effects, Krowke et al. (1989) investigated several loading-dose/maintenance-dose exposure regimens. They found that similar liver/adipose tissue concentrations ranging from 5 to 8 could be maintained in rats over a 22-week period with a loading dose of 25 μg/kg followed by weekly maintenance doses of 5 μg/kg.

A large body of data on the tissue concentrations of TCDD and related compounds over time after exposure can be evaluated by estimating congener-specific half-life values for a given tissue and species. Table 1-6 summarizes pharmacokinetic elimination parameters for TCDD and related compounds from major tissue depots. Data from Abraham et al. (1988) (see Figure 1-1) were used to estimate the half-life for TCDD in the liver and adipose tissue of rats (Table 1-6). The decrease in the TCDD concentration in adipose tissue is a linear function in the semilogarithmic plot in Figure 1-1 (log concentration versus time), which indicates apparent first-order elimination kinetics with a half-life of 24.5 days (Table 1-6). Liver tissue exhibits a biphasic (two-component) exponential decay pattern, with a half-life of 11.5 days for the first component (days 10-49) and a half-life of 16.9 days for the second component (days 49-91) (see Figure 1-1 and Table 1-6). Santostefano et al. (1997) reported a similar half-life of approximately 10 days in female Sprague-Dawley rats administered a 10 μg/kg oral dose of TCDD/kg. Results of Abraham et al. (1988) and Lakshmanan et al. (1986) indicate that in the rat, TCDD is more persistent in the adipose tissue than in the liver. This is in contrast to the mouse, where liver and adipose tissue have similar half-lives (Birnbaum, 1986). TCDD is exceptionally persistent in the adipose tissue of the rhesus monkey, with a half-life approximately ten- to fortyfold greater than that observed in the rat and mouse (Bowman et al., 1989). Thus, the relative persistence of TCDD is tissue-specific and exhibits marked interspecies variability.

Most of the pharmacokinetic data on the relative persistence of other congeners in Table 1-6 have been reported in rat studies, which limits interspecies comparisons. Results in the rat suggest that the distribution and elimination of 2,3,7,8-TBDD from tissue are similar to those of 2,3,7,8-TCDD. The most persistent congeners are OCDD, 2,3,4,7,8-PeCDF, and 1,2,3,6,7,8-HxCDF, which distribute almost entirely to the liver. OCDD and 2,3,4,7,8-PeCDF also exhibit similar elimination kinetics, with a relative half-life in the liver more than twofold greater than that in adipose tissue. The least persistent congeners are 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, and 3,3′,4,4′-TCB. These congeners exhibit similar elimination kinetics in the rat, with half-lives in

the adipose tissue greater than those in liver. The relative tissue distribution of these congeners varies, however, with 2,3,7,8-TCDF and 1,2,3,7,8-PeCDF distributing primarily to the liver while 3,3′,4,4′-TCB distributes predominantly to the adipose tissue.

Viluksela et al. (1997) conducted a subchronic/chronic toxicity study with 1,2,3,4,6,7,8-HpCDD (13 weeks of dosing, 13 week off-dosing) in Sprague-Dawley rats. Liver concentrations during the study provided a hepatic half-life estimate for 1,2,3,4,6,7,8-HpCDD of 237 days in male rats and 314 days in female rats. Under similar exposure conditions, TCDD had half-lives of 12.4 and 15.8 days in male and female rats, respectively. Liver concentrations of CDDs were also assessed in a subchronic/chronic toxicity study in rats administered a mixture of 2,3,7,8-TCDD, 1,2,3,7,8-PeCDD, 1,2,3,4,7,8-HxCDD, and 1,2,3,4,6,7,8-HpCDD orally in corn oil (13 weeks of dosing, 13 weeks of off-dosing) (Viluksela et al., 1998). Average liver half-lives were 14.5, 29.3, 45.6, and 100 days, respectively, in males and 17.8, 38.2, 63.3, and 195.8 days, respectively, in females. When administered individually, 1,2,3,4,7,8-HxCDD had liver half-lives of 36.2 days in males and 55.5 days in females and 1,2,3,7,8-PeCDD had a liver half-life of 36.1 days in male rats. Together, these results indicate that CDDs are more persistent in female rats and that the hepatic half-life of these compounds is similar following exposure to individual CDDs and mixtures of CDDs.

The experimental tissue distribution and elimination data in Table 1-6 were obtained after exposure to a single congener, but real-world exposure to TCDD and related compounds occurs as a complex mixture of congeners. Neubert et al. (1990) examined the persistence of various CDDs and CDFs in hepatic and adipose tissue of male and female marmoset monkeys. Animals received a single subcutaneous exposure to a defined CDD/CDF mixture (total dose of 27.8 μg/kg bw), which contained 0.12 μg 2,3,7,8-TCDD/kg bw. Using the international toxicity equivalency (I-TE) factors (NATO, 1988; U.S. EPA, 1989), the total administered dose corresponded to 0.464 μg I-TE/kg bw. The concentrations of specific congeners in liver and adipose tissue were measured at 1, 6, 16, or 28 weeks after exposure, and elimination constants and half-lives were estimated assuming first-order kinetics (Table 1-7). Data in Table 1-7 were determined from pregnant and nonpregnant female and male marmosets (total of 12 animals), because no obvious differences in tissue concentrations were observed among these groups. All 2,3,7,8-substituted CDDs and CDFs were consistently more persistent in the adipose tissue than in the liver of marmoset monkeys. In general, the persistence in adipose tissue was from ~1.3- to 2.0-fold greater than that in liver, with the exception of 1,2,3,4,7,8-/1,2,3,4,7,9-HxCDF, HpCDFs, and OCDF, which were even more persistent in adipose tissue. For the latter congeners and OCDD, there was marked variance in half-life values, which may be due to delayed and incomplete absorption of the exceptionally persistent congeners and the relatively short (28 weeks) period of investigation. A significant species difference exists for OCDD and

2,3,4,7,8-PeCDF, which, in contrast to the results in the marmoset monkey, was found to be more persistent in the liver of the rat, with half-lives more than twofold greater than that in adipose tissue (Birnbaum and Couture, 1988; Brewster and Birnbaum, 1987) (see Table 1-6). Further comparison of tissue elimination data in the rat (Table 1-6) and monkey (Table 1-7) indicates that 2,3,7,8-TCDD, OCDD, 2,3,7,8-TCDF, 1,2,3,6,7,8-HxCDF, and 2,3,4,7,8-PeCDF (adipose tissue only) are more persistent in the marmoset monkey than in the rat. The exception to this relationship is 2,3,4,7,8-PeCDF, which is more persistent in rat liver compared to the monkey.

The exposure of marmoset monkeys to a complex mixture of CDDs and CDFs included exposure to both 2,3,7,8- and non-2,3,7,8-substituted congeners (Neubert et al., 1990). One week after exposure to this complex mixture, the non-2,3,7,8-substituted CDDs and CDFs were present in liver and adipose tissue in relatively minor quantities when compared with 2,3,7,8-substituted congeners; however, non-2,3,7,8-substituted compounds represented a considerable percent of the exposure mixture. In this study, none of the non-2,3,7,8-substituted TCDDs, PeCDDs, TCDFs, or PeCDFs could be detected in the liver. Some of the hexa- and hepta-congeners were detected in adipose tissue and liver, but after 1 week, the total amount in the liver was >5% of the administered dose only in the case of 1,2,4,6,8,9-HxCDF. Similar results were obtained in rats after exposure to a defined, complex mixture of CDDs and CDFs (Abraham et al., 1989c). Additional short-term studies in rats provide evidence that the low tissue concentrations of non-2,3,7,8-substituted congeners, measured 1 week after exposure, were the result of rapid elimination, as these congeners were detected at higher levels in the liver 13 to 14 hours after exposure (Abraham et al., 1989d). These results in monkeys and rats are compatible with data from analysis of human tissue samples and milk, in which the non-2,3,7,8-substituted congeners have also not been shown to be present in significant concentrations when compared with the 2,3,7,8-substituted congeners (Schecter et al., 1985, 1986; Ryan, 1986; Rappe et al., 1986; Beck et al., 1987, 1989; Thoma et al., 1989).

Several human studies also show the importance of time dependence and age on tissue distribution within the body. Duarte-Davidson and Jones (1994) reported that in a population in the United Kingdom adipose tissue concentrations of PCBs increased at a slower rate as age increased. The researchers attributed this to the dilution effect caused by the increase in body fat with age. Wolfe et al. (1994) reported similar findings with TCDD. They found significant increases in half-life with increases in percent body fat and with age. As will be discussed in a later section, body burden levels could also be decreasing with time because of reduced exposure levels (Furst et al., 1994).

Other recent studies also show that age is an important factor affecting distribution of these compounds within the body. Pegram et al. (1995) show that the hepatic concentration of

TCDD was about 25% greater in young mice than in old mice. No age-related differences in nuclear TCDD concentration was found in the liver fat tissue concentration ratios, adipose tissue, or blood concentrations. In old mice kidney, skin, and muscle concentrations were about twofold higher than in younger mice at a dose of 15 μg/kg. The authors suggest that these age-related differences represent differences in Ah receptor-mediated enzyme induction.

A potential problem of tissue distribution and elimination studies after exposure to a complex mixture of CDDs and CDFs is the possible interaction of the mixture during the uptake and elimination of specific congeners from tissues. A similar hepatic distribution (~25% of dose) and liver/adipose tissue concentrations ratio (~2) for TCDD were observed in rats 7 days after exposure to TCDD (100 ng/kg bw) when the compound was administered alone or in combination with a large amount of other CDDs/CDFs (total 23,222 ng/kg bw) (Abraham et al., 1988, 1989d). This suggests that under these experimental conditions, the tissue distribution of TCDD was not altered when the exposure included a complex mixture of CDDs/CDFs. van den Berg et al. (1989) studied the hepatic disposition and elimination of CDFs administered individually (see Table 1-6) and as mixtures. Co-administration of 1,2,3,7,8- and 2,3,4,7,8-PeCDF resulted in 46% of the dose of 1,2,3,7,8-PeCDF distributing to the liver, while 70% was distributed to the liver after administration of the single-compound (see Table 1-6). Nevertheless, this combined exposure did not alter the rate of elimination of 1,2,3,7,8-PeCDF from the liver. Co-administration of 2,3,4,7,8-PeCDF and 1,2,3,6,7,8-HxCDF did not alter the hepatic uptake of either congener or the hepatic elimination of 2,3,4,7,8-PeCDF but increased the hepatic half-life of 1,2,3,6,7,8-HxCDF to 156 days from the single-compound exposure half-life of 73 days (see Table 1-6). However, these values must be considered rough estimates because the experimental period of 42 days was too short to calculate half-lives accurately. Although there are few investigations of potential interactions of mixtures of CDDs and CDFs on the uptake and elimination of individual congeners, the limited available data suggest that exposure to complex mixtures (see Table 1-7) may alter the tissue disposition of individual congeners.

Several studies have investigated potential pharmacokinetic interactions following exposure to two or more PCDDs, PCDFs, or PCBs (DeJongh et al., 1992, 1993a, 1993b, van Birgelen et al., 1996a). Interactive effects on the hepatic disposition of these compounds may in some cases explain, in part, the potentiation and antagonistic effects on CYP1A1/1A2 activities observed with combined exposure to some of these compounds. In the case of 1,2,3,7,8-PeCDD and 2,4,5,2′,4′,5′-HxCB, no pharmacokinetic bases were found to explain the antagonistic effects of the combined exposure on CYP1A1/1A2 activities in mice (DeJongh et al., 1992). In a subsequent study the hepatic disposition of 1,2,3,7,8-PeCDD in mice was increased with combined exposures to 1,2,3,6,7,8-HxCDD, 2,3,4,7,8-PeCDF, and/or 2,4,5,2′,4′,5′ HxCB (De Jongh et al., 1993b).

De Jongh et al. (1995) report that TCDD co-administration with 2.2',4,4'5,5'-hexachlorobiphenyl (HxCB) in mice results in an increased disposition of TCDD in the liver. At the same time, the results do not show any effect of the TCDD on the HxCB disposition. The distribution of TCDD (0, 0.1, 1.0, or 10 μg/kg) and/or 2.2',4,4',5,5'-hexachlorobiphenyl (PCB 153; 0, 3.58, 35.8, or 358 mg/kg) were investigated alone and in all possible combinations of these doses following oral administration in corn oil to female B6C3F1 mice (van Birgelen et al., 1996b). Coadministration of the low doses of TCDD and PCB 153 had little or no effect on the distribution of either compound. Interactive effects on the pharmacokinetic behavior occurred only at high doses. For example, the hepatic disposition of TCDD increased when it was administered in combination with the highest dose of PCB 153. Although there is evidence that PCDDs, PCDFs, and PCBs may influence each other's pharmacokinetics when administered in mixtures, this area needs investigation.

1.2.4. Dose-Dependent Tissue Distribution

Recent evidence suggests that the tissue distribution of TCDD and related compounds is dose-dependent. Abraham et al. (1988) investigated the distribution of TCDD in liver and adipose tissue of rats 7 days after a single subcutaneous exposure to TCDD at doses of 1-3,000 ng/kg bw. More than 97% of the administered TCDD was absorbed at all doses, with the exception of the 3,000 ng/kg group, where 84% of the dose was absorbed. Figure 1-2 illustrates the dose-dependent disposition of TCDD in liver and adipose tissue (% dose/g) 7 days after exposure. A sharp increase in TCDD concentration in liver was observed at exposure levels >10 ng/kg bw. Disposition in the liver increased from ~11% of the administered dose at an exposure level of 1-10 ng/kg bw to ~37% of the dose at an exposure level of 300 ng/kg bw. The increase in distribution to the liver was accompanied by a dose-related decrease in the concentration of TCDD in the adipose tissue. As a result, the liver/adipose tissue concentration ratio for TCDD at 7 days after exposure increased with increasing doses, starting at an exposure level of 30 ng/kg bw (Table 1-8). Thus, the tissue-specific disposition of TCDD is regulated by a complex relationship, which includes species, time after a given exposure, and dose (see Figures 1-1 and 1-2; Tables 1-6 and 1-7).

Other studies on the tissue disposition of TCDD and related compounds report similar dose-dependent behavior with disproportionately greater concentrations in the liver at high doses compared with low doses. Poiger et al. (1989) observed a dose-related increase in distribution to the liver (% of dose/liver) and an increase in the liver/adipose tissue concentration ratio for 2,3,7,8-TCDD, 2,3,4,7,8-PeCDF, 1,2,3,7,8-PeCDF, and 1,2,3,6,7,8-HxCDF in the rat. Kedderis et al. (1991a) also observed a dose-related increase in hepatic disposition (1.27% versus 10.05% of dose/liver) and an increase in the liver/adipose tissue concentration ratio (0.16 versus 2.59) for

2,3,7,8-TBDD at 56 days after exposure at doses of 0.001 and 0.1 μmol/kg bw, respectively. In a related study, pretreatment of mice with TCDD (5 or 15 μg/kg) produced a dose-related, enhanced hepatic accumulation of a subsequent oral dose of TCDD (Curtis et al., 1990). Diliberto et al. (1993b) also observed a dose-dependent tissue distribution of TCDD in female B6C3F1 mice. In all tissues except the liver, the relative percent of the total dose of TCDD decreased while it increased in the liver with higher doses. Similarly, a dose-related increase in hepatic uptake of [^{125}I]-2-iodo-3,7,8-trichlorodibenzo-p-dioxin was observed after pretreatment of mice with TCDD (Poland et al., 1989a; Leung et al., 1990a). Shen and Olson (1987) also observed an increase in the uptake of TCDD by isolated hepatocytes from TCDD-pretreated mice.

Chronic studies also support dose-dependent alterations in the tissue distribution of these compounds. Kociba et al. (1978a,b) found that female rats maintained on a daily dietary TCDD intake of 100 ng for 2 years had an average TCDD content of 8,100 ppt in fat and 24,000 ppt in the liver. Rats given 10 ng/kg/day had an average of 1,700 ppt TCDD in the fat and 5,100 ppt in the liver. For both of these exposures the liver/adipose tissue concentration ratio of TCDD was ~3. At the lowest dose level of 1 ng/kg/day, both fat and liver contained an average of 540 ppt TCDD. Kociba et al. (1976) presented evidence that steady state had been reached by <13 weeks of feeding of TCDD.

Other studies do not support the dose-dependent tissue distribution of TCDD and related compounds described above. Rose et al. (1976) reported a lack of a dose-dependent accumulation of [^{14}C]-TCDD in male and female rat liver and adipose tissue following 7, 21, and 49 days of exposure at 0.01, 0.1, or 1.0 μg/kg/day, Monday through Friday. The rates of accumulation of TCDD-derived radioactivity were similar in fat, liver and whole body; however, the concentration in the liver was about fivefold greater than in fat. Brewster and Birnbaum (1987) also observed similar concentrations (% dose/g) of 2,3,4,7,8-PeCDF in liver, adipose tissue, and other tissues 3 days after oral exposure at doses of 0.1, 0.5, or 1.0 μmol/kg bw. These results conflict with the above studies, which support the dose-dependent tissue distribution of these compounds. An explanation for the lack of a dose-dependent accumulation is that all of the doses administered in the studies of Rose et al. (1976) and Brewster and Birnbaum (1987) were inducing hepatic CYP1A2, which is now known to be primarily responsible for the hepatic sequestration of these compounds (see Section 1.2.5).

The dose-dependent tissue distribution of TCDD and related compounds is a critical factor that must be considered in estimating the concentration of these compounds in human tissues after chronic low-level exposure. This is particularly important because the general human population is exposed to much smaller daily doses (possibly 0.3 pg TCDD/kg/day) than those used in experimental disposition studies. Owing at least partly to the long half-life of

TCDD in humans, however, this exposure results in concentrations of 3-18 pg/g in human adipose tissue (Leung et al., 1990b). Similar levels of TCDD in adipose tissue (14 pg/g) were observed in rats 7 days after subcutaneous exposure to 3 ng/kg bw (see Table 1-8) (Abraham et al., 1988). Under these experimental conditions, the liver/adipose tissue TCDD concentration was 0.74. Nonetheless, steady state was definitely not reached under these conditions, and with increasing time after exposure, this ratio may decrease, based on the observation that TCDD was more persistent in adipose tissue than in liver in rats exposed to 300 ng/kg bw (see Figure 1-1 and Table 1-6) (Abraham et al., 1988). Human data on the liver/adipose tissue concentration ratio of TCDD and related compounds are limited, but suggest that the ratio may vary by at least an order of magnitude between individuals. Leung et al. (1990b) observed a geometric mean adipose tissue TCDD concentration of 7.78 ppt in 26 individuals and a concentration in liver at about one-tenth of that in adipose tissue on a whole-weight basis. When measured on a total lipid basis, the concentrations of TCDD in both tissues were approximately the same. Thoma et al. (1990) reported a liver/adipose tissue TCDD concentration on a wet weight basis of 0.14, whereas on a lipid basis the ratio was 2.05 (Table 1-5). Considerable variability in CDD and CDF concentrations in liver and adipose tissues was also observed between individual marmoset monkeys (Neubert et al., 1990), suggesting that individual variability may also contribute to the difficulty in assigning a constant liver/adipose tissue ratio for CDDs and CDFs in humans and nonhuman primates.

1.2.5. Potential Mechanisms for Dose-Dependent Tissue Distribution

The observation that exposure to higher doses of TCDD and related compounds results in a disproportionately greater hepatic concentration of these compounds may be explained by a hepatic binding species that is induced by TCDD and other agonists for the Ah receptor. The studies of Voorman and Aust (1987, 1989) and Poland et al. (1989a, b) provide evidence that this binding species is CYP1A2.

Poland et al. (1989a, b) reported that TCDD and other Ah agonists (2,3,7,8-TCDF, β-naphthoflavone, 3,3′,4,4′,5,5′-hexabromobiphenyl) act through the Ah receptor to increase a liver binding species that increases the hepatic uptake of [^{125}I]-2-iodo-3,7,8-trichlorodibenzo-*p*-dioxin (a radiolabeled isosteric analogue of TCDD) in vivo and binding of this radioligand to liver homogenate in vitro. Twenty-four hours after the administration of a non-AHH-inducing dose (1×10^{-10} mol/kg) of [^{125}I]-2-iodo-3,7,8-trichlorodibenzo-*p*-dioxin to C576BL/6J mice, the hepatic concentration of radioactivity was 1%-2% of the administered dose, whereas in mice pretreated 48 hours earlier with an AHH-inducing dose of TCDD (1×10^{-7} mol/kg), the hepatic accumulation of radiolabel was 25%-30% of that administered. A similar, though less dramatic, effect was observed in vitro, with liver homogenate from TCDD-treated mice binding about four

times more [^{125}I]-2-iodo-3,7,8-trichlorodibenzo-*p*-dioxin than homogenate from control mice. The administration of TCDD to C57BL/6J mice produced a dose-related stimulation of in vivo hepatic uptake of [^{125}I]-2-iodo-3,7,8-trichlorodibenzo-*p*-dioxin, increased binding of radioligand to liver homogenate, and induction of hepatic activity, with an ED_{50} ranging from 1.5 to 4.0 × 10^{-9} mol/kg. In congenic C57BL/6J (Ah^d/Ah^d) mice, which express the lower affinity Ah receptor, the ED_{50} values for all three responses were shifted to doses that were about tenfold higher. The observed effects on hepatic disposition were tissue-specific, with no remarkable dispositional changes being observed in kidney, lung, spleen, small intestine, or muscle. This is significant in that TCDD and other agonists for the Ah receptor induce CYP1A1 in liver and other tissues, whereas CYP1A2 is apparently inducible only in liver (Tuteja et al., 1985; Gillner et al. 1987). Furthermore, the changes in hepatic disposition were not species-specific; similar responses were observed in guinea pigs, rats, mice, and hamsters (Poland et al., 1989a).

The following evidence reported by Poland et al. (1989b) supports the hypothesis that the TCDD-inducible hepatic binding protein is CYP1A2: the TCDD-induced hepatic binding species was found predominantly in the microsomal fraction and was inactivated by heating at 60°C, trypsin, and mercurials; the TCDD-induced hepatic binding species was specific for the liver, with a large pool size (B_{max} of 22 ± 5 nmol/g liver); the major microsomal binding species covalently labeled with the photoaffinity ligand [^{125}I]-2-iodo-3-azido-7,8-dibromodibenzo-*p*-dioxin migrates with that immunochemically stained with polyclonal antiserum, which binds to CYP1A2.

One observation of Poland et al. (1989a,b) does not support the hypothesis that the TCDD-inducible hepatic protein is CYP1A2. These investigators found that dietary administration of isosafrole did not stimulate hepatic uptake of [^{125}I]-2-iodo-3,7,8-trichlorodibenzo-*p*-dioxin or the in vitro binding of this ligand to liver homogenate. Isosafrole is not an agonist for the Ah receptor, but it selectively induces CYP1A2 (Ryan et al., 1980). Poland et al. (1989a,b) suggest that this may be attributable to the high affinity binding of an isosafrole metabolite to the protein, which might inhibit the binding of [^{125}I]-iodo-3,7,8-trichlorodibenzo-*p*-dioxin to CYP1A2 at or near the active site of the enzyme. This does not explain why TCDD, which also has high affinity for CYP1A2, cannot displace some of the isosafrole metabolite from the protein, which should produce enhanced hepatic disposition of TCDD.

A more recent study used pretreatment with isosafrole to investigate the role of CYP1A2 in the hepatic disposition of TCDD (Kedderis et al., 1993a). Although isosafrole is an inducer of CYP1A2, it also has high affinity for the protein and thus is a selective inhibitor of CYP1A2. A greater than threefold decrease in the hepatic disposition of TCDD in isosafrole-pretreated rats supports the conclusion that TCDD is bound to CYP1A2 in the liver.

Olson et al. (1994) have reported the results of in-vitro studies with isolated hepatocytes and liver slices of rats pretreated with TCDD. Pretreatment increased the uptake of TCDD but not TCDF. There was an increase in both CYP1A1 and CYP1A2. The authors interpret these results as consistent with CYP1A2 being a hepatic binding protein for TCDD but not TCDF.

Voorman and Aust (1987, 1989) support further the hypothesis that CYP1A2 is the TCDD-inducible hepatic binding species. These investigators found that 3,3′,4,4′,5,5′-HxBB, an agonist for the Ah receptor, was associated only with CYP1A2 through the immunoprecipitation of CYP1A1 and 1A2, which were induced in 3,3′,4,4′,5,5′-HxBB-treated rats. In addition, they found that 3,3′,4,4′,5,5′-HxBB inhibited estradiol 2-hydroxylase activity of purified CYP1A2. A similar association of PAHs with immunoprecipitated CYP1A2 was observed for other agonists for the Ah receptor, including TCDD, 3,3′,4,4′-TCB, 3,3′,4,4′,5-PeCB, and 3,3′,4,4′,5,5′-HxCB. The association of TCDD with CYP1A2 occurred within 2 minutes, with maximum inhibition of estradiol 2-hydroxylase occurring at a concentration comparable to the concentration of the enzyme (50 nm). CYP1A2 was inhibited (complexed) by TCDD with nearly 1:1 stoichiometry, and the K_i for TCDD was calculated to be 8 nM. Therefore, TCDD can be considered a higher binding inhibitor of CYP1A2.

Santostefano et al. (1996) assessed the subcellular and tissue-specific disposition of TCDD in rats and mice. TCDD was equally distributed between the hepatic P9 (mitochondrial, lysosomal, and nuclear) and S9 (cytosol and microsomal) fractions, with the microsomal fraction retaining the TCDD present in the S9 fraction. In contrast, TCDD was retained in the P9 fractions of lung and liver at all doses tested. The lack of pulmonary or renal sequestration coupled with the lack of localization of TCDD to pulmonary and renal microsomes supports the role of CYP1A2 as a hepatic microsomal binding protein involved in the hepatic sequestration of TCDD. Recently, Santostefano et al. (1999) assessed the intralobular hepatic distribution of TCDD in rats and observed that centrilobular hepatocytes had a 2.7- to 4.5-fold higher concentration of TCDD than did periportal hepatocytes. The enhanced centrilobular distribution of TCDD was associated with elevated CYP1A2-mediated MROD activity and CYP1A2 mRNA in centrilobular hepatocytes.

The TCDD-induced binding species was found to have an apparent equilibrium dissociation constant, K_D, for [^{125}I]-2-iodo-3,7,8-trichlorodibenzo-*p*-dioxin of 56 ± 16 nM, and a pool size, B_{max}, of 22±5 nmol/g of liver in C57BL/6J mice (Poland et al., 1989b). The induced microsomal binding species has an affinity about 10^4 times less than the Ah receptor but a pool size that is ~2×10^3 greater. Thus, agonists for the Ah receptor may significantly affect their disposition through a dose-related enhancement of hepatic uptake, which should correlate with induction of CYP1A2.

More recently, Diliberto et al. (1997) used transgenic mice lacking the CYP1A2 gene to study the influence of CYP1A2 in the hepatic sequestration and distribution of TCDD, 2,3,4,7,8-PeCDF, and PCB 153 (2,2',4,4',5,5'-HexCB), a non-dioxin-like PCB. The liver/fat concentration ratios of these compounds in the parental lineage (C57BL6N and 129/Sv) were approximately 3.6, 18, and 0.07, respectively, indicating a high degree of hepatic sequestration for TCDD and 2,3,4,7,8-PeCDF. Under identical exposure conditions, the 1A2 knockout mice had liver/fat concentration ratios of 0.17, 0.34, and 0.10, respectively. Thus, in the absence of the CYP1A2 gene, mice exhibited no hepatic sequestration of these compounds. This study and a related study in CYP1A2 knockout mice by Diliberto et al. (1999) provide direct confirmation of the hypothesis that CYP1A2 is the dioxin-inducible hepatic binding protein responsible for the hepatic sequestration of TCDD and related compounds, such as 2,3,4,7,8-PeCDF.

The disposition and pharmacokinetics of 2,2′,4,4′,5,5′-HxCB and -HxBB have been investigated in several species (Tuey and Matthews, 1980; Lutz et al., 1984). These lipophilic compounds are similar to TCDD in that they are slowly metabolized and that metabolism is required for urinary and biliary elimination; however, they do not exhibit dioxin-like activity. 2,2′,4,4′,5,5′-HxCB and -HxBB distribute primarily to adipose tissue, with partition coefficients (tissue/blood ratio) ranging from 300 to 500 in the mouse, rat, monkey, dog, and human. The liver is not a major site for the disposition of 2,2′,4,4′,5,5′-HxCB and -HxBB, in contrast to TCDD and related compounds. Partition coefficients in the liver range from 10 to 30 in these species. 2,2′,4,4′,5,5′-HxCB and -HxBB do not induce hepatic CYP1A1 or 1A2 and do not exhibit dioxin-like activity. The lack of induction of hepatic CYP1A2 may explain the lack of a dose-dependent hepatic disposition of these compounds.

Kedderis et al. (1991b) assessed the dose-response relationship for the induction of hepatic CYP1A1 and 1A2 in male Fischer 344 rats exposed to 2,3,7,8-TBDD at doses as low as 0.1 nmol/kg. They reported that induction of P-4501A2 by 2,3,7,8-TBDD appeared to be a more sensitive response than P-4501A1 induction over the dose range studied. In addition, comparison of hepatic P-4501A2 levels and liver:adipose tissue concentration ratios suggested that induction of P-4501A2 alone would not directly account for the preferential hepatic accumulation of 2,3,7,8-TBDD and that additional factors must be involved. One explanation may be that at low 2,3,7,8-TBDD concentrations, endogenous substrates bind to CYP1A2, not allowing 2,3,7,8-TBDD to be sequestered by the protein (Kedderis et al., 1993b). At higher 2,3,7,8-TBDD concentrations, new protein is formed and 2,3,7,8-TBDD can compete for binding to CYP1A2, resulting in the increased hepatic disposition observed at higher exposures of 2,3,7,8-TBDD (Kedderis et al., 1991b).

The structure-activity relationship for the disposition and hepatic sequestration of CDDs, CDFs, and PCBs was investigated by DeVito et al. (1998). Female B6C3F1 mice were treated

for 13 weeks with different oral doses of 2,3,7,8-TCDD, 1,2,3,7,8-PeCDD, 2,3,7,8-TBDD, 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, 2,3,4,7,8-PeCDF, OCDF, PCB126 (3,3',4,4',5-PeCB), PCB169 (3,3'4,4',5,5'HxCB), PCB105 (2,3,3',4,4' PeCB), PCB118 (2,3',4,4',5-PeCB), and PCB156 (2,3,3',4,4',5-HxCB). All of these compounds exhibited dose-dependent increases in the liver/fat concentration except PCBs 105, 118, and 156. 4-PeCDF, PeCDD, OCDF, TCDF, and PCB126 were sequestered in hepatic tissue to a greater extent than was TCDD. Together, the results support the presence of an inducible protein (CYP1A2) and the congener-specific binding of some dioxin-like compounds to this hepatic sequestration protein.

Other factors may also regulate the intracellular distribution of TCDD and related compounds. The possible role of hepatic lipoproteins as intracellular carriers in the transport of TCDD has been assessed by in vitro and in vivo studies (Souès et al., 1989a,b). TCDD and 2,3,7,8-TCDF were bound to lipoproteins in mouse and rat liver, which subsequently underwent rapid and pronounced degradative processing, possibly catalyzed by lipoprotein lipase, to heavier entities. The in vitro incubation of TCDD-lipoprotein complex with separated Ah receptor demonstrated that a passive transfer occurred. The authors suggest a carrier role for lipoproteins in the intracellular transport of TCDD and related compounds.

1.3. METABOLISM AND EXCRETION

Although early in vivo and in vitro investigations were unable to detect the metabolism of TCDD (Vinopal and Casida, 1973; van Miller et al., 1976), there is evidence that a wide range of mammalian and aquatic species are capable of biotransforming TCDD to polar metabolites (Ramsey et al., 1979, 1982; Poiger and Schlatter, 1979; Olson et al., 1980; Olson, 1986; Gasiewicz et al., 1983a; Poiger et al., 1982; Sijm et al., 1990; Kleeman et al., 1986a,b, 1988). Although metabolites of TCDD have not been directly identified in humans, recent data regarding feces samples from humans in a self-dosing experiment suggest that humans can metabolize TCDD (Wendling et al., 1990).

Table 1-9 summarizes data on the metabolism and excretion of TCDD and related compounds after exposure to a single radiolabeled congener. Investigations of TCDD in rats, mice, guinea pigs, and hamsters found that >90% of the radiolabeled material excreted in urine and bile represented polar metabolites. Similar results were also observed for other congeners (see Table 1-9), with the exception of OCDD; however, studies were often limited to the rat. OCDD is apparently not metabolized by the rat, or metabolized to a very minimal extent (Birnbaum and Couture, 1988). For all of the congeners in Table 1-9, essentially all of the CDD, BDD, CDF, or PCB-derived radioactivity in liver, adipose tissue, and other tissues represented parent compound, suggesting that metabolites of these compounds were readily excreted. Thus, with the exception of OCDD, the metabolism of TCDD and related compounds is required for

urinary and biliary elimination and therefore plays a major role in regulating the rate of excretion of these compounds. In addition, direct intestinal excretion of parent compound is another route for excretion of TCDD and related compounds that is not regulated by metabolism.

1.3.1. Structure of Metabolites

Several metabolites of TCDD have recently been identified. Sawahata et al. (1982) investigated the in vitro metabolism of TCDD in isolated rat hepatocytes. The major product was deconjugated with β-glucuronidase, derivatized with diazomethane, and separated into two compounds by high-performance liquid chromatography. These metabolites were subsequently identified as 1-hydroxy-2,3,7,8-TCDD and 8-hydroxy-2,3,7-trichlorodibenzo--*p*-dioxin. Poiger et al. (1982) identified six metabolites in the bile of dogs that were given a lethal dose of [^{3}H]-2,3,7,8-TCDD. The major metabolite was 1,3,7,8-tetrachloro-2-hydroxydibenzo-*p*-dioxin; however, 3,7,8-trichloro-3-hydroxydibenzo-p-dioxin and 1,2-dichloro-4,5-hydroxybenzene were identified as minor metabolites. The structures of the three remaining metabolites were not determined; however, two appeared to be trichlorohydroxydibenzo-*p*-dioxins and the third was apparently a chlorinated 2-hydroxydiphenyl ether. Poiger and Buser (1984) reported differences in the relative amounts of various TCDD metabolites in dog and rat bile. Trichlorodihydroxy-dibenzo-*p*-dioxin and tetrachlorodihydroxydiphenyl ether appear to be major metabolites in rat bile. Furthermore, conjugates, presumably glucuronides, were formed in the rat but not in the dog. The investigators also observed a generally higher metabolism rate of TCDD in the dog. This finding is in good agreement with the unique ability of the dog to readily metabolize persistent PCBs such as 2,4,5,2′,4′,5′-HxCB (Sipes et al., 1982).

Biliary metabolites of 2,3,7,8-TCDF have been investigated by Poiger et al. (1984); however, unequivocal structure assignment of the metabolites could not be made using gas chromatography/mass spectroscopy. With the use of synthetic standards and GC/MS, Burka et al. (1990) identified 4-hydroxy-2,3,7,8-TCDF and 3-hydroxy-2,7,8-TCDF as major biliary metabolites of 2,3,7,8-TCDF in rats. Small amounts of 3-hydroxy-2,4,7,8-TCDF and 2,2′-dihydroxy-4,4′,5,5′-TCB were also detected. 4-Hydroxy-2,3,7,8-TCDF was also the major TCDF metabolite formed by hepatic microsomes from TCDD-pretreated rats (Tai et al., 1993). This suggests that the preferred site of metabolism of 2,3,7,8-TCDF is near the furan oxygen, with oxygenation at C4 predominating over C3. The authors speculate that epoxidation of the C4-C4a bond or the C3-C4 bond could lead to formation of the above metabolites. The results of Burka et al. (1990) and Sawahata et al. (1982) suggest that oxygenation of the unsubstituted carbon nearest the bridging oxygen in both 2,3,7,8-TCDF and TCDD is the major route of metabolism of these compounds in the rat. Furthermore, data on the rate of elimination of these compounds summarized in Tables 1-6 and 1-8 indicate that this reaction occurs at a faster rate for

the furan, since the rate of urinary and biliary elimination and resulting persistence of these compounds depend on metabolism.

Data summarized in Tables 1-6 and 1-9 indicate that 1,2,3,7,8-PeCDF is metabolized and eliminated at a greater rate than 2,3,4,7,8-PeCDF. The preference for oxygenation at C4 in 2,3,7,8-TCDF offers an explanation for the observation that 2,3,4,7,8-PeCDF is metabolized at a much slower rate than 1,2,3,7,8-PeCDF because one of the preferred sites for metabolism is blocked in the 2,3,4,7,8-substituted compound. The rate of metabolism of these compounds and their resulting relative persistence in rodents correlate with analysis of human tissues from the Yusho cohort, where the relative concentrations were 2,3,4,7,8-PeCDF > 1,2,3,7,8-PeCDF > 2,3,7,8-TCDF (Masuda et al., 1985).

Pluess et al. (1987) investigated the structure of 1,2,3,7,8-PeCDF metabolites in rat bile. A dihydroxy-tetra-CDF was identified as the major metabolite. The authors propose that this compound could be formed either via further oxidation of the hydroxy-tetra-CDF or possibly via hydrolytic dechlorination of a hydroxy-penta-CDF. Minor metabolites include dihydroxy-tri-CDF, hydroxy-tetra-CDF, and hydroxy-penta-CPF.

Pluess et al. (1987) also investigated the metabolites of 2,3,4,7,8-PeCDF in rat bile. A total of 10 metabolites were detected, with dihydroxy-penta-CB and hydroxy-penta-CDF representing the major metabolites. The biphenyl metabolite indicates that cleavage of the ether bridge of the furan is an important pathway for metabolism of this congener. Other less abundant metabolites of 2,3,4,7,8-PeCDF include hydroxy-tetra-CDF, dihydroxy-tri-CDF, dihydroxy-tetra-CDF, and thio-tetra-CDF. Sulfur-containing metabolites were also identified as minor metabolites of 2,3,7,8-TCDF and 1,2,3,7,8-PeCDF in rats (Kuroki et al., 1990). These sulfur-containing metabolites probably arise from CDF-glutathione conjugates.

In another study, a dihydroxy-PeCDF was identified as the only detectable biliary metabolite of 1,2,3,6,7,8-HxCDF, while no metabolites of 1,2,3,4,6,7,8-HpCDF were detected in the bile of rats treated with this congener (Poiger et al., 1989).

Several in vivo and in vitro studies have investigated the metabolism of 3,3′,4,4′-TCB. Rat feces were found to contain 5-hydroxy-3,3′,4,4′-TCB and 4-hydroxy-3,3′,4′,5-TCB as major metabolites (Yoshimura et al., 1987) and 2,5-dihydroxy-3,3′,4,4′-TCB, 4,4′-dihydroxy-3,3′,5,5′-TCB, 5,6-dihydroxy-3,3′,4,4′-TCB, 4-hydroxy-3,3′,4-TCB, and 4-hydroxy-4′,5′-epoxy-3,3′,4′,5-TCB as minor metabolites (Koga et al., 1989).

Mouse feces were found to contain 5-hydroxy- and 6-hydroxy-3,3′,4,4′-TCB and 4-hydroxy-3,3′,4′,5-TCB, whereas urine contained 2-hydroxy-3,3′,4,4′-TCB in addition to these metabolites (Wehler et al., 1989). 3,3′,4,4′-TCB was the major compound present in mouse liver and a minor portion was due to 4-hydroxy-3,3′,4,4′-TCB (Wehler et al., 1989). Darnerud et al. (1986) found 2-hydroxy-3,3′,4,4′-TCB and methylsulphonyl-TCB as major metabolites in the

mouse fetus. Sulfur-containing metabolites of non-co-planar, nondioxin-like PCBs have also been reported to accumulate in the bronchial mucosa and uterine luminal fluid of mice (Bergman et al., 1979; Brandt et al., 1982) and in human lung, liver, and adipose tissue (Haraguchi et al., 1986, 1989). PCB methyl sulfones are stable lipophilic metabolites formed by the mercapturic acid pathway. The toxicological significance of these metabolites of nondioxin-like PCBs remains generally unknown.

1.3.2. Toxicity of Metabolites

The discussion above indicates that metabolism of TCDD and related compounds is required for urinary and biliary elimination and thus plays a major role in regulating the rate of excretion of these compounds. At present, metabolism is also generally considered a detoxification process.

Data on the metabolism of TCDD suggest that reactive epoxide intermediates may be formed. Poland and Glover (1970) investigated the in vivo binding of [1,6-^{3}H]-2,3,7,8-TCDD-derived radioactivity to rat hepatic macromolecules and found maximum levels equivalent to 60 pmol of TCDD/mol of nucleotide in RNA and 6 pmol of TCDD/mol of nucleotide in DNA. This corresponds to one TCDD-DNA adduct per 35 cells. These investigators suggest that it is unlikely that TCDD-induced oncogenesis is through a mechanism of covalent binding to DNA and somatic mutation. Further studies of TCDD and related compounds are needed to confirm these results and assess the relationship between covalent binding and the short- and long-term toxicity of these compounds.

Weber et al. (1982a) investigated the toxicity of TCDD metabolites by administering extracts of bile from TCDD-treated dogs to male guinea pigs in single oral doses equivalent to 0.6, 6.0, and 60 μg/kg of parent compound. Other groups of guinea pigs were given bile extract from untreated dogs or TCDD itself. A comparison of the mortality data at 5 weeks after dosing indicated that the acute toxicity of TCDD to guinea pigs was at least 100 times higher than the acute toxicity of its metabolites.

Mason and Safe (1986) synthesized 2-hydroxy-3,7,8-TCDD and 2-hydroxy-1,3,7,8-TCDD, which are metabolites of TCDD, and assessed the toxicity of these compounds in male Wistar rats. The compounds produced no significant effect on body weight gain and thymus, liver, or spleen weights after exposure to a dose of ≤5,000 μg/kg bw. 2-Hydroxy-3,7,8-TCDD induced hepatic microsomal AHH, EROD, and 4-chlorobiphenylhydroxylase activity at exposures of 1,000 and 5,000 μg/kg bw, whereas 2-hydroxy-1,3,7,8-TCDD was inactive as an inducer. Thus, while 2-hydroxy-3,7,8-TCDD has dioxin-like activity as an inducer of the hepatic monooxygenase system, the potency of the metabolite is more than three orders of magnitude

less than that of TCDD. Furthermore, results are consistent with the expected rapid conjugation and excretion of these TCDD metabolites (Weber et al., 1982b).

Metabolism of co-planar PCBs and PBBs also appears to be a detoxification process. 5-Hydroxy-3,3′,4,4′-TCB and 4-hydroxy-3,3′,4′,5-TCB did not produce liver hypertrophy, induction of hepatic AHH or DT-diaphorase activities, or thymus atrophy (Yoshimura et al., 1987). Thus, monohydroxy metabolites of 3,3′,4,4′-TCB are much less toxic than the parent compound. Further evidence for metabolism as a detoxification process comes from comparison of the metabolism and toxicity of two co-planar PBBs. Millis et al. (1985) found that 3,3′,4,4′,5,5′-HxBB exhibited greater toxic potency in rats than 3,3′,4,4′-TBB, even though 3,3′,4,4′-TBB had about a 10-fold greater affinity for the Ah receptor. Although receptor binding affinities imply that 3,3′4,4′-TBB should be more toxic than 3,3′,4,4′5,5′-HxBB, it was less toxic than the HxBB because 3,3′,4,4′-TBB was metabolized at a much greater rate than 3,3′,4,4′,5,5′-HxBB. In addition to supporting metabolism as a detoxification process, the results of Millis et al. (1985) also suggest that receptor binding and in vitro AHH induction do not accurately reflect toxicity for PAHs, which are more readily metabolized, presumably because continued occupation of the receptor is required for toxicity.

Structure-activity studies of TCDD and related compounds support the widely accepted principle that this parent compound is the active species. The relative lack of activity of readily excreted monohydroxylated metabolites of TCDD and 3,3′4,4′-TCB suggests that metabolism is a detoxification process necessary for the biliary and urinary excretion of these compounds. This concept has also been generally applied to TCDD-related compounds, although data are lacking on the structure and toxicity of metabolites of other CDDs, BDDs, CDFs, BDFs, PCBs, and PBBs.

It is possible that low levels of unextractable and unidentified metabolites may contribute to one or more of the toxic responses of TCDD and related compounds. Further studies on the nature of the biotransformation products of these compounds will help address this uncertainty.

1.3.3. Autoinduction of Metabolism

Accurate rate constants for metabolism are important in developing pharmacokinetic models that describe the disposition of TCDD and related compounds. Metabolism plays a major role in regulating the excretion and relative persistence of these compounds because metabolism is required for urinary and biliary excretion. Although the relative rate of metabolism of TCDD and related compounds can be estimated from tissue and excretion half-life data (see Tables 1-6 and 1-9), other factors such as relative body composition, hepatic and extrahepatic binding proteins, and direct intestinal elimination of the parent compound can also regulate the excretion of TCDD and related compounds. Therefore, in vivo disposition data (see

Tables 1-6 and 1-9) provide only a limited approximation of the relative rate of metabolism of a specific congener in a given species. In vivo disposition data were also obtained at exposures that were associated with induction of CYP1A1 and 1A2 and other potentially adverse responses that could alter metabolism and disposition. Therefore, it may not be appropriate to directly extrapolate these data to predict the pharmacokinetics at low levels of exposure. Low-dose extrapolations can be assisted by assessments of the potential for autoinduction of metabolism that may occur at exposures associated with enzyme induction. Characterization of the dose-dependent disposition of TCDD and related compounds is particularly important in the extrapolation of high-exposure animal data to low-exposure human data.

The excretion of metabolites of TCDD and related compounds into bile represents a direct means for estimating the rate of metabolism because biliary elimination depends on metabolism and is the major route for excretion of these compounds. The rate of metabolism of CDFs was estimated from the relative abundance of metabolites in rat bile (Poiger et al., 1989). The rates of biotransformation of 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, 2,3,4,7,8-PeCDF, and 1,2,3,6,7,8-HxCDF were characterized as fairly high, moderate, low, and very low, respectively. Kedderis et al. (1991b, 1993a) observed 10% of the dose of [^{3}H]-2,3,7,8-TBDD excreted in bile 5 hours after intravenous administration of 1 nmol/kg to male Fischer 344 rats. All biliary radioactivity was attributable to metabolites. This rate of elimination is similar to the fecal excretion (~8% of the dose) 24 hours after intravenous administration of 1 nmol/kg [^{3}H]-2,3,7,8-TBDD (Kedderis et al., 1991a) and reflects the effect of intravenous bolus versus oral administration on distribution and elimination. The large percent dose excreted within the first few days may also be due to a rapidly excreted impurity in the radiolabeled 2,3,7,8-TBDD (Kedderis et al., 1993a). To assess the ability of TCDD and 2,3,7,8-TBDD to induce their own metabolism (biliary elimination), rats were pretreated with 100 nmol/kg, per of, of each compound 3 days prior to intravenous injection of 1 nmol/kg of the respective [^{3}H]-congeners. Biliary excretion of the radiolabeled dose was quantitatively and qualitatively unaffected by pretreatment, despite a twofold increase in hepatic levels of [^{3}H] in the pretreated animals and significant induction of CYP1A1 and 1A2 (Kedderis et al., 1991b). Therefore, under these conditions, autoinduction of TCDD and 2,3,7,8-TBDD metabolism did not occur in the rat in vivo at doses that elicited enhanced hepatic uptake. Similarly, Curtis et al. (1990) observed no change, or even an apparent decrease, in gastrointestinal contents and fecal elimination of TCDD equivalents in pretreated versus naive mice 24 hours after oral administration of [^{14}C]-2,3,7,8-TCDD, despite significantly enhanced levels of TCDD in the livers of pretreated mice.

Although the above studies suggest that autoinduction of TCDD metabolism does not occur, other results indicate that metabolism may be induced under certain conditions. Poiger and Buser (1984) observed a small yet significant increase in biliary excretion over a 72-hour

period, with pretreated rats (10 μg/kg, intraperitoneal) excreting 9.7±1.9% of the radiolabeled dose of TCDD (200-300 μg/kg, per of) compared with 7.0±0.9% excreted by naive animals. In addition to being small changes, these results were obtained using a dose of TCDD in excess of the LD_{50} in the rat. Poiger and Schlatter (1985) examined the influence of pretreatment with phenobarbital and TCDD on the biliary excretion of [^{3}H]-2,3,7,8-TCDD metabolites in a dog given a single oral dose of the [^{3}H]-congener (31 or 33.8 ng/kg). Without pretreatment, 24.5% of the absorbed dose was excreted in the bile within 110 hours. Phenobarbital did not alter this rate, whereas pretreatment with TCDD (10 μg/kg) 9 days earlier resulted in a doubling of the amount of metabolites excreted in bile (47.4%). Although this observation is limited to one dog and requires further investigation, the results suggest that significant autoinduction of TCDD metabolism and biliary excretion may occur in the dog. Nonetheless, the small increase in metabolism and biliary excretion of TCDD in the rat observed by Poiger and Buser (1984) and the negative results of Kedderis et al. (1991b; 1993a) and Curtis et al. (1990) suggest that autoinduction of TCDD metabolism and biliary excretion in the rat may not occur or occurs to an extent that is not biologically relevant.

More recently, Jackson et al. (1998) investigated the effects of age, sex, and pretreatments with phenobarbital, dexamethasone, and 1-aminobezotriazole (a CYP450 inhibitor) to modulate the rate of metabolism-dependent biliary elimination of TCDD in F344 rats. Biliary excretion of TCDD-derived radioactivity was measured over a 6-hour period following iv administration. Male adult and juvenile rats and female juvenile rats excreted from 0.63% to 0.68% of the administered dose, while adult females, male senescent, and male adults pretreated with the above drugs excreted from 0.28% to 0.45% of the dose of TCDD in bile. The results suggest some variability in the metabolism-dependent biliary excretion of TCDD-derived radioactivity; however, the differences between groups were not great.

Limited data suggest that autoinduction of metabolism and biliary excretion does occur for CDFs. Pretreatment of rats with 2,3,7,8-TCDF (1.0 μmol/kg, 3 days earlier) significantly increased the biliary excretion of a subsequent dose of [^{14}C]-2,3,7,8-TCDF (McKinley et al., 1993). The naive rats excreted 5.69±2.35% of the dose over the initial 8 hours, while the pretreated rats excreted 13.18±3.15% of the [^{14}C]-2,3,7,8-TCDF. Similarly, pretreatment of rats with 2,3,4,7,8-PeCDF (500 μg/kg, per of, 3 days earlier) resulted in a twofold increase in the biliary elimination of a subsequent dose of [^{14}C]-2,3,4,7,8-PeCDF (Brewster and Birnbaum, 1987). These results suggest that pretreatment with 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF induces the metabolism of these congeners.

3,3′,4,4′-TCB and 3,3′,4,4′-TBB appear to be metabolized by a 3-methylcholanthrene-inducible form of hepatic CYP(1A1 or 1A2), which is also induced by 3,3′,4,4′-TCB (Shimada

and Sawabe, 1983; Mills et al., 1985; McKinley et al., 1993). This suggests that these compounds can induce their own rate of metabolism and subsequent excretion.

Isolated hepatocytes in suspension culture have been demonstrated to provide a useful in vitro system for studying the hepatic metabolism of TCDD under the same conditions in species that have a wide range of sensitivity to the compound (Olson et al., 1981). The in vitro rate of metabolism of TCDD in guinea pig, rat, C57BL/6J mouse, DBA/2J mouse, and hamster hepatocytes was estimated to be 0.2, 1.2, 1.1, 0.9, and 1.2 pmol/mg protein/hour, respectively (Wroblewski and Olson, 1985, 1988; Shen and Olson, 1987). These results indicate that TCDD is metabolized by the guinea pig liver at a rate about fivefold less than that observed for the rat, mouse, and hamster. The limited ability of the guinea pig to metabolize TCDD can explain the limited excretion of TCDD metabolites in feces, which represents the major route for TCDD excretion (Olson, 1986). In addition, the limited metabolism in the guinea pig may partly explain the relatively long excretion half-life for TCDD in the guinea pig and may contribute to the remarkable sensitivity of the guinea pig to the acute toxicity of this agent (Olson, 1986).

Isolated hepatocytes in suspension culture have been used as an in vitro system for studying the autoinduction of metabolism of TCDD and related compounds. Wroblewski and Olson (1988) investigated the metabolism of [^{14}C]-2,3,7,8-TCDD (2.2 μM) in hepatocytes isolated from untreated TCDD-, 3-MC-, isosafrole-, and phenobarbital-pretreated rats and hamsters. In both species, TCDD and 3-MC pretreatments elevated the rate of TCDD metabolism by five- to sixfold, while phenobarbital pretreatment had no effect. Isosafrole produced a 1.8- to 2.5-fold increase in metabolism. These in vitro results at a high substrate concentration (2.2 μM) indicate that TCDD can induce its own rate of metabolism in the rat and hamster. In contrast, TCDD was not able to induce its own rate of metabolism in guinea pig and mouse hepatocytes (Wroblewski and Olson, 1985; Shen and Olson, 1987). Together, these results indicate that TCDD is metabolized in the liver by a TCDD-inducible enzyme, which is expressed in the rat and hamster but not in the guinea pig and mouse. More recently, the kinetics of TCDD metabolism were investigated in isolated rat hepatocytes incubated with [^{3}H]-2,3,7,8-TCDD at concentrations of 0.01, 0.1, and 1.0 μM (Olson et al., 1994). Lower TCDD concentrations in the media result in concentrations in hepatocytes that are more similar to the levels in the liver after in vivo exposure. For example, the concentration of TCDD in hepatocytes incubated at 0.01 μM is similar to hepatic levels after in vivo exposure of rats at a dose of ~10 μg/kg. At 0.01 and 0.1 μM, the rate of metabolism of [^{3}H]-2,3,7,8-TCDD was

similar in hepatocytes isolated from control and TCDD-pretreated rats, whereas at 1.0 μM, [^{3}H]-2,3,7,8-TCDD metabolism was greater in hepatocytes isolated from TCDD-pretreated rats. The results indicate that TCDD can induce its own rate of metabolism in the rat, but only at high hepatic concentrations, which are generally not attained after in vivo exposure. Therefore, in vitro studies of the hepatic metabolism of TCDD (at 0.01 and 0.1 μM) are consistent with the lack of autoinduction of TCDD metabolism and biliary excretion observed in vivo in the rat (Kedderis et al., 1991b; Curtis et al., 1990).

The metabolism of [^{3}H]-2,3,7,8-TCDF was also investigated in isolated rat hepatocytes incubated at concentrations of 0.01, 0.1, and 1.0 μM (Olson et al., 1994). At all concentrations, hepatocytes from TCDD-pretreated rats metabolized 2,3,7,8-TCDF at a rate from 4- to 25-fold greater than that observed in hepatocytes from control rats. The results indicate that 2,3,7,8-TCDF is metabolized in rat liver by a TCDD-inducible enzyme, possibly CYP1A1 or 1A2. These in vitro results support the in vivo autoinduction of 2,3,7,8-TCDF metabolism and biliary elimination observed in the rat (McKinley et al., 1993).

2,3,7,8-TCDF metabolism was also investigated in rat liver, kidney, and lung microsomes in the presence and absence of selective chemical inhibitors and antibodies to CYP1A1 and CYP1A2 (Tai et al., 1993). Together, the results of this investigation indicate that CYP1A1 is the primary enzyme responsible for the metabolism of 2,3,7,8-TCDF. 2,3,7,8-TCDF was also metabolized by recombinant yeast microsomes expressing human CYP1A1 and reductase. However, based on EROD activity, a marker of CYP1A1, the relative rate of 2,3,7,8-TCDF metabolism was about 100-fold greater in TCDD-induced rat liver microsomes than in yeast microsomes expressing human CYP1A1 and reductase (Tai et al., 1993). Although 2,3,7,8-TCDF was metabolized by rat and human CYP1A1, the results indicated that there are marked quantitative differences in metabolism that suggest that 2,3,7,8-TCDF will be more persistent in humans.

In summary, there are in vivo and in vitro data suggesting that autoinduction of TCDD and 2,3,7,8-TBDD metabolism does not occur in the rat after exposure to sublethal doses of these agents. This is in contrast to 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF, where in vivo and in vitro results support the autoinduction of metabolism and biliary elimination of these compounds in the rat.

1.3.4. Excretion in Animals

Data regarding the excretion of 2,3,4,7-TCDD and related compounds after exposure to a single radiolabeled congener (see Table 1-9) support the assumption of a first-order elimination process consisting of one or more components. These studies show that TCDD was excreted slowly from all species tested, with half-lives ranging from 11 days in the hamster to 2,120 days

in humans. TCDD is exceptionally persistent in humans relative to other animal models. Elimination data in tissues (see Tables 1-6 and 1-7) also indicate that TCDD and related compounds are exceptionally persistent in nonhuman primates (Bowman et al., 1989; Neubert et al., 1990). These differences may also be in part related to the dose dependency of the excretion of these compounds. In general, the congener- and species-specific rates of elimination of TCDD and related compounds from major tissue depots (see Table 1-6) are similar to the excretion data summarized in Table 1-9.

In the Syrian Golden hamster, the mammalian species least sensitive to the acute toxicity of TCDD, excretion occurred readily through both the urine (35% of administered dose, 41% of total excreted radioactivity) and feces (50% of the administered dose, 59% of total excreted radioactivity) (Olson et al., 1980). A similar excretion pattern, with significant urinary elimination, was observed in mice, although there was significant strain variability (Gasiewicz et al., 1983b; Birnbaum, 1986). In all the other species, excretion occurred mainly through the feces, with relatively minor amounts of TCDD metabolites found in the urine (Piper et al., 1973; Allen et al., 1975; Olson, 1986; Rose et al., 1976; Gasiewicz and Neal, 1979; Pohjanvirta et al., 1990). Results in Table 1-9 also indicate that fecal elimination was the primary route for the excretion of 1,2,3,7,8-PeCDD, OCDD, 2,3,7,8-TBDD, 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, 2,3,4,7,8-PeCDF, and 3,3′,4,4′-TCB. Only Piper et al. (1973) reported the excretion of metabolites in the expired air. During 21 days following administration of a single oral dose of [^{14}C]-2,3,7,8-TCDD to rats, 3.2% of the administered radioactivity (4.6% of the excreted radioactivity) was recovered in the expired air.

Studies in the rat, guinea pig, hamster, and mouse have found that essentially all of the TCDD-derived radioactivity excreted in the urine and bile corresponds to metabolites of TCDD (see Table 1-9). The apparent absence of TCDD metabolites in liver and fat suggests that, once formed, the metabolites of TCDD are excreted readily. Thus, urinary and biliary elimination of TCDD depends on metabolism of the toxin. The more limited data for other compounds also suggest that this relationship may be true for 1,2,3,7,8-PeCDD, 2,3,7,8-TBDD, 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, 2,3,4,7,8-PeCDF, and 3,3′,4,4′-TCB (see Table 1-9).

Although urine and bile appear to be free of unmetabolized TCDD, data indicate that TCDD and its metabolites are excreted in the feces of guinea pigs, rats, mice, and hamsters treated with [^{3}H]- or [^{14}C]-2,3,7,8-TCDD (see Table 1-9). Whereas 15% to 35% of the TCDD-derived radioactivity in rat, mouse, and hamster feces represents unchanged TCDD, 81% of the radioactivity in guinea pig feces represents unmetabolized TCDD (Olson, 1986; Neal et al., 1982; Gasiewicz et al., 1983b; Olson et al., 1980). The daily presence of unchanged TCDD in feces and its absence in bile suggest that direct intestinal elimination may be the source for the fecal excretion of TCDD. Data also suggest that direct intestinal elimination of parent compound

contributes to the fecal excretion for 2,3,7,8-TBDD (Kedderis et al., 1991a). Direct intestinal elimination of the parent compound may occur for other congeners (see Table 1-9), but this conclusion cannot be made at this time because of the lack of experimental data. Nonetheless, the species-specific fecal excretion of 2,3,7,8-TCDF is very similar to that observed for TCDD, with >90% of the 2,3,7,8-TCDF-derived radioactivity excreted in guinea pig feces representing parent compound (Decad et al., 1981a). In addition, the excretion of unchanged CDDs and CDFs was detected in rat feces after subcutaneous exposure to a defined mixture of congeners (Abraham et al., 1989d). Studies in lactating rats have also found that unchanged TCDD may be excreted in the milk of lactating animals (Moore et al., 1976; Lucier et al., 1975; Nau et al., 1986). Lactation, direct intestinal elimination, and perhaps sebum may serve as routes for excretion of TCDD that do not depend on metabolism of the toxin. These data suggest that the in vivo half-life for elimination of TCDD and related compounds provides only an approximation of the rate of metabolism of these compounds in a given animal. The results in Table 1-9 suggest that 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, and 3,3′,4,4′-TCB are metabolized and excreted more rapidly than 2,3,7,8-TCDD, 2,3,7,8-TBDD, 1,2,3,7,8-PeCDD, 2,3,4,7,8-PeCDF, and OCDD.

The rate of excretion of TCDD and related compounds is species- and congener- specific (see Table 1-9). TCDD is most persistent in human and nonhuman primates. In the hamster, the least sensitive species to the acute toxicity of TCDD, the mean $t_{½}$ was 10.8 days (Olson et al., 1980), and in the guinea pig, the most sensitive species to the acute toxicity of TCDD, the mean $t_{½}$ was 94 days (Olson, 1986). 2,3,7,8-TCDF was also most persistent in the guinea pig, with a $t_{½}$ of 20 to 40 days (Decad et al., 1981a; Ioannou et al., 1983). Furthermore, results indicate that the relatively limited ability of the guinea pig to metabolize TCDD and -TCDF may contribute to the greater persistence and greater acute toxicity of these congeners in the guinea pig.

The tissue distribution, metabolism, and excretion of TCDD were also investigated in Han/Wistar and Long-Evans rats, which were, respectively, more resistant (LD_{50}>3,000 μg/kg) versus more susceptible (LD_{50} ~10 μg/kg) to the acute toxicity of TCDD (Pohjanvirta et al., 1990). The results suggest that the metabolism and disposition of TCDD do not have a major role in explaining the strain differences in toxicity.

The intraspecies differences in the $t_{½}$ of TCDD in three mouse strains may be due to the finding that the DBA/2J strain possesses about twofold greater adipose tissue stores than the C57BL/6J and B6D2F_1/J strains (Gasiewicz et al., 1983b). The sequestering of the lipophilic toxin in adipose tissue stores of the DBA/2J mouse may contribute to the greater persistence of TCDD in this strain. Birnbaum (1986) examined the effect of genetic background on the distribution and excretion of TCDD in two sets of congenic mouse strains in which the congenic pairs differed only at the Ah locus. The Ah locus had no effect on the tissue distribution or excretion of TCDD. Thus, the distribution and excretion of TCDD were primarily governed by

the total genetic background rather than the allele present at the Ah locus. These findings are consistent with the in vitro results of Shen and Olson (1987), who found that the hepatic uptake and metabolism of TCDD did not correlate with genetic differences at the murine Ah locus. However, it is important to note that all of these are relatively high-dose studies, which may not allow for detection of Ah receptor-mediated effects on disposition.

Although the dose-related tissue distribution of TCDD and related compounds has been described recently, very limited data are available on the dose-related excretion of these compounds. Rose et al. (1976) investigated the elimination of [^{14}C]-2,3,7,8-TCDD in rats given repeated oral doses of 0.01, 0.1, or 1.0 μg/kg/day Monday through Friday for 7 weeks or a single dose of 1.0 μg/kg. In the single-dose study, no ^{14}C was excreted in the urine or expired air; in the repeated-dose study, however, 3% to 18% of the cumulative dose was excreted in the urine by 7 weeks. This study indicated that steady-state concentrations will be reached in the bodies of rats in ~13 weeks. The rate constant defining the approach to steady-state concentrations was independent of the dose of TCDD over the range studied. Relatively small changes in the excretion of 2,3,7,8-TBDD were also observed after exposures at 1 and 100 nmol/kg (Kedderis et al., 1991a). These results are consistent with the in vivo and in vitro evidence suggesting that autoinduction of TCDD and 2,3,7,8-TBDD metabolism does not occur in the rat after exposure to sublethal doses of these compounds (Kedderis et al., 1991b; Curtis et al., 1990; Olson et al., 1994). In contrast to these compounds, 2,3,7,8-TCDF and 2,3,4,7,8-PeCDF can induce their own rate of metabolism and biliary excretion (Brewster and Birnbaum, 1987; McKinley et al., 1993; Olson et al., 1994). Autoinduction of metabolism suggests that these compounds may exhibit dose-related excretion, with longer half-lives for elimination at lower doses, which are not associated with enzyme induction. Further data are needed to test this hypothesis.

1.3.5. Excretion in Humans

Poiger and Schlatter (1986) investigated the excretion of TCDD in a 42-year-old man (92 kg) after ingestion of 105 ng (1.14 ng/kg) [^{3}H]-2,3,7,8-TCDD in 6 mL corn oil (see Tables 1-9 and 1-10). The half-life for elimination was estimated to be 2,120 days based on fecal excretion over a 125-day period following the single exposure. The concentration of ^{3}H-TCDD-derived radioactivity was also measured in adipose tissue in the same individual over a 6-year period following exposure. A more accurate estimate of TCDD half-life of 9.7 years was calculated based on adipose tissue concentrations over a 6-year period (Schlatter, 1991). Table 1-10 summarizes additional half-life estimates for TCDD and related compounds in humans, on the basis of serum and adipose tissue concentrations at two or more time points.

The Air Force is conducting a 20-year prospective study of veterans of Operation Ranch Hand, the unit responsible for the aerial spraying of herbicides, contaminated with TCDD, in

Vietnam from 1962 to 1971. A subset of the Ranch Hand cohort has had a series of up to four serum TCDD analyses conducted to investigate the elimination of TCDD in humans. Initially, the half-life of TCDD in humans was estimated to be ~7 years on the basis of TCDD levels in serum samples taken in 1982 and 1987 from 36 of the Ranch Hand personnel who had TCDD levels >10 ppt in 1987 (Pirkle et al., 1989). Subsequently, Wolfe et al. (1994) investigated the half-life of TCDD in an expanded cohort of 337 Air Force veterans of Operation Ranch Hand that also included the 36 subjects of the earlier half-life study by Pirkle et al. (1989). Based on paired TCDD measurements from serum collected in 1982 and in 1987, the authors reported a mean predicted half-life of 11.6 years and a median observed half-life of 11.3 years with a nonparametric 95% confidence interval of 10.0 to 14.1 years. The authors also investigated how the TCDD half-life varied with percent body fat (PBF), relative changes in PBF from 1982 to 1987, and age. They found that the TCDD half-life increased significantly with a high PBF, suggesting that persons with more body fat tend to eliminate TCDD more slowly. In contrast, increasing age was associated with a shorter half-life. The redistribution of fat stores from subcutaneous to abdominal areas with aging, resulting in greater mobilization of TCDD, could in part explain the shorter half-life observed in older veterans. An increase in PBF from 1982 to 1987 was also associated with a decrease in half-life, which can be explained by a dilution of the existing body burden of TCDD into the increasing adipose tissue mass.

More recently, Michalek et al. (1996) estimated the half-life of TCDD in 213 veterans of Operation Ranch Hand on the basis of TCDD serum analyses conducted in 1982, 1987, and 1992. Of the 278 subjects with complete data in all 3 years, 213 were included for analysis of half-life 3 on the basis of TCDD levels greater than 22.3 ppt in 1982, >14.9 ppt in 1987, and >10 ppt in 1992. All TCDD levels were background-corrected by subtracting 4 ppt, and the logarithm of the background-corrected levels were modeled as a linear function of time to estimate decay rates using first-order kinetics. Using the Toeplitz assumption, the unadjusted estimated decay rate is 0.0797 per year (95% CI of 0.0727 to 0.0868), giving an unadjusted half-life estimate of 8.7 years (95% CI of 8.0 to 9.5 years). The adjusted half-life was found to increase significantly with an increase in PBF in 1982, but the half-life did not vary with age or relative changes in PBF. Most recently, Michalek and Tripathi (1999) estimated the half-life of TCDD in 97 veterans of Operation Ranch Hand on the basis of TCDD serum analyses conducted in 1982, 1987, 1992, and 1997. Of the 244 subjects with complete data at all four time points, only 97 were included for analysis of half-life based on the criteria of TCDD levels greater than 39.5 ppt in 1982, >25.0 ppt in 1987, >15.8 ppt in 1992, and >10 ppt in 1997. With increasing time since the initial exposure to TCDD, a greater proportion of the population was excluded from the analysis, as more subjects approached background body burdens of TCDD. Using the methods of the previous report (Michalek et al., 1996), the unadjusted estimated elimination rate

was 0.0915 per year (95% CI of 0.0844 to 0.0986), giving an unadjusted half-life estimate of 7.6 years (95% CI of 7.0 to 8.2 years). Because of the smaller sample size, the current elimination rate estimate, based on four measurements per subject, has less precision than the earlier estimate of Michalek et al. (1996), which was based on three measurements per subject. Once again, the elimination rate decreased slightly but significantly as PBF increased, supporting the hypothesis that individuals with more body fat tend to eliminate TCDD more slowly than those with less body fat. Michalek and Tripathi (1999) also reported no significant change in the elimination rate with age or with relative changes in PBF.

The half-life of TCDD has also been investigated in two additional populations. Flesch-Janys et al. (1996) studied a group of 43 German herbicide plant workers that had initial TCDD serum levels from 15.6 to 300 ppt. A median half-life estimate of 7.2 years was reported for this occupational cohort, which received an initial exposure to TCDD similar to that of the Ranch Hand veterans. A similar half-life estimate of 8.2 years was reported in 27 victims of the accident in Seveso, Italy (Needham et al., 1994). This cohort had a greater initial exposure, resulting in serum levels of 130 to 3,830 ppt TCDD. This study also included the early and later portions of the TCDD decay curve, as the initial blood sampling began immediately following exposure and continued for 15.9 years. Thus, based on results from the Ranch Hand, the German, and the Seveso studies, the estimated half-life of TCDD in humans is from 7.2 to 8.7 years (Table 1-10).

Half-life estimates for other CDDs and CDFs have been estimated to range from 0.8 to 19.6 years (Table 1-10). Some of the half-life values in Table 1-10 are rough estimates based on a small number of individuals and analysis at as few as two time points. Phillips (1989) discusses this issue. Estimates also assume a simple, single-compartment, first-order elimination process.

In the largest and most comprehensive study, Flesch-Janys et al. (1996) investigated the elimination of 2,3,7,8-chlorine substituted CDDs and CDFs in a cohort of workers from a herbicide-producing plant in Germany (summarized in Table 1-10). The study group consisted of 45 males and 3 females with a mean duration of employment of 13.1 years. Mean time between end of employment and first blood sample was 5.4 years (median 2 years) and mean time between first and last blood sample was 5.6 yr (median 6.3 years). A total of 43 subjects with two serum samples and 5 subjects with three serum samples were included in the study. For each congener, only those subjects whose congener serum levels exceeded 95% of German background concentration were included in the analysis. The mean background concentration was also subtracted from every original measurement before analysis. For 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF and OCDF, no half-life was estimated because no person in the study passed the above inclusion criteria. 2,3,7,8-TCDF and 1,2,3,7,8-PeCDF are excreted in animals much

more rapidly than other congeners (van den Berg et al., 1994), suggesting that these congeners may also be excreted more rapidly in humans. Conversely, 2,3,4,7,8-PeCDF is far more persistent in animal models than is TCDD, which supports the estimated 19.6-year half-life of 2,3,4,7,8-PeCDF and 7.2-year half-life of TCDD in humans. However, this estimate was based on only five subjects who met the criteria for inclusion in the study. With the exception of 1,2,3,7,8-PeCDD and 1,2,3,6,7,8-HxCDD, the median half-lives of the CDDs are generally similar. The estimates for these two congeners may be somewhat unstable because of variable individual rate constants for elimination and the fact that about 25% of the population showed no decrease in serum levels over the sampling period. Furthermore, the investigation found that increasing age and PBF were associated with increasing half-life for most congeners. Finally, it is important to note that the half-life data reflect only the elimination of CDDs and CDFs from blood lipid and may not reflect elimination from different storage sites for all congeners. In the case of TCDD, it can be assumed that the half-life estimate reflects elimination from the main storage site, because about 90% of the body burden is sequestered in fat and the blood fat/adipose tissue concentration is about 1 (Patterson et al., 1987; Kahn et al., 1988; Schecter et al., 1990a; van den Berg et al., 1994). Data are more limited on the relative amount of other congeners stored in adipose tissue in humans, and limited and somewhat conflicting data suggest that the blood fat/adipose tissue concentration ratio may increase up to a factor of 2 for OCDD (Schecter et al., 1990a; Gurn et al., 1995). Thus, some uncertainties remain regarding the extent that the observed decrease in serum levels of higher CDDs and CDFs reflects the elimination of these compounds from the body.

Ryan and Masuda (1991) reported on their continuing investigation into the elimination of CDFs in humans from the Yusho and Yu-Cheng rice oil poisonings. Yu-Cheng individuals had CDF blood levels on a lipid basis of 1-50 μg/kg, whereas Yusho patients had levels of 0.1-5 μg/kg. In the Yu-Cheng individuals, half-lives for three CDFs were 2 to 3 years, whereas elimination from Yusho individuals was more variable and slower, with half-lives >5 years (see Table 1-10) and, in several cases, no measurable elimination during the 7 years in which samples were available. The limited results suggest that clearance of these CDFs in the human is biphasic, with faster elimination at higher exposure. Schecter et al. (1990b) and Ryan and Masuda (1989) also reported longer half-life values for CDFs in humans at later time points after exposure, when concentrations are closer to the background levels of individuals with no unusual exposure.

While results from animal studies (summarized in Table 1-9) suggest that direct fecal excretion of unmetabolized CDDs and CDFs represents a significant mechanism for the elimination of these lipophilic compounds, human data have been limited until recently. The mass balance study of Schlummer et al. (1998) provided the experimental human data in support

of the two-step model of CDD and CDF transfer in the gastrointestinal tract, where absorption and excretion are distinct processes occurring at the small and large intestine, respectively (see Section 1.1.1.2). Rohde et al. (1999) conducted a digestive tract mass balance study of six German men (age 41 to 73 years) with occupational exposure to CDDs and CDFs. Blood lipid levels of the subjects in 1996 ranged from 84 to 505 pg/g lipid for TCDD and 270 to 640 pg/g lipid for TEQs, compared with background levels in unexposed individuals of 5.2 and 32 pg/g lipid, respectively. The daily quantity of nonmetabolized 2,3,7,8-chlorine-substituted CDDs and CDFs excreted in the feces exceeded the daily uptake from food, indicating significant clearance across the gastrointestinal tract. The concentration of these compounds in feces was also found to be highly correlated with that in blood, demonstrating that the fecal CDD and CDF content was directly related to the body burden of these compounds. No significant clearance (excretion via feces at least fourfold greater than uptake by food) was observed for congeners, including 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, 1,2,3,4,7,8,9-HepCDF, or OCDF, which were not markedly elevated in the serum lipids. Together, these results support the relationship that fecal excretion is regulated by the lipid-based blood concentration of these compounds. Because of fecal clearance of nonmetabolized congeners, the half-lives in these subjects were estimated from the excretion rate and current body burden and ranged from 10 years for OCDD to 22 years for TCDD to 33 years for 2,3,4,7,8-PeCDF. Congener-specific half-lives, similar to those reported by Flesch-Janys et al. (1996), were also calculated based on the decrease in serum lipid level of congeners between 1990/92 and 1996. The fecal clearance of nonmetabolized CDDs and CDFs contributed on average between 37% (2,3,7,8-TCDD) and 90% (OCDD) to the total elimination. Thus, fecal clearance plays an important role in the overall elimination of most congeners, with the daily fecal excretion estimated to be equivalent to the amount of TEQ present in about 1.7 g of blood lipids (Rohde et al., 1999).

Because direct fecal excretion is a significant route for the excretion of nonmetabolized CDDs and CDFs (Schlummer et al., 1998; Rohde et al., 1999), two recent studies investigated whether Olestra, a nonabsorbable sucrose-polyester synthetic fat substitute, may enhance the elimination of these compounds in humans. Moser and McLachlan (1999) compared the fecal excretion of CDDs, CDFs, PCBs, and HCB with background exposures in three subjects who ate an Olestra-free diet and who ate a diet supplemented with 25 g/day of Olestra. The fecal excretion while on the Olestra diet was 1.5 to 11-fold higher, depending on the congener. If fecal excretion is estimated to contribute 40% of the overall elimination of TCDD, and the Olestra diet enhanced fecal excretion 5.7-fold, the overall rate of elimination of TCDD would be more than doubled on the Olestra diet. Geusau et al. (1999) investigated the effect of an Olestra-supplemented diet on the excretion of TCDD in two patients with chloracne and very high serum TCDD levels of 144,000 and 26,000 pg/g lipid. A diet supplemented with fat-free potato chips

(33 to 66 g Olestra/day) enhanced the fecal excretion of TCDD by up to eight- to ten-fold. Results suggest that the increase in fecal excretion of TCDD was due mainly to an increase in the amount of fat (dietary fat plus Olestra) excreted via the feces. The resulting elimination half-lives of TCDD due to fecal excretion were estimated to be 1.4 years in the more highly exposed patient and 1.9 years in the other individual. However, half-lives of 200 days and 230 days, respectively, were determined through analysis of serum and adipose tissue TCDD levels over the 8-month observation period. The observed half-lives were far shorter than could be explained by an enhanced fecal or other elimination mechanism. In addition to the enhanced fecal excretion with Olestra, the authors speculate that the high levels of TCDD may have also induced the metabolism of TCDD in these subjects, resulting in the shorter observed half-lives.

In related studies, Morita et al. (1993, 1995, 1997, 1999) investigated the role of dietary fiber or Chlorella in the fecal excretion of CDDs and CDFs in rats. Chlorella is a unicellular green algae, sold as a health food or health supplement. Chlorella in the diet of rats also enhanced the fecal excretion of CDDs from 0.8- to 5.6-fold and CDFs from 0.9- to 11.1-fold above that of rats on a control diet (Morita et al., 1999). Rice bran fibers enhanced the fecal excretion of CDDs from 0.6- to 2.3-fold and CDFs from 0.5- to 10.4-fold above that of rats on a control diet (Morita et al., 1997). Dietary fiber, chlorophyll, and/or lipid in the Chlorella may be factors responsible for the enhanced fecal excretion of CDDs and CDFs observed in this study. Thus, fiber and/or Chlorella may be other dietary factors capable of increasing the fecal excretion of CDDs and CDFs.

Because of the lipophilic nature of milk, lactation can provide a relatively efficient mechanism for decreasing the body burden of TCDD and related compounds in females. As discussed by Graham et al. (1986), this elimination of TCDD through mother's milk can result in high exposure levels in the infant. The relatively high bioavailability of CDDs and CDFs from mother's milk in nursing infants was discussed earlier in Section 1.1.1.2. Further discussion of lactation as a route for excretion of CDDs and CDFs in women and exposure in infants is given in Section 1.4.5.

1.4. PHARMACOKINETICS AND EXPOSURE

1.4.1. Introduction

Pharmacokinetic models, often simple models that represent the human body or a specific tissue in the human body as a storage compartment for a chemical, can be used to relate doses to internal tissue concentrations or to some other metric of toxic action. These models are represented by a differential equation that accounts for the mass balance about the compartment. In the simplest case, the change in mass of a chemical within the storage compartment is equal to

the difference between the mass entering the compartment and the mass leaving the compartment over a specified time period.

Physiologically based pharmacokinetic (PBPK) models are special extensions of the simple pharmacokinetic model. These models utilize multiple compartments to represent the different tissues or physiological regions of the body. They incorporate known or estimated anatomical, physiological, and physicochemical parameters to describe quantitatively the disposition of a chemical between different tissues. PBPK models are useful to extrapolate between high- to low-dose kinetics within a species, to estimate equivalent doses by different routes of administration, and to extrapolate doses across species (Scheuplein et al., 1990). Given some knowledge of possible exposure patterns and scenarios, PBPK models can be used in an inverse fashion to estimate exposures on the basis of internal body doses. Some examples of how to use simple PK and PBPK models to estimate exposure to TCDD and related compounds will be given here. In addition, this section will utilize model estimations to examine some special cases of exposure, in particular, exposure to lactating infants and the elderly.

1.4.2. Estimating Daily Intake of TCDD

Because TCDD is highly lipophilic, it has been shown that a majority of the TCDD in any body tissue is stored in the fat (van der Molen et al., 1996). As a first approximation, a one-compartment pharmacokinetic model with first-order elimination may be used to compute the daily intake of TCDD based on steady-state concentrations in the fat. The mass balance model is:

$$V_F \frac{dC_F}{dt} = D - k_e A_F \qquad (1\text{-}1)$$

where:

V_F = volume of fat
CF = concentration of TCDD in fat
D = daily dose (mass/time)
A_F = mass of TCDD in fat
k_e = first order elimination constant ($time^{-1}$)

Concentration, C_F, is given by:

$$C_F = \frac{A_F}{V_F} \qquad (1\text{-}2)$$

Then, at steady state ($dC_F/dt = 0$), daily dose exactly balances elimination.

$$D = k_e A_F = k_e V_F C_F \qquad (1\text{-}3)$$

Note that k_e can be expressed in terms of half-life:

$$k_e = \frac{ln2}{t_{1/2}} \qquad (1\text{-}4)$$

Substituting Equation 1-4 into Equation 1-3, one obtains the following expression for daily dose in terms of fat concentration:

$$D = \frac{ln2}{t_{1/2}} V_F C_F \qquad (1\text{-}5)$$

It is important to recall the two assumptions implicit in the derivation of the above formula for daily uptake. First, steady-state conditions are assumed. Given that the half-life of some of these compounds is long (e.g., for TCDD the half-life is 7 years), steady-state levels would only be approached if the level of exposure were constant for 15-30 years. Pinsky and Lorber (1998) compiled data from several studies that indicate that environmental concentrations of TCDD and related compounds have been decreasing over the past 20-30 years. They use a single-compartment model similar to the one presented above, but with a time-varying exposure profile rather than the constant input. The profile was determined statistically on the basis of previously recorded environmental trends. Using the prior exposure knowledge, Pinsky and Lorber found that the pharmacokinetic model was better able to predict body burdens that have been recorded over time than was the steady-state model. By manipulating the non-steady-state model and comparing results to the steady-state approximation, it can be shown for a given body burden measurement, the steady-state approximation would result in an overestimate of daily intake. Using some estimates of the decreasing exposure function presented by Pinsky and Lorber (1998), it appears that the overestimate of daily intake could be 20% or more with the steady-state model.

Another assumption of the simple model presented in this section is that the elimination kinetics are assumed to be constant over the entire life of the individual. Because TCDD and related compounds are stored primarily in fat, sudden weight loss and lactation would result in alterations of the TCDD elimination rate. Again, it would be assumed that for calculation of daily intake due to background exposure, the body burden data from such individuals would be identified and calculations handled accordingly.

Figure 1-3 shows a sample calculation for TCDD using Equation 1-5. A fat volume of 14 L was chosen, representing 20% of the body weight. Also, for the purposes of this example, 1 mL of tissue was assumed to be equivalent to 1 g. Table 1-11 shows the estimated daily intake of TCDD at several conditions. The range of daily intakes calculated is in agreement with those reported elsewhere (Fürst et al., 1991).

Thomaseth and Salvan (1998) developed a minimal PBPK model for TCDD in humans and utilized this model to estimate occupational exposures to TCDD. The model was reduced to one compartment for ease of solution and was based on the following assumptions: (1) dynamic equilibrium of TCDD concentration between different body lipid distribution volumes, (2) first-order elimination proportional to TCDD liver content, and (3) daily intake proportional to body weight. The best parameter estimates based on Ranch Hand data were obtained with log-transformed data under a mixed-effects model, with liver elimination $k_f = 0.022$ days^{-1} (95% CI of 0.02-0.024), and background input = 0.125 pg/kg/day (95% CI of 0.071-0.179). The model accounts for changes in body mass index (BMI) over time, with higher BMI being related to a longer half-life for TCDD. The model was then used to estimate occupational exposure of 253 U.S. chemical plant workers for whom one measure of serum TCDD was available. The estimated exposure of the NIOSH cohort was 233 pg/kg/day (95% CI of 192-273). This model is much more rigorous than the simple steady-state approximation, and if a PK model is to be used to attempt to estimate intake, this model would be preferable. However, solving this model for daily intake is more complex and requires some assumption of the pattern of exposure over time. Alternatively, one could estimate daily intake by direct exposure calculations, that is, by examining the interaction of humans with environmental media containing the highest concentrations of dioxins. More information on this is provided in the chapter on exposure (Part II, Chapter 4).

1.4.3. Daily Intake of Congeners

Steady-state average dose calculations may be performed for other congeners in a manner similar to that presented for TCDD. Three pieces of information are necessary. First, concentrations in the adipose tissues must be known. Second, the half-lives of the compounds within the body must be known. Third, some understanding of the kinetics and exposure

conditions is required to ensure that steady-state conditions were achieved at the time of monitoring.

Concentrations of various congeners in adipose tissues can be found in several sources (Stanley et al., 1986; Schecter, 1991). Values range from around 2 ppt for 2,3,7,8-TCDF to several hundred ppt for 1,2,3,4,6,7,8,9-OCDD.

Half-lives could be determined from elimination data, if available. Methods have been suggested to determine the half-life of such compounds from uptake data relative to TCDD. Schlatter (1991) has proposed one such method. The following has been adapted from that proposed method. Manipulation of Equation 1-5 results in:

$$C_{TCDD} = \frac{D_{TCDD} \quad t_{1/2,TCDD}}{V \ln 2} \tag{1-6}$$

For some other congener x:

$$C_x = \frac{D_x \quad t_{1/2,x}}{V \ln 2} \tag{1-7}$$

Thus, the ratio of concentrations of TCDD to x can be described by:

$$\frac{C_{TCDD}}{C_x} = \left(\frac{D_{TCDD} \quad t_{1/2,TCDD}}{V \ln 2} \right) \quad \left(\frac{V \ln 2}{D_x \quad t_{1/2,x}} \right) \tag{1-8}$$

Which, with algebraic manipulation and simplification, becomes:

$$t_{1/2,x} = \left(\frac{D_{TCDD} \quad t_{1/2,TCDD}}{C_{TCDD}} \right) \quad \left(\frac{C_x}{D_x} \right) \tag{1-9}$$

Assuming intake D to be mostly from food, especially animal-fat products, it can be related to absorption from these foods according to:

$$D_{TCDD} = (k_{a,TCDD}) (A_{TCDD}) \tag{1-10}$$

where:

$k_{a,TCDD}$ = absorption rate constant for TCDD

A_{TCDD} = concentration of TCDD in animal fat (diet)

and

$$D_x = (k_{a,x})\ (A_x) \tag{1-11}$$

where:

$k_{a,x}$ = absorption rate constant for x

A_x = concentration of x in animal fat (diet)

As a result, the half-life for compound x can be described by:

$$t_{1/2,x} = t_{1/2,TCDD}\left(\frac{A_{TCDD}}{C_{TCDD}}\right)\left(\frac{C_x}{A_x}\right)\left(\frac{k_{a,TCDD}}{k_{a,x}}\right) \tag{1-12}$$

When the absorption rate constants for each are equal or when the difference between them is small compared to differences in other parameters (concentration, half lives), Equation 1-12 can be further simplified to:

$$t_{1/2,x} = t_{1/2,TCDD}\left(\frac{A_{TCDD}}{C_{TCDD}}\right)\left(\frac{C_x}{A_x}\right) \tag{1-13}$$

It should be noted that for some of these substances exposure is expected from other than food sources. For such cases Equation 1-12 would be modified to include these other sources as follows.

$$t_{1/2,x} = t_{1/2,TCDD}\left(\Sigma\frac{k_{a,i,TCDD}\ \ A_{i,TCDD}}{C_{TCDD}}\right)\left(\Sigma\frac{C_x}{k_{a,i,x}}\ \ A_{i,x}\right) \tag{1-14}$$

where:

$k_{a,i,TCDD}$ = absorption rate constants for TCDD from each of the i media

$A_{i,TCDD}$ = concentration of TCDD in each of the i media

$k_{a,i,x}$ = absorption rate constants for x from each of the i media

$A_{i,x}$ = concentration of x in each of the i media

Other symbols: as previously defined

Again, if the differences between the absorption rate constants for TCDD and x are judged to be small, then the following variation of Equation 1-14 can be used:

$$t_{1/2,x} = t_{1/2,TCDD}\left(\Sigma\left(\left(\frac{A_{i,TCDD}}{C_{TCDD}}\right)\left(\frac{C_x}{A_{i,x}}\right)\right)\right) \quad (1\text{-}15)$$

Table 1-12 shows the results of some half lives calculated in this manner.

The half lives calculated using Equation 1-15 for the first three compounds in Table 1-12 agree with those calculated by Schlatter (1991). The large difference in the two calculations for OCDD is due to significant differences in absorption rates between TCDD and OCDD. Schlatter notes in his paper that for some compounds, including OCDD, corrections were made of differences in absorption. No explanation was offered on how this was done. However, Flesch-Janys et al. (1996) report a half-life of 6.7 years for OCDD. In addition, Flesch-Janys et al. (1996) report longer half-lives for 1,2,3,7,8-PeCDD (15.7 years) and 2,3,4,7,8-PeCDF (19.6 years). These differences could be due to a variety of factors including the dietary concentrations, absorption rates, other background sources, etc. Table 1-13 summarizes the results reported by Flesch-Janys.

When using this method to estimate daily intake of TCDD and congeners, it should be noted that studies (Kim and Dubin, 1996; Shirai and Kissel, 1996) have indicated that there is considerable uncertainty associated with half-life measurements published in the literature.

1.4.4. Induction of Liver Binding Proteins and Resultant Distribution

Andersen et al. (1997a) developed a multicompartment geometric model of the liver in relation to regional induction of cytochrome P-450s. The model was based on five morphological and functional zones of the liver acinus: a concentric periportal zone, a fenestrated periportal region that interconnects among multiple functional units, and three concentric centrilobular areas. At low doses, TCDD exhibits centrilobular expression of CYP1A1, and with increasing dose, adjacent areas radiating out from the centrilobular region also begin to express CYP1A1. To create realistic total induction curves that are relatively smooth, the differences in K_d (dissociation constant) values between adjacent subcompartments must be less than fivefold. Because of the high n (Hill constant) values, the low-dose induction characteristics predicted with the multicompartment liver model differ significantly from those predicted with a model that considers the liver as a single homogeneous compartment. A physiologically based pharmacokinetic (PBPK) model for TCDD was then combined with a five-compartment geometric model of hepatic zonation to predict both total and regional induction of CYPs within the liver (Andersen et al., 1997b). The model predicts an 81-fold difference in the affinity of the

AhR-TCDD complex binding to DNA response elements for CYP1A1 between the centrilobular and the periportal regions. The PBPK analysis based on the multicompartment liver model suggests that the low-dose behavior for hepatic CYP1A1/1A2 induction by TCDD is highly nonlinear.

1.4.5. Pregnancy and Lactation (Exposure of Offspring)

The distribution and excretion of [^{14}C]-2,3,7,8-TCDD (30 μg/kg) and [^{14}C]-2,3,7,8-TCDF (800 μg/kg) were studied in pregnant C57BL/6N mice after oral exposure on gestation day 11 (Weber and Birnbaum, 1985). The distribution and excretion of TCDD and 2,3,7,8-TCDF in pregnant mice were similar to those of males of the same strain (Gasiewicz et al., 1983b; Decad et al., 1981b) (see Tables 1-6 and 1-9), although elimination rates were higher in the pregnant mice for both congeners. For TCDD, liver, urinary, and fecal elimination was 3.0, 3.4, and 14.4 times faster than that reported for males. For 2,3,7,8-TCDF, liver, urinary, and fecal elimination was 1.3, 1.8, and 1.8 times faster than that observed for males. Elimination data from pregnant mice were based on only three time points (gestation days 12, 13, and 14) and thus represent only rough estimates. In addition, the greater fecal excretion could have been due to incomplete absorption of TCDD after oral exposure. Although these results need further substantiation, it is conceivable that the sex of the animal, pregnancy, and the route of exposure could have a significant impact on the pharmacokinetics of these compounds.

In a related study, Krowke (1986) compared the TCDD concentrations in the livers of pregnant and nonpregnant NMRI mice exposed subcutaneously to 12.5 or 25 nmol/kg/day on gestation days 9-11. At 7 days after exposure to the lower dose, the hepatic TCDD concentrations were 7 and 32 ng/g in pregnant and nonpregnant mice, respectively. At the higher exposure, 5.5 times lower concentrations of TCDD were found in the livers of pregnant animals on gestation day 18. A similar effect on hepatic TCDD levels was observed in combined exposure, which contained 1,2,3,7,8-PeCDD, 1,2,3,4,7,8-HxCDD, or 2,3,7,8-TCDF. The decreased hepatic levels of TCDD in pregnant mice are consistent with the Weber and Birnbaum (1985) observation of more rapid elimination of TCDD in pregnant mice. Further investigations are necessary to better characterize the apparently significant effects of pregnancy on the disposition of TCDD and related compounds.

Weber and Birnbaum (1985) also investigated the distribution of [^{14}C]-2,3,7,8-TCDD (30 μg/kg) and [^{14}C]-2,3,7,8-TCDF (800 μg/kg) to the embryos of pregnant C57BL/6N mice after oral exposure on gestation day 11. On gestation days 12, 13, and 14, the percent of the maternal dose in the embryo remained constant at 0.032%-0.037%/embryo, while the concentrations in the embryo were 0.34%, 0.17%, and 0.15% of the dose/g embryo, respectively. Embryos had approximately 11-fold higher concentrations of TCDD than 2,3,7,8-TCDF when exposed on a

percent of total dose/g tissue basis. This may be due to the more rapid metabolism and excretion of 2,3,7,8-TCDF compared with TCDD. Assuming that all radioactive material found in embryos was parent compound, at most 2.6 ng (8 pmol) of TCDD and 6.4 ng (21 pmol) of 2,3,7,8-TCDF/g tissue were detected under these conditions.

The transfer of [^{14}C]-2,3,7,8-TCDD to the embryo during early gestation was assessed in NMRI mice given a dose of 25 μg/kg by intraperitoneal injection on days 7, 8, 9, 10, 11, or 13 of gestation (Nau and Bass, 1981). The mice were sacrificed after 48 hours, and TCDD concentrations were determined by liquid scintillation counting of solubilized tissue and by GC-ECD and GC/MS. Similar results were given by these methods, suggesting that TCDD-derived [^{14}C] in maternal and embryonic tissue was the parent compound. The maternal liver contained from 4% to 8% of the dose/g, or 40-80 ng/g. TCDD in embryonic tissue from gestation days 11-15 ranged from 0.04% to 0.1% of the dose/g, or 0.4-1.0 ng/g. In contrast, higher levels were found earlier in gestation, with 10 ng/g embryo on gestation day 9 and 2 ng/g on day 10. The higher levels may be related to placentation, which occurs at approximately gestation days 10-11 in this mouse strain. The affinity of fetal liver for TCDD was relatively low, as compared to maternal liver; however, TCDD levels in fetal livers were two to four times higher than levels in other fetal organs. Nau and Bass (1981) also attempted to correlate TCDD levels in the fetuses with the observed incidence of cleft palate. Three groups of mice were given either a single intraperitoneal exposure to 25 μg/kg TCDD on gestation day 7 or 10 or 5 μg/kg/day, intraperitoneally, on gestation days 7-11. On gestation day 13, TCDD concentrations in maternal tissues were very similar in the three exposure groups. At day 13, however, the embryo contained 0.038±0.011% (0.36 ng/g), 0.096±0.027% (0.92 ng/g), and 0.12±0.05% (1.1 ng/g) of the dose (mean±SD) in the 7-, 10-, and 7- to 11-day exposure groups, respectively. Cleft palate incidence on gestation day 18 was 16%, 84%, and 65% for the 7-, 10-, and 7- to 11-day exposure groups, respectively. Although further studies are needed, these results suggest that cleft palate incidence is generally related to the TCDD concentration in the embryo. In a related study, Couture et al. (1990) found that gestation day 12 was the peak period of sensitivity for TCDD-induced cleft palate in C57BL/6N mice; however, tissue levels were not investigated.

In the same laboratory, Abbott et al. (1989) investigated the distribution of TCDD in the C57BL/6N mouse fetus following maternal exposure on gestation day 11 to 30 μg/kg. 2,3,7,7-TCDD was detected in the gestation day-11 embryo at 3 hours postexposure and was equally distributed between the embryonic head and body. At 72 hours postexposure, 0.035% of the total dose was in fetal tissues and 1% of the TCDD in the fetus (1.4-3.5 pg) was found in the palatal shelf. More recently, Abbott et al. (1996) found that TCDD was detected in maternal blood, liver, and fat and in the placenta, embryonic liver, and palate within 30 min after oral exposure of mice on gestation day 12. The levels peaked in blood and placenta at 3 hours and in

the other tissues at 8 hours. At 24 hours following a single oral dose of 24 μg TCDD /kg, the above respective tissues contained 0.25, 98.8, 72.9, 1.22, 1.03, and 0.44 ng TCDD/g.

Krowke (1986) also measured the concentration of TCDD in the placenta, amniotic fluid, and fetus of NMRI mice exposed to 2.5 nmol/kg by subcutaneous injection on days 9-11 of gestation. Similar concentrations of TCDD were observed in the placenta, amniotic fluid, and fetus (~0.5 ng/g) on day 16 of gestation. Fetal liver TCDD concentrations were at least five times greater than in other fetal tissue. Krowke (1986) reported slightly lower TCDD levels in the fetal head relative to other extrahepatic fetal tissue, while Weber and Birnbaum (1985) found a slightly higher TCDD concentration in the head relative to other extrahepatic fetal tissue.

Nau et al. (1986) investigated the transfer of TCDD via the placenta and milk in NMRI mice exposed to 25 μg/kg on day 16 of gestation. The authors confirmed the relatively low fetal tissue levels with prenatal exposure to TCDD (Nau and Bass, 1981) and found that postnatally TCDD was transferred efficiently to mouse neonates and offspring by lactating mothers. During the first 2 postnatal weeks, the pups were given doses of TCDD via the milk that were, on a body-weight basis, similar to those that had been administered prenatally to their mothers. TCDD levels in the tissue of lactating mothers decreased within the first 3 postnatal weeks by two to three orders of magnitude to reach levels that were only ~2% of the corresponding levels in the pups that these mothers had nursed. Thus in mice, excretion into milk represents a major pathway for maternal elimination of TCDD and for the subsequent exposure of pups.

The disposition of TCDD in rat pups was assessed after the prenatal (via placental transfer) and postnatal (via milk) exposure from pregnant Wistar rats given a single dose of 3, 30, or 300 ng/kg, subcutaneously, on day 19 of gestation (Korte et al., 1990). Lactation resulted in the rapid elimination of TCDD from maternal tissues, with the half-life of TCDD in the liver of lactating rats estimated to be ~7 days. This compares to a half-life of 13.6 days in the liver of nonlactating rats (Abraham et al., 1988). At postnatal day 7, exposure via the milk resulted in pup liver TCDD concentrations that were greater than the corresponding levels in maternal liver. In cross-fostering experiments, the concentrations of TCDD in the liver of offspring at postnatal day 7 were 0.47, 2.59, and 4.16 ng/g in the 300 ng/kg groups exposed through the placenta only, via the milk only, and through the placenta and via the milk, respectively. These results support the earlier observations that the placental transfer of TCDD in rats and mice is relatively limited compared with the efficient transfer via maternal milk.

Van den Berg et al. (1987b) investigated the transfer of CDDs and CDFs to fetal and neonatal rats. Prenatal exposure of the fetus was assessed in pregnant Wistar rats fed a diet containing a fly ash extract from a municipal incinerator on days 10-17 of gestation. Postnatal exposure of 10-day-old pups was assessed through feeding lactating mothers the same contaminated diet for the first 10 days after delivery. Although the fly ash extract contained

almost all of the 136 tetra– to octa-CDDs and -CDFs, only 17 CDD and CDF congeners were detected as major compounds in the tissue of fetuses, pups, and dams. All of the congeners were 2,3,7,8-substituted with the exception of 2,3,4,6,7-PeCDF. TCDD had the highest retention (0.0092% of the dose/g) in the fetus, while 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, and hepta- and octa-CDDs and -CDFs were not detected in the fetus. In the liver of offspring, the highest retention was found for TCDD, 1,2,3,7,8-PeCDD, and the three 2,3,7,8-substituted HxCDDs (0.74%-1.13% dose/g). The 2,3,7,8-substituted penta- and hexachlorinated congeners showed the highest retention in the livers of dams (2.05%-5.17% of dose/g liver), while 2,3,7,8-TCDF, 1,2,3,7,8-PeCDF, and 2,3,4,6,7-PeCDF had the lowest retention. A linear relationship was found between the retention of CDDs and CDFs in the livers of pregnant and lactating rats. Furthermore, a linear relationship was found between the retention of CDDs and CDFs in the livers of the lactating rats and livers of the offspring.

In a related study, Hagenmaier et al. (1990) investigated the transfer of CDDs and CDFs through the placenta and via milk in a marmoset monkey. A defined mixture of CDDs and CDFs was given as a single subcutaneous injection to a pregnant marmoset monkey at the end of the organogenesis period (week 10 of gestation, 11 weeks prior to delivery). Transfer of CDDs and CDFs through the placenta was investigated in a newborn 1 day after birth, and transfer through the placenta and via milk was assessed in an infant of the same litter after a lactation period of 33 days. Tissue concentrations of the offspring were compared with those of the mother at the end of the lactation period and with data from other adult marmosets obtained at this time of maximum absorption (1 week after injection) and 6 weeks after injection. Deposition of CDDs and CDFs into the newborn liver was very low, suggesting very little transplacental transport and hepatic accumulation of these compounds. TCDD and 1,2,3,7,8-PeCDD were found at the highest concentration in the liver of the newborn (~0.15% of dose/g). For all other congeners, the concentrations in the liver of the newborn were <10% of the corresponding concentrations in adults. In contrast to liver, concentrations of 2,3,7,8-substituted congeners in the adipose tissue of the newborn were at least 33% of the levels in adults, and in the case of OCDD and OCDF, levels were threefold higher in the newborn than in the adult. The adipose tissue/liver concentration ratios for 2,3,7,8-substituted congeners in the newborn ranged from 2.2 for 1,2,3,4,6,7,8-HpCDF to 10.9 for 2,3,7,8-TCDF. Furthermore, the concentration of these congeners in the newborn was highest in the adipose tissue, followed by the skin and liver. This is in contrast to the relative distribution in the adult, where the liver generally contains the highest levels of these congeners. The results indicate that hepatic concentrations in the fetus may not be representative of the rate of placental transfer of CDDs and CDFs. In the marmoset monkey, substantial placental transfer into fetal adipose tissue can be observed for most of the 2,3,7,8-substituted congeners during the fetal period. As expected from rodent studies, the

transfer of CDDs and CDFs via mothers' milk was considerable, resulting in hepatic concentrations of 2,3,7,8-TCDD, 1,2,3,7,8-PeCDD, and 1,2,3,6,7,8-HxCDD in the suckled infant (postnatal day 33) higher than those in the dam. The hepatic concentration of TCDD in the 33-day-old infant was ~0.9% of the dose/g tissue. Transfer of hepta- and octa-CDDs and CDFs to the suckled infant was rather low, only ~10% of the levels in the dam. When total exposure of the mother and offspring at the end of the 33-day nursing period was assessed in terms of I–TE factors (U.S. EPA, 1989), the liver of the mother contained 2,494 pg I–TE/g, whereas the offspring liver contained 2,022 pg I-TE/g. This approach is necessary to assess total exposure due to the congener-specific transfer via lactation.

The pre– and postnatal transfer of TCDD to the offspring of rhesus monkeys was investigated by Bowman et al. (1989). Animals were fed a diet containing TCDD at concentrations of 5 or 25 ppt for ~4 years and were on a TCDD-free diet for ~18 months prior to parturition. Maternal TCDD levels (mean±SE) in adipose tissue were 49±11 (n=7) and 173±81 (n=3) ppt in the 5 and 25 ppt groups, respectively. Corresponding levels in the adipose tissue of offspring at weaning (4 months) were 187±58 and 847±298 ppt in the 5 and 25 ppt groups, respectively. From these data, a TCDD BCF of 4.29 was estimated from mother to nursing infant. This value is similar to that observed for TCDD in the marmoset monkey (Hagenmaier et al., 1990). The milk of the rhesus monkeys in the 25 ppt group contained from 4 to 14 ppt of TCDD, which corresponds to 150-500 ppt on a lipid basis. The authors calculated that the three mothers in the 25 ppt group excreted from 17% to 44% of their TCDD body burden by lactation. They also concluded that the results are generally consistent with overall triglyceride movement as mediating the excretion of TCDD in milk.

In a subsequent study, Bowman et al. (1990) reported the relative persistence of TCDD in the offspring of rhesus monkeys that were exposed earlier to 5 or 25 ppt of TCDD in the diet. The concentration of TCDD in adipose tissue was measured in offspring at ~4-5, 12, and 24 months of age. The decrease of TCDD levels in adipose tissue of seven young monkeys departed somewhat from first-order, single-compartment kinetics, but with the limited data and an assumption of first-order kinetics, a half-life of 121 days was estimated. When the data were adjusted within each animal for body weight gain and for average fat content at each age, the adjusted data apparently followed first-order, single-compartment kinetics, with a half-life of ~181 days. Thus, young monkeys apparently eliminate TCDD from adipose tissue at a faster rate than adult rhesus monkeys, which had individual half-lives ranging from 180 to 550 days (Bowman et al., 1989).

Several studies provide data in support of the transplacental transport of CDDs and CDFs to the human fetus. Kreuzer et al. (1997) measured the concentration of CDDs and CDFs in the lipids of adipose tissue and livers of 3 stillborn infants and detected 16 of a possible 17

congeners, with the exception of 1,2,3,7,8,9-HxCDF. TEQ levels ranged from 6.2 to 10.8 pg/g lipid, and TCDD levels ranged from 0.8 to 2.1 pg/g lipid for human infants that died at birth. These levels are similar to those reported in the lipid fractions of maternal tissues, suggesting that prenatal exposure to CDDs and CDFs reflects the levels present in maternal tissues. Similar findings were reported earlier by Schecter et al. (1990c), who detected TCDD (1.3 to 4.3 pg/g lipid) in the livers of three stillborn infants. Thus, significant prenatal exposure to CDDs and CDFs occurs, with the concentration of these compounds in the lipids of the newborn infants generally reflecting that in maternal lipids.

A significant source of postnatal exposure of human infants to CDDs and CDFs is through the ingestion of human milk. Several investigators have quantified the levels of TCDD in human milk samples. Many of the milk samples were pooled (Jensen, 1987). Rappe (1984) reported levels of 1-3 ppt TCDD in milk fat (lipid adjusted) from five volunteers in West Germany, and in a later report, Rappe et al. (1985) reported an average level of 0.6 ppt TCDD in milk fat from four volunteers in northern Sweden. Furst et al. (1986) reported an average level of 9.7 ppt TCDD in milk fat from three individuals in the Netherlands and <1.0 ppt TCDD in milk fat from two individuals in Yugoslavia. Nygren et al. (1986) reported average levels of TCDD in human milk samples from four subjects in Sweden to be 0.6 ppt in milk fat, in five subjects from West Germany to be 1.9 ppt in milk fat, and in four subjects from Vietnam to be <0.5 ppt in milk fat.

High levels of TCDD have been detected in the milk of mothers exposed to high levels of TCDD in the environment. Reggiani (1980) reported levels between 2.3 and 28.0 ppt TCDD in whole milk from mothers in Seveso. Baughman (1975) reported levels between 40.0 and 50.0 ppt TCDD in whole milk from mothers in South Vietnam. Schecter et al. (1987) also found high ppt levels of TCDD in human milk samples from South Vietnam. These authors found that levels from samples taken in 1985 from South Vietnamese mothers were comparable to the level of TCDD currently found in North American human milk samples (5 ppt).

Furst et al. (1989) examined the levels of CDDs and CDFs in human milk and the dependence of these levels on the period of lactation. The mean concentrations of CDDs in human milk (on a fat basis) ranged from 195 ppt for OCDD to 2.9 ppt for TCDD, with the levels of the other congeners decreasing with decreasing chlorination. This is in contrast to the generally lower levels of CDFs in human milk, which range from 25.1 ppt for 2,3,4,7,8-PeCDF to 0.7 ppt for 1,2,3,7,8-PeCDF. An evaluation of the CDD and CDF levels in relation to the number of breast-fed children found that the concentrations in milk generally decreased with the greater number of children. The CDD and CDF levels in milk from mothers nursing their second child are on average 20%-30% lower than those for mothers breast-feeding their first child. CDD and CDF levels were also analyzed in one mother over a period of 1 year after delivery of her

second baby to assess the effect of duration of lactation. After breast-feeding for 1 year, the mother had CDD and CDF levels that were 30%-50% of the starting concentration. Levels in milkfat (ppt) at 1, 5, and 52 weeks after delivery were 251, 132, and 119 for OCDD; 7.9, 5.9, and 1.4 for TCDD; and 33.1, 24.5, and 10 for 2,3,4,7,8-PeCDF, respectively. The results suggest a more rapid mobilization of CDDs and CDFs and excretion into human milk during the first few weeks postpartum. Although further studies are necessary, the limited data suggest that there are time-dependent, isomer-specific differences in the excretion of CDDs and CDFs in human milk.

Schecter et al. (1998a) assess the decrease in the levels of CDDs, CDFs, PCBs, DDE, and HCB in the blood and milk lipid in a mother that nursed twins over a 38-month period. During the first 23 months of nursing, the CDD and CDF TEQ decreased 68% (15.7 to 5.0 ppt, lipid) for blood and decreased 77% (13.6 to 3.1 ppt, lipid) for breast milk. Thus, lactation results in a similar reduction in CDD and CDF concentrations in the lipid fractions of blood and milk. During the first 23 months of nursing, the PCB 126 (3,3',4,4',5-PeCB) milk concentration also decreased 71% (21.0 to 6.1 ppt, lipid). The authors estimate that approximately 115 ng TEQ (CDDs, CDFs, coplanar PCBs) was ingested by each infant from breast feeding for this extended period of time.

Abraham et al. (1996) investigated the intake, fecal excretion, and blood levels of CDDs, CDFs, and PCB 126 in two breast-fed and two formula-fed infants. At 1 month, the concentrations of CDDs and CDFs in breast milk were 19.7 and 22.2 TEQ (pg/g lipid), while the formula diet contained only 0.38 TEQ (pg/g lipid). At the age of 11 months, the breast-fed infants' blood CDD and CDF concentrations were 29.2 and 37.5 TEQ (pg/g lipid), whereas the formula-fed infants' blood CDD and CDF concentrations were 2.4 and 2.6 TEQ (pg/g lipid). At this time, the mothers that breast-fed had blood CDD and CDF concentrations of 12.3 and 10.5 TEQ, while the mothers that formula-fed had blood levels of 16.9 and 13.8 TEQ (pg/g lipid). Because PCB 126 has a TEF of 0.1, it is important to note that at 11 months, breast-fed infants also have much higher levels of PCB 126 (287 and 374 pg/g lipid) relative to formula-fed infants (24 and 18 pg/g lipid). PCB 126 levels in mothers that breast-fed were 105 and 86 relative to levels of 193 and 52 (pg/g lipid) in the mothers that formula-fed. Thus, when PCB 126 is included in the TEQ calculation, the breast-fed infants' total TEQ blood concentration (body burden) is more than doubled from that estimated on the basis of CDDs and CDFs alone. The results of this study provide direct, quantitative data showing that the body burden (blood level) of CDDs, CDFs, and PCB 126 is more than 10 times higher in 11-month-old breast-fed infants than in 11-month-old formula-fed infants.

Although data are more limited for the co-planar PCBs, 3,3′,4,4′-TCB, 3,3′,4,4′,5-PeCB, and 3,3′,4,4′,5,5′-HxCB have been detected in human milk from Swedish mothers, at concentrations of 16-32, 72-184, and 46-129 ppt on a fat basis, respectively (Noren et al., 1990).

Therefore, lactation appears to be an effective means for the excretion of co-planar PCBs from mothers and a major source of postnatal exposure of nursing infants. Because 3,3′,4,4′,5-PeCB and other co-planar PCBs are present in human milk at concentrations up to 60-fold higher than TCDD, it is important to consider the relative toxic potency of these dioxin-like compounds and their potential health impact on nursing infants.

Kreuzer et al. (1997) measured the levels of CDDs and CDFs in the lipids of adipose tissue and liver of 17 infants (0.43 to 44 weeks of age) who died of sudden infant death syndrome. As expected, the concentrations of these compounds in breast-fed infants were higher than those in non-breast-fed infants; however, the magnitude of this difference varied because of differences in the age of the subjects and the duration of breast-feeding. The TEQ concentrations in the livers of these subjects were slightly, but not significantly, higher than the respective levels measured in the adipose tissue lipids. The results also suggest that the higher chlorinated congeners preferentially accumulate in liver lipids, an observation made earlier for adults in a study by Thoma et al. (1990) (see Table 1-5).

Kreuzer et al. (1997) used data from the above study and other published results to validate a physiological toxicokinetic model they developed to describe the body burden of TCDD for the entire human lifetime and the influence of breast-feeding on the body burden. The model includes gender- and age-dependent changes in the following parameters: body weight; volumes of liver, adipose, and muscle tissue; food consumption; and excretion of feces. The model also assumes that TCDD exposure occurs primarily from the ingestion of contaminated food, that TCDD is distributed freely in lipids, and that TCDD is excreted unchanged in the lipids of the feces as well as following hepatic metabolism. More complex biochemical processes such as protein binding, saturation of metabolism at high TCDD concentrations, or induction of metabolism are not part of this model, which considers factors more relevant for low-level or background human exposures. With the basis assumption of this single-compartment model and the free distribution of TCDD in all body lipids, including the gastrointestinal tract, the half-life of the nonmetabolic elimination (tf1/2) is proportional to the ratio of volume of body lipids (V) to the mass of lipids in stool excreted per unit time (dFa/dt). During aging, V increases at least 40 times but dFa/dt only 1.7 times (from 3 g/day in infants to 5 g/day in adults). Consequently, the half-life of the nonmetabolic elimination (tf1/2) is calculated to be only 0.42 years in newborns and 9.5 years in 40-year-old adults. According to this model, most TCDD is eliminated as unchanged compound in children, with the role of metabolism-dependent elimination becoming more important with age. Thus, the half-life increases almost linearly from its starting value of about 4 months in newborns and reaches a value of 5 years at the age of 40. An age dependent elimination of TCDD has also been reported experimentally in the rhesus monkey (Bowman et al., 1989, 1990). Furthermore, the model of Kreuzer et al. (1997) predicts

that the relatively high TCDD concentrations that might be reached after 6 months of nursing do not lead to an elevated lifetime body burden of TCDD.

In a related study, Patandin et al. (1999) investigated dietary, including lactational, exposure to CDDs, CDFs, and PCBs from early childhood until the early reproductive age of 25 years in order to assess exposure risk to the next generation. Based on the analysis of 83 milk samples, previously reported analysis of food products, and food questionnaire data, the daily TEQ intake per kg body weight is 50 times higher in breast-fed than bottle-fed infants and 3 times higher in toddlers than in adults. Although exposures are relatively high in breast-fed infants, breast-feeding for 6 months contributes only 12% and 14% to the respective body burdens of men and women at the age of 25 years. After babies are weaned, dairy products, processed foods, and meat are major sources of exposure to these compounds.

1.4.6. Pharmacokinetics and Aging

The influence of aging on the intestinal absorption of TCDD was studied in 13-week-, 13-month-, and 26-month-old (senescent) male Fischer 344 rats (Hebert and Birnbaum, 1987). Absorption was measured by an in situ intestinal recirculation perfusion procedure. When absorption was calculated in terms of ng TCDD absorbed/g mucosal dry weight/hour, the decrease between the senescent rats and the two younger age groups, from 544 ng/g/hour (young) to 351 ng/g/hour (senescent), was not statistically significant ($p<0.05$). The results indicate that, as with other molecules that depend on diffusion for their absorption, aging does not affect the intestinal absorption of TCDD.

Banks et al. (1990) studied the effect of age on the dermal absorption and disposition of TCDD and 2,3,4,7,8-PeCDF in male Fischer 344 rats. When rats were administered the same dose per body weight, dermal absorption of TCDD at 3 days after exposure decreased from 17.7±2.7% (mean±SD) to 5.6±2.5% of the administered dose in 10- and 36-week-old rats, respectively. Dermal absorption in the 96-week-old rats was similar to that of the 36-week-old rats. Dermal absorption of 2,3,4,7,8-PeCDF also decreased from 22.2±0.2% to 14.7±3.8% of the administered dose in 10- and 36-week-old rats, respectively. Dermal absorption of both compounds was also decreased in older rats given the same total dose per surface area. Older animals may have decreased blood flow in the upper dermis, which will decrease the clearance of these compounds from the application site. Potential age-related changes in the intercellular stratum corneum lipids may also play a role in the decreased dermal absorption observed in older animals. Changes in the percentage of the administered dose detected in various depots reflected age-related changes in dermal absorption, whereas age-related changes in the tissue distribution of the absorbed dose reflected changes in the total mass of these tissues at various ages. Overall elimination of the absorbed dose was not affected by age. Although this investigation was

conducted with a lipophilic solvent system and an animal model with skin that is more permeable than human skin, the results suggest that systemic bioavailability after dermal exposure to TCDD or 2,3,4,7,8-PeCDF may be reduced in older age groups.

In a similar study, absorption, tissue distribution, and elimination were examined 72 hours after dermal application of a lower dose of 200 pmol (111 pmol/cm^2) TCDD to weanling (3-week-old), juvenile (5-week-old), pubescent (8-week-old), young adult (10-week-old), and middle-aged (36-week-old) rats (Anderson et al., 1993). Dermal absorption using acetone as the vehicle was greatest in 3-week-old rats (129 pmol; 64% of the administered dose), decreasing to ~80 pmol (40%) in 5-, 8-, and 10-week-old rats and to 45 pmol (22%) in 36-week-old rats. The results indicate that TCDD is absorbed to a greater degree through skin of very young animals and that a significant decrease in potential for systemic exposure may occur during maturation and again during aging.

1.5. SELECTION OF DOSE METRIC

Risk assessment requires the scaling of exposure/dose across endpoints and across species. Given the many responses to TCDD and its congeners, the selection of dose metrics for use in quantitative risk assessments is a complex problem. The biochemical and toxicological responses of TCDD and related chemicals are initiated by their interaction with the Ah receptor. Some responses, such as enzyme induction, require short periods (minutes to hours) of Ah receptor activation. Other responses, such as cancer, require prolonged (months to years) activation of this pathway. Still other responses, such as the developmental toxicities, require receptor activation during specific windows of sensitivity. Because of the different mechanisms involved in these diverse responses, it is unlikely that a single dose metric will be adequate for all of these endpoints. A number of studies have proposed a variety of dose metrics for a number of different responses. These studies have taken different approaches ranging from simple curve fitting exercises (Hurst et al., 2000; van Birgelen et al., 1996) to more complex PBPK modeling approaches (Jusko et al., 1995; Andersen et al., 1997; Kohn et al., 1993; Portier and Kohn, 1996). Area under the curve (AUC), a dose metric traditionally used in the pharmaceutical literature, has also been proposed as a dose metric for dioxin cancer risk estimates (Becher et al., 1998).

The choice of dose metric not only considers mechanistic data but must also consider pragmatic approaches as well. The use of the dose metric plays a role in its choice. Because of differences in life-span and uncertainties in the window of sensitivities for various endpoints, AUC may not be a useful dose metric for cross species extrapolation. However, AUC has been used in the analysis of the human cancer data (Becher et al., 1998) and may be a useful dose metric when applied to accidental or occupational exposures since cross species scaling is not

required. The choice of dose metric is also dependent upon the data available. A number of dose metrics, such as Ah receptor occupancy, induction of CYP1A2, and decreases in EGF receptor have been proposed based on PBPK models (Jusko et al. 1995; Andersen et al.1997; Kohn et al 1993; Portier and Kohn, 1996). While these dose metrics have been useful in hypothesis testing in experimental systems, they are not useful in animal to human extrapolations due to the difficulty in measuring these parameters in humans. In the following section, the strengths and weaknesses of a variety of proposed dose metrics will be presented.

1.5.1 Administered Dose

In experimental studies, animals are administered a defined dose through a variety of routes. A default method used by USEPA (USEPA, 1992; 1996) to estimate the human equivalent dose when scaling across species is to use allometric scaling based on the following equation:

$$Dose_{human} = Dose_{rat} (BW_{rat}/BW_{human})^{0.25}$$

Where BW is the body weight in kg and Dose is the daily administered dose in rats or the scaled human daily dose expressed as ng/kg/d. This method is thought to scale administered dose in such a way as to result in equivalent effective doses in humans and experimental animals (USEPA, 1992). Using this equation a dose of 1 ng TCDD/kg/d in a 0.35 kg rat would result in a scaled human dose of 0.27 ng TCDD/kg/d for a 70 kg human. If this scaling method applies to TCDD and related chemicals, then 1 ng TCDD/kg/d in the rat should produce similar effective dose in a human exposed to 0.27 ng TCDD/kg/d, some 3.8 times lower. Assuming similar sensitivity between rats and humans at the tissue level, effective doses should be a function of tissue concentration. Tissue concentrations of TCDD and related chemicals are directly related to the concentration of TCDD in the body. The steady-state concentration of TCDD in the body, or steady-state body burden, can be estimated in rats and humans using the following equation.

$$\text{Steady-state body burden (ng/kg)} = (Dose*F) * (t_{½}/Ln(2))$$

where Dose is the daily administered dose, F is the fraction absorbed, and $t_{½}$ is the species-specific half-life of TCDD. In the present example, we will assume F is 50% and the species specific half-life of TCDD is 25 days for rats and 2593 days for humans. Starting with an administered dose of 1 ng/kg/d in rats and the scaled human dose of 0.27 ng/kg/d, the steady-

state body burdens are presented in Table 1-14. The steady-state body burden of TCDD using the scaled human dose is approximately 28 times that of the steady-state body burden in the rat (Table 1-14). Using the equation above, the estimated steady-state body burden in rats exposed to 1 ng TCDD/kg/day is 18 ng/kg. An equivalent administered dose in humans that results in a body burden of 18 ng/kg is estimated at 0.0096 ng/kg/day. It should be noted that when body burden is used as the dose metric, an equivalent human dose is over 100 times less than the human equivalent dose estimated using the EPA default scaling method.

Using administered dose as a dose metric has additional uncertainties when route and duration of exposures are varied. Tissue concentrations of a chemical are influenced by the route and duration of exposure. For example, the time course and peak tissue concentrations for the distribution of a dose of TCDD is different when the dose is administered orally, dermally or intratracheally (Diliberto et al., 1994). The dosing vehicle can also influence the absorption and distribution of a chemical (Dix et al., 1997). The amount and rate of absorption of a chemical in an oil vehicle can be very different when the chemical is dissolved or suspended in an aqueous vehicle or bound to soil (Olson et al., 1994). Using administered dose as the metric for exposures occurring through the same route, rate and dosing vehicle within the same species clearly is appropriate. However, in cases where these parameters vary across dosing scenarios, there is increasing uncertainty in the extrapolation.

Clearly, the default scaling method results in an estimated human equivalent dose that produces a much greater estimated steady-state body burden (505 ng/kg) than the rat's. One reason for the discrepancy of the scaling method is that the half-life of TCDD in rodents and humans is much larger than is typically observed for other xenobiotics (Bachmann et al., 1996; Sarver et al., 1997). The half-life of TCDD in humans is approximately 100 fold greater than in rats. The EPA default scaling methodology would estimate human half-lives at approximately 3.8 times greater than in rats. This exercise demonstrates that administered dose does not provide a useful dose metric for cross species extrapolation even if the dose is scaled using the EPA default methodology. However, administered dose can be used to compare exposures between human populations in order to describe potential human health risks, because the species differences in half-life would not exist in this case.

1.5.2 Area Under the Curve

Area under the curve or AUC is frequently used as a dose metric for reversible responses of pharmaceutical agents. Typically, these agents have half-lives on the order of minutes to hours. In the pharmaceutical literature, AUC is most frequently used for drugs with a rapid onset of action and that are rapidly reversed following cessation of exposure (Goodman and Gilman). In addition, the pharmacological actions of the drugs and the length of time of the response is

clearly defined in both animals and humans. In essence, plasma concentrations are readily determined and the time span is easily defined. In cases where repeated doses of a drug is used, the steady-state plasma concentration is the preferred measure of dose. Also, when using drugs with a slow onset (i.e., a week or more), such as the tricyclic antidepressants, dose is typically expressed as steady-state blood concentrations.

Mechanistic considerations also suggest that AUC can be a useful dose metric for chemical carcinogenesis. AUC has been applied as a dose metric in chemical carcinogenesis for DNA reactive chemicals. In these cases, the DNA reactive chemicals, increases in the mutational rates are expected to be related to the integrated tissue exposure to the critical DNA reactive species (Krewski et al., 1994). What is less certain about AUC as a dose metric is whether the risk across species for DNA reactive chemicals should be normalized based on integrated daily tissue concentration or an integrated lifetime tissue concentration. In any event, the dose metric would be the integrated tissue concentration of DNA reactive chemical over the appropriate period of the animal or human life span (Krewski et al., 1994).

There are some concerns over applying AUC as a cancer dose metric for TCDD. TCDD and related chemicals are thought to induce tumors non-genotoxic mechanisms. The evidence supporting the use of lifetime AUC calculations for cancer risk involves genotoxic chemicals and radiation. TCDD lacks direct acting genotoxicity and is considered a tumor promoter. This promotional process requires sustained tissue concentrations of TCDD sufficient to maintain increased gene expression. It is likely that AUC would be an appropriate dose metric for cancer and may also involve the incorporation of a threshold concentration (Hays et al., 1997). Chemicals for which AUC has been applied as a dose metric are DNA reactive chemicals. DNA reactive chemicals produce DNA adducts and the probability of a mutational event occurring from adduct formations increases with the number of adduct formed. Adduct formation is associated with an integrated measure of dose. Because of the difference in mechanism of action, there no evidence supporting or refuting the use of AUC as a cancer dose metric for TCDD.

The need for species extrapolation in toxicology further complicates the use of AUC as a dose metric. While blood or plasma concentrations of TCDD can be determined in both human and animals, the determination of the time span for which the AUC is to be calculated is much less certain. For some of the toxic responses of TCDD, the window of sensitivity is clearly defined in rodents and humans, such as induction of cleft palate. For other responses, such as the developmental reproductive alterations observed in male and female rats, the window of sensitivity has been narrowed to exposures between gestational day 15 and 20 in the rats, but the human window of sensitivity is uncertain. For carcinogenesis, the length of time required to induce the response remains uncertain in both experimental animals and humans. In order to

apply AUC for species comparisons of the sensitivity to TCDD, one must have a better understanding of the species differences in the windows of sensitivity to the various biological effects of TCDD.

Another of the uncertainties in risk assessment is time scaling across species. The difficulty is that there does not appear to be a consistent method of time scaling between species for different biological processes. If we were to compare the length of time of several common biological phenomena in rats and humans, we would observe different ratios of these time frames. For example, rats live approximately 2-2.5 years, while the average human life span is estimated at 70 years. The gestation period is approximately 21 days in a rat and 270 days in humans. The age at the time of puberty in rats is between postnatal days 29-45 and in humans occurs between 8 and 14 years old. In contrast, some processes, such as diurnal cycles or cell replication, have equivalent time spans between species. Due to uncertainties in how to properly account for the differences in time span for different biological responses, lifetime average daily dose is recommended as the default dose metric (Rhomberg, 1990).

In addition, differences in life-span also must be considered. Brody and Reid (1967) proposed that the biological activity of a drug is related to its plasma concentrations. If animals and humans had the same plasma concentrations for their entire lives, the human AUC would be greater because humans have a longer half-life. However, because the plasma concentrations were the same, according to Brody and Reid (1967) the responses should be similar. Hence, in order to use AUC for chronic toxicities, such as cancer, a correction for the difference in life-span must be applied. Typically, this involves the derivation of an average daily AUC (Alyward et al., 1996). An estimation of the average daily AUC is directly related to steady-state body burdens. Hence, once the AUC is corrected for life-span differences, these values are equivalent to steady-state body burdens.

While AUC may not be an appropriate dose metric for animal to human extrapolations, it is a use tool for comparing populations exposed to high concentrations of dioxins over a short period of time to the background population. Becher et al (1998) successfully used this approach to examine dose response relationships for cancer in an occupationally exposed cohort. One difficulty in determining AUC is the accuracy of the intake measurements. Past exposures through the diet are uncertain, although they have been estimated (Pinsky and Lorber, 1998). Future exposures are thought to be decreasing, although the exact magnitude of this decrease are uncertain. Hence, determination of AUC carries a number of uncertainties that must be considered.

1.5.3 Plasma or Tissue Concentrations

Brodie and Reid (1967) have argued that the response to a drug is determined by the amount bound to its biological receptor and since the drug receptor complex is in dynamic equilibrium with the free drug in the plasma, the biological response of a drug will be related to its plasma concentrations. There is no reason to believe that this relationship will not be true for TCDD and related chemicals. However, there are several data gaps that may prohibit the use of plasma or blood concentrations for species extrapolation. First, few animal studies determined blood or plasma concentrations of TCDD, particularly in the subchronic, chronic and lifetime exposures. PBPK models can be used to estimate blood concentrations and should provide reasonable estimates of these values. In contrast, the human exposure data is based predominately on blood, serum or plasma dioxin concentrations. One limitation of the human data is that it is mostly presented on a lipid adjusted basis. Hence in order to compare the human and animal plasma or blood concentrations, one would have to first estimate the blood concentrations in the animals using a PBPK model. Then either the animal data would have to be expressed as a lipid basis or the human data would have to be expressed as a wet weight basis. In either case, assumptions of the percent lipid in the blood would have to be applied as well as a number of assumptions used in the PBPK models.

The use of tissue concentrations as a dose metric has been examined by Van Birgelen et al., (1996) and Hurst et al., (1999). Van Birgelen and coworkers (1996) presented data demonstrating tissue that concentrations provided an accurate prediction of enzyme induction regardless of the exposure scenario (i.e. acute vs subchronic). The use of alternative dose metrics, such as AUC and total administered dose, failed to demonstrate predictive relationships for enzyme induction and immunotoxicity (van Birgelen, 1996). Similarly, Hurst et al. (1999) presented data demonstrating that fetal tissue concentrations of TCDD on gestation day 16 predicted decreases in sperm counts, delays in puberty in males, urethra-phallus distance and the incidence of vaginal threads in rats prenatally exposed to TCDD on either gestational day 9 or 15. These data suggest that target tissue concentrations may be a reasonable dose metric for these responses.

While tissue concentrations may aid in estimating risks, these data are unlikely to be collected in humans in sufficient numbers to be useful, particularly for fetal concentrations. Plasma concentrations are also a useful tool to compare exposures in different human populations. Application of plasma concentrations as a dose metric for species extrapolation require some level of assumptions as described above, but reasonable comparisons could be made, particularly for comparing steady-state exposures in humans and animals. Comparing plasma or blood concentrations following acute exposures in experimental animals to steady-state human blood or plasma concentrations would not be appropriate. One limitation of the use

of either plasma, blood, or target tissue concentrations as dose metrics is the lack of human PBPK models to predict these values based on changes in intake patterns.

1.5.4 Steady-State Body Burdens

Body burden is defined as the concentration of TCDD and related chemicals in the body and is typically expressed as ng/kg. Steady-state body burden is defined as the concentration of TCDD and related chemicals in the body under steady-state exposure conditions and is also expressed as ng/kg. Humans generally reach exposures approximating steady-state between the ages of 20 and 30, with body burdens increasing slightly with age over the course of the next several decades. Humans steady-state body burdens and are estimated based on an intake rate and the half-life of TCDD in humans. Alternatively, body burdens in humans are estimated based on lipid adjusted serum or adipose tissue TCDD or TEQ concentrations. In animals, these values are calculated from studies at or approaching steady-state and are associate with either biochemical or toxicological responses. In addition, these values are calculated based on either knowledge of the species-specific half-life and the exposure regimen or they are estimated based on the TCDD tissue concentration, the size of the tissues and the weight of the animal.

Steady-state body burdens provide a useful dose metric for several reasons. First, tissue and blood concentrations are directly related to body burdens. Thus, body burdens are surrogates for tissue concentrations. Second, the differences in the half-life of TCDD between species is accounted for because these body burdens are estimated at steady-state conditions. Third, DeVito et al. (1995) have demonstrated that for some biochemical responses, chloracne and cancer, species have similar rates of responses when dose is expressed on a body burden basis. Finally, body burdens provide flexibility because they can be estimated based on either intake rates or on measured tissue concentrations.

Body burdens also have some limitations. In order to estimate body burdens from lipid adjusted tissue concentrations, an assumption of the percent body fat must be used. In the reassessment, a value of 25% has been used. It should be noted that there are human populations with body fat compositions less than 10% and greater than 35%. Also when estimating the body burden based on intake rates and half-lives, the uncertainty of these parameters should be considered. In the reassessment, the estimated steady-state body burden of approximately 5 ng TEQ/kg is based on measured serum concentrations from several populations in the mid 1990's. While measured concentrations should eliminate some of the uncertainties around estimates using intake rates and half-life assumptions, it is likely that these measured values represent a past history of higher exposure and we must anticipate a continued downward trend to present a “true” lifetime average concentration. Caution must be used when using body burden in conditions other than steady-state. Under these short-term exposures conditions in experimental

animals, the relationship between tissue concentrations and body burden may not be the same as under steady-state conditions.

1.5.5. Mechanistic Dose Metrics

Several groups have proposed a variety of dose metrics based on mechanistic considerations, such as concentration of occupied AhR (Jusko, 1995), induced CYP1A2 (Andersen et al., 1997; Kohn et al., 1993) and reduced epidermal growth factor receptor (EGFR) (Portier and Kohn, 1996). While these dose metrics are intellectually appealing, it must be kept in mind that they are still hypothesized dose metrics and require further research to demonstrate their utility for cross-species extrapolations. In addition, these dose metrics are unlikely to be measured in sufficient human samples to be useful.

1.5.6. Summary

A variety of dose metrics have been proposed for estimating potential human health effects following exposure to dioxins. Many of these dose metrics have limitations that prohibit their use, such as tissue concentrations and the mechanistic dose metrics. Other dose metrics, such as AUC have limited utility for species extrapolations because of our limited understanding of the concept of physiological time. Some dose metrics can be used to compare different human exposures, such as AUC and administered dose, but are not suitable for species extrapolations. Other dose metrics, such as steady-state body burdens or blood concentrations, are useful dose metric because they are easily estimated, and are directly related to tissue concentrations and can be estimated in both animals and humans. The use of any of these dose metrics requires a number of assumptions discussed above. The choice of dose metric requires an understanding of the data available and their application of the dose metric. Future research efforts on the issue of dose metrics could provide better guidance in choosing the dose metrics for dioxins and related chemicals. However, in the mean time, the use of steady-state body burdens can provide a basis for species extrapolations.

Table 1-1. Gastrointestinal absorption of TCDD and related compounds following a single oral exposure by gavage

Chemical	Species (Sex)	Dose (μmol/kg)	Dose (μg/kg)	Vehicle	% Administered Dose Absorbed[a] [Mean (Range)]	Reference

[a]Source: Neubert et al., 1990.
[b]Animals were treated subcutaneously with a single dose of a defined CDD/CDF mixture, and the tissues were analyzed at different times following treatment. Half-lives were calculated from tissue concentrations of the 2,3,7,8-substituted congeners in hepatic and adipose tissue. Values are given as elimination rate constant K_e including estimated SD and half-life including 95% confidence intervals.
[c]Calculated from the time period: >6 weeks after injection.
[d]Calculated half-life is apparently infinite. Data for OCDD and OCDF are unreliable due to delayed absorption.
[e]Not detected in hepatic tissue 6 weeks after treatment; limits of detection used for calculation.
[f]Due to interference.
NA = Not applicable.

Table 1-8. TCDD concentrations in liver and adipose tissue following different doses and calculated concentration ratios (liver/adipose tissue)[a]

Dose (ng/kg)	Number	TCDD Concentration Liver (ng/g)	TCDD Concentration Adipose Tissue (ng/g)	Concentration Ratio: Liver/Adipose Tissue

Table 1-11. Calculated daily intakes for TCDD

Half-life (yrs)	Fat vol. (L)	Fat conc. (ppt)	Calculated daily intake (PG/KG/Day)
5.8	14.0	6.72	0.44
7.0	14.0	6.72	0.37
5.8	14.0	5.00	0.33
7.0	14.0	5.00	0.27
5.8	7.0	6.72	0.22
7.0	7.0	6.72	0.18
5.8	7.0	5.00	0.16
7.0	7.0	5.00	0.14

Table 1-12. Half-life calculations

Chemical	Food-ppt[a]	Body-ppt[b]	$t_{1/2}$[c] years	$t_{1/2}$[d] years
2378-TCDD	0.23	6.72	7.0	6.0
2378-TCDF	0.84	3.9	1.11	1.3
12378-PeCDD	0.7	21.5	7.35	5.0
23478-PeCDF	1.4	36.8	7.94	6.3
OCDD	19.2	653.0	8.14	50.0

[a]Concentrations in food for TCDD, TCDF, and OCDD were obtained as discussed in Part I, Volume 3; those for PCDD and PCDF were taken from Schlatter (1991).
[b]Concentrations in body (adipose tissue) were all taken from Schecter (1991).
[c]Calculated using Equation 1-19, except for TCDD.
[d]Calculated by Schlatter (1991), except for TCDD.

Table 1-13. Half-life estimates taken from Flesch-Janys et al. (1996)

Compound	N individuals	Median half-life estimate (years)
2,3,7,8-TCDD	48	7.2
1,2,3,7,8-PeCDD	40	15.7
1,2,3,4,7,8-HCDD	41	8.4
1,2,3,6,7,8-HCDD	40	13.1
1,2,3,7,8,9-HCDD	39	4.9
1,2,3,4,6,7,8-HpCDD	26	3.7
OCDD	32	6.7
2,3,4,7,8-PeCDF	5	19.6
1,2,3,4,7,8-HCDF	42	6.2
1,2,3,6,7,8-HCDF	31	6
2,3,4,6,7,8-HCDF	6	5.8
1,2,3,4,6,7,8-HpCDF	22	3
1,2,3,4,7,8,9-HpCDF	6	3.2

Table 1-14. Comparison of administered dose and body burden in rats and humans.

	(A) Rat Daily Administered Dose/Body Burden	(B) Human Scaled Administered Dose/Body Burden[1]	(C) Human Equivalent Administered Dose/Body Burden[2]	(A/B) Ratio of Rat to Human Scaled Dose	(A/C) Ratio of Rat to Human Equivalent Dose
Dose (ng/kg/d)	1	0.27	0.0096	3.7	104
Body Burden (ng/kg)	18	505	18	0.036	1

1. Assumes administered dose scales across species as a function of $BW^{3/4}$
2. Assumes administered dose scales across species as a function of equivalent body burdens

Figure 1-1. Time course of the connection of 14C-TCDD in rat liver and adipose tissue after a single subcutaneous injection of 300 ng TCDD/kg bw to female rats (M±SD).

Source: Abraham et al., 1988.

Figure 1-2. Dose dependency of the percentage of the administered dose of 14C-TCDD/g of tissue recovered in liver and adipose tissue after single subcutaneous doses (values from animals treated with 3000 ng TCDD/kg bw were corrected for 84% adsorption). Concentrations were measured 7 days after the injection.

Source: Abraham et al., 1988.

$$D = \left(\frac{ln2}{t_{1/2}} \right) V_F \, C_F \left(\frac{1}{70KG} \right)$$

$$D = \left(\frac{ln2}{5.8years} \right) \left(14L \;\; 1000 \; \frac{ml}{L} \right) \left(6.72 \frac{pg}{ml} \right) \left(\frac{1}{70KG} \right) \left(\frac{1year}{365days} \right)$$

$$D = 0.44 \;\; pg/kg/day$$

2. MECHANISM(S) OF ACTION*

2.1. INTRODUCTION

2,3,7,8-Tetrachlorodibenzo-*p*-dioxin (TCDD, dioxin) is the prototype for a class of halogenated aromatic hydrocarbons (HAHs) that produce similar patterns of toxicity and appear to have a common mechanism of action, although they differ in potency (Poland and Knutson, 1982; Safe, 1986). Because it is the most potent, TCDD has been studied much more extensively than other structurally related compounds (Figure 2-1). TCDD achieved notoriety in the 1970s, when it was discovered to be a contaminant in the herbicide Agent Orange and was shown to produce birth defects in rodents. Subsequently, dioxin has continued to generate concern because of its widespread distribution, its persistence as an environmental contaminant, its accumulation within the food chain, and its toxic potency. In animals, TCDD elicits a wide range of biological effects, including alterations in metabolic pathways, immunological changes, reproductive and developmental abnormalities, and neoplasia (Poland and Knutson, 1982; Safe, 1986; Birnbaum, 1994b). In humans, dioxin and related compounds can produce the skin condition known as chloracne. Increased cancer rates have also been associated with exposures to dioxin-like chemicals (International Agency for Research on Cancer, 1997). The possibility that dioxins also produce birth defects and developmental abnormalities is a particular public health concern. Many individuals have been exposed to TCDD, primarily from dietary sources, although occupational and accidental exposures have also occurred. TCDD is a poor substrate for detoxification systems such as the microsomal cytochrome P450 enzymes, which oxygenate other lipophilic compounds to inactive derivatives during their metabolic processing. Because of its relative resistance to metabolism, TCDD persists in the body, with a half-life in humans on the order of 7 to 10 years (Pirkle et al., 1989; Michalek et al., 1996; Michalek and Tripathi, 1999). Therefore, dioxin tends to accumulate in human tissues over time, raising concern that repeated exposures, even to "low" concentrations, may evoke adverse health effects. Epidemiological studies performed to date have not produced well-defined estimates of the health risk that dioxin poses to humans. There has been hope that knowledge of the mechanism of dioxin action will bring about a greater understanding of these issues (Andersen et al., 1994; Denes et al., 1996).

Mechanistic studies can reveal the biochemical pathways and types of biological and molecular events that contribute to dioxin's adverse effects. For example, much evidence indicates that TCDD acts via an intracellular protein (the aryl hydrocarbon receptor; Ah receptor), which functions as a ligand-dependent transcription factor in partnership with a second protein (known as the Ah receptor nuclear translocator; Arnt). Therefore, from a mechanistic standpoint, TCDD's adverse effects appear likely to reflect alterations in gene expression that occur at an inappropriate time and/or for an inappropriately long time. Mechanistic studies also indicate that several other proteins contribute to TCDD's gene regulatory effects and that the response to TCDD probably involves a relatively complex interplay between multiple genetic and environmental factors. If TCDD operates through such a mechanism, as all evidence indicates, then there are certain constraints on the possible models that can plausibly account for TCDD's biological effects and, therefore, on the assumptions used during the risk assessment process (e.g. Poland, 1996; Limbird and Taylor, 1998). Mechanistic knowledge of dioxin action may also be useful in other ways. For example, a further understanding of the ligand specificity and structure of the Ah receptor will likely assist in the identification of other chemicals to which humans are exposed that may either add to, synergize, or block the toxicity of TCDD. Knowledge of genetic polymorphisms that influence TCDD responsiveness may also allow the identification of individuals at greater risk from exposure to dioxin. In addition, knowledge of the biochemical pathways that are altered by TCDD may help identify novel targets for the development of drugs that can antagonize dioxin's adverse effects.

As described below, biochemical and genetic analyses of the mechanisms by which dioxin may modulate particular genes have revealed the outline of a novel regulatory system whereby a chemical signal can alter cellular regulatory processes. Future studies of dioxin action have the potential to provide additional insights into mechanisms of mammalian gene regulation that are of a broader interest. Additional perspectives on dioxin action can be found in several recent reviews (Birnbaum, 1994a,b; Schecter, 1994; Hankinson, 1995; Schmidt and Bradfield, 1996; Gasiewicz, 1997; Rowlands and Gustafsson, 1997; Denison et al., 1998; Hahn, 1998; Wilson and Safe, 1998; Gu et al., 2000).

2.2. THE "RECEPTOR" CONCEPT

The idea that a drug, hormone, neurotransmitter, or other chemical produces a physiological response by interacting with a specific cellular target molecule, i.e., a "receptor," evolved from several observations. First, many chemicals elicit responses that are restricted to specific tissues. This observation implies that the responsive tissue (e.g., the adrenal cortex) contained a "receptive" component whose presence is required for the physiologic effect (e.g., cortisol secretion). Second, many chemicals are quite potent. For example, picomolar to

nanomolar concentrations of numerous hormones and growth factors elicit biological effects. This observation suggests that the target cell contains a site(s) to which the particular chemical binds with high affinity. Third, stereoisomers of some chemicals (e.g., catecholamines, opioids) differ by orders of magnitude in their ability to produce the same biological response. This observation indicates that the molecular shape of the chemical strongly influences its biological activity. This, in turn, implies that the binding site on or in the target cell also has a specific, three-dimensional configuration. Together, these types of observations predict that the biological responses to some chemicals involve stereospecific, high-affinity binding of the chemicals to specific receptor sites located on or in the target cell.

The availability of compounds of high specific radioactivity has permitted quantitative analyses of their binding to cellular components in vitro. To qualify as a potential "receptor," a binding site for a given chemical must satisfy several criteria: (1) the binding site must be saturable, i.e., the number of binding sites per cell should be limited; (2) the binding should be reversible; (3) the binding affinity measured *in vitro* should be consistent with the potency of the chemical observed *in vivo*; (4) if the biological response exhibits stereospecificity, so should the *in vitro* binding; (5) for a series of structurally related chemicals, the rank order for binding affinity should correlate with the rank order for biological potency; and (6) tissues that respond to the chemical should contain binding sites with the appropriate properties.

The binding of a chemical ("ligand") to its cognate receptor is assumed to obey the law of mass action; that is, it is a bimolecular, reversible interaction. The concentration of the liganded, or occupied, receptor [RL] is a function of both the ligand concentration [L] and the receptor concentration [R]:

$$[L] + [R] \underset{k_2}{\overset{k_1}{\rightleftharpoons}} [RL]$$

Inherent in this relationship is that the fractional occupancy (i.e. $[RL] / [R_t]$) is a function of ligand concentration [L] and the apparent equilibrium dissociation constant K_D, which is a measure of the binding affinity of the ligand for the receptor, that is, $[RL] / [R_t] = [L] / (K_D + [L])$, where $K_D = [L] [R_t] / [LR] = k_2 / k_1$. Therefore, the relationship between receptor occupancy and ligand concentration is hyperbolic. At low ligand concentrations (where $[L] << K_D$), a small increase in [L] produces an approximately linear increase in fractional receptor occupancy. At high ligand concentration (where $[L] >> K_D$), the fractional occupancy of the receptor is already very close to 1, that is, almost all receptor sites are occupied. Therefore, a small increase in [L] is likely to produce only a slight increase in receptor occupancy.

Ligand binding constitutes only one aspect of the receptor concept. By definition, a receptor mediates a response, and the functional consequences of the ligand-receptor binding represent an essential aspect of the receptor concept. Receptor theory attempts to quantitatively relate ligand binding to biological responses. The classical "occupancy" model of Clark (1933) postulated that (1) the magnitude of the biological response is directly proportional to the fraction of receptors occupied and (2) the response is maximal when all receptors are occupied. However, analyses of numerous receptor-mediated effects indicate that the relationship between receptor occupancy and biological effect is not as straightforward as Clark envisioned. In certain cases, no response occurs even when there is some receptor occupancy. This suggests that there may be a threshold phenomenon that reflects the biological "inertia" of the response (Ariens et al., 1960). In other cases, a maximal response occurs well before all receptors are occupied, a phenomenon that reflects receptor "reserve" (Stephenson, 1956). Therefore, one cannot simply assume that the relationship between fractional receptor occupancy and biological response is linear. Furthermore, for a ligand (such as TCDD) that elicits multiple receptor-mediated effects, one cannot assume that the binding-response relationship for a simple effect (such as enzyme induction) will necessarily be identical to that for a different and more complex effect (such as cancer). The cascades of events leading to different complex responses (e.g., altered immune response to pathogens or development of cancer) are likely to be different, and other rate-limiting events likely influence the final biological outcome resulting in different dose-response curves. Thus, even though ligand binding to the same receptor is the initial event leading to a spectrum of biological responses, ligand-binding data may not always mimic the dose-effect relationship observed for particular responses.

Another level of complexity is added when one considers different chemical ligands that bind to the same receptor. Relative potencies are determined by two properties of the ligand: affinity for the receptor, and capacity to confer a particular response in the receptor (e.g., a particular conformational change), also called efficacy (Stephenson, 1956). Ligands with different affinities and the same degree of efficacy would be expected to produce parallel dose-response curves with the same maximal response within a particular model system. However, ligands of the same affinity with different efficacies may result in dose-response curves that are not parallel or that differ in maximal response.

2.3. THE Ah (DIOXIN) RECEPTOR

The unusual toxic potency of TCDD suggested the possible existence of a receptor for dioxin. Poland and coworkers, using radiolabeled TCDD as a ligand, demonstrated that the cytosolic fraction of C57BL/6J mouse liver contained a protein that bound the dioxin saturably (i.e., ~10^5 binding sites per cell), reversibly, and with high affinity (i.e., in the nanomolar range,

consistent with TCDD's biological potency in vivo). Competition binding studies with congeners of TCDD revealed that ligands with the highest binding affinity were planar and contained halogen atoms in at least three of the four lateral positions; thus, ligand binding exhibited stereospecificity. In addition, the ligand-receptor binding relationship resembled a rectangular hyperbola and, therefore, appeared to obey the law of mass action. Together, these findings demonstrated that the intracellular TCDD-binding protein had the ligand binding properties expected for a "dioxin receptor." The protein has been designated as the "Ah receptor" because it binds and mediates the response to other aromatic hydrocarbons (such as 3-methylcholanthrene) in addition to TCDD (Poland and Knutson, 1982).

Inbred mouse strains differ quantitatively in their responsiveness to TCDD and other aromatic hydrocarbons. For example, TCDD elicits its effects at about 10-fold lower concentrations in the more responsive mouse strains (typified by C57BL/6) than in the less responsive strains (typified by DBA/2). This polymorphism in responsiveness is genetic in origin, and, in crossbreeding studies, the more responsive phenotype segregates as an autosomal dominant trait. Numerous responses to TCDD (e.g., enzyme induction, thymic involution, cleft palate formation, hepatic porphyria) exhibit a segregation pattern identical to that for the binding of TCDD to the Ah receptor. Thus, the genetic locus (designated *Ah*) that governs this receptor polymorphism also governs the biological responses to TCDD. These findings implicate the Ah receptor in the mechanism of dioxin action (Poland and Knutson, 1982; Nebert et al., 1991). The resistance of recently developed Ah receptor null-allele ("knockout") mice to the enzyme inductive and toxic effects of very high doses of TCDD further corroborates the role of this protein in these responses (Fernandez-Salguero et al., 1996; Schmidt et al., 1996; Mimura et al., 1997; Hundeiker et al., 1999; Peters et al., 1999).

Studies of structure-activity relationships (SARs) reveal that, within groups of structurally-related compounds, a ligand's receptor-binding affinity often correlates with its potency in eliciting a biological response(s). Such SAR analyses are useful for assessing possible participation of the AhR in ligand-induced responses in experimental systems where genetic polymorphisms of the receptor are not available. Such SAR studies constitute biochemical evidence that implicates the Ah receptor in the mechanism of dioxin action. In general, the rank order binding affinity of TCDD and related chemicals to the Ah receptor has been demonstrated to be similar to their rank order of potency to elicit a broad spectrum of biochemical, morphologic, immunologic, neoplastic, developmental, and reproductive effects (Poland and Knutson, 1982; Safe, 1986, 1990). This rank order appears largely dependent on several structural constraints. For example, relatively planar aromatic compounds with approximate van der Waals dimensions of 14 x 12 x 5 Å with few bulky substituent groups have, in general, the highest ligand binding affinity and are the most potent for eliciting biological

effects (Poland and Knutson, 1982; Gillner et al., 1993; Waller and McKinney, 1995). However, it is becoming increasingly recognized that some Ah receptor ligands have both agonist and antagonist activity (Harris et al., 1989b; Kurl et al., 1993; Lu et al., 1996; Henry et al., 1999), suggesting that not all Ah receptor ligands have the same degree of efficacy (Hestermann et al., 2000).

The cloning of receptor cDNA (Burbach et al., 1992; Ema et al., 1992) has added important new insights into Ah receptor structure and function (reviewed in Hankinson, 1995; Rowlands and Gustafsson, 1997). The deduced amino acid sequence reveals that the Ah receptor has several features in common with a class of transcription factors known as basic helix-loop-helix (bHLH) proteins. The Ah receptor contains a bHLH domain, located towards the N-terminal end of the receptor. An analysis of this and other bHLH proteins indicates that the basic region mediates DNA binding, whereas the helix-loop-helix domain is necessary for dimerization with other proteins. Two other receptor regions function in dimerization. These are designated as "PAS" regions due to their sequence homology with Per (a *Drosophila* circadian rhythm protein), Arnt (another protein that contributes to dioxin responsiveness, described below), and Sim (a regulatory protein that participates in *Drosophila* central nervous system development) (Huang et al., 1993). In the AhR, the PAS domain consists of approximately 300 amino acid residues containing two copies of a repeat of about 50 amino acids, referred to as the PAS-A and PAS-B repeats. In the absence of an agonist, the PAS-B region associates with one heat shock protein 90 (hsp90) molecule, permitting binding of a second hsp90 to the HLH region (Whitelaw et al., 1993; Antonsson et al., 1995; Coumailleau et al., 1995; Whitelaw et al., 1995; Fukunaga et al., 1995). TCDD has been shown to interact with a ligand-binding pocket near the PAS-B region, the conformation of which is maintained by hsp90. Dimerization between AhR and Arnt is mediated through their HLH regions, but is further stabilized by PAS-PAS interactions (Reisz-Porszasz et al., 1994; Fukunaga et al., 1995). Immunohistochemical studies, using anti-receptor antibodies, reveal that the unliganded receptor resides in the cytoplasm; exposure of cells to (under in vitro conditions) TCDD leads to the accumulation of the receptor within the nucleus (Pollenz et al., 1994). Association with hsp90 is also thought to limit nuclear uptake of the receptor by blocking a N-terminal nuclear localization sequence (Pongratz et al., 1992; Ikuta et al., 1998). The carboxyl end of the protein contains a glutamine-rich region, which resembles certain "activation domains" present in some other transcription factors; by analogy, this region could interact with coactivator proteins that have yet to be characterized. Thus, like many proteins, the Ah receptor appears to be composed of several different functional domains. It is notable that the TCDD-bound Ah receptor does not, by itself, bind strongly to DNA; acquisition of DNA-binding capability appears to require that the receptor interact with another factor (such as the Arnt protein). Thus, the active form of the

receptor is heteromeric. The bHLH proteins identified to date are involved in transcriptional regulation and have a variety of roles in tissue growth and differentiation processes (Murre et al., 1994; Schmidt and Bradfield, 1996).

Human cells also contain an intracellular protein whose ligand-binding and hydrodynamic properties resemble those of the Ah receptor identified in other species (see Cook and Greenlee, 1989; Harris et al., 1989a; Roberts et al., 1990; Lorenzen and Okey, 1991; Harper et al., 1991; Ema et al., 1994). Furthermore, the sequence of this protein shows homology with that of other mammalian species (Dolwick et al., 1993; Ema et al., 1994; Hahn, 1998). Compared with the rat or mouse Ah receptor, however, the human Ah receptor appears, at least under cell-free conditions, to have a several-fold lower affinity for TCDD (Manchester et al., 1987; Ema et al., 1994). Some data also suggest that the human Ah receptor may be many times less sensitive in terms of eliciting a response. For example, cultured human embryonic palatal cells were approximately 200 times less sensitive than mouse palatal cells with respect to the inducibility of *CYP1A1* by TCDD (Abbott et al., 1999a). Although these data might imply that human tissues would be less sensitive to the toxic effects of TCDD, the Ah receptor in human cells has also been shown to exist in more than one form (Perdew and Hollenbeck, 1995). The relative sensitivity and function of these different forms have not been evaluated. Furthermore, these observed differences may be related to the greater lability of the human receptor during tissue preparation and cell fractionation procedures (Manchester et al., 1987). Data also suggests considerable heterogeneity of Ah receptor concentrations and characteristics in the human population (e.g., Roberts et al., 1986, 1990, 1991). However, a limited analysis for human AhR polymorphisms identified only one amino acid exchanging polymorphism, and this is thought to have little or no functional significance (Wanner et al., 1999). Additional studies of the human receptor should increase our knowledge of its functional properties and role in mediating altered cell- and tissue-specific responses elicited by TCDD and related chemicals.

Evidence indicates that the Ah receptor evolved prior to the introduction of HAHs into the environment (Czuczwa et al., 1984; Hahn et al., 1997). Furthermore, what is known about the structure, regulation, and expression of the Ah receptor in different tissues indicates a purposeful regulation for some normal function. The ontogenically related and tissue-specific expression of the receptor (e.g., Abbott et al., 1995; Jain et al., 1998), as well as the conservation of its presence and protein sequence in diverse groups of vertebrates, implies an essential function (Hahn, 1998). Furthermore, the level and activity of the Ah receptor appear to be regulated by changes in cell differentiation stages, growth factors, cell activation, diurnal cycle, and prior exposure to receptor agonists (Vaziri et al., 1996; Crawford et al., 1997; Shimba et al., 1998; Hayashi et al., 1995; Wanner et al., 1995; Liu et al., 1996; Pollenz, 1996; Richardson et al., 1998). These aspects might, at least in part, contribute to the ability of TCDD to cause

tissue- and developmental stage-specific effects. The best evidence for a normal physiological function of the Ah receptor comes from studies with Ah receptor-deficient animals. These mice have altered hepatic growth and development, immune system abnormalities, development of vasculature, adverse reproductive outcomes and reproductive tissue development, and abnormal processes in a variety of tissues (Fernandez-Salguero et al., 1995; Schmidt et al., 1996; Fernandez-Salguero et al., 1997; Abbott et al., 1999b; Hushka et al., 1998; Thurmond et al., 2000; Robles et al., 2000; Benedict et al., 2000; Lahvis et al., 2000).

Several reports have indicated stimulation of Ah receptor-dependent responses under certain conditions in the absence of added ligand (Sadek and Allen-Hoffman, 1994; Ma and Whitlock, 1996; Weiss et al., 1996; Crawford et al., 1997; Chang and Puga, 1998). However, it is not yet clear whether this occurs via an endogenously present ligand or some other process. Nevertheless, it has been postulated that some other compound(s) must represent the "natural" ligand(s) for the receptor (Poellinger et al., 1992). Naturally occurring high-affinity ligands for the receptor exist in the environment, particularly in plants (Gillner et al., 1985, 1989; Rannung et al., 1987; Bjeldanes et al., 1991). Other candidates for endogenous ligands include tryptophan derivatives (Helferich and Denison, 1991), carotinoids (Gradelet et al., 1996), arachidonic acid metabolites (Schaldach et al., 1999), and tetrapyrroles or their derivatives (Sinal and Bend, 1997). Thus, it is possible that the Ah receptor might have evolved as part of a substrate-inducible system designed to metabolize and/or activate dietary lipophilic substances, and TCDD may mimic the binding of such substances to the receptor. TCDD has been observed to produce changes in the proliferative/differentiated phenotype of a variety of cell types (Knutson and Poland, 1980; Blankenship et al., 1993; Gaido and Maness, 1994; Gierthy et al., 1994; Brodie et al., 1996; Yang et al., 1999). Thus, an additional possibility is that TCDD mimics an endogenous Ah receptor ligand involved in the regulation of such tissue-specific phenotypes. Several reports have also suggested a role of the Ah receptor in cell cycle control (Ma and Whitlock, 1996; Weiss et al., 1996; Kolluri et al., 1999), possibly through regulation of tissue growth factors such as transforming growth factor-β (Zaher et al., 1998).

2.4. THE ARNT PROTEIN

Biochemical and hydrodynamic findings suggest that more than one protein participates in the response to TCDD. In particular, overwhelming evidence indicates that the Ah receptor interacts with the Arnt protein to form a heteromeric, DNA-binding protein complex that can activate gene transcription (reviewed in Hankinson, 1995; Schmidt and Bradfield, 1996; Rowlands and Gustafsson, 1997; Denison et al., 1998; Whitlock, 1999).

The human Arnt cDNA encodes a protein of about 86 kDa, which has several features in common with the Ah receptor. Like the Ah receptor, it contains a bHLH domain, which

contributes both to DNA binding and to protein-protein interactions (Hoffman et al., 1991; Li et al., 1994; Reisz-Porszasz et al., 1994). Furthermore, the Arnt protein contains PAS domains homologous to Per and Sim, and C-terminal domains functional in transcriptional activation (Huang et al., 1993; Reisz-Porszasz et al., 1994; Lindebro et al., 1995) . The Arnt protein does not bind TCDD. Furthermore, it does not bind to Ah receptor recognition sites on DNA (termed dioxin or xenobiotic response elements; DREs or XREs) on DNA in the absence of the liganded Ah receptor protein (Whitelaw et al., 1993). Immunohistochemical studies, using anti-Arnt antibodies, reveal that the Arnt protein resides in the nucleus in uninduced mouse hepatoma cells and that TCDD exposure of cells produces no change in its intracellular distribution (Pollenz et al., 1994). Thus, Arnt appears to be a nuclear protein. Furthermore, the nuclear accumulation of the Ah receptor occurs in Arnt-defective cells. Together, these findings argue against a primary role for Arnt in the translocation per se of the receptor from cytoplasm to nucleus. Instead, it has been suggested that Arnt interacts with the liganded Ah receptor to form a heteromeric, DNA-binding protein complex that can activate gene transcription. Experiments in vitro support this idea. For example, immunoprecipitation experiments reveal that the liganded Ah receptor and the Arnt protein can interact in solution. The liganded receptor alone does not exhibit substantial DNA-binding activity in the absence of Arnt; rather, the presence of both proteins is required to generate a specific DNA-binding species and to activate the expression of a dioxin-responsive reporter gene. Furthermore, deletion of the bHLH domain of Arnt abrogates its functional interaction with the liganded Ah receptor (Whitelaw et al., 1993). Together, these findings imply that the transcriptionally active component of the dioxin-responsive system is a protein heteromer consisting of (at least) the liganded Ah receptor and Arnt. Although both proteins contain a C-terminal transactivation domain, the Ah receptor appears to provide the dominant activation function, and the relative contribution of the Arnt domain largely depends on the availability of other cell-specific factors (Corton et al., 1996; Ko et al., 1996).

Multiple forms of Arnt have been detected in several species (Drutel et al., 1996; Hirose et al., 1996; Pollenz et al., 1996). In mice and rats, Arnt1 and Arnt2 are 83% identical in amino acid sequence, and have the ability to dimerize with the AhR and bind to specific DNA elements in vitro (Hirose et al., 1996). However, the expression patterns for these two isoforms are quite different. Arnt1 is widely expressed in a variety of tissues, whereas Arnt2 is detected primarily in adult brain and kidney (Drutel et al., 1996; Hirose et al., 1996). In addition, each protein has a distinct expression pattern in the developing mouse (Jain et al., 1998). The respective roles of these proteins in contributing to the variety of TCDD-elicited responses are not yet clear.

Both the Ah receptor and Arnt protein belong to the bHLH class of transcription factors, which function as heterodimers and contribute to the control of numerous genes (Kadesch, 1993). The dimerization capabilities of bHLH proteins provides a potential mechanism for

generating regulatory diversity. For example, different heterodimers may exhibit different stabilities, may have different DNA-binding affinities, or may recognize different DNA sequences. The bHLH structure of the Ah receptor raises the possibility that it might form heterodimeric complexes with proteins other than Arnt, generating regulatory molecules with potentially novel properties. By analogy with other bHLH systems, both the absolute amount of each partner and their relative ratios could influence the extent and type of response to TCDD. Thus, diversity in heteromer formation might contribute to the diversity of responses that typifies dioxin action. Arnt1 has been shown to be a dimerization partner for several proteins including the Ah receptor, single-minded (Sim), hypoxia inducible factor-1α, and endothelial PAS protein 1, and several other as yet uncharacterized proteins (Ema et al., 1997; Hogenesch et al., 1997; Probst et al., 1997). In addition, Arnt1 has been shown to have an essential role in development (Kozak et al., 1997; Maltepe et al., 1997). However, Arnt is the only protein that has been demonstrated to be a functional partner for the Ah receptor in terms of conferring specificity of DNA binding and transactivation. Some HLH proteins, which lack a basic region (typified by Id), may act as dominant negative regulators of transcription by dimerizing with bHLH proteins and inhibiting their DNA binding ability (Kadesch, 1993). There is evidence for an inducible dominant negative regulator of the Ah receptor, termed the Ah receptor repressor, that interacts with Arnt (Mimura et al., 1999). It is possible that the tissue-specific presence or absence of this factor regulates Ah receptor function and thus its response to xenobiotics by competing with the receptor for Arnt. In any case, the bHLH structure of the Ah receptor and the Arnt protein suggests that some of the diversity in TCDD's biological effects might reflect differential gene regulation by a mechanism involving formation of different protein heterodimers. Future mechanistic studies should aid in elucidating how such processes regulate dioxin action.

2.5. OTHER PROTEINS THAT PARTICIPATE IN THE RESPONSE TO DIOXIN

Attempts to purify the unliganded Ah receptor under nondenaturing conditions revealed that it tends to associate with other proteins in vitro, in particular the 90-kDa heat shock protein (hsp90). The hsp90 protein is an abundant factor that can interact with numerous other proteins and that may have multiple functions (Buchner, 1999). Immunoprecipitation studies and immunosedimentation experiments using anti-hsp90 antibodies reveal that the unliganded Ah receptor associates with hsp90 in vitro (Denis et al., 1988; Perdew, 1988). In view of previous findings implicating hsp90 in glucocorticoid receptor function (Picard et al., 1990), the association between the Ah receptor and hsp90 in vitro may be more than fortuitous. Hsp90 may be needed to maintain the unliganded receptor in a configuration that facilitates ligand binding. It might have a role in regulating nuclear translocation and DNA binding of the Ah receptor (Pongratz et al., 1992; Antonsson et al., 1995; Coumailleau et al., 1995; Phelan et al., 1998).

Studies in yeast have demonstrated the requirement for hsp90 in the formation of a functional Ah receptor (Carver et al., 1994). However, since complete hsp90 dissociation does not appear to be essential for nuclear localization (Heid et al., 2000), the dissociation of the two hsp90 molecules may occur during separate events in the cytosol and the nucleus, initiated by ligand binding and Arnt association, respectively. An additional protein, ARA9/AIP/XAP2, has been shown to enhance the transcriptional activity of the AhR-Arnt complex (Ma and Whitlock, 1997; Carver et al., 1998; Meyer et al., 1998). Although this protein does not appear to be required for AhR-hsp90 interaction, it apparently stabilizes this interaction and has some function in regulating the rate of AhR turnover in the cytosol or intracellular localization (Meyer and Perdew, 1999; LaPres et al., 2000; Petrulis et al., 2000; Bell and Poland, 2000). Recently, a 23-kDa protein has been shown to associate with the ligand-binding form of the Ah receptor. This protein is thought to play a role in stabilizing the complex containing receptor and hsp90 (Kazlauskas et al., 1999). Given the important functions of these proteins in stabilizing an Ah receptor form that can bind ligand and transduce the ligand-initiated signal to the nuclear compartment, the relative presence of these proteins might play an important role in the tissue-specific sensitivity to Ah receptor ligands like TCDD.

Several lines of evidence suggest that phosphorylation/dephosphorylation of the Ah receptor and the Arnt protein may contribute to the function of the dioxin-responsive system. Treatment of nuclear extracts with potato acid phosphatase, which dephosphorylates proteins, inhibits the binding of the liganded receptor heteromer to its DNA recognition sequence in vitro (Pongratz et al., 1991). Modulation of protein kinase C (PKC) activity is also associated with a reduction in DNA-binding capability of the receptor heteromer in vitro and alteration of Ah receptor-dependent transcriptional function in vivo (Carrier et al., 1992; Okino et al., 1992; Berghard et al., 1993; Chen and Tukey, 1996; Long et al., 1998). Furthermore, immunoprecipitation experiments using anti-receptor antibodies reveal that the receptor can undergo phosphorylation in vivo (Berghard et al., 1993; Mahon and Gasiewicz, 1995). Additional experiments in vitro suggest that phosphorylation of the Arnt protein is required for its heterodimerization with the Ah receptor; however, phosphorylation of the receptor is not required (Berghard et al., 1993). Together, these findings suggest that PKC and other protein kinases might influence heterodimerization, binding of the receptor-Arnt heteromer to DNA, or transcriptional activation of the Ah receptor. Although tyrosine phosphorylation in particular appears to be important for regulation of DNA binding of the AhR-Arnt complex (Park et al., 2000), the exact amino acid residue, the mechanism of regulation, and if this, or other, phosphorylation may be partially responsible for tissue- and developmental stage-specific regulation of AhR activity, have yet to be determined. It is known that many mammalian transcription factors undergo cycles of phosphorylation and dephosphorylation; however, in

most cases, the physiological significance of the modification is unknown (Hunter and Karin, 1992). Additional research is necessary to fully delineate the role of protein phosphorylation in the biological response to TCDD, and to identify the particular protein kinases and phosphatases that participate in the regulation of Ah receptor and Arnt protein.

The Ah receptor has been shown to physically interact with both retinoblastoma and NF-kB proteins (Ge and Elferink, 1998; Tian et al., 1999; Puga et al., 2000a). Both proteins are known to function in the regulation of cell cycle and cell differentiation in response to a variety of cytokines and growth factors (e.g., Beg and Baltimore, 1996; Van Antwerp et al., 1996; Zacksenhaus et al., 1996). It is reasonable to speculate that these interactions contribute to the noted ability of TCDD and related xenobiotics to affect cell cycle and cellular differentiation states, but the exact pathways that lead to these cell- and tissue-specific responses have yet to be determined. Nevertheless, this certainly represents a promising area of future research.

It appears likely that additional proteins, which remain to be identified and characterized, also contribute to the dioxin-response system. Both the Ah receptor and Arnt activate gene expression, at least in part, through direct interaction with basal transcription factors (Rowlands et al., 1996). Furthermore, there appears to be considerable cross-regulation of the Ah receptor with other signaling proteins including hypoxia inducible factor, estrogen receptors, and the retinoic acid and thyroid hormone receptors (e.g., Caruso et al., 1999; Chan et al., 1999; Duan et al., 1999; Kumar et al., 1999; Nguyen et al., 1999). There is evidence to indicate that protein-protein interactions have an important part in regulating the transcriptional activity of several nuclear receptors (e.g., Chen and Evans, 1995). Likewise, Ah receptor-Arnt complex-mediated transcriptional activities may be modulated by coactivator/corepressor proteins in a cell- and gene-specific manner (Watson and Hankinson, 1988; Watson et al., 1992; Ma et al., 1995; Kobayashi et al., 1997; Kress and Greenlee, 1997; Gradin et al., 1999; Kumar et al., 1999; Nguyen et al., 1999; Eltom et al., 1999). The relative importance of these interactions in the dose-related and tissue-specific responses elicited by TCDD are unknown.

2.6. ACTIVATION OF GENE TRANSCRIPTION BY DIOXIN

2.6.1. In Vitro Studies

Much of our current understanding of the mechanism of dioxin action is based on analyses of the induction of particular enzyme activities by TCDD. Aryl hydrocarbon hydroxylase activity reflects the action of the cytochrome P4501A1 (*CYP1A1*) enzyme, which catalyzes oxygenation of polycyclic aromatic substrates as the initial step in their metabolic processing to water-soluble derivatives (Conney, 1982). TCDD induces *CYP1A1* activity in many tissues. In particular, the relatively strong induction of *CYP1A1* activity by TCDD in cultured cells has facilitated the application of molecular genetic techniques to the analysis of the

induction mechanism (Whitlock, 1999). Table 2-1 and Figure 2-2 summarize some of the molecular events involved in this induction response.

In mouse hepatoma cells, nuclear transcription experiments reveal that TCDD induces hydroxylase activity by stimulating transcription of the corresponding *CYP1A1* gene. The response to TCDD occurs within a few minutes and is direct in that it does not require ongoing protein synthesis. Thus, the regulatory components required for the activation of *CYP1A1* transcription are present constitutively within the cell. TCDD fails to activate *CYP1A1* transcription in Ah receptor-defective cells and in Arnt-defective cells, indicating that the response requires both the Ah receptor and Arnt.

Observations that TCDD activates transcription and the liganded Ah receptor binds to DNA led to the discovery of a dioxin-responsive regulatory DNA sequence upstream of the *CYP1A1* gene. Recombinant DNA methods were used to construct chimeric genes in which potential regulatory DNA sequences from the *CYP1A1* gene were ligated to a heterologous "reporter" gene. After transfection of the recombinant genes into mouse hepatoma cells, TCDD was observed to activate the expression of the reporter gene. Additional transfection experiments defined the size of the dioxin-responsive domain and revealed that it had the properties of a transcriptional enhancer (Jones et al., 1986; Neuhold et al., 1986; Fujisawa-Sehara et al., 1987; Fisher et al., 1990). Furthermore, the recombinant gene responded poorly when transfected into Ah receptor-defective cells or Arnt-defective cells. Thus, both the receptor protein and the Arnt protein are required for enhancer function. Analyses of stable transfectants revealed that the dioxin-responsive enhancer can function in a chromosomal location distinct from that of the *CYP1A1* gene (Fisher et al., 1989). Therefore, in principle, an analogous enhancer element could mediate the transcriptional response of other genes to TCDD.

The DNA upstream region of the *CYP1A1* gene contains a second control element, a transcriptional promoter, that functions to ensure that transcription is initiated at the correct site. The promoter binds proteins that are expressed constitutively by the cell; however, the promoter contains no binding sites for the liganded Ah receptor heteromer. Transfection experiments indicate that neither the enhancer nor the promoter functions in the absence of the other (Jones and Whitlock, 1990). On might question how the enhancer and promoter, which are separated by hundreds of nucleotides, function in concert. TCDD-induced alterations in the chromatin structure of the *CYP1A1* gene play an important part in this process, as described later.

As indicated above, enhancer function requires both Ah receptor and Arnt proteins. Furthermore, the liganded, heteromeric form of the receptor exhibits an increased affinity for DNA. Together these data indicate that activation of *CYP1A1* transcription involves binding of the receptor heteromer to the enhancer. Analyses of protein-DNA interactions in vitro by gel retardation were done using enhancer DNA sequences and nuclear extracts from uninduced and

TCDD-induced cells. These studies revealed the existence of an inducible, receptor-dependent, and Arnt-dependent protein-DNA interaction, whose characteristics were those expected for the binding of the receptor heteromer to DNA (Denison et al., 1989; Hapgood et al., 1989; Saatcioglu et al., 1990a,b). The receptor heteromer recognizes the specific core nucleotide sequence

5'-NTGCGTG-3'
3'-NACGCAC-5'

present in multiple copies within the enhancer. These are often referred to as a DRE or XRE. Studies with a [^{125}I]-labeled dioxin indicate that the receptor heteromer binds in a 1:1 ratio to its DNA recognition sequence (Denison et al., 1989). Methylation protection and interference experiments in vitro reveal that the receptor heteromer lies within the major DNA groove and contacts the four guanines of the recognition sequence (Neuhold et al., 1989; Shen and Whitlock, 1989; Saatcioglu et al., 1990a, b). Transfection analyses of the six enhancer binding sites (in the mouse) for the receptor heteromer, as well as several mutated sites synthesized in vitro, reveal that nucleotides adjacent to the core recognition sequence contribute to enhancer function because the core nucleotides alone fail to exhibit enhancer activity (Denison et al., 1988). Studies of protein-DNA interactions reveal that there is no strict relationship between the affinity of the receptor heteromer for DNA and the extent of enhancer activation (Shen and Whitlock, 1992; Neuhold et al., 1989). These latter observations suggest that the protein-DNA interaction per se does not suffice to activate transcription and that an additional event (such as DNA bending--see below) is necessary. Mutational analyses reveal that the four base-pair sequence

5'-CGTG-3'
3'-GCAC-5'

is required for the receptor heteromer to bind to DNA in vitro (Shen and Whitlock, 1992; Yao and Denison, 1992; Lusska et al., 1993). Six distinct DRE sites have been identified within the mouse *CYP1A1* promoter (Lusska et al., 1993), whereas the rat and human *CYP1A1* gene promoters contain two and three copies of the core DRE sequence, respectively (Swanson and Bradfield, 1993). Thus, the homologous gene from different species may have different regulatory units. It is inappropriate to assume that the relative sensitivity of these genes to modulation by TCDD may be increased or decreased based on the number of DREs or their relative position in the upstream regulatory region, because this is also influenced by a variety of other regulatory factors. It is also possible that additional transcription factors, activators or

repressors, may have overlapping DNA binding specificities with that of the Ah receptor-Arnt complex (e.g., Duan et al., 1999; Klinge et al., 1999).

The DNA recognition sequence for the receptor heteromer contains two CpG dinucleotides. Studies in other systems have revealed that cytosine methylation at CpG is associated with decreased gene expression, often in tissue-specific fashion. Cytosine methylation of the CpG dinucleotides within the recognition sequence diminishes both the binding of the receptor heteromer to the enhancer (as measured by gel retardation) and the functional activity of the enhancer element (as determined by transfection experiments). Therefore, given that the TCDD-responsive receptor/enhancer system can regulate the transcription of genes other than *CYP1A1*, methylation of the enhancer may constitute one mechanism for controlling expression of such genes in a tissue-specific fashion (Shen and Whitlock, 1989).

An extensive analysis of the manner in which other bHLH proteins dimerize and bind to their respective DNA recognition sequences has been performed (reviewed in Swanson et al., 1995; Schmidt and Bradfield, 1996; Wilson and Safe, 1998). The bHLH/PAS family can be subdivided based on the basic region amino acid sequence and the DNA recognition sequence of its members. Arnt-like proteins recognize a 3'-half-site GTG, whereas heterodimer partners for Arnt, such as the Ah receptor, are more selective with unique basic domains. This suggests that although the Arnt-like component may function as a generic coregulator, specificity may be designated by Arnt's dimerization partner. These data are consistent with the finding that Arnt can dimerize with several other bHLH proteins; to date, the Ah receptor has been found to dimerize only with Arnt. Thus the family of bHLH/PAS proteins may exhibit a multitude of possible dimerizations, each complex recognizing a unique DNA sequence. The relative presence and state of activation of these proteins represent a novel mechanism to determine diversity of tissue-, cell-, and gene-specific regulation.

Promoter regions of TCDD-responsive genes have also been found to contain negative regulatory elements (Hines et al., 1988; Walsh et al., 1996; Piechocki and Hines, 1998). Superinducibility of *CYP1A1* by TCDD has been observed following the treatment of cells with cycloheximide, a protein synthesis inhibitor, suggesting that constitutively bound proteins are involved in negative regulation of *CYP1A1* (Lusska et al., 1992). The function and regulation of these negative elements are not completely understood and are likely to be gene-, cell-, and species-specific.

Gel retardation analyses also reveal that binding of the receptor heteromer to its recognition sequence bends the DNA in vitro. The site of the bend is at, or very near, the site of the protein-DNA interaction (Elferink and Whitlock, 1990). These findings suggest that binding

of the receptor heteromer to chromatin might also alter the configuration of the enhancer DNA in vivo.

2.6.2. In Vivo Studies

Studies that use transfection and in vitro techniques for analyzing protein-DNA interactions provide important clues about the functional components of the TCDD-responsive system. However, such experimental approaches necessitate removing the DNA regulatory elements from their native context within the chromosome and, therefore, have the potential to generate misleading results. For example, in the intact cell, nuclear DNA is complexed with histones and other chromosomal proteins, and the structure of the nucleoprotein complex (chromatin) makes important contributions to the control of gene transcription (Grunstein, 1990; Felsenfeld, 1992; Kornberg and Lorch, 1992). Transfection experiments and studies of protein-DNA interactions in vitro do not adequately control for this variable. For this reason, the protein-DNA interaction at the dioxin-responsive enhancer was analyzed in intact cells (Wu and Whitlock, 1993). These experiments revealed that the inactive (i.e., uninduced) enhancer binds few, if any, proteins within the major DNA groove. This finding implies that the inactive enhancer is relatively inaccessible to DNA-binding proteins in vivo. In addition, from a mechanistic standpoint, the absence of protein-enhancer interactions in uninduced cells argues against the idea that, at least for the *CYP1A1* gene, a specific repressor protein maintains the enhancer in an inactive configuration. Exposure of cells to TCDD leads to rapid binding of receptor heteromers, and a few other proteins, to the enhancer in the regulatory region of the *CYP1A1* gene. Therefore, in isolated hepatoma cells the liganded receptor heteromer appears to activate transcription of *CYP1A1* by a mechanism that does not require other enhancer-binding proteins (Wu and Whitlock, 1993).

Proteins that bind to the *CYP1A1* promoter are expressed constitutively, and TCDD has no effect on their interactions with promoter DNA in vitro, as measured by DNase footprinting (Jones and Whitlock, 1990). However, in intact cells, these proteins fail to bind to the inactive (i.e., uninduced) promoter. Thus, the promoter, like the enhancer, is inaccessible in uninduced cells. Exposure of cells to TCDD induces a rapid conformational change at the promoter region, such that it becomes accessible to the constitutively expressed proteins. This change represents a primary effect of TCDD that does not require transcription since it is insensitive to actinomycin D. In addition, it is receptor dependent and Arnt dependent, because it does not occur in Ah receptor- and Arnt-deficient cells. These observations indicate that the receptor-enhancer interaction increases accessibility of the downstream promoter to transcription factors (Durrin and Whitlock, 1989; Wu and Whitlock, 1992).

Studies of *CYP1A1* gene chromatin structure reveal that, in the transcriptionally inactive state, the enhancer/promoter region assumes a nucleosomal structure that is specifically positioned at the promoter (Morgan and Whitlock, 1992). Its organization into nucleosomes plausibly accounts for the inaccessibility of the enhancer/promoter region to DNA-binding proteins in uninduced cells. Exposure to TCDD produces a rapid and actinomycin D-insensitive loss of the positioned nucleosomes at the promoter; this change in chromatin structure accounts for the TCDD-induced increase in promoter accessibility and increased *CYP1A1* transcription in vivo (Morgan and Whitlock, 1992). However, studies indicate that Ah receptor-Arnt binding to DNA and increased chromatin accessibility at the enhancer are not sufficient to induce *CYP1A1* gene expression, but that enhancer-promoter communication is also required. This is postulated to be mediated, at least in part, by the ability of the C-terminal region of the Ah receptor to interact with other proteins (Okino and Whitlock, 1995; Ko et al., 1996).

The mechanism by which binding of liganded receptor heteromers to the enhancer alters chromatin structure is unknown. One possibility is that the DNA-bound receptor complex affects histones (e.g., by recruiting other proteins possessing and/or activating histone acetylase activity), thereby weakening histone-DNA interactions and destabilizing nucleosomes. Studies using trichostatin A, a histone deacetylase inhibitor, show that histone acetylation plays an important role in Ah receptor-elicited activation of the *CYP1A1* and *1A2* genes (Xu et al., 1997). The Ah receptor-Arnt complex has been shown to interact with several coactivator proteins that may enhance transcription under some contexts (Kobayashi et al., 1996; Kumar et al., 1999; Nguyen et al., 1999). Furthermore, several coactivators have been identified that contain regions homologous to the PAS domain of the Ah receptor, Arnt and other bHLH proteins (Kamei et al., 1996; Voegel et al., 1996). Under in vitro conditions, AhR and Arnt have been found to directly interact with several proteins that make up the basal transcriptional machinery, such as TBP (TATA-box binding protein), TFIIF, and TFIID, which has acetyltransferase activity (Rowlands et al., 1996; Swanson and Yang, 1998). A second possibility is that the receptor-enhancer interaction alters the DNA structure of the enhancer/promoter region, thereby stabilizing it in a non-nucleosomal configuration. This idea is consistent with the observation that the receptor heteromer bends DNA in vitro (Elferink and Whitlock, 1990).

The six binding sites for the receptor heteromer on the *CYP1A1* enhancer in mice are arranged in an irregular pattern. The absence of regular spacing between sites suggests that enhancer activation does not require protein-protein interactions between adjacent DNA-bound receptor heteromers. Instead, irregular spacing of binding sites may reflect constraints imposed by chromatin structure because the receptor heteromer must bind to nucleosomes. For example, as the DNA helix wraps around the histone core of the nucleosome, the major groove (which contains the binding sites for the receptor heteromer) is periodically accessible. Increasing the

number of binding sites at irregular intervals increases the probability that at least one site will be accessible even when the DNA is nucleosomal. In addition, the receptor heteromer contacts a relatively short (six base-pair) DNA segment, increasing the probability that the entire binding site in the nucleosome will be accessible. Thus, the multiplicity, irregular distribution, and small size of the binding sites may have evolved as a mechanism for overcoming the steric constraint imposed by the nucleosomal organization of the inactive enhancer in vivo.

2.7. EVIDENCE FOR DIFFERENT MECHANISMS OF TOXICITY.

As indicated above, much of our understanding of the possible mechanisms by which TCDD and related chemicals may act has been elucidated through analyses of how they induce *CYP1A1* gene expression. Based on this model, it is logical to hypothesize that the binding of TCDD to the Ah receptor, receptor-Arnt dimerization, binding of this complex to DREs present in 5' promoter regions of responsive genes, and inappropriate modulation of gene expression, represent the initial steps in a series of biochemical, cellular, and tissue changes that result in the toxicity observed. This hypothesis is further supported by numerous studies evaluating structure-activity relationships of various Ah receptor ligands, the genetics of mutant Ah receptor genes, receptor-deficient mice, and the molecular events contributing to and regulating expression of the Ah receptor and its activity. For example, it is striking that dosages of TCDD, that produce a variety of toxic effects in normal mice, produce no effects in Ah receptor knockout mice. Although the promoter regions of many genes, including *CYP1A1*, contain DREs (Lai et al., 1996), only a few of these are known to be directly regulated by the Ah receptor-Arnt complex (reviewed in Denison et al., 1998). However, the modulated expression of these genes does not completely explain (at least not as yet) the diversity of toxic effects elicited by TCDD in numerous animal species. By analogy, it is predicted that other genes have inappropriate expression (or repression) directly related to particular toxic events. The findings that many Ah receptor-modulated genes are regulated in a species-, cell-, and developmental stage-specific manner suggest that molecular and cellular pathways leading to any particular toxic event are extremely complex. Recent work demonstrated the modulation of at least 310 known genes in human hepatoma cells exposed to TCDD (Puga et al., 2000b). Indeed, precise dissection of these events represents a considerable challenge, especially in that a toxic response may depend on timely modulation of several genes rather than of just one particular gene, and possibly modulation of these genes in several rather than just one cell type.

As our understanding of the receptor and the molecular events that regulate its activity has progressed, it has become apparent that biochemical and biological outcomes of TCDD exposure can be modulated by numerous other proteins with which the Ah receptor interacts. Thus, it is possible that dioxin could modulate gene expression by pathways that do not involve

interaction of the receptor with either Arnt or DREs. Although conditional disruption of the Arnt gene results in the inability of TCDD to induce several responsive genes including CYP1A1 (Tomita et al., 2000), there are, in fact, no data proving that Arnt is required for any toxic effects elicited by dioxin. No other functional heterodimer partner for the Ah receptor has been identified. Thus, it is conceivable that, through interaction with other proteins, the receptor could bind to DNA elements that are uniquely different from the consensus DRE identified. This possibility seems even more plausible given the multiple dimerization partners identified for Arnt and other bHLH-PAS proteins.

It is also reasonable to hypothesize that the Ah receptor might modulate gene expression by a mechanism that does not require its direct interaction with DNA. It is plausible, for example, that the Ah receptor and the Ah receptor-Arnt complex could divert other proteins and transcription factors from other signaling pathways. Several studies provide evidence to support this possibility. For example, direct interaction between the Ah receptor and retinoblastoma protein has been shown (Ge and Elferink, 1998; Puga et al., 2000a). Progression of the cell cycle through G1 phase is regulated, in part, by the retinoblastoma protein (Weinberg, 1995). TCDD exposure has been shown to arrest cells in G1 (Weiss et al., 1996; Kolluri et al., 1999), and the Ah receptor appears to be necessary for progression of mouse hepatoma cells through G1 (Ma and Whitlock, 1996). These observations are consistent with a hypothesis that the dioxin-activated Ah receptor may disrupt normal retinoblastoma protein-mediated differentiation processes. Notably, another protein, p27Kip1, which is important for regulating the progression of cells from G1 to S phase, has been shown to be induced by TCDD (Kolluri et al., 1999). Furthermore, the Ah receptor is expressed in cells in a cycle-dependent manner, with expression peaking in the late S phase (Vaziri et al., 1996). Similarly, recently described interactions between the Ah receptor and the transcription factor NF-kB could potentially explain several biological effects associated with TCDD exposure (Tian et al., 1999). Data suggests that activation of the AhR may increase the activity of specific NF-kB subunits (Kim et al., 2000; Schlezinger et al., 2000). For example, the AhR has been shown to associate with the RelA subunit of NF-kB to activate the C-myc gene promoter in human breast cancer cells (Kim et al., 2000). Likewise, dioxin treatment has been shown to inhibit progesterone receptor signaling (Kuil et al., 1998). This might be due to the sequestration of common accessory factors or coactivator proteins used by other transcription factors. It has been demonstrated that overexpression of one steroid hormone receptor can decrease transcriptional activity of another, presumably through this mechanism (Meyer et al., 1989). It is also possible that because Arnt (or other as yet unidentified partners for the Ah receptor) can dimerize with other proteins, some of the biological effects of the dioxins could be related to recruitment of Arnt by the Ah receptor away from these other pathways. Thus, toxicity could result from loss of Arnt function. At this

point, there is no evidence for this mechanism. In fact, recent data suggest that the noted functional interference between hypoxia-induced pathways and Ah receptor-mediated signaling (Gradin et al., 1996) does not occur through competition between the Ah receptor and HIF-1α for Arnt (Pollenz et al., 1999). Data also suggest that ligand binding to the Ah receptor initiates a phosphorylation/dephosphorylation cascade resulting in modulated activity of other transcription factors (Enan and Matsumura, 1996; Blankenship and Matsumura, 1997). Precise components and events of these modulated pathways have yet to be delineated. How or whether any of these interactions in fact lead to any or all of the toxic effects elicited by dioxin exposure has yet to be established. Nevertheless, it is clear that inappropriate activation of the Ah receptor could have profound effects on regulation of a variety of signal transduction pathways; disruption of these could have serious consequences on a number of cell and tissue processes.

Despite the wealth of evidence to indicate a role of the Ah receptor in the toxicity elicited by the dioxins, it also seems possible that these chemicals may cause toxic effects through mechanisms involving their interaction with biological effector molecules other than the receptor. Clearly, a causal link between Ah receptor-regulated gene expression (regardless of the mechanism of gene modulation) and any of the demonstrated toxic effects has not been established. Furthermore, even though data from structure activity relationship and genetic studies are consistent with the notion that the Ah receptor mediates some toxic effects, not all effects have been thoroughly examined by these parameters. Similarly, Ah receptor knockout mice have not been thoroughly examined for the ability of dioxin to elicit all of its known toxic effects. Finally, although the Ah receptor is present in human cells and tissues, and studies using human cells are consistent with the hypothesis that the Ah receptor mediates effects of the dioxins, it is not known whether these same relationships would exist following exposure of intact humans. Thus, it seems possible that dioxin might cause effects in people and animals by a mechanism involving macromolecules other than the Ah receptor. Furthermore, within the same organism some effects may involve the receptor and others may not. To date, there is, however, no relevant evidence to support these possibilities.

It has been demonstrated that Ah receptor-deficient mice show no signs of toxicity at doses of TCDD (200 µg/kg) approximating the LD50 dose in mice containing the Ah receptor (Fernandez-Salguero et al., 1996). However, a single exposure of 2000 µg/kg to Ah receptor-deficient animals produced several minor lesions including scattered necrosis and vasculitis in the liver and lungs. These data suggest that a pathway leading to toxicity exists, albeit at very high doses, that is independent of the Ah receptor. However, these data also clearly indicate that the major in vivo effects of TCDD are mediated, at least in mice, through the Ah receptors. Notably, the level of TCDD exposure in these Ah receptor-deficient animals is well beyond that known to occur in any human population.

There is much evidence to indicate that the immunotoxic effects of TCDD are mediated by the Ah receptor (Luster et al., 1985; Silkworth and Antrim, 1985; Davis and Safe, 1988, 1989, 1990; Safe, 1990; Ackerman et al., 1989; Pavylak et al., 1989; Kerkvliet et al., 1990; Silkworth et al., 1993). These studies primarily investigate structure-activity relationships following a single dose, and compare mouse strains that are sensitive or less sensitive to TCDD because of alterations in the amino acid sequence of the Ah receptor. However, the results of other investigations using repeated dosing schedules could be interpreted to indicate that the Ah receptor is not involved in some immunotoxic responses. When TCDD was administered to mice daily for 2 weeks, no differences in the inhibition effects of TCDD on antibody-forming cells in the spleen were observed between sensitive and less sensitive strains of mice (Morris et al., 1992). A simple interpretation of these results might be that molecules other than the Ah receptor may mediate the effects of TCDD following multiple or chronic exposures. However, the authors did observe differences in sensitivity between different control groups, and when the data were expressed as a percentage of the appropriate control, strain differences in response to TCDD were observed. It also seems likely that relative sensitivity to TCDD contributes to strain differences in the pharmacokinetics of this chemical. TCDD and related chemicals have been shown to induce expression of cytochrome P4501A2 (CYP1A2) in the liver, and the presence or absence of this protein has been shown to influence tissue distribution of TCDD (Poland et al., 1989; Kedderis et al., 1993; Diliberto et al., 1997). Thus, it is likely that, because of the induction of CYP1A2 and greater sequestration of dioxin in the livers of responsive animals, less is available to other tissues compared with less responsive animals. Data have been presented that indicate this (Diliberto et al., 1999).

Several other studies performed in isolated cells might also be interpreted to indicate that some of the immunotoxic effects of the dioxins are Ah receptor independent (Tucker et al., 1986; Davis and Safe, 1991; Morris et al., 1991; Morris and Holsapple, 1991). However, these data appear to conflict with results obtained in vivo and have been shown to be dependent on culture conditions (Morris and Holsapple, 1991). Furthermore, actual cellular concentrations of chemicals used in several of these in vitro studies were much higher than those known to occur in vivo where immunotoxic effects are observed (Neumann et al., 1992).

Several biochemical responses have been shown to occur rapidly in isolated cells following exposure to TCDD and related dioxins. These include increases in protein kinase and phospholipase C activities, and affects on plasma membranes (Bombick et al., 1984; Bombick et al., 1985; Beebe et al., 1990; Ma et al., 1992; Puga et al., 1992; Ashida et al., 2000b). Some of these responses occur in cells lacking Arnt and in cells with highly reduced levels of Ah receptor (Puga et al., 1992), implying either a non nuclear role of the Ah receptor in mediating these events or an Ah receptor-independent process. Blankenship and Matsumura (1997) have shown

that TCDD, directly or indirectly, activates protein tyrosine kinase activity in murine hepatic cytosol, also suggesting non-nuclear activity of this chemical. In another recent study, TCDD was shown to stimulate c-fos activity in CV-1 cells in which no Ah receptor could be detected by immunoblot analysis or by the induction of *CYP1A1* activity (Hoffer et al., 1996). However, this study failed to completely rule out the presence of very low levels of receptor. Notably, certain bone marrow stromal cell lines lack immunodetectable Ah receptor and fail to show induction of *CYP1A1* following treatment with TCDD. However, in these same cell lines, Ah receptor mRNA transcripts could be detected and *CYP1B1* mRNA was clearly inducible by TCDD (Lavin et al., 1998).

Thus, at present the wealth of evidence available indicates that most, if not all, of the biological and toxic effects of dioxins are mediated by the Ah receptor. Although the receptor may be necessary for the occurrence of these events, clearly it is not sufficient because other proteins and conditions are known to affect activity of the receptor and its ability to alter gene expression. There is some evidence to support mechanisms involving pathways for Ah receptor action that do not involve Arnt, although the exact steps involved in these pathways have yet to be fully detailed. Certain studies could be interpreted to indicate Ah receptor-independent mechanisms, although these have not clearly ruled out involvement of the Ah receptor. The only consistent, but limited, evidence for dioxin-elicited effects that do not involve the Ah receptor comes from studies using Ah receptor-deficient animals. Here however, observed minor effects occurred only following treatment with extremely high doses of TCDD. Notably, these doses are well beyond that which any humans are known to have been exposed.

2.8. FUTURE RESEARCH

The cloning of cDNAs encoding the Ah receptor and Arnt proteins, and the development of anti-receptor and anti-Arnt antibodies, open the way for additional mechanistic studies of dioxin action. It is now practical to analyze the structure and function of these proteins using mutagenesis techniques, to analyze the structure and regulation of the corresponding genes, to determine whether different forms of the receptor and Arnt exist, and to directly analyze the role of posttranslational modifications on receptor and Arnt function. In vitro transcription can be used to study the functional components of the dioxin-responsive pathway.

The observation that the Ah receptor and Arnt proteins heterodimerize via HLH motifs raises the likelihood that they may also dimerize with other partners (perhaps in a tissue-specific fashion) to generate different protein combinations that may have novel regulatory properties. The types of protein complexes formed may depend on the relative amount of each potential partner protein present in different cell types and at different times of tissue development/differentiation, as well as on the stability of each type of heterodimer. This

combinational mechanism for regulating dioxin responses may also allow for functional interactions with other signal transduction pathways, increasing the potential diversity of dioxin-induced responses even further (see, e.g., Pimental et al., 1993; Hogenesch et al., 1997; Caruso et al., 1999; Chan et al., 1999; Nebert et al., 2000). These are promising areas for future research, and are likely to provide novel insights into the mechanism of dioxin action, in particular, and the regulation of mammalian gene transcription (especially by bHLH proteins), in general. If such studies reveal new proteins (and corresponding genes) that influence rate-limiting steps in the response to dioxin, the findings might also prove useful from a risk assessment standpoint.

The teratogenic and tumor-promoting effects of TCDD, its effects on differentiation of a variety of cell types, and results from Ah receptor deficient animals suggest that the Ah receptor and other components of the dioxin-responsive system contribute to important developmental and proliferative pathways. Further study of transgenic animals, in which both alleles for the Ah receptor or the Arnt protein have been permanently or conditionally inactivated, will provide new insights into such pathways. In addition, the use of transgenic animals in toxicological studies might be helpful to assess what cellular components participate in the adverse responses to particular chemicals.

Chromatin structure and nucleosome positioning have important effects on mammalian gene expression (Grunstein, 1990; Felsenfeld, 1992; Kornberg and Lorch, 1992). The TCDD-responsive *CYP1A1* gene is an interesting model system that can be used to analyze the mechanism by which a protein complex, such as the liganded receptor heteromer, can trigger chromatin structural changes that increase DNA accessibility. Such studies may also provide novel insights into the function of the dioxin-responsive system.

Some dioxin-responsive genes (e.g., *CYP1A2*, *CYP1B1*, *glutathione S-transferase Ya*) exhibit substantial constitutive ("basal") transcription, which is increased further upon TCDD treatment. The constitutive expression of these genes implies that the promoter must be maintained in an accessible configuration even in the absence of dioxin; therefore, TCDD may induce the transcription of such genes by a mechanism that does not involve major changes in chromatin structure. As such, the liganded receptor heteromer may be able to increase gene transcription by both chromatin-dependent and chromatin-independent mechanisms. This may be an interesting area for future research.

The overall evidence indicates that the Ah receptor participates in every biological response to TCDD (Poland and Knutson, 1982; Safe, 1986; Birnbaum, 1994). Thus, through its interaction with Arnt and other transcription factors, TCDD likely activates transcription of other genes via a receptor- and enhancer-dependent mechanism analogous to that described for the *CYP1A1* gene. For example, TCDD induces the expression of genes encoding CYP1A2,

CYP1B1, glutathione S-transferase Ya subunit, aldehyde dehydrogenase, prostaglandin endoperoxide H synthase 2, and quinone reductase. In some cases, induction has been shown to occur at the transcriptional level, to be Ah receptor and Arnt dependent, and to involve a DNA recognition sequence analogous to that found upstream of the *CYP1A1* gene (Dunn et al., 1988; Quattrochi and Tukey, 1989; Favreau and Pickett, 1991; Takimoto et al., 1992; Pimental et al, 1993; Rushmore and Pickett, 1993; Sutter et al., 1994; Kraemer et al., 1996). Other observations reveal that TCDD activates the transcription of several other genes by unknown mechanisms (see Denison et al., 1998). For dioxin-responsive genes other than *CYP1A1*, and especially for genes that respond in a tissue-specific fashion, the presence of the receptor/enhancer system may not be sufficient for dioxin action. Rather, other tissue-specific regulatory components may play a dominant role in governing the response to TCDD. For example, estrogens (presumably via estrogen receptors) influence TCDD-induced liver neoplasia in rats (Lucier et al., 1991). In addition, in vitro experiments suggest that, in some cell types, a repressor protein inhibits the response to TCDD by competing for the receptor binding site(s) on DNA (Gradin et al., 1993; Walsh et al., 1996; Piechocki and Hines, 1998). Future research may reveal the existence of additional stimulatory or inhibitory gene regulatory components that can modulate the activity of the dioxin-responsive receptor/enhancer system. Further research is also needed to determine whether Ah receptor-dependent modulation of gene expression is exclusively dependent on Arnt. Other heterodimeric partners for the Ah receptor may be identified and these complexes may recognize unique DNA response elements that are involved in the control of a variety of genes. In addition, it is also possible that the Ah receptor controls certain activities, such as phosphorylation/dephosphorylation, through pathways that do not directly involve nuclear localization and transcriptional activation.

The potential teratogenic, developmental, and neoplastic effects of TCDD have raised particular concerns about the human health effects of dioxin. In particular, experimental studies in animals suggest that developing tissues are especially sensitive. These effects have been characterized by altered cell proliferation, metaplasia, and modified terminal differentiation, and can occur at dosages that have no overt toxicity to the pregnant dam (see Theobald and Peterson, 1994; Gray and Ostby, 1995; Roman et al., 1995). Concentrations of TCDD as low as 0.8 ng/g in the murine embryonic palate have been shown to result in cleft palate (Abbott et al., 1996). These responses may reflect complicated cascades of biochemical changes that are difficult to analyze mechanistically; therefore, a major challenge for the future will be to establish experimental systems in which such complex phenomena are amenable to study at the molecular level.

The actual molecular mechanisms underlying differences in sensitivity between species, tissues, and periods of development have yet to be determined. Indeed, this is a central issue for

relating animal studies to human exposures and sensitivity. A major obstacle has been our lack of understanding of the direct tissue and cell targets, critical periods of increased sensitivity, and actual dose to the target cell type. Even with the same dosage per cell, it is not difficult to envision that given the multitude of regulatory controls for any particular gene at a particular period of cellular development, different dose-dependent response curves for these genes would be observed. For example, rat *UDP glucuronosyltransferase 1A6* gene is about 1000 times less sensitive than the *CYP1A1* gene to induction of transcription by dioxin (Vanden Heuvel et al., 1994). Furthermore, considering the likely multitude of additional molecular events that contribute to the ultimate biological/toxic response following initial gene modulation, it is also not difficult to envision that different endpoints might have very different sensitivities, even though binding to the same receptor is the common initial trigger. Considering this complexity, it remains a particular challenge to develop appropriate model systems that accurately mimic the in vivo effects associated with exposure. It is also important to consider that a particular response to TCDD may be mediated through effects on multiple cells. Evidence was recently presented to indicate that Ah receptor activation in both hepatic parenchymal and hematopoietic cells contributes to the hepatic lesions induced by TCDD in mice (Thurmond et al., 1999).

Clearly, most data are consistent with the belief that the Ah receptor has some normal cellular function. We can now appreciate that the Ah receptor is a member of a family of proteins that are conserved through evolution and involved in growth and differentiation processes. The expression and activity of the Ah receptor appear to be well regulated in a differentiation and cell cycle stage-specific manner. Furthermore, we now know that the genes regulated by the receptor are involved in not only xenobiotic metabolism, but also in cell growth and differentiation processes. Further identification of other Ah receptor-regulated genes and their function, as well as factors that may control the ability of the receptor to regulate these in a cell-specific manner, will undoubtedly assist in our understanding of its normal function and how aberrant function may lead to toxicity. For example, recognition that the Ah receptor influences cell cycle regulation, and a further dissection of the pathways involved, will likely help us understand how dioxins affect developmental and neoplastic processes. In addition, further research to characterize and identify possible endogenous ligands for the receptor, and its role in regulating cellular processes, will have a great impact in these areas. It seems plausible that the spectrum of genes regulated by the receptor may mediate both endogenous ligand function and prevention of its inappropriate action through metabolism (Nebert et al., 2000).

2.9. MECHANISTIC INFORMATION AND RISK ASSESSMENT

A substantial body of evidence from investigations using experimental animals indicates that the Ah receptor mediates the biological effects of TCDD. Although studies using human

tissues are much less extensive, it appears reasonable to assume that dioxin's effects in humans are also receptor mediated. Studies using human organs and cells in culture are consistent with this hypothesis. A receptor-based mechanism would predict that, except in cases where the concentration of TCDD is already high (i.e., [TCDD]~K_D), incremental exposure to TCDD will lead to some increase in the fraction of Ah receptors occupied. However, it cannot be assumed that an increase in receptor occupancy will necessarily elicit a proportional increase in all biological response(s), because numerous molecular events (e.g., cofactors, other transcription factors, genes) contributing to the biological endpoint are integrated into the overall response. That is, the final biological response should be considered as an integration of a series of dose-response curves with each curve dependent on the molecular dosimetry for each particular step. Dose-response relationships that will be specific for each endpoint must be considered when using mathematical models to estimate the risk associated with exposure to TCDD. It remains a challenge to develop models that incorporate all the complexities associated with each biological response. Furthermore, the parameters for each mathematical model may only apply to a single biological response within a given tissue and species.

Given TCDD's widespread distribution, its persistence, and its accumulation within the food chain, it is likely that most humans are exposed to some level of dioxin; thus, the population at potential risk is large and genetically heterogeneous. By analogy with the findings in inbred mice, polymorphisms in the Ah receptor probably exist in humans. Therefore, a concentration of TCDD that elicits a particular response in one individual may not do so in another. For example, studies of humans exposed to dioxin following an industrial accident at Seveso, Italy, fail to reveal a simple and direct relationship between blood TCDD levels and development of chloracne (Mocarelli et al., 1991). These differences in responsiveness to TCDD may reflect genetic variation either in the Ah receptor or in some other component of the dioxin-responsive pathway. Therefore, analyses of human polymorphisms in the Ah receptor and Arnt genes have the potential to identify genotypes associated with higher (or lower) sensitivities to dioxin-related effects. Such molecular genetic information may be useful in the future for accurately predicting the health risks dioxin poses to humans.

Complex responses (such as cancer) probably involve multiple events and multiple genes. For example, a homozygous recessive mutation at the *hr* (hairless) locus is required for TCDD's action as a tumor promoter in mouse skin (Poland et al., 1982). Thus, the *hr* locus influences the susceptibility of a particular tissue (in this case skin) to a specific effect of dioxin (tumor promotion). An analogous relationship may exist for the effects of TCDD in other tissues. For example, TCDD may produce porphyria cutanea tarda only in individuals with inherited uroporphyrinogen decarboxylase deficiency (Doss et al., 1984). Such findings suggest

that, for some adverse effects of TCDD, the population at risk may be limited to individuals with a particular genetic predisposition.

Other factors can influence an organism's susceptibility to TCDD. For example, female rats are more prone to TCDD-induced liver neoplasms than are males; this phenomenon is related to the hormonal status of the animals (Lucier et al., 1991). In addition, hydrocortisone and TCDD synergize in producing cleft palate in mice. Retinoic acid and TCDD produce a similar synergistic teratogenic effect (Couture et al., 1990). These findings indicate that, in some cases, TCDD acts in combination with hormones or other chemicals to produce adverse effects. Such phenomena might also occur in humans. If so, the difficulty in assessing risk is increased, given the diversity among humans in hormonal status, lifestyle (e.g., smoking, diet), and chemical exposure. For example, several compounds present in the diet have been found to inhibit activation of the AhR induced by TCDD (Ashida et al., 2000a).

Dioxin's action as a tumor promoter and developmental toxicant presumably reflects its ability to alter cell proliferation and differentiation processes. There are several plausible mechanisms by which this could occur. First, TCDD might activate a gene (or genes) that is directly involved in tissue proliferation. Second, TCDD-induced changes in hormone metabolism may lead to tissue proliferation (or lack thereof) and altered differentiation secondary to altered secretion of a trophic hormone. Third, TCDD-induced changes in the expression of growth factor or hormone receptors may alter the sensitivity of a tissue to proliferative stimuli. Fourth, TCDD-induced toxicity may lead to cell death, followed by regenerative proliferation. These mechanisms likely differ among tissues and periods of development, and might be modulated by different genetic and environmental factors. As such, this complexity increases the difficulty associated with assessing the human health risks form dioxin exposure.

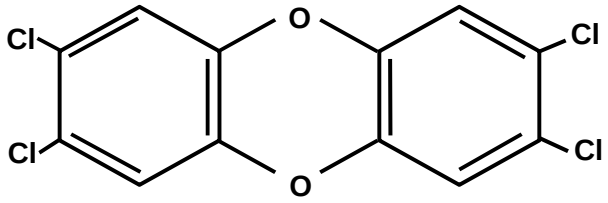
Under certain circumstances, exposure to TCDD may elicit beneficial effects. For example, TCDD protects against the carcinogenic effects of PAHs in mouse skin, possibly reflecting induction of detoxifying enzymes (Cohen et al., 1979; DiGiovanni et al., 1980). In other situations, TCDD-induced changes in estrogen metabolism may alter the growth of hormone-dependent tumor cells, producing a potential anticarcinogenic effect (Spink et al., 1990; Gierthy et al., 1993). However, several recent studies in mice indicate that the Ah receptor has an important role in the genetic damage and carcinogenesis caused by components in tobacco smoke such as benzo[a]pyrene through its ability to regulate *CYP1A1* gene induction (Dertinger et al., 1998, 2000; Shimizu et al., 2000). These issues complicate the risk assessment process for dioxin.

TCDD's biological effects likely reflect a complicated interplay between genetic and environmental factors. Thus, it may be overly simplistic to use mechanistic information derived

largely from the relatively simple responses described in this chapter (i.e., *CYP1A1* induction) as the basis for developing a quantitative approach to dioxin risk assessment in humans. While this approach represents a start toward incorporating mechanistic information into risk assessment, future biologically based dose-response models will require a better understanding not only of the TCDD-induced biochemical alterations that produce disease, but also of the relationships between genetic and environmental factors that influence an individual's susceptibility to TCDD. Molecular toxicology and mechanistic studies have great potential to provide new insights into such issues in the future.

Table 2-1. Events in the activation of *CYP1A1* gene transcription by dioxin

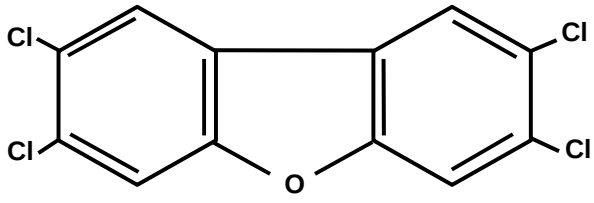
●	Diffusion into the cell
●	Binding to the Ah receptor protein
●	Conversion of liganded receptor to the DNA-binding form
●	Dissociation from hsp90
●	Active translocation from cytoplasm to nucleus
●	Association with Arnt protein
●	Binding of liganded receptor heteromer to enhancer DNA
●	Enhancer activation
●	Altered DNA configuration
●	Histone modification
●	Recruitment of additional proteins
●	Nucleosome disruption
●	Increased accessibility of transcriptional promoter
●	Binding of transcription factors to promoter
●	Enhanced mRNA and protein synthesis



2,3,7,8-Tetrachlorodibenzo-p-dioxin

Polychlorinated dibenzopara-dioxins

75 congeners



2,3,7,8-Tetrachlorodibenzofuran

Polychlorinated dibenzofurans

3. ACUTE, SUBCHRONIC, AND CHRONIC TOXICITY

3.1. SCOPE AND LIMITATIONS

The acute, subchronic, and chronic toxicology of the chlorinated dioxins, dibenzofurans, biphenyls, and related compounds have been reviewed extensively in recent years. This chapter summarizes knowledge on the toxicology of tetrachlorodibenzo-*p*-dioxin (TCDD), but also includes references to other dioxin-like compounds when relevant data are available. Included are selected various data that are considered to be of importance to risk assessment, particularly experimental animal data. Immunotoxicity, reproductive/developmental toxicity, carcinogenicity, toxicity to humans, and epidemiology are all covered in other chapters. Ecotoxicology is not covered in this chapter, but examples from mammalian and avian laboratory species are included.

3.2. ACUTE TOXICITY

The range of doses of TCDD that are lethal to animals varies extensively with both species and strain, as well as with sex, age, and the route of administration within a single strain (Table 3-1). One of the characteristics of TCDD-induced toxicity is delayed manifestation of lethality after acute exposure, with the time to death after exposure being several weeks. Death usually occurs as a consequence of loss of body weight (wasting syndrome) from TCDD-induced inhibition of gluconeogenesis and appetite suppression. Deaths within the first week after exposure—an unusually rapid course for TCDD toxicity—have been observed in guinea pigs (Schwetz et al., 1973), rabbits (Schwetz et al., 1973), and Syrian Golden hamsters (Olson et al., 1980). A more than 8,000-fold difference exists between the dose of TCDD reported to cause 50% lethality (LD_{50}) in male Hartley guinea pigs, the most sensitive species tested (Schwetz et al., 1973), and the LD_{50} dose in male Syrian Golden hamsters (Henck et al., 1981). Another animal with extremely high sensitivity is the mink (*Mustela vision)*; for the female, the calculated 28-day LC_{50} value is 0.264 µg TCDD/kg bw/day (Hochstein et al., 1998), which is an order of magnitude less than the 28-day LD_{50} of 4.2 µg TCDD/kg bw/day for male mink (Hochstein et al., 1988).

The rat seems to be the third most sensitive species among experimental animals, although there is a >300-fold variability in LD_{50} values among different strains. The Han/Wistar (H/W) Kuopio strain of rat has been shown to be particularly resistant to TCDD exposure (Pohjanvirta and Tuomisto, 1987). Among the five-rats-per-dose group (0, 1,500, 2,000, 2,500, or 3,000 µg TCDD/kg bw), only one animal died within the 40-day observation period. The DBA/2 male mouse has also been shown to have a high resistance to TCDD toxicity (Chapman and Schiller, 1985).

Data on gender differences in sensitivity to the lethal effects of TCDD are conflicting. The gender differences in the acute toxicity of TCDD are likely due to differences in toxicokinetics, i.e., higher tissue concentrations and longer half-life in females than in males (Li et al., 1995). Acute toxicity data that address the effect of age at the time of exposure to TCDD are scarce, and comparisons are hampered by either the absence or inadequacy of information on the age and body weight of the tested animals. As demonstrated with other chemicals, the acute toxicity of TCDD may vary several-fold depending on the vehicle used or the presence of other substances that affect uptake.

Differences in sensitivity toward TCDD among various strains of mice have been shown to depend on a genetic variability in the Ah locus (see Chapter 2). In two strains of male C57B/6J mice that differ only at the Ah locus, Birnbaum et al. (1990) found LD_{50} values of 159 and 3,351 µg/kg for wild-type mice ($Ah^{b/b}$) and congenic mice ($Ah^{d/d}$), respectively. The mean time to death, 22 days, was independent of dose and genotype. Signs of toxicity were similar in the two strains, and it was concluded that the spectrum of toxicity is independent of the allele at the Ah locus. The relative dose needed to bring about various acute responses, however, is ~8-24 times greater in congenic mice homozygous for the "d" allele than in the wild-type mice carrying two copies of the "b" gene.

The DBA/2 mouse strain requires 10 to 20 times higher doses of 2,3,7,8-TCDD than does the C57BL/6 strain for lethality (Chapman and Schiller, 1985). The reason for this difference between the two strains is the low TCDD-binding affinity to the Ah receptor in the DBA/2 strain (Okey et al., 1994). The difference in ligand-binding affinity, associated with susceptibility to TCDD-induced lethality that segregates with the Ah locus (Chapman and Schiller, 1985), is due to a point mutation (translated as alanine to valine) in the ligand-binding domain of codon 375 (Poland et al., 1994; Ema et al., 1994).

Wasting, hemorrhage, and anemia are the three primary causes for dioxin-induced lethality in rats, and a body weight loss of 25% is considered to be the minimum threshold to assign the presence of wasting syndrome for rats (Viluksela et al., 1997a,b, 1998).

1,2,3,4,5,6,7,8-HeptaCDD (HpCDD)-induced dose-response for wasting and hemorrhage overlap in female Sprague-Dawley rats (Rozman, 1999). Death from wasting and hemorrhage occur within the first few weeks of exposure. Animals that did not exhibit wasting or hemorrhage died from anemia, which did not start before day 126 postexposure (Rozman, 1999). Furthermore, unlike rats dying of wasting syndrome, the ones dying of anemia or hemorrhage had fat depots in the body, suggesting that increased body fat may aid them in surviving beyond the 30-day mark (Rozman,1999), only to succumb later to hemorrhage and anemia.

Long-Evans (L-E) *Turku* AB strain rats are around 1000-fold more sensitive to TCDD-induced acute lethality (LD_{50} about 10 µg/kg) than H/W Kuopio strain rats (LD_{50} > 9,600 µg/kg)

(Pohjanvirta et al., 1999). This feature of the H/W rat being highly resistant to acute TCDD toxicity, yet sensitive to enzyme induction, may be due in part to differences in AhR types between rat strains. The H/W strain has point mutations at exon 10 and at the first invariant nucleotide at the 5' end of intron 10 in the AhR gene. These cause alterations in AhR protein structure, leading to loss and alteration of multiple amino acid sequences at the carboxyl terminal region of the transactivation domain (Pohjanvirta et al., 1998). The homozygous AhR $^{hw/hw}$ type fails to mediate some endpoints of TCDD toxicity that parallel lethality. At lethal doses, H/W rats show only slight changes in bilirubin and body weight, while L-E rats show a five-fold increase in bilirubin and a 20% to 30% decrease in body weight as early as 6 days postexposure (Unkila et al., 1994a). Furthermore, at lethal doses H/W rats manifest only slight or transient inhibition of daily food intake and body weight gain, whereas in L-E rats progressive decrease in daily feed intake and body weight gain occur within 4 to 7 days postexposure (Unkila et al., 1994a).

Tuomisto et al. (1999) suggested that an uncharacterized gene, other than AhR, determines resistance of H/W Kuopio rats to TCDD-induced acute toxicity.

Geyer et al. (1990) utilized both their own and other data to determine a correlation between total body fat content and acute toxicity in various species and strains of laboratory mammals. They found a correlation of 0.834, and suggested that the reason for this correlation was that an increased total body fat content (TBF) may enhance the capacity to remove TCDD from the systemic circulation. This factor may be important, but it almost certainly does not explain all of the interspecies differences. Geyer et al. (1997) have determined that there is a linear relationship in mammals independent of strain and species between the logarithm of the oral 30-day LD_{50} in units of µg/kg bw and the mammal's TBF in percent via the regression equation:

$$\log LD_{50} = 5.30 \times \log TBF - 3.22$$

Data from studies of H/W Kuopio rats, which are extremely resistant to TCDD-induced lethality (Pohjanvirta and Tuomisto, 1987), were not included in this equation.

In chickens, acute toxicity is characterized by clinical signs such as dyspnea, reduced body weight gain, stunted growth, subcutaneous edema, pallor, and sudden death (chick edema disease). The disease first gained attention in 1957, but the causal agents were not identified as CDDs until much later (Firestone, 1973). Chick edema occurred in birds given oral doses of 1 or 10 µg TCDD/kg/day or 10 or 100 µg hexaCDD/kg/day, but it was not observed in chicks maintained on a diet containing 0.1% or 0.5% OCDD (Schwetz et al., 1973).

The female mink (*Mustela vision)* is more sensitive than the male mink to TCDD-induced lethality. Hochstein et al. (1998) fed 2- or 3-year-old adult female mink diets

supplemented with 0, 0.001, 0.01, 0.1, 1, 10, or 100 ppb TCDD for up to 125 days. Feed consumption was significantly depressed in the 10 and 100 ppb groups beginning in weeks 4 and 3, respectively. When adjusted for body weight (g food intake/100 g bw/day), the feed intake in TCDD-exposed groups was not significantly different from the control, except in the 10 ppb-dosed group during week 5. Significant body weight loss associated with classic symptoms of wasting syndrome resulting in mortality was observed in the 1, 10, and 100 ppb-dosed groups, respectively, from the third, second, and first week of exposure. Mortality reached 12.5%, 62.5% and 100% by day 28 in the 1, 10, and 100 ppb-dosed groups, respectively. By day 125, mortality increased to 62.5% and 100% in the 1 and 10 ppb groups. Based on the average feed intake of 5.5 g/100 g bw/day for the control mink, the dietary LC_{50} values of 4.8 and 0.85 ppb approximate 0.264 and 0.047 µg TCDD/kg bw/day, respectively, for 28 and 125 days of exposure.

3.2.1. Signs and Symptoms of Toxicity

TCDD affects a variety of organ systems in different species. It should be noted that much of the comparative database is derived from high-dose effects. The liver is the organ primarily affected in rodents and rabbits, while atrophy of the thymus and lymphatic tissues seems to be the most sensitive marker of toxicity in guinea pigs (WHO/IPCS, 1989; U.S. EPA, 1984, 1985). It is not possible to specify a single organ whose dysfunction accounts for lethality. Dermal effects are prominent signs of toxicity in nonhuman primates, and changes in epithelial tissues dominate both cutaneously and internally. This is most apparent in nonhuman primates in which the TCDD-induced cutaneous lesions closely mimic the chloracne and hyperkeratosis observed in humans. The histopathological alterations observed in epithelial tissues include hyperplastic and/or metaplastic alterations, as well as hypoplastic responses. The toxic responses of various species to TCDD are summarized in Table 3-2.

Loss of body weight, or wasting syndrome, is a characteristic sign observed in most animals exposed to TCDD. The weight loss usually manifests itself within a few days after exposure, and results in a substantial reduction of the adipose (Peterson et al., 1984) and muscle tissue (Max and Silbergeld, 1987) observed at autopsy. With sublethal doses of TCDD, a dose-dependent decrease in body weight gain occurs.

The greatest species-specific differences in toxicity concern pathological alterations in the liver. Administering lethal doses to guinea pigs does not result in liver damage comparable to the liver lesions observed in rabbits and rats, or to the liver changes observed in mice (McConnell et al., 1978a; Moore et al., 1979; Turner and Collins, 1983). In the hamster, manifest liver lesions do not occur even after fatal doses of TCDD; however, the ED_{50} for increased hepatic weight is only ~15 µg/kg (Gasiewicz et al., 1986). Liver-related enzyme

activities in serum are elevated in those animal species where liver damage is a prominent sign of TCDD toxicity. In animal species where hepatotoxicity is not as apparent, such as monkeys and guinea pigs, these enzyme activities are nearly normal.

Thymic atrophy has also been found in all animal species given lethal doses of TCDD. Treatment with TCDD inhibits bone marrow hematopoiesis in mice, both in vivo and in vitro, by directly altering the colony growth efficiency of stem cells (Chastain and Pazdernik, 1985; Luster et al., 1980, 1985).

Among other signs and symptoms that have been demonstrated in various species, the following should be noted: hepatic porphyria, hemorrhages in various organs, testicular atrophy, reduced prostate weight, reduced uterine weight, increased thyroid weight, lesions of the adrenal glands, inhibited bone marrow hematopoiesis, decreased serum albumin, and increased serum triglycerides and free fatty acids. The details of all underlying studies for these observations have been extensively reviewed (U.S. EPA, 1984, 1985; WHO/IPCS, 1989).

Effects on heart muscle have also been observed in guinea pigs and rats (Brewster et al., 1987; Kelling et al., 1987; Canga et al., 1988). Five days after a single lethal dose of TCDD (10 µg/kg intraperitoneally) was administered, a significantly decreased beta-adrenergic responsiveness was observed in the right ventricular papillary muscle of the guinea pig (Canga et al., 1988). In the TCDD-treated animals, a decrease in the positive inotropic effects of isoproterenol at 0.03-0.3 µM, but not at 0.1-10 nM, was also demonstrated. Additionally, enhanced responsiveness to low-frequency stimulation and increases in extracellular calcium were observed in these animals. Based on these findings, the authors suggest that the heart may be a major target for TCDD lethality at acutely toxic doses.

In the monkey, several additional symptoms have been registered, such as periorbital edema, conjunctivitis, and thickening of the meibomian glands followed by loss of the eyelashes, facial hair, and nails (McConnell et al., 1978b). These symptoms are similar to those observed in cases of human intoxication, such as from occupational exposure, the Seveso incident, and the Yusho and Yu-Cheng toxic oil intoxications, the latter involving exposure to PCBs and CDFs (see Chapter 7).

3.2.2. Studies In Vitro

Over 30 cell types, including primary cultures and cells from established and transformed cell lines derived from various tissues of at least six animal species, have been examined for their general cellular responses to TCDD (Beatty et al., 1975; Knutson and Poland, 1980a; Niwa et al., 1975; Yang et al., 1983a). The effects studied were changes in viability, growth rate, and morphology. Overall, there were few effects documented on these general cellular parameters in early studies.

Other in vitro studies, using more specific endpoints of toxicity, have clearly indicated effects of TCDD at comparatively low concentrations. For example, several studies have shown that TCDD affects cultured epidermal keratinocytes through interactions with differentiation mechanisms, and that this effect may be regulated by the modulation of epidermal growth factor (EGF) binding to the cells (Hudson et al., 1986). Additionally, in epithelial cells of human origin, TCDD has been shown to alter differentiation (Hudson et al., 1985), while aryl hydrocarbon hydroxylase (AHH) and 7-ethoxyresorufin O-deethylase (EROD) activity have been induced in vitro (see Section 3.5.4).

TCDD was found to inhibit high-density growth arrest in human squamous carcinoma cells in culture (Hebert et al., 1990a). Wiebel et al. (1991) identified a cell line (H4IIEC3-derived 5L hepatoma cells) that responds with decreased proliferation at low TCDD concentrations. In this cell line, half-maximum inhibition of proliferation occurs at a concentration of 0.1-0.3 nM. The onset of the effect is fairly rapid, manifesting itself as early as 4-8 hours after treatment. Further studies demonstrated that insensitive variants of this cell line were deficient in cytochrome P-4501A1 activity and lacked measurable amounts of the Ah receptor (Göttlicher et al., 1990). In addition, 3,3',4,4'-TCB inhibited proliferation in the sensitive cell line, although at higher concentrations.

3.2.3. Appraisal

Numerous studies of acute toxicity in various mammalian species have demonstrated dramatic species- and strain-specific differences in sensitivity. However, most species and strains respond at some level with a spectrum of symptoms that is generally the same, although species differences do exist.

Lethality is typically delayed by several weeks, and there is a pronounced wasting syndrome in almost all laboratory animals. Studies in congenic mice differing in their Ah responsiveness indicate that the sensitivity to acute toxicity of TCDD segregates with the Ah locus. Furthermore, studies of other CDDs, CDFs, and coplanar PCBs demonstrate that the potency for inducing lethality correlates with their ability to bind to the Ah receptor. In contrast, studies in various other species, including various strains of rats, have demonstrated a wide range of sensitivities regardless of rather comparable levels of the Ah receptor. This in no way obviates the necessary, but not sufficient, role of AhR.

3.3. SUBCHRONIC TOXICITY

Available studies on the subchronic toxicity of TCDD have been reviewed by the U.S. EPA (1984, 1985) and WHO/IPCS (1989). Overall, the signs and symptoms observed are in agreement with those observed after administration of single doses.

The study of Kociba et al. (1976) is of special interest, as it has been used for comparisons of the relative toxicities of other CDDs and CDFs (Plüess et al., 1988a,b). Adult male and female SD rats, in groups of 12, were given 0, 0.001, 0.01, 0.1, and 1.0 µg TCDD/kg bw by gavage 5 days/week for 13 weeks. At the end of the treatment period, five rats of each sex were sacrificed for histopathological examination. The remaining animals were observed for postexposure effects. The highest dose caused five deaths among the females, three during the treatment period and two after, while two deaths occurred in males in the posttreatment period. The rats given 0.01 µg TCDD/kg did not differ overtly from the controls except for a slight increase in the mean liver-to-body weight ratio.

A 13-week dietary study of SD rats given 1,2,3,4,8-PeCDF, 1,2,3,7,8-PeCDF, 2,3,4,7,8-PeCDF, or 1,2,3,6,7,8-HxCDF demonstrated that both subchronic toxicity and the depletion of hepatic vitamin A followed the rank order of the ability of the compounds to bind to the Ah receptor and to cause induction of AHH (Plüess et al., 1988a,b; Håkansson et al., 1990). Direct comparisons of the effects are hampered, however, by differences in the toxicokinetic behavior of the compounds. Slightly different relationships with regard to toxicity were observed in a tumor promotion study, where an initial loading dose (subcutaneous) of 2,3,4,7,8-PeCDF was given, followed by repeated lower doses (subcutaneous), in order to obtain a steady-state concentration (Wærn et al., 1991a). Both of these studies support the assumption that most signs and symptoms obtained may be mediated through the Ah receptor.

In another study primarily aimed at investigating TCDD-induced porphyria (Goldstein et al., 1982), groups of eight female SD rats were exposed to 16 weekly oral doses of 0, 0.01, 0.1, 1.0, and 10.0 µg TCDD/kg bw. The animals were killed and studied 1 week after the last treatment. Additional groups of rats received doses of 0 or 1.0 µg/kg/week for 16 weeks and were allowed to recover for 6 months. The high-dose level was lethal to all animals within 12 weeks, while the only other gross sign of toxicity was a decrease in body weight gain in the group receiving 1.0 µg/kg/week. After 16 weeks of exposure to TCDD, liver porphyrins were elevated ~1,000-fold in 7 of 8 animals receiving 1.0 µg/kg/week. Only 1 of 8 animals in the 0.1 µg/kg/week group had elevated porphyrin levels. The no-effect dose for porphyria was 0.01 µg/kg/week. After a 6-month recovery period, the porphyrin level in animals exposed to 1.0 µg/kg/week was still 100-fold higher than the values in the control group. A similar pattern was observed for urinary excretion of uroporphyrin. A 6-month recovery period was not sufficient for complete reversal of TCDD-induced porphyria.

Two studies were conducted (Harris et al., 1973; Vos et al., 1973) in which four weekly oral doses of 0.2, 1, 5, or 25 µg TCDD/kg bw were given to male C57Bl/6 mice in corn oil. No effects were noted at 1 µg/kg/week, which corresponds to ~0.1 µg/kg bw/day. In a subchronic exposure study, van Birgelen et al. (1996a) observed a synergistic effect of PCBs and TCDD on

hepatic porphyrin in rats at levels comparable with those found in human milk and fat samples. Coadministration of TCDD with 2,2',4,4',5,5'-PCB (PCB 153) resulted in elevated hepatic porphyrin levels not observed in TCDD cotreated with 3,3',4,4',5-PCB (PCB126) or 2,3,3',4,4',5-PCB (PCB156) groups. In this experiment, LOAELs for hepatic porphyrin accumulation for TCDD, PCB126, and PCB 156 were found to be 0.047, 3.18, and 365 µg/kg/d, respectively. van Birgelen et al. (1996b) have further extended the observation on hepatic porphyrin activity in female B6C3F1 mice after subchronic exposure to individual PCDD, PCDF, and PCB congeners. A dose-response relationship with potencies, relative to TCDD, for increased hepatic porphyrin accumulation was observed for all of the individual congeners studied. The relative potencies of PCDDs and PCDFs tested, based on hepatic porphyrin and enzymatic activities associated with hepatic CYP1A1 and CYP1A2, were found to be in a comparable range.

A 90-day TCDD feeding study of male and female Hartley guinea pigs was performed by DeCaprio et al. (1986), in which surviving animals were subjected to extensive pathologic, hematologic, and serum chemical analyses. The diets contained 0, 2, 10, 76, or 430 ng TCDD/kg bw. The two lowest doses, 2 and 10 ng/kg, produced no dose-related alterations. Based on this study, a no-observed-adverse-effect level (NOAEL) of 0.6 ng TCDD/kg bw/day in guinea pigs was estimated. At the highest dose, severe body weight losses and mortality were observed. No dose-related mortality occurred at 76 ng/kg.

A cumulative dose of 0.2 µg TCDD/kg bw, which was divided into nine oral doses 3 times/week during days 20-40 of gestation, produced no clinical signs of toxicity in pregnant rhesus monkeys (Macaca mulatta) (McNulty, 1984). Signs of toxicity such as body weight loss, epidermal changes, and anemia did occur, however, in monkeys that received cumulative doses of 1.0 and 5.0 µg TCDD/kg bw over the same time period.

3.3.1. Appraisal

Utilizing the above data, subchronic no-observable-adverse-effect levels (NOAELs) for rats, mice, and guinea pigs are estimated to be 1 ng, 100 ng, and 0.6 ng TCDD/kg bw/day, respectively. These studies cannot be directly compared with each other, however, and these subchronic NOAELs cannot be used for extrapolating human risk. None of the studies utilized initial loading doses and, due to the long half-life of TCDD, steady-states may not have been reached in the animals except toward the end of the study periods. Distribution between tissues in the animals depends on both time of exposure and dose level (see Chapter 1), which further complicates any comparisons.

In spite of this, the limited data available seem to indicate that signs and symptoms of subchronic toxicity follow the same rank order as Ah receptor-mediated effects, such as induction of AHH.

3.4. CHRONIC TOXICITY

The results of chronic toxicity studies performed on laboratory animals exposed to TCDD are summarized in Table 3-3. Details have been reviewed by the U.S. EPA (1984, 1985) and WHO/IPCS (1989).

The most important study in rats is the chronic toxicity study of Kociba et al. (1978, 1979). Groups of 50 male and 50 female SD rats were fed diets providing daily doses of 0.001, 0.01, and 0.1 µg TCDD/kg bw for 2 years. Control rats, 86 males and 86 females, received diets containing the vehicle alone. Increased mortality was observed in females given 0.1 µg/kg/day, while increased mortality was not observed in male rats at this dose or in animals receiving doses of 0.01 or 0.001 µg/kg/day. From month 6 to the end of the study, the mean body weights of males and females decreased at the highest dose and, to a lesser degree, in females given 0.01 µg/kg/day. During the middle of the study, lower-than-normal body weights were also occasionally recorded in the low-dose group, although during the last quarter of the study the body weights were comparable with those of the controls.

Increased urinary coproporphyrin and uroporphyrin were noted in female rats, but not in males, given TCDD at a dose rate of 0.01 and 0.1 µg/kg/day. Analyses of blood serum collected at terminal necropsy revealed increased enzyme activities related to impaired liver function in female rats given 0.1 µg TCDD/kg/day. Necropsy examination of the rats surviving TCDD exposure until the end of the study revealed that effects in the liver constituted the most consistent alteration in both males and females. Histopathological examination revealed multiple degenerative, inflammatory, and necrotic changes in the liver that were more extensive in females. Multinucleated hepatocytes and bile-duct hyperplasia were also noted. Liver damage was dose related, and no effect was observed at the low-dose rate. The NOAEL was estimated to be 0.001 µg/kg/day. At the end of the study, the fat and liver concentration of TCDD at this dose was 540 ppt.

In male Swiss mice, weekly oral doses of 0, 0.007, 0.7, and 7.0 µg TCDD/kg bw for 1 year resulted in amyloidosis and dermatitis (Toth et al., 1979). The incidence of these lesions was 0 of 38, 5 of 44, 10 of 44, and 17 of 43 in the control-, low-, medium-, and high-dose groups, respectively. The LOAEL in this study was estimated to be 0.001 µg/kg/day (=1 ng/kg/day).

In the National Toxicology Program (NTP, 1982) gavage study of B6C3F1 male and female mice, no adverse effects were seen at the lowest dose tested (0.01 and 0.04 µg/kg bw/week for males and females, respectively; corresponding to ~1.4 and 6 ng/kg bw/day).

The limited studies (9-20 months) available in rhesus monkeys (Allen et al., 1977; Barsotti et al., 1979; Schantz et al., 1979) revealed signs and symptoms similar to those recorded

in more short-term studies. Adverse effects were noted down to the lowest dose tested (~2-3 ng/kg bw/day for 20 months) (Schantz et al., 1979).

3.4.1. Appraisal

From different long-term studies on TCDD, it can be estimated that the NOAEL for the rat is 1 ng/kg bw/day, corresponding to a fat and liver concentration (NOAEL) of 540 ppt. For the male Swiss mouse, dermatitis and amyloidosis in 5 of 44 animals were noted at the lowest dose tested (the LOAEL was 1 ng/kg bw/day). NOAELs of 1.4 and 6 ng/kg/day were obtained for male and female B6C3F1 mice, respectively. The reported studies on rhesus monkeys are problematic for use in such a determination, because adverse effects were observed at the lowest dose tested, ~2-3 ng/kg bw/day.

3.5. SPECIFIC EFFECTS

3.5.1. Wasting Syndrome

TCDD at high doses (lethal or near lethal) causes a starvation-like effect, or wasting syndrome, in several animal species. In young animals, or following a sublethal dose to adults, this response is manifested as a cessation of weight gain. Animals exposed to near lethal or higher doses characteristically lose weight rapidly. Numerous studies utilizing pair-feeding, total parenteral nutrition, and everted intestinal sacs have been performed to elucidate the mechanisms behind the wasting syndrome (U.S. EPA, 1984, 1985; WHO/IPCS, 1989), but no single explanation has been obtained thus far. No generalized impairment of intestinal absorption seems to occur.

Peterson et al. (1984) conducted behavior experiments and suggested a model for the TCDD-induced wasting syndrome that is based on the hypothesis, advocated by Keesey and Powley (1975, 1986), that body weight in rats is regulated to an internal standard or hypothalamically programmed set-point. According to this hypothesis, the body weight at a given age is constantly being compared to this set-point value and, if differences occur, feed consumption is adjusted. When TCDD lowers this set-point, reduction in food consumption results as the rat attempts to reduce its weight to a new lower level. This hypothesis has been tested in several experiments under carefully controlled feeding conditions. Repeated studies have demonstrated that reduction of feed intake due to increased food spillage is not sufficient to account for the loss of body weight in TCDD-treated SD rats. Additionally, TCDD-treated rats maintain and defend their reduced weight level with the same precision that ad libitum-fed control rats defend their normal weight level (Seefeld and Peterson, 1983, 1984; Seefeld et al., 1984a,b). The percentage of the daily feed intake that is absorbed by the gastrointestinal tract of TCDD-treated and control rats is similar (Potter et al., 1986; Seefeld and Peterson, 1984).

Reduced appetite as a result of inhibition of tryptophan-2,3,-dioxygenase causes gradual development of eventual lethal hypoglycemia in TCDD-induced wasting syndrome in rats (Weber et al., 1994). No reduced appetite associated with gradual body weight loss and no tryptophan effects are observed in TCDD-exposed mice, although appetite and body weight loss are observed in mice at the terminal stage of wasting syndrome. Hypophagia was the major cause of adipose and lean tissue loss in male Fischer 344 rats, C57Bl/6 mice, and albino guinea pigs when exposed to a calculated LD_{50} dose of TCDD. Body weight loss followed a similar time-course in TCDD-treated and pair-fed control animals of all three species (Kelling et al., 1985).

Body weight loss appears to contribute to lethality in a species- and strain-dependent fashion, but weight loss appears to play a greater role in causing death in SD rats and guinea pigs than it does in Fischer 344 rats and C57Bl/6 mice. Loss of body weight and loss of appetite are also prominent signs of thyroid dysfunction. However, some data indicate that the effect of TCDD on thyroid hormones cannot explain the TCDD-induced decrease in body weight gain.

Reduced gluconeogenesis due to inhibition of phosphoenol pyruvate carboxykinase (PEPCK) by TCDD has been suggested as one of the primary contributing factors to a gradual development of an eventual lethal hypoglycemia in wasting syndrome in rats (Stall et al., 1993) and mice (Weber et al., 1995).

TCDD-induced wasting is associated with reduction of adipose tissue mass, hypertriglyceridemia, redistribution of fatty acids (Gasiewicz and Neal, 1979; Chapman and Schiller, 1985; Brewster and Matsumura, 1988), and diabetic-like symptoms (Brewster and Matsumura, 1988). Carbohydrate and lipid metabolism are severely impaired in the liver and adipose tissue by TCDD. Glucose transport systems play vital roles in controlling the rate of energy utilization in adipose tissues. TCDD also affects lipoprotein lipase (LPL) activity. The rate of fat storage is determined by LPL, which controls the serum level of triglycerides. Brewster and Matsumura (1984) found that LPL activity was decreased in guinea pigs to 20% of the value of ad libitum-fed controls after 1 day, and that this effect persisted throughout the study (10 days). The authors suggest that TCDD irreversibly reduces adipose LPL activity, thus making the animals less capable of adapting to nutritional changes and needs. In the pancreas, LPL regulates the production and release of insulin, and in the liver it controls glucose metabolism and fatty acid synthesis. From their observations on the significant reduction of glucose-transporting activity in adipose tissue and pancreas in guinea pigs by TCDD at a very low dose (single IP injection of 0.03 µg/kg), Enan et al. (1992a,b) concluded that the reduction in glucose transporters is one of the major causes of TCDD-induced wasting syndrome in this species. Downregulation of the cellular glucose uptake in NIH 3T3 L1 preadipocyte cell line in culture by TCDD has also been observed (Olsen et al., 1994). Pretreatment of these cells with

4,7,-phenanthroline, an Ah receptor blocker, prevents the effect of TCDD on glucose uptake, suggesting that TCDD-induced downregulation of functional glucose transporter proteins is mediated through the Ah receptor.

The insulin-recruitable form of glucose transporter Type 4 (GLUT4) provides energy to the cell by supplying glucose to the muscle and tissue tissues. Impairment of GLUT4 in adipose tissue, liver, and pancreas (Enan et al., 1992a,b), and reduction of PEPCK in liver (Viluksela et al., 1995), could play important roles in the pathogenesis of TCDD-induced diabetes.

In a series of studies on Wistar rats, Lakshman et al. (1988, 1989, 1991) demonstrated that single intraperitoneal injections of TCDD (from 1 µg/kg) caused a dose-dependent inhibition of fatty acid synthesis in the liver and adipose tissue. Adipose tissue was found to be more sensitive than the liver. They also found an increased mobilization of depot fat into the plasma compartment, accompanied by an increase in plasma free fatty acid concentrations.

In vitro studies of isolated heart mitochondria have indicated that a TCDD concentration of 1.5 nmol/mg in mitochondrial protein affects oxygen activation associated with cell respiration. Superoxide radicals and H_2O_2 were indicated to be involved in the development of the observed effects (Nohl et al., 1989).

Loss of muscle tissue, accompanied by a decreased glucocorticoid receptor-binding capacity and an increased glutamine synthetase activity, has been observed in male Fischer 344N rats given a single oral TCDD dose of 100 µg/kg (Max and Silbergeld, 1987).

Another biochemical effect associated with TCDD-induced wasting syndrome is the decrease in hepatic vitamin A storage in TCDD-exposed animals (Thunberg et al., 1979; Håkansson et al., 1989a, 1991). Vitamin A is necessary for growth; vitamin A deficiency will result in depressed body weight gain and reduced food intake. However, in contrast to TCDD-treated animals, the vitamin A-deficient animals continue to eat and grow, though body weight gain is less than normal (Hayes, 1971).

The hypothesis that decreased feed intake could be a result of a direct TCDD effect on the brain was initially indicated by Pohjanvirta et al. (1989), although contradictory information has been provided by other studies (Stall and Rozman, 1990). The intraperitoneal administration of TCDD at 50 µg/kg to male SD rats (~LD_{50} level) caused a significant decrease in the serum concentration of prolactin, detectable after 4 hours, compared with pair-fed vehicle controls and noninjected controls (Jones et al., 1987). Further studies have demonstrated that the effect of TCDD was reversed by pimozide, a dopamine receptor antagonist, and [that the rate constant of dopamine depletion after α-methyl-p-tyrosine and the turnover rate were significantly elevated.] This suggests a hypothalamic site of TCDD action in their experiments (Russell et al., 1988), a finding supported by additional data on changes to central thermoregulation by dioxin in golden hamsters (Gordon et al., 1996) and rats (Gordon and Miller, 1998).

Changes in intermediary metabolism have been demonstrated in TCDD-treated experimental animals. Conflicting data on how TCDD affects serum glucose and hepatic glycogen levels have been reported earlier (WHO/IPCS, 1989). Several studies have suggested that the ultimate cause of death in some mammalian species may be a progressive hypoglycemia (Ebner et al., 1988; Gorski and Rozman, 1987; Gorski et al., 1990). Serum glucose levels in the guinea pig, however, were not affected by treatment of the animals with TCDD (Gasiewicz and Neal, 1979). Slight reductions in serum glucose levels were noted in both L-E and H/W rats (Pohjanvirta et al., 1989). Rozman et al. (1990) have suggested that the subchronic and chronic toxicities of TCDD are related to the inhibition of key enzymes of gluconeogenesis. They demonstrated that the induction of appetite suppression was preceded by the inhibition of PEPCK, which caused a reduction in gluconeogenesis. This was followed by a progressive increase in plasma tryptophan levels that was suggested to cause a serotonin-mediated reduction of the feed intake. In SD rats, TCDD in doses of 25 and 125 µg caused a rapid decrease (50%) in PEPCK activity 2 days after dosing, followed by a dose-dependent decrease in glucose-6-phosphatase activity 4 to 8 days after exposure. Both appetite suppression and reduced PEPCK activity occurred in the same dose range (Weber et al., 1991). TCDD-induced impairments of carbohydrate synthesis have also been suggested by studies in chick embryos (Lentnek et al., 1991).

Numerous studies have measured serum levels of free fatty acids, cholesterol, and triglycerides in various species after TCDD treatment (WHO/IPCS, 1989), but no pronounced qualitative differences have been observed between species or strains of mice.

The wasting syndrome seems to be a generalized effect, elicited in all species and strains, but at various dosages (single or repeated administration). Specific studies have not been performed to elucidate the extent to which this syndrome is elicited through the interaction of TCDD with the Ah receptor, although the binding affinities of various CDDs and CDFs to the Ah receptor, as well as those of related PCBs, have been shown to strongly correlate with their potency to induce the wasting syndrome in both rats and guinea pigs (Safe, 1990).

3.5.2. Hepatotoxicity

Even at sublethal doses, TCDD induces hyperplasia and hypertrophy of parenchymal cells and, thus, hepatomegaly in all species investigated. There is, however, considerable variation in the extent and severity of this lesion among the species tested. Other liver lesions are more species-specific. Lethality following the administration of TCDD cannot be explained by these liver lesions alone, although they may be a contributing factor in the rat and rabbit. The morphological changes in the liver are accompanied by impaired liver function characterized by liver enzyme leakage, increased microsomal monooxygenase activities, porphyria, impaired

plasma membrane function, hyperlipidemia, and increased regenerative DNA synthesis (U.S. EPA, 1984, 1985; WHO/IPCS, 1989).

Hepatotoxic reaction in various strains of rats given lethal doses of TCDD is characterized by degenerative and necrotic changes including the appearance of mononuclear cell infiltration, multinucleated giant hepatocytes, increased numbers of mitotic figures and pleomorphism of cord cells, an increase in the hepatic smooth endoplasmic reticulum, and parenchymal cell necrosis. The histological findings are accompanied by hyperbilirubinemia, hypercholesterolemia, hyperproteinemia, and increased serum glutamic oxaloacetic transaminase (SGOT) and serum glutamic pyruvic transaminase (SGPT) activities, which further indicate damaged liver function (WHO/IPCS, 1989). These lesions may be severe enough to be a contributing factor in death. The lesions observed after sublethal doses are qualitatively almost identical to those observed after lethal doses.

Early studies in mice found similar effects. More recently, Shen et al. (1991) reported a comparative study on the hepatotoxicity of TCDD in Ah-responsive and Ah-nonresponsive mice (C57BL/6J and DBA/2J, respectively). The C57BL/6J mice given a single dose of 3 µg/kg TCDD developed mild to moderate hepatic lipid accumulation but no inflammation or necrosis. Severe fatty change, mild inflammation, and necrosis occurred at 150 µg/kg. The DBA/2J mice given 30 µg/kg developed hepatocellular necrosis and inflammation but no fatty change. Lipid accumulation was only slight after 600 µg/kg. The authors concluded that the Ah locus may be involved in determining the steatotic effects of TCDD. This is consistent with the findings of Birnbaum et al. (1990) on the differential toxicity of TCDD in C57BL/6J mice congenic at the Ah locus. In this study, wild type mice were 8- to 24-fold more sensitive than congenic mice deficient at the Ah locus for a spectrum of effects, including increased liver weight, hepatocellular cytomegaly, fatty change, bile duct hyperplasia, and serum liver enzyme changes.

The guinea pig shows less severe morphological alteration in the liver than other species, although ultrastructural changes of the liver are found. Likewise, the hamster exhibits little or no liver damage even after a fatal dose, but liver lesions have been observed after prolonged periods following the administration of nonlethal doses.

Several parameters relating to disturbed hepatic plasma membrane function have been studied (U.S. EPA, 1984, 1985; WHO/IPCS, 1989). Adenosine triphosphatase (ATPase) activities were depressed and protein kinase C activity was increased in rats, but not in guinea pigs, treated with TCDD (Bombick et al., 1985). TCDD also induced a decrease in the binding of EGF. The relative doses of TCDD needed to suppress EGF binding to 50% of the control level were 1, 14, and 32 µg/kg for the guinea pig, the SD rat, and the Syrian Golden hamster, respectively (Madhukar et al., 1984). A single intraperitoneal dose of 115 µg TCDD/kg bw

decreased the EGF binding by 93.1%, 97.8%, and 46.0% in C57Bl/6, CBA, and AKR mice, respectively, 10 days after treatment (Madhukar et al., 1984).

Further studies on the interaction of TCDD with the EGF receptor have been performed in congenic mice of the strain C57BL/6J (Lin et al., 1991a,b). The ED_{50} for the TCDD-induced decrease in maximum binding capacity of the EGF receptor was 10 times higher in the Ah-nonresponsive mice than the Ah-responsive animals. This study supports the hypothesis that the effects of TCDD on EGF receptor ligand binding are mediated by the Ah receptor.

The effects of TCDD on biliary excretion of various compounds have also been studied. Of special interest are studies on the excretion of ouabain, a model compound for neutral nonmetabolized substrates such as estradiol, progesterone, and cortisol, which was depressed in a dose-related manner by a single oral dose of TCDD in rats (Yang et al., 1977, 1983b). The available data suggest that the hepatic membrane transport of ouabain may be selectively impaired by TCDD. Peterson et al. (1979a,b) have indicated that changes in ATPase activities are not responsible for reduced ouabain excretion.

TCDD administration stimulates the accumulation of porphyrins in the liver and an increase in urinary porphyrin excretion (Goldstein et al., 1973, 1976, 1982). Indeed, during manifest porphyria, accumulation of porphyrins occurs not only in the liver but also in the kidney and spleen of rats (Goldstein et al., 1982).

Contradictory results on species variations have been published. It seems clear that porphyria can be produced in both mice and rats, but the condition is always the result of subchronic or chronic administration. Exposure to single doses has not been demonstrated to produce porphyria. The mechanism underlying the induction of porphyria has not been elucidated. Cantoni et al. (1981) exposed rats orally to 0.01, 0.1, and 1 µg TCDD/kg bw/week for 45 weeks. Increased coproporphyrin levels were observed at all dose levels. A marked porphyric state appeared only at the highest dose tested, after 8 months of exposure.

Induction of aminolevulinic acid (ALA)-synthetase, the initial and rate-limiting enzyme involved in heme synthesis, does not seem to be a necessary event in TCDD-induced porphyria. Despite porphyria being evident, mice exposed to 25 µg TCDD/kg bw/week for 11 weeks were not found to have any increased ALA activity (Jones and Sweeney, 1980). A more likely suggestion is that decreased hepatic porphyrinogen decarboxylase is the primary event in porphyria induced by halogenated aromatics (Elder et al., 1976, 1978). TCDD depresses this enzyme activity in vivo in the liver of mice (Cantoni et al., 1984a,b; Elder and Sheppard, 1982; Jones and Sweeney, 1980), but not in vitro (Cantoni et al., 1984b). Of interest, too, are the results reported in van Birgelen et al. (1996a), where the porphyrinogenic effects of TCDD were correlated with CYPIA2 induction, and demonstrated a strong synergistic relationship with coadministered PCBs.

A comparative study of TCDD-induced porphyria has not been conducted in responsive and nonresponsive mice. In a study on Ah-responsive (Ah^b) and Ah-nonresponsive (Ah^d) C57BL/6J female mice, however, the urinary excretion of porphyrins was examined after treatment of the animals with hexachlorobenzene for 17 weeks (Hahn et al., 1988). After 15 weeks of treatment with 200 ppm hexachlorobenzene in the diet, the excretion of porphyrins was 200 times higher in the Ah^b mice than the controls. In contrast, the Ah^d mice only showed a sixfold increase. Induction of P-450c(1A1) was observed only in Ah^b mice, while induction of P-450d(lA2) was observed in both strains, but to a lesser degree in the Ah^d mice.

3.5.3. Epidermal Effects

Chloracne and associated dermatological changes are common responses to high exposures to TCDD in humans. However, this type of toxicity is expressed only in a limited number of animal species (e.g., rabbits, monkeys, cows, and hairless mice).

In a rabbit ear bioassay, a total dose of 80 ng TCDD gave a chloracnegenic response, while no response was obtained when the total dose applied to the ear was 8 ng (Jones and Krizek, 1962; Schwetz et al., 1973). The application of TCDD in various vehicles has been demonstrated to markedly decrease this response (Poiger and Schlatter, 1980). The hairless mouse is a less sensitive model for chloracnegenic response than the rabbit ear bioassay (Knutson and Poland, 1982; Puhvel et al., 1982). Following repeated applications of ~0.1 µg TCDD over several weeks, however, an acnegenic response was noted in the hairless mouse strains, SkH:HR1 and HRS/J. An acnegenic response was also caused by repeated applications of 2 mg of 3,4,3′,4′-TCB (Puhvel et al., 1982). Female HRS/J hairless mice have also been used to test the dermal toxicity and skin tumor-promoting activity of 2,3,7,8-TCDD, 2,3,4,7,8-PeCDF, and 1,2,3,4,7,8-HxCDF (Hebert et al., 1990b). All of the tested compounds induced coarse, thickened skin with occasional desquamation. These effects were more severe after the application of PeCDF and HxCDF.

Keratinocytes, the principal cell type in the epidermis, have been utilized as an in vitro model for studies of TCDD-induced hyperkeratosis both in human- and animal-derived cell cultures. The response to TCDD is analogous to the hyperkeratinization observed in vivo.

A TCDD-induced keratinization response in vitro was first demonstrated in a keratinocyte cell line derived from a mouse teratoma (XB cells). The keratinization was doserelated (Knutson and Poland, 1980b). Late-passage XB cells (termed XBF cells) lost their ability to respond by keratinization after TCDD treatment. Both XB cells (keratinization assay) and XBF cells (flat-cell assay) have proven to be useful in in vitro bioassays to determine the dioxin-like activities of both environmental samples and pure isomers (Gierthy and Crane, 1985a,b; Gierthy et al., 1984).

Several continuous lines of human keratinocytes, derived from neonatal foreskin or squamous cell carcinomas, have been shown to respond to TCDD in nM concentrations, with a variety of signs indicating alterations in the normal differentiation process (WHO/IPCS, 1989). The responses include decreased DNA synthesis, decreased number of proliferating basal cells, decreased binding of EGF, and an increase in the state of differentiation (Osborne and Greenlee, 1985; Hudson et al., 1986). The responses were also obtained with TCDF, but not with 2,4-diCDD (Osborne and Greenlee, 1985). TCDD has also been shown to inhibit high-density growth arrest in human squamous carcinoma cell lines. Indeed, the minimum concentration for increases in cell proliferation was 0.1 nM in the most sensitive cell line (SCC-15G). This effect is not due to modulation of the transforming growth factor-β binding (Hebert et al., 1990b,c).

3.5.4. Enzyme Induction

TCDD has repeatedly been found to increase the activities of various enzymes. While observations of enzyme inhibition have also been made, enzyme induction has been one of the most extensively studied biochemical responses produced by TCDD. The mixed-function oxidase (MFO) system is the most thoroughly investigated, and AHH and EROD (as markers for CYPlA1 induction) are the most frequently assayed enzyme activities. The induction of MFO activities might potentiate the toxicity of other foreign compounds that require metabolic transformation by the MFO system before they can exert their toxic effects. Furthermore, increased MFO activities might adversely affect important metabolic conversions of endogenous compounds. TCDD also affects a variety of other enzymes (e.g., uridine diphosphate-glucoronosyltransferase [UDPGT] and glutathione-s-transferase [GST]) that are components of multifunctional enzyme systems involved in the conjugation, biotransformation, and detoxification of a wide variety of endogenous and exogenous compounds.

Several investigators have studied the relative potency of various halogenated dioxins, dibenzofurans, and biphenyls to induce AHH or EROD activities (Safe, 1990). An apparent structure-activity relationship was found between the location of the halogen atoms on the dibenzo-p-dioxin molecule and the ability to induce AHH activity both in vivo and in vitro. Isomers with halogens at the four lateral ring positions produced a greater biological response than those with halogens at three lateral ring positions. Two lateral halogen atoms seemed to be insufficient to produce a biological response. Numerous studies have indicated that there is very strong agreement between the Ah-binding affinity of various CDDs, CDFs, and related PCBs and their potency to induce AHH, both in vivo and in vitro (Safe, 1990). Structure-activity studies have also demonstrated a clear correlation between the toxicity and induction potency of a series of CDDs, CDFs, and coplanar PCBs (Poland and Glover, 1973; Safe, 1990). This is discussed in Chapter 2 of this report.

On a molecular basis, TCDD is the most potent MFO-inducing compound known, and MFO induction seems to be the most sensitive biochemical response produced. Measurements of the induction of AHH or EROD (mediated through CYPlA1) are considered to be very sensitive markers of TCDD-induced enzyme induction. According to Kitchin and Woods (1979), induction in the rat takes place at doses as low as 0.002 µg TCDD/kg bw. The NOAEL for a single administration to rats seems to be 1 ng/kg, while a single dose of 3 ng/kg causes a detectable induction of AHH or EROD (Kitchin and Woods, 1979; Abraham et al., 1988). For more detailed dose-response information, see Chapter 8 of this report. Enzyme induction has also been observed in the offspring of various species after prenatal and postnatal (milk) exposure to TCDD (Lucier et al., 1975; Korte et al., 1990; Wærn et al., 1991b).

The effect of TCDD on enzyme activities has been most frequently investigated in the rat (WHO/IPCS, 1989). TCDD has been shown to increase both the contents of cytochrome P-450lA1 and cytochrome P-450lA2 in the liver, as well as other microsomal enzyme activities involved in the oxidative transformation and conjugation of xenobiotics (e.g., aniline hydroxylase, AHH, biphenyl hydroxylase, 7-ethoxycoumarin-O-deethylase [ECOD], EROD, and UDPGT) (U.S. EPA, 1984, 1985; WHO/IPCS, 1989).

TCDD also affects some other hepatic enzymes not related to the MFO system, including aldehyde dehydrogenase, δ-ALA synthetase DT-diaphorase, transglutaminase, ornithine decarboxylase, transaminases (L-alanine aminotransferase [ALT] and L-aspartate aminotransferase [AST]), plasma membrane ATPases, porphyrinogen carboxylase, prostaglandin synthetase, enzymes involved in testosterone metabolism, and RNA polymerase (U.S. EPA, 1984, 1985; WHO/IPCS, 1989).

Studies of different species have also revealed that enzyme induction due to TCDD exposure varies with both species and strain. Pohjanvirta et al. (1988) studied enzyme induction in the L-E and H/W (Kuopio) rat strains (LD_{50} ~10 and >3,000 µg/kg, respectively). Differences in the inducibility of EROD, ECOD, or ethylmorphine N-demethylase were not found, nor were there any differences with regard to the amount of available Ah receptor or the amount of cytochrome P-450 in the hepatic microsomal fractions. Similarly, differences regarding possible induction of UDPGT were absent (Pohjanvirta et al., 1990).

Enzyme induction studies on mice have been performed mainly with strains that are genetically different at the Ah locus, thus making them responsive or nonresponsive to the induction of hepatic cytochrome P-4501A1-related enzyme activities. Qualitatively, and in general, the same responses can be obtained in both strains, but there may be more than one order of magnitude difference with regard to the doses required to elicit a response. TCDD is thus 10-fold more potent in inducing hepatic cytochrome P-450lA1 and the related AHH activity in C57BL/6J mice (Ah-responsive) than in DBA/2 mice (Ah-nonresponsive) (Poland and

Knutson, 1982; Nebert, 1989) and C57BL/6L mice congenic at the Ah locus (Birnbaum et al., 1990).

Although the guinea pig is the most sensitive species to the toxic effects of TCDD, it does not respond to the administration of TCDD with liver toxicity or extensive enzyme induction. Indeed, even at lethal doses, the induction of MFO, as measured by AHH activity, is only very slight (Beatty and Neal, 1977; Håkansson et al., 1994). The data on enzyme induction in rabbits are rather limited and somewhat conflicting with regard to increases in the amount of cytochrome P-450 (Hook et al., 1975; Liem et al., 1980). Similarly, hepatic enzyme induction has been only partially studied in Syrian Golden hamsters. When hamsters were given a lethal dose of TCDD, increased hepatic GST and glutathione reductase activities were found. The ED_{50} values for the induction of hepatic ECOD and reduced NADP:menadione oxidoreductase activities and cytochrome P-450 content in male Syrian Golden hamsters were 1.0, 2.0, and 0.5 µg TCDD/kg bw, respectively (extremely low doses, compared with doses that produce tissue damage and lethality in this species) (Gasiewicz et al., 1986).

In a comparative study of EROD induction in guinea pigs, rats, C57BL/6 and DBA/2 mice, and Syrian Golden hamsters, the animals were given single doses that were intended to be equitoxic (i.e., 1, 40, 100, 400, and 400 µg TCDD/kg, respectively) compared with the acute toxicity for the respective species and strain. EROD induction was noted in all species except for the hamster. During the observation period (112 days), the EROD induction dropped to more or less normal values in all rats and mice, while the induction (albeit low compared with the other species) was sustained for the whole period in the guinea pig (Håkansson et al., 1994). This might be due to higher half-life of TCDD in guinea pigs than rats or mice.

The N-demethylation of caffeine has been applied as a noninvasive method for studying enzyme induction in vivo. Studies on the marmoset monkey (Callithrix jacchus), utilizing ^{14}C-labeled caffeine and measuring $^{14}CO_2$ exhalation by a breath test, has indicated a NOAEL of 1 ng/kg and a LOEL of 3 ng/kg (Kruger et al., 1990). Studies by Butler et al. (1989) and others indicate that this reaction is dependent on cytochrome P-450lA2.

In the chick embryo, both AHH and δ-ALA synthetase have been reported to be extremely sensitive to the inductive effects of TCDD and related compounds (Poland and Glover, 1973; Brunström and Andersson, 1988; Brunström, 1990).

Although TCDD is relatively nontoxic in cell cultures, it is a very potent inducer of AHH or EROD activities in in vitro systems, including lymphocytes and primary hepatocytes, as well as established and transformed cell lines.

The ED_{50} values for AHH induction by TCDD have been determined in 11 established cell lines and in fetal primary cultures from 5 animal species and cultured human lymphocytes. The values ranged from 0.04 ng/mL medium in C57BL/6 mouse fetal cultures and 0.08 ng/mL in

the rat hepatoma H-4-II-E cell line to >66 ng/mL in the HTC rat hepatoma cell line (Niwa et al., 1975). Several cultured human cells or cell lines have been shown to be inducible for AHH activity by TCDD including lymphocytes (Atlas et al., 1976), squamous cell carcinoma lines (Hudson et al., 1983; Hebert et al., 1990a), breast carcinoma cell lines (Jaiswal et al., 1985), and lymphoblastoid cells (Nagayama et al., 1985).

TCDD was demonstrated to be the most potent AHH inducer of 24 chlorinated dibenzo-p-dioxin analogues (Bradlaw et al., 1980) in a rat hepatoma cell culture (H-4-II-E) that is extremely sensitive to AHH induction. The EC_{50} values for AHH and EROD induction in the same cell system varied over 7 orders of magnitude for 14 different CDDs, the most potent being TCDD and the least potent being 2,3,6-triCDD (Mason et al., 1986). Additional details on these and other enzyme induction dose-response characteristics and modeling are included in Chapter 8 of this report.

3.5.4.1. Appraisal

Based on data from Kitchin and Woods (1979), Abraham et al. (1988), Kruger et al. (1990), and Neubert (1991), a NOAEL value of 1 ng/kg bw can be calculated for enzyme induction for both rats and marmoset monkeys. At this dose, the tissue concentrations for both species were found to be 4 ppt for adipose tissue and 3 ppt for the liver. It is interesting to note that the wide range of sensitivities toward the acute toxicity of TCDD is also reflected in the wide range of sensitivities for enzyme induction both in vivo and in vitro, although the two groups of effects are not necessarily parallel. Finally, it is evident that the structure-activity relationships revealed from in vitro testing correlate fairly well with in vivo studies within a given species or strain.

3.5.5. Endocrine Effects

In many respects, TCDD toxicity mimics endocrine imbalance. Alterations in endocrine regulation have been suggested from human exposure to TCDD that resulted in hirsutism and chloracne. Chronic exposure to TCDD causes impaired reproduction in experimental animals, possibly by interfering with the estrus cycle in combination with some steroid-like activities of TCDD. This has prompted studies on the interaction of TCDD with steroid hormones and their receptors.

Evidence has been provided suggesting that chronic or subchronic exposures to TCDD impair thyroid functions. Dose-dependent reductions of plasma thyroid hormone levels have been observed in TCDD- and PCB-exposed animals (van der Kolk et al., 1992; van Birgelen et al., 1995a,b).

In a subchronic 13-week TCDD feeding study with female Sprague-Dawley (S-D) rats, a decrease in thyroid hormone (T_4) levels occurred, associated with elevation of microsomal UDPGT activity when thyroxine was used as substrate for thyroxine glucuronosyltransferase (T_4UGT) (van Birgelen et al., 1995b). In addition, involvement of CYP1A1 and UGT1A1 by TCDD indicates that the TCDD-induced thyroid functional abnormalities are mediated though the AhR (van Birgelen et al., 1995b). 2,3,3',4,4',5-hexachlorobiphenyl (PCB 156) has also been shown to reduce plasma total T_4 levels, and induces UDPGT by using thyroxine as substrate for T_4UGT (van Birgelen, 1995a). Similar results have also been observed in a 30-week chronic study with female S-D rats suggesting that TCDD-induced thyroid hormone function is caused by chronic perturbation of the liver-pituitary-thyroid axis (Sewell et al., 1995).

van Birgelen et al. (1995a,b) demonstrated the effects of TCDD and coplanar PCB126 (3,3,4,4',5-PCB) on thyroid hormone metabolism in female SD-rats. Oral exposure to 0.2, 0.4, 0.7, 5, and 20 µg/kg diet of TCDD and 7 to 180 µg/kg diet of PCB 126 significantly decreased the plasma total thyroxine (TT_4) levels. An intake of 0.047 µg/kg/day was estimated to be the LOAEL for decrease in plasma thyroid hormone levels.

A dose-dependent decrease in serum T_4 levels has also been observed in male and female SD rats as a result of high-dose subchronic exposures to 1,2,3,7,8-pentaCDD (PeCDD) or 1,2,3,4,7,8-hexaCDD (HxCDD) and low-dose subchronic exposures to TCDD/kg. Serum T_4 levels in PeCDD or HxCDD-exposed males returned to close to normal levels by the end of the off-dose period (Viluksela et al., 1998).

van Birgelen et al. (1995b), in a 13-week TCDD feeding study using 7-week-old female S-D rats, found that the LOAEL for decrease in plasma T_4 was 47 ng/kg bw/day. Dose-response relationships for CYP1A1 and CYP1A2 were determined by nonlinear curve fitting. The critical values for the 95% confidence limits for CYP1A1 and CYP1A2 inductions ranged from 0.7 and 4 ngTCDD/kg bw/day.

Janz and Bellward (1997) reported that a single intraperitoneal dose of 20 µg/kg bw of TCDD to adult great blue heron, Ardea heidias, increased plasma T_4 levels (control: 39 ± 4 ng/mL; exposed: 55 ± 5 ng/mL; $p<0.05$), but no effect occurred on plasma total T_3 levels or on the plasma T_3 to T_4 ratio.

Increased systemic levels of glucocorticoids may mimic some of the symptoms of TCDD toxicity (e.g., involution of lymphoid tissues, edema, and mobilization of fatty acids from adipose tissues). Thus, it has been suggested that TCDD increases glucocorticoid activity through indirect effects on glucocorticoid receptors. Poland et al. (1976) demonstrated that cortisol and synthetic glucocorticoids do not bind to the TCDD receptor.

Conflicting data have been reported on TCDD-induced levels of glucocorticoids. However, significant changes to the liver cytosolic glucocorticoid receptor were induced by

TCDD at doses 10,000-fold lower in adrenalectomized SD rats than in control rats (Sunahara et al., 1989). The data further indicate that the binding capacity of hepatic glucocorticoid receptor was altered, but not the apparent equilibrium dissociation constant (Kd). Studies in congenic strains of Ah-responsive and Ah-nonresponsive C57BL/6J female mice (Goldstein et al., 1990; Lin et al., 1991a,b) have also demonstrated that TCDD decreased the maximum binding capacity of the hepatic glucocorticoid receptor in both strains of mice by ~30%.

Steroids are endogenous substrates for the hepatic MFO system. TCDD influences the activity of this enzyme system and may alter steroid metabolism in vivo and the magnitude of steroid-mediated functions.

Early studies reported contradictory data on changes in steroid levels. Umbreit and Gallo (1988) suggest that estrogen receptor modulation, and the animal's physiological response to this modulation, can explain some of the toxicity observed in TCDD-treated animals. The susceptibility of different species to TCDD correlates, to some extent, with their steroid glucuronidation capacity. For example, hamsters have low steroid UDPGT activity while guinea pigs have a corresponding high activity. Another example is given by comparing the SD and Gunn rat, the latter being defective in producing some UDPGTs. The homozygous Gunn rat is 3-10 times more resistant to the effects of TCDD than is the SD rat (Thunberg, 1984; Thunberg and Håkansson, 1983). The results of TCDD exposure in various species and strains are complex. The ability of the strain to counteract TCDD-induced modulation of the estrogen receptor depends on its ability to synthesize and excrete estrogens. Interactions of TCDD and related compounds with estrogen have been reviewed by Safe et al. (1991).

The importance of estrogens as modulators of TCDD-induced toxicity has also been demonstrated by Lucier et al. (1991), who found that the tumor-promoting effects of TCDD could be effectively prevented by removing the ovaries from female rats before exposure to TCDD. This finding agrees with the results obtained from long-term bioassays that demonstrated liver tumors only in female rats (Kociba et al., 1978; NTP, 1982).

Studies on congenic strains of Ah-responsive and Ah-nonresponsive C57BL/6J female mice found a statistically significant difference in the responsiveness of the hepatic estrogen receptor. This indicates that the Ah receptor regulates the effects of TCDD on the hepatic estrogen receptor (Goldstein et al., 1990; Lin et al., 1991a, b).

TCDD-induced changes in levels or activities of testosterone or its metabolites have been reported from several studies (Keys et al., 1985; Mittler et al., 1984; Moore and Peterson, 1985; Neal et al., 1979). A single oral dose of 50 µg TCDD/kg bw increased the plasma corticosterone level in SD rats 7 and 14 days postexposure (Neal et al., 1979). It has also been shown, however, that a single oral dose of 25 µg TCDD/kg bw decreases the plasma corticosterone in

SD rats 14 and 21 days postexposure. It is important to note that Neal et al. (1979) also observed a slight decrease in serum corticosterone during days 1-4 posttreatment.

Mittler et al. (1984) demonstrated a decreased activity of testicular 16-α-testosterone hydroxylase, 6-ß-hydroxytestosterone, and 7-α-hydroxytestosterone in young SD rats 90 hours postexposure to single intraperitoneal doses of 0.2, 1, or 5 µg TCDD/kg bw.

A single dose of 0.06 µmol TCDD/kg bw decreased levels of 3α-, 6α-, and 16ß-hydroxytestosterone and an increase of 7α-hydroxytestosterone has also been observed in young male Wistar rats (Keys et al., 1985). Moore et al. (1985) noted decreases in serum testosterone and dihydrotestosterone levels in 15 µg TCDD/kg bw-dosed male SD rats. The data do not, however, allow for any conclusions with regard to the possible relationship to receptor-mediated toxicity. TCDD induces several enzymes related to testosterone metabolism, which suggests that the changes observed may be secondary to the induction of various enzymes. Serum testosterone and dihydrotestosterone were found to be dose-dependently depressed by TCDD treatment in male SD rats, when compared with pair-fed and ad libitum-fed controls. The ED_{50} for this effect was ~15 µg/kg (Moore et al., 1985). It was further shown that testosterone synthesis was decreased in the animals due to depressed production of pregnenolone by the testis (Kleeman et al., 1990). In the same strain of rats, a single 100 µg/kg oral dose of TCDD was found to cause a 55 percent decrease in testicular cytochrome $P\text{-}450_{scc}$ activity and to inhibit the mobilization of cholesterol to cytochrome $P\text{-}450_{scc}$. The authors concluded that the latter effect probably was responsible for the inhibition of testicular steroidogenesis (Moore et al., 1991). Maternal exposure to TCDD has been shown to affect the male reproductive system at low doses; the lowest dose tested was 64 ng/kg (Mably et al., 1991, 1992a,b,c). This is discussed in Chapter 5.

In ovo exposure of white Leghorn chickens to TCDD, in the dose range of 1-10,000 pmol/egg, increased the cardiac release of prostaglandins (Quilley and Rifkind, 1986). Studies on chick embryos have indicated that the induction of cytochrome P-450 by TCDD results in a major increase in the NADPH-dependent metabolism of arachidonic acid (Rifkind et al., 1990). These effects are clearly related to receptor-mediated enzyme induction.

3.5.6. Vitamin A Storage

Decreased hepatic vitamin A storage has been reported in animals exposed to various chlorinated aromatic compounds. Because only minute quantities are needed to produce ill effects, and because of its persistence in nature, TCDD is unique in its capacity to reduce the vitamin A content of the liver. A single oral dose of 10 µg TCDD/kg bw decreased both the total amount and the concentration of vitamin A in the liver of adult male SD rats (Thunberg et al., 1979). The decrease was evident 4 days after dosing and progressed with time. After 8 weeks, the treated animals had a total liver vitamin A content corresponding to 33% of that of controls.

Decreased dietary intake of vitamin A could not account for this difference. A significant increase in the UDPGT activity was observed, suggesting an increased excretion of glucuronide-conjugated vitamin A. No correlation between the UDPGT activity and the hepatic vitamin A reduction was seen, however, when homozygous Gunn rats lacking inducible UDPGT (Aitio et al., 1979) and heterozygous Gunn rats with inducible UDPGT were treated with a single oral dose of 10 µg TCDD/kg bw (Thunberg and Håkansson, 1983).

A study combining pair-feed restriction and a single TCDD treatment found that decreases in liver reserves of vitamin A were not related to a decreased intake of vitamin A via the diet (Håkansson et al., 1989b).

Puhvel et al. (1991) reported a comparative study in which congenic haired (+/+) and hairless (hr/hr) HRS/J mice were fed a vitamin A-deficient diet and treated topically with TCDD. The sensitivity to TCDD-induced cutaneous changes was essentially 100 times higher in hairless mice than in haired mice (0.01 and 1.0 µg 3 times/week for 3 and 2 weeks, respectively). In the haired phenotype, the effects of vitamin A depletion by itself were not seen by cutaneous histology, nor were any changes observed in cutaneous morphology attributable to TCDD. In the hairless mice, however, vitamin A deficiency increased the keratinization of dermal epithelial cysts and increased the sensitivity of these cysts to TCDD-induced keratinization. Analysis of vitamin A demonstrated that TCDD exposure did not affect cutaneous levels of the vitamin but did significantly lower levels of vitamin A in the liver. TCDD-induced body weight loss and atrophy of the thymus glands were not affected by the vitamin A status in either strain.

In a study on tumor promotion by TCDD, in which enzyme-altered hepatic foci were induced in the livers of female SD rats, Flodström et al. (1991) found that vitamin A deficiency by itself enhanced foci development. The effects of TCDD treatment were also markedly enhanced, including TCDD-induced thymus atrophy.

Several studies have been performed to elucidate the mechanism of TCDD-vitamin A interaction. Håkansson et al. (1989c) and Håkansson and Hanberg (1989) have demonstrated that TCDD specifically inhibits the storage of vitamin A in liver stellate cells. Brouwer et al. (1989) demonstrated that a single dose of TCDD (10 µg/kg) to female SD rats reduced vitamin A in the liver, lungs, intestines, and adrenal glands, while increasing its concentration in serum, kidneys, and urine. They also found a 150% increase in the free fraction of serum retinol binding protein. Taken together, all of these data in the rat indicate that TCDD induces an increased mobilization of vitamin A from hepatic and extrahepatic storage sites into the serum, accompanied by an enhanced elimination of the vitamin via the kidney into the urine.

In a comparative study of TCDD toxicity in male SD rats and Hartley guinea pigs (Håkansson et al., 1989a), the animals were given single intraperitoneal doses of 40 and 0.5 µg/kg bw, respectively (i.e., comparable fractions of their respective LD_{50}). Similar

reductions in hepatic vitamin A were observed for both species, while serum and renal vitamin A concentrations were increased in the rat but unaffected in the guinea pig. Hepatic EROD activity was markedly increased in the rat but unchanged in the guinea pig. Furthermore, rats seemed to recover from the wasting, thymic atrophy, and liver enlargement and resumed their ability to store vitamin A in the liver at 4-8 weeks after exposure. No such trends for wasting and vitamin A storage were observed in guinea pigs, even 16 weeks after exposure. A complementary study also included C57BL/6 mice, DBA/2 mice, and Syrian Golden hamsters (Håkansson et al., 1991). The effects on TCDD-induced decrease of vitamin A in the liver and lung correlated reasonably well with other toxic symptoms observed in the animals. On the other hand, studies of two strains of rats, L-E and H/W (the H/W being >300 times more resistant to TCDD toxicity), could not demonstrate significant differences in the TCDD-induced changes in vitamin A in the liver, kidney, testicles, or serum after a sublethal dose of 4 µg/kg (Pohjanvirta et al., 1990). These findings show that the correlation between TCDD-induced lethality and changes in vitamin A status found among other species also apply to these strains of rats.

The interaction of 3,4,3′,4′-TCB with vitamin A has been studied by Brouwer and van den Berg (1983, 1984, 1986), Brouwer et al. (1985, 1986), and Brouwer (1987). The effects of TCB on vitamin A differ in many respects from those of TCDD. TCB is rapidly converted in vivo into a polar 5-OH-TCB metabolite, which binds with a relatively high affinity to transthyretin (TTR). As a consequence of this interaction, the physiological functions of TTR in retinoid and thyroid hormone transport are severely affected in TCB-exposed animals. The model proposed by Brouwer (1987) may explain some of the characteristic toxicological lesions related to exposure to this PCB. This mechanism of action seems to be clearly separated from the Ah receptor-mediated toxicity of CDDs and CDFs. Hydroxylated metabolites of TCDD have also been demonstrated to bind in a similar manner to TTR (Lans et al., 1993). Due to the very slow metabolism of TCDD (or other 2,3,7,8-substituted CDDs/CDFs), however, this mechanism probably plays a very minor role in toxicity.

Taken together, these data indicate that TCDD interferes with the metabolism and storage mechanisms for vitamin A (Kelley et al., 1998). Because supplementation of dietary vitamin A seems unable to counteract all of the observed toxic effects, this would imply either that the effect on vitamin A storage is secondary to TCDD toxicity or that the cellular utilization of vitamin A is affected by TCDD.

3.5.7. Lipid Peroxidation

Lipid peroxidation and oxidative stress have been indicated as factors that affect the acute toxicity of TCDD (WHO/IPCS, 1989; Wahba et al., 1989a,b, 1990a,b; Pohjanvirta et al., 1989; Alsharif et al., 1990; Stohs et al., 1990). Among the effects noted have been membrane

lipid peroxidation, decreased membrane fluidity, and increased incidence of single-strand breaks in DNA. No studies relating these observations to the Ah receptor have been performed. When considering the available data on TCDD and lipid peroxidation, it is not possible to define a relationship between lipid peroxidation and TCDD-induced lethality. However, oxidative stress is observed only at high doses of TCDD following acute exposure. Acute TCDD exposure at high doses has been shown to produce reactive oxygen species (Alsharif et al., 1994 a,b), lipid peroxidation (Alsharif et al., 1994b), and decreased membrane fluidity (Alsharif et al., 1990) in the mouse and rat.

Oxidative stress has been proposed as one of the reasons for increased susceptibility of female mice to TCDD-induced toxicity. In female C57BL/6J mice, intraperitoneal exposure to 5 µg/kg of TCDD for 3 consecutive days results in a long-term increase in hepatic oxidized glutathione and 8-hydroxydeoxyguanosine levels. Levels of 8-hydroxydeoxyguanosine, a product of DNA base oxidation and subsequent excision repair, remain elevated about 20-fold 8 weeks after treatment. This suggests a sustained TCDD-induced oxidative stress resulting in potentially promutagenic DNA base damage (Shertzer et al., 1998). Induction of CYP1A1 by TCDD has also been suggested to cause an increased excretion rate of 8-oxoguanine, a biomarker of oxidative DNA damage (Park et al., 1996).

Oxidative brain tissue damage may play a role in TCDD-induced central nervous system abnormalities. Hassoun et al. (1998) reported that subchronic oral exposure of B6C3F1 mice to TCDD for 13 weeks can result in a dose-dependent increase in superoxide anions (indicated by reduction in cytochrome c), lipid production, and DNA single-strand breaks in brain tissues. The authors posited involvement of the cytochrome P-450 system in TCDD-induced oxidative stress. Slezak et al. (1999), using CYP1A2 knockout ($CYP1A2^{-/-}$) mice, demonstrated that TCDD-induced oxidative stress (indicated by production of thiobarbituric acid-reactive substances as a measure of lipid peroxidation, production of reactive oxygen species via in vitro reduction of CYC, and changes in glutathione) is not mediated through the cytochrome P-450 type 1A2 isozyme (CYP1A2). Hassoun et al. (1997) also posited that TCDD-induced fetal death and fetal and placental weight reductions in C57BL/6J mice may be caused by oxidative damage induced by TCDD. Ellagic acid at 6 mg/kg/day on days 10, 11, and 12 of gestation and 3 mg/kg on day 13 protected against TCDD administration on day 12 at 30 µg/kg bw. Vitamin E succinate administered at 100 mg/kg/day through gestation days 10, 11, and 12 and at 40 mg/kg on day 13, instead of ellagic acid, was a less effective protective agent.

Iron administered before TCDD administration (75 µg/kg bw) to AhR-responsive AhRb-1 C57BL/6J mice potentiated hepatic porphyria, hepatocellular damage, and plasma hepatic enzyme markers (Smith et al., 1998). The mechanism was oxidative because hydroxylated and peroxylated derivatives of the uroporphyrins formed from uroporphyrinogen,

and μ-glutathione transferase were also induced. Iron overcame the weak porphyria and toxicity responses of TCDD in AhRb-2 BALB/c and AhRd SWR mice, but not in DBA/2 mice, which remained TCDD resistant. Thus, metabolic factors may play a part in the responses of some mice strains to TCDD through an oxidative process that disturbs iron regulatory protein capacity.

Increased accumulation of lipofuscin pigments, which are by-products of lipid peroxidation, in heart muscles of TCDD-exposed rats (Albro et al., 1978) and iron deficiency in animals resulting in in vitro inhibition of lipid peroxidation and reduced TCDD-induced hepatotoxicity (Sweeney et al., 1979) suggested that oxidative stress may play a role in TCDD-induced acute toxicity. Subsequently, Stohs et al. (1983) demonstrated that lipid peroxidation is increased in isolated liver microsomes from TCDD-exposed rats. Further observations suggest a possible role of reactive oxygen species in TCDD acute toxicity. Alsharif et al. (1994a,b) observed that a maximum increase in superoxide anion production occurs on day 1 of posttreatment in female SD rats treated with 50 and 125 μg/kg bw of TCDD, and that TCDD-induced oxidative stress is mediated through the Ah receptor in mice. TCDD-induced superoxide anion production by peritoneal lavage primary macrophages and its mediation through the Ah receptor suggests involvement of reactive oxygen species in a broad spectrum of TCDD-induced toxicity. Bagchi et al. (1993) found that products from altered lipid peroxidation and increased oxidative stress result in elevated serum and urinary levels of certain lipid metabolic products, such as malondialdehyde, formaldehyde, acetaldehyde, and acetone, following a single oral exposure to 50 μg/kg bw of TCDD in female SD rats. Vos et al. (1978) suggested that endotoxin shock may be the cause of TCDD-induced lethality, and that the tumor necrosis factor-α (TNF-α) may be a contributing factor, even though it has not been detected in the serum of TCDD-treated mice without exposure to endotoxin. Alsharif et al. (1994c) demonstrated that anti-TNF-α antibody can decrease phagocytic cell activity following TCDD treatment. This suggests that TNF-α release, a possible activator of TCDD-induced oxidative stress, may have some role in TCDD-induced activation of phagocytic cells.

3.5.8. Neurotoxicity

Exposure to dioxin-like coplanar PCBs may result in neurotoxicity. Eriksson et al. (1991) suggested that dioxin-like coplanar PCBs have neurologic activities that affect the cholinergic receptors in the hippocampus. Seegal (1996) provided evidence that perinatal exposure to coplanar 3,3',4,4'-PCB (PCB 77) results in significant elevation of dopamine in the frontal cortex. Dopamine is an important neurotransmitter, dependent on tyrosine, that is associated with initiation and control of motor behavior, learning, and memory functions. The neurons and astroglia of rat hippocampal neural cells are responsive to relatively low levels of TCDD through mechanisms that are probably not associated with altered gene transcription and

that may involve other cellular targets (Hanneman et al., 1996). TCDD induces phosphorylation and other responses within minutes of treatment, probably through a nonnuclear role of the Ah receptor.

Eriksson and Fredriksson (1998) demonstrated that a single oral exposure of NMRI mice to either 0.51 or 51 mg/kg bw of 3,3',4,4',5,5'-hexachlorobiphenyl (PCB 169) on postnatal day 10 can result in derangement of spontaneous motor behavior. In addition, permanent impairment of learning and working memory was revealed when these animals reached adulthood. This study suggests that exposure to PCB 169 during the neonatal period, at a time when there is incomplete development of the infant's blood-brain barrier and during rapid brain development, can result in vulnerability of the brain to neurologic effects, which in many cases can only be manifested during adulthood. In utero and lactational exposure to TCDD (100 ng/kg/d) or coplanar PCBs resulted in reduction of errors on a radial arm maze working memory task in grown up S-D rats exposed through their mothers (Seo et al., 1999). The effect was more pronounced in males than females. There was no difference in performance of the Morris water maze task or the spatial discrimination-reversal learning task for exposed males and females or unexposed rats. Both adult male and female S-D rats exposed maternally to TCDD showed a deficit in learning a visual discrimination-reversal learning task, a finding also observed in monkeys.

Postnatal oral exposure of primates to PCBs can result in long-term behavioral dysfunctions. In monkeys, oral exposure from birth to 20 weeks of age to 7.5 µg/kg/day of a PCB mixture, representative of the PCB residues generally found in human breast milk samples, also results in significant impairment in discrimination-reversal learning activities (Rice, 1997).

3.6. MECHANISMS OF TOXICITY

The most reliable and consistent symptom of TCDD toxicity among all experimental animals is weight loss. The cause of the body weight loss seems to be reduced food intake, apparently occurring secondarily to a physiological adjustment that reduces the body weight to a maintenance level that is lower than normal. The physiological trigger for this body weight set-point might be a target for TCDD.

Delayed expression of TCDD-induced toxic responses, including lethality, suggests that these toxic responses may not be the result of a direct insult by the parent compound (Mukerjee, 1998; Rozman, 1999). Progressive hypoglycemia from feed refusal and reduced gluconeogenesis seems to be the ultimate cause of TCDD-induced lethality (Gorski et al., 1990). In the L-E strain rat, reduced gluconeogenesis, indicated by decreased PEPCK activity, has been suggested to contribute to the acute toxicity of TCDD (Fan and Rozman, 1994; Viluksela et al., 1999). One of the major causes of TCDD-induced lethality also is dose-dependent reduction of tryptophan 2,3-dioxygenase (TdO) activity (Fan and Rozman, 1994; Stall et al., 1993), indicating

that subtle differences in the regulation of intermediary metabolism may be responsible for strain differences in the susceptibility of rats to TCDD (Fan and Rozman, 1994).

There have been significant advances in understanding the cause of TCDD-induced voluntary feed refusal. The neurotransmitter 5-hydroxytryptamine (5-HT), or serotonin, controlled by the availability of the amino acid tryptophan (Carlsson and Lindquist, 1978), suppresses feed intake behavior (Leibowitz, 1993). TCDD increases the plasma level of free tryptophan in L-E rats but not H/W rats (Unkila et al., 1994a). Increase in brain tryptophan levels (Rozman et al., 1991; Unkila et al., 1994b) and 5-HT turnover are closely connected with changes in plasma tryptophan (Unkila et al., 1994b). In L-E and H/W rats, the potencies of dioxin congeners highly correlate with their ability to disrupt tryptophan homeostasis. The order of potency is: TCDD > 1,2,3,7,8-PeCDD > 1,2,3,4,7,8-HxCDD > 1,2,3,4,6,7,8-HpCD (Unkila et al., 1998). TCDD lethal dose exposure results in increased brain 5-HT synthesis in L-E rats (Unkila et al., 1993), whereas in resistant H/W rats no such increase of 5-HT occurs. The dose-related changes in plasma free tryptophan are closely associated with the severity of the wasting syndrome observed in L-E rats (Unkila et al., 1994b). Increased circulating tryptophan and rapid turnovers of tryptophan and 5-HT in the brain are associated with TCDD-induced reduced feed intake, wasting, and lethality (Rozman et al., 1991; Unkila et al., 1994b). However, tryptophan metabolism or carbohydrate homeostasis does not explain the wide interspecies differences in susceptibility to acute lethality encountered between guinea pigs (the most acutely susceptible species) and hamsters (the most resistant species) (Unkila et al., 1995).

Despite extensive research to elucidate the ultimate events underlying the toxic action of TCDD, definitive answers are not yet available. The toxicity of TCDD apparently depends on the fact that the four lateral positions of the molecule are occupied by chlorine, resulting in high-affinity binding to the AhR. Mechanisms of toxicity are discussed in detail in Chapter 2. TCDD toxicity involves many different types of symptoms, which vary from species to species and from tissue to tissue, both quantitatively and qualitatively. Age- and sex-related differences in sensitivity have also been reported. Another characteristic of TCDD toxicity is the delay before all the endpoints of toxicity are manifested (from 2 weeks to 2 months), which is seen in all species.

Polymorphism in the Ah locus, which has been shown to be the structural gene for the cytosolic receptor, seems to determine the sensitivity of genetically different strains of mice to TCDD and congeners. Ah-responsive strains of mice (e.g., C57BL/6) are characterized by high hepatic levels of a high-affinity TCDD-receptor protein, highly elevated levels of hepatic cytochrome P-4501A1 and associated enzyme activities in response to treatment with 3-MC (3-methylcholanthrene), and sensitivity to the ulcerative action of DMBA (7,12-

dimethylbenz[a]anthracene) on the skin. Ah-nonresponsive mice (e.g., DBA/2) lack these characteristics.

Based on these findings, several genetic studies have been performed to elucidate the role of the receptor in TCDD toxicity. In contrast to 3-MC, TCDD induces AHH activity and several toxic effects both in Ah-responsive and Ah-nonresponsive strains of mice. The dose required to produce the effect in an Ah-nonresponsive strain, however, is approximately 10-fold greater than that needed in an Ah-responsive strain. This indicates that the Ah-nonresponsive strain also contains the TCDD receptor, but the receptor is defective (Okey and Vella, 1982). Data from studies of DBA/2 mice given either single or multiple doses of TCDD (Jones and Sweeney, 1980; Smith et al., 1981) suggest that the LD_{50} in this strain of mice is at least fivefold greater than the values recorded for the C57BL/6 and C57BL/10 strains (Jones and Greig, 1975; Smith et al., 1981; Vos et al., 1974). TCDD-induced hepatic porphyria has also been shown to segregate with the Ah locus in mice (Jones and Sweeney, 1980). The correlative differences between the C57Bl/6 and DBA/2 strains of mice, in terms of altered specific binding of TCDD and sensitivity to this compound, may not be applicable to other species (Gasiewicz and Rucci, 1984).

In a genetic-crossing experiment between L-E and H/W rats (Pohjanvirta, 1990), it was demonstrated that the F_1 offspring were as resistant to TCDD toxicity as the H/W rats (LD_{50}, >3,000 μg/kg). Further studies on the F_2 generation indicated that the distribution of resistant and susceptible phenotypes was consistent with inheritance regulated by 2 (possibly 3) autosomal genes displaying complete dominance, independent segregation, and an additive coeffect.

Despite enormous variability in the recorded LD_{50} values for the guinea pig, rat, mouse, rabbit, and hamster, the amount and physical properties of the hepatic and extrahepatic receptors are comparable in these species (Gasiewicz and Rucci, 1984; Poland and Knutson, 1982). Furthermore, although the recorded LD_{50} values for TCDD vary >100 times among the chick embryo, the C3H/HeN mouse, and the SD rat, the ED_{50} doses for AHH induction in these species are comparable (Poland and Glover, 1974). Even between strains of rats with a difference of >300 times in LD_{50}, no differences in enzyme induction could be demonstrated (Pohjanvirta et al., 1988). In the guinea pig, the most TCDD-susceptible species, AHH induction is not a prominent symptom, even at lethal doses of TCDD. A number of cell types, including primary cultures and established and transformed cell lines from several species and tissues, are inducible for AHH activity, indicating the presence of the receptor. Yet toxicity is not expressed in these systems (Knutson and Poland, 1980a). The available data thus suggest that the receptor for TCDD may be a prerequisite but is not sufficient in itself for the mediation of toxicity.

Recent observations suggest that some of the TCDD-induced toxicity in mice require other modes of action, beyond AhR-mediated DNA transcription. For example, wasting syndrome, thymus involution, and loss of adipose tissue in c-src$^{+/+}$ mice are correlated to c-src kinase activation, which is physically linked to AhR. These TCDD-induced toxic effects are not induced in src$^{-/-}$ mice and are marginal in c-src$^{-/+}$ mice (Matsumura et al., 1997a,b). These toxic effects can also be prevented in c-src$^{+/+}$ mice pretreated with geldanamycin, a c-src kinase inhibitor (Enan et al., 1998a; Dunlap et al., 1999). Based on c-src deficiency not affecting TCDD induction of the cytochrome P-450 type 1A1 isozyme (CYP1A1), the gene activation pathway of TCDD's action through the AhR nuclear translocator (ARNT) gene appears to be independent of the phosphorylation pathway of TCDD toxic activities modulated through the c-src gene. Involvement of c-src kinase activation in TCDD-induced toxicity has also been observed in the guinea pig. Enan et al. (1998b) showed that male guinea pigs pretreated with the src-kinase inhibitor geldanamycin did not suffer TCDD wasting. These investigators obtained similar results with src-deficient mice. Treatment with estradiol also protected male guinea pigs from TCDD-induced wasting. Furthermore, a nuclear AhR complex is not required for one of the signal transduction pathways associated with TCDD-induced early response of the c-fos and junB genes (Puga et al., 1992; Hoffer et al., 1996).

A strong correlation between lack of AhR affinity and lack of acute TCDD toxicity has been demonstrated in the knockout AhR$^{-/-}$ mouse. No significant difference in short-term toxicity was observed between the vehicle control group and knockout homozygous AhR$^{-/-}$ mice receiving TCDD at 2,000 µg/kg bw. Postexposure effects at day 28 were limited to vascularities of the lung and scattered necrosis of hepatocytes in AhR$^{-/-}$ resistant mice. In contrast, lipid accumulation and inflammatory cell infiltration of the liver were seen in heterozygous AhR$^{+/-}$-susceptible mice at the much lower dose of 200 µg/kg TCDD (Fernandez-Salguero et al., 1996). Although some of the TCDD-induced toxicity of the liver and thymus are mediated by the AhR, the mechanism for vascularities of the lung and the scattered necrosis of the lung and liver in AhR knockout mice may involve alternative pathways. As proposed by Matsumura et al. (1997a, b), these toxicity pathways still require the AhR and associated cytosolic proteins (Enan and Matsumura, 1996), but not nuclear AhR and DNA transcription.

Mutation of the p53 tumor suppresser gene associated with certain cancers confers resistance to TCDD-induced acute toxicity. The DBA/2 mouse has a complex mutation in the promoter region of the Tryp53 locus (the p53 region of the mouse). Both homozygous and heterozygous Tryp53 knockout mouse types have a high spontaneous incidence of cancer (Harvey et al., 1993). Inhibition of hepatocellular proliferation due to acute TCDD exposure also increases expression of the hepatic tumor suppressor p53 gene associated with the cell cycle inhibitory protein in the Balb/c mouse (Rininger et al., 1997). Results from these studies support

the hypothesis, proposed by Blagosklonny (1997), that high levels of the tumor suppressor p53 protein that confer protection against cancer may also increase sensitivity to the acute toxicity of TCDD.

3.7. SUMMARY

Most of the toxicity data available for TCDD are from oral experiments in animals. Very few percutaneous and no inhalation exposure toxicity data are available in the literature. Animal data following oral exposure indicate that TCDD is one of the most toxic compounds known and that it produces a wide spectrum of toxic effects.

There is a wide range of differences in sensitivity to TCDD lethality. The male guinea pig is the most sensitive, with an oral LD_{50} value of 0.6 µg/kg (Schwetz et al., 1973), and the male hamster the least sensitive, with an LD_{50} value of 5,051 µg/kg (Henck et al., 1981). This difference in sensitivity is more than 8,000-fold. The mink seems to be the second most sensitive to lethality, with an oral LD_{50} dose of 4.2 µg/kg for the male (Hochstein et al., 1988) and an LC_{50} value of 0.26 µg/kg for the female (Hochstein et al., 1998). The oral LD_{50} value for the male rat is 22 µg/kg (Schwetz et al., 1973). The rabbit LD_{50} value is 115 µg/kg (Schwetz et al., 1973). Unlike most toxic chemicals, the lethality of TCDD is delayed, with time to death being species and strain specific. Single lethal dose exposure results in death within 7-50 days and is generally associated with a wasting syndrome involving progressive loss of up to 50% body weight and eventual death without any clear or identifiable lethal pathological lesions. The characteristic signs and symptoms of lethal toxicity by TCDD are severe weight loss and thymic atrophy.

At least for acute exposure, the TCDD-induced toxicity appears to depend on the total dose administered over a given time, either through a single treatment or a limited number of multiple treatments. One of the consistent signs of TCDD toxicity in most species is thymic atrophy. Other toxic effects include hyperplasia or atrophy of the spleen, testes, or ovaries, bone marrow depletion, and systemic hemorrhage. Severe chloracne is one of the signs of TCDD exposure in people (Crow, 1978). Similar lesions or precursor lesions can be induced by TCDD in cattle (McConnell et al., 1980), rhesus monkeys (Norback and Allen, 1973; McConnell et al., 1978b), rabbits (Schwetz et al., 1973), and hairless mice (Knutson and Poland, 1982; Puhvel et al., 1982). The liver is extremely sensitive to TCDD toxicity in all animals, regardless of duration of exposure. The degree of severity of liver toxicity seems to be species-specific. Morphological alterations in liver toxicity are less severe in the guinea pig, the most sensitive species to lethality, than other species. The hamster, the most resistant species for lethality, shows liver lesions after a prolonged period of chronic exposure to nonlethal doses. Toxic effects include liver weight changes, fatty liver, impaired liver function characterized by increased microsomal monooxygenase, SGOT and SGPT activities, porphyrin accumulation,

impaired membrane function, hyperbilirubinemia, hypercholesterolemia, and hyperproteinemia. Severe episodes of toxic hepatitis have been observed in rats and mice. Various physiological equilibrium processes, such as vitamin A storage, plasma membrane functions, and the formation of keratin and cell differentiation, are affected by TCDD exposure. Pericardial and peritoneal edema resulting in death occur in chickens (Firestone, 1973). Systemic edema has also been observed in monkeys (Norback and Allen, 1973) and mice (Vos et al., 1974).

Sensitivity to TCDD toxicity segregates with the Ah locus. The potency of other congeners to induce lethality correlates with their ability to bind to the Ah receptor. Other congeners are less toxic than 2,3,7,8-TCDD. The lateral 2,3,7, and 8 position of the dioxin molecule must be chlorinated (or halogenated) to induce the greatest toxicity. The addition of chlorine atoms reduces toxicity. Increased microsomal AHH and EROD activities are markers for CYP1A1 (discussed in Chapter 2) and are associated — not necessarily causally — with the systemic toxicity of PCDDs, PCDFs, and coplaner PCBs.

Except for 2,3,7,8-TCDD and a mixture of 1,2,3,6,7,8- and 1,2,3,7,8,9-HxCDD, there are no long-term chronic bioassay data for PCDD/PCDF congeners that can be used for assessing the chronic risk. In the absence of any long term chronic toxicity bioassay data, enzymatic activity and other short-term in vivo and in vitro data are used in developing a toxicity ranking scheme (see Chapter 9).

One of the possible mechanisms by which TCDD and related compounds interfere with normal endocrine function is the ability to disrupt natural hormones. Hirsutism and diminished libido caused by TCDD seems to be due to its endocrine disruptive activities. A single oral dose of 20 µg/kg to rats can reduce serum testosterone levels (Nienstedt et al., 1979). Catabolism of exogenous estrone in TCDD-pretreated, ovariectomized rats is decreased (Shiverick and Muther, 1983). Alterations in hormonal levels by TCDD and its antiestrogenic action are discussed in Chapter 5. TCDD tumor promotion activity in liver carcinogenesis can be prevented in ovariectomized rats, indicating that estrogen status influences TCDD toxicity (Lucier et al., 1991). Animals exposed to TCDD and related compounds in utero or as infants exhibit varying degrees of behavioral disorders. These disorders resemble those seen in infants exposed to agents resulting in thyroid hormone deficiencies in utero or in infancy. Thyroidectomy of animals resulted in partial protection from TCDD-induced wasting syndrome and immunotoxicity, suggesting possible involvement of thyroid function in the manifestation of pathological conditions (Bastomsky, 1977; Rozman et al., 1984; Pazdernik and Rozman, 1985). Monkeys exposed for 4 years to TCDD at low ppt levels and studied for an additional 7-10 years have been reported to develop endometriosis (Rier et al., 1993). Estrogen, glucocorticoid, prolactin, insulin, gastrin, melatonin, and other hormones are affected by TCDD either by its

activity on the hormone or receptor. Further studies are needed to elucidate the mechanism of TCDD-induced endocrine disruptive activities.

The subchronic NOAEL for porphyria in female SD rats is estimated to be 0.01 µg/kg/week (= 0.001 µg/kg/day = 1 ng/kg/day) (Goldstein et al., 1982). A chronic NOAEL of 1 ng/kg/day for hepatotoxicity is estimated for SD rats from a 2-year chronic study (Kociba et al., 1978). In addition to liver toxicity, chronic exposure has been found to be associated with amyloidosis and dermatitis in Swiss mice (Toth et al., 1979). From this study, a LOAEL of 1 ng/kg/day for amyloidosis and dermatitis has been estimated for mice. Chronic exposure to 1.5 ng/kg/day in diet results in hair loss, edema, and pancytopenia in monkeys (Allen et al., 1977; Schantz et al., 1979). The lowest doses that have been demonstrated to elicit various biological responses in certain animals are compiled in Table 3-4.

Single-dose acute exposures to CDDs yield a large area under the curve (AUC) because of their long half-life and thus may be viewed as subchronic exposures. Subchronic/chronic exposures yield similar toxicity profiles to an acute exposure when similar total cumulative doses are administered. When corrected for excretion, depending on half-life, the corrected cumulative subchronic/chronic exposure doses seem to be analogous to the acute exposure doses. Similar data are available for 2,3,7,8-TCDF (Ioannou et al., 1983).

It is evident, from the complex picture evolving from the data outlined above, that TCDD elicits a variety of toxic responses following both short-term and long-term exposure. It is also clearly evident that there are very large differences in the sensitivity to specific TCDD-induced toxicities among various species and strains. This conclusion is valid for the severity of effects of almost all the responses studied. Qualitatively, however, there seems to be fairly good agreement among the types of responses that can be observed. For example, almost all responses can be produced in every species and strain if the right dose is chosen. Tissues or cell lines from humans and animals seem to respond to dioxin at similar exposure levels and in identical ways in regard to CYP1A1 activity, cytotoxicity, and inhibition of cell proliferation (DeVito et al., 1995). In highly sensitive species (e.g., the guinea pig), lethality may prevent some responses from occurring. Our present knowledge rules out enzyme induction as such, as the proximate cause of toxicity and death. Although the toxicokinetics of TCDD vary between species, these differences are not sufficient to explain the variabilities in sensitivity to TCDD lethality. The available data indicate an involvement of TCDD in processes regulating cellular differentiation and proliferation, as well as those controlling endocrine homeostasis. Alterations in the regulation of such processes, which are not equally active in all cells throughout the organism, would be expected to result in effects that vary among tissues and species. The overwhelming number of toxic responses to TCDD, including lethality, typically show a delay in their appearance. This supports the assumption that these responses are not the result of a direct insult

from the compound. A lethal dose of TCDD in rats increases the neurotransmitter 5HT, controlled by increased levels of tryptophan in plasma and brain, suppresses voluntary feed consumption resulting in wasting syndrome, and leads eventually to mortality a few weeks postexposure. The induction of hepatic cytochrome P-450-dependent monooxygenases (such as CYP1A1) is one of the hallmarks of TCDD exposure. This effect has been demonstrated to be mediated through interaction with a specific protein called the Ah receptor. This process involves the binding of TCDD to the receptor, followed by the binding of the receptor-ligand complex to DNA recognition sites. This leads to the expression of specific genes and translation of their protein products, which then mediate their biological effects. As discussed in detail in Chapter 2, the mechanisms of action for enzyme induction are understood mainly at the molecular level, where the Ah receptor and its genetic regulation is clearly an important mechanistic step. Very little, however, is known about the mechanisms of the middle and high dose responses at the molecular level.

Studies in congenic mice that are relatively Ah-responsive or Ah-nonresponsive have demonstrated that the majority of TCDD-induced toxic responses segregate with the Ah locus. However, the number and affinity of Ah receptor expressed in most laboratory species and strains are rather comparable. The Ah receptor is thus unlikely to be the only determinant of TCDD-induced toxicity. Rather, it has to be assumed that species and strain differences are confined to the latter parts of the receptor-mediated chain of events (e.g., binding of the receptor-ligand complex to DNA and the subsequent expression of specific genes). In some cases, the binding affinity of the Ah receptor is different or defective. Some of the responses may be secondary in the sense that they are caused by the altered homeostasis of endogenous compounds, caused by TCDD-induced increased activities of various enzymes. An additional AhR-related pathway involving c-src kinase in the cytoplasm has been implicated in wasting syndrome, thymus atrophy, and loss of adipose tissue in mice.

4. IMMUNOTOXICITY

4.1. INTRODUCTION

Concern over the potential toxic effects of chemicals on the immune system arises from the critical role of the immune system in maintaining health. It is well recognized that suppressed immunological function can result in increased incidence and severity of infectious diseases as well as some types of cancer. Conversely, inappropriate enhancement of immune function or the generation of misdirected immune responses can precipitate or exacerbate development of allergic and autoimmune diseases. Thus, both suppression and enhancement of immune function are considered to represent potential immunotoxic effects of chemicals.

The immune system consists of a complex network of cells and soluble mediators that interact in a highly regulated manner to generate immune responses of appropriate magnitude and duration. Consequently, comprehensive evaluation of immunotoxicity must include specific assessments of multiple functional parameters on a kinetic basis. In addition, because an immune response develops in a time-dependent manner relative to antigen exposure, the immunotoxicity of a chemical can be profoundly influenced by the timing of chemical exposure relative to antigen challenge. Consideration of these levels of complexity involved in immunotoxicology assessment is critical for interpreting the effects of chemical exposure on immune function (Kerkvliet, 1994).

Extensive evidence has accumulated to demonstrate that the immune system is a target for toxicity of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) and structurally related polyhalogenated aromatic hydrocarbons (PHAHs), including the polychlorinated dibenzodioxins (PCDDs), polychlorinated dibenzofurans (PCDFs), polychlorinated biphenyls (PCBs), and polybrominated biphenyls (PBBs). This evidence was derived primarily from numerous studies in various animal species, mainly rodents, but also guinea pigs, rabbits, monkeys, marmosets, and cattle. Epidemiological studies also provide some evidence that PHAHs alter immune parameters in humans. In animals, relatively high doses of PHAHs produce lymphoid tissue depletion, except in the thymus, where lower doses cause cellular depletion. Alterations in specific immune effector functions and increased susceptibility to infectious disease have been identified at doses of TCDD well below those that cause significant lymphoid tissue depletion. Both cell-mediated and humoral immune responses are suppressed following TCDD exposure, which suggests that multiple cellular targets within the immune system are altered by TCDD. Evidence also suggests that the immune system is indirectly targeted by TCDD-induced changes in nonlymphoid tissues. In addition, in parallel with increased understanding of the cellular and molecular mechanisms involved in immunity, studies on TCDD are beginning to establish

biochemical and molecular mechanisms of TCDD immunotoxicity. These advances are highlighted in this document.

There is an enormous literature based on descriptive studies of the immunotoxic effects of TCDD and related PHAHs in laboratory animals. Unfortunately, widely differing experimental designs, exposure protocols, and immunologic assays used, have made it difficult to define a "TCDD-induced immunotoxic syndrome" in a single species, let alone across species. Before 1994, only one report directly compared the effects of TCDD on the immune system of rats, mice, and guinea pigs, and even then, different immunologic parameters were assessed, and different antigens were used in the different species (Vos et al., 1973). In that study, the delayed-type hypersensitivity (DTH) response to tuberculin was evaluated in guinea pigs and rats for assessment of cell-mediated immunity, and the graft versus host (GVH) response was measured in mice. A decreased DTH response to tuberculin was observed in guinea pigs following 8 weekly doses of 40 ng/kg TCDD (total dose, 320 ng/kg), whereas in rats the DTH response to tuberculin was unaffected by 6 weekly doses of 5 μg/kg TCDD (total dose, 30,000 ng/kg). The GVH response in mice was suppressed by 4 weekly doses of 5 μg/kg TCDD (total dose, 20,000 ng/kg). The greater sensitivity of guinea pigs compared with rats and mice to the immunosuppressive effects of TCDD is consistent with their greater sensitivity to other toxic effects of TCDD (McConnell et al., 1978; Poland and Knutson, 1982).

Although the results of Vos et al. (1973) appear to suggest that cell-mediated immunity in mice is more sensitive to TCDD than in rats, no studies have directly compared cell-mediated immunity in rats and mice using the same antigens and endpoints. However, a 1994 study made a direct comparison of the effects of TCDD on humoral immunity in rats and mice (Smialowicz et al., 1994). In this study, the primary plaque-forming cell (PFC) response to sheep red blood cells (SRBCs) was suppressed in B6C3F$_1$ mice (ED_{50} of 0.68 μg/kg TCDD), but the anti-SRBC response was either unaffected or enhanced in Long Evans and Fischer 344 rats, respectively, at a dose as high as 30 μg/kg TCDD. This response of rats was corroborated by Fan et al. (1996), who observed that TCDD at 20 and 40 μg/kg did not alter serum IgM levels to SRBC, whereas IgG levels were enhanced. In contrast, the primary PFC and serum antibody response to the T cell–independent (TI) antigen trinitrophenyl lipopolysaccharide (TNP-LPS) was reported to be suppressed in both mice and rats following exposure to TCDD at 10 and 30 μg/kg, respectively (Smialowicz et al., 1996).

In a study in mice (Clark et al., 1981), the DTH response to oxazolone was suppressed by 4 weekly doses of 4 μg/kg TCDD (total dose, 16,000 ng/kg), whereas the DTH response to SRBC was unaffected by a 10-fold higher dose of TCDD, which illustrates that DTH responses to different antigens are not equally sensitive to TCDD-induced suppression, even in the same species. When PCB and PBB studies are considered, variable effects on DTH and other immune

reactions are also apparent (Vos and van Driel-Grootenhuis, 1972; Thomas and Hinsdill, 1978; Fraker, 1980; Luster et al., 1980a). Because the exact basis for the interstudy variability is not known, it would serve no useful purpose in terms of risk assessment to catalog all of the reported effects of TCDD and other PHAHs on the immune system. Several comprehensive reviews have been published on the immunotoxic effects of PHAHs in general (Kerkvliet, 1984; Vos and Luster, 1989; Kerkvliet and Burleson, 1994; Holsapple, 1995) and TCDD in particular (Holsapple et al., 1991a, b). The reader is also referred to the previous EPA TCDD risk assessment document (Sonawane et al., 1988) for another perspective on TCDD immunotoxicity. The present document does not address this extensive literature, but rather emphasizes more recent developments in the field of PHAH immunotoxicity that may assist in the risk assessment process. Gaps in our knowledge that require further research are also identified.

4.2. ROLE OF THE AH LOCUS IN PHAH IMMUNOTOXICITY

One of the most important advances in the study of PHAH toxicity in recent years has been the elucidation of a genetic basis for sensitivity to the toxicity of these chemicals, which may ultimately provide a logical explanation for many of the controversial data in the literature on PHAH toxicity in different species and in different tissues of the same species. In this regard, many biochemical and toxic effects of PHAHs appear to be mediated via binding to an intracellular protein known as the aryl hydrocarbon (Ah) or TCDD receptor in a process similar to steroid hormone receptor-mediated responses (Poland and Knutson, 1982; Cuthill et al., 1988). Ah receptor (AhR) activation follows stereospecific ligand binding; interaction of the receptor-ligand complex with dioxin-response elements (DREs) in the genome induces transcription of the structural genes encoding mRNA for CYP1A1 enzyme activity (i.e., cytochrome P4501A1) as well as expression of additional unidentified genes, the products of which are hypothesized to mediate PHAH toxicity (Whitlock, 1990). Differences in toxic potency between various PHAH congeners generally correlate with differences in AhR-binding affinities. The most toxic PHAH congeners are approximate stereoisomers of 2,3,7,8-TCDD and are halogen substituted in at least three of the four lateral positions in the aromatic ring system.

In mice, allelic variation at the Ah locus has been described (Poland et al., 1987; Poland and Glover, 1990). The different alleles code for AhRs that differ in their ability to bind TCDD and thus help to explain the different sensitivities of various inbred mouse strains to TCDD toxicity. Ah^{bb}-C57Bl/6 (B6) mice represent the prototype "responsive" strain and are the most sensitive to TCDD toxicity, whereas Ah^{dd}-DBA/2 (D2) mice represent the prototypic "nonresponsive" strain and require higher doses of TCDD to produce the same toxic effect. Congenic Ah^{dd} mice on a B6 background have been derived that differ from conventional B6 mice primarily at the Ah locus. The spectrum of biochemical and toxic responses to TCDD

exposure was similar in both strains, but the doses needed to bring about the responses were significantly higher in congenic mice homozygous for the Ah^d allele compared with mice carrying two Ah^b alleles (Birnbaum et al., 1990; Kerkvliet et al., 1990a).

Two lines of evidence have been used to investigate AhR dependence of acute immunotoxicity of TCDD and related PHAHs: (1) comparative studies using PCDD, PCDF, and PCB congeners that differ in their binding affinity for the AhR and (2) studies using mice of different genetic background known to differ at the Ah locus.

A comparison of the relative potency of PHAHs that differ in their binding affinity for the AhR is presented in Tables 4-1 and 4-2. These data are based on single-dose exposure (oral or intraperitoneal) of B6 mice to the various PHAHs for suppression of the anti-SRBC response and the cytotoxic T lymphocyte (CTL) response, respectively. As shown in Table 4-1, the potency of TCDD to suppress the primary antibody response to SRBCs has been reported by several laboratories, with remarkable agreement in the ID_{50} value of 0.7 μg/kg in B6 mice. The ID_{50} of $B6C3F_1$ mice has been reported to be lower (<0.1 μg/kg) (Narasimhan et al., 1994), similar (<1 μg/kg) House et al., 1990; Smialowicz et al., 1994), or slightly higher (1.2 μg/kg) (Holsapple et al., 1986a) in comparison with B6 mice. It should be noted that 4 weekly i.p. doses of 10 but not 1 or 0.1 μg/kg TCDD significantly suppressed the anti-SRBC response in B6 mice (Clark et al., 1981). This sub-chronic dosing protocol (Clark et al., 1981) does not readily explain this decreased potency because Vecchi et al. (l983) reported that 5 weekly doses of 2 μg/kg or 8 weekly doses of 0.5 μg/kg TCDD significantly suppressed the anti-SRBC response. The basis for the discrepancies between the data of Clark et al. (1981) and other laboratories regarding the potency of TCDD to suppress the anti-SRBC response is unknown.

In contrast to the reproducible data on TCDD, relative potency for other PHAH congeners shown in Table 4-1 is difficult to evaluate because few congeners have been examined in more than one study. In the few cases where the same congener has been evaluated independently, discrepancies in the data exist. For example, both Davis and Safe (1990) and Silkworth et al. (1984) evaluated the potency of the 2,3,4,5,3′,4′-HxCB congener (PCB 156) in the anti-SRBC response. The ID_{50}s from these two data sets differ by almost two orders of magnitude (0.7 mg/kg vs. 31 mg/kg, respectively). When the same congener was compared with TCDD for suppression of the CTL response, the ID_{50} was 70 mg/kg (Table 4-2). Although the basis for these discrepancies between laboratories and immune function endpoints is unknown, it is apparent that the immunotoxicity database should be expanded so that these differences can be resolved.

Vecchi et al. (1983) were the first to report that antibody response to SRBCs was differentially suppressed by TCDD in B6 mice compared with D2 mice, such that D2 mice required a dose approximately 10 times higher to produce the same degree of suppression.

Immunosuppression in F1 and backcross mice supported the role of the Ah locus in expression of TCDD immunotoxicity. 2,3,7,8-TCDF was significantly less potent than TCDD and showed a similar differential immunosuppressive effect in B6 and D2 mice. At the same time, Silkworth and Grabstein (1982) reported a B6 versus D2 strain-dependent difference in sensitivity to suppression of the anti-SRBC response by 3,4,3′,4′-tetrachlorobiphenyl (PCB 77), a ligand for the AhR. In comparison, the 2,5,2′,5′-tetrachlorobiphenyl (PCB 52) isomer, which lacks affinity for the AhR, was not immunosuppressive in either B6 or D2 mice. Structure-activity relationships were extended by Kerkvliet et al. (1985) in studies that compared the immunosuppressive potency of chlorinated dioxin and furan isomers that contaminate technical-grade pentachlorophenol. The 1,2,3,6,7,8-hexachlorinated dibenzo-*p*-dioxin (HxCDD), 1,2,3,4,6,7,8-heptachlorinated dibenzo-*p*-dioxin (HpCDD), and 1,2,3,4,6,7,8-heptachlorinated dibenzofuran (HpCDF) isomers, which bind the receptor, were all significantly immunosuppressive. The dose of each isomer that produced 50% suppression of the anti-SRBC response (ID_{50}) was 7.1, 85, and 208 μg/kg for HxCDD, HpCDD, and HpCDF, respectively (Figure 4-1). The ID_{50} for TCDD was 0.65 μg/kg based on the data of Vecchi et al. (1980). More extensive structure-dependent immunosuppressive activities of technical grade PCB mixtures (Davis and Safe, 1990), PCB congeners (Davis and Safe, 1989), and PCDF congeners (Davis and Safe, 1988) have also been reported. Results of these studies using different PHAH congeners are summarized in Table 4-1.

The role of the AhR in suppression of the anti-SRBC response was verified in studies using B6 mice congenic at the Ah locus (Kerkvliet et al., 1990a). As expected, congenic Ah^{dd}-B6 mice were significantly less sensitive to TCDD-induced immune suppression as compared with wild-type Ah^{bb}-B6 mice. Unexpectedly, however, the dose response in congenic Ah^{dd}-B6 mice appeared to be bimodal, with a portion of the response sensitive to suppression by low doses of TCDD. Because of the bimodal response, the data did not permit extrapolation of an ID_{50} dose in the congenic mice. The results were interpreted to suggest potential non-AhR-mediated immunosuppressive effects. It should be noted, however, that studies by Silkworth et al. (1993) using rederived congenic Ah^{dd}-B6 mice did not corroborate a bimodal dose response. Their data, which indicated an ID_{50} of 7.5 μg/kg in congenic Ah^{dd}-B6 mice compared with an ID_{50} of 0.54 μg/kg in Ah^{bb}-B6 mice, are consistent with an AhR-dependent mechanism of immune suppression.

AhR dependency of PHAH immunotoxicity has also been demonstrated in mice using other immunologic responses. For example, Kerkvliet et al. (1990a) reported that the ID_{50} for suppression of the antibody response to TNP-LPS in Ah^{bb}-B6 mice was 7.0 μg/kg compared with a significantly higher ID_{50} of 30 μg/kg in congenic Ah^{dd}-B6 mice. Because the antibody response to TNP-LPS shows little requirement for macrophages or T helper cells (Jelinek and Lipsky,

1987), these results suggest an AhR-dependent B cell response. In terms of cytotoxic T cells, Clark et al. (1983) were first to report data suggesting that TCDD and PCB isomers suppressed in vitro CTL responses of B6 and D2 mice through an AhR-dependent mechanism. Subsequently, Kerkvliet et al. (1990b) reported that B6 mice congenic at the Ah locus showed Ah-dependent sensitivity to suppression of the CTL response following exposure to either TCDD or 3,4,5,3′,4′,5′-hexachlorobiphenyl (HxCB) (PCB 169). Furthermore, the potency of TCDD and of three HxCB congeners to suppress the CTL response of mice directly correlated with their relative binding affinities for the AhR (Table 4-2, from Kerkvliet et al., 1990b). The ID_{50} of TCDD for suppression of the CTL response in B6 mice was 7.0 μg/kg.

It should be noted that the dose of TCDD required to suppress the CTL response reported by Kerkvliet et al. (l990b) is significantly greater than that reported by Clark et al. (1981), who reported CTL suppression following 4 weekly doses of 0.1 μg/kg TCDD. Clark et al. (1983) also reported that doses of TCDD as low as 4 ng/kg to B6 mice suppressed in vitro generation of CTL and that the suppression was Ah dependent. The potency of TCDD described in Clark's studies has not been corroborated by other laboratories (Holsapple et al., 1991b; Hanson and Smialowicz, 1994). For example, the in vivo and in vitro CTL response in B6 mice was not affected at doses ranging from 0.01 to 3.0 μg/kg given at weekly intervals for 4 weeks (Hanson and Smialowicz, 1994).

If immunotoxicity of TCDD and structurally related PHAHs depends on AhR-mediated mechanisms, then co-exposure to subsaturating levels of more than one Ah agonist should produce additive effects. An additive interaction has been demonstrated in mice coexposed to 1,2,3,6,7,8-HxCDD and 1,2,3,4,6,7,8-HpCDD, two relatively strong AhR ligands (Kerkvliet et al., 1985). On the other hand, coexposure of mice to an immunotoxic dose of TCDD and a subimmunotoxic dose of different commercial Aroclors or certain PCB congeners resulted in partial antagonism of TCDD suppression of the anti-SRBC response (Bannister et al., 1987; Davis and Safe 1988, 1989). An apparently similar antagonism was observed following coexposure to 2,3,7,8-TCDF (10 μg/kg) and TCDD (1.2 μg/kg) (Rizzardini et al., 1983). The mechanism for this antagonism has not been fully elucidated, but the effects are consistent with competition for binding at the AhR because the weaker agonist was administered in excess compared with TCDD. In other studies, Silkworth et al. (1988, 1993) have shown that immunotoxicity of TCDD can be modified by coexposure to other PHAHs present as cocontaminants of actual environmental samples from Love Canal, New York. Smialowicz et al. (1997) examined the anti-SRBC response in mice cotreated with TCDD and 2, 2', 4, 4', 5, 5'-hexachlorobiphenyl (PCB153). PCB153 alone enhanced this response such that when given with an immunosuppressive dose of TCDD (1 μg/kg) the anti-SRBC response was not suppressed.

These results indicate that PCB153 acts as a functional rather than an AhR or dispositional antagonist of TCDD-induced immunosuppression.

Recent work by Sulentic et al. (1998) provides evidence for the critical role of the AhR in TCDD-induced suppression of IgM secretion. B cell lines, which differ in their expression of the AhR (i.e., CH12.LX cells express AhR and BCL-1 cells do not), were used in this study. TCDD treatment resulted in marked induction of AhR expression as well as suppression of LPS-induced IgM secretion in CH12.LX but not BCL-1 cells. Furthermore, TCDD induced CYP1AI induction in CH12.LX but not BCL-1 cells. These results implicate the AhR as a critical factor in TCDD-induced inhibition of IgM secretion.

The data indicate that suppression of the antibody response to T cell–dependent and –independent antigens and the CTL response by PHAHs are primarily AhR-dependent. However, the underlying mechanism(s) for these effects remain to be elucidated. It should also be emphasized that the data supporting an AhR dependency have been obtained from studies in inbred mice using an acute or subacute exposure regimen. Except for thymic atrophy, structure-immunotoxicity relationships in other species, including rats, have not been established, and inbred strains of other species with defined Ah genotype are not currently available. Nevertheless, it is important to note that thymic cortical atrophy does not occur in AhR deficient ($AhR^{-/-}$) mice despite having received a 10-fold higher TCDD dose than mice expressing a functional AhR ($AhR^{+/-}$), which experience significant reduction in the size and cellularity of thymic cortical areas (Fernandez-Salguero et al., 1996).

Results from other studies suggest that non-Ah-dependent effects may also occur. For example, mice exposed for 14 days to 2,7-dichlorodibenzo-*p*-dioxin (2,7-DCDD), a dioxin congener with very weak affinity for the AhR, had suppressed antibody responses to SRBC (Holsapple et al., 1986b). This suppression was observed in the absence of any change in thymus weight or in AHH activity. More recently, Morris et al. (1992) reported that sensitivity of D2 mice to TCDD-induced suppression of the anti-SRBC response increased significantly when TCDD was administered daily over 2 weeks rather than as an acute single dose. Unfortunately, in these studies, the lowest dose of TCDD produced near-maximum suppression of the anti-SRBC response of $B6C3F_1$ mice in the acute exposure model, precluding detection of any similar increase in sensitivity of the $B6C3F_1$ mice to chronic dosing. In contrast to these findings, Vecchi et al. (1983) reported that multiple exposures to TCDD (2 μg/kg for 5 weeks or 0.5 μg/kg for 8 weeks) did not increase the sensitivity of D2 mice to suppression of the anti-SRBC response. Thus, the basis for any change in potency resulting from multiple treatment or chronic exposure to TCDD and the role of AhR-mediated events in the phenomenon remain to be elucidated.

Some in vitro studies also suggest that suppression of the in vitro antibody response may occur independent of the AhR. Tucker et al. (1986) and Holsapple et al. (1986a) reported that direct addition of TCDD in vitro suppressed the antibody response to SRBCs. However, based on the response of cells from congenic mice as well as a limited structure-activity study, the data of Tucker et al. (1986) supported an AhR-dependent suppression, whereas the data of Holsapple et al. (1986a) did not. In the latter study, the magnitude of suppression was comparable using cells from responsive B6C3F_1 or congenic heterozygous (Ah^{bd}-B6) mice compared with nonresponsive D2 or homozygous Ah^{dd}-B6 mice. In addition, Holsapple et al. (1986a) reported that 2,7-DCDD, which lacks affinity for the AhR, was equipotent with TCDD in suppressing the in vitro response.

Davis and Safe (1991) directly compared the in vitro structure-immunotoxicity relationships for a series of PHAH congeners that show >14,900-fold difference in in vivo immunotoxic potency. Results of these studies indicated that all of the congeners were equipotent in vitro and produced a similar concentration-dependent suppression of the in vitro anti-SRBC response using cells from either B6 or D2 mice. Coexposure to the AhR antagonist α-napthoflavone antagonized the immunosuppression induced by either TCDD or 1,3,6,8-TCDF (a weak AhR agonist). Collectively, these results suggested a mechanism of suppression in vitro that was independent of the AhR.

Morris et al. (1991) demonstrated that suppression of the in vitro antibody response to SRBC by TCDD was critically dependent on the type and concentration of the serum used in the in vitro culture. When splenocytes were cultured in the presence of normal mouse serum (NMS), the profile of activity was dependent on the genotype (i.e., Ah^{bb} or Ah^{dd}) of the lymphocytes rather than the source of NMS (Morris et al., 1994). These results are important, because they may help to explain the variable effects observed by different laboratories performing in vitro TCDD-antibody response assays.

The majority of evidence indicates that immunotoxicity of PHAHs is AhR mediated. This evidence comes primarily from the in vivo mouse data described above. Recent studies also indicate that murine T lymphocytes and leukocytes express the Ah receptor (Lawrence et al., 1996; Williams et al., 1996). A complete understanding of the role of the AhR in murine leukocytes and PHAH-mediated immunotoxicity, however, requires further study. Although other data suggest that non-AhR mechanisms may have some role in TCDD-induced immunotoxicity, further studies are required to provide definitive evidence for this mechanism. Studies employing novel approaches -such as the development and use of variant lymphoma cells that express variable levels of the AhR (e.g., hepatoma cells [Miller et al., 1983; Karenlampi et al., 1988]), the use of AhR knockout mice (Fernandez-Salguero et al., 1995; Gonzalez et al.,

1995), or the use of pure binding antagonists (Lu et al., 1995, 1996), would help to provide such evidence.

4.3. SENSITIVE TARGETS FOR PHAH IMMUNOTOXICITY

Despite considerable investigation, the cells that are most sensitive to alteration by PHAH exposure leading to suppressed immune function have not been unequivocally identified. The in vivo immunotoxicity of TCDD, expressed in terms of suppression of the anti-SRBC response of B6 or B6C3F_1 mice, is highly reproducible between laboratories. Because the magnitude of the anti-SRBC response depends on the concerted interactions of antigen-presenting cells (APCs), regulatory T cells (helper and suppressor), and B cells, this response has been used most widely to evaluate target cell sensitivity to PHAHs. In addition, the CTL response has served as a model for evaluating PHAH-induced suppression of T cell function. These immune responses can be modulated by nonimmunological factors, including hormonal and nutritional variables, and PHAHs are known to affect endocrine and metabolic functions. These indirect effects will be apparent only in in vivo studies, whereas direct effects on APC and lymphocyte functions would be evident following in vitro exposure to PHAHs.

One potentially important indirect mechanism is through effects on the endocrine system, because the activity of several endocrine hormones (e.g., glucocorticoids, sex steroids, thyroxine, growth hormone, and prolactin) that regulate immune responses have been shown to be altered by TCDD and other PHAHs (see Chapter 3, Acute, Subchronic and Chronic Toxicity and Chapter 5, Developmental and Reproductive Toxicity). Consequently, studies have been performed to examine the possible role of PHAH-induced indirect effects on the immune systems of rodents.

Kerkvliet et al. (1990b) reported that exposure of mice to 3,4,5,3′,4′,5′-HxCB (PCB169)followed by injection of P815 allogeneic tumor cells induced a dose-dependent elevation of serum corticosterone concentrations that correlated with the dose-dependent suppression of the anti-P815 CTL response. However, because adrenalectomy or treatment with the glucocorticoid receptor antagonist RU38486 failed to protect mice from the immunosuppressive effect of PCB169 (DeKrey et al., 1993), a role for the elevated CS in the suppression of the CTL response seems unlikely. Adrenalectomy and hypophysectomy also failed to prevent TCDD-induced thymic atrophy in rats (van Logten et al., 1980).

In other studies using the P815 allogeneic tumor model, Kerkvliet and Baecher-Steppan (1988a) reported that male mice were more sensitive than female mice to suppression of the CTL response by PCB169. Castration of male mice partially ameliorated the immunosuppressive effects of HxCB (DeKrey et al., 1993), suggesting a role for testosterone in suppression of this response. Male mice were found to be more sensitive than female mice to PCB169-induced

reductions in serum prolactin levels (DeKrey et al., 1994). However, it was concluded that PCB169-induced hypoprolactinemia was not responsible for CTL suppression in mice, because bromocryptine, which severely suppressed serum prolactin levels, failed to alter CTL activity.

Pazdernik and Rozman (1985) suggested that thyroid hormones may play a role in TCDD immunotoxicity based on the finding that radiothyroidectomy prevented the suppression of the anti-SRBC response in rats treated with TCDD. However, because thyroidectomy alone suppressed immune function, the significance of the findings requires further study. Taken together, the current data do not provide convincing evidence supporting a role for hormones in PHAH-induced indirect mechanisms of immunosuppression.

Kerkvliet and Brauner (1987) compared the sensitivity of antibody responses to antigens that differ in their requirements for APC and T cells as an in vivo approach to evaluate the cellular targets of 1,2,3,4,6,7,8-HpCDD humoral immunotoxicity. The TI antigens, DNP-Ficoll and TNP-LPS, were used in these studies. These TI antigens differ from each other in their requirement for APC (higher for DNP-Ficoll) and their sensitivity to regulatory (amplifier and suppressor) T cell influence (DNP-Ficoll is sensitive, TNP-LPS is not) (Braley-Mullen, 1982). Obviously, all antibody responses require B cell differentiation into antibody-secreting plasma cells. Although HpCDD produced dose-dependent suppression of the antibody response to all three antigens, sensitivity to suppression directly correlated with the sensitivity of the response to T cell regulation. The ID_{50}s were 53, 127, and 516 µg/kg for SRBC, DNP-Ficoll, and TNP-LPS, respectively. These results were interpreted as follows: If one assumes that B cell function is targeted in the TNP-LPS response, then regulatory T cells and/or APC may represent the more sensitive target in the SRBC and DNP-Ficoll responses. The difference in sensitivity between the SRBC and DNP-Ficoll responses suggests that the T helper cell may be a particularly sensitive target. The differential sensitivity of the antibody responses to TNP-LPS versus SRBC has been corroborated in TCDD-treated mice (House et al., 1990; Kerkvliet et al., 1990a). Thus, the in vivo sensitivity of the antibody response to SRBC, described in these studies, appears to depend on the T cell and/or APC components of the response rather than the B cell, unless the B cells that respond to SRBC are different from the B cells that respond to TNP-LPS. Currently, evidence for such a difference is lacking.

These in vivo results differ from the ex vivo data of Dooley and Holsapple (1988). Using in vitro immunization with SRBC, DNP-Ficoll or LPS of separated and reconstituted splenic T cells, B cells, and adherent cells from vehicle- and TCDD-treated mice, they reported that B cells from TCDD-treated mice were functionally compromised in in vitro antibody responses but T cells and macrophages were not. These ex vivo results corroborated an earlier study in which TCDD suppressed the in vitro antibody response to these same antigens in a dose-related manner and at comparable concentrations (Holsapple et al., 1986a). Taken together, these ex vivo data

suggested that the B cell is the primary target for the direct effects of TCDD, because the antigens employed differ in their dependence on T cells and accessory cells (Holsapple, 1995).

The basis for the different responses to TI antigens in these studies has not been established. However, it has been suggested for the ex vivo work that the effects of TCDD on T cells may be indirectly induced following antigen exposure such that removal of the cells from the TCDD environment of the host prior to antigen challenge would preclude detection of T cell dysfunction (Kerkvliet and Burleson, 1994). This interpretation is supported by the findings of Tomar and Kerkvliet (1991) that spleen cells taken from TCDD-treated mice were not compromised in their ability to reconstitute the antibody response of lethally irradiated mice, and the reported lack of direct effects of TCDD and other PHAHs on T cells in vitro (Clark et al., 1981; Kerkvliet and Baecher-Steppan, 1988a, b).

Although the direct effects of TCDD on T cells in vitro have not been demonstrated, it is clear that functional T cell responses generated in vivo are compromised following in vivo exposure. Nude mice that are congenitally T cell deficient were significantly less sensitive to HpCDD-induced immunotoxicity when compared with their T cell–competent littermates (Kerkvliet and Brauner, 1987). Likewise, exposure to TCDD or PCB169 suppressed the development of CTL activity following alloantigen challenge (Kerkvliet et al., 1990b). The influence of TCDD exposure on regulatory T cell functions has been addressed in several studies. Clark et al. (1981) first proposed that T suppressor cells were induced by TCDD in the thymus that were responsible for the suppressed CTL response. However, increased suppressor cell activity in peripheral lymphoid tissue was not observed in mice exposed to TCDD (Dooley et al., 1990) or PCB169 (Kerkvliet and Baecher-Steppan, 1988b). In terms of T helper cell activity, Tomar and Kerkvliet (1991) reported that a dose of 5 μg/kg TCDD suppressed the in vivo generation of carrier-specific T helper cells. Lundberg et al. (1990) reported that thymocytes from B6 mice treated with TCDD (50 μg/kg) were less capable of providing help for an in vitro anti-SRBC response. However, Clark et al. (1983) reported in ex vivo studies that T cells from TCDD-treated mice produced normal levels of interleukin-2 (IL-2). A study using the P815 tumor allograft model suggests that TCDD alters early $CD4^+$ T cell activation events, which lead to premature termination of cytokine production by $CD8^+$ T cells, suppression of CTL activity, and suppression of alloantibγody production by B cells (Kerkvliet et al., 1996). Tumor necrosis factor (TNF), IL-2, and interferon γ (IFNγ) were suppressed in P815-injected mice exposed to TCDD. In contrast, TNF and IL-2 were not affected and IFNγ was reduced in anti-CD3 injected mice exposed to TCDD (Prell et al., 1995). These results suggest that the effects of TCDD on cytokine production may be determined by the inducing stimulus.

The influence of TCDD exposure on B cell function has been addressed primarily in in vitro studies, but direct effects of PHAHs on macrophages and T cells in vitro have not been

described. The issue of TCDD effects on B cells is difficult to address in vivo given that most B cell responses (except perhaps anti-LPS responses) depend on interactions with T cells and macrophages. In vitro studies have described the direct effects of TCDD on activation and differentiation of purified B cells (Holsapple et al., 1986a; Luster et al., 1988; Morris et al., 1991; Karras and Holsapple, 1994a, b; Karras et al., 1995). These studies suggest that TCDD inhibits terminal differentiation of B cells via alteration of an early activation event (Luster et al., 1988; Karras and Holsapple, 1994b). Increased phosphorylation and tyrosine kinase activity in TCDD-treated B cells may underlie this B cell dysfunction (Kramer et al., 1987; Clark et al., 1991a). Also, Karras and Holsapple (1994a) suggest that the antiproliferative effect of TCDD on B cells is due to inhibition of calcium-dependent activation; this inhibition results in suppression of B cell surface Ig-induced antibody production (Karras et al., 1996).

Macrophage functions have also been examined following TCDD exposure and generally found to be resistant to suppression by TCDD when assessed ex vivo. Macrophage-mediated phagocytosis, macrophage-mediated tumor cell cytolysis or cytostasis, oxidative reactions of neutrophils and macrophages, and spontaneous natural killer (NK) cell activity were not suppressed following TCDD exposure, with doses as high as 30 μg/kg failing to suppress NK and macrophage functions (Vos et al., 1978; Mantovani et al., 1980). More recent studies, however, indicate that virus-augmented pulmonary NK activity, but not spontaneous pulmonary NK activity, is suppressed by TCDD (Yang et al., 1994). Phorbol ester–activated antitumor cytolytic and cytostatic activity of neutrophils is also selectively inhibited by TCDD (Ackermann et al., 1989).

On the other hand, it is interesting to note that the pathology associated with TCDD toxicity often includes neutrophilia and an inflammatory response in liver and skin characterized by activated macrophage and neutrophil accumulation (Vos et al., 1973; Weissberg and Zinkl, 1973; Vos et al., 1974; Puhvel and Sakamoto, 1988; Herbert et al., 1990). Although these observations may reflect a normal inflammatory response to tissue injury, some experimental evidence suggests that inflammatory cells may be activated by TCDD exposure. For example, Alsharif et al. (1994) reported that TCDD increased superoxide anion production in rat peritoneal macrophages. In addition, it has been shown that TCDD exposure results in an enhanced inflammatory response following SRBC challenge (Kerkvliet and Oughton, 1993). This effect of TCDD was characterized by a twofold to fourfold increase in the number of neutrophils and macrophages locally infiltrating the intraperitoneal site of SRBC injection. However, the kinetics of the cellular influx were not altered by TCDD. Likewise, the expression of macrophage activation markers (I-A and F4/80) and the antigen-presenting function of the peritoneal exudate cells were unaltered by TCDD. Using specific inhibitors of the proinflammatory cytokines TNF and IL-1 (Moos et al., 1994) found that the TCDD-induced

hyperinflammatory response was mediated by TNF . However, although exogenous TNF suppressed the antibody response to SRBC, the increased inflammatory response and suppression of the response to SRBC were not apparently linked, because coincident treatment with the soluble TNF receptor rhuTNFR:Fc, which blocks TNF activity, further suppressed rather than normalized the immunosuppression by TCDD alone (Moos and Kerkvliet, 1995). Thus, the relationship, if any, between the inflammatory and immune effects of TCDD remains to be elucidated.

Evidence also suggests that the long-recognized hypersusceptibility of TCDD- and PCB-treated animals to endotoxin (LPS) (Thomas and Hinsdill, 1978, 1979; Vos et al., 1978; Loose et al., 1979) may be related to an increased production of proinflammatory factors. TNF production may be responsible for endotoxin hypersensitivity in TCDD-treated mice and that the Ah locus mediates this response (Clark et al., 1991b; Taylor et al., 1992). The ability of methylprednisolone to reverse the mortality associated with TCDD/LPS treatment is also consistent with an inflammatory response (Rosenthal et al., 1989). Similarly, increased inflammatory mediator production may underlie the enhanced rat paw edema response to carrageenan and dextran in TCDD-treated rats (Theobald et al., 1983; Katz et al., 1984). Whereas serum complement activity has been reported to be suppressed in dioxin-treated mice (White et al., 1986), enhanced activity was reported at the lowest exposure level when 1,2,3,6,7,8-HxCDD was tested. Work by Sutter et al. (1991) indicates that IL-1β gene expression, as well as plasminogen activator inhibitor-2, in keratinocytes is elevated by TCDD. On the other hand, House et al. (1990) reported that inflammatory macrophages obtained from TCDD-treated mice produced control levels of IL-1 when examined ex vivo. Thus, the effect of TCDD on inflammatory mediator production may be a "priming effect" and require coexposure to antigen or LPS. The influence of TCDD on inflammatory mediator production and action is an important area for further study.

Since the rapid influx of phagocytic cells to the site of pathogen invasion is an important factor in host resistance to infection, the ability of TCDD to augment the production of inflammatory chemoattractive mediators would imply that TCDD exposure could result in enhanced host resistance. However, because TCDD exposure is, at the same time, immunosuppressive, which results in decreased specific immune responses generated by T and B lymphocytes, the overall impact of TCDD exposure on disease susceptibility will likely vary depending on the nature of the pathogen and the major mode of host response to the specific infectious agent. Such effects may in fact help explain the disparate effects of TCDD in different host resistance models that are described below.

Taken together, it is obvious that multiple targets exist for PHAH-induced immunosuppression, including both T and B lymphocytes. Lymphocyte precursor cells as well

as lymphoid-associated tissue such as thymus epithelium and bone marrow stromal elements are also affected by dioxins (discussed later in the chapter). The class or subclass of T or B lymphocytes that is the proximate target for PHAH-induced immunosuppression remains to be determined, as do the mechanisms by which immunosuppression by these chemicals is achieved.

4.4. INFLUENCE OF TCDD ON HOST RESISTANCE TO DISEASE

The ability of an animal to resist and/or control viral, bacterial, parasitic, and neoplastic diseases is determined by both nonspecific and specific immunological functions. Decreased functional activity in any immunological compartment may result in increased susceptibility to infectious and neoplastic diseases. Animal host resistance models that mimic human disease are available and have been used to assess the effect of TCDD on altered host resistance.

TCDD exposure increases susceptibility to challenge with the gram-negative bacterium *Salmonella*. TCDD was given per os at 0.5 to 20 μg/kg once a week for 4 weeks to male 4-week-old C57Bl/6Jfh (J67) mice and challenged 2 days after the fourth dose (when mice were 8 weeks old) with either *Salmonella bern* or *Herpesvirus suis* (also known as pseudorabies virus). Results with *S. bern* indicated increased mortality at 1 μg TCDD/kg (total dose of 4 μg/kg) and reduced time to death after bacterial challenge with 5 μg TCDD/kg (total dose of 20 μg/kg). In contrast, the same doses of TCDD did not alter the time to death or the incidence of mortality following *Herpesvirus suis* infection (Thigpen et al., 1975). A TCDD feeding study by Hinsdill et al. (1980) also demonstrated increased susceptibility of 7-week-old Swiss Webster outbred female mice to *S. typhimurium* var. *copenhagen*. Mice were fed control feed or feed containing 10, 50, or 100 ppb TCDD for 8 weeks, after which they were injected intravenously with $10^{3.5}$ *S. typhimurium* var. *copenhagen*. Results indicated that 50 and 100 ppb TCDD increased mortality from *Salmonella* and shortened the time to death, whereas 10 ppb caused an increased bacteremia.

Vos et al. (1978) reported that TCDD resulted in increased sensitivity to endotoxin (*E. coli* O 127:B 8 lipopolysaccharide) and suggested that the increased susceptibility to *Salmonella* caused by TCDD might be caused by the endotoxin of this gram-negative bacterium. Vos et al. demonstrated reduced resistance to endotoxin with a single oral dose of 100 μg TCDD/kg using 3- to 4-week-old outbred female mice and challenged with endotoxin 5 days later. Vos et al. also reported enhanced mortality from intravenous injection of endotoxin 2 days after the final oral dose of TCDD (1.5, 5, 15, or 50 μg/kg, once a week for 4 weeks) in 3- to 4-week-old male outbred Swiss mice. These studies indicate a reduced resistance to endotoxin after single or multiple doses of TCDD. Thomas and Hinsdill (1979), using *S. typhimurium* lipopolysaccharide, demonstrated a reduced resistance to endotoxin in the offspring of female Swiss Webster mice fed TCDD prior to mating, during gestation, and between parturition and weaning. Rosenthal et

al. (1989) used female B6C3F_1, DBA/2, as well as congenic mice to demonstrate that acute doses of 50, 100, or 200 μg/kg TCDD per os increased endotoxin-induced mortality in B6C3F_1 mice, which was associated with hepatotoxicity and decreased clearance of the endotoxin. D2 and Ah^{dd} congenic mice were relatively resistant to this effect, implicating AhR-dependent mechanisms in endotoxin hypersensitivity.

White et al. (1986) reported that *Streptococcus pneumoniae*, a gram-positive bacterium that does not contain endotoxin, caused increased mortality in 5- to 6-week-old female B6C3F_1 mice after subchronic oral administration of TCDD (1 μg/kg for 14 days) and challenged with *S. pneumoniae* intraperitoneally 1 day after the last treatment. The 1,2,3,6,7,8-hexachlorodibenzo-*p*-dioxin (HCDD) isomer also resulted in a dose-dependent increase in susceptibility to *S. pneumoniae*.

Enhanced susceptibility to viral disease has also been reported after TCDD administration. Clark et al. (1983) injected TCDD intraperitoneally once a week for 4 weeks and challenged mice 7 to 22 days later with *Herpes simplex* type II strain 33 virus. Mice receiving TCDD at 0.04, 0.4, or 4.0 μg/kg weekly (total dose of 160, 1,600, and 16,000 ng/kg) all had significantly enhanced mortality to Herpesvirus type II infection. House et al. (1990) also reported an enhanced susceptibility to viral infection following low-level singledose TCDD administration intraperitoneally. B6C3F_1 female mice, 6 to 8 weeks of age, were challenged with influenza A/Taiwan/1/64 (H2N2) virus 7 to 10 days following TCDD. TCDD administration at 10, 1.0, or 0.1 μg/kg decreased resistance to virus. The lowest observable effect level was 0.1 μg/kg, making this one of the most sensitive endpoints for TCDD immunotoxicity. However, the only immune parameter suppressed by TCDD, which is related to host resistance to this virus, was the serum hemagglutination antibody titers to influenza. Unfortunately, only mice dosed at 10 μg/kg TCDD were evaluated for these virus-specific antibodies. No alterations in macrophage function, NK cell activity, or interferon levels were observed in TCDD-exposed mice (House et al., 1990).

Recently, the sensitivity of TCDD-exposed mice to influenza virus challenge was corroborated by Burleson et al. (1996), who observed enhanced mortality to influenza A/Hong Kong/8/68 (H3N2) virus following a single exposure to 0.1, 0.05, or 0.01 μg/kg TCDD. Increased mortality at 0.01 μg/kg TCDD was the lowest observable effect level and as such represents the most sensitive adverse effect level yet reported for TCDD (Burleson et al., 1996). However, the role of TCDD in altering immune-mediated mechanisms important in resistance to this virus remains to be elucidated. Furthermore, because increased mortality was not correlated with increased virus titers in the lungs of mice, and TCDD did not alter the expected virus-enhanced increase in lung:body weight ratio nor the virus-induced decrease in thymus weight, other nonimmune virus-mediated physiological changes may be involved in this increased

mortality. Further studies are warranted to confirm this very low level, TCDD-induced effect and to delineate the underlying mechanisms responsible for this altered host resistance.

Rats exposed to TCDD daily for 14 days at a total dose of 10 μg/kg had significantly augmented rat-adapted influenza virus replication in the lungs (Yang et al., 1994). The increased virus replication was correlated with a significant suppression of virus-augmented but not spontaneous pulmonary NK cell activity, suggesting that reduced NK activity may be at least in part related to enhanced susceptibility of rats to influenza virus (Yang et al., 1994).

TCDD exposure has also been shown to result in more severe infections from parasites. Tucker et al. (1986) studied the effects of TCDD administration on *Plasmodium yoelii* 17 XNL, a nonlethal strain of malaria, in 6- to 8-week-old $B6C3F_1$ female mice. A single dose of TCDD at 5 μg/kg or 10 μg/kg per os resulted in increased susceptibility to *P. yoelii*. The peak parasitemia was greater and of longer duration in TCDD-treated animals than in controls, the difference being significant at 5 μg/kg on day 10 and at 10 μg/kg on days 12 and 14. A single dose of TCDD at 10 or 30 μg/kg intraperitoneally 7 days prior to infection of $B6C3F_1$ mice with *Trichinella spiralis* resulted in delayed onset of adult parasite elimination, and at 1.0 μg/kg TCDD suppressed the proliferative response of splenocyte and mesenteric lymph node cells stimulated with *T. spiralis* antigen (Luebke et al., 1994). Tissue levels of TCDD were also higher in infected versus noninfected mice in this study. In a separate study, TCDD at 1, 10, or 30 μg/kg administered intraperitoneally 7 days prior to infection of Fischer 344 rats with *T. spiralis* did not affect adult parasite elimination or the numbers of encysted larvae in muscle. Furthermore, proliferative responses of lymphocytes from rats dosed at 30 μg/kg and stimulated with parasite antigen were enhanced in contrast to the suppression observed in $B6C3F_1$ mice (Luebke et al., 1995). The different responses observed in mice versus rats for this host resistance model are similar to those reported by Smialowicz et al. (1994) for the antibody response to SRBCs, in that the latter response was suppressed in mice and enhanced in rats. In a recent study, aged (76-week-old) rats exposed to TCDD and infected with *T. spiralis*, were less able to limit the burden of encysted larvae, compared to young (10-week-old) rats (Luebke et al. 1999). These results suggest that TCDD may exacerbate the age-related decreased resistance to this parasite.

Luster et al. (1980a) demonstrated enhanced growth of transplanted tumors in mice treated with TCDD at doses of 1.0 or 5.0 μg/kg in $B6C3F_1$ mice. Dams were given TCDD by gavage at day 14 of gestation and again on days 1, 7, and 14 following birth; host resistance studies were performed 6 to 8 weeks after weaning. This exposure protocol resulted in an increased incidence of PYB6 tumors in pups from dams receiving repeated doses of 1.0, but not 5.0, μg TCDD/kg.

Although it is clear that TCDD adversely affects numerous host resistance models detailed above, the effects of TCDD on susceptibility to *Listeria monocytogenes* infections are ambiguous. The disparate results may reflect different study designs, including dose, route, single versus multiple administrations, mouse strain, age, or sex. However, it is clear that TCDD, under certain conditions, results in increased susceptibility to *Listeria*. Hinsdill et al. (1980) reported the increased susceptibility of 7-week-old Swiss Webster outbred female mice to *Listeria*. Mice were fed control feed or feed containing 10 or 50 ppb TCDD for 8 weeks, after which they were injected intravenously with 10^5 *Listeria*. Results indicated that the 50 ppb diet increased bacteremia and mortality. Luster et al. (1980b) used doses of 1.0 or 5.0 μg TCDD/kg in $B6C3F_1$ mice. Dams were given TCDD by gavage at day 14 of gestation and again on days 1, 7, and 14 following birth, and host resistance studies were performed 6 to 8 weeks after weaning. This exposure protocol resulted in an increased susceptibility to *Listeria* in pups from dams receiving repeated doses of 5.0 μg TCDD/kg. However, Vos et al. (1978) reported that oral administration of 50 μg TCDD/kg once a week for 4 weeks to 3- to 4-week-old male Swiss mice followed by intravenous challenge 4 days after the last dose with *Listeria* had no effect on nonspecific phagocytosis and killing of *Listeria*. House et al. (1990) used $B6C3F_1$ female mice, 6 to 8 weeks of age and challenged intravenously with *Listeria* 7 to 10 days following a single dose of TCDD at 10, 1.0, and 0.1 μg/kg. TCDD did not enhance mortality from *Listeria*.

In summary, results from host resistance studies provide evidence that under certain conditions exposure to TCDD results in increased morbidity and mortality for bacterial, viral, parasitic, and neoplastic disease. These effects are observed at relatively low doses and likely result from TCDD-induced suppression of immunological function. However, the specific immunological functions targeted by TCDD in each of the host resistance models remain to be fully defined. Possible nonimmunological mechanisms, which may also contribute to altered host resistance by PHAHs, should also be investigated. Future work should also address the role of the AhR in host resistance.

4.5. ROLE OF THE THYMUS IN PHAH IMMUNOTOXICITY

Thymic involution is one of the hallmarks of exposure to TCDD and related PHAHs in all species examined. In mice, thymic involution occurs by an AhR-dependent mechanism. Poland and Knutson (1982) demonstrated that C57Bl/6 mice were 10-fold more sensitive to TCDD-induced thymic atrophy than DBA/2 mice. Because the thymus has a critical role in the ontogeny of T lymphocytes, thymic involution is often referred to as an immunotoxic effect. However, although an intact thymus is crucial to the developing immune system during the prenatal and early postnatal period of rodents as well as during the prenatal period of humans, the physiological role played by the thymus in adult life has not been established. In animal models,

adult thymectomy has little effect on the quantity or quality of T lymphocytes, which have already matured and populated the secondary lymphoid organs (Benjamini and Leskowitz, 1991). Likewise, in humans, childhood and adult thymectomy produces no clearly identifiable adverse consequences in terms of altered immune function, although some might argue that such studies have not been done. On the basis of this knowledge, it is not surprising that a direct relationship between the effects of TCDD on the thymus and immune suppression has not been established in studies using adult animals. In fact, adult thymectomy prior to PHAH exposure did not modify TCDD- or HpCDD-induced suppression of the anti-SRBC response (Tucker et al., 1986; Kerkvliet and Brauner, 1987). Furthermore, suppression of immune responses occurs at dose levels of PHAH significantly lower than those required to induce thymic atrophy (Vos et al., 1978; Silkworth and Antrim, 1985; Holsapple et al., 1986b; Tucker et al., 1986; Kerkvliet and Brauner, 1990). Thus, thymic involution does not represent a surrogate marker for TCDD immunotoxicity in adult animals. On the other hand, it is possible that chronic exposure to TCDD resulting in chronic thymic atrophy may produce more delayed, subtle effects on immune function not yet identified (Clarke and MacLennan, 1986).

In contrast to adult animals, congenital thymic aplasia or neonatal thymectomy results in severe reduction in the number and function of T lymphocytes and produces a potentially lethal wasting disease (Benjamini and Leskowitz, 1991). Similarly, there is evidence from studies that rodents exposed to TCDD or PCBs during the prenatal or neonatal period are more sensitive to immune suppression compared with rodents exposed as adults and that the prenatal effects are more selective for cell-mediated immunity (Vos and Moore, 1974; Faith and Moore, 1977; Luster et al., 1980b). Perinatal exposure of mice and rats to TCDD alters thymocyte differentiation and maturation in vivo (Holladay et al., 1991; Blaylock et al., 1992; Gehrs and Smialowicz, 1997, 1999; Gehrs et al., 1997).

TCDD has also been shown to alter thymocyte maturation in vitro by inducing terminal differentiation of thymic epithelial cells (Greenlee et al., 1985; Cook et al., 1987). Addition of TCDD to fetal thymic organ cultures (FTOCs) also alters thymocyte maturation (Dencker et al., 1985; d'Argy et al., 1989). 3,3',4,4'-Tetrachlorobiphenyl (PCB77) has also been found to alter the normal developmental pathways of fetal thymocytes in vitro (Esser and Welzel, 1993; Kremer et al., 1994). In mouse FTOCs the addition of TCDD or PCB77 resulted in an overall reduction in thymocytes but a significant increase in mature $CD4^{-}CD8^{+}$ thymocytes which were $CD3^{+}$,$\alpha\beta TCR^{+}$,$CD69^{+}$,HSA^{-},$IL\text{-}2R^{-}$ (Esser and Welzel, 1993; Kremer et al., 1995). These mature $CD8^{+}$ thymocytes were functionally competent, in that they responded to stimulation by Con A or anti-CD3 and possessed cytotoxic activity when cultured with H-2 allogeneic spleen cells (Lai, et al., 1995). Data from experiments using FTOC recultivation techniques, in which intact thymic lobes and thymocyte-depleted (i.e., stroma) lobes were employed, suggested that TCDD drives

thymocytes into differentiation faster than the precursor pool can be replenished by self-renewal (Kremer et al., 1994). Because TCDD affected thymic stroma but did not directly affect thymocytes, the findings of Kremer et al. (1994) suggest that the nonlymphoid compartment (i.e. stroma) rather than the thymocytes themselves may be the target of these PHAHs.

Work by Silverstone et al. (1994a) indicates that TCDD-induced thymic atrophy can be mediated, at least in part, by damage to prethymic T cell precursor stem cells in both bone marrow and liver. Perinatal exposure of mice to TCDD resulted in alteration in the lymphocyte stem cell population, as indicated by a significant reduction in the lymphocyte stem cell–specific enzyme terminal deoxynucleotidyl transferase (TdT) in fetal liver and neonatal bone marrow lymphoid cells (Fine et al., 1989). In contrast, thymic TdT synthesis was relatively unaffected on a per cell basis by perinatal TCDD exposure. TCDD also inhibited the ability of pre-T stem cells (prothymocytes), from both fetal livers and neonatal bone marrow, to repopulate the thymus of irradiated syngeneic mice (Fine et al., 1990). TCDD-induced thymic atrophy did not involve apoptotic mechanisms in thymocytes affected by the bcl-2 proto-oncogene, and this atrophy appears to be mediated through the AhR and not through effects on the estrogen receptor (Silverstone et al., 1994a, b; Frazier et al., 1994).

Thymic alterations in adult mice exposed to TCDD appear to depend on AhR activation in hemopoietic cells. Using chimeric mice with TCDD-responsive (AhR[+/+]) stromal components and TCDD-unresponsive (AhR[-/-]) hematopoietic components, or the reverse, Staples et al. (1998a) demonstrated that the hemopoietic compartment is the target of TCDD-induced thymic atrophy and thymic phenotype alterations. The mechanisms underlying these alterations are not clear, although TCDD-induced apoptosis of thymocytes, via Fas-Fas ligand interactions, has been reported (Kamath et al., 1997, 1999). However, other evidence indicates that apoptosis is not a key mechanism of TCDD-induced thymic atrophy (Staples et al. 1998b)

Taken together, the data indicate that PHAHs induce alterations of T cell maturation in the thymus. These are mediated in part by effects on accessory cells and on extra-thymic precursor cells. In addition, TCDD also influences B cell development in the bursa of chick embryos (Nikolaidis et al., 1990), as well as lymphocyte stem cells in the fetal liver and bone marrow of mice (Fine et al., 1989, 1990). Such alterations may have an important role in the observed suppression of immune function by PHAHs in perinatally exposed animals.

4.6. IMMUNOTOXICITY FOLLOWING PRENATAL/NEONATAL EXPOSURE TO PHAHS

The reported increase in susceptibility of very young animals to PHAH immunotoxicity necessitates close examination of the available literature on prenatal or neonatal immunotoxic effects. Several studies have examined immune function in mice, rats, and guinea pigs following

exposure to TCDD or PCB during fetal development (Vos et al., 1973; Vos and Moore, 1974; Thomas and Hinsdill, 1979; Luster et al., 1980b).

Results of work in which exposure of the progeny occurred via placental transfer and lactation are summarized in Table 4-3. Study 1 presents results of two studies, one using B6 (Vos and Moore, 1974) and the other $B6C3F_1$ mice (Luster et al., 1980a); study 2 presents results of outbred Swiss mice (Thomas and Hinsdill,1979); and study 3 presents results from two studies of rats (Vos and Moore, 1974; Faith and Moore, 1977). The most sensitive indicator of TCDD immunotoxicity in these studies was an increase in the growth of transplanted tumor cells in the offspring of $B6C3F_1$ mice (Ah responsive strain) treated with 1 μg/kg TCDD at 4 weekly intervals. (Total TCDD dose to dam was 4 μg/kg; dose to offspring was not determined.) The offspring of Swiss mice fed a diet containing 1 ppb TCDD for 7 weeks showed enhanced mortality following endotoxin challenge, while the plaque-forming cell response to SRBCs and delayed hypersensitivity response were suppressed in offspring of mice fed 5.0-ppb TCDD diets. (Estimated daily dose to 20 g dam consuming 5 g of 5-ppb TCDD diet is equivalent to 1.25 μg/kg TCDD/day.) Rats appeared to be relatively more resistant to the immunotoxic effects of prenatal or neonatal exposure to TCDD than mice based on the finding that 5, but not 1, μg/kg TCDD given four times at weekly intervals produced immunotoxicity in the offspring. Immunotoxic end points that were unaffected by the highest exposure levels in these studies included blastogenesis induced by LPS and serum antibody titers to bovine gamma globulin (BGG). However, a significant finding of this study was that suppression of the DTH response to oxazalone was relatively long lived in that suppression of this response was evident in 145-day-old rats. Taken together, these studies suggest that cell-mediated rather than humoral immunity is more sensitive to perinatal TCDD exposure.

Two later studies examined immune function in offspring of female mice, in the first study exposed to TCDD (Holladay et al., 1991) and in the second study to PCBs (Kanechlor 500) (Takagi et al., 1987), with the offspring cross-fostered to unexposed lactating mice at birth. Thus, exposure was limited to placental exposure. B6 mice exposed to 3.0 μg/kg TCDD on gestational days 6 to 14 gave birth to offspring that had significant thymic atrophy and hypoplasia measured on gestational day 18 or on day 6 postnatally. The thymic effects were no longer apparent by day 14. At 7 to 8 weeks postnatally, mitogen responses and antibody plaque-forming cell response to SRBCs were unaltered, but the CTL response was significantly suppressed compared with controls (Holladay et al., 1991). These results suggest a selectivity of prenatal TCDD on the CTL and not the T helper cells involved in the antibody response to SRBCs. In contrast to these results, Takagi et al. (1987) exposed female C3H mice per os to 50 mg/kg Kanechlor 500 twice per week for 4 weeks, at which time steady-state tissue levels were noted. The offspring derived from mating to unexposed males had an unaltered antibody response to the

T-independent antigen DNP-dextran. On the other hand, carrier-primed T helper cell activity assessed by adoptive transfer was significantly suppressed by PCB exposure when assessed 4 and 7 weeks after birth but fully recovered by 11 weeks. Together, these studies confirm prior studies to indicate that T cell function is selectively altered by PHAH when exposure is prenatal. Although both T helper cells and CTL show altered function, T helper cell activity may recover faster than CTL function.

Fine et al. (1990) reported on TCDD levels in mouse offspring following maternal treatment with TCDD (10 μg/kg) on gestational day 14. The fetal liver had the highest concentration on gestational day 18 (235 fg/mg), which declined slightly by postnatal day 6 to around 100 fg/mg. Concentration of TCDD in the thymus on gestational day 18 was 140 fg/mg, which declined to 20 fg/mg on day 6 after birth. (These thymic TCDD concentrations are equivalent to 60 to 425 pM, assuming 1 kg of tissue is equivalent to 1 L of water.) TCDD concentrations in the spleen remained constant at about 40 fg/mg during the same timeframe, whereas bone marrow concentrations were very low (about 3 fg/mg). These concentrations of TCDD were associated with thymic atrophy (Fine et al., 1989) and significant reduction in the ability of prothymocytes in liver and bone marrow to repopulate an irradiated thymus (Fine et al., 1990).

Recent studies in rats indicate that perinatal exposure to TCDD results in relatively long-lived and persistent suppression of immune responses. Lactating female Leeds rats were exposed to TCDD in their feed, starting on postnatal day 1 through 18, at 0.1, 0.5, or 2.5 μg TCDD/kg, with an estimated total TCDD consumption of 0.2, 1.0, or 5.0 μg/kg/body weight, respectively (Badesha et al., 1995). Both T cell–dependent (i.e., SRBC) and T cell–independent (i.e., DNP-Ficoll, TNP-LPS, and LPS) antibody responses were suppressed in a dose-related manner in 130-day-old offspring.

In another group of studies, a single oral exposure of pregnant Fischer 344 dams on GD-14 to 0.1, 0.3, 1.0, or 3.0 μg TCDD/kg resulted in suppression of the DTH response to BSA (Gehrs et al., 1997; Gehrs and Smialowicz, 1999). Depressed DTH responses persisted for up to 19 months in the male offspring of dams exposed to 3.0 μg TCDD/kg. While both male and female offspring exposed to TCDD on GD-14 displayed reduced DTH responses, the DTH response of males appears to be more affected than that of females. A cross-fostering study indicated that both gestational and lactation exposure of the offspring are required for suppression of the DTH response following gestational day 14 exposure of the dams (Gehrs et al., 1997). A single low dose (0.1 μg/kg) of TCDD given to dams on gestational day 14 resulted in suppression of the DTH response that persists in the offspring for up to age 14 months (Gehrs and Smialowicz, 1999). These results suggest that perinatal exposure to TCDD may lead to a permanent defect in the immune defenses associated with the DTH response, which are critical

for protection against certain intracellular bacterial and parasitic infections as well as certain viruses. If so, then the fetus and neonate may be more at risk for TCDD-induced immune perturbation, which may manifest, early or later in life, as susceptibility to certain infectious diseases.

4.7. IMMUNOTOXICITY OF PHAHS IN NONHUMAN PRIMATES

Studies using nonhuman primates as surrogate models for humans have been conducted to assess PHAH immunotoxicity. Immunological effects were described in rhesus monkeys and their offspring chronically exposed to TCDD at levels of 5 or 25 ppt for 4 years (Hong et al., 1989). In the mothers, the total number of T cells increased in monkeys fed 25 ppt TCDD, with a selective increase in $CD8^+$ cells and a decrease in $CD4^+$ cells. However, no significant effect on T cell function was established when assessed as proliferation response to mitogens, alloantigens, or xenoantigens. NK cell activity and production of antibodies to tetanus immunization were normal. In the offspring of TCDD-exposed dams examined 4 years after exposure, a significantly increased antibody response to tetanus toxoid (TT) immunization was observed that correlated with TCDD tissue levels. Body burden of TCDD in the offspring ranged from a low of 290 ppt to a high of 1,400 ppt. Interestingly, there was no strict correlation between exposure levels and resulting body burden. Immunoenhancement of the antibody response to TT in the offspring of the monkeys exposed to TCDD is in contrast to immunosuppression observed in rodents exposed perinatally. However, other studies in nonhuman primates cited below indicate that humoral immunity is suppressed in nonhuman primates by other PHAHs.

In other TCDD studies, a single injection of TCDD in marmosets (*Callithrix jacchus*) resulted in a delayed decrease in the percentage of $CD4^+$ T cells and $CD20^+$ B cells in the blood and an increase in the percentage of $CD8^+$ cells (Neubert et al., 1990). The total number of T cells was not significantly altered by TCDD exposure. The $CD4^+$ subset most affected was the $CDw29^+$ "helper-inducer" or "memory" subset, with significant effects observed after a TCDD dose of 10 ng/kg. The no-observed-effect level for this effect was 3 ng/kg TCDD. Concomitant with suppression of the CDw29 subset in TCDD treated animals, the percentage of $CD4^+CD45RA^+$ cells increased. This subset has been classified as "suppressor-inducer" or "naive" cells. The changes in the T cell subsets were intensified following in vitro culture of the cells with mitogen (Neubert et al., 1991).

Interestingly, however, another study from the same laboratory reported that chronic exposure of young marmosets to very low levels of TCDD (0.3 ng/kg/week for 24 weeks) produced the opposite effect on the $CD4^+CDw29^+$ subset, resulting in a significant increase in this population (Neubert et al., 1992). Concomitantly, the $CD4^+CD45RA^+$ subset decreased.

Upon transfer of the animals to a higher dose of TCDD (1.5 ng/kg/week) for 3 weeks, the enhancement effect was reversed and suppression of the $CD4^+CDw29^+$ subset was observed, with maximum suppression after 6 weeks of exposure to the higher dose. In addition, the $CD8^+CD56^+$ T cytotoxic T cell subset was transiently increased but normalized even though TCDD dosing continued. After discontinuation of dosing, the reduction in the percentage and absolute number of $CD4^+CDw29^+$ cells persisted for 5 weeks, reaching normal range 7 weeks later. These results led the authors to conclude that extrapolation of the results obtained at higher doses to very low exposures is not justified with respect to the effects induced by TCDD on the immune system of marmosets (Neubert et al., 1992).

Neubert et al. (1995b) performed a study to determine if a functional deficiency could be detected in marmosets that displayed altered peripheral blood T and B subsets following exposure to TCDD (Neubert et al., 1990). No reduction was observed in the in vitro lymphoproliferative response to TT by peripheral blood lymphocytes from marmosets vaccinated with tetanus and exposed to a single dose of 100 ng/kg TCDD at the time of the second booster vaccination (Neubert et al., 1995b). These results are interesting because no association was established between this functional endpoint and the earlier observed TCDD-induced peripheral blood lymphocyte subset changes in mature marmosets given a single injection of TCDD (Neubert et al., 1990).

Immunomodulatory effects of chronic low-level PCB exposure in monkeys have also been investigated. In early studies, Thomas and Hinsdill (1978) reported that rhesus monkeys fed diets containing 2.5 or 5 mg/kg of Aroclor 1248 had significantly suppressed antibody responses to SRBCs but not to TT. These monkeys also had chloracne, alopecia, and facial edema. Similarly, exposure of cynomolgus monkeys to Aroclor 1254 (100 or 400 μg/kg/day) for 3 months suppressed antibody responses to SRBCs but not TT (Truelove et al., 1982). Suppressive effects on anti-SRBC responses were more severe in cynomolgus monkeys when the PCB mixture contained PCDFs (Hori et al., 1982). Tryphonas et al. (1989; 1991a, b) reported results of studies in rhesus monkeys exposed chronically to Aroclor 1254 (5 to 80 μg/kg/day) for 23 or 55 months. These exposures resulted in steady-state blood PCB levels that ranged from a mean low of 0.01 ± 0.001 ppm in the 5 μg/kg group to a mean high of 0.11 ± 0.01 ppm in the 80 μg/kg group. The only consistently altered immune parameter was the primary and anamnestic antibody responses to SRBCs, which were suppressed in a dose-dependent manner. In contrast, the antibody response to pneumococcus vaccine antigen measured at 55 months of exposure was not significantly altered. At 23 months, the percentage of T helper cells in the blood was significantly decreased in the 80 μg/kg group, and the percentage and absolute number of T suppressor cells were increased; however, these effects were not apparent at 55 months of exposure (Tryphonas et al., 1991b). Lymphoproliferative responses to PHA and Con A were not

significantly altered at 23 months but were dose- dependently suppressed at 55 months. Proliferation to alloantigens was not significantly altered. Likewise, serum immunoglobulin and hydrocortisone levels did not differ between treatment groups. After 55 months, chemiluminescent response (time to peak) of monocytes from PCB-exposed monkeys was slower than that from controls. Also noted at 55 months were a significant elevation in serum hemolytic complement levels, a dose-related increase in NK cell activity, and a dose-related increase in thymosin alpha-1 levels but not thymosin beta-4 levels (Tryphonas et al., 1991a). Effects on interferon levels were inconsistent, and TNF production was not altered.

The studies in nonhuman primates are important from the standpoint that the antibody response to SRBCs emerges as the only immunological parameter consistently suppressed by PHAH in several different animal species. Notable exceptions are the reports that TCDD does not suppress antibody response to SRBCs in rats (Smialowicz et al., 1994; Fan et al., 1996). At the present time, it is not clear why the antibody response to SRBCs is most consistently altered by PHAH exposure in different species. Sensitivity of the anti-SRBC response does not appear to be caused solely by T cell dependency of the response because antibody responses to other T-dependent antigens (e.g., TT, BGG) are not suppressed and may be enhanced following PHAH exposure. It is possible that the particulate nature of the SRBC antigens is an important factor even though a mechanistic basis for this is not readily apparent. The sensitivity of the technique used to quantify the antibody response may also contribute to apparent increased sensitivity of the SRBC model, which is most often measured as the PFC response rather than serum antibody titers which are usually more variable. Nonetheless, the finding that the SRBC response is also suppressed in nonhuman primates exposed to PCBs lends support to the use of the anti-SRBC database for risk assessment of PHAHs.

4.8. IMMUNOTOXICITY OF PHAHS IN HUMANS: IN VIVO EXPOSURE

Immunotoxicity of TCDD and related PHAHs in humans has been the subject of several studies derived from accidental, occupational, or environmental exposure to PCDDs, PCDFs, and/or PCBs(see Chapter 7, Human Effects). Perhaps the most important human case studies involve two incidents in which large numbers of individuals were exposed to PCB-contaminated rice oil containing PCDFs and other PHAHs. The first occurred in Japan in 1968 and the second in Taiwan in 1979, and the resulting symptoms associated with exposure were called "Yusho" and "Yu-Cheng" which mean "oil disease" in Japanese and Chinese, respectively (Tsukamoto, 1969; Chang et al., 1980a). The most common clinical symptoms included acne-form eruptions and follicular accentuation, pigmentation of the skin and nails, swelling of the eyelids and increased discharge, nausea, headaches, and numbness of the limbs (Chang et al., 1980b).

Clinical studies revealed decreased serum concentration of γ-globulin and decreased DTH responses in Yu-Cheng patients (Chang et al., 1980b).

Patients also presented with increased frequency of various kinds of infection, especially of the respiratory tract and skin (Shigematsu et al., 1978; Nakanishi et al., 1985; Lu and Wu, 1985). Immunologic effects, in studies that compared a group of 30 Yu-Cheng patients and 23 normal controls, included decreased serum IgA and IgM, but not IgG, and decreased percentage of total T cells (E rosettes), active T cells (active E rosettes), and T helper (Tμ) cells in peripheral blood (Chang et al., 1981). Monocytes and polymorphonuclear cells from these exposed patients also had reduced numbers of Fc receptors compared with controls (Chang et al., 1982a). In a subsequent study, the DTH response to streptokinase and streptodornase in 30 exposed patients was significantly reduced compared with 50 controls (Chang et al., 1982b). The percentage of anergic patients increased, and the degree of induration decreased with increased PCB concentration in the blood. In contrast, lymphoproliferative responses of peripheral blood lymphocytes (PBLs) to PHA, pokeweed mitogen (PWM), and tuberculin PPD, but not Con A, were significantly augmented in PCB-exposed patients (Lu and Wu, 1985). PCB concentrations in the blood ranged from 3 to 1,156 ppb, with a mean of 89 ± 6.9 ppb. The oil was contaminated at PCB concentrations of 4.8 to 204.9 ppm, with a mean of 52 ± 39 ppm (Ko et al., 1981a, b). Followup studies 3 years later indicated that the DTH to PPD was reduced, that the percentage of total T cells had recovered but the percentage of helper T cells was reduced and of suppressor T cells increased, and that lymphoproliferative responses were enhanced in exposed patients compared with controls (Wu et al., 1984; Lu and Wu, 1985).

The patterns of immune function alterations in the Yu-Cheng patients described above were relatively consistent between the original and 4-year followup studies. These observations would suggest a rather robust and persistent alteration in the immune parameters examined. Unfortunately, it is not clear how many, if any, of the same patients were tested in each of these different studies to allow a direct assessment of the persistence of these effects.

Mothers of Yu-Cheng children reported increased incidence of pneumonia and bronchitis in their children during the first 6 months of life (Rogan et al. 1988). In a followup study, school-age children prenatally exposed to PCBs and PCDFs (n=103), were compared with nonexposed control children (n=96) for middle-ear disease (Chao et al., 1997). The exposed children had a higher prevalence of otitis media compared with their matched controls. Furthermore, exposed children with ear disease had higher serum levels of 2,3,4,7,8-pentachloro- and 1,2,3,4,7,8-hexachloro-dibenzofurans than did children with no middle-ear disease. In the summer of 1995, 105 Yu-Cheng children and 101 control children were given physical exams (Yu et al., 1998). The frequency of influenza, but not otitis media, asthma, or enteronitis attacks, during the 6 months prior to examination, as reported by the parents of the Yu-Cheng children,

was higher than for the controls. Blood samples were obtained from 29 Yu-Cheng and 22 control children for evaluation of total serum IgM, IgG, and IgA levels, as well as percentages of circulating T cells, B cells, and NK cells. There were no differences between Yu-Cheng and control children for any of these immune parameters (Yu et al., 1998).

Tests of altered immune function were also described in Michigan dairy farmers exposed to PBBs through contaminated dairy products and meat in 1973 (Bekesi et al., 1979). As in the PCB-exposed patients, the percentage and absolute numbers of T cells in peripheral blood of PBB-exposed farmers were significantly reduced compared with a control group. However, in contrast to PCB-exposed individuals (Lu and Wu, 1985), lymphoproliferation responses to PHA, PWM, and allogeneic leukocytes were significantly decreased in PBB-exposed persons. Also in contrast to PCB exposure, skin testing using standard recall antigens indicated that PBB-exposed farmers had significantly increased responses, particularly to candida and Varidase. Tissue levels of PBBs in the subjects were not determined in this study.

In contrast, another study of Michigan residents exposed to PBBs revealed no significant differences in lymphocyte number or function compared with nonexposed individuals (Landrigan et al., 1979; Silva et al., 1979). The exposed cohort in this study was drawn from individuals who lived on PBB-quarantined farms, who received food directly from such farms, or who worked or were related to workers engaged in PBB manufacture. No differences in the total leukocyte counts, the absolute numbers of T or B peripheral blood lymphocytes, or the in vitro responses to PHA, Con A, and PWM were observed between this high-exposure group (mean serum PBB level of 787 ppb [range of 188 to 2560], n=32) and a low- exposure group (mean serum PBB level of 2.8 ppb [range of <1 to 11], n=51).

Several studies have also examined the effects of occupational or environmental exposure to TCDD in human populations. Webb et al. (1989) reported the findings from immunologic assessment of 41 persons from Missouri with documented adipose tissue levels of TCDD resulting from occupational, recreational, or residential exposure. Of the participants, 16 had tissue TCDD levels less than 20 ppt, 13 had levels between 20 and 60 ppt, and 12 had levels greater than 60 ppt. The highest level was 750 ppt. Data were analyzed by multiple regression based on adipose tissue level and the clinical dependent variable. Increased TCDD levels were correlated with an increased percentage and total number of $OKT8^+$ ($CD8^+$) cells and increased percentages of $OKT11^+$ (i.e., $CD2^+$) and $OKT3^+$ (i.e., $CD3^+$) T lymphocytes. However, the percentage and total number of $OKT4^+$ cells were not altered. Lymphoproliferative responses to Con A, PHA, PWM, or TT were unaltered, as was the cytotoxic T cell response. Serum IgA, but not IgG, was increased. No adverse clinical disease was associated with TCDD levels in these subjects. Only 2 of the 41 subjects reported a history of chloracne.

The above findings differ from those reported for the Quail Run Mobile Home Park resident cohort study using 152 exposed and 151 unexposed individuals (tissue levels unknown) in which decreased T cell percentages and suppressed cell-mediated immunity were reported (Hoffman et al., 1986). The exposed group was reported to have decreased percentages of PBL $OKT3^+$, $OKT4^+$, and $OKT11^+$ T cells. Using seven standardized recall antigens (i.e., tetanus, diphtheria, *Streptococcus*, tuberculin, *Candida*, *Proteus*, and *Trichophyton*), the researchers observed a significant decrease in the DTH response of TCDD-exposed individuals compared with unexposed controls. The exposed group had an increased frequency of anergy (11.8% vs. 1.1%) and relative anergy (35.3% vs. 11.8%) compared with unexposed controls. However, it is important to note that there were significant technical problems with the interpretation of the skin test responses in this study. Nearly 50% of the skin test data were not used because two of the four skin test readers were inexperienced. Subsequent retesting of these anergic subjects, however, failed to confirm the DTH anergy (Evans et al., 1988). The only T cell measures outside the normal range, which were determined from the initial Quail Run study of Hoffman et al. (1986), were the percentage of $OKT4^+$ cells and the $OKT4^+/OKT8^+$ ratios, which were lower compared with unexposed controls (Evans et al., 1988). On the other hand, when serum from some of these individuals was tested for levels of the thymic peptide, thymosin alpha-1 (Thy_{a-1}), the entire frequency distribution for the TCDD-exposed group shifted toward lower Thy_{a-1} levels (Stehr-Green et al., 1989). The significant difference between the TCDD-exposed persons and controls remained after controlling for age, sex, and socioeconomic status, with a trend of decreasing Thy_{a-1} levels with increasing number of years of residence in the TCDD-contaminated residential area. Thy_{a-1} levels were not correlated with changes in other immune system parameters or with any increased incidence of clinically diagnosed immune suppression. The decrease in Thy_{a-1} levels in humans contrasts with the increase in Thy_{a-1} seen in PCB-treated monkeys (Tryphonas et al., 1991b). Thy_{a-1}, a product of thymic epithelial cells, has a role in modulating the differentiation of prothymocytes to mature thymocytes (Low and Goldstein, 1984).

In July 1976 an explosion in a chemical plant producing trichlorophenol herbicides near Seveso, Italy resulted in the release of TCDD estimated at 1.7 kg (Pocchiari et al., 1979). Several epidemiological evaluations were performed on exposed individuals after the accident. Pocchiari et al. (1979) summarized results of periodic evaluations of immune status of a group of 45 children (21 of whom had chloracne) age 3 to 7 years exposed to TCDD in Zone A, which was the most heavily contaminated area. No abnormalities were reported for the following parameters: serum immunoglobulin concentrations, levels of circulating complement, lymphoproliferative responses to T and B cell mitogens or alloantigens in the MLR, or PBL T and B cell populations. Interestingly, in the summary of a study conducted 6 years after the

explosion, a different cohort of TCDD-exposed children was reported to have exhibited a significant increase in complement protein levels, which reportedly correlated with incidence of chloracne as well as increased numbers of peripheral blood lymphocytes and increased lymphoproliferative responses (Tognoni and Bonaccorsi, 1982; Mocarelli et al., 1986, 1991). However, no specific health problems were correlated with dioxin exposure in these children. Unfortunately, none the studies cited above present any quantitative data. Specific information about the methods and results are not presented. A cursory description of the tests employed and the results obtained are the only information provided for the immune function evaluations. This is extremely unfortunate, because a critical evaluation of these studies and their conclusions cannot be made.

A more thorough study examined possible associations between occupational exposure to the herbicide Agent Orange and its dioxin contaminate and adverse health experienced by Air Force personnel who served in Operation Ranch Hand units in Vietnam from 1962 to 1971 (Roegner et al., 1991) and is summarized by Wolfe et al. (1992). Immunological tests were carried out on a random sample of approximately 40% of the 1,670 participants for whom dioxin measurements in serum were made. Statistical models were used to evaluate associations between test parameters and serum dioxin levels using estimated initial and current serum dioxin levels. The statistical models were implemented using minimal assumptions (only Ranch Hands with current dioxin levels above 10 ppt) and maximal assumptions (all Ranch Hands with current dioxin levels above 5 ppt). The immunological tests included the following: DTH response to the recall antigens *Candida*, mumps, *Trichophyton*, and Staphage-lysate; PBL subsets CD2 (total T cells), CD20 (B cells), CD4 (helper/inducer T cells), CD8 (suppressor/cytotoxic T cells), CD14 (APC monocytes), CD25 (IL-2 receptor positive activated T cells), HLR-DR (B cells, activated T cells and monocytes that present antigen to $CD4^+$ T cells), CD4/CD8 ratio, and TLC (total lymphocytes in circulation); total serum IgM, IgG, and IgA levels; lymphoproliferative response to PHA; NKCI and NKCA activity, which measure NK cell lytic activity with and without IL-2 treatment, respectively; and mixed leukocyte culture (MLC) response (Roegner et al., 1991). This immunological assessment did not find any clinically significant alterations associated with current or initial levels of serum dioxin. A significant association between initial dioxin level and increased IgA levels was found; however, IgM and IgG levels did not indicate the presence of any dioxin-related effects. There was no association between the DTH response and serum dioxin levels. Despite several significant findings for some of the other immunological parameters examined, these data were deemed to be either internally inconsistent or not in a direction expected in an impaired immune system (Roegner et al., 1991; Wolfe et al., 1992).

Results of a followup examination of Air Force personnel involved in Operation Ranch Hand are presented in a report by Grubbs et al. (1995). Many of the immunologic parameters in

the earlier study were examined in this study, with the following exceptions. The PBL subset CD3 (pan T cells) replaced CD2, and CD5 (T cells and B cells) and CD16+CD56 (NK cells) were added to the test screen. The PBL PHA response, NKCI and NKCA activity assays, and MLC response were not performed. However, an autoantibody lupus panel, including tests for antinuclear antibodies; thyroid microsomal antibody; mouse stomach and kidney (MSK) smooth muscle, mitochondrial, and parietal antibodies; and rheumatoid factor, was included in this study. A marginal positive association was found between IgA levels and initial serum dioxin (Grubbs et al., 1995), as reported in the earlier study (Roegner et al., 1991). Also, an inverse relationship was found with dioxin exposure and the presence of autoantibodies to MSK smooth muscle, rheumatoid factor, and the lupus panel summary index. Although Grubbs et al. (1995) recommended that these findings be investigated and clarified in further followups, they concluded that no clinically significant indicators that reflected a consistent relationship between serum dioxin and immune function deficiencies were found in this study.

The most recent followup examination of Air Force personnel involved in Operation Ranch Hand occurred in 1992, and the results and analyses of immune parameters and dioxin body burden were reported by Michalek et al. (1999). A total of 2,233 veterans (Ranch Hand, n=952; Comparison, n=1,281) participated in this physical exam. The immunologic parameters examined in this study were the same as those in the previous followup study (Grubbs et al., 1995). Analysis of the results of the 1992 followup exam revealed only three statistically significant differences. First, an increase was observed in absolute $CD20^+$ (B cells) count in the Background group, whereas the mean absolute count of $CD16^+CD56^+CD3^+$ (T) cells was decreased in the High category. Second, three dioxin-exposed veteran categories (Background, Low, and High) had increased positive thyroid microsomal autoantibody tests; however, only the Low category was significant. Third, there was no significant association between dioxin-exposed veterans and total serum immunoglobulin levels, or in the presence of other autoantibodies. As with the earlier Ranch Hand studies, the authors concluded that there was no consistent relationship between dioxin exposure category and immune system alteration in Ranch Hand veterans (Michalek et al., 1999).

Other human studies involving smaller cohorts, in which exposure to PHAHs was documented, report alterations in certain immunological parameters. Eighteen workers (8 of whom had chloracne) were evaluated for immunological abnormalities 17 years after exposure to TCDD (no tissue levels were reported) in an industrial accident in a plant manufacturing the herbicide 2,4,5 trichlorophenoxyacetic acid (Jennings et al., 1988). Immunological parameters evaluated were the following: serum IgM, IgG, and IgA levels; antinuclear antibodies; immune complexes; T lymphocyte subsets and NK cells; and lymphoproliferative response to PHA. Antinuclear antibodies and immune complexes were detected more frequently in the peripheral

blood of workers exposed to dioxin. No differences were observed in the total number of T or B lymphocytes or in the T4/T8 ratio; however, NK cells identified by the surface marker Leu-7 were higher in the dioxin-exposed workers (Jennings et al, 1988). The significance of these findings is unknown, because only a small cohort was studied and the autoantibody results were opposite to those reported by Grubbs et al. (1995). Also, there are no animal data that indicate increased NK cells associated with TCDD exposure. The NK results also differ from results of a more recent human study by Svensson et al. (1994), who reported that men with high consumption of PHAH-contaminated Baltic Sea fatty fish (n=23) had lower proportions and numbers of PBL NK cells (i.e., $CD56^+$ cells) compared with men with virtually no fish consumption (n=20). NK cells were negatively associated with blood levels of several persistent organochlorine compounds and with estimated intake of fish. Fish consumption, however, was not associated with any alterations in other cell subsets, plasma immunoglobulin levels, or liver enzyme activities. It is important to point out that no attempt was made to determine if the decreased numbers of NK cells were correlated with reduced NK function in this study or with increased NK activity in the study described by Jennings et al. (1988).

A retrospective cohort morbidity study of 158 men accidentally exposed in 1953 to TCDD during the production of trichlorophenol was reported by Zober et al. (1994), in which 73 men had back calculated TCDD values of >1,000 ppt and 85 had values of <1,000 ppt. Increased frequency of upper respiratory tract infections was observed in individuals who had severe chloracne. However, it was indicated that differences in the utilization rates of medical care by the exposed and referent groups could have biased the findings. A clinical study of the 138 men exposed to TCDD in the accident described above attempted to determine if any TCDD dose relationships existed within the exposed population for a number of clinical and immunological parameters (Ott et al., 1994). Increases in serum IgA and IgG and increases in complement C3 and C4 were seen with high current and back-calculated TCDD concentrations and with high current TCDD concentrations, respectively. Marginal decreases in the percentage of lymphocytes, NK cells, T cells, T helper cells, and T suppressor cells were also observed (Ott et al., 1994). However, mean values for all of these parameters were comparable to those of internal referent groups of 42 to 196 individuals (number of referents differed among the parameters examined) who were not part of this clinical study but who participated in routine occupational medical examinations during the same period (Ott et al., 1994).

In another retrospective study, T helper cell function was evaluated in 11 workers, 45 to 63 years of age, who were exposed to high levels of TCDD and other PCDDs between 1966 and 1976 in production and maintenance operations at a German chemical factory producing 2,4,5-trichlorophenol (Tonn et al., 1996). TCDD body burdens were still high (43 to 874 pg/g blood or a mean of 330, which is 10 times higher than in the average German population) 20 years after

exposure. No differences were detected between exposed and control groups for surface marker distribution (e.g., CD3, CD4, CD8, CD19, CD45RO, CD45RA, CD56 or CD57) or mitogen-induced lymphoproliferation responses (e.g., PHA or PWM). However, the exposed group showed reduced lymphoproliferation in response to human lymphocyte antigen-allogeneic lymphocytes (e.g., MLR) and IL-2 stimulation. It was concluded that TCDD has a long-term immunosuppressive effect on T helper cells manifested by reduced function of these cells rather than by reduction in the cell numbers in peripheral blood (Tonn et al., 1996).

Neubert et al. (1993) attempted to determine if workers with moderately increased body burdens of TCDD and related PHAHs (25 to 140 ppt TCDD or 104 to 522 ppt International-Toxicity Equivalencies [I-TE] in blood lipids) displayed altered patterns of PBL subsets similar to those observed in TCDD-exposed marmosets (Neubert et al., 1990, 1991, 1992). A slight trend in increased percentage of $CD4^{+}CD45RO^{+}$ helper-inducer T cells was observed. However, Neubert et al. (1993) concluded that these alterations were of no medical relevance. Furthermore, the data did not support an assumption that moderately increased body burdens of PCDDs/PCDFs in adults result in decreased cellular components of the human immune system. Because adult humans, as well as adult marmosets, are less susceptible to PCDD/PCDF-associated alterations in PBL subsets than are adolescent marmosets, Neubert et al. (1993) suggested that exposure to PHAHs during early development may be the important factor influencing altered lymphocyte subsets.

In a more recent study, Neubert et al. (1995a) evaluated the in vitro lymphoproliferative responses to Con A, PHA, PWM, anti-CD3, and TT of PBL from the same workers described above. No decrease in the lymphoproliferative capacity of lymphocytes from these workers with moderately increased PCDD/PCDF body burdens was observed compared with lymphocyte responses of individuals with PCDD/PCDF body burdens within the reference range (1 to 3 ppt TCDD or 9 to 29 ppt I-TE in blood lipids) for any of these lymphocyte stimulators.

A retrospective examination of possible associations between altered immune parameters and occupational exposure to TCDD of chemical plant workers involved in the manufacture of 2,4,5-trichlorophenate and its derivatives between 1951 and 1972 was reported by Halperin et al. (1998). A total of 259 workers and 243 unexposed referents were included in this study. The workers had had substantial exposure to TCDD as indicated by a lipid adjusted mean serum TCDD concentration of 229 ppt, whereas the controls had a mean TCDD concentration of 6 ppt. Peripheral blood leukocytes and lymphocytes were enumerated, and lymphocytes were evaluated by flow cytometry for a variety of populations including T cells, B cells, and NK cells. In vitro assays for peripheral blood NK cell activity and lymphoproliferative activity of cultured lymphocytes in the presence of the mitogens PHA, ConA, or PWM, or the antigens mumps, Candida, or TT were performed. Total serum concentrations of IgM, IgG, and IgA and

complement factor C3 were also determined. Of the various TCDD categories (based on workers' serum TCDD concentration) except the lowest, there were increased odds of having lower CD26 (activated T cells) counts. In addition, there was a decreased spontaneous proliferation of cultured lymphocytes (i.e., no mitogen or antigen present in the culture); however, lymphocytes from workers in the high TCDD category had increased proliferation in the presence of ConA and PWM. No other immune parameters were affected. It was concluded that the results were unlikely to be of clinical significance (Halperin et al., 1998).

The immunologic effects of pre- and postnatal background exposure to PCBs/dioxins of Dutch infants from birth to 18 months of age were presented in a study by Weisglas-Kuperus et al. (1995). Prenatal PCB exposure was estimated from the sum of PCB congeners 118, 138, 153, and 180 in maternal blood (i.e., 2.25 ± 0.98 μg/L, n=206) and the TEQ level in milk based on 17 PCDDs/PCDFs and 8 dioxin-like PCB congeners (i.e., 66.6 ± 24.4 pg/g fat, n=80). Postnatal exposure was calculated as a product of the total TEQ level in milk multiplied by the weeks of breast-feeding. No relationship was found between pre- and postnatal PCB/dioxin exposure and respiratory tract symptoms (i.e., number of periods with rhinitis, bronchitis, tonsillitis, and otitis) or humoral antibody production at 18 months to vaccination against mumps, measles and rubella at 14 months. Higher prenatal exposure was associated with alterations in T cell subsets, in which increased number of $TCR\gamma\delta^+$ T cells correlated with a total higher TEQ level at birth. Further, higher prenatal exposure was also associated with increased total numbers of T cells, $CD8^+$ cells and $TCR\gamma\delta^+$ T cells at 18 months of age; correlating with higher TEQ levels. A higher TEQ level was also associated with a decreased number of monocytes and granulocytes at 3 months. Despite these statistical associations of cell types with TEQ levels, all values were found to be within normal range. It was indicated that the subtle changes in the number of blood leukocytes do not necessarily mirror alterations in the cell composition of lymphoid and nonlymphoid organs nor do they reflect functional defects (Weisglas-Kuperus et al., 1995).

In a followup study, Weisglas-Kuperus et al. (2000) examined whether changes associated with prenatal exposure to PCBs persist into later childhood. At 42 months of age, antibody levels to measles and mumps were negatively correlated with cord and maternal PCB levels, respectively. A higher prevalence of recurrent middle ear infections and chicken pox, as well as a lower incidence of allergic reactions, were associated with current PCB body burdens. Also, there were significant positive correlations between prenatal PCB exposure and the numbers of peripheral blood lymphocytes and $CD3^+CD8^+$(cytotoxic), $CD4^+CD45RO^+$ (memory), $TcR\alpha\beta^+$, and $CD3^+$HLA-DR^+ (activated) T cells. These values, however, were within the normal range for children at this age. The authors concluded that perinatal background exposure to PCBs and dioxins might be associated with increased susceptibility to infectious diseases.

In summary, no clear pattern of altered immune parameters following exposure to TCDD or related PHAHs has emerged from studies in humans. The basis for the lack of consistent, exposure-related effects is unknown and may depend on several factors. These include the generic difficulties in assessing subclinical immunomodulation using assays with very broad ranges of normal responses, which reduce the sensitivity to detect small changes in a heterogeneous human population. Furthermore, the choice of immune parameters used to evaluate humans exposed to TCDD and related PHAHs has been based to a greater extent on what is clinically feasible than on what has been shown to be sensitive in animal studies. Thus, lack of consistent or significant immunotoxic effects in humans resulting from TCDD exposure may be as much a function of the assays used as of the immune status of the cohort.

An interesting observation, relative to the human data, is that T cells and T cell functions appear to be more frequently affected than other immune cells or functions when PHAH exposure related effects have been reported. This may simply reflect the fact that T cell assays predominate over other assays employed in these studies. Nevertheless, it is interesting that several studies report slight reductions in $CD4^+$ T helper cells (Chang et al., 1981; Wu and Lu, 1984; Lu and Wu, 1985; Hoffman et al., 1986; Evans et al., 1988). Reductions in $CD4^+$ cells and $CD4^+$ subsets have also been reported in non-human primates exposed to PHAHs (Hong et al., 1989; Neubert et al., 1990, 1991, 1992; Tryphonas et al., 1991b). These reductions may not translate into significant immune effects. However, the fact that these cells play a pivotal role in regulating immune responses and that their reduction may presage immunosuppression suggests that these observations are worth further investigation.

4.9. IMMUNOTOXICITY OF PHAHS IN HUMANS: IN VITRO EXPOSURE

Several laboratories have examined the direct effects of TCDD on human lymphocytes in vitro. Neubert et al. (1991) reported decreased PBL subpopulations from humans and nonhuman primates cultured in the presence of TCDD. $CD4^+CD29^+$ helper-inducer/memory T cells and $CD20^+$ B cells were dose-dependently decreased in PWM-stimulated cultures of human PBLs at concentrations as low as 10^{-12} to 10^{-14} M TCDD. However, an attempt to corroborate these findings failed to detect any suppression in human PBL subpopulations, including $CD4^+CD29^+$ helper-inducer/memory T cells and $CD19^+$ B cells, at TCDD concentrations ranging from 10^{-7} to 10^{-14} M (Lang et al., 1994). Furthermore, PWM- or anti-CD3-stimulated lymphocyte proliferation was not altered by TCDD at concentrations of 10^{-7} to 10^{-11} M (Lang et al., 1994).

Similar negative results were obtained by Wood et al. (1992), who reported that exposure of human tonsillar lymphocytes (HTLs) to concentrations of 3×10^{-8} to 3×10^{-10} M TCDD did not affect either PWM-induced proliferation or IgM antibody production. In contrast, 3×10^{-8} to 3×10^{-10} M TCDD suppressed toxic shock syndrome toxin (TSST-1)–induced IgM secretion of

HTL B cells (Wood and Holsapple, 1993). The sensitivity of the HTL B cells to TCDD suppression of TSST-1–induced IgM secretion, however, was found to be highly variable among the different donors. In a separate study, concentrations of 3×10^{-8} to 3×10^{-10} M TCDD suppressed the background proliferation and IgM secretion of low-density HTL B cells (predominately activated cells), but not high-density HTL B cells (predominately resting cells) (Wood et al., 1993). TCDD also suppressed LPS plus T cell replacement factor–stimulated proliferation and IgG secretion of low-density, but not high-density, HTL B cells. These results suggest that TCDD may have a direct effect on HTL low-density B cells and that this lymphocyte subpopulation may be a sensitive target for TCDD.

More recently, Masten and Shiverick (1995) investigated the effect of TCDD on expression of the CD19 gene in the IM-9 human B lymphocyte cell line in an attempt to determine a possible mechanism for TCDD-induced inhibition of human and murine B lymphocyte Ig production. CD19 is a B cell surface signal transducing protein that is expressed from early stages of B cell development, but is lost when B cells differentiate into antibody-producing plasma cells (Tedder et al., 1994). TCDD treatment of IM-9 cells decreased the steady state levels of CD19 mRNA by 67%. A DNA-binding complex in IM-9 nuclear extracts was identified that, based on several criteria, appeared to be the AhR. Furthermore, the AhR complex recognized a DNA binding site for B cell lineage–specific activator protein (BSAP) in the promotor region of the CD19 gene. This BSAP binding site is similar to the consensus AhR DNA binding site. Based on these results, Matsen and Shiverick (1995) suggest that the decrease in CD19 gene expression following TCDD exposure may result from the AhR interfering with BSAP-stimulated CD19 transcription. Further work, however, is required to support this hypothesis. Nevertheless, it is interesting that this work supports the animal in vitro work of Holsapple and coworkers, which indicates that the B cell is a primary cellular target for the direct effects of TCDD (Holsapple, 1995). It also goes beyond the in vitro animal work in that it provides further evidence that the AhR is involved in PHAH-induced immunotoxicity.

4.10. SUMMARY

Cumulative evidence from a number of studies indicates that the immune system of various animal species is a target for toxicity of TCDD and structurally related PHAHs, including other PCDDs, and PCDFs and PCBs. Both cell-mediated and humoral immune responses are suppressed following TCDD exposure, suggesting that multiple cellular targets within the immune system are altered by TCDD. Evidence also suggests that the immune system is indirectly targeted by TCDD-induced changes in nonlymphoid tissues. TCDD exposure of experimental animals results in decreased host resistance following challenge with certain

infectious agents, which likely result from TCDD-induced suppression of immunological functions.

The primary antibody response to the T cell–dependent antigen SRBCs is the most sensitive immunological response that is consistently suppressed in mice exposed to TCDD and related PHAHs. The degree of immunosuppression is related to the potency of the dioxin-like PHAH congeners. There is remarkable agreement among several different laboratories for the potency of a single acute dose of TCDD (suppression at a dose as low as 0.1 μg TCDD/kg with an average ID_{50} value of approximately 0.7 μg TCDD/kg) to suppress this response in Ah-responsive mice. Results of studies that have compared the effects of acute exposure to individual PCDD, PCDF, and PCB congeners, which differ in their binding affinity for the AhR, on this response have provided critical evidence that certain dioxin-like congeners are also immunosuppressive. The degree of immunosuppression has been found to be related to potency of the dioxin-like congeners. Antibody responses to T cell–independent antigens, such as TNP-LPS, and the CTL response are also suppressed by a single acute exposure to TCDD, albeit at higher doses than those that suppress the SRBC response. A limited number of studies reveal that dioxin-like congeners also suppress these responses, with the degree of suppression related to the congeners' AhR binding affinity. Although a thorough and systematic evaluation of the immunotoxicity of TCDD-like congeners in different species and for different immunological endpoints has not been performed, it can be inferred from the available data that dioxin-like congeners are immunosuppressive.

In addition to the TCDD-like congener results, studies using strains of mice that differ in the expression of the AhR have provided critical evidence to support a role for Ah-mediated immune suppression following PHAH exposure. Recent in vitro work also supports a role for Ah-mediated immune suppression. Other in vivo and in vitro data, however, suggest that non-Ah-mediated mechanisms may also function in PHAH-induced immunotoxicity. However, more definitive evidence remains to be developed to support this latter view.

Although in mice the immunosuppressive potency of individual PHAHs is related to their structural similarity to TCDD, this pattern of suppression is observed only after exposure to an individual PHAH. The immunotoxicity of TCDD and related congeners can be modified by co-exposure to PHAHs in simple binary or more complex mixtures resulting in additive or antagonistic interactions. Dose-response data are needed on acute, subchronic, and chronic exposure to the individual PHAHs in a mixture and on the mixture itself in order to fully evaluate potential synergistic, additive, or antagonistic effects of environmentally relevant PHAH mixtures.

Perinatal exposure of experimental animals to TCDD results in suppression of primarily T cell immune functions, with evidence of suppression persisting into adulthood. The effects on

T cell functions appear to be related to the fact that perinatal TCDD exposure of mice alters thymic precursor stem cells in the fetal liver and bone marrow, and thymocyte differentiation in the thymus. These studies suggest that perinatal development is a critical and sensitive period for TCDD-induced immunotoxicity. Efforts should be made to determine the consequences of perinatal exposure to TCDD congeners and PHAH mixtures on immune system integrity.

Animal host resistance models that mimic human disease have been used to assess the effects of TCDD on altered host susceptibility. TCDD exposure increases susceptibility to challenge with bacteria, viruses, parasites, and tumors. Mortality is increased in TCDD-exposed mice challenged with certain bacteria. Increased parasitemia occurs in TCDD-exposed mice and rats challenged with parasitic infections. Low doses of TCDD also alter resistance to virus infections in rodents. Increased susceptibility to infectious agents is an important benchmark of immunosuppression; however, the role of TCDD in altering immune-mediated mechanisms important in murine resistance to infectious agents remains to be elucidated. Also, since little is known about the effects of dioxin-like congeners on host resistance and nothing is known about the relation between the AhR and host resistance, more research is recommended in this area.

Studies in nonhuman primates exposed acutely, subchronically, or chronically to PHAHs have revealed variable alterations in lymphocyte subpopulations, primarily T lymphocyte subsets. On the other hand, in three separate studies in which monkeys were exposed subchronically or chronically to PCBs, the antibody response to SRBC was consistently found to be suppressed. These results in nonhuman primates are important because they corroborate the extensive database of PHAH-induced suppression of the antibody response to SRBC in mice and thereby provide credible evidence for immunosuppression by PHAHs across species. In addition, these data indicate that the primary antibody response to this T cell–dependent antigen is the most consistent and sensitive indicator of PHAH-induced immunosuppression.

The available database derived from well-controlled animal studies on PHAH immunotoxicity can be used for the establishment of no-adverse-effect levels. Because the antibody response to SRBCs has been shown to be dose-dependently suppressed by TCDD and related PHAHs, this database is best suited for the development of dose-response modeling.

Accidental or occupational exposure of humans to TCDD and related PHAHs variably affects a number of immunological parameters. Unfortunately, evaluation of immune system integrity in humans exposed to PHAHs has provided data that are inconsistent across studies. The broad range of "normal" responses in humans due to the large variability inherent in a heterogenous population, the limited number and sensitivity of tests performed, and the poor exposure characterization of the cohorts in these studies compromise any conclusions about the ability of a given study to detect immune alterations. Consequently, there are insufficient clinical data from these studies to fully assess human sensitivity to PHAH exposure. Nevertheless, the

database of the results of the extensive animal work is sufficient to indicate that immune effects could occur in the human population from exposure to PHAHs at some dose level.

It is interesting that a common thread in several human studies is the observed reduction in $CD4^+$ T helper cells, albeit generally within the "normal" range, in cohorts exposed to PHAHs. These reductions may not translate into clinical effects, but it is important to note that such cells have an important role in regulating immune responses and that their reduction in clinical diseases is associated with immunosuppression. Another important consideration is that a primary antibody response following immunization was not evaluated in any of the human studies. In that this immune parameter has been revealed to be the most sensitive in animal studies, this parameter should be included in future studies of human populations exposed to PHAHs. It is also recommended that research continue on delineating the mechanism(s) underlying PHAH-induced immunotoxicity.

5. DEVELOPMENTAL AND REPRODUCTIVE TOXICITY*

5.1. INTRODUCTION

The potential for dioxins and related compounds to cause reproductive and developmental toxicity has been recognized for many years. Recent laboratory studies have broadened our knowledge in this area and demonstrate that altered development is among the most sensitive endpoints of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). This chapter reviews much of the literature on dioxin's developmental and reproductive toxicity but is not intended to be exhaustive. Special emphasis is placed on that part of the database that has accumulated since the last major EPA review of this topic (Kimmel, 1988; Peterson et al., 1993). In addition, the database is viewed in light of the Ah receptor model of TCDD action that is being examined for its applicability in the current EPA risk assessment.

To focus the analysis of the database, the chapter is divided into developmental toxicity and male and female reproductive toxicity. The authors recognize the interrelatedness of developmental and reproductive events at all levels of biological complexity. Therefore, the reader should not view the chapter subheadings within each of these divisions as defining discrete endpoints that are exclusive of other endpoints. For example, the effects of TCDD on circulating levels of sex hormones or on responsiveness to sex hormones may be translated into reproductive dysfunction if exposure occurs in adulthood or abnormal development of sexual behavior if exposure occurs perinatally. Likewise, even though organ structure and growth are considered separate manifestations in developmental toxicity that are associated with perinatal exposure to TCDD, the normal development of an organ is dependent on normal growth processes, and inhibiting perinatal growth can significantly disrupt the structural integrity of an organ system.

2,3,7,8-TCDD is one of 75 possible CDD congeners and 135 possible CDF congeners. It is one of the most potent of the CDDs, BDDs, CDFs, BDFs, PCBs, and PBBs, and as such serves as the prototype congener for investigating the toxicity elicited by these classes of chemicals. Developmental and reproductive toxicity is generally believed to be caused by the parent compound; there is no evidence that TCDD metabolites are involved. The toxic potency of TCDD is due to the number and position of chlorine substitutions on the dibenzo-*p*-dioxin molecule. CDD congeners with decreased lateral (2, 3, 7, and 8) or increased nonlateral chlorine and bromine substituents are less potent than TCDD (Safe, 1990); however, most of these

*The information contained in portions of this chapter has been published previously as follows: Peterson, RE; Theobald, HM; Kimmel, GL. (1993) Critical Reviews in Toxicology 23(3):283-335. The article underwent Agency and peer review and was approved for publication.

congeners will produce toxicity, and the pattern of responses within animals of the same species, strain, sex, and age will generally be similar to that of TCDD (McConnell and Moore, 1979; Poland and Knutson, 1982). PCB congeners with zero or one *ortho* chlorines, two *para* chlorines, and at least two *meta* chlorines can assume a coplanar conformation sterically similar to TCDD and also produce a pattern of toxic responses similar to that of TCDD. In contrast, PCB congeners with two or more *ortho* chlorines cannot assume a coplanar conformation and do not resemble TCDD in toxicity (Poland and Knutson, 1982; Safe, 1990).

CDD and CDF congeners chlorinated in the lateral positions, as compared with those lacking chlorines in the 2, 3, 7, and 8 positions, are preferentially bioaccumulated by fish, reptiles, birds, and mammals (Stalling et al., 1983; Cook et al., 1991; U.S. EPA, 1991). Furthermore, coplanar PCBs and/or monoortho-chlorine-substituted analogs of the coplanar PCBs bioaccumulate in fish, wildlife, and humans (Tanabe, 1988; Kannan et al., 1988; Mac et al., 1988; Kubiak et al., 1989; Smith et al., 1990). This is of concern because combined effects of the lateral-substituted CDD, BDD, CDF, BDF, PCB, and PBB congeners acting through an Ah receptor mechanism have the potential of decreasing feral fish and wildlife populations secondary to developmental and reproductive toxicity (Gilbertson, 1989; Walker and Peterson, 1991; Walker et al., 1991; Cook et al., 1991). Humans are not exempt from the developmental and reproductive effects of complex halogenated aromatic hydrocarbon mixtures. Such mixtures that contain both TCDD-like congeners and non-TCDD-like congeners have been implicated in causing developmental and reproductive toxicity in the Yusho and Yu-Cheng poisoning incidents in Japan and Taiwan (Kuratsune, 1989; Hsu et al., 1985; Rogan, 1989). Thus, exposure to TCDD-like congeners is a health concern for humans as well as for domestic animals, fish, and wildlife, although the relative contributions of TCDD-like and non-TCDD-like congeners are not known in some exposure situations.

A mechanism of action that CDD, BDD, CDF, BDF, PCB, and PBB congeners substituted in the lateral positions have in common is that they bind to the Ah receptor, which dimerizes with the Ah receptor nuclear translocator protein (ARNT) in the nucleus. These liganded heterodimeric complexes bind to specific sequences of DNA referred to as dioxin-responsive enhancers (DREs), resulting in alterations in gene transcription. There is evidence that this Ah receptor mechanism may be involved in the antiestrogenic action of TCDD and in its ability to produce the structural malformations of cleft palate and hydronephrosis in mice. Recent interest has also focused on the potential nonnuclear interaction of the Ah receptor within the cell (see Chapter 2).

5.2. DEVELOPMENTAL TOXICITY

The manifestations of developmental toxicity from exposure to TCDD have been divided into three categories for convenience in assessing the database with respect to an Ah receptor-mediated response. These categories include death/growth/clinical signs, structural malformations, and postnatal functional alterations. Exposure-related effects on death/growth/clinical signs are described for fish, birds, laboratory mammals, and humans along with structure-activity results that are consistent with, but do not prove, an Ah receptor-mediated mechanism. Structural malformations, particularly cleft palate formation and hydronephrosis, occur in mice. In other mammalian species, however, postnatal functional alterations, some of which may be irreversible, are the most sensitive adverse developmental effects of TCDD-like congeners. These include effects on the male and female reproductive systems in rats and hamsters, and object learning behavior in monkeys.

5.2.1. Death/Growth/Clinical Signs

5.2.1.1. *Fish*

Early life stages of fish appear to be more sensitive to TCDD-induced mortality than adults. This is suggested by the LD_{50} of TCDD in rainbow trout sac fry (0.4 μg/kg egg weight) being 25 times less than that in juvenile rainbow trout (10 μg/kg body weight) (Walker and Peterson, 1991; Kleeman et al., 1988). The significance of this finding is that early life stage mortality caused by high concentrations of TCDD-like congeners in fish eggs may pose the greatest risk to feral fish populations (Walker and Peterson, 1991; Cook et al., 1991). Cooper (1989) reviewed the developmental toxicity of CDDs and CDFs in fish, and Cook et al. (1991) discussed components of an aquatic ecological risk assessment for TCDD in fish. The reader is referred to this literature for more indepth coverage than is presented here.

TCDD is directly toxic to early life stages of fish. This has been demonstrated for Japanese medaka, pike, rainbow trout, and lake trout exposed as fertilized eggs to graded concentrations of waterborne TCDD. In these species, TCDD causes an overt toxicity syndrome characterized by edema, hemorrhages, and arrested growth and development culminating in death (Helder, 1980, 1981; Wisk and Cooper, 1990a; Spitsbergen et al., 1991; Walker et al., 1991; Walker and Peterson, 1991). Histopathologic evaluation of lake trout embryos and sac fry has shown this syndrome to be essentially identical to that of blue sac disease (Helder, 1981; Spitsbergen et al., 1991). Following egg exposure to TCDD, signs of toxicity are not detected in medaka until after the liver rudiment forms (Wisk and Cooper, 1990a), and in lake trout toxicity is first detected ~1 week prior to hatching but becomes fully manifest during the sac fry stage (Spitsbergen et al., 1991; Walker et al., 1991). Among all fish species investigated thus far, lake trout are the most sensitive to TCDD developmental toxicity. Following exposure of fertilized

lake trout eggs to graded waterborne concentrations of TCDD, the no observable adverse effect level (NOAEL) for sac fry mortality is 34 pg TCDD/g egg, the lowest observed adverse effect level (LOAEL) is 55 pg TCDD/g egg, and the egg TCDD concentration that causes 50% mortality above control at swim up (LD_{50}) is 65 pg TCDD/g egg (Walker et al., 1991). Thus, TCDD is a potent developmental toxicant in fish, and the effect is not secondary to maternal toxicity.

The Ah receptor has not been identified in early life stages of fish; however, it is assumed to be present because PCBs induce hepatic cytochrome P-4501A1 in lake trout and brook trout embryos and fry (Binder and Stegeman, 1983; Binder and Lech, 1984). The Ah receptor has been identified in adult rainbow trout liver (Heilmann et al., 1988) and in a rainbow trout hepatoma cell line (Lorenzen and Okey, 1990). CDD and CDF congeners that are approximate isostereomers of TCDD produce essentially the same pattern of toxic responses as TCDD in early life stages of medaka and rainbow trout, suggesting that they may act through a common mechanism (Wisk and Cooper, 1990b; Walker and Peterson, 1991). Also, in rainbow trout their potencies relative to TCDD (i.e., toxic equivalency factors, TEFs) for causing early life stage mortality (TCDD LD_{50}/congener LD_{50}) are in the same range as those proposed for human health risk assessment based on a diverse spectrum of acute and subchronic toxicity tests in mammalian species (Safe, 1990; Walker and Peterson, 1991). However, for the coplanar PCBs and monoortho-chlorinated analogs of the coplanar PCBs, TEFs based on early life stage mortality in rainbow trout are 1/14 to 1/80 less (Walker and Peterson, 1991) than the TEFs proposed for risk assessment (Safe, 1990).

5.2.1.2. *Birds*

Bird embryos are also more sensitive to TCDD toxicity than adults. The LD_{50} of TCDD in the chicken embryo (0.25 μg/kg egg weight) is 100 to 200 times less than the TCDD dose that causes mortality in adult chickens (25-50 μg/kg body weight) (Greig et al., 1973; Allred and Strange, 1977). The LD_{50} of TCDD injected into fertilized ring-necked pheasant eggs (1.1-1.8 μg/kg egg weight) is 14 to 23 times less than the TCDD dose that causes 75% mortality in ring-necked hen pheasants (25 μg/kg body weight) (Nosek et al., 1993).

Among bird species, most developmental toxicity research has been done on chickens. Injection of TCDD or its approximate isostereomers into fertilized chicken eggs causes a toxicity syndrome in the embryo characterized by pericardial and subcutaneous edema, liver lesions, inhibition of lymphoid development in the thymus and bursa of Fabricius, microphthalmia, beak deformities, cardiovascular malformations, and mortality (Cheung et al., 1981a,b; Brunstrom and Darnerud, 1983; Rifkind et al., 1985; Brunstrom and Lund, 1988; Brunstrom and Andersson, 1988; Nikolaidis et al., 1988a,b). On the other hand, injection of a coplanar PCB into fertilized

turkey eggs at a dose high enough to cause microphthalmia, beak deformities, and embryo mortality did not produce liver lesions, edema, or thymic hypoplasia, all hallmark signs of TCDD toxicity in the chicken embryo (Brunstrom and Lund, 1988). This disparity in signs of TCDD embryotoxicity among bird species is not unique to the turkey and chicken. In fertilized eggs of ring-necked pheasants and eastern bluebirds, injection of TCDD produces embryo mortality, but all of the other signs of toxicity seen in the chicken embryo are absent, including cardiovascular malformations (Thiel et al., 1988; Martin et al., 1989; Nosek et al., 1993). Thus, in bird embryos the signs of toxicity elicited by TCDD and its approximate isostereomers are highly species dependent; the only toxic effect common to all bird species is embryo mortality.

There is evidence in chicken embryos that the Ah receptor may be involved in producing developmental toxicity. The Ah receptor has been detected in chicken embryos (Denison et al., 1986; Brunstrom and Lund, 1988) and the rank order potency of PCB congeners for producing chicken embryo mortality (3,3',4,4',5-PCB > 3,3',4,4'-TCB > 3,3',4,4',5,5'-HCB > 2,3,3',4,4'-PCB > 2,3,4,4',5-PCB, with 2,2',4,5'-TCB, 2,2',4,4',5,5'-HCB, and 2,2',3,3',6,6'-HCB being inactive) is similar to that for a classic Ah receptor-mediated response in the chicken embryo, cytochrome P-4501A1 induction (Rifkind et al., 1985; Brunstrom and Andersson, 1988; Brunstrom, 1989). However, although induction of cytochrome P-4501A1 and toxicity may both be part of a pleiotropic response linked to the Ah receptor, they are not otherwise causally related. This is demonstrated by the nonsteroidal anti-inflammatory drug benoxoprofen that suppresses 3,3',4,4'-TCB-induced toxicity in the chicken embryo without altering its ability to induce microsomal enzyme activity (Rifkind and Muschick, 1983). Also, for 3,3',4,4'-TCB, 3,3',4,4',5,5'-HCB, and TCDD there is a marked dissociation of the dose-response relationship for lethality and enzyme induction in the chicken embryo (Rifkind et al., 1985).

A decreased activity of uroporphyrinogen decarboxylase (URO-D) and an increased accumulation of uroporphyrins are effects that are readily produced by exposure of cultured chicken embryo liver cells to TCDD, 3,3',4,4'-TCB, and other PCBs (Sinclair et al., 1984; Marks, 1985; Lambrecht et al., 1988). Coplanar PCB congeners are more potent inhibitors of URO-D activity in cultured chicken embryo liver cells than are noncoplanar PCB congeners (Sassa et al., 1986), suggesting an Ah receptor-mediated mechanism. Unlike the results in cultured cells, however, a lethal dose of TCDD (6 nmol/egg) does not affect URO-D activity or cause an increased accumulation of uroporphyrins in chicken embryos (Rifkind et al., 1985). Thus, TCDD-induced lethality in chicken embryos is not associated with the effects of TCDD on URO-D activity, even though a decrease in URO-D activity might be expected to occur if a sufficient dose of TCDD could be reached without being lethal.

The chicken embryo heart is a target organ for TCDD and other halogenated aromatic hydrocarbons that act by an Ah receptor mechanism. Expression of the Ah receptor occurs

ubiquitously in cardiac myocytes, while ARNT expression is restricted to myocytes that overlay the atrioventricular canal, outflow tract, and atrial and ventricular septa (Walker et al., 1997). Both Ah receptor and ARNT appear to be absent from the endocardium and endocardial- derived mesenchyme. In addition, cardiac expression of cytochrome P-4501A1 is restricted to myocardium that expresses Ah receptor and ARNT. The classic sign of chick embryo toxicity involving the heart is pericardial edema. However, TCDD has other effects on the chick embryo heart that are less well known. These include its ability to produce cardiovascular malformations and to increase cardiac release of arachidonic acid metabolites. When fertilized chicken eggs are injected with graded doses of TCDD, cardiovascular malformations are produced including ventricular septal defects, aortic arch anomalies, and conotruncal malformations. Approximately 1.6 pmol TCDD/egg (9 ng/kg egg, assuming a 55 g egg weight) causes cardiovascular malformations in 46% of treated embryos versus 29% of control embryos (Cheung et al., 1981a,b). The cardiovascular malformation response may be unique to the chicken embryo because in fertilized ring-necked pheasant and eastern bluebird eggs injected with TCDD the incidence of such malformations is not increased (Thiel et al., 1988; Martin et al., 1989; Nosek et al., 1993).

In the chicken embryo heart, arachidonic acid metabolism is stimulated by TCDD, resulting in increased formation of prostaglandins (Quilley and Rifkind, 1986). Dose-response relationships for the release of immunoreactive PGE_2, PGF_{2a}, and TxB_2 from chick embryonic heart are biphasic, with an apparent maximally effective dose of 100 pmol TCDD/egg. When the egg tetrachloroabenzene (TCDD) dose is further increased, release of these prostaglandins tends to decline towards levels in control hearts. Biphasic dose-response curves for cardiac PGE_2 release also were obtained with 3,3',4,4'-TCB and 3,3',4,4',5,5'-HCB (Quilley and Rifkind, 1986). The thymus and bursa of Fabricius are other TCDD target organs in the chicken embryo. TCDD, 3,3',4,4'-TCB, and 3,3',4,4'-TCAOB cause dose-related decreases in the lymphoid development of both of these immune system organs (Nikolaidis et al., 1988a,b, 1990). Cultured thymus anlage from chick embryos are 100 times more sensitive to TCDD's inhibitory effect on lymphoid development than cultured thymus anlage from turkey and duck embryos (Nikolaidis et al., 1988a). This suggests that the reason thymic atrophy was not seen in turkey embryos at egg doses of 3,3',4,4'-TCB that were overtly toxic (Brunstrom and Lund, 1988) was not because the turkey embryo thymus was incapable of responding to 3,3',4,4'-TCB. Rather, turkey embryos appear to be more sensitive to the lethal than to the immunotoxic effect of this coplanar PCB.

Within the same bird species, the signs of developmental toxicity elicited by TCDD and its approximate isostereomers are similar. In the chicken embryo, TCDD, 3,3',4,4',5-PCB, 3,3',4,4'-TCB, and 3,3',4,4',5,5'-HCB all cause pericardial and subcutaneous edema, liver lesions, microphthalmia, beak deformities, and mortality, and TCDD, 3,3',4,4'-TCB, and 3,3',4,4'-

TCAOB inhibit lymphoid development (Cheung et al., 1981a; Brunstrom and Andersson, 1988; Nikolaidis et al., 1988a,b). In pheasant embryos, an altogether different pattern of responses is seen. Nevertheless, the TCDD-like congeners injected into fertilized pheasant eggs, TCDD and 3,3',4,4'-TCB, produce the same pheasant embryo-specific pattern. This pattern consists of embryo mortality in the absence of edema, liver lesions, thymic hypoplasia, and structural malformations (Brunstrom and Reutergardh, 1986; Nosek et al., 1993).

The lethal potency of TCDD and its approximate isostereomers in embryos of different bird species varies widely. The chicken embryo is an outlier in that it is by far the most sensitive of all bird species to TCDD. Turkey, ring-necked pheasant, mallard duck, domestic duck, domestic goose, golden-eye, herring gull, black-headed gull, and eastern bluebird embryos are considerably less sensitive to the embryo-lethal effect of TCDD and TCDD-like congeners (Brunstrom and Reutergardh, 1986; Brunstrom and Lund, 1988; Thiel et al., 1988; Martin et al., 1989; Elliott et al., 1989; Nosek et al., 1993). TCDD is 4 to 7 times more potent in causing embryo mortality in chicken than pheasant embryos, and 3,3',4,4'-TCB is 20 to 100 times more potent in chicken than turkey embryos (Allred and Strange, 1977; Brunstrom and Lund, 1988; Nosek et al., 1989). In chicken embryos, an egg dose of 3,3',4,4'-TCB of 4 μg/kg increased embryo mortality, whereas an egg dose of 100 μg/kg of the same coplanar PCB had no embryotoxic effect in pheasants and mallard ducks and a dose of 1,000 μg/kg egg had no effect on embryo mortality in domestic ducks, domestic geese, golden eyes, herring gulls, and black-headed gulls (Brunstrom, 1988; Brunstrom and Reutergardh, 1986). In contrast to the above species differences, the potency of 3,3',4,4'-TCB in causing embryo mortality among different strains of chickens is quite similar, with the LD_{50} in six different strains varying less than fourfold (Brunstrom, 1988).

Graded doses of TCDD have been administered to fertilized eastern bluebird and ring-necked pheasant eggs for the purpose of determining a LOAEL and NOAEL for embryotoxicity. Mortality was the most sensitive embryotoxic effect in both species. For eastern bluebirds, the LOAEL was 10,000 pg TCDD/g egg and the NOAEL was 1,000 pg TCDD/g egg (Martin et al., 1989). For ring-necked pheasants, the LOAEL was 1,000 pg TCDD/g egg and the NOAEL was 100 pg TCDD/g egg. The LD_{50} for embryo mortality in the ring-necked pheasant is 1,354 pg TCDD/g egg when the dose is injected into the egg albumin and 2,182 pg TCDD/g egg when the dose is injected into the egg yolk (Nosek et al., 1993). In contrast, for chickens the LD_{50} for embryo mortality is 240 pg TCDD/g egg (Allred and Strange, 1977).

5.2.1.3. *Laboratory Mammals*

5.2.1.3.1. ***Developmental expression of Ah receptor and ARNT***. The Ah receptor and its dimerization partner ARNT are expressed in a specific spatial and temporal pattern in the

developing mammalian embryo and fetus, suggesting that they play a fundamental role in development. Preimplantation mouse embryos express Ah receptor mRNA and protein (Peters et al., 1995), and spatial and temporal patterns of ARNT1, ARNT2, and Ah receptor mRNA expression occur in specific developing tissues and organs of the mouse embryo from gestational day 9.5 to 16 (Abbott et al., 1995; Abbott et al., 1995; Jain et al., 1998). On gestational day 9.5, ARNT1 mRNA is highly expressed in the neuroepithelium of the brain and spinal cord, trigeminal ganglion, branchial arches 1 and 2, heart, hepatic primordia, and primitive gut. ARNT2 message is also expressed in the neuroepithelium and in the remainder of the embryo but at comparatively lower levels. Ah receptor mRNA, in contrast to ARNT1 and ARNT2, is not expressed significantly at gestational day 9.5, but by gestational day 10 Ah receptor mRNA was expressed in the neuroepithelium of the developing brain, in the visceral arches, and in the heart. By day 13.5 or 14 of gestation, Ah receptor mRNA was abundantly expressed in the primitive pituitary, palatal shelf, nasal septal cartilage, dorsal surface of the tongue, developing thymus, lung parenchyma, liver, developing gut mucosa, kidney, urogenital sinus, and tip of the genital tubercle. ARNT1 mRNA was expressed to a high extent in various cell types of endodermal and mesodermal origin such as the lung and tongue muscle and was barely above background in the developing nervous system. The tissue distribution of ARNT2 mRNA was the inverse of ARNT1, being highest in the mantle layer of the spinal cord and brain and lowest in the endodermal and mesodermally derived tissues. The expression patterns observed at gestational day 13.5 or 14 continued to be found at gestational day 15.5 or 16 with the additional finding that ARNT2 was clearly expressed in neural crest derivatives like the dorsal root ganglia, adrenal medulla, and in developing tubules in the renal cortex. Thus, the expression of Ah receptor, ARNT1, and ARNT2 mRNAs was specific for cell type, organ/tissue, and developmental stage. Furthermore, immunohistochemical localization of Ah receptor and ARNT1 protein correlated, in general, with in situ localization of Ah receptor and ARNT1 mRNA expression at each gestational age (Abbott et al., 1995; Abbott and Probst, 1995).

5.2.1.3.2. ***Transgenic Ah receptor null mice and ARNT null mice.*** Ah receptor null (knockout) mice have been developed to determine which adverse effects of TCDD exposure are Ah receptor mediated, and to determine the effects of absence of the Ah receptor on organ system development and function. Three lines of Ah receptor null mice have been generated using different targeting methods and they are on the following genetic backgrounds: C57BL/6N x Sv/129 (Fernandez-Salguero et al., 1995), substrain of C57BL/6 x Sv/129 (Schmidt et al., 1996) and C57BL/6J x Sv/129 (Mimura et al., 1997). Ah receptor null mice in all the lines are viable, and offspring of both sexes are fertile and capable of reproduction. However, Abbott et al. (1999) reported adverse reproductive outcomes in homozygous AhR null female mice in the line

of Fernandez-Salguero et al. (1995). The range of adverse reproductive effects included deaths of the females during pregnancy and lactation, small litter size at birth, poor survival of pups during the first 2 weeks after birth, and death of Ah receptor null pups after weaning. Because low survival of the weaned homozygous Ah receptor null pups was independent of genotype of the dam, it was probably not caused by maternal factors like lactational insufficiency or aberrant maternal behaviors. However, the increased mortality of fetuses and pups prior to weaning could be due in part to impaired ability of the homozygous Ah receptor null female to support development of the fetuses, to survive pregnancy and lactation herself, and to rear pups until weaning (Abbott et al., 1999c).

The profile of effects observed in the homozygous Ah receptor null offspring were dependent on the Ah receptor null line investigated and consisted of lesions in the immune system, skin, liver, heart, stomach, spleen, and uterus (Fernandez-Salguero et al., 1995, 1996, 1997; Schmidt et al., 1996). These findings suggest that the AhR signaling pathway plays an important physiological role in development and in maintaining homeostasis as offspring age (Fernandez-Salguero et al., 1996, 1997; Schmidt et al., 1996;). Transgenic mice with a null mutation in the ARNT1 gene have also been evaluated, and unlike their AhR counterparts homozygous ARNT1 null embryos are not viable (Kozak et al., 1997; Maltepe et al., 1997). They are affected by neural tube closure defects, forebrain hypoplasia, delayed rotation of the embryo, placental hemorrhaging, visceral arch abnormalities, and death between gestational days 9.5-10.5 (Kozak et al., 1997). The primary cause of embryo mortality may be failure of the embryonic component of the placenta to vascularize and form the labyrinthine spongiotrophoblast, which is consistent with ARNT1's role in hypoxic induction of angiogenesis (Kozak et al., 1997). Thus, the ARNT1 protein appears to play an indispensable role during development that is essential for embryo survival.

5.2.1.3.3. ***Prenatal mortality.*** When exposed to TCDD during adulthood, laboratory mammals display wide differences in the LD_{50} of TCDD. It is interesting to note, however, that when exposure occurs during prenatal development, the potency of TCDD tends to be more similar across species. The LD_{50} of TCDD in adult hamsters, 1,157 to 5,051 μg/kg, makes adult hamsters three orders of magnitude more resistant to TCDD-induced lethality than are adult guinea pigs (Olson et al., 1980; Henck et al., 1981). Yet, a maternal dose of 18 μg TCDD/kg can increase the incidence of prenatal mortality in the hamster embryo/fetus. Because this dose is only twelvefold higher than the dose (1.5 μg TCDD/kg) that increases the incidence of prenatal mortality in the guinea pig, the hamster embryo/fetus approaches other rodent species in its sensitivity to TCDD-induced lethality (Olson and McGarrigle, 1990, 1991). Thus, the magnitude

of the species differences in lethal potency of TCDD is affected by the timing of TCDD exposure during the life history of the animal.

Exposure to TCDD during pregnancy causes prenatal mortality in the monkey, guinea pig, rabbit, rat, hamster, and mouse (Table 5-1). The rank order of susceptibility from the most sensitive to least sensitive species would appear to be monkey = guinea pig > rabbit = rat = hamster > mouse. However, an important caveat must be applied to the information presented in Table 5-1; i.e., that the time period during which exposure of the embryo/fetus to TCDD occurs is just as important a determinant of prenatal mortality as is the dose of TCDD administered. This point will be illustrated in the text that follows when prenatal mortality is described for different strains of mice.

It is important to note that the concept of a critical time period for exposure makes the analysis of lethality data in the embryo/fetus qualitatively different from that which might be applied to similar data in adult animals. For example, a common dosing regimen used in mice, rats, and rabbits (Table 5-1) is to administer 10 daily doses of TCDD to the pregnant dam on days ~6 to 15 of gestation. This dosing regimen is expected to cover the critical period of early development that results in the greatest incidence of prenatal toxicity. In nearly all species of adult laboratory mammals, however, a single lethal dose of TCDD would be expected to produce a similar delayed-onset death regardless of the age of the adult animal. Susceptibility to TCDD-induced prenatal mortality, in contrast, may be greatly dependent on the age of the embryo/fetus. In this case, multiple doses of TCDD that cover this critical period might result in prenatal mortality, whereas a single dose might miss the critical time and not result in prenatal mortality.

The following paragraphs illustrate a type of analysis using an index of cumulative maternal dose similar to the type of analysis that might be applied to lethality data resulting from multiple dosing of adult animals. After presenting the results of applying this type of analysis to prenatal mortality data from different species, the caveat of critical time dependence will be applied to the data obtained by using different strains of mice. This will illustrate the importance of considering dosage regimen when evaluating prenatal mortality data that are available in the literature. In this case, a difference of 1 gestational day might be critically important. It turns out that the form of analysis using cumulative maternal dose may give the greatest possible degree of species variation. As such, different species may actually be more similar with respect to susceptibility to prenatal mortality than would be apparent from results of this type of analysis.

Using the cumulative dose data that are given in Table 5-1, there appears to be a tenfold to twentyfold difference in the fetolethal potency of TCDD when the monkey/guinea pig is compared with the rabbit/rat/hamster. In the CD-1 mouse treated with TCDD on gestational days 7 to 16, it appears that a daily dose of 200 μg TCDD/kg is required to significantly increase prenatal mortality. Given a ~5.5-day half-life of TCDD in the pregnant dam (Weber and

Birnbaum, 1985), the pregnant CD-1 mouse would be exposed to a maximal accumulated dose of ~1,200 μg TCDD/kg by the lowest dosage regimen that significantly increased prenatal mortality. Therefore, by using the index of cumulative dose, the CD-1 mouse would appear to be ~1,200-fold less sensitive than the monkey/guinea pig for TCDD-induced prenatal mortality. However, in NMRI mice administered TCDD only on day 6 of gestation, prenatal mortality begins to increase after a single dose of 45 μg TCDD/kg (Neubert and Dillman, 1972). The NMRI embryo/fetus is less susceptible to TCDD-induced prenatal mortality when the TCDD is administered on later gestational days up to day 15. Thus, there appears to be only an approximate 45-fold difference between the monkey/guinea pig and the NMRI mouse when the NMRI embryo/fetus is exposed specifically on day 6. In C57BL/6 mice, prenatal mortality is significantly increased after a single maternal dose of 24 μg TCDD/kg given on gestational day 6 (Couture et al., 1990a). This mouse strain, therefore, is about twentyfold to thirtyfold less sensitive to TCDD-induced prenatal mortality than is the monkey/guinea pig when exposed specifically on day 6. As with the NMRI mouse, there was little or no increase in prenatal mortality for the C57BL/6 strain when TCDD was administered to the pregnant dam on gestational days 8, 10, 12, or 14.

Peters et al. (1999) administered a single maternal dose of 25 μg/kg of TCDD on gestational day 10 to Ah receptor wild-type or null female mice (Fernandez-Salguero et al., 1995). In the homozygous Ah receptor wild-type dams and their homozygous Ah receptor wild-type fetuses there was no increase in prenatal mortality. However, in the homozygous Ah receptor null dams and their homozygous Ah receptor null fetuses TCDD increased prenatal mortality, as evidenced by an increase in percentage of resorptions. Mimura et al. (1997) also found that TCDD increased resorptions to a greater extent in Ah receptor null dams compared with Ah receptor wild-type dams. These findings suggest that mechanisms that do not require the Ah receptor may mediate, in part, the increase in prenatal mortality caused by TCDD (Peters et al., 1999).

An important finding about predicting TCDD-induced prenatal mortality is that strain differences in lethal potency of TCDD, when animals are exposed in adulthood, does not predict strain differences in lethal potency of TCDD for causing embryo/fetal mortality. Certain rat strains display wide differences in sensitivity to lethality when TCDD is given in adulthood. The Long Evans rat has a wild-type Ah receptor while the Han/Wistar rat contains a point mutation in its Ah receptor gene that results in a splice variant Ah receptor protein that binds TCDD (Pohjanvirta et al., 1998). While Long Evans and Han/Wistar rats are equally sensitive to TCDD-induced hepatic cytochrome P-4501A1 induction, the Han/Wistar strain is far less sensitive to TCDD-induced lethality than the Long Evans strain when both strains are treated with TCDD in adulthood (Pohjanvirta et al., 1993; Unkila et al., 1994). However, when these

same strains are exposed to TCDD during pregnancy, the maternal doses of TCDD administered on gestational days 8 and 12 that cause fetotoxicity and fetal lethality are similar (Huuskonen et al., 1994).

Mammalian pregnancies (including human) are characterized by critical periods or "windows" during which the embryo/fetus exhibits different susceptibilities and responses to chemical exposures. The susceptibility of any particular endpoint depends on the developmental state of that endpoint at the time of exposure. The embryo/fetus is constantly changing at all biological levels (e.g., cellular, tissue, organism), and the mechanisms of action, response, and repair of a particular endpoint at the time of exposure are the determinants of whether a response to a given exposure will result in a developmental alteration or not.

The concept of a critical window for TCDD-induced lethality in the embryo/fetus suggests an explanation for the apparent insensitivity of the CD-1 mouse embryo/fetus exposed to cumulative doses of TCDD. It could very well be that the critical window for prenatal mortality in the mouse occurs on or before gestational day 6. If the embryo/fetus is not exposed to TCDD by gestational day 6, much larger doses of TCDD are required to produce prenatal mortality. Given that exposure of the pregnant CD-1 dams did not begin until gestational day 7, this interpretation is consistent with the ability of a single 24 μg TCDD/kg dose to increase the incidence of prenatal mortality when administered to pregnant C57BL/6 mice on gestational day 6, but not when administered on gestational days 8, 10, 12, or 14 (Couture et al., 1990a). Similarly, Neubert and Dillman (1972) found that the largest increase in prenatal mortality occurred when a single dose of TCDD was given on gestational day 6 compared with prenatal mortality when the TCDD dose was administered on one of gestational days 7 to 15. In addition, this would suggest that the CD-1 embryo/fetus does not have quite the relative insensitivity to the lethal effects of TCDD compared with the embryo/fetus of other species indicated by using cumulative maternal dose as the index of exposure.

It should be noted that the concept of a critical window for prenatal mortality could potentially alter all of the species comparisons made previously that were based on the cumulative maternal doses shown in Table 5-1. If this turned out to be the case, then the true differences between species with respect to their susceptibility to TCDD-induced prenatal mortality could be substantially less than those indicated by using the cumulative maternal dose. This, of course, would involve a comparison between species using only single doses of TCDD given during the critical time period for each species. At the present time, it is not possible to make such a comparison from the information available in the literature.

Similar to fish and birds, the mammalian embryo/fetus is more sensitive to the lethal action of TCDD than the adult. The maternal dose of TCDD that causes 58% fetal mortality in hamsters is 64 to 280 times less than the LD_{50} of TCDD in adult hamsters (Olson et al., 1980;

Henck et al., 1981; Olson et al., 1990). In Sprague-Dawley rats, the cumulative maternal dose of TCDD that causes 41% prenatal mortality is 5 to 10 times less than the approximate LD_{50} of TCDD in adult rats of the same strain (Sparschu et al., 1971; Seefeld et al., 1984). In rhesus monkeys, the cumulative maternal TCDD dose that causes 81% prenatal mortality is 6 and 25 times less, respectively, than the lowest TCDD dose reported to cause mortality in 1-year-old and adult rhesus monkeys (McNulty, 1977, 1985; Seefeld et al., 1979).

Table 5-1 suggests that in many animal species (guinea pig, rabbit, rat, and mouse), TCDD-induced prenatal mortality is most commonly associated with maternal toxicity that is not severe enough to result in maternal lethality. In each of these species, the dose-response relationship for maternal toxicity, indicated by decreased maternal weight gain and/or marked subcutaneous edema of the dam, is essentially the same as that for increased prenatal mortality. Even in the hamster, where maternal toxicity is far less severe, fetuses exhibit increases in neutrophilic metamyelocytes and bands, and increases in leukocyte number and bands are also found in maternal blood (Olson and McGarrigle, 1991). In mice, it has been shown that TCDD exposure causes rupture of the embryo-maternal vascular barrier, which results in hemorrhage of fetal blood into the maternal circulation (Khera, 1992). Also, pregnant CF1 mice treated with 30 μg TCDD/kg on gestational day 12 exhibited 1.9- and 1.5-fold increases in lipid peroxidation in placental and fetal tissues, respectively, on gestational day 14. This was associated with 1.4- to 2.5-fold increases in lipid metabolite levels of malondialdehyde, formaldehyde, acetaldehyde, and acetone in amniotic fluid (Hassoun et al., 1995).

In spite of this general association between maternal and fetal toxicity, prenatal and postnatal lethality can occur in the absence of overt maternal toxicity. Olson and McGarrigle (1991) reported prenatal death but no maternal toxicity in the hamster at 18 μg/kg TCDD, the highest dose in their study. Likewise, studies in the rat demonstrate that both prenatal death (Bjerke and Peterson, 1994) and postnatal death (Gray et al., 1995) can occur in response to exposure during gestation that does not result in overt maternal toxicity (see Section 5.2.3).

In rhesus monkeys, fewer data are available to make the association between prenatal mortality and maternal toxicity. Nevertheless, the results following dietary exposure to 25 ppt TCDD (Bowman et al., 1989a; Schantz and Bowman, 1989) and 50 ppt TCDD (Allen et al., 1977, 1979; Barsotti et al., 1979; Schantz et al., 1979) before and during pregnancy suggest that TCDD-induced prenatal mortality can occur in monkeys in the absence of overt toxic effects on the mother (see Section 5.3.1). In other studies, developmental toxicity in monkeys exposed to a total cumulative maternal dose of 1 μg TCDD/kg administered during the first trimester indicated a high incidence of prenatal mortality (McNulty, 1984, 1985). However, maternal toxicity occurred in some but not all of the mothers exposed. In these monkeys, 13 of 16 pregnancies resulted in prenatal mortality. Within 20 to 147 days after aborting, 8 of the 13 females that had

aborted showed signs of maternal toxicity and 3 of these monkeys died. Thus, the remaining 5 of 13 instances of prenatal mortality apparently occurred in the absence of overt maternal toxicity. The results of these studies indicate that some levels of TCDD exposure can result in prenatal mortality in monkeys even though overt toxicity seems absent in the mother. As will be described (Section 5.3.1.1), however, only limited attention has been given to female reproductive toxicity in general and to the effects of maternal toxicity during pregnancy on fetal development in particular. Therefore, the relationship between maternal toxicity and prenatal mortality in the monkey is not well established. The integrity of the embryo-vascular barrier, for example, has not been evaluated after TCDD exposure.

Gestational exposure to TCDD produces a characteristic pattern of fetotoxic responses in most laboratory mammals consisting of thymic hypoplasia, subcutaneous edema, decreased fetal growth, and prenatal mortality. Added to these common effects on development are other effects of TCDD that are highly species-specific. Examples of the latter are cleft palate formation in the mouse and intestinal hemorrhage in the rat. Table 5-2 shows those maternal and developmental responses that are produced by gestational exposure to TCDD in various species of laboratory mammals. In the mouse, hydronephrosis is the most sensitive effect of prenatal toxicity, followed by cleft palate formation and atrophy of the thymus at higher doses, and by subcutaneous edema and mortality at maternally toxic doses (Couture et al., 1990b; Courtney, 1976; Courtney and Moore, 1971; Neubert and Dillman, 1972). In the rat, TCDD prenatal toxicity is manifested by intestinal hemorrhage, subcutaneous edema, decreased fetal growth, and mortality (Sparschu et al., 1971; Khera and Ruddick, 1973). Structural abnormalities do occur in the rat, but only at relatively large doses (Couture et al., 1990b). In the hamster fetus, hydronephrosis and renal congestion are the most sensitive effects, followed by subcutaneous edema and prenatal mortality (Olson and McGarrigle, 1991). In the rabbit, an increased incidence of extra ribs and prenatal mortality is found (Giavini et al., 1982a), and in the guinea pig and rhesus monkey, prenatal mortality is seen (Olson and McGarrigle, 1991; McNulty, 1984).

5.2.1.4. *Structure-Activity Relationships in Laboratory Mammals*

The structure-activity relationship for developmental toxicity in laboratory mammals is generally similar to that for Ah receptor binding. Gestational treatment of rats with CDD congeners that do not bind the Ah receptor (2-MCDD, 2,7-DCDD, 2,3-DCDD, or 1,2,3,4-TCDD) do not cause TCDD-like effects on development (Khera and Ruddick, 1973). On the other hand, hexachlorodibenzo-*p*-dioxin, which has intrinsic Ah receptor activity, produces fetotoxic responses in rats that are essentially identical to those of TCDD (Schwetz et al., 1973). Similarly, when administered to pregnant rhesus monkeys or CD-1 mice, PCB congeners that act by an Ah receptor-mediated mechanism (3,3',4,4'-TCB and 3,3',4,4',5,5'-HCB) cause the same

type of developmental effects as TCDD. In contrast, 4,4'-DCB, 3,3',5,5'-TCB, 2,2',4,4',5,5'-HCB, 2,2',4,4',6,6'-HCB, and 2,2',3,3',5,5'-HCB, which have essentially no or a very weak affinity for the Ah receptor, do not produce a TCDD-like pattern of prenatal toxicity in mice (Marks and Staples, 1980; Marks et al., 1981, 1989; McNulty, 1985). Thus, most structure-activity results for overt developmental effects of the halogenated aromatic hydrocarbons are consistent with an Ah receptor-mediated mechanism. Nevertheless, one finding that stands out as being inconsistent is that 2,2',3,3',4,4'-HCB, which has a very weak, if any, affinity for binding to the Ah receptor, causes the same pattern of developmental effects in mice as TCDD (Marks and Staples, 1980).

5.2.1.5. *Humans*

In the Yusho and Yu-Cheng poisoning episodes, developmental toxicity was reported in babies born to affected mothers who consumed rice oil contaminated with PCBs, CDFs, and PCQs (Hsu et al., 1985; Yamashita and Hayashi, 1985; Kuratsune, 1989; Rogan, 1989; Masada, 1994; Hsu et al., 1994). In these incidents, it is essentially impossible to determine the contribution of TCDD-like versus non-TCDD-like congeners to the fetal/neonatal toxicity. Nevertheless, high perinatal mortality was observed among hyperpigmented infants born to affected Yu-Cheng women who themselves did not experience increased mortality (Hsu et al., 1985). Thus, in humans the developing embryo/fetus may be more sensitive than the intoxicated mother to mortality caused by halogenated aromatic hydrocarbons.

In most cases, women who had affected children in the Yusho and Yu-Cheng episodes had chloracne themselves (Rogan, 1982). Based on this evidence, Rogan (1982) suggested that "exposure to amounts insufficient to produce some effect on the mother probably lessens the chance of fetopathy considerably." In support of this interpretation, overt signs of halogenated aromatic hydrocarbon toxicity were not observed in infants born to apparently unaffected mothers in the Seveso, Italy, and Times Beach, Missouri, TCDD incidents (Reggiani, 1989; Hoffman and Stehr-Green, 1989).

Effects of chemical exposure on normal development of the human fetus can have four outcomes depending on the dose and time during gestation when exposure occurs: fetal death, growth retardation, structural malformations, and organ system dysfunction. In the Yusho and/or Yu-Cheng incidents, all of these outcomes were found (Yamashita and Hayashi, 1985; Kuratsune, 1989; Rogan, 1989; Masada; 1994; Hsu et al., 1994). Increased prenatal mortality and low birthweight suggesting fetal growth retardation were observed in affected Yusho and Yu-Cheng women (Wong and Hwang, 1981; Law et al., 1981; Yamashita and Hayashi, 1985; Hsu et al., 1985; Miller, 1985; Lan et al., 1989; Rogan et al., 1988). In a follow-up of the Yu-Cheng children at elementary school age, Guo et al. (1994) reported decreased height and muscle

development in children who were the first born to women who were exposed. A structural malformation, rocker bottom heel, was observed in Yusho infants (Yamashita and Hayashi, 1985). Organ dysfunction involving the central nervous system (CNS) that was characterized by delays in attaining developmental milestones and by neurobehavioral abnormalities was reported in Yu-Cheng children exposed transplacentally (Rogan et al., 1988).

Organs and tissues that originate from embryonic ectoderm are well-known targets for toxicity following exposure to TCDD-like halogenated aromatic hydrocarbons. For example, treatment of adult monkeys with TCDD results in effects involving the skin, meibomian glands, and nails (Allen et al., 1977). Similarly, a hallmark sign of fetal/neonatal toxicity in the Yusho and Yu-Cheng episodes is an ectodermal dysplasia syndrome. It is characterized by hyperpigmentation of the skin and mucous membranes, hyperpigmentation and deformation of fingernails and toenails, hypersecretion of the meibomian glands, conjunctivitis, gingival hyperplasia, presence of erupted teeth in newborn infants, altered eruption of permanent teeth, missing permanent teeth, and abnormally shaped tooth roots (Taki et al., 1969; Yamaguchi et al., 1971; Funatsu et al., 1971; Wong and Hwang, 1981; Hsu et al., 1985; Yamashita and Hayashi, 1985; Rogan et al., 1988; Kuratsune, 1989; Rogan, 1989; Lan et al., 1989). Accelerated tooth eruption has been observed in newborn mice exposed to TCDD by lactation (Madhukar et al., 1984), as well as in the human infants mentioned above. In addition, other effects have been reported in Yusho and Yu-Cheng exposed infants that resemble those observed following TCDD exposure in adult monkeys. These include subcutaneous edema of the face and eyelids (Allen et al., 1977; Moore et al., 1979; Law et al., 1981; Yamashita and Hayashi, 1985; Rogan et al., 1988). Also, larger and wider fontanels and abnormal lung auscultation were found in the human infants (Law et al., 1981; Yamashita and Hayashi, 1985; Rogan et al., 1988). The similarities between certain effects reported in human infants exposed during the Yusho and Yu-Cheng incidents, as well as in adult monkeys and neonatal mice exposed to TCDD, enhance the probability that certain effects reported in human infants were caused by the TCDD-like PCB and CDF congeners in the contaminated rice oil ingested by the mothers of these infants.

Although chloracne is the most often cited effect of TCDD exposure involving the skin in adult humans, has an animal correlate in the hairless mouse, and can be studied by using a mouse teratoma cell line in tissue culture (Poland and Knutson, 1982), it has rarely been recognized in the TCDD literature that the nervous system, like the skin, is derived from embryonic ectoderm (Balinsky, 1970). As will be described in Section 5.2.3.2, neurobehavioral effects occur following transplacental and neonatal exposure to TCDD-like congeners in mice, as well as transplacental exposure to TCDD itself in monkeys. In addition, in some of the Yu-Cheng children who were exposed transplacentally to PCBs, PCDFs, and PCQs, there was a clinical impression of developmental delay or psychomotor delay including impairment of intellectual

development (Rogan et al., 1988). As there is a clustering of effects due to TCDD-induced toxicity in organs derived from ectoderm, it is possible to speculate that direct effects of TCDD-like congeners on the CNS are responsible for some of the neurobehavioral effects observed in these children. Effects of TCDD on EGF receptors are associated with certain aspects of the ectodermal dysplasia syndrome such as hyperkeratinization of the skin (Osborne and Greenlee, 1985) and accelerated tooth eruption (Madhukar et al., 1984). Decreased autophosphorylation of the EGF receptor in human placentas is associated with decreased birthweight in infants born to exposed mothers 4 years after the initial Yu-Cheng exposure incident (Sunahara et al., 1987). This last result supports the earlier conclusion that careful study is needed to define the relationship between maternal toxicity, placental toxicity, and developmental toxicity in humans. In addition, further research is needed to characterize and elucidate the mechanisms by which TCDD affects the nervous system.

5.2.2. Structural Malformations

Developmental effects consisting of cleft palate, hydronephrosis, and thymic hypoplasia are produced in mice following in utero exposure to halogenated dibenzo-*p*-dioxin, dibenzofuran, biphenyl, and naphthalene congeners, which bind stereospecifically to the Ah receptor (Weber et al., 1985; Miller and Birnbaum, 1986; Birnbaum et al., 1987a,b, 1991). Of these effects in the mouse, cleft palate is less responsive than hydronephrosis, as the latter is induced in the absence of cleft palate (Couture et al., 1990b). Both responses can be induced at TCDD doses that are not otherwise overtly toxic (Couture et al., 1990a). The oral surface of the palate in the mouse is characterized by 8 or 9 pairs of transverse ridges, rugae. TCDD and 3,3',4,4',5-PCB (PCB 126) produce palatal ruga anomalies in mice (Yasuda et al., 1999). The potency of TCDD for producing teratogenesis in the mouse is clearly evident when one considers that only 0.0003% of a maternally administered dose can be isolated from the fetal palatal shelves or kidneys. More specifically, a maternal TCDD dose of 30 μg/kg administered on gestational day 11 results in a tissue concentration of 0.65 pg TCDD/mg in the palatal shelves 3 days after dosing, and the same tissue concentration of TCDD is present in the kidneys at that time (Abbott et al., 1989).

Susceptibility to the developmental actions of TCDD in mice depends on two factors: genotype of the fetus and stage of development at the time of exposure. One genetically encoded parameter that determines the responsiveness of different mouse strains is the Ah receptor protein. The Ah receptor is thought to mediate the structural malformations caused by TCDD in the mouse, namely cleft palate and hydronephrosis (Poland and Knutson, 1982). After gestational day 12, the Ah receptor and its dimerization partner ARNT are expressed in the embryonic palate and developing urinary tract of the C57BL/6 mouse fetus. Expression of Ah receptor and ARNT mRNA increases significantly during palatal shelf outgrowth from

gestational day 12 to 14. While the increase in Ah receptor expression was not affected by a maternal dose of 24 μg/kg of TCDD administered on gestational day 12, there was a decrease in the expression of ARNT (Abbott et al., 1999b). Similarly, Ah receptor protein levels in the mouse urinary tract increase from gestational days 12 to 14 regardless of exposure to 12 μg/kg of TCDD on gestational day 10, whereas the expression of ARNT protein on gestational day 14 is reduced by TCDD (Bryant et al., 1997). Thus, Ah receptor and ARNT are expressed in the developing palate and urinary tract, and the opportunity exists for the Ah receptor-ARNT complex to regulate gene expression in these developing tissues. It may be important for normal development that an appropriate relative expression of these genes is maintained, and decreasing the availability of ARNT could be a significant factor in the response of the embryonic palate and urinary tract to TCDD.

Mouse strains that produce Ah receptors with relatively high affinity for TCDD respond to lower doses of TCDD than mouse strains that produce relatively low-affinity Ah receptors (Poland and Glover, 1980; Hassoun et al., 1984a). The differences that exist between mouse strains with respect to developmental responsiveness to these chemicals are not absolute, as all strains, including those with Ah receptors of relatively low affinity, respond when exposed to sufficiently large doses during the critical period of organogenesis (Birnbaum, 1991). In the mouse, the peak times of fetal sensitivity vary slightly depending on which developmental effect is used as the endpoint. However, exposure between days 6 and 15 of gestation will produce teratogenesis (Couture et al., 1990a,b).

In inbred strains of mice, the developmental response, characterized by altered cellular proliferation, metaplasia, and modified terminal differentiation of epithelial tissues (Poland and Knutson, 1982), is extremely organ-specific, occurring only in the palate, kidney, and thymus (Birnbaum, 1991). Pharmacokinetic differences are not responsible for this high degree of tissue specificity, and Ah receptors are not found exclusively in the affected organs (Carlstedt-Duke, 1979; Gasiewicz et al., 1983). Therefore, other factors intrinsic to the palate, kidney, and thymus appear to play a role along with the Ah receptors in these tissues in producing the structural malformations. For certain developmental effects, the time at which exposure occurs is important, as there may be a critical period during which the toxicant must be present in order to produce the effect. This critical period can be different for different organs and tissues.

Differences exist between mammalian species with respect to susceptibility to the developmental effects of TCDD. Although genetic differences between species or strains might affect absorption, biotransformation, and/or elimination of TCDD by the maternal system and its absorption across the placenta, such species differences do not account for the lack of cleft palate formation in species other than mice (Birnbaum, 1991). Rather, the species differences in susceptibility to cleft palate formation appear due to differences in the interaction between

TCDD and the developing palatal shelves themselves. This is demonstrated by the occurrence of similar responses when palatal shelves from different species are exposed to TCDD in organ culture (Abbott et al., 1989; Abbott and Birnbaum, 1990a, 1991). The key difference is that in other species much higher concentrations of TCDD are required to elicit essentially the same palatal response that is seen in the mouse (Table 5-3). Thus, since palatal shelves of the mouse are 200 times more sensitive to TCDD than those of the human, it is considered unlikely that human embryos would be exposed to high enough concentrations of TCDD to cause changes in palatal differentiation sufficient to produce cleft palate (Abbott et al., 1999a).

With respect to the occurrence of similar developmental effects in mammalian species other than the mouse, no other species develops cleft palate except at maternal doses that are fetotoxic and maternally toxic (Couture et al., 1990a; Birnbaum, 1991). In mice and hamsters, hydronephrosis can be elicited at TCDD doses that are neither fetotoxic nor maternally toxic (Olson and McGarrigle, 1991), whereas thymic hypoplasia is a fetal response to TCDD observed in virtually all laboratory mammalian species that have been tested (Vos and Moore, 1974). Studies in humans have not clearly identified an association between TCDD exposure and structural malformations (Fara and Del Corno, 1985; Mastroiacovo et al., 1988; Stockbauer et al., 1988; Reggiani, 1989).

5.2.2.1. *Cleft Palate*

5.2.2.1.1. ***Characterization of TCDD effect.*** Palatal shelves in the mouse originate as outgrowths of the maxillary process. Eventually, they come to lie vertically within the oral cavity on both sides of the tongue. In order to form the barrier between the oral and nasal cavities, the shelves in the mouse must reorient themselves from a vertical direction to a horizontal direction. Once they come together horizontally, their medial aspects bring apposing epithelia into close contact (Coleman, 1965; Greene and Pratt, 1976). At this stage, the apposing medial edge epithelia of the separate palatal shelves each consist of an outer layer of periderm that overlays a strata of cuboidal-shaped basal cells. These basal cells, in turn, rest on top of a continuous basal lamina. There is a sloughing of the outer periderm cells followed by the formation of junctions between the newly apposing basal epithelial cells. The midline seam so formed consists of the two layers of basal cells, all of which appear healthy, even though the outer periderm cells are shed before adhesion occurs. As fusion proceeds, the bilayer seam breaks up into small islands of cells. Eventually, the basal lamina disappears and the elongating former basal cells within the small islands extend filopodia into the adjacent connective tissue. During this process, the former basal cells lose epithelial characteristics and gain fibroblast-like features. Essentially, the medial edge epithelium is an ectoderm that retains the ability to transform into mesenchymal cells. Upon completion of this epithelial to mesenchyme transformation, the once separate and

apposing palatal shelves are fused so that a single continuous tissue is formed (Fitchett and Hay, 1989; Shuler et al., 1992).

Cleft palate can result from a failure of the shelves to grow and come together or a failure of the shelves to fuse once they are in close apposition (Pratt et al., 1985). TCDD and other Ah receptor agonists are unusual inducers of cleft palate because the shelves grow and make contact, but the subsequent processes involving loss of periderm, shelf adhesion, and the epithelial to mesenchyme transformation does not occur. Therefore, a cleft is formed as the palatal shelves continue to grow without fusing. When TCDD is administered to pregnant mice on gestational days 6 to 12, the incidence of cleft palate formation increases with time. However, day 12 is a critical window, after which the incidence of cleft palate formation decreases. No cleft palates are formed when TCDD is administered on day 14, since fusion has already occurred (Couture et al., 1990b).

Palatal shelves of the mouse, rat, and human can be removed from the fetus and placed into organ culture. Under these conditions, when the separate shelves are placed in an apposing condition in vitro, sloughing periderm cells are trapped within the seam (Fitchett and Hay, 1989). Thus, due to the presence of these trapped dead cells, the fusion process was previously believed to require programmed cell death to remove epithelial cells at the fusion seam (Coleman, 1965; Greene and Pratt, 1976; Pratt et al., 1984). However, the newer model, which involves transformation of the basal epithelial cells into mesenchyme rather than their death, is believed to be valid under explant conditions in vitro, as well as in vivo (Fitchett and Hay, 1989). When exposed to TCDD as explants in vitro, the palatal shelves of the mouse, rat, and human all respond to TCDD in a similar way by retaining medial epithelial cells that proliferate and differentiate into a stratified epithelium (Abbott et al., 1989; Abbott and Birnbaum, 1989, 1990a, 1991). The epithelial to mesenchyme transformation of the basal epithelial cells does not occur, and instead there is a differentiation into a stratified squamous epithelium such that these cells resemble the squamous keratinizing oral cells within the tissue.

Table 5-3 shows the lowest TCDD concentration that prevents the epithelial to mesenchyme transformation process in isolated palatal shelves (lowest observed effect level, LOEL), TCDD concentration that produces a 100% maximal response (EC_{100}), and lowest concentration of TCDD that produces cytotoxicity. Palatal shelves of rats and humans respond to TCDD in a manner identical to the mouse; however, higher concentrations of TCDD are required to induce the epithelial responses. The relative insensitivity of rat palatal shelves may explain the lack of cleft palate when fetal rats are exposed to nonmaternally toxic doses of TCDD. Sensitivity of human palatal shelves to TCDD in vitro is similar to the rat. This suggests that exposure to maternally toxic and fetotoxic doses of TCDD may be required to cause cleft palate formation in humans.

A disruption in the normal spatial and temporal expression of EGF, thyroid growth factor (TGF)-α, TGF-β1,and TGF-β2 correlates with altered proliferation and differentiation in the medial region of the developing palate, resulting in a palatal cleft. Thus, the abnormal proliferation and differentiation of TCDD-exposed medial cells may be related to reduced expression of EGF and TGF-α. Also, decreased levels of immunohistochemically detectable TGF-β1 could contribute to the continued proliferation and altered differentiation of medial cells (Abbott and Birnbaum, 1990b). It is important to note that EGF and TGF-α both exert their actions by binding to EGF receptors.

Based on these results, biochemical and genetic differences between mouse and human palates have been described that may explain the different sensitivities to cleft palate formation in the mouse and human. Ah receptor concentrations in the mouse palate are 346 times greater than those in the human, and ARNT levels are also greater in the mouse (Abbott et al., 1999a). In addition, gene expression studies have demonstrated that human and mouse palates cultured in vitro are dissimilar with respect to their particular spatial and temporal patterns of EGF, EGF receptor, TGF-α, and TGF-β3 mRNA expression. Because the proteins that are the translation products of these mRNAs are important for palatal development, it has been suggested that species differences in the expression patterns of these genes could contribute to the lower sensitivity of human palates to TCDD when compared with the mouse (Abbott et al., 1998).

The differentiation of basal cells to a stratified squamous epithelium, which resembles the keratinizing oral epithelium within the developing palate that is mentioned above, is similar to certain effects of TCDD that can be studied in cultured human keratinocytes. These effects in cultured human keratinocytes involve altered EGF binding to those cells. In addition, the Ah receptor is implicated in producing this response in cultured cells (Osborne and Greenlee, 1985). Thus, the mechanisms by which TCDD produces a palatal cleft in the mouse may have similarities to the mechanisms by which TCDD produces other effects that are part of the ectodermal dysplasia syndrome. This is consistent with the description given by Fitchett and Hay (1989) that the medial edge epithelium within the developing palate is essentially an ectoderm that retains the ability to transform into mesenchymal cells.

5.2.2.1.2. *Evidence for an Ah receptor mechanism.*

5.2.2.1.2.1. *Genetic.* When wild-type C57BL/6 (Ah^bAh^b) mice are crossed with DBA/2 (Ah^dAh^d) mice that contain a mutation at the Ah locus, all of the heterozygous B6D2F1 progeny (Ah^bAh^d) resemble the wild-type parent in that AHH activity is inducible by TCDD and other halogenated aromatic hydrocarbons (Nebert and Gielen, 1972). Test crosses between the B6D2F1 progeny and each original parent strain, and other B6D2F1 progeny mice, demonstrate that in the C57BL/6 and DBA/2 strains, susceptibility to AHH induction segregates as a simple

dominant trait in the backcross and F_2 progeny. Thus, the trait of AHH induction is expressed in progeny that contain the Ah^bAh^b and Ah^bAh^d genotypes, but is not expressed in the Ah^dAh^d progeny from these crosses. Certain other effects of TCDD, such as its binding affinity for the hepatic Ah receptor (Okey et al., 1979), thymic atrophy (Poland and Glover, 1980), hepatic porphyria (Jones and Sweeney, 1980), and immunosuppressive effects (Vecchi et al., 1983; Nagarkatti et al., 1984) have been shown in similar genetic crosses and test crosses to segregate with the Ah locus that permits AHH induction. Thus, for these effects of TCDD, genetic evidence demonstrates an involvement of the Ah locus (Poland and Knutson, 1982).

Nebert's group was the first to relate developmental toxicity to the Ah locus in mice (Lambert and Nebert, 1977; Shum et al., 1979). Subsequently, Poland and Glover (1980) administered a single 30 μg TCDD/kg dose to pregnant mice on gestational day 10. A 54% incidence of cleft palate was found in homozygous C57BL/6 (Ah^bAh^b) fetuses, a 13% incidence in heterozygous B6D2F1 (C57BL/6 and DBA/2 hybrid, Ah^bAh^d) fetuses, and only a 2% incidence in homozygous DBA/2 (Ah^dAh^d) fetuses. This pattern of inheritance, in which the incidence of developmental toxicity in the heterozygous F1 generation is intermediate between that of the homozygous parental strains, is consistent with the autosomal dominant pattern of inheritance described for AHH inducibility and the Ah locus (Nebert and Gielen, 1972), even if dominance is incomplete in the case of developmental toxicity. However, the pattern of inheritance for developmental toxicity described when Poland and Glover (1980) crossed C57BL/6 and DBA/2 mice is not sufficient proof that the Ah locus is the genetic locus that controls susceptibility to TCDD-induced developmental toxicity in these mouse strains.

To provide such proof, it is necessary to show genetic linkage between the susceptibility for developmental toxicity and the Ah locus. The standard of proof would be that developmental toxicity and a particular allele at the Ah locus must always segregate together in genetic crosses because if the loci are the same there can be no recombination between the loci. This is generally accomplished by demonstrating cosegregation between the two loci, not only in crosses between the two homozygous parental strains, which in and of itself is insufficient proof of genetic linkage, but also in test crosses or backcrosses between the heterozygous F1 hybrids with each homozygous parental strain.

It was stated previously that certain effects of TCDD are well known to segregate with the Ah locus due to the results of appropriate crosses and backcrosses between responsive and nonresponsive mouse strains and their hybrid F1 progeny. With this standard of proof in mind, the evidence that specifically links certain endpoints of developmental toxicity with the Ah locus can be described. It is intended that this information be provided with a considerable degree of detail, so the reader can independently determine whether the standard of proof has been satisfied by the evidence available.

To strengthen their conclusion based on the results of simple crosses between C57BL/6 and DBA/2 mice, Poland and Glover (1980) planned to perform a backcross between the hybrid B6D2F1 and DBA/2. However, the low incidence of cleft palate in B6D2F1 mice would have required characterizing and phenotyping a prohibitively large number of fetuses. Alternatively, the backcross between B6D2F1 and C57BL/6 was considered, in which Ah^bAh^b and Ah^bAh^d progeny would have been distinguished by the amount of high-affinity specific binding for TCDD in fetal liver. In this case, however, overlap between individual mice would have made the results uncertain in some of the progeny. Therefore, it was not possible to obtain satisfactory results from either backcross.

Instead, Poland and Glover (1980) examined the incidence of cleft palate in 10 inbred strains of mice: 5 strains with high-affinity Ah receptors and 5 strains with low-affinity receptors. In the five latter strains, there was only a 0% to 3% incidence of cleft palate formation, whereas four of the five strains with high-affinity Ah receptors developed a ~50% incidence. The one strain with high-affinity Ah receptors that did not follow the pattern, CBA strain, is also resistant to cleft palate formation induced by glucocorticoids. Overall, these results indicate that cleft palate formation probably segregates with the Ah locus.

The incidence of cleft palate formation was studied in fetuses from a cross between C57BL/6 and AKR/NBom mice administered 3,3',4,4'-TCAOB on gestational day 12 (Hassoun et al., 1984b). Although C57BL/6 mice are responsive for AHH induction and cleft palate formation, AKR mice are less responsive, requiring higher doses for both effects. In a manner unlike the result of a cross between C57BL/6 and DBA/2, the incidence of cleft palate formation in the B6AKF1 progeny was <2%, showing that nonresponsiveness segregates as the dominant trait when C57BL/6 mice are crossed with AKR mice. Similarly, cleft palate formation was virtually absent in the progeny of a backcross between AKR/NBom and B6AKF1, demonstrating dominance of the noninducible trait. Although Ah phenotyping of the backcross progeny was not performed in this particular study, Robinson et al. (1974) had previously evaluated segregation of the Ah locus in backcrosses between C57BL/6 and AKR/N mice. They found in these two strains that noninducibility for AHH activity segregates as the dominant trait. Thus, inducibility for cleft palate formation and AHH activity both segregate as dominant traits when C57BL/6 mice are crossed with DBA/2, but noninducibility is dominant for both traits when C57BL/6 mice are crossed with AKR/N. These results are consistent with the interpretation that cleft palate induction probably segregates with the Ah locus.

Like Poland and Glover (1980), Hassoun et al. (1984a) were unable to determine whether cleft palate formation segregates with the Ah locus in C57BL/6 and DBA/2 mice by performing simple backcrosses. Instead, they evaluated cosegregation of the Ah locus and 2,3,7,8-TCDF-induced cleft palate formation using a series of recombinant strains called BXD mice. These

strains are fixed recombinants produced from an original cross between the two parental strains C57BL/6J and DBA/2J. Hybrid B6D2F1 mice were crossed to produce F_2 progeny and these were strictly inbred by sister and brother matings into several parallel strains. The mice used in this study were from the F_{42} and F_{58} generations of inbreeding. It was found that the incidence of TCDF-induced cleft palate formation after matings within eight different BXD strains with high-affinity Ah receptors is >85%. After similar matings with eight different BXD strains with low-affinity Ah receptors, the incidence of TCDF-induced cleft palate formation is <2%. These results of Hassoun et al. (1984a) corroborate those of Poland and Glover (1980) and provide further evidence that cleft palate formation segregates with the Ah locus. Thus, the Ah locus and the Ah receptor are involved in the formation of palatal clefts that are induced by TCDD-like congeners.

Consistent with this interpretation, the Ah receptor null mouse line of Mimura et al. (1997) is completely resistant to TCDD-induced cleft palate formation and the Ah receptor null line of Fernandez-Salguero et al. (1995) is almost entirely resistant to this teratogenic effect of TCDD (Peters et al., 1999). Taken together, these findings support the conclusion that the Ah receptor plays a key role in TCDD-induced cleft palate formation. However, because 9% of the homozygous Ah receptor null fetuses of the Fernandez-Salguero et al. (1995) transgenic line developed cleft palate when exposed to TCDD (compared with 0% of vehicle-exposed wild-type and 0% of vehicle-exposed Ah receptor null fetuses), a TCDD-induced alteration in processes that do not require the Ah receptor might also be involved. Further research is needed to explore this possibility.

As additional evidence for an Ah receptor-mediated mechanism for cleft palate formation by TCDD and related compounds, stereospecific, high-affinity Ah receptors can be isolated from cytosol fractions prepared from embryonic palatal shelves. These receptors are present in palatal shelves of Ah^bAh^b, C57BL/6 fetuses but are not detectable in similar tissue from Ah^dAh^d, AKR/J fetuses (Dencker and Pratt, 1981). However, the significance of this finding may be mitigated to some extent by the following observation. In cytosols prepared from homogenates of whole embryo/fetal tissue (minus head, limbs, tail, and viscera), the concentration of specific binding TCDD receptors is 256 fmol/mg protein in C57BL/6 mice, compared with a concentration of 21 fmol/mg protein in the less responsive DBA/2 strain, 15 fmol/mg protein in the less responsive AKR/J strain, and 19 fmol/mg protein in the less responsive SWR/J strain. However, when embryonic tissue is cultured, the differences between the strains in receptor number are less pronounced, and in the receptors isolated from cultured embryonic cells of different strains, there is only about a twofold difference in the relative binding affinity for ^{3}H-TCDD. The mechanistic reasons for the diminished degree of difference between responsive and less responsive mouse strains during embryonic cell culture are not known (Harper et al., 1991).

The possible influence of maternal toxicity on cleft palate formation was evaluated by performing reciprocal blastocyst transfer experiments using the high-affinity-Ah receptor NMRI and lower affinity-Ah receptor DBA strains of mice (D'Argy et al., 1984). After administration of 30 μg TCDD/kg or 8 mg TCAOB/kg to pregnant dams on gestational day 12, 75% to 100% of all NMRI fetuses developed cleft palates. This is true whether the fetuses remained within the uterus of their natural mother or were transferred into the uterus of a DBA mouse. Under the same conditions, none of the 24 DBA fetuses transferred into an NMRI mother developed a cleft palate, even though 89% of their NMRI litter mates were affected. Thus, these results, along with the presence of Ah receptors in palatal shelves and responsiveness of palatal shelves in organ culture to TCDD, indicate that cleft palate formation in mice is due to a direct effect of TCDD on the palatal shelf itself and is not secondary to maternal toxicity.

5.2.2.1.2.2. ***Structure activity.*** As genetic evidence in mice indicates that the Ah receptor mediates TCDD-induced cleft palate formation and hydronephrosis (see Section 5.3.2.2.2.1), structure-activity requirements based on Ah receptor-binding characteristics should predict the relative potencies of different agonists for producing cleft palate and hydronephrosis. Of the halogenated aromatic hydrocarbons, TCDD has the greatest affinity for binding to the Ah receptor and it is the most potent teratogen in inbred mouse strains. Table 5-4 shows the relative potencies for cleft palate induction and hydronephrosis in C57BL/6 mice for a number of TCDD-like congeners. As TCDD is the most potent, it is assigned a value of 1.000. When examined by probit analysis, the dose-response curve of each congener, compared with all of the others, did not deviate from parallelism. Therefore, the relative potencies of the congeners are valid for any given incidence of cleft palate formation or hydronephrosis. The main finding, however, is that the rank order potency of the various congeners for producing these two developmental effects is generally similar to that for binding to the Ah receptor (see Table 5-4), with the notable exception that the apparent binding affinities for the brominated dibenzofurans have not yet been reported. There are additional ligands for the Ah receptor that cause cleft palate formation in C57BL/6 mice at nonmaternally toxic doses, but they are not listed in the table. These include 3,3',4,4'-TCAOB (Hassoun et al., 1984a), 3,3',4,4'-tetrachlorobiphenyl (Marks et al., 1989), 3,3',4,4',5,5'-hexachlorobiphenyl (Marks et al., 1981), and a mixture that contained 1,2,3,4,6,7- and 2,3,4,5,6,7-hexabromonaphthalenes (Miller and Birnbaum, 1986).

Also consistent with the structure-activity relationships for binding to the Ah receptor is the finding that a number of hexachlorobiphenyls do not induce cleft palate formation. These congeners either lack sufficient lateral substitution or are substituted in such a manner that they cannot achieve a planar conformation. Included in this category are the diortho and tetraortho chlorine-substituted 2,2',3,3',5,5'-; 2,2',3,3',6,6'-; 2,2',4,4'5,5'-; and 2,2',4,4',6,6'-hexachloro-

biphenyls (Marks and Staples, 1980). In addition, it is consistent with the structure-activity relationships that the monoortho chlorine-substituted 2,3,4,5,3',4'-HCB is a weak teratogen. Its potency relative to that of TCDD varies from 3×10^{-5} to 9×10^{-5} for cleft palate formation, AHH induction, and hydronephrosis (see Table 5-4) (Kannan et al., 1988).

A result that would not be expected according to the structure-activity relationships for binding to the Ah receptor is that the diortho chlorine-substituted 2,2',3,3',4,4'-hexachlorobiphenyl causes cleft palate formation and hydronephrosis in mice (Marks and Staples, 1980). However, another diortho chlorine-substituted PCB congener, 2,2',4,4',5,5'-hexachlorobiphenyl, also can cause hydronephrosis and is a very weak inducer of 7-ethoxyresorufin-O-deethylase (EROD) activity (Biegel et al., 1989; Morrissey et al., 1992). It is consistent with the interpretation that 2,2',4,4',5,5'-hexachlorobiphenyl is a partial Ah receptor agonist, that it can competitively displace TCDD from the murine hepatic cytosolic receptor, and that at large enough doses it can inhibit TCDD-induced cleft palate formation and immunotoxicity in C57BL/6 mice (Biegel et al., 1989; Morrissey et al., 1992). These results suggest that PCB congeners do not have to be in a strictly planar configuration to cause teratogenesis.

5.2.2.1.3. ***Species differences.*** Cleft palate is induced in rats only at maternally toxic TCDD doses that are associated with a high incidence of fetal lethality. Schwetz et al. (1973) reported an increased incidence of cleft palate after maternal administration of 100 μg hexachlorodibenzo-*p*-dioxin/kg/day to Sprague-Dawley rats on days 6 to 15 of gestation. Couture et al. (1989) also observed an increased incidence of cleft palate formation after a single dose of 300 μg/kg of 2,3,4,7,8-pentachlorodibenzofuran given to Fischer 344 rats. In Long Evans rats administered 5 μg/kg of TCDD on gestational day 8 there was a 71.4% incidence of cleft palate (Huuskonen et al., 1994). However, in Han/Wistar rats that have a mutated form of the Ah receptor, exposure to 10 μg/kg of TCDD on gestational day 8 failed to cause cleft palate formation (Huuskonen et al., 1994). Thus, there are rat strain differences in susceptibility to cleft palate formation as has been shown for mice. Cleft palate also can be produced in fetal hamsters following maternally toxic and fetotoxic doses of TCDD (Olson et al., 1990).

In monkeys, bifid uvula (Zingeser, 1979) and bony defects in the hard palate (McNulty, 1985) were reported, but there were no corresponding soft tissue defects or clefts of the secondary palate. Cleft palates have not been reported in human fetuses of mothers accidentally exposed to TCDD or mixtures of PCBs and CDFs (Fara and Del Corno, 1985; Mastroiacovo et al., 1988; Stockbauer et al., 1988; Rogan, 1989). Thus, sensitivity of the palate in mice to TCDD is unique. In other species, including humans, other forms of fetal toxicity occur at doses lower than those required for cleft palate formation.

5.2.2.2. *Hydronephrosis*

5.2.2.2.1. ***Characterization of TCDD effect.*** Hydronephrosis is the most sensitive developmental response elicited by TCDD in mice. It is produced by maternal doses of TCDD too low to cause palatal clefting and is characterized as a progressive hydronephrosis preferentially occurring in the right kidney, which can be accompanied by hydroureter and/or abnormal nephron development (Courtney and Moore, 1971; Moore et al., 1973; Birnbaum et al., 1985; Weber et al., 1985; Abbott et al., 1987a,b). Hyperplasia of the ureteric lumenal epithelium results in ureteric obstruction. Therefore, the TCDD-induced kidney malformation in the mouse is a true hydronephrosis in that blockage of urine flow results in back pressure damaging or destroying the renal papilla (Abbott et al., 1987a). In addition, mRNA and protein for both the Ah receptor and ARNT are expressed in the fetal ureters and metanephric tubules of the mouse (Bryant et al., 1997), so it is possible that hydronephrosis is caused by a direct action of TCDD on the developing kidney.

When dissected on gestational day 12 from control embryos, isolated ureters exposed to 1×10^{-10} M TCDD in vitro display evidence of epithelial cell hyperplasia (Abbott and Birnbaum, 1990c). This is significant in that it shows that the hydronephrosis response is due to a direct effect of TCDD on the ureteric epithelium. Embryonic cell proliferation within the ureter may be regulated by the actions of growth factors, including EGF (Abbott and Birnbaum, 1990c). In control ureteric epithelia, the expression of EGF receptors decreases with advancing development, whereas after TCDD exposure the rate of ^{3}H-thymidine incorporation and expression of EGF receptor does not decline. Therefore, in TCDD-treated mice there is a correlation between excessive proliferation of ureteric epithelial cells and inappropriate expression of EGF receptors.

Other effects of TCDD on the developing kidney involve changes in the extracellular matrix components and basal lamina (Abbott et al., 1987b). In TCDD-exposed fetal kidneys, extracellular matrix fibers are of a diameter consistent with Type III collagen similar to such fibers in unexposed fetal kidneys. However, the abundance of these Type III collagen fibers is reduced by TCDD treatment. In the developing kidney, these collagen fibers are associated with undifferentiated mesenchymal cells. Similarly, the expression of fibronectin, which is also associated with undifferentiated mesenchymal cells, is decreased by TCDD exposure. In the glomerular basement membrane, the distribution of laminin and Type IV collagen is altered by TCDD exposure. These changes in the glomerular basement membrane may affect the functional integrity of the filtration barrier and could exacerbate the hydronephrosis and hydroureter. The proteins within the extracellular matrix and basal lamina that are altered by TCDD exposure (laminin, fibronectin, and collagen) are considered markers of a commitment to differentiate into epithelial structures. In the mouse embryo/fetus, TCDD exposure also blocks differentiation

within the epithelium of the developing palate. Although there are effects of TCDD exposure on EGF in the developing ureter as well as the developing palate, the urinary system, unlike parts of the soft palate, is derived from mesoderm. Thus, it is important to note that the ectodermal dysplasia syndrome is intended to denote a clustering of effects that appears to involve ectoderm-derived organs. It is not intended to imply that all TCDD-induced developmental toxicity involves organs derived from ectoderm.

5.2.2.2.2. ***Evidence for an Ah receptor mechanism.***

5.2.2.2.2.1. ***Genetic.*** With respect to involvement of the Ah locus in TCDD-induced hydronephrosis, very few genetic studies have been done. Prior to the discovery of the Ah locus, however, Courtney and Moore (1971) reported a 62% incidence of hydronephrosis in C57BL/6 mice exposed to a maternal TCDD dose of 3 μg/kg/day on days 6 to 15 of gestation, whereas the incidence in similarly exposed DBA/2 mice was only 26%. More recently, Silkworth et al. (1989) reported that when TCDD is administered on gestational days 6 to 15, the incidence of hydronephrosis is dose related. As the maternal dose of TCDD is increased from 0.5 to 4μg/kg/day, the incidence of hydronephrosis in C57BL/6 mice increases from 31% to 92%, whereas in DBA/2 mice the incidence varies from 5% to 37% over the same dose range. In DBA/2 mice the incidence of hydronephrosis increases to 60% when the largest dose of TCDD administered is doubled to 8 μg/kg/day (but does not reach the 92% level seen in C57BL/6 mice at 4μg TCDD/kg). Thus, the incidence of hydronephrosis is higher in the mouse strain that produces high-affinity Ah receptors (C57BL/6) compared with that strain (DBA/2) that produces Ah receptors having lower ligand-binding affinity (Okey et al., 1989). The largest dose of TCDD used in these experiments resulted in hydronephrosis of the fetus without affecting the mean body weight or body weight gain of the dam. In the BXD strains (Hassoun et al., 1984a), the incidence of 2,3,7,8-TCDF-induced hydronephrosis is 34% to 48% in eight strains with high-affinity Ah receptors and 3% to 4% in eight strains with low-affinity Ah receptors. These results obtained in the BXD strains of mice provide the best evidence currently available of an association between the ability of TCDD-like congeners to induce hydronephrosis and the wild-type Ah^b allele. Thus, the Ah locus and the Ah receptor are involved in the hydronephrosis that is induced by TCDD-like congeners.

More recently, transgenic Ah receptor null mutant mice have been used to study the effects of Ah receptor deletion on the ability of TCDD exposure to cause hydronephrosis. Female mice heterozygous for Ah receptor expression were mated to males of the same genotype and exposed during pregnancy to 40 μg TCDD/kg on gestational day 12.5 (Mimura et al., 1997). Nearly all TCDD-exposed wild-type and heterozygous progeny developed hydronephrosis. In sharp contrast, there was no hydronephrosis in offspring from the same litters that were

homozygous for the Ah receptor null mutation. Similarly, Ah receptor null mice generated by a different targeting method (Fernandez-Salguero et al., 1995) were also completely resistant to TCDD-induced hydronephrosis (Peters et al., 1999). These results, coupled with the difference in incidence of TCDD- or TCDF-induced hydronephrosis in C57BL/6 and DBA/2 mouse strains, demonstrate that this teratogenic response to TCDD is Ah receptor mediated. Since haplo-insufficiency was observed for the cleft palate response, but not for hydronephrosis, Mimura and coworkers suggest that the mechanisms by which the Ah receptor mediates these two teratogenic effects of TCDD may be different (Mimura et al., 1997).

5.2.2.2.2.2. ***Structure activity.*** The rank order of potencies for various halogenated aromatic hydrocarbon congeners to cause hydronephrosis in mice is consistent with the structure-activity requirements for binding to the Ah receptor (see Table 5-4). This provides further evidence that the Ah receptor mediates the effects of these TCDD-like congeners on the developing mouse kidney.

5.2.2.2.2.3. ***Species differences.*** Hydronephrosis has been reported after administration of low maternal doses of TCDD to rats and hamsters. Possibly due to the small numbers of fetuses examined, the observed incidences of hydronephrosis in rats after exposure to cumulative maternal doses <2 μg TCDD/kg have not been statistically significant (Courtney and Moore, 1971; Giavini et al., 1983). There are also interstrain differences in rats in susceptibility to hydronephrosis. This is illustrated in the TCDD-resistant Han/Wistar and TCDD-sensitive Long Evans rat strains by 1 and 10 μg/kg of TCDD administered on gestational day 8 causing 3% and 11.9% hydronephrosis in the Han/Wistar strain while a 5 μg/kg dose of TCDD administered on the same day of gestation failing to cause hydronephrosis in the Long Evans strain (Huuskonen et al., 1994). Following a 1.5 μg TCDD/kg dose administered on gestational days 7 and 9, the incidence of hydronephrosis in hamster fetuses was 11% and 4.2%, respectively. This is in contrast to an incidence of <1% in control hamster fetuses. Accordingly, hydronephrosis is one of the most sensitive indicators of prenatal toxicity in hamsters (Olson and McGarrigle, 1991).

5.2.2.3. *Tooth Development*

The interpretation that lactational exposure to CDDs and CDFs may lead to mineralization defects in the first molars of human infants (Alaluusua et al., 1996, 1999) was further investigated in experiments where primordial mandibular molar teeth from mouse embryos were cultured in the presence of 1 μM TCDD (Partanen et al., 1998). In these cultured primordial teeth, TCDD caused toxicity to odonotoblasts and ameloblasts. This led to a failure of dentin to undergo mineralization and a lack of enamel deposition. Cuspal morphology also

was disrupted by TCDD exposure in the cultured teeth. While the concentration of TCDD required to produce these effects was high, 1 μM, the authors suggest that barriers to diffusion inherent in tooth structure may result in TCDD concentrations at the cellular site of action in the primordial teeth being much lower than that in the culture medium (Partanen et al., 1998). Exposure to EGF (10 μg/L) similarly retarded molar tooth development in cultured explants from wild-type embryos, because layers of mineralized dentin and the enamel matrix were thinner than those in vehicle-exposed explants. In cultured primordial molar teeth from EGF receptor null embryos, the effects of EGF were completely ameliorated, and TCDD had only a mild effect. When cultured explants from wild-type mouse embryos were simultaneously exposed to EGF and TCDD, the adverse effects of TCDD on mineralization and enamel deposition were largely, but not completely prevented (Partanen et al., 1998). In utero and lactational exposure of male Holtzman rats to 0.064, 0.16, 0.40, or 1.0 μg/kg of TCDD on gestational day 15 failed to accelerate the age at which incisor eruption occurred. At the highest TCDD dose used there was a tendency for incisor eruption to be accelerated by about 1 day (9.9 days in the control versus 8.9 days in the TCDD group), but the effect was not statistically significant (Mably et al., 1992a). Taken together, these results are consistent with the interpretation that TCDD alters tooth development in organ culture by interfering with EGF receptor signaling. However, TCDD also may affect tooth development by perturbing other signaling pathways, which either act in concert with or interfere with EGF receptor signaling, and probably involve additional mechanisms of cell and/or tissue interactions. Finally, the involvement of EGF receptor signaling in this effect of TCDD is consistent with aberrant tooth development being a part of the TCDD ectodermal dysplasia syndrome.

5.2.3. Postnatal Effects

5.2.3.1. *Eye Opening*

In utero and lactational exposure to TCDD caused external developmental effects in male rodent offspring that are not androgen dependent. The most prominent of these is accelerated eye opening. Mably et al. (1992a) reported that the age of eye opening was accelerated by 1.0 μg/kg of TCDD administered on gestational day 15. Lower doses of TCDD that affected growth and development of several male reproductive tract organs, however, had no effect on eye opening, demonstrating that this endpoint could be clearly dissociated from the more sensitive male reproductive endpoints by the dose of TCDD needed to cause them. Gray et al. (1997) found accelerated eye opening to be one of the most sensitive endpoints in the Long Evans rat, occurring at 0.05 μg/kg of TCDD administered on gestational day 15. This was the lowest dose used in their study, and it also significantly decreased ejaculated sperm numbers, by 25%. In the ICR mouse exposure to 15, 30, or 60 μg/kg of TCDD on gestational day 14 accelerated eye

opening in male pups at all dosage levels (Theobald and Peterson, 1997). However, there was no effect on age to eye opening in female pups from the same TCDD-exposed mouse litters.

5.2.3.2. *Male Reproductive System*

TCDD has been shown to decrease plasma androgen concentrations in the adult male rat (see Section 5.3.2.2). Because TCDD is known to be transferred from mother to young in utero and during lactation (Moore et al., 1976; van den Berg et al., 1987), it can be expected to have an impact on the male reproductive system during early development (Mably et al., 1991). Testosterone and/or its active metabolite 5α-dihydrotestosterone (DHT) are essential prenatally and/or during the early postnatal stage for imprinting and development of accessory sex organs (Chung and Raymond, 1976; Rajfer and Coffey, 1979; Coffey, 1988) and for initiation of spermatogenesis (Steinberger and Steinberger, 1989). For example, exposure of the male rat fetus on gestational days 14 to 16 to a 5α-reductase inhibitor, which inhibits conversion of testosterone to DHT, impairs development of urogenital sinus-derived accessory sex organs such as the prostate (Clark et al., 1993). If perinatal imprinting fails to occur in the Wolffian duct or urogenital sinus-derived accessory sex organs of a neonatal male rat, the result could be that these male sex organs do not develop a normal trophic response to androgenic stimulation and do not grow and develop normally as the animal matures. In addition, aromatization of testosterone to 17ß-estradiol within the CNS is required perinatally for the imprinting of typical adult male patterns of reproductive behavior (Gorski, 1974) and luteinizing hormone (LH) secretion (Barraclough, 1980). Thus, normal development of male reproductive organs and imprinting of typical adult sexual behavior patterns require sufficient testosterone to be secreted by the fetal and neonatal testis at critical times in early development before and shortly after birth (MacLusky and Naftolin, 1981; Wilson et al., 1981).

To determine how the male reproductive system is affected by in utero and lactational TCDD exposure, Mably et al. (1991, 1992a,b,c) treated pregnant rats with a single oral dose of TCDD (0.064, 0.16, 0.4, or 1.0 μg/kg) or vehicle on day 15 of gestation (day 0 = sperm positive). Day 15 was chosen because most organogenesis in the fetus is complete by this time and the hypothalamic/pituitary/testis axis is just beginning to function (Warren et al., 1975, 1984; Aubert et al., 1985). The pups were weaned 21 days after birth. The consequences of this single, maternal TCDD exposure for the male offspring were characterized at various stages of postnatal sexual development. These original studies of male sexual development following in utero and lactational TCDD exposure have been expanded and further defined in subsequent studies using Holtzman, Long Evans, Sprague-Dawley, and Wistar rats, Syrian hamsters, and mice. These studies have been conducted in five different laboratories and in the vast majority of the studies, TCDD was used as the prototype Ah receptor agonist. However, some studies used 3,3'4,4',5-

PCB (PCB 126), 3,3',4,4',5,5'-HCB (PCB 169), and 2,3,4,7,8-PCDF. In general, the collective findings have produced qualitatively similar results that define a significant effect of TCDD and related Ah receptor agonists on the developing male reproductive system. The effects do not appear to result from reduced plasma androgen concentrations during the perinatal period as originally hypothesized by Mably et al. (1992a) and do not overlap completely with developmental effects of known antiandrogens (Roman et al., 1998b; Gray et al., 1999).

5.2.3.2.1. ***Overt toxicity assessment.*** Mably et al. (1992a) found that TCDD treatment had no effect on daily feed intake during pregnancy and the first 10 days after delivery, nor did it have an effect on the body weight of dams on day 20 of gestation or on days 1, 7, 14, or 21 postpartum. Treating dams with graded doses of TCDD on day 15 of gestation had no effect on gestation index, length of gestation, or litter size. Except for an 8% decrease at the highest maternal dose, TCDD had no effect on live birth index. Neither the 4-day nor 21-day survival index was significantly affected by TCDD. In all dosage groups, the number of dead offspring was equally distributed between males and females, and of the females that failed to deliver litters, none were pregnant. Signs of overt toxicity among the offspring were limited to the above-mentioned 8% decrease in live birth index (highest dose only), initial 10% to 15% decreases in body weight (two highest doses), and initial 10% to 20% decreases in feed intake (measured for males only, two highest doses). The latter two effects disappeared by early adulthood, after which the body weights of the maternally exposed and nonexposed rats were similar.

These findings have essentially been confirmed by both Gray's and Peterson's laboratories (Bjerke et al., 1994a; Gray et al., 1995a, 1997; Roman et al., 1995). A single oral exposure of 1 μg/kg TCDD on day 15 of gestation does not result in maternal toxicity, but compromises perinatal viability and growth of the offspring. A difference in the findings was that the reduced viability occurred prenatally in the studies using the Holtzman rat (Bjerke et al., 1994a; Roman et al., 1995) and postnatally in the Long Evans rat (Gray et al., 1995a).

5.2.3.2.2. ***Prenatal plasma androgen levels and testicular androgen production***. Exposure of Holtzman rats to 1.0 μg/kg of TCDD on gestational day 15 was originally reported to decrease plasma testosterone concentrations in male fetuses from gestational days 17 to 21 and in neonates 2 hours after birth (Mably et al., 1992a). However, a subsequent study from the same laboratory was not able to reproduce these findings (Chen et al., 1993). They found, contrary to their original study (Mably et al., 1992a), that exposure of Holtzman rats to 1.0 μg/kg of TCDD on gestational day 15 did not reduce plasma testosterone concentrations in male fetuses on gestational days 18 or 20 or in male neonates 2 hours after birth. Furthermore, perinatal TCDD exposure did not decrease intratesticular testosterone content or interfere with the ability of the

LH analog, human chorionic gonadotropin (hCG), to stimulate testosterone production from bisected testis preparations at these times (Chen et al., 1993). No other studies have examined the effects of in utero and lactational TCDD exposure on plasma testosterone levels or testicular testosterone production in rat fetuses or neonates at these specific times perinatally when plasma testosterone concentrations are elevated. In control rats the neonatal testosterone peak that occurs 2 hours after birth is followed from 6 hours to 5 days after birth by plasma testosterone concentrations that are 70% to 80% lower than the neonatal peak concentration. When evaluated at these times there was no effect of 1.0 μg/kg of TCDD administered on gestational day 15 on plasma testosterone concentrations in male offspring of either the Holtzman or Long Evans strains (Mably et al., 1992a; Gray et al., 1995a). Also, when evaluated 6 hours after birth there was no effect on LH-stimulated testosterone production in neonatal rats of the Long Evans strain exposed perinatally to TCDD (Gray et al., 1995a). Taken together, these results suggest that effects of in utero and lactational TCDD exposure on the male rat reproductive system cannot be explained by decreased testicular testosterone production or plasma testosterone concentrations during perinatal development (Roman and Peterson, 1998b).

5.2.3.2.3. ***Postnatal plasma androgen levels and testicular androgen production.*** Mably et al. (1992a) failed to find a significant decrease in plasma testosterone or 5α-DHT concentrations in male Holtzman rat offspring that were 32, 49, 63, or 120 days of age and had been exposed on gestational day 15 to either 0.064, 0.16, 0.40, or 1.0 μg/kg of TCDD. Consistent with these negative results, Roman et al. (1995) and Loeffler and Peterson (1999) were also unable to observe any consistent pattern of reduction of plasma testosterone or 5α-androstane-3α,17β-diol concentration in male Holtzman rats that were 21, 32, 49, and 63 days of age and had been exposed to 0.25 or 1.0 μg/kg of TCDD on gestational day 15. Similarly, at the three dosage regimens used for in utero and lactational exposure to TCDD, there was no effect on plasma testosterone concentration in male Wistar rat offspring at postnatal day 70 and only at the highest TCDD dosage regimen was there a reduction in plasma testosterone at postnatal day 170 (Faqi et al., 1998). Gray et al. (1995a) found no effect on serum testosterone concentrations or on basal or LH-stimulated testicular testosterone production from in utero and lactational exposure to 1.0 μg/kg of TCDD administered on gestational day 8 or 15 in male Long Evans rats at 49 or 270 days of age. These investigators also reported that there was no effect of in utero and lactational exposure to 2.0 μg/kg of TCDD administered on gestational day 11 on serum testosterone concentrations of male Syrian hamsters at 140 days of age (Gray et al., 1995a). Theobald and Peterson (1997) failed to find a significant decrease in plasma testosterone concentrations in male ICR mouse offspring that were 44, 65, or 114 days of age and had been exposed on gestational day 14 to either 15, 30, or 60 μg/kg of TCDD. In utero and lactational exposure of rats to other

Ah receptor agonists have produced results similar to those caused by TCDD. 3,3'4,4'5-PCB (PCB 126), 2,3',4,4',5-PCB (PCB 118), or 2,3,4,7,8-PCDF administered on gestational day 1 had no effect on plasma testosterone concentrations in male Wistar rat offspring at 112 days of age (Bouwman et al., 1996). Overall, these findings suggest that the spectrum of effects caused by in utero and lactational exposure to TCDD on the male reproductive system cannot be explained by decreased postnatal testicular androgen production or plasma androgen concentrations (Gray et al., 1995a; Roman and Peterson, 1998b).

5.2.3.2.4. ***External indicators of androgenic status*****.** The androgenic status of the male offspring can be determined from the structure and function of androgen-dependent systems and from the levels of circulating androgens. Anogenital distance, which is dependent on both circulating androgen concentrations and androgenic responsiveness (Neumann et al., 1970), was reduced in 1- and 4-day-old Holtzman male pups by a single maternal TCDD dose as low as 0.16 μg/kg, even when slight decreases in body length were considered (Mably et al., 1992a). However, this effect was not observed in subsequent studies in Holtzman and Long Evans rats exposed perinatally to TCDD when anogenital distance was determined relative to body weight (Gray et al., 1993; 1995a) or crown-rump length (Bjerke et al., 1994a,b; Roman et al, 1995). Also, when Wistar rats were exposed in utero and via lactation to TCDD or 3,3',4,4',5,5'-HCB (PCB 169), anogenital distance was not affected (Faqi et al., 1998a; Smits-van Prooije et al., 1994). This lack of effect on relative anogenital distance was also found when Long Evans rats were exposed to 3,3'4,4'5,5'-HCB (PCB 169) on gestational day 15 (Gray et al., 1999). Thus, these findings suggest that androgenic status of the male rat neonate is not affected by perinatal exposure to TCDD and PCB 169.

Two other external indicators of androgenic status are time to testis descent and time to preputial separation (Rajfer and Walsh, 1977; Korenbrot et al., 1977). These occur in control rats between postnatal days 20-23 and 42-45, respectively. Exposure to 0.16, 0.40, or 1.0 μg/kg of TCDD on gestational day 15 delayed testis descent in the Holtzman rat strain by 1.0 to 1.6 days (Mably et al., 1992a). However, this effect was significant in only two of four rat studies (Mably et al., 1992a; Bjerke et al., 1994a,b; Faqi et al., 1998a) and in the ICR mouse TCDD had no effect on the age at testis descent (Theobald and Peterson, 1997). Puberty, assessed by age at preputial separation, was more reproducibly affected by TCDD across rat strains and species. It was delayed by as much as 3.6 days in Long Evans rats exposed to 1.0 μg/kg TCDD on gestational day 15 (Gray et al., 1995, 1997). The effect was dose-related and significant at a maternal TCDD dose as low as 0.20 μg/kg (Gray et al., 1997). Delays in age at preputial separation were also reported in Holtzman and Wistar rats and in the Syrian hamster following in utero and lactational exposure to TCDD (Bjerke et al., 1994a,b; Roman et al., 1995; Gray et al.,

1995a; Faqi et al., 1998a). The only species studied where TCDD failed to delay the age at preputial separation was the ICR mouse (Theobald and Peterson, 1997). The ability of TCDD to delay puberty in the Long Evans rat was also observed following in utero and lactational exposure to 1.8 mg/kg of 3,3'4,4'5,5'-HCB (PCB 169) administered on gestational day 8 (Gray et al., 1999).

The spectrum of external effects caused by in utero and lactational exposure to TCDD and 3,3',4,4',5,5'-HCB (PCB 169) have been interpreted not to resemble those caused by known antiandrogens such as flutamide (Gray et al., 1999). This is evident in Holtzman and Long Evans rats by perinatal exposure to TCDD or 3,3',4,4',5,5'-HCB (PCB 169) failing to affect external androgen-dependent tissues either by reducing relative anogenital distance or by inducing areolas, retained nipples, or hypospadias (Roman and Peterson, 1998b; Loeffler and Peterson, 1999; Gray et al., 1999). Flank gland development, an androgen-dependent process that occurs in young adulthood in male hamsters, also was not affected by in utero and lactational exposure to TCDD (Gray et al., 1995a). However, other effects of in utero and lactational exposure to TCDD on the androgen-dependent endpoints of preputial separation (weight of the ventral prostate, seminal vesicle, glans penis, testis, and epididymis; daily sperm production; cauda epididymal sperm number; epididymal malformation; demasculinized and feminized sexual behavior; and feminized regulation of LH secretion) resemble effects caused by antiandrogens (Roman and Peterson, 1998b).

5.2.3.2.5. ***Prostate*****.** One of the most sensitive effects of in utero and lactational exposure to TCDD in the male Holtzman rat is a dose-related reduction in ventral prostate weight. The lowest dose of TCDD that caused this effect was 0.064 μg/kg administered on gestational day 15. It reduced ventral prostate weight in male offspring at 32 days of age (Mably et al., 1992a). However, when expressed on a relative body weight basis, 0.16 μg/kg of TCDD was the lowest dose that caused a significant reduction in ventral prostate weight. At a maternal TCDD dose of 1.0 μg/kg, significant decreases in ventral prostate weight have been detected in Holtzman rats as early as postnatal day 14 and as late as postnatal day 120 (Roman and Peterson, 1998; Mably et al., 1992a). In addition to weight of the ventral prostate being reduced by in utero and lactational TCDD exposure in Holtzman rats (Mably et al., 1992a; Bjerke et al., 1994a,b; Roman et al., 1995; Roman and Peterson, 1998), this effect of perinatal TCDD exposure has also been observed in Long Evans and Sprague-Dawley rats (Gray et al., 1997; Wilker et al., 1996) and in ICR and C57BL/6 mice (Theobald and Peterson, 1997; Sommer and Peterson, 1997; Lin et al., 2000). Although a decrease in ventral prostate weight following in utero and lactational exposure to TCDD was not observed in Wistar rats, this may have been caused by the low level of TCDD exposure used in this study (Faqi et al., 1998a). When the same investigators

administered 10 μg/kg of 3,3'4,4'5-PCB (PCB 126) on gestational day 15 to Wistar rats, ventral prostate weights in 70- and 170-day-old offspring were reduced (Faqi et al., 1998b). Administration of 1.8 mg/kg of 3,3',4,4',5',5-HCB (PCB 169) on gestational day 8 reduced ventral prostate weight in Long Evans rats at 65, 260, and 600 days of age (Gray et al., 1999). However, exposure to 100 μg/kg of 3,3'4,4'-TCB (PCB 77) on gestational day 15 had no effect on ventral prostate weight of Wistar rats at 70 and 170 days of age (Faqi et al., 1998b). Taken together, these results demonstrate that in utero and lactational exposure to certain Ah receptor agonists, namely, TCDD, PCB 126, and PCB 169, are capable of reducing ventral prostate weight in various strains of rats and mice. PCB 77 does not appear to share this effect with the other Ah receptor agonists, and this may be due to the more rapid rate of metabolism and elimination of PCB 77 in the rat than TCDD and the other coplanar PCB congeners tested.

The ability of in utero and lactational exposure to TCDD to decrease ventral prostate weight in the rat is greatest from the earliest age at which the organ can be accurately weighed until just after puberty (50 days of age). Thereafter, the magnitude of the weight reduction is progressively attenuated with advancing age, either completely or partially, depending on the dose of TCDD administered during pregnancy (Mably et al., 1992a). At minimally effective doses the reduction in ventral prostate weight is transient and not seen in adulthood. However, at maximally effective doses ventral prostate weight of adult males is reduced significantly. This has been demonstrated for TCDD in Holtzman rats, PCB 169 in Long Evans rats, PCB 126 in Wistar rats, and TCDD in ICR mice (Mably et al., 1992a; Gray et al., 1999; Faqi et al., 1998b; Theobald and Peterson, 1997). In utero and lactational exposure to TCDD also decreases weight of the dorsolateral prostate and anterior prostate (coagulating gland) in the Holtzman rat, ICR mouse, and C57BL/6 mouse (Roman et al., 1995; Theobald and Peterson, 1997; Sommer and Peterson, 1997; Roman and Peterson, 1998; Loeffler and Peterson, 1999; Lin et al., 2000). Thus, TCDD exposure is capable of interfering with ventral, dorsolateral, and/or anterior prostate growth and morphogenensis early in development. Depending on the dose administered during pregnancy, timing of the exposure, species or strain of animal, and lobe of the prostate, TCDD is capable of causing a prostate lesion that cannot be compensated for later in life. Besides size of the ventral prostate being smaller in adulthood, its responsiveness to testosterone stimulation in adulthoood is also impaired by perinatal exposure to TCDD (Bjerke et al., 1994b).

The mechanism by which in utero and lactational exposure to TCDD impairs prostate growth and development is unknown. It cannot be explained in Holtzman rats by TCDD decreasing plasma androgen concentrations (Chen et al., 1993; Roman et al., 1995; Gray et al., 1995a) or inhibiting the conversion of circulating androgens to DHT in the prostate (Roman et al., 1995; Theobald et al., 2000). TCDD probably acts directly on the urogenital sinus from which the prostate develops and on the developing lobes of the prostate as they undergo

differentiation. The Ah receptor and ARNT are expressed in both the rat urogenital sinus and the developing ventral and dorsolateral prostate (Roman et al., 1998a; Sommer et al., 1998) and the infantile rat ventral prostate is responsive to in utero and lactational TCDD exposure in terms of CYP1A induction (Roman and Peterson, 1998). Also, various androgen-regulated mRNAs that code for secretory proteins that are produced by prostate luminal epithelial cells and are markers for functional differentiation of these cells show transient decreases in response to perinatal TCDD exposure in the Holtzman rat (Roman and Peterson, 1998a).

In utero and lactational exposure to TCDD begins to impair rat prostate development during fetal life (Roman et al., 1998a). Therefore, it is important to determine the concentration of TCDD that is present in the fetal urogenital tract after gestational day 15 because this is when fetal prostate development is initiated in the rat. Administration of 1.15 μg/kg of TCDD on gestational day 8 to Long Evans rats results in concentrations of TCDD in the urogenital tract of the fetus of 0.04 and 1.1 pg/g on gestational days 16 and 21, respectively (Hurst et al., 1998). This is significant because a slightly lower dose of TCDD, 1.0 μg/kg, administered to Long Evans rats on either gestational day 8 or 15, causes a decrease in ventral prostate weight of the offspring peripubertally that disappears in adulthood (Gray et al., 1993, 1995a, 1997, 1999). Furthermore, 1.0 μg/kg of TCDD administered on gestational day 15 to Holtzman rats impairs prostate growth and development postnatally (Roman and Peterson, 1998b) and reduces the number of prostatic buds that emerge from the fetal urogenital sinus on gestational day 20 to form the various lobes of the prostate (Roman et al., 1998a). In addition, this same dose of TCDD decreased cell proliferation in the ventral prostate of Holtzman rat neonates that were 1 day of age (Roman et al., 1998a). Subsequent analysis of the effects of TCDD on early postnatal development of the ventral prostate revealed that differentiation of both smooth muscle cells and luminal epithelial cells was delayed and striking alterations in histology of the ventral prostate were apparent in male offspring at 32 days of age (Roman et al., 1998a). These alterations consisted of epithelial hyperplasia, decreased abundance of fully differentiated luminal epithelial cells, increased density of basal epithelial cells, altered spatial distribution of the androgen receptor, and increased thickness of the periductal smooth muscle sheath. Thus, the effects of in utero and lactational TCDD exposure on prostate growth and development are contributed by impaired growth of the developing organ prenatally and neonatally and by delayed and/or impaired differentiation postnatally that, if the dose of TCDD is high enough, could be permanent.

Essentially nothing is known about the long-term consequences of in utero and lactational exposure to Ah receptor agonists on the prostate of laboratory rodent species during old age. The only study available found that the incidence of acute prostatitis in the dorsolateral prostate of 600-day-old Long Evans rats was increased significantly by exposure to a single dose of 1.8

mg/kg of 3,3',4,4',5,5'-HCB on gestational day 8 (Gray et al., 1999). Also, 1 of 9 males displayed diffuse epithelial hypertrophy of the ventral prostate compared with 0 of 15 control males (Gray et al., 1999).

To understand the mechanism by which TCDD impairs the initial step in rat prostate formation, it is important to note that both the Ah receptor and ARNT proteins are expressed in high concentrations in the fetal Holtzman rat urogenital sinus (Sommer et al., 1999). The fetal rat prostate develops from the urogenital sinus. Solid cords of basal epithelial cells (prostatic buds) emerge from the urogenital sinus and invade the surrounding mesenchyme on gestational day 18.5. By gestational day 20.5 this budding process, which TCDD partially blocks (Roman et al., 1998a), is complete. Ah receptor and ARNT proteins were expressed at high levels in the rat urogenital sinus on gestational days 16, 18, and 20, with mean concentrations of 600 fmoles Ah receptor and 140 fmoles ARNT per mg total tissue lysate (Sommer et al., 1999). From a mechanism point of view, it is significant that Ah receptor protein levels were approximately four times greater than ARNT. Since ARNT dimerizes with several members of the bHLH PAS family of transcription factors, it raises the possibility that TCDD activation of the Ah receptor in the urogenital sinus might sequester ARNT from participating in endogenous protein-protein interactions that may be essential for prostate development. Whatever the mechanism, it is clear that the Ah receptor plays a role. The recent finding that impairment of ventral prostate growth and development in Ah receptor wild-type mice by in utero and lactational exposure to 5 μg/kg of TCDD on gestational day 14 is blocked in Ah receptor knockout mice administered the same dose of TCDD supports this view (Lin et al., 2000).

Ah receptor and ARNT proteins are also expressed in human fetal, benign hyperplastic, and malignant prostate (Kashani et al., 1998). Also, TCDD exposure in a human prostate cancer cell line, LNCaP, dose-dependently inhibits androgen-dependent transcriptional activity and prostate-specific antigen expression (Jana et al., 1999). Thus, the human prostate, like the rat and mouse prostate, is capable of responding to TCDD.

5.2.3.2.6. ***Seminal vesicle*****.** Weight of the seminal vesicle is decreased in Holtzman, Sprague-Dawley, and Long Evans rats and Syrian hamsters by in utero and lactational exposure to TCDD (Mably et al., 1992a; Bjerke and Peterson, 1994; Gray et al., 1995a; Wilker et al., 1996; Gray et al., 1997). The same effect has been observed in Long Evans rats with 3,3',4,4',5,5'-HCB (PCB 169) and in Wistar rats with 3,3'4,4'-TCB (TCB-77) (Gray and Kelce, 1996; Gray et al., 1999; Faqi et al., 1998b). The lowest maternal dose of TCDD to decrease seminal vesicle weight was 0.16 μg/kg administered on gestational day 15. It significantly decreased seminal vesicle weight in Holtzman rat offspring at 32 and 63 days of age (Mably et al., 1992a).

In Wistar rats a multiple dosing regimen with TCDD that caused a significant decrease in cauda epididymal sperm numbers, daily sperm production, and sperm morphology failed to decrease seminal vesicle weight (Faqi et al., 1998a). This implies that the TCDD-induced decrease in seminal vesicle weight is not the most sensitive effect of TCDD on the developing male reproductive system. 3,3',4,4',5-PCB (PCB 126) administered as a single dose of 10 μg/kg on gestational day 15 also had no effect on seminal vesicle weight in the Wistar rat even though it did significantly decrease ventral prostate weight (Faqi et al., 1998b). Thus, the TCDD-induced reduction in seminal vesicle weight is not as sensitive as some of the other developmental reproductive system endpoints in the Wistar rat (Faqi et al., 1998a). Similarly, in Holtzman rats and ICR mice sensitivity of the seminal vesicle to TCDD is not as great as that of the ventral prostate (Mably et al., 1992a; Roman et al., 1995; Theobald and Peterson, 1997). In Long Evans rats the two accessory sex organs seem equivalent in their sensitivity to TCDD administered on day 15 of gestation (Gray et al., 1997).

The time course of the response of the prostate and seminal vesicle to in utero and lactational TCDD exposure in the Holtzman rat is very different (Roman et al., 1995). The ventral and dorsolateral prostate respond with the greatest relative weight reduction early in development and the magnitude of the response lessens with increasing age. In the case of the seminal vesicle, the opposite is true. Significant TCDD-induced decreases in weight are generally not detected until the peripubertal stage when androgen concentrations are rapidly increasing (Roman et al., 1995). Also, the magnitude of the decrease in seminal vesicle relative weight is not as great as it is for the prostate. The difference in time course of weight reduction between the seminal vesicle and prostate suggest that small TCDD-induced reductions in plasma androgen concentrations peripubertally might account for the small decreases in weight of the seminal vesicles in Holtzman rats at this age (Roman et al., 1995; Roman and Peterson, 1998a). A deficiency in number of androgen receptors in the seminal vesicle is not involved, because the decrease in seminal vesicle weight in 330-day-old Long Evans rat exposed to 1.0 μg/kg of TCDD on gestational day 15 was not associated with a decrease in the concentration of androgen receptors in the seminal vesicle (Gray et al., 1995a).

Another difference between the two accessory sex organs is the effect of in utero and lactational exposure to TCDD on their responsiveness to androgenic stimulation in adulthood. The adult ventral prostate is clearly affected by such exposure and is relatively refractory in its responsiveness to androgens. On the other hand, responsiveness of the adult seminal vesicle to testosterone stimulation is not affected by in utero and lactational exposure to TCDD (Bjerke et al., 1994b).

Consistent with the findings in Holtzman rats (Roman et al., 1995), Long Evans rats exposed on gestational day 15 to 1.0 μg/kg of TCDD and assessed on postnatal days 15, 25, 32,

49, 63, and 120 did not exhibit a decrease in weight of the paired seminal vesicles and attached coagulating glands until postnatal day 32 (Hamm et al., 2000). Furthermore, in utero and lactational exposure to TCDD reduced the amount of secretory fluid contained in the seminal vesicles at this age, which contributed to their decreased weight (Hamm et al., 2000). As with the TCDD-exposed ventral prostate at 32 days of age (Roman et al., 1998a), there were striking alterations in histology of the seminal vesicle at 32 days of age (Hamm et al., 2000). Compared with control animals where seminal vesicle epithelium displayed extensive branching, TCDD-exposed rats had seminal vesicles with fewer and shorter epithelial branches. The epithelium of control rats was characterized by tall columnar cells, whereas that of TCDD-exposed rats contained smaller cells with a lower cytoplasmic-volume to nuclear-volume ratio (Hamm et al., 1999, 2000). Immunostaining for proliferating cell nuclear antigen (PCNA) in control seminal vesicles at 32 days of age was localized to undifferentiated basal cells and no immunoreactivity was observed in terminally differentiated luminal epithelial cells. In contrast, the undifferentiated seminal vesicles of TCDD-exposed rats at the same age exhibited PCNA immunoreactivity at both the basal and luminal surfaces of poorly branched glands (Hamm et al., 2000). Thus, the collective database demonstrates that in utero and lactational exposure to TCDD interferes with epithelial proliferation and differentiation in the seminal vesicle as has been reported for the rat prostate (Hamm et al., 2000; Roman et al., 1998a).

5.2.3.2.7. ***Glans penis.*** Like the prostate and seminal vesicle, the glans penis is an androgen-dependent tissue. In utero and lactational exposure to 1.0 μg/kg of TCDD on gestational day 15 decreased glans penis diameter and absolute weight in Holtzman rats at 63 days of age, but had no effect on glans penis length or relative weight (Bjerke and Peterson, 1994). Weight of the glans penis was reduced in 450-day-old Long Evans rats exposed on gestational day 15 to either 0.20 or 0.80 μg/kg of TCDD (Gray et al., 1997).

5.2.3.2.8. ***Testis weight.*** In utero and lactational exposure to a single dose of TCDD administered on gestational day 15 decreases testis weight in Holtzman, Long Evans, and Sprague-Dawley rats (Mably et al., 1992c; Gray et al., 1995a; Wilker et al., 1996). The effect is transient, being manifested to the greatest extent peripubertally and then decreasing with age. It is not as sensitive an endpoint as the decrease in ventral prostate weight or reduction in cauda epididymal sperm numbers in Holtzman rats or the decrease in ejaculated sperm numbers in Long Evans rats (Mably et al., 1992a,c; Gray et al., 1995a, 1997). Also, in Wistar rats exposed in utero and via lactation to TCDD in a multiple dosing regimen, testis weight is not affected at levels of TCDD exposure that decrease daily sperm production (Faqi et al., 1998a). In utero and lactational exposure to TCDD had no effect on testis weight in the ICR mouse, but did decrease

it in the Syrian hamster (Theobald and Peterson, 1997; Gray et al., 1995a). Thus, among laboratory rodent species there are both strain and species differences in susceptibility to TCDD-induced decreases in testis weight.

There is also variability in the extent to which in utero and lactational exposure to individual non-ortho-substituted PCB congeners are capable of producing this effect. Exposure to 3,3',4,4',5,5'-HCB (PCB 169) on gestational day 8, or to 3,3',4,4'-TCB on gestational day 15, reduced testis weight in Wistar rat offspring (Gray and Kelce, 1996; Gray et al., 1999; Faqi et al., 1998b). However, exposure to 3,3',4,4',5-PCB (PCB 126) on gestational day 15 had no effect on testis weight in the Wistar rat strain (Faqi et al., 1998b).

5.2.3.2.9. ***Epididymis weight and malformation.*** In utero and lactational exposure to TCDD has been shown to reduce epididymal weight in Holtzman, Long Evans, and Sprague-Dawley rat strains (Mably et al., 1992c; Bjerke and Peterson, 1994; Gray et al., 1995a, 1997, 1999; Wilker et al., 1996). In these studies TCDD was administered on gestational day 15, except for the studies by Gray et al. (1995a), where it was also administered on gestational day 8. In the Wistar rat strain a multiple dosing regimen was used for in utero and lactational TCDD exposure and it was not associated with a reduction in the epididymal weight of the progeny (Faqi et al., 1998a). Weight of the epididymis was also not reduced by in utero and lactational TCDD exposure in the ICR mouse (Theobald and Peterson, 1997), but cauda epididymal weight was reduced by TCDD exposure on gestational day 11 in the Sryrian hamster (Gray et al., 1995a). In rat strains that responded to perinatal TCDD exposure by reducing epididymal weight in progeny, certain non-ortho-substituted PCB congeners had the same effect. Administration of 3,3'4,4'5,5'-HCB (PCB 169) on gestational day 8 decreased whole epididymal weight in Long Evans rats, whereas weight of the epididymides in Wistar rats was either not affected or slightly reduced by 3,3',4,4'-TCB (PCB 77) or 3,3',4,4',5-PCB (PCB 126) administered on gestational day 15 (Gray and Kelce, 1996; Gray et al., 1999; Faqi et al., 1998b) .

Compared with decreased testis weight, decreased epididymis and cauda epididymis weights in the Holtzman rat were more sensitive and persistent effects of in utero and lactational TCDD exposure. This is demonstrated by dose-related decreases in weight of the cauda epididymis occurring in Holtzman rats at 120 days of age and cauda epididymal weight being reduced significantly at this age by the lowest dose of TCDD used in the study, 0.064 μg/kg (Mably et al., 1992c). The lowest dose of TCDD reported to decrease epididymal weight in other studies was 0.20 μg/kg in the Long Evans rat (Gray et al., 1997) and the lowest dose tested in the Sprague-Dawley rat, 0.5 μg/kg (Wilker et al., 1996).

The reduction in epididymal weight following in utero and lactational exposure to 1.0 μg/kg of TCDD on gestational day 15 could be permanent in certain rat strains. Significant

decreases in whole epididymal or cauda epididymal weights have been observed in 120-day-old Holtzman rats and 240- to 330-day-old Long Evans rats (Mably et al., 1992c; Gray et al., 1995a). Since epididymal growth is androgen dependent, a TCDD-induced androgenic deficiency and/or decrease in androgen responsiveness of the epididymis could account for decreased size of the organ (Setty and Jehan, 1977; Dhar and Setty, 1990). However, if an antiandrogenic mechanism is involved, it does not appear to be associated with decreases in plasma androgen levels or epididymal androgen receptor levels. This is because in utero and lactational exposure to TCDD has been shown not to reduce circulating androgen concentrations in Holtzman or Long Evans rats at various stages of postnatal development (Roman et al., 1995; Gray et al., 1995a). Also TCDD does not reduce androgen receptor concentrations in either the caput or corpus epididymis when measured in 240- to 330-day-old Long Evans rat progeny exposed perinatally to TCDD (Gray et al., 1995a).

The highest dose of TCDD to be investigated on epididymal development was 2.0 μg/kg administered on gestational day 15 to Sprague-Dawley rats (Wilker et al., 1996). The effects of this high dose on morphological development of the rat epididymis are useful in providing insight into possible mechanisms of action of TCDD on the epididymis. More specifically, this dose of TCDD induced a high incidence of malformations in the epididymis (27%) that were characterized by the segmental absence of regions of the epididymis (Wilker et al., 1996). This high incidence is similar to that reported for rats and mice exposed in utero to the antiandrogen flutamide (van der Schoot, 1992; Cain et al., 1994a,b) and suggests that TCDD may alter testosterone-dependent differentiation of the Wolffian duct into the epididymis (Wilker et al., 1996).

5.2.3.2.10. ***Testicular and epididymal sperm numbers.*** Among the most robust, sensitive, persistent, and reproducible effects of in utero and lactational TCDD exposure in rats, hamsters, and mice are reductions in sperm numbers (Roman and Peterson, 1998b). Generally when TCDD is administered as a single dose during pregnancy, daily sperm production is affected the least. Caput epididymal sperm numbers are reduced to a greater extent than daily sperm production (Gray et al., 1997). Cauda epididymal sperm numbers are reduced more than caput epididymal sperm numbers by in utero and lactational exposure to TCDD. In fact, statistically significant, dose-related reductions in cauda epididymal sperm numbers have been reported for four strains of rats, mice, and hamsters following in utero and lactational exposure to TCDD (Mably et al., 1992c; Gray et al., 1995a, 1997; Wilker et al., 1996; Theobald and Peterson, 1997; Faqi et al., 1998a). The greatest magnitude of reduction in sperm numbers at any given dose of TCDD, however, has been reported for ejaculated sperm numbers in two strains of rats and the hamster (Gray et al., 1995a, 1997; Sommer et al., 1996). Thus, the overall effect of exposure to a

single dose of TCDD administered on gestational day 15 in rats and hamsters is that it causes a progressively greater percentage decrease in sperm numbers in going from the testis (daily sperm production), to caput epididymal sperm numbers, to cauda epididymal sperm numbers, to ejaculated sperm numbers. Taken together, these results imply that in utero and lactational TCDD exposure alters epididymal function such that epididymal sperm storage is permanently reduced (Gray et al., 1995a).

An entirely different profile of inhibitory effects of in utero and lactational exposure to TCDD on sperm numbers, however, was observed in Wistar rats that were exposed to multiple doses of TCDD during mating, pregnancy, and lactation (Faqi et al., 1998b). With this multiple-dosage TCDD exposure paradigm in Wistar rats, the percentage decrease in daily sperm production was greater than the percentage decrease in cauda epididymal sperm numbers (Faqi et al., 1998a)—just the opposite of what was observed in Long Evans and Holtzman rats where TCDD was administered as a single dose (Gray et al., 1995a, 1997; Sommer et al., 1996). It is possible that the difference in rat strain or the TCDD exposure paradigm between these studies accounts for the testis being more sensitive than the cauda epididymis to TCDD-induced decreases in sperm numbers in the study by Faqi and coworkers (1998a).

The lowest single dose of TCDD to decrease cauda epididymal sperm numbers in 120-day-old Holtzman rats was 0.064 μg/kg administered on gestational day 15 (Mably et al., 1992c). The lowest single dose to decrease ejaculated sperm numbers in 450 day old Long Evans rats was 0.050 μg/kg of TCDD administered on gestational day 15 (Gray et al., 1997). Faqi and coworkers (1998a), using a multiple dosing regimen for in utero and lactational exposure of Wistar rat progeny to TCDD, found that the lowest dosing regimen to significantly decrease daily sperm production and cauda epididymal sperm numbers in 170-day-old Wistar rats was a 0.025 μg TCDD/kg loading dose followed by a 0.005 μg TCDD/kg weekly maintenance dose (Faqi et al., 1998a). When the male offspring exposed in utero and via lactation to TCDD in this manner were weaned at 22 days of age, the mean concentration of TCDD in the testis and liver was 0.25 ng/g and 0.24 ng/g, respectively (Faqi et al., 1998a).

5.2.3.2.10.1. ***Daily sperm production.*** In utero and lactational exposure to TCDD in Holtzman rats caused a dose-related decrease in daily sperm production in progeny at 49, 63, and 120 days of age (Mably et al., 1992c). The lowest dose of TCDD administered on gestational day 15 to reduce daily sperm production in 120-day-old Holtzman rats was 0.064 μg/kg. Other studies have also reported that in utero and lactational exposure to TCDD is capable of significantly decreasing daily sperm production in Holtzman, Long Evans, and Wistar rats (Bjerke and Peterson, 1994; Sommer et al., 1996; Gray et al., 1997; Faqi et al., 1998b), but this effect was not observed in Sprague-Dawley rats (Wilker et al., 1996), ICR mice (Theobald and Peterson, 1997),

or Syrian hamsters (Gray et al., 1995a). In the three rat strains where decreased daily sperm production is observed, the response lessens in severity as the progeny age and in some cases returns to control levels (Mably et al., 1992c; Gray et al., 1995a). The Long Evans rat is an example of a rat strain where the decrease in daily sperm production caused by perinatal TCDD exposure is transient (Gray et al., 1995a, 1997). Among the most persistent effects of TCDD on daily sperm production was found in 170-day-old Wistar rats exposed to TCDD dosing during mating, pregnancy, and lactation (Faqi et al., 1998b). It has also been observed in Long Evans rats that administration of TCDD on gestational day 15 is more effective than administering it on gestational day 8 (Gray et al., 1995a; Gray and Kelce, 1996).

Effects on daily sperm production in Long Evans and Wistar rat strains by certain non-ortho-substituted PCBs was variable. In utero and lactational exposure to 3,3',4,4',5',5-HCB (PCB 169) on gestational day 8 reduced daily sperm production in Long Evans rats (Gray et al., 1995b, 1999; Gray and Kelce, 1996). However, exposure of Wistar rats on gestational day 15 to 3,3',4,4',5-PCB (PCB 126) had no effect (Faqi et al., 1998b). Furthermore, in utero and lactational exposure to 3,3',4,4'-TCB (PCB 77) increased both testis size and daily sperm production in 65- and 140-day-old Wistar rats. It was hypothesized that this latter paradoxical effect for an Ah receptor agonist of increasing daily sperm production may be secondary to a possible non-Ah receptor-mediated effect of PCB 77, such as neonatal hypothyroidism (Faqi et al., 1998b).

While severe undernutrition of rat pups and weanlings can adversely affect the male reproductive system and decrease spermatogenesis (Ghafoorunissa, 1980; Jean-Faucher et al., 1982a,b; Glass et al., 1986), it is unlikely that this was involved in reducing daily sperm production caused by in utero and lactational exposure of Holtzman rats to TCDD (Mably et al., 1992c). At the two highest maternal TCDD doses, 0.40 and 1.0 μg/kg, feed consumption and body weight of male offspring were decreased up to 21%, but there was essentially no effect on feed intake or body weight at the two lowest doses, 0.160 and 0.064 μg/kg. However, reduction in daily sperm production, cauda epididymal sperm numbers, and certain sex organ weights, occurred at the two lowest doses. Thus, undernutrition cannot account for these effects (Mably et al., 1992a,c).

Because follicle-stimulating hormone (FSH) and testosterone are essential for quantitatively normal spermatogenesis (Steinberger and Steinberger, 1989), an alternative explanation for the decreases in daily sperm production is a decrease in FSH and/or testosterone levels. In rats, the duration of spermatogenesis is 58 days (Blazak et al., 1985; Amann, 1986; Working and Hurtt, 1987), so the decreases in plasma FSH concentrations in 32-day-old male offspring could contribute to the reductions in daily sperm production when the progeny were 49 and 63 days of age (Mably et al., 1992c). However, the modest depressant effect of perinatal

TCDD exposure on plasma FSH concentrations was transitory, with no effect on plasma FSH levels being found when the offspring were 49, 63, and 120 days old (Mably et al., 1992c). Therefore, it was concluded that reduced daily sperm production in 120-day-old rats perinatally exposed to TCDD is not due to decreases in plasma FSH levels when the animals were 49 to 120 days of age (Mably et al., 1992c). Also, administration of 1.0 μg/kg of TCDD on gestational day 15 to Holtzman rats did not affect testicular testosterone production of their progeny at either prenatal or postnatal stages of development (Chen et al., 1993; Roman et al., 1995). Therefore, a reduction in intratesticular testosterone levels following such TCDD exposure would not be sufficient to reduce spermatogenesis (Zirkin et al., 1989; Mably et al., 1992c; Gray et al., 1993).

In normal rats, daily sperm production does not reach a maximum until 100 to 125 days of age (Robb et al., 1978), but in rats perinatally exposed to TCDD it takes longer for sperm production to reach the adult level. Furthermore, the length of the delay for daily sperm production to attain control levels appears to be directly related to TCDD dose (Mably et al., 1992c). If the dose is high enough, the reduction in daily sperm production may be permanent. This is suggested by in utero and lactational exposure to TCDD decreasing daily sperm production in 170-day-old Wistar rats (Faqi et al., 1998b) and 300-day-old Holtzman rats (Moore et al., 1992). However, in Long Evans rat the TCDD-induced reduction in daily sperm production is transient and does not last beyond the peripubertal stage of development (Gray et al., 1997).

5.2.3.2.10.2. *Testis histology*. A key observation for postulating mechanisms by which perinatal TCDD exposure reduces spermatogenesis in the Holtzman rat strain in adulthood is the finding that the ratio of leptotene spermatocytes per Sertoli cell in the testes of 49-, 63-, and 120-day-old Holtzman rats is not affected by in utero and lactational TCDD exposure even though daily sperm production is reduced (Mably et al., 1992c). Because Sertoli cells provide spermatogenic cells with functional and structural support (Bardin et al., 1988) and the upper limit of daily sperm production in adult rats is directly dependent on the number of Sertoli cells per testis (Russell and Peterson, 1984), three possible mechanisms for the decrease in daily sperm production in Holtzman rats may be involved. TCDD could increase the degeneration of cells intermediate in development between leptotene spermatocytes and terminal-stage spermatids (the cell type used to calculate daily sperm production); decrease postleptotene spermatocyte cell division (meiosis); and/or decrease the number of Sertoli cells per testis (Orth et al., 1988). In a histological study of the testis in Holtzman rats exposed to TCDD in utero and via lactation, it was found that spermatogenesis was qualitatively normal; there was no indication of a gross histological lesion nor any evidence of germ cell degeneration (Shinomiya et al., 1994).

In Long Evans rats exposed in utero and via lactation to TCDD, testicular histopathology was not typically affected (Gray et al., 1995a). That is, there was generally no histological evidence for degeneration of the seminiferous tubules, Sertoli cell abnormalities, or retained spermatids in progeny exposed in utero and via lactation to TCDD (Gray et al., 1997). On occasion, however, both Long Evans rat progeny and Syrian hamster progeny of dams exposed to TCDD exhibited severe atrophy of the seminiferous tubules that was associated with a marked loss of spermatogenic activity (Gray et al., 1997).

In Wistar rats that were exposed to TCDD using a multiple dosing regimen during mating, pregnancy, and lactation, the decrease in daily sperm production observed at the two lowest TCDD exposure levels was not associated with any testicular pathology (Faqi et al., 1998a). However, at the highest level of in utero and lactational TCDD exposure some seminiferous tubuli showed pyknotic nuclei and cell debris in the lumen (Faqi et al., 1998a). In utero and lactational exposure to 1.0 μg/kg of TCDD on gestational day 15 did not cause abnormal testicular histology in 62-day-old Sprague-Dawley rats (Wilker et al., 1996). The number of Sertoli cells per testis and number of Sertoli cells per gram testis was not affected by TCDD. However, the ratio of the number of elongated spermatids in testicular homogenates to the number of Sertoli cells per testis was significantly lower in TCDD-exposed progeny (Wilker et al., 1996).

5.2.3.2.10.3. ***Epididymal sperm numbers.*** The epididymis has two functions: in the caput and corpus epididymis, proximal regions of the organ, spermatozoa mature gaining the capacity for motility and fertility, whereas in the cauda epididymis, the distal region, mature sperm are stored before ejaculation (Robaire and Hermo, 1989). Mably et al. (1991, 1992c) found that motility and morphology of sperm taken from the cauda epididymis on postnatal days 63 and 120 were unaffected by perinatal TCDD exposure. Exposure of Wistar rats to TCDD in a multiple-dosing regimen during mating, pregnancy, and lactation caused small but significant increases in the percentage of abnormal sperm in 170-day-old male offspring (Faqi et al., 1998a). However, in Wistar rats exposed in utero and via lactation to a single dose of 3,3',4,4'-TCB (PCB 77) or 3,3',4,4',5-PCB (PCB 126) on gestational day 15, no effect on the percentage of abnormal sperm was found in 65- or 140-day-old male progeny (Faqi et al., 1998b).

It bears repeating at this time that the most sensitive, robust, persistent, and reproducible effect of in utero and lactational exposure to TCDD on the male reproductive system of laboratory rodents is a decrease in cauda epididymal sperm numbers. This effect has been demonstrated for Holtzman, Long Evans, Sprague-Dawley, and Wistar rats as well as ICR mice and Syrian hamsters (Mably et al., 1992c; Gray et al., 1995a, 1997; Wilker et al., 1996; Theobald

and Peterson, 1997; Faqi et al., 1998a). The lowest dose of TCDD to produce this effect is 0.064 μg/kg administered on gestational day 15 to Holtzman rats (Mably et al., 1992c).

Following in utero and lactational exposure to a single dose of TCDD there is a graded decline in sperm numbers as they travel from the testis through the caput, corpus, and cauda epididymis and are ejaculated (Gray et al., 1995a, 1997; Sommer et al., 1996). While these results suggest that sperm transit rate through the epididymis should be increased by in utero and lactational TCDD exposure, three studies that have determined epididymal sperm transit rates have reached different conclusions. The most rigorous examination of this endpoint was the study by Sommer et al. (1996). They found that in Holtzman rats administered TCDD on gestational day 15 there was no effect on epididymal sperm transit rate. This rules out the possibilities of sperm loss via spontaneous ejaculation or abnormal introduction of sperm into urine (Sommer et al., 1996). In contrast, in utero and lactational exposure of Sprague-Dawley rats to TCDD on gestational day 15 was reported to increase in epididymal sperm transit rate (Wilker et al., 1996), and using a multiple-dosing regimen for in utero and lactational TCDD exposure in Wistar rats, a decrease in epididymal sperm transit rate was found (Faqi et al., 1998a).

In association with the reduction in cauda epididymal sperm numbers, there is a distinct tendency for an increased incidence of a chronic inflammatory reaction in the epididymis of Long Evans rats exposed in utero and via lactation to 3,3',4,4',5,5'-HCB (PCB 169) (Gray et al., 1999) and in Holtzman rats exposed to TCDD (Sommer and Peterson, unpublished results). Furthermore, the decrease in cauda epididymal sperm numbers in adult hamsters following in utero and lactational exposure to TCDD is associated with an increased incidence of sperm granulomas in epididymides and/or testes. This lesion was characterized by a nodular accumulation of fibrous connective tissue and mixed inflammatory cells surrounding degenerating sperm in the interstitium of the epididymides and testes. Taken together, these findings suggest that the reduction in cauda epididymal sperm numbers caused by in utero and lactational exposure to TCDD in the hamster are due in part to sperm resorption from the epididymis. Furthermore, since resorption of sperm in the epididymis is often associated with the accumulation of inflammatory cells in the organ, sperm resorption from the epididymis might also be occurring in postpubertal Holtzman rats exposed to TCDD in utero and via lactation (Sommer and Peterson, unpublished results).

5.2.3.2.10.4. ***Ejaculated sperm numbers.*** Although it has been assessed in only two rat strains, Long Evans and Holtzman, and in the Syrian hamster, the effect on the male reproductive system that is detected at the lowest dose of TCDD administered during pregnancy is that which causes a decrease in ejaculated sperm numbers. The lowest single dose of TCDD administered during

pregnancy that causes this effect is 0.050 μg/kg administered on gestational day 15 in the Long Evans rat with ejaculated sperm numbers assessed in adulthood (Gray et al., 1997). In addition to the reduction in total number of sperm ejaculated during the mating period there was also a reduction in the number of sperm in copulatory plugs. The small reduction in sperm produced by the testis of Long Evans rats, exposed perinatally to TCDD, was not sufficient to account for the larger reductions in cauda epididymal sperm numbers and ejaculated sperm numbers. Finally, there was no reduction in the number of copulatory plugs produced by TCDD-exposed males, indicating no interference with copulation (Gray et al., 1995a).

5.2.3.2.11. ***Reproductive capability.*** To assess reproductive capability, male Holtzman rats born to dams given TCDD (0.064, 0.16, 0.40, or 1.0 μg/kg) or vehicle on day 15 of gestation were mated with control virgin females when the males were 70 and 120 days of age (Mably et al., 1991, 1992c). The fertility index of the males is defined as number of males impregnating females divided by number of males mated. The two highest maternal TCDD doses decreased the fertility index of the male offspring by 11% and 22%, respectively. However, these decreases were not statistically significant, and at lower doses the fertility index was not reduced. The gestation index, defined as the percentage of control dams mated with TCDD-exposed males that delivered at least one live offspring, was also not affected by in utero and lactational TCDD exposure.

With respect to progeny of these matings, the results of the above study (Mably et al., 1992c) and more recent studies are somewhat inconsistent possibly due to differences in the rat strain used. Gray et al. (1995a) reported in the Long Evans that there were fewer implants in females mated to gestational day 15 TCDD-treated male offspring. On the other hand, all male Wistar rat offspring exposed during mating, pregnancy, and lactation to TCDD were able to impregnate unexposed female rats and to produce viable fetuses (Faqi et al., 1998a). For these TCDD-exposed male rat progeny, their mating, pregnancy, and fertility indices were similar to control. Also, the number of implantations, resorption rate, number of viable and dead fetuses, and sex ratio of the progeny were similar among control and TCDD treatment groups (Faqi et al., 1998a). Similar to the results in Wistar rats, Mably et al. (1992c) reported that there was no effect on litter size, live birth index, or 21-day survival index for male Holtzman rat offspring that were mated to unexposed females.

Effects of in utero and lactational exposure to non-ortho-substituted PCB congeners has also been investigated on the reproductive capability of male rat progeny when they reach sexual maturity. Exposure to 1.8 mg/kg of 3,3',4,4',5,5'-HCB (PCB 169) on gestational day 1 reduced the fertility of the PCB 169-exposed male Wistar rat progeny when they were mated with unexposed control females (Smits-van Prooije et al., 1993). In contrast, treatment with either

3,3',4,4'-TCB (PCB 77) or 3,3',4,4',5-PCB (PCB 126) on gestational day 15 had no effect on the outcomes of matings between PCB 77- or PCB 126-exposed male Wistar rat progeny mated with unexposed females for the following endpoints: implantations per litter, viable fetuses per litter, or percentage resorptions (Faqi et al., 1998b).

Since rats produce and ejaculate 10 times more sperm than is necessary for normal fertility and litter size (Aafjes et al., 1980; Amann, 1982), the absence of a reduction in fertility of male rats exposed perinatally to TCDD is not inconsistent with the substantial reductions in testicular spermatogenesis and epididymal sperm reserves. In contrast, reproductive efficiency in human males is very low, the number of sperm per ejaculate being close to that required for fertility (Working, 1988). Thus, measures of fertility using rats are not appropriate for low-dose extrapolation in humans (Meistrich, 1992). A percentage reduction in daily sperm production in humans, similar in magnitude to that observed in rats (Mably et al., 1991, 1992c), could be associated with reduced fertility in men.

5.2.3.2.12. Possible mechanisms for effects on male reproductive tract growth and development. The mechanisms by which TCDD and related compounds impair male reproductive tract development are not known. Several possibilities exist and since these have been reviewed recently (Roman and Peterson, 1998b), only an overview will be presented here. It is generally assumed that most effects of in utero and lactational exposure to TCDD on development of the male reproductive system are Ah receptor mediated. While this is probable, it has not yet been proven conclusively for these endpoints. A comparison of male reproductive endpoints in wild-type and Ah receptor knockout mice, following in utero and lactational exposure to TCDD, is needed to provide this insight. Such studies in Ah receptor wild-type and Ah receptor knockout mice have shown that the decrease in prostate and seminal vesicle weight caused by perinatal exposure to TCDD is dependent on the Ah receptor (Lin et al., 2000). However, this kind of information is not available for any of the other male reproductive endpoints. Three possible Ah receptor-dependent mechanisms by which in utero and lactational exposure to TCDD could impair male reproductive development are as follows. First, the liganded Ah receptor could dimerize with ARNT and this complex could then bind to dioxin-responsive elements in the 5' regulatory regions of genes and alter their transcription in male reproductive tissues during the endocrine phase of fetal and neonatal sexual differentiation. Second, the liganded Ah receptor could compete with other PAS proteins for dimerization with ARNT at critical periods of male repoductive tract development and downregulate genes dependent on ARNT and an alternative dimerization partner for transcription. Third, the ligand-activated Ah receptor could be rapidly depleted from cells, thereby decreasing the pool of Ah receptor available for binding of an endogenous ligand or activating the transcription of genes

important in normal male reproductive development at the cellular level. Treatment of adult rats with TCDD is known to downregulate Ah receptor expression in several male rat reproductive tract tissues (Roman et al., 1998c). However, it was recently found that this does not occur in the developing rat prostate when 1.0 μg/kg of TCDD is administered on gestational day 15, making this latter Ah receptor mechanism seem less likely (Sommer et al., 1999).

In utero and lactational exposure to TCDD produces a novel constellation of growth and developmental alterations in the male rat reproductive system. These consist of decreases in accessory sex organ weights, delays in preputial separation, decreases in daily sperm production by the testis and sperm storage in the cauda epididymis, decreases in ejaculated sperm numbers, and partial demasculization of sexual behavior and partial feminization of sexual behavior and the regulation of LH secretion. Taken together, these effects are consistent with decreased testicular androgen production and/or circulating androgen concentrations. But these parameters have not been shown to be affected perinatally or at later times by perinatal exposure to TCDD (Mably et al., 1992a; Chen et al., 1993; Roman et al., 1995; Gray et al., 1995a). Nevertheless, the possibility remains that the androgenic deficiency-like syndrome caused by developmental exposure to TCDD could be the result of interference with androgen action at the level of the androgen receptor. While no effect of in utero and lactational exposure to TCDD on androgen receptor concentrations in the caput epididymis, cauda epididymis, ventral prostate, or seminal vesicle was found in 336- to 339-day-old Long Evans rats (Gray et al., 1995a), alterations in the spatial distribution of the androgen receptor were found in the ventral prostate of infantile and weanling Holtzman rats exposed perinatally to TCDD (Roman et al., 1998a). This latter effect of TCDD may explain why the ventral prostate exhibits decreased growth and abnormal differentiation in the presence of normal circulating levels of androgens (Roman et al., 1998a). Thus, it is possible that TCDD acts at or beyond the androgen receptor to interfere with prostate development.

Just because development of androgen-dependent tissues such as the prostate, seminal vesicle, epididymis, and testis are affected by in utero and lactational TCDD exposure does not necessarily mean that an antiandrogenic action of TCDD is the only mechanism by which TCDD could disrupt their development (Roman and Peterson, 1998b; Gray et al., 1999). Impaired growth and development of these organs could arise by TCDD acting on multiple components of the endocrine axis to alter concentrations of other hormones, growth factors and/or their receptors. Epidermal growth factor, prolactin, thyroid hormones, and growth hormones can influence development of certain of these organs, and their signaling pathways may be modulated by perinatal exposure to TCDD (Gray et al., 1999). Also, an important finding is that the spectrum of TCDD's effects on male reproductive system development and function does not quite match that which is produced by perinatal exposure to known antiandrogens, 5α-reductase

inhibitors, or antiestrogens (Roman and Peterson, 1998b; Gray et al., 1999). Therefore, it is possible that TCDD modulates cell proliferation and differentiation in these tissues by interfering with nonhormonal aspects of these processes. For example, prostatic budding and ductal morphogenesis are of course androgen-dependent but they also involve important mesenchymal-epithelial interactions occurring downstream of androgen receptor action that might be modulated by TCDD (Roman and Peterson, 1998b).

5.2.3.2.13. ***Sexual differentiation of the CNS*****.** Sexual differentiation of the CNS is dependent on the presence of androgens during early development. In rats, the critical period of sexual differentiation extends from late fetal life through the first week of postnatal life (MacLusky and Naftolin, 1981). In the absence of adequate circulating levels of testicular androgen during this time, adult rats display high levels of feminine sexual behavior (e.g., lordosis), low levels of masculine sexual behavior, and a cyclic (i.e., feminine) pattern of LH secretion (Gorski, 1974; Barraclough, 1980). In contrast, perinatal androgen exposure of rats will result in the masculinization of sexually dimorphic neural parameters, including reproductive behaviors, regulation of LH secretion, and several morphological indices (Raisman and Field, 1973; Gorski et al., 1978). The mechanism by which androgens cause sexual differentiation of the CNS is not completely understood. In the rat, it appears that 17ß-estradiol, formed by the aromatization of testosterone within the CNS, is one of the principal active steroids responsible for mediating sexual differentiation (McEwen, 1978); however, androgens also are involved.

5.2.3.2.13.1. ***Demasculinization of sexual behavior*****.** Mably et al. (1991, 1992b) assessed sexually dimorphic functions in male rats born to dams given graded doses of TCDD or vehicle on day 15 of gestation. Masculine sexual behavior was assessed in male offspring at 60, 75, and 115 days of age by placing a male rat in a cage with a receptive control female and observing the first ejaculatory series and subsequent postejaculatory interval. The number of mounts and intromissions (mounts with vaginal penetration) before ejaculation was increased by a maternal TCDD dose of 1.0 μg/kg. The same males exhibited twelvefold and elevenfold increases in mount and intromission latencies, respectively, and a twofold increase in ejaculation latency. All latency effects were dose related and significant at a maternal TCDD dose as low as 0.064 μg/kg (intromission latency) and 0.16 μg/kg (mount and ejaculation latencies). Copulatory rates (number of mounts + intromissions/time from first mount to ejaculation) were decreased to less than 43% of the control rate (Mably et al., 1992b). This effect on copulatory rates was dose related, and a statistically significant effect was observed at maternal TCDD doses as low as 0.16 μg/kg. Postejaculatory intervals were increased 35% above the control interval, and a statistically

significant effect was observed at maternal doses of TCDD as low as 0.40 μg/kg. Collectively, these results demonstrate that perinatal TCDD exposure demasculinizes sexual behavior.

Because perinatal exposure to a maternal TCDD dose of 1.0 μg/kg has no effect on the open field locomotor activity of adult male rats (Schantz et al., 1991), the increased mount, intromission, and ejaculation latencies in Holtzman rats (Mably et al., 1992b) appear to be specific for these masculine sexual behaviors, not secondary to a depressant effect of TCDD on motor activity. The reported postpubertal plasma testosterone and DHT concentrations in litter mates of the rats evaluated for masculine sexual behavior were as low as 56% and 62%, respectively, of controls (Mably et al., 1991, 1992a). However, plasma testosterone concentrations that were only 33% of controls are still sufficient to masculinize sexual behavior of adult male rats (Demassa et al., 1977). Therefore, the modest reductions in adult plasma androgen concentrations following perinatal TCDD exposure were not of sufficient magnitude to demasculinize sexual behavior.

Reductions in perinatal androgenic stimulation can inhibit penile development and subsequent sensitivity to sexual stimulation in adulthood (Nadler, 1969; Södersten and Hansen, 1978). Therefore, the demasculinization of sexual behavior could, to some extent, be secondary to decreased androgen-dependent penile development. However, perinatal TCDD exposure had no effect on gross appearance of the rat penis. In addition, TCDD-exposed males exhibited deficits in such masculine sexual behaviors as mount latency and postejaculatory interval, which do not depend on stimulation of the penis for expression (Sachs and Barfeld, 1976). Thus, although some effects of TCDD, such as decreased copulatory rate and prolonged latency until ejaculation, could be due to reduced sensitivity of the penis to sexual stimulation, the twelvefold increase in mount latency and increase in postejaculatory interval cannot be explained by this mechanism.

The effect of in utero and lactational exposure to 0.7 μg/kg of TCDD on gestational day 15 on the expression of masculine sexual behavior was assessed in male Holtzman rats at 61-65 and 75-79 days of age (Bjerke et al., 1994). A partial demasculinization of sexual behavior was evidenced by increased intromission latencies and a greater number of intromissions prior to ejaculation. Overall, the effects were more similar to those observed in Holtzman rats exposed on gestational day 15 to 0.4 μg/kg of TCDD (Mably et al., 1992b).

The effect of in utero and lactational exposure to 1.0 μg/kg of TCDD administered on gestational day 8 or 15 on masculine sexual behavior was assessed in Long Evans rats (Gray et al., 1998a). The expression of masculine sexual behaviors was altered to a greater extent in rats exposed to TCDD on gestational day 15 than gestational day 8. In males exposed to TCDD on gestational day 15, partial demasculinization of sexual behavior was evidenced by increases in total number of mounts prior to ejaculation, number of mounts with intromissions prior to

ejaculation, number of mounts without intromissions prior to ejaculation, and latency prior to ejaculation (Gray et al., 1995a). While the same profile of results was obtained in males exposed to TCDD on gestational day 8, the effects were not as great and were not statistically significant (Gray et al., 1995a).

Masculine sexual behavior was also assessed in male Wistar rats exposed in utero and via lactation to TCDD administered to dams during mating, pregnancy, and lactation (Faqi et al., 1998a). Mount latency and intromission latency were increased at two of three TCDD exposure levels. However, ejaculation latency, number of mounts with intromissions prior to ejaculation, and intromission frequency were not affected. Of the five endpoints of masculine sexual behavior assessed in male Wistar rat progeny that were exposed to 10 μg/kg of 3,3',4,4',5-PCB (PCB 126) on gestational day 15, only one endpoint was affected, the number of mounts with intromissions prior to ejaculation, and it was increased (Faqi et al., 1998b).

Taken together, these results demonstrate in three different rat strains, Holtzman, Long Evans, and Wistar, that in utero and lactational exposure to TCDD affects some, but not all, endpoints of masculine sexual behavior. Therefore, TCDD only partially demasculinizes sexual behavior. The response is not as robust as other endpoints, and the degree to which TCDD affects the expression of masculine sexual behavior depends on the rat strain, Ah receptor agonist, and dose administered. It is notable that male hamster progeny do not exhibit demasculinized sexual behavior following perinatal exposure to TCDD, making it difficult to extrapolate this response with certainty to other species.

5.2.3.2.13.2. ***Feminization of sexual behavior*****.** Mably et al. (1991, 1992b) determined if the potential of adult male rats to display feminine sexual behavior was altered by perinatal TCDD exposure. Male offspring of dams treated on day 15 of gestation with various doses of TCDD up to 1 μg/kg or vehicle were castrated at ~120 days of age, and beginning at ~160 days of age were injected weekly for 3 weeks with 17ß-estradiol benzoate, followed 42 hours later by progesterone. Four to six hours after the progesterone injection at weeks 2 and 3, the male was placed in a cage with a sexually excited control stud male. The frequency of lordosis in response to being mounted by the stud male was increased from 18% (control) to 54% by the highest maternal TCDD dose, 1.0 μg/kg. Lordosis intensity, scored after Hardy and DeBold (1972) as 1 for light lordosis, 2 for moderate lordosis, and 3 for a full spinal dorsoflexion, was increased in male rats by perinatal TCDD exposure. Both effects on lordosis behavior in males were dose related and significant at maternal TCDD doses as low as 0.16 μg/kg (increased lordotic frequency) and 0.40 μg/kg (increased lordotic intensity). Together, they indicate a feminization of sexual behavior in these animals. Although severe undernutrition from 5 to 45 days after birth potentiates the display of lordosis behavior in adult male rats (Forsberg et al., 1985), the

increased frequency of lordotic behavior was seen at a maternal TCDD dose of 0.16 μg/kg, which had no effect on feed intake or body weight. It was concluded that perinatal TCDD exposure feminizes sexual behavior in adult male rats independent of undernutrition.

Defeminization of sexual behavior in male rats occurs during the first week or so after birth (Goy and McEwen, 1980; Perakis and Stylianopoulou, 1985). Therefore it was hypothesized that if TCDD interferes with defeminization of sexual behavior that lactational exposure to TCDD would be more important than in utero exposure. A subsequent study by Bjerke and Peterson (1994) is consistent with this hypothesis. In their cross-fostering study on the effects of in utero versus lactational TCDD exposure in the Holtzman rat, it was found, as predicted, that feminization of male sexual behavior required lactational exposure. When exposure was restricted to the in utero period, the male offspring did not display a significant increase in lordotic behavior, whereas such behavior was increased following exposure during the lactational period, either alone or in combination with in utero exposure. Also, in a separate study it was shown following in utero and lactational exposure to 1.0 μg/kg of TCDD administered on gestational day 15 that feminine sexual behavior of male rats was partially feminized as indicated by an increase in lordosis quotient (Bjerke et al., 1994b).

In contrast to the above three studies that show in utero and lactational TCDD exposure increases the expression of feminine sexual behavior in male Holtzman rats (Mably et al., 1992b; Bjerke and Peterson, 1994; Bjerke et al., 1994b), this effect was not observed in male Long Evans rats (Gray et al., 1995a). They showed no significant increase in lordotic behavior as adults following in utero and lactational exposure to 1.0 μg/kg of TCDD on gestational day 8 or 15 (Gray et al., 1995a). This may be due to a rat strain difference in susceptibility to this endpoint.

5.2.3.2.13.3. ***Feminization of LH secretion regulation.*** The effect of perinatal TCDD exposure on regulation of LH secretion by ovarian steroids was determined in male offspring at ~270 days of age. There is normally a distinct sexual dimorphism to this response. In rats castrated as adults, estrogen-primed females greatly increase their plasma LH concentrations when injected with progesterone, whereas similarly treated males fail to respond (Taleisnik et al., 1969). Progesterone had little effect on plasma LH concentrations in estrogen-primed control males, but significant increases were seen in males exposed to maternal TCDD doses as low as 0.40 μg/kg. Thus, perinatal TCDD exposure increases pituitary and/or hypothalamic responsiveness of male rats to ovarian steroids in adulthood, indicating that regulation of LH secretion is permanently feminized.

5.2.3.2.13.4. ***Estrogen receptor concentrations in the brain and volumes of sexually dimorphic brain nuclei.*** In the Holtzman rat, in utero and lactational exposure to TCDD partially demasculinizes and feminizes sexual behavior in adult male rats, possibly by causing incomplete sexual differentiation of the CNS. To determine if TCDD exposure affects other aspects of sexual differentiation of the CNS in this rat strain, the effects of perinatal exposure to 0.7 μg/kg of TCDD administered on gestational day 15 on estrogen receptor binding in specific brain nuclei was examined along with effects on the volumes of brain nuclei that are dependent on hormone stimulation during the period of CNS sexual differentiation (Bjerke et al., 1994b). It was found that estrogen receptor concentrations in three brain nuclei—the medial preoptic nucleus (MPO), the ventrolateral aspect of the ventromedial nucleus, and the periventricular preoptic area—were higher in control females than males, but in utero and lactational exposure to TCDD had no effect on estrogen receptor concentrations in these sexually dimorphic brain nuclei (Bjerke and Peterson, 1994). It also had no effect on estrogen receptor concentrations in other brain nuclei where there was not a sex difference in estrogen receptor concentrations.

The volumes of sexually dimorphic brain nuclei were also not affected by in utero and lactational exposure to TCDD in Holtzman rats. In control rats the volume of the sexually dimorphic nucleus of the preoptic area (SDN-POA) is greater in males, whereas the MPO is greater in females. Perinatal TCDD exposure had no effect on the volume of either nucleus in male and female Holtzman rat offspring in adulthood (Bjerke and Peterson, 1994). Thus, in utero and lactational TCDD exposure is capable of partially demasculinizing and partially feminizing sexual behavior of Holtzman rat progeny (Mably et al., 1992b; Bjerke and Peterson, 1994; Bjerke et al., 1994b), but it is not associated with an effect on sexual differentiation of the estrogen receptor system in the brain or the volume of sexually dimorphic brain nuclei (Bjerke et al., 1994b; MacLusky et al., 1998).

5.2.3.2.13.5. ***Comparison to other Ah receptor-mediated responses.*** The induction of hepatic cytochrome P-4501A1 and its associated EROD activity are extremely sensitive Ah receptor-mediated responses to TCDD exposure. Yet in 120-day-old male Holtzman rats that had been exposed to TCDD perinatally, alterations in sexual behavior, LH secretion, sex organ weights, and sperm numbers were observed when induction of hepatic EROD activity could no longer be detected (Mably et al., 1991, 1992a,b,c). These results suggest that TCDD affects sexual behavior, gonadotrophic function, and sperm counts when virtually no TCDD remains in the body. Therefore, the partial demasculinization and feminization of sexual behavior, partial feminization of LH secretion, and reduced cauda epididymal sperm numbers caused by in utero and lactational exposure to TCDD have the potential to be irreversible effects of transient

exposure to TCDD during the endocrine phase of fetal and neonatal sexual differentiation (Mably et al., 1992b,c).

5.2.3.2.13.6. ***Possible mechanisms for effects on sexual behavior*.** The most plausible explanation for the demasculinization of sexual behavior and feminization of sexual behavior and LH secretion is that perinatal exposure to TCDD impairs sexual differentiation of the CNS. Neither undernutrition, altered locomotor activity, reduced sensitivity of the penis to sexual stimulation, nor modest reductions in adult plasma androgen concentrations of the male offspring can account for this effect (Mably et al., 1992b). On the other hand, exposure of the developing brain to testosterone, conversion of testosterone into 17ß-estradiol within the brain, and events initiated by the binding of 17ß-estradiol to its receptor are all critical for sexual differentiation of the CNS and have the potential to be modulated by TCDD. If TCDD interferes with any of these processes during late gestation and/or early neonatal life, it could irreversibly demasculinize and feminize sexual behavior (Hart, 1972; McEwen et al., 1977; Whalen and Olson, 1981) and feminize the regulation of LH secretion (Gogan et al., 1980, 1981) in male rats in adulthood. However, results that argue against this hypothesis are that in utero and lactational exposure to TCDD does not alter either estrogen receptor concentrations in various brain nuclei or volumes of sexually differentiated brain nuclei of male and female Holtzman rat progeny at doses that affect the expression of masculine and feminine sexual behavior (Bjerke et al., 1994). Also, while in utero and/or lactational exposure to TCDD may cause similar effects on sexual behavior in other animal species, including nonhuman primates (Pomerantz et al., 1986; Thornton and Goy, 1986; Goy et al., 1988), in which sexual differentiation is under androgenic control; this was not able to be demonstrated for male hamster progeny exposed in utero and via lactation to TCDD (Gray et al., 1995a). In humans, there is evidence that social factors account for much of the variation in sexually dimorphic behavior; there is also evidence that prenatal androgenization influences both the sexual differentiation of such behavior and brain hypothalamic structure (Erhardt and Meyer-Bahlburg, 1981; Hines, 1982; LeVay, 1991).

5.2.3.2.14. ***Cross-species comparisons*.** Gray et al. (1995a) demonstrated that many of the results observed on male rat reproductive system development following in utero and lactational TCDD exposure are also observed in male hamster offspring exposed perinatally to TCDD. Pregnant hamsters were exposed to 2 μg/kg of TCDD on gestational day 11. This exposure level caused no maternal toxicity or decrease in viability of the offspring. The number of litters in the study was small (three dams/treatment group). Nevertheless, growth retardation, reduced adrenal and brain weight at postnatal day 136 to 140, delayed eye opening, and reduced sperm in the epididymis and ejaculate were observed in the male hamster offspring exposed to TCDD.

Anogenital distance and testicular sperm number were not affected. As regards androgen-dependent organ development, age at preputial separation was delayed and seminal vesicle weight was reduced, but flank gland development was not affected. In contrast to the rat, none of the masculine sexual behavior parameters measured in male hamster offspring appeared to be altered. At sacrifice (postnatal day 136 to 140), there was an increase in sperm granulomas and in the severity of kidney lesions in the TCDD-exposed male hamster progeny. While the findings of this study show some species specificity in the hamster's response to in utero and lactational TCDD exposure, they generally support the above findings in male rat offspring.

Male ICR mice, CD-1 derived, exposed in utero and via lactation to TCDD are also affected by developmental toxicity to the reproductive system (Theobald et al., 1997). The doses of TCDD used in this study did not alter maternal or offspring body weights and were not associated with prenatal or postnatal mortality. However, ventral prostate weight assessed on postnatal days 44, 65, and 114 was significantly decreased in male offspring after exposure to 15 μg TCDD/kg administered on gestational day 14. Coagulating gland weight was also reduced on the same postnatal days, but this lobe of the prostate was not as sensitive as the ventral prostate because larger doses of TCDD were required to produce the effect. The dorsal prostate in the ICR mouse was not affected even at the largest maternal TCDD dose (60 μg/kg). There was no statistically significant decrease in daily sperm production after TCDD exposure, but whole epididymal sperm numbers were decreased at maternal doses of 30 and 60 μg TCDD/kg. Thus, ventral prostate weight in this strain of mouse was a more sensitive endpoint of TCDD exposure than the reduction in epididymal sperm number. The C57BL/6 mouse is more sensitive to the developmental effects of TCDD on accessory sex organ growth (Lin et al., 2000). Ventral prostate, dorsolateral prostate, and coagulating gland weight in mouse progeny exposed to 5 μg/kg of TCDD on gestational day 13 were all significantly reduced when assessed on postnatal days 21 to 90. Histological examination revealed an impairment of ductal development in the ventral prostate on postnatal day 21, and only 50% of the luminal epithelial cells in ventral prostate from TCDD-exposed mice expressed androgen receptors, compared with 100% of the epithelial cells in tissue from vehicle-exposed mice. Urogenital sinus epithelial complexes from male offspring exposed to a single maternal dose of 5 μg/kg of TCDD administered on gestational day 13 were examined by scanning electron microscopy, and complete agenesis of ventral prostate buds on gestation day 18 was found. In Ah receptor knockout mice obtained from Bradfield (Schmidt et al., 1996) and backcrossed into C57BL/6, there was no reduction in seminal vesicle or prostate weight due to in utero and lactational TCDD exposure, and prostatic bud formation occurred normally by gestational day 18. Therefore, these effects on the prostate and seminal vesicle of perinatal TCDD exposure in the mouse appear to be Ah receptor mediated.

Taken together, these results indicate that there is species specificity in sensitivity to certain effects of in utero and lactational TCDD exposure on male reproductive system development. In general, however, the results reported in the hamster and mouse are consistent with those reported in male rat offspring. There is evidence that at least some of these effects are Ah receptor mediated, namely those that occur in the prostate and seminal vesicle. Because the fetal human prostate expresses the Ah receptor (Kashani et al., 1998), it is plausible that the human prostate could be affected by sufficient exposure to TCDD and TCDD-like Ah receptor agonists during development.

5.2.3.3. *Female Reproductive System*

Effects of in utero and lactational exposure to TCDD on female reproductive system development has not been investigated for as long as the male reproductive system. However, the results from these studies clearly show that the effects of gestational exposure to TCDD is not limited to the male offspring.

5.2.3.3.1. ***Vaginal thread malformation.*** One of the most sensitive effects of in utero and lactational exposure to TCDD on the female reproductive system is the occurrence of a vaginal thread malformation. It has been detected in two strains of rats, Long Evans and Holtzman, but not in ICR mice or Syrian hamsters (Gray et al., 1995; Flaws et al., 1997; Theobald and Peterson, 1997; Gray et al., 1997b; Wolf et al., 1999; Dienhart et al. 2000). The lowest dose of TCDD to significantly increase the incidence of vaginal threads in female progeny is 0.20 μg/kg administered on gestational day 15 to Long Evans rat dams (Gray et al., 1997b). This dose was effective in increasing the incidence of the malformation when expressed either as percentage of females with a temporary or permanent vaginal thread or as percentage of females with a permanent vaginal thread (Gray et al., 1997b). In utero and lactational exposure to other Ah receptor agonists are also capable of producing this same type of malformation in Long Evans rats. 3,3',4,4',5,5'-HCB (PCB 169) administered on gestational day 8 at a dose of 1.8 mg/kg caused a significant increase in the percentage of female progeny with vaginal threads (Gray et al., 1999).

The original study to report an increase in vaginal thread malformation following in utero and lactational exposure to TCDD was that of Gray and Ostby (1995). They reported on the effects in Long Evans rats of a single maternal exposure to 1 μg/kg of TCDD on either gestational day 8 or 15 on postnatal vaginal development in female offspring. Both exposures were associated with incomplete (vaginal thread) or absent vaginal opening, and a smaller vaginal orifice. Similar malformations involving the vaginal canal have been reported for Holtzman rats (Gray and Ostby, 1995; Flaws et al., 1997). The incidence of vaginal threads was

greater in the Long Evans rat when TCDD was administered on gestational day 15 compared with gestational day 8 (Gray and Ostby, 1995). On the other hand, in the Holtzman rat the incidence of vaginal threads was essentially the same when TCDD was administered on gestational days 11, 15, or 18 (Flaws et al., 1997).

The vaginal thread is manifested in pubertal rats as a persistent thread of mesenchymal tissue surrounded by keratinized epithelium that partially occludes the vaginal opening (Flaws et al., 1997). However, it was not known how early in development this abnormality could be detected. Vaginal threads in TCDD-exposed Holtzman rat offspring were identified in histological sections of the developing vagina in 2-day-old pups, demonstrating that this malformation was actually present at birth (Flaws et al., 1997). This suggested that prenatal exposure to TCDD should be sufficient to cause the vaginal thread malformation. This was confirmed in a cross-fostering study in Long Evans rats (Gray et al., 1997b) where female progeny that received prenatal TCDD exposure developed vaginal threads but those that received only postnatal exposure to TCDD did not. The earliest time during fetal development that morphologic signs of this malformation were present was gestational day 19 in Holtzman rats (Dienhart et al., 2000) and gestational day 18 in Long Evans rats (Hurst et al., 1999). At this time there was an increased thickness of mesenchymal tissue between the caudal Mullerian ducts. The presence of this mesenchymal tissue caused the Mullerian ducts to fail to fuse, a process that is normally completed prior to birth. TCDD was also found to block regression of the Wolffian ducts, which contributed to the changes in morphology of the vagina (Dienhart et al., 2000). Thus, prenatal TCDD exposure leads to altered development of the rat vagina as early as gestational day 18 or 19 depending on the strain, 3 or 4 days after treatment of the dams. This effect is produced by TCDD interfering with two critical morphogenetic events involved in the formation of the female reproductive tract, namely, regression of the Wolffian ducts and fusion of the Mullerian ducts (Hurst et al., 1999; Dienhart et al., 2000).

The mechanisms by which TCDD produces these effects at the molecular level are unknown. TCDD modulates cellular responses to both hormones and growth factors including androgens, estrogens, EGF, and TGF (Abbott, 1997; Birnbaum, 1998; Roman and Peterson, 1998b). Developmental processes such as the timing of morphogenetic signals and events like cell proliferation, cell movement, receptor expression, apoptosis, and terminal differentiation are tightly regulated by these and other hormones and growth factors. Thus, TCDD modulation or interference with the activity of hormones and/or growth factors in the female rat reproductive tract may play a role in causing the vaginal thread malformation (Dienhart et al., 2000).

5.2.3.3.2. ***Cleft phallus and mild hypospadias*****.** Other morphological effects of in utero and lactational exposure to TCDD on the female reproductive tract are cleft phallus and mild

hypospadias. The hypospadias are considered mild because the urethral opening was always separate from the vaginal opening. These two types of malformations have been observed in rats and hamsters, but not in mice (Gray and Ostby, 1995; Flaws et al., 1997; Theobald and Peterson, 1997; Gray et al., 1997b; Wolf et al., 1999; Dienhart et al., 2000). The lowest dose of TCDD to significantly increase the incidence of cleft phallus and mild hypospadias is 0.80 and 0.20 μg/kg of TCDD, respectively, administered on gestational day 15 in Long Evans rats (Gray et al., 1997b). The morphometric indices of mild hypospadias that were significantly affected by exposure to 0.2 μg/kg of TCDD on gestational day 15 were length of the urethral slit (increased by TCDD), distance from the tip of the phallus to the urethral opening (increased by TCDD), and distance from the urethral to vaginal opening (decreased by TCDD) (Gray et al., 1997b). Other Ah receptor agonists are also capable of producing cleft phallus and mild hypospadias in female Long Evans rats. 3,3',4,4',5,5'-HCB (PCB 169) administered on gestational day 8 at a dose of 1.8 mg/kg caused a significant increase in the percentage of female progeny with cleft phallus (Gray et al., 1999). It also caused the female offspring to have a significantly longer urethral slit and a shorter distance between the urethral and vaginal openings (Gray et al., 1999). The incidence of cleft phallus was greater in female Long Evans rat progeny administered TCDD on gestational day 15 compared to gestational day 8 (Gray and Ostby, 1995). In Holtzman rats the incidence was greater when TCDD was administered on gestational day 11 compared with gestational day 15 or 18 (Flaws et al., 1997).

These TCDD-induced malformations of the external genitalia in female rats and hamsters (cleft phallus and mild hypospadias) closely resemble the mild form of hypospadias caused by in utero exposure to diethylstilbestrol (DES) and other potent estrogens. In hamsters estradiol causes cleft phallus (Whitsett et al., 1978) and in rats DES and the synthetic estrogen RU2858 are capable of producing a mild form of hypospadias (Voherr et al., 1979; Vannier et al., 1980). This raises the possibility that TCDD, which is often characterized as being an antiestrogen, might cause these effects through an estrogen-like developmental action (Gray et al., 1997b). In this context, it is important to stress that the other type of malformation produced by in utero and lactational exposure to TCDD in the female rodent, vaginal thread formation, is unique to TCDD and TCDD-like Ah receptor agonists. Vaginal thread formation, which can be detected as early as gestational day 19 in the rat, is not known to be produced by any other class of chemical, including potent estrogens like DES.

Gray and Ostby reported that in utero and lactational exposure to TCDD caused a significant reduction in ovarian and brain weights when necropsied as adults (Gray and Ostby, 1995). Hamster offspring, like rats, display clefting of the phallus, mild hypospadias, and reduced ovarian weight, but not formation of the vaginal thread (Gray and Ostby, 1995; Gray et al., 1997b; Wolf et al., 1999). Female ICR mouse offspring were not susceptible to either cleft

phallus or vaginal thread malformations nor were their ovarian or brain weights reduced by perinatal TCDD exposure (Theobald and Peterson, 1997).

5.2.3.3.3. ***Ovary.*** In utero and lactational exposure to TCDD decreased ovarian weight in the rat and hamster but not in the mouse (Gray and Ostby, 1995; Theobald and Peterson, 1997; Wolf et al., 1999). Shiverick and Muther (1983) reported that there was no change in circulating levels of estradiol in the rat after exposure to 1 μg/kg/day on gestational days 4 to 15. Similarly, Gray et al. have found no effect on serum estradiol levels after perinatal exposure to a single maternal dose of 1 μg TCDD/kg administered on gestational day 15 in the Long Evans rat, evaluated on postnatal days 21 and 28 (Gray et al., 1997b). In addition, these authors found no effect on ovarian estradiol production when ovaries from vehicle- and TCDD-exposed rats removed on postnatal days 21 and 28 were placed in organ culture for 3 hours. However, Chaffin et al. found that serum estradiol and ovarian secretion of estradiol in vitro were decreased by a similar exposure regimen in the Holtzman rat (Chaffin et al., 1996, 1997). Histologic examination of ovaries from 21- to 22-day-old rats that had been exposed to a single maternal dose of 1 μg TCDD/kg in utero and via lactation revealed decreases, compared with vehicle-exposed rats, in the number of ovarian follicles without alterations in ovarian size, or apoptosis in the affected follicular regions (Heimler et al., 1998). Similarly, the administration of a single maternal dose of 0.6 mg/kg of 3,3',4,4',5,5'-HCB (PCB 169) on gestational day 1, combined with daily doses of 1 mg/kg of 3,3',4,4'-TCB (PCB 77) on gestational days 2-18 resulted in a statistically significant increase in the incidence of cystic dilated ovarian follicles (Smits-van Prooije et al., 1994).

5.2.3.3.4. ***Estrous cyclicity and reproductive performance.***

5.2.3.3.4.1. ***Rats.*** With regard to effects on estrous cyclicity and reproductive performance, Long Evans rats exposed on gestational day 8 to 1.0 μg/kg of TCDD had a significantly increased number of the female offspring displaying constant estrus by 1 year of age (Gray and Ostby, 1995). This was accompanied by a significant reduction in fertility during a continuous breeding trial. The gestational day 15 exposure did not have the same effect on cyclicity, and the occurrence of constant estrus was not significantly different from control rats. There was also no effect on female sexual behavior. Nevertheless, the number of mounts of control males and the latency to ejaculation were increased in matings with females exposed to TCDD on gestational day 15. This was possibly due to the vaginal abnormalities interfering with normal copulation.

Gray and Ostby (1995) also compared the gestational day 15 exposure to 1.0 μg/kg of TCDD in the Long Evans female offspring with that in the Holtzman. There was a greater reduction in neonatal viability in Holtzman than Long Evans female offspring (50% vs. 11%, respectively) following TCDD exposure. In the surviving Holtzman offspring, the

morphological effects were similar to those in the Long Evans offspring, including genital clefting and vaginal threads. Reproductive behavior was not assessed in the Holtzman strain.

As Gray and Ostby (1995) have noted, their observations are consistent with previous reports of infertility in female offspring after in utero exposure to TCDD (Khera and Ruddick, 1973) and are likely due to the alterations in estrous cyclicity and ovarian function. In utero and lactational exposure of Wistar rats to 0.5 μg/kg/day of TCDD administered on gestational days 6 to 15 caused infertility in both sexes (Khera and Ruddick, 1973). Also, in utero and lactational exposure to 1.8 mg/kg of 3,3',4,4',5,5'-HCB (PCB 169) on gestational day 1 decreased mating success and female fecundity in female Wistar rat progeny (Smits-van Prooije et al., 1994). Taken together, in utero and lactational exposure to TCDD and TCDD-like Ah receptor agonists in the rat causes morphological and functional reproductive alterations in female offspring at relatively low doses that do not induce overt maternal toxicity.

5.2.3.3.4.2. ***Hamsters.*** TCDD produced adverse effects in female hamsters that persisted through two generations (F1 and F2). This occurred despite the F1 generation being the only generation that was exposed in utero and via lactation to 2.0 μg/kg of TCDD administered on gestational day 11.5 (Wolf et al., 1999). In the female progeny of the F1 generation, vaginal opening was delayed and vaginal estrous cycles were altered. However, most TCDD-exposed females had regular 4-day behavioral estrous cycles. This suggests in utero and lactational TCDD exposure did not cause a marked disruption in the hypothalamic-pituitary-gonadal hormonal cyclicity. While the F1 TCDD-exposed females mated successfully with a control male, 20% of them did not become pregnant and 38% of those that did become pregnant died near term. Both the number of implants in pregnant TCDD-exposed hamsters and the number of pups they produced that were born alive were reduced significantly.

An important finding was that survival of F2 generation offspring through weaning was virtually eliminated by treating with TCDD the dams that produced the F1 generation (Wolf et al., 1999). The cause of death of the F2 generation offspring has not been reported.

5.2.3.3.5. ***Histopathology of the aging female reproductive tract.*** In utero and lactational exposure to TCDD affects the histopathology of the female rat reproductive tract (Gray et al., 1997b). In the ovary of TCDD-exposed female offspring, cystic follicles with luteinization and sertoliform hyperplasia were observed. Diffuse squamous hyperplasia of the cervix and hyperkeratosis of the vagina were seen in the TCDD-exposed progeny, but not in the controls.

5.2.3.3.6. ***Ovarian and mammary gland tumors.*** Ovarian tumors were found in female rats following in utero and lactational exposure to TCDD, but not in control rats (Gray et al., 1997b).

In addition, in utero and lactational exposure of rats to 1.0 μg/kg of TCDD on gestational day 15 rendered mammary glands of the female offspring more susceptible to tumor formation induced by 7,12-dimethylbenz[a]anthracene (DMBA) (Brown et al., 1998).

5.2.3.4. *Neurobehavior*

Because differentiated tissues derived from ectoderm, namely, skin, conjunctiva, nails, and teeth, are sites of action of halogenated aromatic hydrocarbons in transplacentally exposed human infants, another highly differentiated tissue derived from ectoderm, the CNS, should be considered a potential site of TCDD action. In support of this possibility, sexual differentiation of the CNS in adult male rats is irreversibly altered in a dose-related fashion by perinatal exposure to TCDD (Mably et al., 1991, 1992b). As will be shown below, the central nervous systems of mice transplacentally exposed to 3,3′,4,4′-TCB, monkeys perinatally exposed to TCDD, and children transplacentally exposed to a mixture of PCBs, CDFs, and PCQs in the Yu-Cheng incident are also affected. Thus, functional CNS alterations, which may or may not be irreversible, are observed following perinatal exposure to halogenated aromatic hydrocarbons.

5.2.3.4.1. ***Ah receptor and ARNT in the central nervous system.*** Ah receptors have been identified in rat brain (Carlstedt-Duke, 1979). However, while an early study suggested the Ah receptor may be associated with glial cells rather than neurons (Silbergeld, 1992), a more recent study of the adult male rat brain that used in situ hybridization to localize mRNAs for the Ah receptor and ARNT proteins found mRNAs for both proteins in the same neuronal populations in the olfactory bulb, hippocampus, cerebral, and cerebellar cortices (Kainu et al., 1995). Unexpectedly, detectable levels of Ah receptor mRNA were not detected in the hypothalamus. The significance of these findings is that they suggest that TCDD and related Ah receptor agonists may act in discrete neuronal populations in the brain.

Following administration of ^{14}C-TCDD in the rat, the highest concentrations of TCDD-derived ^{14}C are found in the hypothalamus and pituitary. Much lower concentrations are found in the cerebral cortex and cerebellum (Pohjanvirta et al., 1990). In another study, the Ah receptor was not detected in whole rat or mouse brain but was detected in the cerebrum of the hamster and cerebrum and cerebellum of the guinea pig (Gasiewicz, 1983).

5.2.3.4.2. ***Neurobehavior in mice.*** CD-1 mice exposed transplacentally to 3,3',4,4'-TCB at a maternal oral dose of 32 mg/kg administered on days 10 to 16 of gestation exhibited neurobehavioral, neuropathological, and neurochemical alterations in adulthood (Tilson et al., 1979; Chou et al., 1979; Agrawal et al., 1981). The neurobehavioral effects consisted of circling, head bobbing, hyperactivity, impaired forelimb grip strength, impaired ability to traverse a wire

rod, impaired visual placement responding, and impaired learning of a one-way avoidance task (Tilson et al., 1979). The brain pathology in adult mice exhibiting this syndrome consisted, in part, of alterations in synapses of the nucleus accumbens (Chou et al., 1979). This suggested that in utero exposure to 3,3',4,4'-TCB may interfere with synaptogenesis of dopaminergic systems. In support of this possibility, Agrawal et al. (1981) found that adult mice transplacentally exposed to 3,3',4,4'-TCB had decreased dopamine levels and decreased dopamine receptor binding in the corpus striatum, both of which were associated with elevated levels of motor activity. It was concluded that transplacental exposure to 3,3',4,4'-TCB in mice may permanently alter development of striatal synapses in the brain.

Eriksson (1988) examined the neurobehavioral effects of 3,3',4,4'-TCB in NMRI mice exposed to a single oral dose of 0.41 or 41 mg/kg on postnatal day 10. Following sacrifice of the mice on day 17, muscarinic receptor concentrations in the brain were significantly decreased at both dose levels. This effect was shown to occur in the hippocampus but not in the cortex. More recently (Eriksson et al., 1991), NMRI mice were exposed to the same two doses of 3,3',4,4'-TCB similarly administered on postnatal day 10. At 4 months of age, the effects of the PCB on locomotor activity were assessed. At both dose levels, abnormal activity patterns were exhibited in that the treated mice were significantly less active than controls at the onset of testing, but were more active than controls at the end of the test period. This pattern of effects can be interpreted as a failure to habituate to the test apparatus. In contrast to the previous results with CD-1 mice, circling or head bobbing activities were not observed in these animals. Upon sacrifice after the activity testing was complete, a small but statistically significant increase (as opposed to the decrease found after sacrifice on postnatal day 17) in the muscarinic receptor concentration of the hippocampus was found in animals from the high-dose group. These results suggest that the neurochemical effects of 3,3',4,4'-TCB are complex. Cholinergeric as well as dopaminergic systems in the brain are involved.

Of all the developmental and reproductive endpoints reported in this chapter for laboratory animals, the only ones that have not yet been demonstrated to occur following perinatal exposure to TCDD are the above neurotoxic effects in mice. These have only been studied following perinatal exposure to 3,3'4,4'-TCB. In addition, there is as yet no evidence to show (1) that among inbred mouse strains having low- and high-affinity Ah receptors, susceptibility to 3,3',4,4'-TCB-induced neurotoxicity segregates with the Ah locus or (2) that the rank order binding affinity of congeners for the Ah receptor correlates with their rank order potency for causing these neurotoxic effects in mice. The rapid metabolism of 3,3',4,4'-TCB compared with the relatively slow metabolism of TCDD in mice causes some uncertainty about the potential involvement of the Ah receptor in 3,3',4,4'-TCB-induced neurotoxicity. Contributing to this uncertainty is the hypothesis that 3,3',4,4'-TCB might produce CNS effects

by being converted to a hydroxylated metabolite that is neurotoxic. Although there is no evidence for or against this hypothesis, there is also no evidence for or against the Ah receptor mechanism hypothesis of 3,3',4,4'-TCB neurotoxicity. Further research is needed to test these hypotheses. In so doing, it should become apparent whether 3,3',4,4'-TCB-induced neurotoxicity effects are relevant to TCDD-induced developmental toxicity.

5.2.3.4.3. ***Neurobehavior in rats.*** A considerable number of neurobehavioral endpoints have been evaluated following perinatal exposure to either TCDD and coplanar PCBs that are Ah receptor agonists, or to ortho-substituted PCBs that do not interact with the Ah receptor. Interest in the latter, for the purposes of this section, arises from the fact that mixtures to which children have been exposed in utero and via lactation typically contain Ah receptor agonists and non-Ah receptor agonists. Therefore, it is important from a mechanistic point of view to determine whether the effects of Ah receptor agonists can be distinguished from the effects of structurally similar non-Ah receptor agonists. It is plausible that some effects of TCDD on neurobehavior in rodents could be Ah receptor mediated because this protein has been detected in the developing neuroepithelium of the mouse fetus (Abbott et al., 1995) and in neuronal tissue of the adult rat brain (Kainu et al., 1995).

Two hypotheses have been advanced: (1) TCDD and TCDD-like PCB congeners do not produce behavioral impairment at biologically relevant doses (Rice et al., 1998; Rice, 1999) and (2) the effects of TCDD and TCDD-like PCB congeners on learning and memory might be distinguishable from effects of ortho-substituted PCB congeners that are not Ah receptor agonists (Schantz et al., 1996; Rice et al., 1999). These hypotheses have not been fully resolved. To the extent that effects of individual ortho-substituted PCB congeners on neurobehavior depend on reductions in thyroid hormone concentrations during the perinatal period (Collins et al., 1980; Ness et al., 1993), it is important to note that TCDD and coplanar PCBs do not reduce thyroid hormone concentrations to the same extent as the ortho-substituted PCBs (Seo et al., 1995). Difficulty in resolving these hypotheses also occurs because different laboratories, using the same testing methods, have not always obtained similar results. In addition, different testing paradigms that appear, at least superficially, to test similar phenomena can arrive at discordant conclusions. Where the results of testing by different methods are not in agreement, the differences are not easy to resolve, in part because the relative sensitivities of the different measures are not always clear.

Despite these difficulties, in utero and lactational exposure to TCDD-like Ah receptor agonists have affected endpoints that measure learning and memory, discrimination reversal learning, transitional behavior, avoidance behavior, neurotransmitter function, and locomotor activity. Perinatal exposure to Ah receptor agonists have inhibited long-term potentiation (LTP)

in the visual cortex, but not in the hippocampus evaluated in vitro (Altmann et al., 1995, 1998). In some cases, effects observed with Ah receptor agonists are similar to those of ortho-substituted PCB congeners (Schantz et al., 1995, 1996, 1997; Seo et al., 1999). Therefore, the available data obtained following in utero and lactational exposure of rats to these compounds tend to support the notion that TCDD and coplanar PCBs can affect neurobehavioral endpoints by a variety of mechanisms, only one of which is Ah receptor mediated. The results of neurobehavioral tests following perinatal exposure to TCDD and various PCBs are summarized below.

5.2.3.4.3.1. ***Spatial learning*****.** Female rats were administered 3,3',4,4'-TCB (PCB 77, 2 and 8 mg/kg/day), 3,3',4,4',5-PCB (PCB 126, 0.25 and 1 μg/kg/day), and TCDD (0.25 and 1 μg/kg/day) by gavage on gestational days 10-16 (Schantz et al., 1996). Beginning on postnatal day 80, spatial learning was evaluated in male and female offspring by using the radial arm maze. While no effects on overt toxicity were found, it was observed that the exposed rats made fewer errors than controls. This result was different from that of a previous study in which exposure to the ortho-substituted PCBs 2,4,4'-TCB (PCB 28), 2,3,4,4',5-PCB (PCB 118), and 2,2',4,4',5,5'-HCB (PCB 153) had no effect on the number of errors (Schantz et al., 1995).

The ability of in utero and lactational TCDD exposure to reduce the number of errors made by male rat offspring in the radial arm maze test were confirmed, even at a reduced exposure level (0.1 μg/kg/day) on gestational days 10-16 (Seo et al., 1999). In addition, no significant decreases in the error rate were found in female rats. However, further statistical analysis of the data suggested that the affected male rats were using a response strategy whereby they tended to enter adjacent arms of the maze. Because of this strategy, there might not be an effect of TCDD on working memory. The lack of an effect of TCDD on the Morris Water Maze test supports this interpretation (Seo et al., 1999). However, the test for adjacent arm selection behavior, which detects the use of a response strategy, had not been significant in the original study at the higher level of TCDD exposure (Schantz et al., 1996).

The low-dose TCDD exposure decreased latency in male rats in the radial arm maze test (Seo et al., 1999). This suggests an apparent feminization of this parameter similar to that caused by PCB 153 (Schantz et al., 1995). In addition, there may be other similarities between TCDD and at least some of the ortho-substituted PCBs, because a similar evaluation of 2,2',3,5',6-PCB (PCB 95) demonstrated an exposure-associated decrease in the error rate of male rat offspring (Schantz et al., 1997). Similar to the original result with the low-exposure dose of TCDD (Seo et al., 1999), the test for use of a response strategy was negative with PCB 95, but unlike the results with TCDD and PCB 153, there was no gender-related decrease in latency. In contrast to the decrease in the error rate that was caused by the perinatal exposure of Sprague-Dawley rats to

PCB 77, PCB 95, PCB 126, and TCDD (Schantz et al., 1996), there was no effect of perinatal exposure to PCB 77 or the diortho- substituted 2,2',4,4'-TCB (PCB 47) on the error rate of male Wistar rats that were tested on a similar radial arm maze (Weinand-Harer et al., 1997).

The male and female rat offspring that were exposed to the ortho-substituted PCB 28, PCB 118, and PCB 153 and tested on the radial arm maze were subsequently evaluated for delayed spatial alternation on the T-maze beginning after postnatal day 135 (Schantz et al., 1995). Exposed females learned this task more slowly than exposed males, and all compounds tested caused a decrease in the number of correct responses. There was no effect on the number of correct responses in exposed male offspring, but their latency to enter the maze was decreased compared with that of control male offspring. This effect on latency again suggests a more female-like pattern of response in male offspring exposed to the ortho-substituted PCBs, even though distinct gender differences remained for the delayed spatial alternation response. In contrast, in utero and lactational exposure to the coplanar PCBs produced no effect on the errors made by male or female offspring, or in their latency in the T-maze test (Schantz et al., 1996; Seo et al., 1999). In addition, another group also found that delayed spatial alternation was unaffected in both male and female Long Evans rat offspring exposed to PCB 126 and tested in an operant chamber setting (Rice, 1999). In this case, even prolonged dietary exposure of female rats to PCB 126, which began 7 weeks before mating to an unexposed male and continued until the offspring were weaned, caused no treatment-related differences in performance (Rice, 1999). However, the impression that delayed spatial alternation is selectively affected by the ortho-substitited PCBs is again offset by the results with PCB 95. Unlike the other ortho-substituted PCBs, PCB 95 did not affect the response (Schantz et al., 1997). Differences between the activities of PCB 95 and PCB 126 have also been found on parameters relevant to neurological function in vitro (Wong et al., 1997). Because effects of the triortho-substituted PCB 95 on delayed spatial alternation are similar to those of PCB 126, a coplanar PCB, but different from those of other ortho-substituted PCBs it remains possible that this effect of PCB 126 is non-Ah receptor mediated. However, not all ortho-chlorinated PCBs are equivalent (Schantz et al., 1995; Schantz et al., 1997), suggesting the existence of structural selectivity in the mechanism.

5.2.3.4.3.2. ***Visual discrimination reversal learning*****.** No effect was observed when the T-maze was used to assess spatial discrimination reversal learning following in utero and lactational exposure of male and female rat offspring to maternal doses of 0.1 μg TCDD/kg/day on gestational days 10-16 (Seo et al., 1999). Visual discrimination reversal learning was tested by placing electric light stimuli onto the cross-arms of the same T-maze used to evaluate spatial discrimination reversal learning. Male and female rat offspring were exposed to maternal doses of 0.1 μg TCDD/kg/day administered on gestation days 10-16 (Seo et al., 1999). When evaluated

beginning at approximately 100 days of age, the exposed offspring performed similar to controls during the original learning phase of the trial. However, TCDD-exposed offspring were slower to reach the testing criterion of 10 correct trials in a 12-trial session. This effect occurred equally in males and females and was most evident during the first and second reversal period. In the following reversal periods, no further differences were evident between the TCDD and vehicle exposure groups. Similarly, PCB 118 and PCB 126 were reported to impair visual discrimination learning in male rat offspring evaluated in an operant chamber (Holene et al., 1995). However, the authors of this study used more than one male offspring per litter, and they appear to have evaluated all rats from the same litter as if they were independent observations. Therefore, the results of this study have been considered to be uninterpretable on statistical grounds (Rice and Hayward, 1998; Rice, 1999), based on the criteria established by Holson and Pearce (1992).

One study using mixtures evaluated visual discrimination learning in the offspring of female rats exposed to Clophen A30 (32 mg total PCBs/kg diet) or a normal diet for 60 days prior to mating, and through pregnancy (Lilienthal et al., 1991). After birth some offspring exposed to each diet were cross-fostered to dams exposed to the other diet. When male and female offspring were evaluated at 120 to 180 days of age, there was no effect of PCB exposure during the acquisition phase of the paradigm (visual discrimination learning tested on a jumping stand). However, performance in all PCB-exposed groups was inferior during the retention phase, relative to their performance at the end of the acquisition phase. Because the effect was more pronounced in the prenatal-only and prenatal + lactational exposure groups, compared with the lactational-only exposure group, the results indicate that prenatal-only exposure to PCBs is all that is required to alter visual discrimination learning.

5.2.3.4.3.3. ***Transitional behavior*****.** Female Long Evans rats were exposed to PCB 126 (0.25 and 1 μg/kg/day) via dietary supplementation that began 35 days prior to mating, and continued through pregnancy and lactation (Rice and Hayward, 1999). After postnatal day 400, transitional behavior was tested in male and female offspring by using a concurrent random interval-random interval reinforcement schedule in an operant chamber. In this test offspring of both sexes apportioned their responses less accurately than control offspring with respect to the pattern of scheduled reinforcements on the two levers. However, the treated rats perceived the reward offered by the reinforcements similarly to the control rats, because testing by a progressive ratio reinforcement schedule resulted in no treatment-related differences in the relative strength of the reinforcing event (Rice and Hayward, 1999). No treatment-related differences had previously been found in the same rats tested on postnatal day 220 by using a multiple fixed interval-fixed ratio reinforcement schedule (Rice and Hayward, 1998). Therefore, the results obtained on the

concurrent random interval-random interval schedule of reinforcement may indicate a selective effect of PCB exposure on adaptive ability in the offspring (Rice and Hayward, 1999).

5.2.3.4.3.4. ***Behavioral responses to CNS drugs*.** Haloperidol-induced catalepsy was evaluated in male Wistar and Long Evans rat offspring exposed to the diortho-substituted PCB 47 (1 mg/kg/day) or the coplanar PCB 77 (1 mg/kg/day) from days 7 to 18 of gestation (Weinand-Harer et al., 1997; Hany et al., 1999). At 100 and 180 days of age, catalepsy was induced in the male offspring by the dopaminergic antagonist haloperidol. Developmental exposure to PCB 77, but not to PCB 47, caused an increase in the time required for the affected rat to move its paw after the paw had been placed into certain positions by the experimenter. The effects of similar exposure to PCB 77 on dopaminergic function have also been tested in Long Evans rats by evaluating their ability to discriminate between the dopaminergic agonist apomorphine and saline (Lilienthal et al., 1997). As a positive control, the antithyroid drug propylthiouracil (PTU) given to adult control animals just prior to testing blocked their ability to discriminate between apomorphine and saline, whereas no effect was found on this discrimination in rats exposed to PCB 77 in utero and via lactation. However, the administration of buspirone to the adult animals just prior to testing blocked the ability of vehicle-exposed rats to recognize apomorphine much more than it blocked this ability in the PCB 77-exposed offspring, or PTU-dosed groups. As buspirone is a mixed serotonin receptor agonist and partial dopamine receptor antagonist, the authors suggested that perinatal exposure to PCB 77 may produce long-lasting effects on the interaction between dopaminergic and serotonergic processes in the CNS (Lilienthal et al., 1997).

Since PCB 77 was effective in prolonging haloperidol-induced catalepsy, whereas PCB 47 was not, it is interesting that perinatal exposure to coplanar PCBs and ortho-substituted PCBs also produce opposite effects on dopamine synthesis in the brain (Seegal et al., 1990, 1997). Perinatal exposure to ortho-substituted PCB congeners decreases dopamine synthesis in adulthood, whereas perinatal exposure to coplanar PCBs causes persistent elevations in brain dopamine and metabolite concentrations (Seegal et al., 1997). An increase in endogenous brain dopamine concentrations could be related to the ability of PCB 126 to alter the recognition of exogenous apomorphine. Dopaminergic function is one area where the effects of coplanar and ortho-substituted PCB congeners may be distinguishable. However, only a few PCB congeners have been evaluated.

Female Long Evans rats were exposed to PCB 126 (0.25 and 1.0 μg/kg/day) by dietary supplementation that began 35 days prior to mating and continued through pregnancy and nursing (Bushnell et al., 1999). After postnatal day 112, a chlordiazepoxide (CDP, 0, 3, 5, and 8 mg/kg) challenge test was used to evaluate neurobehavior. In control offspring all doses of CDP reduced performance. This result suggested that the control offspring were affected by an

increase in the visual threshold. Rats exposed in utero and via lactation to the low dose of PCB 126 were unaffected by CDP, whereas those exposed to the high dose exhibited less of a decrement in their performance than did the control offspring. Since additional test results demonstrated that PCB 126 exposure did not cause deficits in attention, the altered performance of these rats after the administration of CDP suggests that perinatal exposure to PCB 126 may affect γ-aminobutyric acid (GABA)-mediated pathways in the CNS during development (Bushnell and Rice, 1999).

5.2.3.4.3.5. ***Passive avoidance behavior*****.** Male Wistar rats were exposed to the coplanar PCB 77 or the diortho-substituted PCB 47 on gestational days 7 to 18. Passive avoidance behavior was tested on a step-down platform when the rats were 220 days old (Weinand-Harer et al., 1997). The latency of male rat offspring to step onto a grid that had previously given them an electric shock was used to evaluate the effects of perinatal PCB exposure. Latency was decreased by both PCBs, compared with control rats, up to 24 hours after the initial shock. However, only the effect of PCB 77 was significant when evaluated at a single time (5 min, 4 hours, and 24 hours). A similar paradigm was used to evaluate the effects of perinatal exposure to PCB 77, PCB 47, and a combination of both PCBs in Long Evans rats on postnatal day 85 (Hany et al., 1999). Under these conditions the most significant effect observed was a decreased latency in the PCB 77 and combined exposure groups at the 5-minute time. No significant effect was found when rats were exposed to PCB 47 only. These results suggest that differences in passive avoidance behavior may exist following perinatal exposure to non-ortho- and ortho-substituted PCBs, but only one congener of each type has been tested.

5.2.3.4.3.6. ***Open field locomotor activity*****.** When open field activity was tested in male offspring on postnatal day 25, rats exposed to PCB 57 in utero and via lactation had a significantly higher activity level than rats similarly exposed to PCB 77. However, there were no significant differences between the PCB-exposed groups and the unexposed control group (Weinand-Harer et al., 1997). When tested on postnatal day 340, offspring exposed to PCB 47, PCB 77, and a combination of both PCBs were hyperactive when compared with controls (Hany et al., 1999).

Locomotor activity has also been tested in an operant chamber setting in rats exposed to PCBs only during lactation. Female DA/OLA/HSD female rats were mated to Lewis male rats, and the pregnant dams were administered vehicle, 2,2',4,4',5,5'-HCB (PCB 153, 5 mg/kg), or PCB 126 (2 μg/kg) (Holene et al., 1998). Dosing of the female rats was accomplished on every second day from postnatal days 3 to 13. PCB-exposed, 112-day-old male rats were found to be hyperactive during both the fixed interval and extinction components of the reinforcement

schedule. In addition, the PCB 153-exposed offspring displayed a behavior pattern similar to that of spontaneous hypertensive (SHR) rats, which are used as an animal model of attention-deficit hyperactivity disorder (ADHD) in children. With the results of only one congener of each type being tested, the SHR-like pattern of activity appeared to be selective for the ortho-substituted PCB. However, with both congeners, the activity level was increased by exposure solely during the postnatal period. In contrast to all results that show that in utero and/or lactational PCB exposure causes hyperactivity, perinatal exposure to PCB 95 caused hypoactivity in offspring (Schantz et al., 1997).

5.2.3.4.4. ***Neurobehavior in monkeys.*** Schantz and Bowman (1989) and Bowman et al. (1989b) have conducted a series of studies on the long-term behavioral effects of perinatal TCDD exposure in monkeys. Because these were the first studies to evaluate the behavioral teratology of TCDD, monkeys exposed to TCDD via the mother during gestation and lactation were screened on a broad selection of behavioral tests at various stages of development (Bowman et al., 1989b). At the doses studied (5 or 25 ppt in the maternal diet), TCDD did not affect reflex development, visual exploration, locomotor activity, or fine motor control in any consistent manner (Bowman et al., 1989a). However, the perinatal TCDD exposure did produce a specific, replicable deficit in cognitive function (Schantz and Bowman, 1989). TCDD-exposed offspring were impaired on object learning, but were unimpaired on spatial learning. TCDD exposure also produced changes in the social interactions of mother-infant dyads (Schantz et al., 1986). TCDD-exposed infants spent more time in close physical contact with their mothers. The pattern of effects was similar to that seen in lead-exposed infants and suggested that mothers were providing increased care to the TCDD-exposed infants (Schantz et al., 1986).

5.2.3.4.5. ***Neurobehavior in humans.*** The intellectual and behavioral development of Yu-Cheng children transplacentally exposed to PCBs, CDFs, and PCQs was studied through 1985 by Rogan et al. (1988). In Yu-Cheng children matched to unexposed children of similar age, area of residence, and socioeconomic status, there was a clinical impression of developmental or psychomotor delay in 12 (10%) Yu-Cheng children compared with 3 (3%) control children and of a speech problem in 8 (7%) Yu-Cheng children versus 3 (3%) control children. Also, except for verbal IQ on the Wechsler Intelligence Scale for Children, Yu-Cheng children scored lower than control children on three developmental and cognitive tests (Rogan et al., 1988). Neurobehavioral data on Yu-Cheng children obtained after 1985 shows that the intellectual development of these children continues to lag somewhat behind that of matched control children. In addition, Yu-Cheng children are rated by their parents and teachers as having a higher activity level; more health, habit, and behavioral problems; and a temperamental

clustering closer to that of a "difficult child." It is concluded that in humans, transplacental exposure to halogenated aromatic hydrocarbons can affect CNS function postnatally. However, which congeners, TCDD-like versus non-TCDD-like, are responsible for the neurotoxicity is unknown.

Further research on the mechanism of these postnatal neurobehavioral effects, dose-response relationships, and reversibility of the alterations is needed before the role of TCDD-like congeners versus non-TCDD-like congeners in causing this toxicity can be understood. Mechanisms that respond uniquely to TCDD-like congeners may not necessarily be involved, as three lightly chlorinated, ortho-substituted PCB congeners, 2,4,4'-TCB, 2,2',4,4'-TCB, and 2,2',5,5'-TCB, have been detected in monkey brain following dietary exposure to Aroclor 1016 and appear to be responsible for decreasing dopamine concentrations in the caudate, putamen, substantia nigra, and hypothalamus of these animals (Seegal et al., 1990). These nonplanar PCB congeners are believed to cause these effects by acting through a mechanism that does not involve the Ah receptor. On the other hand, the results presented for mice and monkeys suggest that TCDD-like congeners could be involved in producing the observed postnatal neurobehavioral effects in humans.

5.2.3.5. *Thermoregulation*

In adult rats TCDD-induced reductions in body temperature are associated with reduced serum thyroxin levels and a decrease in basal metabolism (Potter et al., 1983, 1986). More recently the offspring of rats exposed in utero and via lactation to a maternal diet that contained Aroclor 1254 were affected by decreased body core temperature, reduced metabolic rate, and marked reductions in serum thyroxin up to an age of 14 days (Seo et al., 1995). As part of a larger study, male rats that had been exposed to vehicle or a single maternal dose of 1 μg/kg of TCDD on gestational day 15 were castrated (for reasons unrelated to the study of thermoregulation) at approximately 8 months of age (Gordon et al., 1995). When evaluated at 15.4 to 17.7 months of age, TCDD-exposed animals exhibited significantly lower core body temperatures than controls when the ambient temperature was varied between 10° and 28°C. However, the metabolic rate was not affected by TCDD, which indicates that the effector regulating body core temperature during cold exposure was unaffected. In addition, in utero and lactational TCDD exposure had no effect on evaporative heat loss or on skin blood flow when the rats were anesthetized so that this parameter could be measured. These results suggest that perinatal exposure to TCDD can decrease core temperature set point and cause a reduction in the regulated body temperature.

In a subsequent study pregnant Long Evans rats were administered a single maternal dose of vehicle or 1 μg TCDD/kg on gestational day 15, and their male offspring were implanted with

transmitters to monitor core temperature and motor activity (Gordon et al., 1998). At various ages these TCDD-exposed male rats were affected by a nocturnal hypothermia that was accompanied by decreased motor activity. These effects were especially pronounced at 7 and 11 months of age, did not occur at 3 months of age, and were reduced at 16 months of age. In addition, TCDD-exposed animals exhibited a greater febrile response compared with vehicle-exposed control rats when challenged with lipopolysaccharide (LPS) to induce fever. However, when 8-month-old rats were placed in a temperature gradient and allowed to select their own most favored ambient temperature, vehicle- and TCDD-exposed offspring selected the same ambient temperatures. This suggests that hypothalamic thermoregulatory centers were not permanently altered and that there was not a change in body temperature set point.

Similar alterations in thermoregulation have been produced in hamsters exposed to TCDD in utero and via lactation. When monitored by radiotelemetry, like the rats cited above, these offspring exhibited a persistent hypothermia in spite of normal metabolic responses to cold exposure (Gordon et al., 1996). In addition, there was no effect of TCDD exposure on the selection of an ambient temperature when hamsters were placed in a temperature gradient for 22 hours. These results are important because the adult hamster has an unusually high resistance to the lethal and thyrotoxic effects of TCDD. However, the rat and hamster have approximately the same sensitivity to perinatal TCDD-induced reproductive dysfunction and thermoregulatory dysfunction. The mechanisms for these responses have not yet been determined.

5.2.3.6. *Auditory Function and Thyroid Hormones*

Long Evans rats were exposed to daily maternal doses of 0, 1, 4, and 8 mg Aroclor 1254/kg/day administered from gestational day 6 to weaning. Low-frequency auditory thresholds evaluated in these male and female offspring beginning on postnatal day 85 were increased at the two largest levels of PCB exposure (Goldey et al., 1995a). This effect was statistically significant at 1 kHz, but not at 4 kHz or higher test frequencies. Since similar low-frequency hearing loss can be produced by perinatal exposure to the antithyroid drug propylthiouracil (PTU), the effect of Aroclor 1254 is believed to be associated with neonatal hypothyroidism (Goldey et al., 1995b). Indeed, there were dramatic decreases in total and free plasma thyroxin (T4) concentrations at all doses of Aroclor 1254 and at all times evaluated between postnatal days 7-42 (Goldey et al., 1995a, 1998). Plasma total and free triiodothyronine (T3) concentrations were decreased only by the largest two exposure levels of Aroclor 1254, and statistically significant effects were observed only on postnatal days 21 and 28, with no decrease on postnatal day 42.

Perinatal exposure to a daily maternal dose of 1 μg/kg/day of 3,3'4,4',5-PCB (PCB 126) administered to the dam for 7 weeks prior to breeding and throughout breeding, gestation, and

lactation to weaning decreased the auditory threshold in Long-Evans rat offspring to 0.5 and 1 kHz (Crofton et al., 1999). However, the 0.25 μg PCB 126/kg/day maternal dose did not affect the auditory threshold in exposed offspring. Thus, it is plausible that AhR agonists within the Aroclor 1254 PCB mixture caused the hearing loss.

While the daily maternal dose of 1 mg Aroclor 1254/kg/day did not significantly increase the auditory threshold to 1 kHz, it did cause alterations in brain stem auditory-evoked responses in exposed male and female offspring that were evaluated at 1 year of age (Herr et al., 1996). This result is consistent with the hypothesis that developmental exposure to Aroclor 1254 can damage the peripheral auditory system. It is believed by the authors that this apparently irreversible damage might occur at the level of the cochlea and/or auditory nerve. This result is important because offspring exposed to a maternally administered level of 1 mg Aroclor 1254/kg/day were affected by less substantial reductions in plasma thyroxin concentration than were those exposed to 4 mg/kg/day or 8 mg/kg/day doses of Aroclor 1254, which increased the auditory threshold (Goldey et al., 1995a; Goldey and Crofton, 1998). Thus, it is possible that less of a thyroid deficit during development could result in hearing loss. In support of the relationship between the chemical-induced auditory deficit and thyroid hormone status, the auditory deficit was partially alleviated by daily doses of thyroxin given to the Aroclor 1254-exposed pups from postnatal day 4 to postnatal day 21 (Goldey and Crofton, 1998).

Even as early as gestational day 20 brain thyroxin levels in the forebrain and cerebellum of fetal rats can be depressed after maternal exposure to Aroclor 1254 (Morse et al., 1996). However, in late-gestation fetuses, induction of the brain type II thyroxin 5'-deiodinase results in compensation for the decrease in thyroxin levels so that brain triiodothyronine levels are maintained. Similar alterations occur after exposure to the non-ortho-substituted PCB congeners 3,3'4,4'-TCB (PCB 77) and 3,3',4,4',5,5'-HCB (PCB 169) that are Ah receptor agonists (Morse et al., 1993). The authors suggest that increases in deiodinase activity could be indicative of a local hypothyroidism occurring in the brains of fetal and neonatal rats exposed to these PCBs.

In utero and lactational exposure to a daily maternal dose of 0.1 μg TCDD/kg/day administered on gestational days 10-16 can produce a statistically significant decrease in plasma thyroxin concentration in female offspring evaluated on postnatal day 21 (Seo et al., 1995). However, this reduction in plasma thyroxin concentration in Sprague-Dawley rat offspring was less than those associated with no effect on auditory threshold in Long Evans rat offspring (Goldey et al., 1995a). Therefore, it has not been demonstrated that perinatal exposure to TCDD will decrease plasma thyroxin concentrations enough to evoke an increase in the auditory threshold. It may turn out that TCDD doses larger than those already tested may be required to cause these effects. While it is possible that prenatal TCDD exposure might produce a functional hypothyroidism prior to birth or that mechanisms other than perinatal hypothyroxinemia may

play a role in producing the hearing loss, it is also possible that PCBs and/or their metabolites could affect auditory functional development by decreasing plasma thyroxin concentrations via non-Ah receptor-related mechanisms (Brouwer et al., 1995). Paradoxically, Aroclor 1254 and a single maternal dose of 50 ng TCDD/kg administered to Long-Evans rats on day 15 of gestation can accelerate eye opening (Goldey et al., 1995a; Gray et al., 1997a). This effect of Arochlor 1254 is exacerbated by thyroxin replacement in the pups (Goldey and Crofton, 1998), whereas hypothyroidism is typically associated with a delay in this developmental landmark (Comer et al., 1982; Goldey et al., 1995b). This suggests that some developmental effects of Aroclor 1254 can resemble those of hyperthyroidism, rather than hypothyroidism. Additional mechanistic work on the ability of Ah receptor agonists to induce hypothyroidism early in development, and their ability to decrease auditory function and cause postnatal hearing loss, appears to be required.

5.2.3.7. *Night Vision*

Pregnant Long Evans rats were exposed to the ortho-chlorinated 2,2',4,4'-tetrachloro-biphenyl (PCB 47) and/or the coplanar 3,3',4,4'-tetrachlorobiphenyl (PCB 77) on days 7-18 of gestation. Daily doses 1.5 mg PCB 47/kg/day, 1.5 mg PCB 77/kg/day, a combination of 1.0 mg PCB 47/kg/day + 0.5 mg PCB 77/kg/day, or an equivalent volume of vehicle were administered subcutaneously to each dam (Kremer et al., 1999). The effects of PCB exposure on visual processes were then assessed in male and female offspring at 200 days of age. The scotopic b-wave, maximum potential, and oscillatory potentials were recorded on the electroretinogram after the rats were adapted to the dark. Perinatal exposure to PCB 77 reduced the amplitudes of these potentials in female offspring in adulthood, but not their male littermates. Exposure to PCB 47 alone was without effect; however, many of the decreases that resulted from PCB 77 appeared to be alleviated after simultaneous exposure to PCB 47. While this suggests that functional antagonism between these ortho-substituted and coplanar PCBs can occur in the endpoints measured, it is also possible that this apparent antagonism resulted from the lower level of PCB 77 administered in the combination. These results indicate that in utero and lactational exposure to PCB 77, but not PCB 47 exposure, can produce long-lasting effects on night vision in female rat offspring (Kremer et al., 1999). Interestingly, the susceptibility to this effect was congener-specific, suggesting that the effect may be Ah receptor mediated. In addition, it was gender dependent.

5.2.4. Cross-Species Comparison of Effect Levels

TCDD exposure levels that cause a variety of developmental effects in different species are summarized for fish in Table 5-5, birds in Table 5-6, and mammals in Table 5-7. Fertilized lake trout eggs and Japanese medaka eggs were exposed to different waterborne concentrations

of ^{3}H-TCDD. Estimates of the amount of TCDD in these eggs were then made from measurement of the TCDD-derived radioactivity within them. Fertilized rainbow trout, chicken, ring-necked pheasant, and eastern bluebird eggs were injected directly with the indicated doses of TCDD. Thus, the doses of TCDD given in Tables 5-5 and 5-6 for all fish and bird species represent TCDD egg burdens where a significant portion of the dose may be present within the yolk of the egg rather than the developing embryo.

Mammalian embryo/fetuses, on the other hand, were exposed via administration of TCDD to the pregnant female. Therefore, the doses given in Table 5-7 are maternal TCDD doses, where a significant portion of the dose may be retained by the mother and never actually reach the embryo/fetus. In some studies, pregnant rats and rhesus monkeys were exposed to TCDD on a chronic or subchronic basis, respectively. The doses given in Table 5-7 for these particular studies represent the calculated maternal body burdens at the time of conception. In rats, the duration of chronic exposure was much longer than the whole body elimination half-life for TCDD in rats. Therefore, the body burden of TCDD given for the rat is 92.8% of the calculated steady-state body burden. In rhesus monkeys, the half-life for whole body elimination of TCDD is longer than the duration of exposure prior to conception. Therefore, the steady-state body burdens that would be expected for rhesus monkeys exposed to the different levels of dietary TCDD intake are approximately three times greater than the maternal body burdens estimated at the time of conception (Table 5-7).

In both rats and rhesus monkeys, the maternal body burdens are calculated using a one-compartment open model, assuming 86.1% bioavailability for TCDD. The bioavailability used for TCDD was determined in rats (Rose et al., 1976). As no estimate for TCDD bioavailability has been reported in rhesus monkeys, the same 86.1% value was used. The whole body elimination half-life used for TCDD in the rat is 23.7 days (Rose et al., 1976).

McNulty et al. (1982) estimated a half-life of approximately 1 year for TCDD elimination from adipose tissue in the rhesus monkey, and for calculation of the body burdens estimated in Table 5-7, this half-life was rounded to 400 days for whole body elimination. The maternal body burden given for chronic exposure in the rat was calculated from the data of Murray et al. (1979). The maternal body burden given for subchronic exposure in the rhesus monkey was calculated from data obtained from Dr. R. E. Bowman (personal communication), which included the daily dietary TCDD exposure level for each pregnant female used in the studies reported by Bowman et al. (1989a,b) and Schantz and Bowman (1989). Dr. Bowman's results indicate that the range of TCDD half-lives in these monkeys was 200 to 600 days, which is consistent with the results of McNulty et al. (1982). The body burdens estimated for rhesus monkeys used in these studies are averages based on the average daily TCDD consumption of all pregnant females used at a particular level of maternal TCDD exposure.

As summarized in Table 5-5, lake trout and rainbow trout sac fry and Japanese medaka embryos are similarly affected by a spectrum of lesions that includes hemorrhage, edema, collapse of the yolk sac, cessation of blood flow, and embryo mortality. Estimates of the NOAEL and LOAEL are given in Table 5-5 for the appearance of these lesions in Japanese medaka embryos and for embryo mortality in the two trout species. Although fertilized lake trout eggs and Japanese medaka eggs were exposed to various TCDD concentrations dissolved in static water, and fertilized rainbow trout eggs were injected directly with TCDD, the egg doses given in Table 5-5 represent the concentration of TCDD within the eggs themselves. Therefore, the different NOAELs and LOAELs for developmental toxicity in different fish species probably represent species differences in susceptibility to TCDD-induced developmental toxicity rather than differences in method of TCDD exposure. Of the three fish species, lake trout sac fry are the most sensitive to TCDD-induced mortality. However, based on the LOAELs shown in Table 5-5, the difference in susceptibility between fish species may be less than tenfold.

Based on the LOAELs shown in Table 5-6, the sensitivity of different bird species to TCDD-induced embryo mortality varies by more than fortyfold. The chicken embryo is more susceptible to TCDD-induced mortality than are embryos of the ring-necked pheasant and eastern bluebird. In addition, chicken embryos are highly sensitive to the formation of TCDD-induced structural defects in the heart and aortic arch. The incidence of cardiac malformations in the chicken embryo is increased at an egg exposure level as low as 9 ng TCDD/kg egg. However, such cardiac malformations have not been found in any other bird species that has been examined.

Table 5-7 summarizes the levels of TCDD exposure that cause certain structural malformations, functional alterations, and prenatal mortality in the embryo/fetus of different mammalian species. Based on the LOAELs given for rats and monkeys in Table 5-7, functional

alterations in learning behavior and the male reproductive system occur at lower TCDD doses than those required to produce structural malformations. Maternal doses of TCDD between 19 and 160 ng/kg decreased object learning in monkeys, accelerated eye opening, produced adverse effects on the male reproductive system, and altered sexual behavior in rats. Developmental toxicity to the female reproductive tract in rats occurred at TCDD doses between 200 and 800 ng/kg. Although TCDD-induced developmental toxicity has been extensively studied in mice and rats, the LOAELs in Table 5-7 indicate that the embryo/fetus of rodent species is generally not as sensitive to TCDD-induced prenatal mortality as is the embryo/fetus of the rhesus monkey. The sensitivity of the embryo/fetus to TCDD-induced prenatal mortality in different mammalian species varies approximately 240-fold. This is in contrast to the 1,000- to 5,000-fold variation in the LD_{50} of TCDD when adult animals of these same species are exposed. The agreement between studies with respect to the LOAEL in Table 5-7 for prenatal mortality in rats and monkeys is particularly striking. The 500 ng/kg dose of TCDD on gestational days 6 to 15 that caused prenatal mortality in rats (Sparschu et al., 1971) agrees with the maternal TCDD body burden of 270 ng/kg calculated from the chronic exposure of rats by Murray et al. (1979) to within a factor of 2. Similarly, the TCDD dose of 111 ng/kg that was given to rhesus monkeys nine times during the first trimester of pregnancy (McNulty, 1984) agrees with the maternal body burden of 97 ng/kg that increased prenatal mortality in rhesus monkeys following subchronic dietary exposure (Schantz and Bowman, 1989).

5.3. REPRODUCTIVE TOXICITY

5.3.1. Female

5.3.1.1. *Reproductive Function/Fertility*

TCDD and its approximate isostereomers have been shown to affect female reproductive endpoints in a variety of animal studies. Among the effects reported are reduced fertility, reduced litter size, and effects on the female gonads and menstrual/estrous cycle. These studies are reviewed below. Other TCDD effects on pregnancy maintenance, embryo/fetotoxicity, and postnatal development are covered in Section 5.2 of this chapter.

5.3.1.1.1. ***Rats.*** The study by Murray et al. (1979) employed a multigenerational approach, examining the reproductive effects of exposure of male and female rats over three generations to relatively low levels of TCDD (0, 0.001, 0.01, and 0.1 μg/kg/day). There was variation in the fertility index in both the control and the exposed groups, and a lower than desirable number of impregnated animals in the exposed groups. Nevertheless, the results showed exposure-related effects on fertility, an increased time between first cohabitation and delivery, and a decrease in litter size. The effects on fertility and litter size were observed at 0.1 μg/kg/day in the F_0

generation and at 0.01 μg/kg/day in the F_1 and F_2 generations. Additionally, in a 13-week exposure to 1 to 2 μg/kg/day of TCDD in nonpregnant female rats, Kociba et al. (1976) reported anovulation and signs of ovarian dysfunction, as well as suppression of the estrous cycle. However, at exposures of 0.001 to 0.01 μg/kg/day in a 2-year study, Kociba et al. (1978) reported no effects on the female reproductive system.

5.3.1.1.2. ***Monkeys.*** Allen and colleagues reported on the effects of TCDD on reproduction in the monkey (Allen et al., 1977, 1979; Barsotti et al., 1979; Schantz et al., 1979). In a series of studies, female rhesus monkeys were fed 50 or 500 ppt TCDD for ~9 months. Females exposed to 500 ppt showed obvious clinical signs of TCDD toxicity and lost weight throughout the study. Five of the eight monkeys died within 1 year after exposure was initiated. Following 7 months of exposure to 500 ppt TCDD, seven of the eight females were bred to unexposed males. The remaining monkey showed such severe signs of TCDD toxicity that she was not bred due to her debilitated state. Of the seven females that were evaluated for their reproductive capabilities, only three were able to conceive and, of these, only one was able to carry her infant to term (Barsotti et al., 1979). When females exposed to 50 ppt TCDD in the diet were bred at 7 months, two of eight females did not conceive and four of six that did conceive could not carry their pregnancies to term. As one monkey delivered a stillborn infant, only one conception resulted in a live birth (Schantz et al., 1979). As described in an abstracted summary, these results at 50 and 500 ppt TCDD are compared with a group of monkeys given a dietary exposure to PBB (0.3 ppm, Firemaster FF-1) in which seven of seven exposed females were able to conceive, five gave birth to live, normal infants, and one gave birth to a stillborn infant (Allen et al., 1979). Although the effects at 500 ppt TCDD may be associated with significant maternal toxicity, this would not appear to be the case at the lower dose. After administration of 50 ppt TCDD, no overt effects on maternal health were observed, but the ability to conceive and maintain pregnancy was reduced (Allen et al., 1979).

In a similar series of experiments, female rhesus monkeys were fed diets that contained 0, 5, and 25 ppt TCDD (Bowman et al., 1989a; Schantz and Bowman, 1989). Reproductive function was not altered in the 5 ppt group, as seven of eight females mated to unexposed males after 7 months of dietary exposure to TCDD were able to conceive. Six of these females gave birth to viable infants at term and one gave birth to a stillborn infant. This was not significantly different from the results of the control group, which was fed a normal diet that contained no TCDD. All seven of the monkeys in this control group were able to conceive and give birth to viable infants. The 25 ppt dietary exposure level, however, did affect reproductive function. Only one of the eight females in this group that was mated gave birth to a viable infant. As in the 50 ppt group from earlier studies, there were no serious health problems exhibited by any females

exposed to 0, 5, or 25 ppt TCDD. Therefore, the results in the 25 and 50 ppt groups suggest that maternal exposure to TCDD before and during pregnancy can result in fetomortality without producing overt toxic effects in the mother.

McNulty (1984) examined the effect of a TCDD exposure during the first trimester of pregnancy (gestational age 25 to 40 days) in the rhesus monkey. At a total dose of 1 μg/kg given in nine divided doses, three of four pregnancies ended in abortion and two of these abortions occurred in animals that displayed no maternal toxicity. At a total dose of 0.2 μg/kg, one of four pregnancies ended in abortion. This did not appear to be different from the control population, but the low number of animals per group did not permit statistical analysis. McNulty (1984) also administered single 1 μg/kg doses of TCDD on gestational days 25, 30, 35, or 40. The number of animals per group was limited to three, but it appeared that the most sensitive periods were the earlier periods, days 25 and 30, and that both maternal toxicity and fetotoxicity were reduced when TCDD was given on later gestational days. For all days at which a single 1 μg TCDD/kg dose was given (gestational day 25, 30, 35, or 40), 10 of 12 pregnancies terminated in abortion. Thus, of 16 monkeys given 1 μg TCDD/kg in single or divided doses between days 25 and 40 of pregnancy, only three normal births occurred (McNulty, 1984, 1985).

5.3.1.2. *Ovarian Function*

Signs of ovarian dysfunction in rats and monkeys such as anovulation and suppression of the estrous cycle had been reported previously (Kociba et al., 1976; Barsotti et al., 1979; Allen et al., 1979), and Li et al. (1995a,b) recently extended these studies. In their initial study (Li et al., 1995a), adult female rats were given a single oral dose of 10 μg TCDD/kg BW and observed for changes in estrous cyclicity and ovulation. The number of ova ovulated per female and the number of females ovulating were decreased by 75%, and the estrous cycle was also altered, with a significant increase in the time spent in diestrus and a decrease in proestrus and estrus. However, these findings were clouded by the fact that the exposure caused a body weight loss in the females. A subsequent dose-response study in immature hypophysectomized/eCG-primed females provided support that the effects on ovulation were dose-dependent (Li et al., 1995b). However, the effects were only statistically significant at exposure levels that also caused a significant loss in body weight over the experimental period.

5.3.1.3. *Reproductive Capability of Ah Receptor Knockout Mice*

Reproductive success is adversely affected in some Ah receptor null mouse lines (in the absence of TCDD exposure). Ah receptor null female mice (Fernandez-Salguero et al., 1995) become pregnant at similar rates and implant similar numbers of embryos as control females. However, these Ah receptor null dams experience increased prenatal loss of conceptuses and

difficulty in surviving the stress of lactation, and their pups show poor survival during lactation and shortly after weaning (Abbott et al., 1999c). In contrast, offspring from a different Ah receptor null mouse line (Schmidt et al., 1996) exhibit low neonatal mortality. Possible reasons for this and other phenotypic differences between offspring of these two Ah receptor null mouse lines is unclear (Schmidt et al., 1996).

5.3.1.4. *Endometriosis*

5.3.1.4.1. *Humans*

Endometriosis is characterized by endometrial cell growth outside the uterus and can be associated with infertility and pain. Of increasing interest is the initial report that women with endometriosis in Germany are more likely to have elevated concentrations of PCBs in their blood (Gerhard and Runnebaum, 1992). While this report did not provide sufficient methodological detail (reviewed in Ahlborg et al., 1995), Koninckx and coworkers (1994) reported that Belgium also has a high incidence of endometriosis and that TCDD concentrations in breast milk in Belgian women are among the highest in the world. Similarly, a larger number of women in Israel with endometriosis were found to have measurable blood levels of TCDD when compared to age-matched control women that had tubal infertility but no endometriosis (Mayani et al., 1997). More recently in Belgian women, high serum TCDD-like toxic equivalent concentrations (TEQs) were associated with a greater risk for endometriosis (Pauwels et al., 1999), but no association was found between endometriosis and total serum PCB concentrations in this study. This suggests that only TCDD-like PCBs may be capable of producing the response in women.

A recent study has demonstrated the occurrence of certain TCDD-induced biochemical changes that facilitate the ectopic growth of human endometrial tissue (Bruner-Tran et al., 1999). When the human tissue is exposed to TCDD *in vitro* and implanted into immunologically impaired nude mice, TCDD exposure inhibits the ability of progesterone to decrease the expression of matrix metalloproteinase enzymes. This effect, which is associated with a TCDD-induced decrease in the ability of human endometrial organ cultures to produce TGF-β_2, enhances ectopic growth of the endometrial lesions. These results begin to provide a biochemical basis for the ability of TCDD exposure to facilitate the expression of endometriosis in women, and they strengthen the association between elevated exposure to TCDD-like AhR agonists and the increased incidence and severity of this disease.

5.3.1.4.2. *Monkeys*

An association between TCDD exposure and endometriosis has found some experimental support in studies using the rhesus monkey. However, the association between PCB exposure

and endometriosis in monkeys is less clear. Rier and coworkers chronically exposed rhesus monkeys to TCDD in their diet for 4 years and then maintained the monkeys for an additional 10 years. These monkeys were then compared to similar unexposed animals in the same colony (Rier et al., 1993; Rier et al., 1995). In monkeys exposed to dietary levels of 5 ppt and 25 ppt TCDD, the incidence of endometriosis was 43% and 71%, respectively, whereas the incidence in control monkeys was 33%. Moreover, the severity of endometriosis was TCDD dose-dependent. Monkeys in the studies by Rier and coworkers appeared to be quite sensitive to TCDD-induced increases in the incidence and severity of endometriosis. It has been calculated that the female monkeys exposed to 5 ppt TCDD in the diet for 4 years had accumulated a TCDD body burden of 69 ng/kg (DeVito et al., 1995). However, another study found no association between the incidence and severity of endometriosis and exposure to Aroclor 1254 when rhesus monkeys were exposed for up to 6 years. Unlike the Rier studies, these monkeys were not held for evaluation a long time after exposure (Arnold et al., 1996). Interestingly, both the Rier and the Arnold studies reported a similar high background incidence (33% -37%) of endometriosis in unexposed monkeys. When taken together the results of these studies indicate that it may take some time for a TCDD-induced increase in endometriosis to become manifest above the background level, that sensitivity to halogen aromatic hydrocarbon-induced increases in endometriosis may be more readily detected when TCDD equivalent concentrations (TEQs) rather than total PCB concentrations are considered, and that the effect, if produced by PCBs at all in monkeys, could be PCB congener-specific. In this last sense, the results in monkeys correspond to those recently obtained by Pauwels et al. (1999) in women, which also suggest that the effect on endometriosis is congener specific for those halogenated aromatic congeners with AhR agonist activity.

5.3.1.4.3. ***Rats and mice.*** An animal model has been developed in the rat and mouse to evaluate the effects of TCDD exposure on the development of endometriosis (Cummings et al., 1995, 1996). While rodents do not spontaneously develop endometriosis, the surgical implantation of uterine tissue at ectopic sites in the abdominal cavity is a way of mimicking aspects of the disease. The formation of clear vesicles, fibrosis, inflammation, and adhesions are common to the disease in primates and to the rodent model of endometriosis (Cummings et al., 1996). Female rats and mice were administered 0, 3, or 10 μg TCDD/kg 3 weeks before, at the time of, and at 3, 6, and 9 weeks after surgery to induce endometriosis (Cummings et al., 1996). At 3, 6, 9, and 12 weeks following surgery, there were dose-dependent increases in lesion diameter in both species if all time points were pooled. In addition, rats showed a decrease in body weight and ovarian weight at 9 and 12 weeks, accompanied by an increase in the time spent in vaginal estrus, and histology of the ovary at 12 weeks indicated ovulatory arrest. These effects on body

weight and the ovary were not observed in the mouse, but the mouse seemed more susceptible to the TCDD-increase in lesion diameter than the rat at 9 and 12 weeks postsurgery.

Additional studies done to assess the effects of TCDD in the mouse model of endometriosis used slightly different methodology and resulted in different results. In these studies mice were first subjected to the surgery to induce endometriosis and then were exposed chronically to daily doses of 0, 10, 50, or 100 ng TCDD/kg for 28 days. When the effects of TCDD exposure on the endometriosis lesions were assessed 2 days after the last dose, it was found that there was a dose-dependent decrease in lesion diameter (Yang et al., 1997). In addition, uterine tissue implant survival and growth was decreased in ovariectomized mice and restored by estrogen replacement (Foster et al., 1997). Exposure to TCDD inhibited the ability of estrogen replacement to promote implant survival and growth, suggesting that TCDD acts as an antiestrogenic compound in this form of the model. The authors of this study noted the difference between their results and those of Cummings et al., and they suggested that when TCDD is administered prior to the induction of endometriosis in ovary-intact mice, immune suppression facilitates the growth of the endometriosis implants, or that factors of ovarian origin other than steroids may play a role in the establishment, maintenance, and growth of endometriosis. In contrast, when TCDD is administered after surgically induced endometriosis is established, the antiestrogenic effects of TCDD inhibit lesion growth. In spite of these suggestions, it seems possible that insufficient time is allowed when this model is used for the severity of surgically-induced endometriosis to be increased by TCDD exposure subsequent to the initial inhibition.

Unlike TCDD, the Ah receptor agonists 3,3',4,4',5-PCB (PCB 126), 1,3,6,8-tetrachlorodibenzo-*p*-dioxin, and 2,3,4,7,8-pentachlorodibenzofuran were not able to alter lesion diameter or lesion weight in the mouse model (Johnson et al., 1997). This is reminiscent of the ability of TCDD, but not Aroclor 1254, to increase the incidence of endometriosis in rhesus monkeys. Interestingly, the dose-response relationship for TCDD in the mouse model was U-shaped, with low doses promoting endometriosis and larger doses resulting in a decreased response. Therefore, the effects of Ah receptor agonists on endometriosis may depend on a complex interplay between immune suppression and antiestrogenicity.

5.3.1.5. *Mammary Gland*

5.3.1.5.1. ***Postnatal mammary gland development.*** The mammary gland of weanling rats and mice is a system of branching ducts that terminate in actively growing terminal end buds (TEBs). Elongation of the mammary ducts and penetration of the epithelium into the surrounding adipose stroma results from the rapid cellular proliferation of the TEBs (Williams et al., 1983). The density of TEBs (number of TEB/mm^2) increases steadily after birth until it reaches a maximum

value in the rat on postnatal day 21 (Russo et al., 1978). This is accompanied by a concomitant increase in the total area of the mammary gland. After postnatal day 21 numerous lateral buds develop along the growing ducts as further growth of the gland occurs. During this time septation and cleavage in the TEBs and lateral ducts result in the formation of 3-5 smaller buds per structure, the alveolar buds (ABs) (Russo and Russo, 1978). With the initiation of estrus cycling (postnatal days 35-42), alveoli form from the ABs, and until cessation of mammary growth occurs, these branched structures increase progressively in number with each successive estrus cycle resulting in the formation of lobules. TEBs that do not further differentiate in this manner regress into finger-shaped structures called terminal ducts (TDs).

5.3.1.5.2. ***Effects of postnatal TCDD exposure in vivo*.** Female rats that were orally administered daily doses of 2.5 μg TCDD/kg or vehicle on postnatal days 24, 26, 28, and 30 were affected by decreased cellular proliferation within their mammary glands and by decreased mammary gland development (Brown et al., 1995). When evaluated 18 hours after the last TCDD dose, body weight in the treated rats was slightly but not significantly reduced. However, the combined uterine-ovarian weights were less than half, and mammary gland size was only 61% that of vehicle-treated control rats. TCDD treatment caused a statistically significant 59% reduction in the number of TEBs without significantly affecting the numbers of ABs, lobules, and TDs. Therefore, the postnatal TCDD exposure-induced inhibition of mammary growth is accompanied by a selective size reduction within the most rapidly dividing portion of the mammary ducts, the TEBs. While TCDD exposure did not decrease the percentage of TEB cells that are proliferating (PCNA labeling index) or percentage of TEB cells in S-phase, it decreased these parameters in TDs and lobules. Consistent with the decrease in the number of TEBs in TCDD- treated rats, the total numbers of PCNA-labeled and S-phase cells were decreased (even though percentages were not) compared with the values obtained in vehicle-exposed control rats. In addition, TCDD exposure decreased the total numbers of PCNA-labeled and S-phase cells in TDs and lobules. These results are consistent with the finding that early postnatal TCDD exposure in the rat causes an inhibition of mammary epithelial cell proliferation, but the mechanism for this effect remains to be determined. It may be a consequence of the antiestrogenic properties of TCDD (Harris et al., 1990; Safe et al., 1991).

5.3.1.5.3. ***Expression of Ah receptor and effects of the Ah receptor null mutation.*** Mammary glands from estrous cycling C57BL/6J mice express high levels of Ah receptor mRNA and protein (Hushka et al., 1998). Lower or undetectable levels of the Ah receptor mRNA and protein were found during late pregnancy and during mammary gland involution immediately after the cessation of nursing. Transgenic female mice heterozygous for the Ah receptor null

mutation were mated with transgenic heterozygous males. Comparative analysis of mammary gland development in 6- to 8-week-old female Ah receptor wild-type and Ah receptor null littermates demonstrated that there was a 50% reduction in TEBs and an increase in TDs in the Ah receptor null females. In most Ah receptor null females the ductal architecture, branching patterns, and overall organization of specific cell types in the mammary epithelium did not appear to be altered. However, a small percentage of mammary glands from Ah receptor null females exhibited little or no branching. These findings support the conclusion that Ah receptor-dependent processes may play a role in TEB development even in the absence of endogenous ligand. However, as indicated below, the effects of the Ah receptor null mutation and Ah receptor activation by exogenous ligand in the mouse turn out to be similar rather than opposite.

5.3.1.5.4. ***Response of organ-cultured mammary gland to exogenous ligand.*** Nulliparous C57BL/6J mice were primed with 15 daily injections of estradiol and progesterone (Hushka et al., 1998). Mammary glands were removed 24 hours after the last priming and cultured in the presence of 0.1% DMSO or 1 to 100 nM 2,3,7,8-TCDF for 5 days and prepared for histology and immunohistochemistry. Lobule size after culturing was suppressed by TCDF in a dose-related manner, such that lobules in mammary glands exposed to the largest dose of TCDF were less than one-half the size of vehicle-exposed lobules. The ^{3}H-thymidine labeling index was also reduced in the TCDF-exposed lobules. Therefore, the growth and development of TEBs into lobules appeared to be suppressed by TCDF, but the effects of TCDF on TEB number after organ culture were not reported, and therefore it is not known whether TCDD exposure caused the expected increase in the number of TEBs. Overall, these results are consistent with the effects of TCDD on mammary growth and development that were previously mentioned for the rat. In addition, they suggest that toxicity results from direct effects of TCDF on the mammary gland.

5.3.1.5.5. ***Effects of prenatal TCDD exposure.*** Pregnant rats were orally administered 1 μg TCDD/kg or vehicle on gestational day 15 (Brown et al., 1998). Mammary development was evaluated in female offspring at 21 and 50 days of age. While body weight of the TCDD-exposed female offspring, compared with that of vehicle-exposed female offspring, was reduced at both time points, liver weight was reduced only on postnatal day 50. TCDD exposure delayed the time of vaginal opening and caused a disruption in the estrus cycle. However, uterus weight and mammary gland size were unaffected by in utero and lactational TCDD exposure. Nevertheless, the number of TEBs was increased in the mammary glands of TCDD-exposed female offspring, and there was a corresponding decrease in the number of lobules. Cellular proliferation (BrdU labeling index) was not affected by TCDD exposure in TDs at either time

point, but the results indicate that the differentiation pathway from TEBs to lobules was inhibited.

When the carcinogen DMBA is administered to 50- to 60-day-old female rats, the differentiation pathway of the mammary gland epithelium is disrupted (Russo and Russo, 1978). Between 14 and 21 days post-DMBA inoculation, TEBs increase markedly in size and do not differentiate into lobules. Instead, these TEB-derived larger structures, termed intraductal proliferations (IDPs), may progress along an alternate pathway to form microtumors that have the characteristics of rat mammary adenocarcinomas. These structures are derived exclusively from TEBs. In utero and lactational exposure to a single maternal dose of 1 μg TCDD/kg administered on gestational day 15 increased the number of TEBs in 50-day-old female offspring (Brown et al., 1998). In addition, these glands were rendered more susceptible to the formation of DMBA-induced mammary tumors. While neither epidemiological data nor occupational studies provide clear support for an association between TCDD and the occurrence of breast cancer in women, it is interesting to note that prenatal and postnatal exposure to TCDD can have opposite effects in laboratory animals. Postnatal exposure to TCDD decreased the incidence of DMBA-induced mammary tumors in female rats (Holcomb et al., 1994). This latter effect was believed to be due to the antiestrogenic properties of TCDD. The mechanism whereby in utero and lactational TCDD exposure alters TEB differentiation and promotes DMBA-induced mammary tumorigenesis is not yet known.

5.3.1.5. Summary. The primary effects of TCDD on female reproduction appear to be decreased fertility, inability to maintain pregnancy for the full gestational period, and in the rat, decreased litter size. It is likely that ovarian dysfunction and alterations in normal estrous cyclicity also result from TCDD exposure. The growing body of data also indicate that TCDD exposure may lead to or favor the appearance of endometriosis. Koninckx et al. (1994) have noted that Belgium has a high incidence of endometriosis and that TCDD concentrations in breast milk in Belgium women are among the highest in the world, and a similar relationship between measurable blood levels of TCDD and endometriosis has been reported in women in Israel (Mayani et al., 1997). Mammary gland development in rats and mice can be adversely affected by in utero and lactational TCDD exposure potentially leading to the formation of tumors. Effects of TCDD exposure on the formation of mammary gland tumors can depend on the life-stage at which exposure occurs. Continued attention to these and other effects on the female reproductive system, especially in the nonpregnant state, will be important to determining the potential female reproductive toxicity of TCDD.

5.3.1.6. *Alterations in Hormone Levels*

The potential for TCDD to alter circulating female hormone levels has been examined, but only to a very limited extent. In monkeys fed a diet that contained 500 ppt TCDD for ~9 months, the length of the menstrual cycle, as well as the intensity and duration of menstruation, were not appreciably affected by TCDD exposure (Barsotti et al., 1979). However, there was a decrease in serum estradiol and progesterone concentration in five of the eight exposed monkeys, and in two of these animals the reduced steroid concentrations were consistent with anovulatory menstrual cycles. In summary form, Allen et al. (1979) described the effects of dietary exposure of female monkeys to 50 ppt TCDD. After 6 months of exposure to this lower dietary level of TCDD, there was no effect on serum estradiol and progesterone concentrations in these monkeys. Thus, the presence of these hormonal alterations is dependent on the level of dietary TCDD exposure.

5.3.1.7. *Antiestrogenic Action*

5.3.1.7.1. ***In vivo.*** Estrogens are necessary for normal uterine development and for maintenance of the adult uterus. The cyclic production of estrogens partially regulates the cyclic production of FSH and LH that results in the estrous cycling of female mammals. In addition, estrogens are necessary for the maintenance of pregnancy. Any effect that causes a decrease in circulating or target cell estrogen levels can alter normal hormonal balance and action.

Early experimental results in rats and monkeys indicated that TCDD may have an antiestrogenic action. Following administration of 1 μg TCDD/kg/day to rats for 13 weeks, Kociba et al. (1976) reported morphologic changes in the ovaries and uterus that were interpreted as being due to a suppression or inhibition of the estrous cycle. Rhesus monkeys exposed to 500 ppt of TCDD in the diet for 6 months developed hormonal irregularities in their estrous cycles that were associated with reduced conception rates as well as a high incidence of early spontaneous abortions (Allen et al., 1977; Barsotti et al., 1979).

In rhesus monkeys, the severity of the TCDD-associated reproductive alterations was correlated with decreased plasma levels of estrogen and progesterone (Barsotti et al., 1979). Thus, one possible mechanism for these effects would be increased metabolism of estrogen and progesterone due to induction by TCDD of hepatic microsomal enzymes and/or a decrease in the rate at which these steroids are synthesized. On the other hand, serum concentrations of 17β-estradiol are not significantly affected when TCDD is administered to pregnant rats (Shiverick and Muther, 1983). Thus, an alternative mechanism for TCDD-associated reproductive dysfunction could involve effects of TCDD on gonadal tissue itself, such as a decrease in its responsiveness to estrogen. In support of this latter mechanism, the administration of TCDD to CD-1 mice results in a decreased number of cytosolic and nuclear estrogen receptors in

hepatocytes and uterine cells. Although TCDD treatment induces hepatic cytochrome P-450 levels in these animals, it has no effect on serum concentrations of 17β-estradiol (DeVito et al., 1992). This indicates that the antiestrogenic effect of TCDD in CD-1 mice is not caused by a decrease in circulating levels of estrogen.

Effects of estrogen on the uterus include a cyclic increase in uterine weight, increased activity of the enzyme peroxidase, and an increase in the tissue concentration of progesterone receptors. Antiestrogenic effects of TCDD administration to female rats include a decrease in uterine weight, decrease in uterine peroxidase activity, and a decrease in the concentration of progesterone receptors in the uterus (Safe et al., 1991). In addition, when TCDD and 17β-estradiol are coadministered to the same female rat, the antiestrogenic action of TCDD diminishes or prevents 17β-estradiol-induced increases in uterine weight, peroxidase activity, progesterone receptor concentration, and expression of EGF receptor mRNA (Astroff et al., 1990; Safe et al., 1991). Similarly, in mice TCDD administration decreases uterine weight and antagonizes the ability of 17β-estradiol to increase uterine weight (Gallo et al., 1986).

The ability of TCDD to antagonize the effects of exogenously administered estrogen in the rat is dependent on the age of the animal. In 21-day-old rats, TCDD does not affect 17β-estradiol-induced increases in uterine weight or progesterone receptor concentration. On the other hand, in 28-day-old intact rats and 70-day-old ovariectomized rats, both of these 17β-estradiol-mediated responses are attenuated by TCDD (Safe et al., 1991). Previously, it had been reported that TCDD administration does not alter the dose-dependent increase in uterine weight due to exogenously administered estrone in sexually immature rats (Shiverick and Muther, 1982). The later work by Safe et al. (1991) suggests that this apparent lack of an antiestrogenic effect of TCDD may have been due to the young age of the rats used.

5.3.1.7.2. ***In vitro.*** Both TCDD and progesterone can affect a decrease in the nuclear estrogen receptor concentration in rat uterine strips (Romkes and Safe, 1988). However, the effect of progesterone is inhibited by actinomycin D, cycloheximide, and puromycin, whereas the effect of TCDD is inhibited only by actinomycin D. The reasons that the TCDD-induced decrease in nuclear estrogen receptors is blocked by a transcription inhibitor, but not by protein synthesis inhibitors, are not understood. However, these results indicate that TCDD and progesterone decrease the nuclear estrogen receptor concentration by different mechanisms. In addition, the antiestrogenic actions of TCDD can be demonstrated in cell culture, and two prominent mechanisms could potentially be involved. They are (1) increased metabolism of estrogen due to Ah receptor-mediated enzyme induction and (2) a downregulation of estrogen receptors within the target cell.

In MCF-7 cells, which are estrogen-responsive cells derived from a human breast adenocarcinoma, antiestrogenic effects caused by the addition of TCDD to the culture medium include a reduction of the 17β-estradiol-induced secretion of a 160 kDa protein, 52 kDa protein, and 34 kDa protein (Biegel and Safe, 1990). These last two proteins are believed to be procathepsin D and cathepsin D, respectively. In addition, treatment of MCF-7 cells with TCDD suppresses the 17β-estradiol-enhanced secretion of tPA and inhibits estrogen-dependent postconfluent cell proliferation (Gierthy et al., 1987; Gierthy and Lincoln, 1988). Thus, cultured MCF-7 cells have several estrogen-dependent responses that are inhibited by TCDD; this characteristic makes them a useful model system for studying the antiestrogenic actions of dioxin.

In cultured MCF-7 cells, TCDD treatment induces aryl hydrocarbon hydroxylase (AHH) activity, the hallmark response of Ah receptor binding, and increases hydroxylation of 17β-estradiol at the C-2, C-4, C-6α, and C-15α, positions (Spink et al., 1990). It turns out that the particular cytochrome P-450 that catalyzes the C-2, C-15α, and C-6α hydroxylations of 17β-estradiol is cytochrome P-4501A1, which is identical to AHH (Spink et al., 1992). TCDD treatment also results in reduced levels of occupied nuclear estrogen receptors (Harris et al., 1990). These results indicate, in MCF-7 cells, that the antiestrogenic effect of TCDD could result from (1) an increased metabolism of estrogens due to Ah receptor-mediated enzyme induction and/or (2) a decreased number of estrogen receptors in the nucleus. Safe and his colleagues have published TCDD-concentration-response information for both the TCDD-induced decrease in occupied nuclear estrogen receptors (Harris et al., 1989) and the induction of AHH and EROD activities in MCF-7 cells (Harris et al., 1990). In addition, they have reported that TCDD causes a decreased number of cytosolic and nuclear estrogen receptors in Hepa 1c1c7 cells, which are a mouse hepatoma cell line (Zacharewski et al., 1991).

Independent analysis of the data suggests that the EC_{50} values for these effects are not dissimilar enough to distinguish between the proposed mechanisms. Instead, it appears as though TCDD induces the enzymes AHH and EROD over the same concentration range that it causes a decreased concentration of occupied nuclear estrogen receptors in MCF-7 cells. In Hepa 1c1c7 cells, the lowest concentration used was 10 pM. Although exposure to 10 pM TCDD resulted in a statistically significant downregulation of estrogen receptors, Israel and Whitlock (1983) reported that this concentration is the approximate EC_{50} for the induction of cytochrome P-4501A1 mRNA and enzyme activity in these cells. Therefore, in Hepa 1c1c7 cells as well as in MCF-7 cells, it would appear that the TCDD concentrations required to produce enzyme induction and reduction in occupied nuclear estrogen receptor levels are not dissimilar enough to distinguish between the two proposed mechanisms.

More recently, Safe and his colleagues have used an analog of TCDD, MCDF, which inhibits the 17β-estradiol-induced secretion of the 34, 52, and 160 kDa proteins and downregulates estrogen receptors in MCF-7 cells. These effects occurred at concentrations of MCDF at which there is no detectable induction of EROD activity (Zacharewski et al., 1992). In addition, it has been stated that the downregulation of estrogen receptors in Hepa 1c1c7 cells can be detected as early as 1 hour after exposure of the cell cultures to 10 nM TCDD (Zacharewski et al., 1991). This time is slightly less than the 2 hours that was required for Israel and Whitlock (1983) to detect an increase in cytochrome P-4501A1 mRNA levels after exposure of Hepa 1c1c7 cells to 10 pM TCDD. After exposure of Hepa 1c1c7 cells to a maximally inducing concentration of 1 nM TCDD, however, there are significant increases in the cellular concentration of cytochrome P-4501A1 mRNA after 1 hour, whereas the induction of AHH activity takes slightly longer (Israel and Whitlock, 1983).

Gierthy et al. (1987) reported that exposure of MCF-7 cells to 1 nM TCDD caused suppression of the 17β-estradiol-induced secretion of tPA. This effect of TCDD, however, occurred in the absence of any measurable decrease in the whole cell concentration of estrogen receptors, even though the cultures were pretreated with serum-free medium to reduce cell proliferation and maximize the cellular content of estrogen receptors. Gierthy's group pretreated their cultures with serum-free medium, which was done to reduce cell proliferation and maximize the cellular content of estrogen receptors. The disparity between this result of Gierthy et al. (1987), which suggests no effect of TCDD on the estrogen receptor content of MCF-7 cells, and the results of Safe and his colleagues to the contrary in this same cell line remains largely unexplained. Overall, it appears as though no obvious distinction between the two proposed mechanisms can be made at the present time. Therefore, it seems that the antiestrogenic effect of TCDD results from both an increased metabolism of estrogen and a decreased number of estrogen receptors. It is important to note that TCDD does not compete with radiolabeled estrogens or progesterone for binding to estrogen or progesterone receptors and that these steroids do not bind to the Ah receptor or compete with radiolabeled TCDD for binding (Romkes et al., 1987; Romkes and Safe, 1988).

5.3.1.7.3. *Evidence for an Ah receptor mechanism*

5.3.1.7.3.1. *Ah receptor mutants*. Although the precise cellular mechanism by which TCDD produces its antiestrogenic effect is subject to a discordance between two primary schools of thought, there is agreement that the response is mediated by the Ah receptor. Thus, the antiestrogenic effects of TCDD in cultured cells appear to involve an Ah receptor-mediated alteration in the transcription of genes. This is indicated by studies using wild-type Hepa 1c1c7 cells and mutant Hepa 1c1c7 cells in culture (Zacharewski et al., 1991). In wild-type cells,

TCDD reduces the number of nuclear estrogen receptors, and this response can be inhibited by cycloheximide and actinomycin D. However, in class 1 mutants, which have relatively low Ah receptor levels, TCDD has only a small effect. Similarly, in class 2 mutants, which have a defect in the accumulation of transcriptionally active nuclear Ah receptors, there was no effect of TCDD on the number of nuclear estrogen receptors. Taken together, these results indicate that the downregulation of estrogen receptors in Hepa 1c1c7 cells involves an Ah receptor-mediated effect on gene transcription. As previously noted, TCDD induces cytochrome P-4501A1 mRNA transcription and enzyme activity in Hepa 1c1c7 cells (Israel and Whitlock, 1983). This effect is also Ah receptor mediated (Nebert and Gielen, 1972).

5.3.1.7.3.2. ***Structure-activity relationships in vivo.*** The relative potencies of halogenated aromatic hydrocarbon congeners as inhibitors of uterine peroxidase activity in the rat are similar to their relative Ah receptor-binding affinities (Astroff and Safe, 1990). Only limited relative potency information is available for the reduction of hepatic and uterine estrogen receptor concentrations per se by these substances in rats. TCDD and 1,2,3,7,8-PeCDD both exhibit high affinity for the Ah receptor. At an 80 μg/kg dose of either of these two substances, hepatic estrogen receptor concentrations are reduced 42% and 41%, whereas uterine estrogen receptor concentrations are reduced 53% and 49% by TCDD and 1,2,3,7,8-PeCDD, respectively. On the other hand, 1,3,7,8-TCDD and 1,2,4,7,8-PeCDD bind less avidly to the Ah receptor. At a 400 μg/kg dose of either of these two substances, hepatic estrogen receptor concentrations are reduced 36% and 40%, whereas uterine estrogen receptor concentrations are reduced 21% and 24% by 1,3,7,8-TCDD and 1,2,4,7,8-PeCDD, respectively (Romkes et al., 1987). As the potency of these congeners for reducing estrogen receptor concentrations correlates with their Ah receptor-binding affinities, these in vivo results provide evidence that the antiestrogenic effect of TCDD is mediated by the Ah receptor.

5.3.1.7.3.3. ***Genetic evidence.*** Consistent with the interpretation based on structure-activity relationships, there is a greater reduction in the number of hepatic estrogen receptors when Ah^bAh^b C57BL/6 mice are exposed to TCDD than when Ah^dAh^d DBA/2 mice are similarly exposed (Lin et al., 1991). To date, however, the antiestrogenic effects have not been studied in the progeny of test crosses between Ah^bAh^b and Ah^dAh^d mouse strains that respectively produce Ah receptors with high- or low-binding affinity for TCDD. Therefore, the potential segregation of the antiestrogenic effects of TCDD with the Ah locus has not been verified by the results of genetic crosses.

5.3.1.7.3.4. ***Structure-activity relationships in vitro.*** The Ah receptor is detectable in MCF-7 cells, and AHH as well as EROD activities are both inducible in these cells (Harris et al., 1989). The relative abilities of TCDD and other CDD, CDF, and PCB congeners to suppress 17β-estradiol-induced secretion of tPA by MCF-7 cells are consistent with the structure-activity relationships for other Ah receptor-mediated responses (Gierthy et al., 1987). In addition, the rank order of potency for several Ah receptor agonists in reducing nuclear estrogen receptors in MCF-7 cells is TCDD > 2,3,4,7,8-PeCDD > 2,3,7,8-TCDF > 1,2,3,7,9-PeCDD > 1,3,6,8-TCDF (Harris et al., 1990). The rank order of potency for these substances is consistent with their relative activities as Ah receptor agonists. These results in vitro support a role for the Ah receptor in the antiestrogenic actions of TCDD.

5.3.2. Male

5.3.2.1. *Reproductive Function/Fertility*

TCDD and related compounds decrease testis and accessory sex organ weights, cause abnormal testicular morphology, decrease spermatogenesis, and reduce fertility when given to adult animals in doses sufficient to reduce feed intake and/or body weight. Certain of these effects have been reported in chickens, rhesus monkeys, rats, guinea pigs, and mice treated with overtly toxic doses of TCDD, TCDD-like congeners, or toxic fat that was discovered later to contain TCDD (Allen and Lalich, 1962; Allen and Carstens, 1967; Khera and Ruddick, 1973; Kociba et al., 1976; van Miller et al., 1977; McConnell et al., 1978; Moore et al., 1985; Chahoud et al., 1989; Morrisey and Schwetz, 1989). In testis of these different species, TCDD effects on spermatogenesis are characterized by loss of germ cells, the appearance of degenerating spermatocytes and mature spermatozoa within the lumens of seminiferous tubules, and a reduction in the number of tubules containing mature spermatozoa (Allen and Lalich, 1962; Allen and Carstens, 1967; McConnell et al., 1978; Chahoud et al., 1989). The lowest cumulative dose of TCDD to decrease spermatogenesis in the rat was 1 μg/kg/day administered 5 days a week for 13 weeks (Kociba et al., 1976). With this dosage regimen, which resulted in a TCDD body burden of approximately 20 μg/kg at the end of the dosing period (Rose et al., 1976), body weights and feed consumption of the rats also were significantly depressed. A similar 13-week dosing study using adult male mice found that 3 and 30 mg 3,3',4,4'-TCAOB/kg/day caused reductions in epididymal sperm number (van Birgelen et al., 1999). In adult male Sprague-Dawley rats a single dose of 25 μg TCDD/kg decreased epididymal sperm numbers, whereas testicular Leydig cell volume was decreased at 12.5 μg TCDD/kg (Johnson et al., 1992). By comparison, daily sperm production was not affected, even by 50 μg TCDD/kg. Thus, the suppression of spermatogenesis and reduction in epididymal sperm number are not highly sensitive effects when Ah receptor agonists are administered to adult animals.

In contrast, daily sperm production assessed on postnatal day 90 was significantly decreased in weanling Sprague-Dawley rats administered 1 μg TCDD/kg on postnatal day 21 (el-Sabeawy et al., 1998). In addition, testis histology revealed that a dose of 10 μg TCDD/kg caused a decrease in seminiferous tubule diameter compared with that in vehicle-dosed control rats. The spermatogonial population normally located in the basal area of the tubules was absent in the TCDD-treated rats. However, these effects on testis histology were not found at TCDD doses less than 10 μg TCDD/kg. Motility studies were performed on epididymal sperm, and dose-related decreases in sperm curvilinear velocity and beat cross frequency were found over the dose range from 0.1-5.0 μg TCDD/kg. Average path and straight line velocity were significantly decreased at 5 μg TCDD/kg (el-Sabeawy et al., 1998).

Effects of TCDD administration to 21-day-old rats on epidermal growth factor receptor-, protein tyrosine kinase-, protein kinase A-, protein kinase C-, mitogen-activated protein 2 kinase, and c-Src tyrosine kinase-mediated pathways in the testis were also examined (el-Sabeawy et al., 1998). Dose-related increases in the activity of c-Src kinase were found on postnatal days 34 and 90 over the dose range from 0.1-5.0 μg TCDD/kg. In addition, the administration of multiple doses of the c-Src kinase inhibitor geldanamycin over the time period from postnatal days 21-90 blocked the effects of TCDD on testis weight and daily sperm production. The authors conclude that these results provide evidence for the involvement of epidermal growth factor and Src kinasesignaling pathways in the mechanism by which TCDD disrupts testicular development and subsequently affects testis function.

5.3.2.2. *Alterations in Hormone Levels*

The effects of TCDD on the male reproductive system are believed to be due in part to an androgenic deficiency. This deficiency is characterized in adult rats by decreased plasma testosterone and DHT concentrations, unaltered plasma LH concentrations, and unchanged plasma clearance of androgens and LH (Moore et al., 1985, 1989; Mebus et al., 1987; Moore and Peterson, 1988; Bookstaff et al., 1990a). The ED_{50} of TCDD for producing this effect in adult male rats on day 7 after dosing is 15 μg/kg (Moore et al., 1985), and it can be detected within 1 day of treatment. As described in the following sections, the cause of the androgenic deficiency is decreased testicular responsiveness to LH and increased pituitary responsiveness to feedback inhibition by androgens and estrogens (Moore et al., 1989, 1991; Bookstaff et al., 1990a,b; Kleeman et al., 1990).

5.3.2.3. *Target Organ Responsiveness*

5.3.2.3.1. ***Inhibition of testicular steroidogenesis.*** Testicular steroidogenesis occurs within Leydig cells and is regulated primarily by plasma LH concentrations (Payne et al., 1985; Hall,

1988). Binding of LH to the LH receptor causes cAMP and possibly other second messengers to be formed (Cooke et al., 1989). In response, cholesterol is rapidly transported to the initial enzyme in the testosterone biosynthetic pathway, a cholesterol side-chain cleavage enzyme, which is a cytochrome P-450 (cytochrome P-450_{scc}) located on the inner side of the inner mitochondrial membrane that converts cholesterol to pregnenolone. The mobilization of free cholesterol rather than its conversion to pregnenolone and other metabolites is generally considered to be the rate-limiting step in testicular steroidogenesis. TCDD inhibits testosterone biosynthesis, predominantly if not exclusively by inhibiting the mobilization of free cholesterol that acts as a substrate for cytochrome P-450_{scc} (Moore et al., 1991). Thus, in the testes of TCDD-treated rats, cholesterol is provided to the cytochrome P-450_{scc} enzyme at too slow a rate to maintain androgenic homeostasis, even when the plasma LH concentration characteristic of "normal" androgen levels is present.

Leydig cell volume was significantly reduced 4 weeks after a single intraperitoneal injection of TCDD (Johnson et al., 1994). The effect was dose related and observed at the lowest dose tested, 12.5 μg TCDD/kg BW. This reduction in total cell volume resulted from both a reduced number of cells and a reduced size of individual cells. Wilker et al. (1995) were able to establish that this effect of TCDD can be prevented by hCG.

5.3.2.3.2. ***Altered regulation of pituitary LH secretion.*** In TCDD-treated male rats, the expected increase in plasma LH concentration that would facilitate testicular compensation for the decreased plasma androgens does not occur (Moore et al., 1989; Ruangwises et al., 1991). The failure of the plasma LH concentration to rise appropriately is not caused by an increase in the plasma clearance of LH or by a decrease in the maximal rate of pituitary LH synthesis or secretion (Bookstaff et al., 1990a,b). Rather, TCDD alters the feedback regulation of LH secretion in male rats by increasing the potency of testosterone and its metabolites (DHT and 17β-estradiol) as inhibitors of LH secretion. The ED_{50} of TCDD for enhancing the testosterone-mediated inhibition of LH secretion 7 days after treatment is the same as its ED_{50} for causing the androgenic deficiency (15 μg/kg). Also, both responses are detected within 1 day of TCDD dosing and are fully developed after 7 days when the ED_{50}s were determined.

Decreased plasma androgen concentrations normally result in compensatory increases in both the number of pituitary gonadotropin-releasing hormone (GnRH) receptors and the responsiveness of the pituitary to GnRH. TCDD treatment prevents the increases in GnRH receptor number and responsiveness that would be expected in the light of the decreased plasma androgen concentrations (Bookstaff et al., 1990b). The pituitary is thus a target organ for TCDD because its responsiveness to hormones secreted by the testis (testosterone) and hypothalamus (GnRH) is altered by TCDD.

If the plasma LH concentrations in TCDD-treated rats did increase appropriately in response to decreased plasma androgens, it is expected that plasma androgens would return to normal levels (Kleeman et al., 1990). This is because the testes of TCDD-treated rats are capable of synthesizing more testosterone than is needed to maintain androgen concentrations in the physiological range, although this would require significantly elevated levels of LH in TCDD-treated rats. The fact that there is a testicular reserve capacity to provide for sufficient amounts of androgen synthesis, even when compromised, underscores the importance of the effects of TCDD on pituitary LH secretion in producing the effects of TCDD on plasma androgen concentrations.

5.3.2.3.3. ***Differential responsiveness of androgen target organs.*** The dose-related reductions in plasma testosterone and DHT concentrations in intact adult rats are accompanied by similar dose-related reductions (ED_{50} 15 μg TCDD/kg) in seminal vesicle and ventral prostate weights measured 7 days after dosing (Moore et al., 1985). In contrast, TCDD has no effect on accessory sex organ weights (or plasma androgen concentrations) in castrated adult rats implanted with either testosterone- or DHT-containing capsules (Moore and Peterson, 1988; Bookstaff et al., 1990a,b). As trophic responsiveness of the seminal vesicles and ventral prostate to testosterone and DHT are unaffected by postpubertal TCDD treatment, it follows that TCDD can increase responsiveness of the pituitary to androgens without affecting responsiveness of the accessory sex organs to androgens.

5.3.2.3.4. ***Relative sensitivity.*** The male reproductive system in rats is ~100 times more susceptible to TCDD toxicity when exposure occurs perinatally (ED_{50} for the most sensitive effects, 0.16 μg/kg) rather than in adulthood (ED_{50} for the most sensitive effects, 15 μg/kg). To illustrate this sensitivity, a single maternal TCDD dose as low as 0.064 μg/kg given on day 15 of gestation significantly decreases epididymis and cauda epididymis weights, cauda epididymal sperm numbers, and daily sperm production in male offspring at various stages of sexual development. Decreases in ventral prostate weights in 32-day-old male offspring and in older males, increases in the number of mounts preceding ejaculation, and increases in intromission latency also are produced by maternal TCDD doses as low as 0.064 μg/kg. The 0.064 μg TCDD/kg dose is not maternally toxic and produces no signs of overt toxicity in male or female offspring. Other effects of perinatal exposure on the male reproductive system were detected at a maternal TCDD dose of 0.16 μg/kg or higher (Mably et al., 1991, 1992a,b,c). On the other hand, when exposure occurs in adulthood, relatively large doses in the overtly toxic range are required to cause decreases in spermatogenesis and in ventral prostate and caput epididymis weight (Kociba et al., 1976; Moore et al., 1985). Kociba et al. (1976) reported that accessory sex organ

weights and spermatogenesis are decreased in rats following exposure to 1 μg TCDD/kg/day, 5 days per week for 13 weeks. Using the parameters for TCDD half-life and bioavailability in the rat determined by Rose et al. (1976), this dosage regimen results in a TCDD body burden of approximately 20 μg/kg at the end of the dosing period.

In adult rats, the most sensitive toxic responses to TCDD have been observed following long-term, low-level exposure. In a three-generation reproduction study, Murray et al. (1979) reported that dietary administration of TCDD at doses as low as 0.01 μg/kg/day significantly affected reproductive capacity in female rats, with no effects seen at 0.001 μg/kg/day (NOAEL). The same NOAEL was found in a 2-year chronic toxicity and oncogenicity study in which an increased incidence of certain types of neoplasms was altered among rats given TCDD doses of 0.01 or 0.1 μg/kg/day (Kociba et al., 1978). Based on the pharmacokinetics of TCDD in the rat (Rose et al., 1976), the steady-state body burden of TCDD in these rats that were chronically dosed (>90 days) with either 0.01 or 0.001 μg TCDD/kg/day is approximately 0.29 μg/kg (LOAEL) and 0.029 μg/kg (NOAEL), respectively. Yet, Mably et al. (1991, 1992a,b,c) found that a single TCDD dose of 0.064 μg/kg given on day 15 of gestation produces a number of statistically significant effects on the reproductive system of male rat offspring. Because 0.064 μg TCDD/kg was the lowest dose tested, a NOAEL for developmental male reproductive toxicity, which is defined as the lowest dose used that has no statistically significant effect, could not be determined by Mably et al. (1991, 1992a,b,c). It is concluded that developmental effects on spermatogenesis occur at a maternal TCDD dose that is lower than any previously shown to produce toxicity in rats.

5.4. SUMMARY

This chapter has focused on the variety of effects that dioxin and dioxin-like agents can have on human reproductive health and development. The review is not exhaustive, and emphasis has been placed on the more recent reports. These have been put into context with previous reviews of the literature applicable in risk assessment (Kimmel, 1987) to develop a profile of the potential for dioxin and dioxin-like agents to cause reproductive or developmental toxicity based on the available literature. A portion of this report has been previously published (Peterson et al., 1993).

5.4.1. Human

The literature base with regard to potential human effects is detailed in Chapter 7. In general, there is no epidemiological evidence that makes a direct association between exposure to TCDD or TCDD-related agents and effects on human reproduction or development. However, the evidence that has been accumulated is suggestive of such an effect, at least with respect to

developmental toxicity. All four manifestations of developmental toxicity (reduced viability, structural alterations, growth retardation, and functional alterations) have been observed to some degree following presumed exposure to TCDD-related agents. The incidents at Yusho and Yu-Cheng resulted in increased perinatal mortality and low birthweight in infants born to women who had been exposed. Rocker bottom heal was observed in Yusho infants, and functional abnormalities have been reported in Yu-Cheng children.

Of particular interest is the ectodermal origin of many of the organs and tissues that are affected in the human. An ectodermal dysplasia syndrome has been clearly associated with the Yusho and Yu-Cheng episodes, involving hyperpigmentation, deformation of the fingernails and toenails, conjunctivitis, gingival hyperplasia, and abnormalities of the teeth. The developmental effects that can be associated with the nervous system are also consistent with this pattern because the nervous system is of ectodermal origin.

5.4.2. Experimental Animal

In developing a toxicological profile, it is rare to have sufficient data from human studies for quantitative analysis. Consequently, the risk assessment most often relies on data from experimental animal studies. For dioxin and the dioxin-related agents, the experimental animal database is fairly extensive with respect to reproductive and developmental toxicity. Dioxin exposure has been observed to result in both male and female reproductive effects, as well as effects on development. These latter effects are among the most responsive health endpoints to dioxin exposure. In general, the prenatal and developing postnatal animal is more sensitive to the effects of dioxin than the adult.

5.4.2.1. Developmental Toxicity

Dioxin exposure results in a wide variety of developmental effects and these are observed in three different vertebrate classes and in several species within each class. All four of the manifestations of developmental toxicity have been observed following exposure to dioxin, including reduced viability, structural alterations, growth retardation, and functional alterations. As summarized previously (Peterson et al., 1993), increased prenatal mortality (rat and monkey), functional alterations in learning and sexual behavior (rat and monkey), and changes in the development of the reproductive system (rat) occur at the lowest exposure levels.

Dioxin exposure results in reduced prenatal or postnatal viability in virtually every species in which it has been tested. Previously, increased prenatal mortality appeared to be observed only at exposures that also resulted in maternal toxicity. However, the studies of Olson and McGarrigle (1991) in the hamster and Schantz et al. (1989) in the monkey were suggestive that this was not the case in all species. Although the data from these two studies were limited,

prenatal death was observed in cases where no maternal toxicity was evident. In the rat, Peterson's laboratory (Bjerke et al.,1994a,b; Roman et al., 1995) reported increased prenatal death following a single exposure to TCDD during gestation that did not cause maternal toxicity, and Gray et al. (1995a) observed a decrease in postnatal survival under a similar exposure regimen. While identifying the presence or absence of maternal toxicity may be instructive as to the specific origin of the reduced prenatal viability, it does not alter the fact that pre- and postnatal death were observed. In either case, the Agency considers these effects as being indicators of developmental toxicity in response to the exposure (U.S. EPA, 1991).

Some of the most striking findings regarding dioxin exposure relate to the effects on the developing reproductive system. The findings are even more impressive with the understanding that only a single, low-level exposure during gestation is required to initiate these developmental alterations. Mably et al. (1992a,b,c) originally reported that a single exposure of the Holtzman maternal animal to as low as 0.064 μg/kg could alter normal sexual development in the male offspring. More recently, these findings have been further defined (Bjerke et al., 1994; Gray et al., 1995; Roman et al., 1995), as well as extended to females and another strain and species (Gray et al., 1995). In general, the findings of these later studies have produced qualitatively similar results that define a significant effect of dioxin on the developing reproductive system.

In the developing male, dioxin exposure during the prenatal and lactational periods results in the delay of the onset of puberty as measured by age at preputial separation. There is a reduction in testis weight, sperm parameters, and sex accessory gland weights. In the mature male exposed during the prenatal and lactational periods, there is an alteration of normal sexual behavior and reproductive function. Males exposed to TCDD during gestation are demasculinized. Feminization and a reduction in the number of implants in females mated with exposed males have also been reported, although these effects have not been consistently found. These effects do not appear to be related to reductions in circulating androgens, which were shown in the most recent studies to be normal. Most of these effects occur in a dose-related fashion, some occurring at 0.05 μg/kg and 0.064 μg/kg, the lowest TCDD doses tested (Mably et al., 1992c; Gray et al., 1997a).

In the developing female, Gray and Ostby (1995) have demonstrated altered sexual differentiation in both the Long Evans and Holtzman rat. The effects observed depended on the timing of exposure. Exposure during early organogenesis altered cyclicity, reduced ovarian weight, and shortened reproductive life span. Exposure later in organogenesis resulted in slightly lowered ovarian weight, structural alterations of the genitalia, and a slight delay in puberty. However, cyclicity and fertility were not affected with the later exposure. The most sensitive dose-dependent effects of TCDD in the female rat were structural alterations of the genitalia that occurred at 0.20 μg/kg (Gray et al., 1997b).

Structural malformations, particularly cleft palate and hydronephrosis, occur in mice. While these are not the most sensitive developmental endpoints, the findings indicate that exposure during the critical period of organogenesis can affect the processes involved in normal tissue formation. The TCDD-sensitive events appear to require the Ah receptor. Mouse strains that produce Ah receptors with relatively high affinity for TCDD respond to lower doses than strains with relatively low-affinity receptors. Moreover, congeners with a greater affinity for the Ah receptor are more developmentally toxic than those with a lower affinity.

5.4.2.2. Adult Female Reproductive Toxicity

The primary effects of TCDD on female reproduction appear to be decreased fertility, inability to maintain pregnancy for the full gestational period, and in the rat, decreased litter size. In some studies, signs of ovarian dysfunction such as anovulation and suppression of the estrous cycle have been reported (Kociba et al., 1976; Barsotti et al., 1979; Allen et al., 1979; Li et al., 1995a,b). Rier et al. (1993) reported TCDD-associated endometriosis in the monkey, and similar effects have now been reproduced in rats and mice (Cummings et al., 1996). Unfortunately, the amount of attention given to the female reproductive system, especially in the nonpregnant state, has been limited. Additional studies on the female reproductive system will be important to determining the potential female reproductive toxicity of TCDD.

5.4.2.3. Adult Male Reproductive Toxicity

TCDD and related compounds decrease testis and accessory sex organ weights, cause abnormal testicular morphology, decrease spermatogenesis, and reduce fertility when given to adult animals in doses sufficient to reduce feed intake and/or body weight. In the testis of these different species, TCDD effects on spermatogenesis are characterized by loss of germ cells, the appearance of degenerating spermatocytes and mature spermatozoa within the lumens of seminiferous tubules, and a reduction in the number of tubules containing mature spermatozoa (Allen and Lalich, 1962; Allen and Carstens, 1967; McConnell et al., 1978; Chahoud et al., 1989). This suppression of spermatogenesis is not a highly sensitive effect when TCDD is administered to postweanling animals, as an exposure of 1 μg/kg/day over a period of weeks appears to be required to result in these effects.

The effects of TCDD on the male reproductive system when exposure occurs in adulthood are believed to be due in part to an androgenic deficiency. This deficiency is characterized in adult rats by decreased plasma testosterone and DHT concentrations, unaltered plasma LH concentrations, and unchanged plasma clearance of androgens and LH (Moore et al., 1985, 1989; Mebus et al., 1987; Moore and Peterson, 1988; Bookstaff et al., 1990a). The cause of the androgenic deficiency is decreased testicular responsiveness to LH and increased pituitary

responsiveness to feedback inhibition by androgens and estrogens (Moore et al., 1989, 1991; Bookstaff et al., 1990a,b; Kleeman et al., 1990).

5.4.3. Conclusion

TCDD and related compounds have reproductive and developmental toxicity potential. It is assumed that the responses observed in animal studies are indicative of the potential for reproductive and developmental toxicity in humans. This is an established assumption in the risk assessment process for developmental toxicity (U.S. EPA, 1991). It is supported by the number of animal species and strains in which effects have been observed. The limited human data are consistent with an effect following exposure to TCDD or TCDD-like agents.

Many of the effects have been shown to be dose-response related. The effects on perinatal viability and male reproductive development are among the most sensitive effects reported, occurring at a single prenatal exposure range of as little as 0.05-0.075 μg/kg. In these studies, this was the lowest exposure level tested; thus a NOAEL has not been established for these endpoints.

In general, the structure-activity results are consistent with an Ah receptor-mediated mechanism for many of the developmental effects that are observed. The structure-activity relationship in laboratory mammals appears to be similar to that for Ah receptor binding. This is especially the case with cleft palate in the mouse. However, a direct relationship with Ah receptor binding is less clear for other effects, including those involving the nervous system.

Table 5-1. Relationship between maternal toxicity and prenatal mortality in laboratory mammals exposed to TCDD during gestation

Hamster	Prenatal mortality	Single dose	18,000 ng/kg/day, gd 7 or 9	LOAEL	Olson et al., 1990
Mouse	Prenatal mortality	Single dose	24,000 ng/kg/day, gd 6	LOAEL	Couture et al., 1990b

[a]Maternal body burdens of TCDD at the time of conception were calculated by assuming a one-compartment open model and half-life for whole body TCDD elimination of 400 days in the monkey (McNulty et al., 1982) and 23.7 days in the rat (Rose et al., 1976). A bioavailabilty of 86.1 percent was used in the monkey and rat (Rose et al., 1976). The daily dietary exposure levels in rhesus monkeys were approxiately 5 and 25 ppt at the NOAEL and LOAEL doses, respectively. Rhesus monkeys were exposed to these levels of TCDD for 7 months prior to conception. At this time (0.525 half-lives) the cumulative amount of TCDD in rhesus monkeys was 30.5 percent of the calculated steady-state level. Rats were exposed to the indicated daily doses of TCDD for a period of 90 days (3.8 half-lives) prior to conception. At this time the cumulative amount of TCDD in rats was 92.8 percent of the calculated steady-state level.
gd=gestational day.

6. CARCINOGENICITY OF TCDD IN ANIMALS

6.1. INTRODUCTION

Additional scientific information on the use of animal cancer data for estimating human risks from 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) has become available since the 1988 health risk assessment for dioxin. Much of the data on tumor incidence in experimental animals available in 1988 demonstrated that TCDD is a carcinogen at multiple sites in both sexes of rats and mice. Some of the cancers occurred following particularly low doses. Since 1988, TCDD has been shown to be a carcinogen in hamsters, and some of the tumor incidence data in rat liver have been reevaluated.

There is considerable evidence that TCDD does not damage DNA directly through the formation of DNA adducts. Mechanisms have been proposed that support the possibility that TCDD might be indirectly genotoxic, either through the induction of oxidative stress or by altering the DNA-damaging potential of some endogenous compounds, including estrogens. In addition, there have been numerous reports on TCDD-induced modifications of growth factor signaling pathways and cytokines in experimental animals and cell systems. Some of the altered systems include those for epidermal growth factor, transforming growth factor alpha, estrogen, glucocorticoids, tumor necrosis factor-alpha, interleukin 1-beta, plasminogen inactivating factor-2, and gastrin. Many of these pathways are involved in cell proliferation and differentiation and provide plausible avenues for researching the mechanisms responsible for the carcinogenic actions of TCDD. These effects are consistent with the generally accepted conclusion that TCDD acts as a "tumor promoter" in multistage models for chemical carcinogenesis and is virtually devoid of initiating activity in these models. It is important to note that "tumor promotion" is an operational and not a mechanistic term and that multiple mechanisms of tumor promotion are likely. Each of these mechanisms may be fundamentally different from the others.

There is a scientific consensus that most, if not all, of the biochemical and toxic effects of TCDD require an initial interaction with its cognate receptor, the aryl hydrocarbon (Ah). The properties of the Ah receptor (AhR) and the mechanisms whereby this receptor regulates gene expression are described in more detail in other chapters. However, formation of the AhR-TCDD complex is only the first of many steps involved in the production of a biochemical and toxic effect. Although there is considerable knowledge of details regarding activation of expression of the TCDD-inducible cytochrome P450 1A1 by the AhR, we still know very little about many components of AhR-mediated responses and their relationship to the development of adverse responses such as cancer. It is clear, however, that tissue- and cell-specific factors other than the AhR must be involved in determining tissue responses once TCDD binds the AhR.

Evaluation of dose-response is one of the more important issues that affect dioxin risk assessments. The focus of this controversy centers on the shape of the dose-response curve, particularly at low doses, and whether the effects of dioxin may exhibit operational thresholds. It now appears that for some responses there is a proportional relationship between receptor occupancy and response, which is evidenced by a linear relationship between target dose and effect over a wide dose range. However, different dose-response relationships are seen for different responses, so it is probably inappropriate to use a single surrogate marker to estimate dioxin's risks. Furthermore, these data reveal there is no unifying dose-response relationship for all AhR-mediated events. A more detailed evaluation of dose-response relationships for TCDD-modulated responses is described in Chapter 8.

Another controversial area in risk assessment is whether experimental animal models are appropriate for estimating human risks. There has been increasing evidence that biochemical and toxic responses resulting from human exposure to TCDD and its structural analogues appear to be similar to responses in experimental animals. However, it may be possible that humans are sensitive or resistant to some responses. There also is increasing awareness that interindividual variations in human responses to dioxin are a complicating factor in risk assessment, as it appears that there are individuals who are responsive and nonresponsive to numerous environmental chemicals, including TCDD.

Much of the controversy surrounding dioxin risk assessment reflects the selection of mathematical models: threshold, linear multistage, or others. We now know considerably more about the mode of action of dioxin, and this knowledge has allowed the construction of biologically based models that may reduce some of the uncertainty in current risk estimates.

These approaches and advances in our understanding of the mechanisms of tumor promotion and dose-response relationships will be discussed in more detail in Chapter 8, Dose-Response Modeling for 2,3,7,8 TCDD.

6.2. ANIMAL BIOASSAYS FOR CANCER

Long-term studies for carcinogenicity of TCDD have been conducted in several species (van Miller et al., 1977; Kociba et al., 1978; NTP, 1982a; Rao et al., 1988; Johnson et al., 1992). All studies have produced positive results. It is clear that TCDD is a multi-site carcinogen in both sexes of rats and mice (U.S. EPA, 1985; Huff et al., 1991; Zeise et al., 1990, IARC 1997). It is a carcinogen in the hamster (Rao et al., 1988), which is considered the most resistant species to the acute toxic effects of TCDD, and a preliminary report indicates that TCDD is also carcinogenic in fish (Johnson et al., 1992). The important studies are summarized in Table 6-1, including information on species, sex, and tumor site.

The 2-year rodent bioassays conducted by Dow Chemical (Kociba et al., 1978) and the National Toxicology Program (NTP, 1982a) studies are the most comprehensive to date and most relevant to risk characterization, and are described in the following paragraphs.

6.2.1. Kociba Study

The most cited cancer bioassay for TCDD was published by Kociba et al. (1978). It was a lifetime feeding study of male and female Sprague-Dawley rats using doses of 0, 1, 10, and 100 ng/kg/day. There were 50 males and 50 females in each group. Data derived from these studies have been used as the basis for many risk assessments for TCDD.

The most significant finding was an increase in hepatocellular hyperplastic nodules and hepatocellular carcinomas in female rats. The incidence of hepatocellular carcinomas was significantly elevated above the control incidence at the 100 ng/kg/day dose, whereas increased incidence of hyperplastic nodules was evident in the 10 ng/kg/day dose group.

There have been two reevaluations of slides of liver sections from the Kociba study (Squire, 1980; Sauer, 1990; Goodman and Sauer, 1992). The Squire review was requested by EPA as an independent review of the slides. The Sauer review was carried out using refined criteria for the diagnosis of proliferative hepatocellular lesions (Maronpot et al., 1986, 1989). Liver tumor incidences for the three evaluations are compared in Table 6-2. Although there are some quantitative differences between the evaluations, the lowest detectable effect for liver tumor incidence is consistently observed at 10 ng/kg/day.

In the 10 ng/kg/day dose group, significant increases in the incidence of hyperplastic nodules of the liver were observed in female rats (18/50 in the Kociba evaluation, 27/50 in the Squire evaluation). Two females (2/50) had hepatocellular carcinomas. In the 1990 reevaluation (Sauer, 1990; Goodman and Sauer, 1992), nine females (9/50) were identified with hepatocellular adenomas and none with carcinomas; thus only one-third of the previously observed “tumors” were identified when using the refined diagnostic criteria.

In addition to nodules in the liver, increased incidence of stratified squamous cell carcinoma of the tongue and nasal turbinates/hard palate, and keratinizing squamous cell carcinoma of the lung were also observed in female rats in the 100 ng/kg/day dose group. One possible cause for the induction of lung tumors in the Kociba feeding study may have been the inhalation of dosed feed into the lungs. However the promotion of lung tumors has been observed in mice treated systemically by i.p. injections of TCDD (Beebe et al 1995). In addition the induction of hyperplastic and metaplastic lesions in rats has been observed following chronic oral gavage treatment with TCDD (Tritscher et al 2000). More recently chronic oral exposure to HCDD resulted in the induction of lung tumors in treated female rats (Rozman 2000). These

data indicate that the induction of lung tumors in the Kociba was most likely primarily the result of systemic chronic dietary exposure to TCDD rather than due to a localized inhaled exposure.

There was no detectable increase in liver tumor incidences in male rats in any of the dose groups (Table 6-1). The mechanism responsible for dioxin-mediated sex specificity for hepatocarcinogenesis in rats is not clear, but may involve ovarian hormones (Lucier et al., 1991). This is discussed in Section 6.3 on tumor promotion.

Although there was no increase in liver tumors in male rats in this study, in the 100 ng/kg/day group there was an increased incidence of stratified squamous cell carcinoma of the hard palate/nasal turbinate, stratified squamous cell carcinoma of the tongue, and adenoma of the adrenal cortex.

Kociba et al. (1978) had reported that chemically related increases in preneoplastic or neoplastic lesions were not found in the 1 ng/kg/day dose group. However, Squire identified two male rats in the 1 ng/kg/day dose group with squamous cell carcinoma of the nasal turbinates/hard palate, and one of these male rats had a squamous cell carcinoma of the tongue. These are both rare tumors in Sprague-Dawley rats, and these sites are targets for TCDD, implying that 1 ng/kg/day may not represent a no-observed-effect level (NOEL). However, no dose-response relationships were evident for tumors at these sites (Huff et al., 1991)

One of the more interesting findings in the Kociba bioassay was a TCDD-induced reduction in the incidence of spontaneous tumors including pituitary adenoma, benign tumor of the uterus, benign mammary neoplasm and mammary carcinoma in female rats, and acinar adenoma of the pancreas and adrenal pheochromocytoma in male rats. For example, carcinomas of the mammary gland occurred in 8 of 86 control female rats, whereas the incidence was 0/49 in the 1 ng/kg/day dose group. However, the incidence of mammary gland carcinomas in the medium- and high-dose groups was similar to that of control rats, suggesting that protection against breast cancer might be a low-dose effect. A relationship between body-weight reduction and spontaneous cancer incidence in rodents has been observed across numerous studies (Rao et al., 1987). This suggest that the reduction in the incidence of the spontaneous tumors by TCDD is likely related to the TCDD-induced reduction in body-weight gain. These findings, coupled with the sex specificity of TCDD-induced liver tumors in rats, highlight that the carcinogenic actions of TCDD may involve a complex interaction of hormonal factors. Moreover, it appears likely that tissue- and cell-specific factors modulate TCDD/hormone actions relevant to cancer.

There is considerable controversy concerning the possibility that TCDD-induced liver tumors are a consequence of cytotoxicity. Goodman and Sauer (1992) have extended the reevaluation of the Kociba slides to include liver toxicity data and have reported a correlation between the presence of overt hepatotoxicity and the development of hepatocellular neoplasms in female rats. With the exception of two tumors in controls and one each in the low- and

mid-dose groups, all liver tumors occurred in livers showing clear signs of toxicity. However, male rat livers exhibit cytotoxicity in response to high TCDD doses, yet they do not develop liver tumors. Moreover, both intact and ovariectomized female rats exhibit liver toxicity in response to TCDD, yet TCDD is a more potent promoter in intact but not ovariectomized rats (Lucier et al., 1991). Therefore, if cytotoxicity is playing a role in liver tumorigenesis, other factors must also be involved. Also, there is little information on the role of cytotoxicity in TCDD-mediated cancer at other sites such as the lung and thyroid.

6.2.2. NTP Study

The NTP study was conducted using Osborne-Mendel rats and B6C3F1 mice (NTP, 1982a). Groups of 50 male rats, 50 female rats, and 50 male mice received TCDD as a suspension in corn oil:acteone (9:1) by gavage twice each week (Tuesday and Friday) to achieve doses of 0, 10, 50, or 500 ng TCDD/kg/week for 2 years; groups of 50 female mice were treated similarly to achieve doses of 0, 40, 200, or 2,000 ng/kg/week. These exposures correspond to daily averaged doses of 1.4, 7.1, or 71 ng/kg/day for rats and male mice and to doses of 5.7, 28.6, or 286 ng/kg/day for female mice, so the doses were comparable to those used in the Kociba feeding study. There were no statistically significant dose-related decreases in survival in any sex-species group.

Tumor data in the NTP bioassay are summarized in Tables 6-3 and 6-4. TCDD-induced malignant liver tumors occurred in the high-dose female rats and in male and female mice. These can be considered to result from TCDD exposure because they are relatively uncommon lesions in control Osborne-Mendel rats (male, 1/208; female, 3/208), are seen in female rats and mice of both sexes, and their increasing incidence with increasing dose is statistically significant (Cochran-Armitage trend test, p=0.004). Because liver tumors were increased in both sexes of mice, this effect is not female-specific as was observed in rats. Interestingly, liver tumor incidences were decreased in female rats in both the NTP and Kociba low doses (not statistically significant compared with controls). For example, the combined control incidence data were 11/161 (7%) compared with 4/99 (4%) in the low-dose group.

The incidences of thyroid gland (follicular cell) tumors were increased in all three dose groups in male rats. Because the responses in the two highest dose groups are highly significant, the statistically significant elevation of incidence in the lowest dose group (Fisher exact p-value=0.042) is considered to be caused by exposure to TCDD. Thus, for this study the lowest-observed-effect level (LOEL) is 1.4 ng/kg/day and a NOEL was not achieved within the specified dose range, suggesting that thyroid tumor incidence may be the most sensitive site for TCDD-mediated carcinogenesis. Because 71 ng/kg/day is above the maximum tolerated dose

(MTD) (Huff et al., 1991), thyroid tumors occur at doses more than 50 times lower than the MTD.

TCDD-induced neoplasms of the adrenal gland were observed in the 7.1 ng/kg/day/dose group in male rats and in high-dose female rats. Fibrosarcomas of the subcutaneous tissue were significantly elevated in high-dose female mice and female rats. One additional tumor type, lymphoma, was seen in high-dose female mice. Lung tumors were elevated in high-dose female mice; the increase was not statistically significant when compared with concurrent controls, but the increase was dose related (Cochran-Armitage trend test, p=0.004).

Therefore, TCDD is a multisite complete carcinogen (Huff, 1992) and induced neoplasms in rats and mice of both sexes. As was observed in the Kociba study (Kociba et al., 1978), liver tumors were observed with greater frequency in treated female rats, but in male rats the thyroid appears to be the most sensitive (increased tumor incidence at doses as low as 1.4 ng/kg/day).

6.2.3. Syrian Golden Hamster

Groups of 10 to 24 male Syrian Golden hamsters were given two to six intraperitoneal or subcutaneous injections of TCDD over a 4-week period at doses of 0, 50, or 100 µg TCDD/kg in dioxane (Rao et al., 1988). The experiments were terminated after 12 to 13 months. The 100 µg/kg groups (total dose of 600 µg/kg) from both injection routes developed squamous cell carcinomas of the skin in the facial region: 4/18 (22%) from the intraperitoneal injection and 3/14 (21%) from the subcutaneous injection. The lesions were large (1.5 to 3 cm) with extensive necrosis, and some metastasized to the lung. The earliest neoplasms were detectable 8 months after the initial injection. Similar lesions were not seen in hamsters receiving two intraperitoneal injections of 100 µg/kg TCDD or six subcutaneous injections of dioxane vehicle, and none have been reported over the past 10 years in this laboratory. An extensive study by Pour et al. (1976) identified only 1 skin papilloma in 533 control Syrian hamsters. This report demonstrates that the hamster, a nonresponsive species for acute toxic effects, is susceptible to the carcinogenic actions of TCDD at doses well below the MTD.

6.2.4. B6C3 and B6C Mice

In a study by Della Porta et al. (1987), TCDD was administered intraperitoneally in corn oil at doses of 0, 1, 30, and 60 µg/kg to groups of 89 to 186 B6C3 and B6C mice of both sexes once weekly for 5 weeks starting at day 10 of life, and the animals were observed until 78 weeks of age. Histopathological observations were limited to the liver, kidney, and organs with apparent or suspected pathological changes. Thymic lymphomas were induced at the 60 µg/kg level in both sexes of both hybrids and at 30 µg/kg in all but female B6C3 mice. Neoplasms of

the liver occurred in male B6C3 mice at 30 µg/kg and female B6C3 mice at 60 µg/kg. In a separate experiment, groups of 42 to 50 B6C3 mice were exposed to 0, 2.5, and 5.0 µg/kg TCDD in corn oil by gavage once weekly for 52 weeks starting at 6 weeks of age. The study was stopped at 110 weeks. Increased incidences of liver tumors were related to TCDD exposure at both dose levels.

6.2.5. Fish

A preliminary study, reported in abstract form only, examined the carcinogenicity of TCDD in medaka (*Oryzias latipes*) immersed in 2,3,7,8 TCDD-treated water for 28 days, followed by immersion in clean water for up to 8 months (Johnson et al., 1992). Exposure to 33.9 ppq TCDD led to an increase in tumors at multiple sites including gills, thyroid, and swim bladder. Total body burden of TCDD in these fish was 2 ppb (Johnson et al., 1992).

6.2.6. Carcinogenicity of Related Compounds

A mixture of two isomers of hexachlorodibenzo-*p*-dioxin (HCDD) (1,2,3,6,7,8 and 1,2,3,7,8,9) was given by gavage twice weekly for 2 years to Osborne-Mendel rats and B6C3F1 mice (NTP, 1980). The doses of HCDD were 0, 1.25, 2.5, or 5 µg/kg/week in rats and male mice. Doses for female mice were 0, 2.5, 5, and 10 µg/kg/week. There was no effect of administration of HCDD on survival of either sex of rats or mice (NTP, 1980). Results revealed that HCDD increased liver tumors in both sexes of rats and mice, although female rats seemed to be more sensitive than male rats (significant increases detected in female rats in the 1.25 µg/kg/week dose group, equivalent to 180 ng/kg/day). Therefore, HCDD is approximately 1/20 as potent a liver carcinogen as TCDD.

Dermal applications of the HCDD mixture described above (NTP, 1982b) were given to Swiss Webster mice for 104 weeks (three times per week). For the first 16 weeks, doses of 5 ng/application were used. Thereafter, doses of 10 ng/application were used. No HCDD-exposure-related carcinogenic responses were noted.

Dibenzo-*p*-dioxin given in the diet for 2 years at concentrations of 0, 5,000, and 10,000 ppm did not increase carcinogenic responses in Osborne-Mendel rats or B6C3F1 mice (NCI, 1979a). 2,7-Dichlorodibenzo-*p*-dioxin (DCDD) in the diet of Osborne-Mendel rats for 110 weeks or B6C3F1 mice for 90 weeks at levels of 0, 5,000, or 10,000 ppm did not increase neoplasms in male or female rats or in female mice. In male mice, increased incidences of lymphoma or hemangiosarcoma were observed in the low-dose group and neoplasms of the liver were observed in both dose groups (NCI, 1979b). The more highly chlorinated dibenzo-*p*-dioxins (CDDs) and dibenzofurans (CDFs) have not been studied in long-term animal

cancer bioassays. Many of the CDDs and CDFs bioaccumulate and exhibit toxicities similar to those of TCDD and are considered to be carcinogens (EPA Science Advisory Board, 1989).

There are no carcinogenicity data on individual congeners of coplanar (dioxin-like) polychlorinated biphenyls. However, laboratory studies found statistically significant increased incidences of liver tumors in rats ingesting Aroclor 1260 or Clophen A60. Significant increases in gastric cancer, leukemia, and lymphoma were found in rats ingesting Aroclor 1254. Partial lifetime studies found precancerous liver lesions in rats and mice ingesting PCB mixtures of high or low chlorine content. More recent studies have compared the carcinogenicity of several Aroclor mixtures (Mayes et al., 1998). The Aroclor 1254 mixture contains the highest level of dioxin-like coplanar PCBs of these mixtures. All Aroclors tested, 1016, 1242, 1254, and 1260, resulted in an increased incidence of liver neoplasms in female rats. However, only Aroclor 1260 at high doses was carcinogenic in males. In addition, Aroclor, 1242, 1254, and 1260 induced thyroid tumors in male rats. Analysis of liver levels of specific PCB congeners suggests that in males the induction of tumors is dependent on total PCB content, whereas the liver tumor incidence in females is dependent upon the total TCDD toxic equivalents level (TEQ) as a result of accumulation of dioxin-like PCBs from the Aroclor mixture (Silkworth et al., 1997).

With regard to studies of the carcinogenicity of dioxin-like compounds, including PCBs, the National Toxicology Program is currently conducting 2-year carcinogenicity bioassays of multiple dioxin-like compounds and mixtures in female Sprague-Dawley rats (van Birgelen et al., 1997). Compounds under study include TCDD 2,3,4,7,8-pentachlorodibenzofuran (PeCDF), 3,3',4,4',5-pentachlorobiphenyl (PCB 126, a coplanar dioxin-like PCB), 2,3',4,4'5 -pentachlorobiphenyl (a mono-ortho PCB, PCB 118), 2,2',4,4',5,5'-hexachlorobiphenyl (a non-dioxin-like PCB, PCB 153), a binary mixture of a non-dioxin-like (PCB 153) and a dioxin-like PCB (PCB 126), and a mixture of dioxin-like compounds (TCDD, PeCDF, and PCB126).

6.3. INITIATION/PROMOTION STUDIES

The multistage nature of chemical carcinogenesis is being defined by an increasing understanding of the discrete steps required to produce a genetically altered cell that is clonally expanded and ultimately progresses to a tumor (IARC, 1992; Barrett and Wiseman, 1987; Swenberg et al., 1987; Barrett, 1992) (Figure 6-1). Briefly, the process involves damage to a specific site on DNA, a round of cell replication to fix that damage into the genome, clonal expansion of the genetically altered cells (tumor promotion), and additional genetic damage and rounds of cell replication (tumor progression). Figure 6-1 schematizes the multistage nature of cancer. The birth and death rates of genetically altered cells compared with normal cells are the centerpiece of risk assessment models that recognize the multistage nature of chemical carcinogenesis (Moolgavkar and Knudson, 1981; Portier, 1987).

The roles of proto-oncogene activation and tumor suppression gene inactivation have provided clues in attempts to discern discrete steps in carcinogenesis. It is also clear that cell proliferation is an essential component of chemical carcinogenesis, for without it, DNA damage would not be fixed into the genome and clonal expansion of genetically altered cells would not occur.

Concurrent with our increased understanding of the mechanistic underpinnings of chemical carcinogenesis, multistage models have been developed to identify the particular stage or stages in which carcinogens act to increase tumor incidence.

There is a wealth of information on liver initiation/promotion protocols in the scientific literature (Pitot and Sirica, 1980; Farber, 1984; Pitot and Campbell, 1987). These protocols frequently employ a single initiating dose of a chemical that damages DNA, followed by enhancement of cell replication (partial hepatectomy or cytotoxicity) to fix that damage into the genome (initiation), and then chronic exposure to a chemical that produces clonal expansion of the genetically altered cells (promotion). Increased tumor incidence is produced by chemicals that act at either stage. It is important to note that "initiation" and "promotion" are operational and not mechanistic terms because both stages are likely to be composed of multiple steps, and the mechanisms are not mutually exclusive. Nevertheless, the protocols have provided valuable information in our attempts to understand chemical carcinogenesis. Detailed descriptions of initiation/promotion protocols in liver and skin are provided elsewhere (Pitot and Campbell, 1987; Dragan et al., 1991; Pitot et al., 1987; Farber, 1984; Slaga et al., 1982; Peraino et al., 1981; Ito et al., 1980).

6.3.1. TCDD Is Not a Direct Genotoxic Agent

There is substantial evidence that TCDD is not a direct genotoxic agent. Because "genotoxic" and "nongenotoxic" are controversial and often misused terms, it is prudent to describe accurately the scientific criteria used to call a chemical "genotoxic" or "nongenotoxic" (IARC, 1992). Some of the criteria for designating TCDD a nongenotoxic agent are that it does not bind covalently to DNA (does not form DNA adducts). Although one study detected radioactivity associated with crude DNA preparations after in vivo exposure, no study that has rigorously looked for TCDD-DNA adducts has been positive. TCDD is negative in short-term tests for genotoxicity and is a potent promoter and weak initiator in multistage models for chemical carcinogenesis. In a another study (Turteltaub et al., 1990) using accelerator mass spectrometry, DNA adducts were not detected in rodent tissue following exposure to TCDD. This method is extraordinarily sensitive, being capable of detecting one adduct in 10^{12} normal nucleotides. Randerath et al. (1988) were unable to detect TCDD-related DNA adducts by the sensitive ^{32}P postlabeling method (limit of detection of one adduct in 10^{9} normal nucleotides).

For comparison, approximately one adduct in 10^6 normal nucleotides is found in rodent tissues following carcinogenic doses of benzo(a)pyrene (7,8-diol-9,10 epoxide deoxyguanosine DNA adduct) or methylnitrosourea (O^6 methylguanine).

Another criterion for designating TCDD a "nongenotoxic carcinogen" is that numerous studies have demonstrated that TCDD is negative in the *Salmonella*/Ames test in the presence or absence of a mixed-function oxidase (MFO) activating system. These negative studies have encompassed 13 different bacterial strains with tests performed in 9 laboratories (Wassom et al., 1977; Kociba, 1984; IARC, 1982; Giri, 1987; Shu et al., 1987). Using its battery of tests for genetic toxicity, the NTP (1984) concluded that TCDD was nonmutagenic. Additionally, several scientific panels have stated that false negatives for TCDD genetic toxicity are highly unlikely (EPA Science Advisory Board, 1984). TCDD has been found to promote the transformation of C3H/10T1/2 cells; it was concluded that this response did not reflect TCDD's ability to directly damage DNA (Abernethy et al., 1985). In human populations accidentally or occupationally exposed to TCDD, there is no consistent evidence for increased frequencies of chromosomal aberrations in workers exposed to TCDD (Shu et al., 1987).

However, Yang et al. (1992) demonstrated that immortalized human keratinocytes cultured with TCDD were neoplastically transformed, as evidenced by tumorigenic activity of those cells in nude mice. This response is characteristic of genotoxic carcinogens and occurred at a low TCDD concentration (0.1 nM). For comparison, induction of CYP1A2 in these same cells was not detected until a dose of 3 nM was used (Yang et al., 1992).

6.3.2. Two-Stage Models of Liver Tumor Promotion by TCDD

TCDD is designated as a nongenotoxic carcinogen because it is negative in most assays for DNA damaging potential, a potent tumor promoter, and a weak initiator or noninitiator in two-stage models for liver (Pitot et al., 1980; Graham et al., 1988; Lucier et al., 1991; Clark et al., 1991a; Flodstrom and Ahlborg, 1991) and skin (Poland et al., 1982).

Pitot et al. (1980) were the first to report that TCDD was a potent liver tumor promoter in female rats. Animals were initiated with a single dose of diethylnitrosamine (DEN)(10 mg DEN/kg) 24 hours following a 2/3 hepatectomy, followed by chronic TCDD exposure (0.14 and 1.4 µg/kg subcutaneously once every 2 weeks for 7 months). When expressed as a daily averaged dose, these doses are equivalent to 10 and 100 ng TCDD/kg/day (the medium and high dose in the Kociba bioassay). Histological evaluation revealed that five of seven animals that had received DEN and 100 ng TCDD/kg/day had hepatocellular carcinomas. No liver tumors were evident in rats receiving DEN only, DEN/low-dose TCDD, or TCDD only (high or low dose). Altered hepatocellular foci (AHF) exhibiting altered expression of the marker enzymes glucose-6-phosphatase, canalicular ATPase, and gamma glutamyl transpeptidase were also

evaluated in this study. AHF are considered to represent preneoplastic lesions because increases in AHF are associated with liver cancer in rodents (Maronpot et al., 1989; Popp and Goldsworthy, 1989; Pitot et al., 1989; Williams, 1989). The AHF data were consistent with the tumor data in that a large proportion of the liver was occupied by AHF (43%) in animals initiated with DEN and the high dose of TCDD. A much smaller proportion of the liver was occupied by AHF in the other groups. This work provides strong evidence that TCDD is a potent tumor promoter in liver.

A second set of studies (Graham et al., 1988; Lucier et al., 1991; Clark et al., 1991a; Dragan et al., 1992) confirmed and extended Pitot's findings, including data suggesting a mechanistic basis for TCDD's tumor-promoting effects in rat liver. These DEN studies, using a necrogenic dose of DEN (200 mg/kg) as the initiator, have demonstrated that the effect of TCDDs on the promotion of AHF are reduced following ovariectomy. This finding is consistent with 2-year bioassays showing that TCDD is a hepatocarcinogen in female rats but not in male rats. In the tumor-promoting studies (Graham et al., 1988; Lucier et al., 1991), DEN was used as the initiating agent and TCDD (biweekly doses of 1.4 µg TCDD/kg, equivalent to 100 ng/kg/day for 30 weeks) was used as the promoter. There were four groups of intact female rats (controls, TCDD only, DEN only, and DEN/TCDD). The same four groups were used following ovariectomy. Data revealed that TCDD was a weaker liver tumor promoter in ovariectomized rats (Table 6-5). For example, there were 387 gamma glutamyl transpeptidase (GGT) positive AHF/cm^3 in intact rats compared with 80 in ovariectomized rats in the DEN/TCDD groups. Corresponding differences were evident in the proportion of liver occupied by GGT positive AHF: 0.37% in DEN/TCDD intact rats compared with 0.08% in DEN/TCDD ovariectomized rats. Few or no AHF were found in the control or TCDD-only groups. Placental glutathione S-transferase (PGST) is being used increasingly as a phenotypic marker of AHF (Ito et al., 1989), and results with this marker of preneoplasia were similar to those for GGT in that ovariectomy reduced the liver tumor-promoting actions of TCDD. The influence of ovariectomy on liver tumor incidence was evaluated in a parallel experiment using the same treatment groups in which TCDD was administered for 60 weeks. In the intact DEN/TCDD rats, liver tumor incidence was 13/37, with a total of 32 tumors compared with 7/39 (11 total tumors) in DEN/TCDD ovariectomized rats. Both hepatocellular adenomas and carcinomas were evident, along with a smaller incidence of hepatocholangiomas and hepatocholangiocarcinomas.

The mechanisms responsible for the protective effect of ovariectomy are not clear, but ovarian influences on liver TCDD retention do not seem to be involved; liver TCDD concentrations were ~20 ppb in both intact and ovariectomized rats (Lucier et al., 1991), which is similar to liver concentrations reported by Kociba et al. (1978) using the same dose of TCDD (100 ng/kg/day) but for 2 years rather than 60 weeks. One plausible mechanism may be related

to cell proliferation. Another possible mechanism for the influence of the ovaries is that TCDD induces cytochrome P4501A2, which could lead to DNA-reactive metabolites of 17-beta-estradiol, the naturally occurring estrogen. P4501A2 catalyzes the formation of catechol estrogens that are carcinogens in hamsters and are considered by some to be DNA-reactive precursors (Metzler, 1984; Li and Li, 1990, Yager and Liehr, 1996).

In addition to these initial studies, a large number of studies have addressed the effect of dioxins on the development of preneoplastic AHF in the rat liver. These studies are summarized in Tables 6-5, 6-6, and 6-7. These studies, while using different rat strains, different initiation protocols, and different dosing regimens, are consistent in showing that the induction of AHF by TCDD in the female Sprague-Dawley rat liver is dose-dependent (Maronpot et al., 1993; Teeguarden et al., 1999) (Table 6-8), exposure duration-dependent (Dragan et al., 1992; Walker et al., 2000; Teeguarden et al., 1999), and reversible after cessation of treatment (Dragan et al., 1992; Tritscher et al., 1995; Walker et al., 2000).

Other studies indicate that the capacity to induce the development of AHF in the liver by compounds structurally related to TCDD, such as the polychlorinated dibenzo-dioxins and polychlorinated dibenzo-furans, exhibits a rank-order potency similar to that for the induction of CYP1A1 activity (Flodstrom and Ahlborg, 1992; Waern et al., 1991; Schrenk et al., 1994). Although these data suggest that the potency of different dioxin-like compounds cannot be predicted solely on the basis of their potency for induction of CYP1A1, they provide evidence that liver tumor promotion likely requires an initial interaction with the AhR. Studies also demonstrate that the non-ortho-substituted (dioxin-like) polychlorinated biphenyls (PCBs) that induce the development of AHF exhibit a similar potency to that required to induce CYP1A1 activity (Hemming et al., 1995; van der Plas, 1999). Furthermore, when PCBs are administered in combination with TCDD, the effects on AHF development are additive, suggesting that tumor promotion by dioxins and dioxin-like PCBs likely acts through similar mechanisms.

6.3.3. Lung

Because the lung and respiratory tract seem to be target sites for TCDD carcinogenesis in humans (Fingerhut et al., 1991), it is of interest to evaluate whether TCDD is a tumor promoter in rodent lung. There are few published reports on the promotion of lung tumors in rats. Clark et al. used DEN as the initiating agent and TCDD (100 ng/kg/day for 60 weeks) as the promoting agent (Clark et al., 1991a) in both intact and ovariectomized rats. In contrast to liver tumor promotion, lung tumors were seen only in DEN/TCDD ovariectomized rats (4/37). No lung tumors were present in DEN/TCDD intact rats, in DEN only/TCDD only, or in control rats with or without ovariectomy. The background incidence of lung tumors in rats is very low, so the

lack of tumors in controls was not unexpected (Haseman et al., 1984). The four tumors in DEN/TCDD intact rats were two squamous cell carcinomas and two adenocarcinomas.

More recently, the induction of lung lesions was examined in DEN-initiated female rats exposed biweekly to 1,750 ng TCDD/kg for up to 61 weeks. Although there was no significant effect on the development of lung tumors, TCDD exposure was associated with an increase in alveo-bronchiolar metaplasia and bronchiolar hyperplasia (Tritscher et al., 1999).

There is only a single report of the effect of TCDD on promotion of lung tumors in mice (Beebe et al., 1995). Three weeks following a single initiating dose of 25 mg NDMA/kg, male Swiss mice were administered a single dose ranging from 0.05 µg up to 48 µg TCDD/kg, or were treated with 50 ng TCDD/kg per week for 20 weeks. The incidence of lung tumors (alveolar adenomas and carcinomas) in the initiated animals that received vehicle alone was 100%, but treatment with TCDD, either as a single dose of 1.6 µg/kg or as 50 ng/kg/week, resulted in a significant increase in tumor multiplicity. Single doses of TCDD greater than 1.6 µg/kg had no effect on tumor multiplicity, although the authors note that this may have been due to observed pulmonary toxicity.

The rodent tumorigenicity data provide clues to the complex hormonal interactions that produce site-specific carcinogenic actions of TCDD. Liver tumors are ovarian dependent, whereas the ovaries appear to protect against TCDD-mediated tumor promotion in lung. Therefore, the rat tumor data are of interest because recent epidemiologic studies (Chapter 7) have shown that TCDD exposure is associated with an increase in respiratory tract tumors.

6.3.4. Mouse Skin

Initiation/promotion studies on skin have demonstrated that TCDD is a potent tumor promoter in mouse skin as well as rat liver. Poland et al. (1982) administered a single dermal initiating dose of *N*-methyl-*N*-nitrosoguanidine (MNNG) to HRS/J hairless mice followed by twice-weekly doses of TCDD (3.75, 7.5, 15, or 30 ng) or TPA (1 or 3 µg) for 20 weeks. TCDD promoted the development of papillomas at all doses, and the response was dose dependent (100% of the animals in the high-dose TCDD group had tumors). Control animals or animals receiving only MNNG or TCDD exhibited a low incidence of tumors. These studies demonstrate that TCDD is at least two orders of magnitude more potent an agent than tetradecanoyl phorbol acetate (TPA) in mouse skin (Poland et al., 1982). On the basis of structure activity and genetic studies, it appears that the skin tumor-promoting actions of TCDD are AhR dependent. Moreover, tumorigenic responses segregate with the *hr* locus, and biochemical responses such as CYP1A1 induction can occur without carcinogenesis (Poland and Knutson, 1982; Poland et al., 1982).

Other studies have tested TCDD as an initiator and TPA as a promoter in CD-1 mice (DiGiovanni et al., 1977). Results revealed that TCDD had weak or no initiating activity in this system. To better understand the possible influence of TCDD-mediated induction of cytochrome P450 on the carcinogenicity of PAHs, TCDD was coadministered with benzo(a)pyrene or dimethylbenzanthracene to mice, followed by promotion with TPA (Cohen et al., 1979). Results revealed that TCDD decreased tumor incidence of both PAHs compared with controls. However, coadministration of TCDD with 3-methylcholanthrene to mice produced tumor incidences similar to those produced by 3-methylcholanthrene alone (Kouri et al., 1978). These results are consistent with the findings that TCDD induction of drug-metabolizing enzymes is associated with both metabolic activation deactivation of PAHs (Lucier et al., 1979).

The relative toxicity and tumor-promoting capacity of two CDFs (2,3,4,7,8-CDF and 1,2,3,4,7,8-CDF) have been investigated in hairless mice (Hebert et al., 1990). These studies used a treatment protocol similar to that of Poland et al. (1982), including the use of MNNG as the initiating agent and varying doses of TCDD, 2,3,4,7,8-CDF, or 1,2,3,4,7,8-CDF for 20 weeks. Proliferative lesions (squamous cell papilloma, squamous cell carcinoma, or hyperproliferative nodules) were quantified. Results demonstrated that 2,3,4,7,8-CDF was 0.2 to 0.4 times as potent as TCDD and that 1,2,3,4,7,8-CDF was 0.08 to 0.16 times as potent as TCDD. These data suggest that the tumor-promoting potencies of structural analogues of TCDD, like the promotion of liver tumors, reflect relative binding properties to the AhR as well as pharmacokinetic parameters.

Taken together, results on initiation/promotion protocols indicate that TCDD is an extraordinarily potent promoter of liver and skin tumors (Pitot et al., 1987), and the results provide strong evidence that the carcinogenic actions are AhR mediated. A summary of studies on tumor promotion by TCDD or the polychlorinated dibenzofurans is given in Table 6-6. Plausible mechanisms responsible for the tumor-promoting actions of TCDD and the impact of these mechanisms on dose-response relationships are presented in Section 6.4.

6.3.5. Transgenic Models

Studies on the effect of TCDD on tumor promotion in rat liver and mouse skin require the use of an exogenous initiating agent such as diethylnitrosamine or *N*-methyl-*N*-nitrosoguanidine. Recently transgenic models for classifying the mechanism of action of carcinogens have been used to examine the mechanism of carcinogenicity of TCDD in mice (Eastin et al., 1998). These are the Tg.AC transgenic mouse, which harbors an activated mouse v-Ha-ras oncogene, and the p53 +/- transgenic mouse models, which are heterozygous for the wild-type tumor suppressor p53. Dermal application of tumor promoters such as phorbol esters results in the development of epidermal papillomas in the Tg.AC. Topical application of

166 ng TCDD/kg in acetone three times per week for 24 weeks led to a significant increase in the incidence of squamous cell papillomas in both male Tg.AC mice (8/15 TCDD-treated vs. 1/15 controls) and female Tg.AC mice (10/15 TCDD-treated vs. 1/15 controls) (Eastin et al., 1998). Treatment of p53 +/- mice by gavage with 250 ng/kg (males) or 1,000 ng/kg (females) twice a week for 24 weeks did not result in any neoplastic lesions.

Subsequent studies showed that the induction of papillomas by dermal application of TCDD to hemizygous Tg.AC mice is dose dependent over a dose range of 0-760 ng TCDD/kg 3 times per week for 26 weeks, with the lowest observed effect occurring in the 17 ng/kg dose group (7.3 ng/kg/day) (van Birgelen et al., 1999, Dunson et al., 2000). In addition, the induction of skin papillomas in this model occurs when administration is at a site distant to the site of administration. Treatment of Tg.AC mice for 26 weeks by oral gavage with 0, 105, 450, or 1,250 ng TCDD/kg led to an increase in skin papillomas in the 1,250 ng/kg dose group only (5/20 TCDD-treated vs. 0/18 in controls) (van Birgelen et al., 1999). These data provide further support for the potent tumor-promoting action of TCDD.

6.4. MECHANISMS OF TCDD CARCINOGENICITY

6.4.1. Indirect DNA Damage

Although TCDD is negative in genetic toxicity tests, high doses of TCDD (50 to 100 µg/kg) induce single-strand breaks in Sprague-Dawley rats, presumably as a consequence of increased lipid peroxidation (Wahba et al., 1988, 1989). In addition, though TCDD may not be directly genotoxic, it has been suggested that it may be indirectly genotoxic through the formation of potentially DNA reactive oxygen species. This may result from cytochrome P450 induction by TCDD (Park et al., 1996), through the induction of oxidative stress (Slezak et al., 1999), or through the formation of catechol estrogens (Graham et al., 1988; Spink et al., 1992; Yager et al., 1996). Indeed, higher levels of oxidative DNA damage (8-OH-dG adducts) have been observed in chronically exposed female rats (Tritscher et al., 1996) and these TCDD-induced increases were not observed in ovariectomized rats. Other evidence to support this hypothesis includes the observation that mathematical modeling of the development of altered hepatocellular foci indicates that TCDD may have an effect on the initiation rate within the framework of a one-cell two-stage initiation-promotion model (Portier et al., 1996; Moolgavkar et al., 1996)(see Chapter 8). However, alternate two-cell models for tumor promotion do not suggest an effect on the initiation rate (Conolly et al., 1997).

6.4.2. Endocrine Disruption/Growth Dysregulation/Altered Signal Transduction

One of the characteristics of TCDD is that it is a potent growth dysregulator and alters the signaling of numerous hormonal systems. TCDD induces the expression of a large number

of genes involved in growth regulation, hormonal signaling and signal transduction, and hormone metabolism. In addition to these effects, which are presumably mediated through the AhR-ARNT heterodimer, there are also AhR-dependent effects on signaling pathways independent of activation of gene expression by the AhR-ARNT heterodimer that may be related to the mechanism of toxicity of TCDD. These effects are described in more detail in Chapter 2. Although many of the effects of TCDD have not been directly assessed for their role in the carcinogenicity of TCDD, it is likely that sex, species, and tissue specificity of dioxin carcinogenicity is due to a combination of these effects. Consequently, it is unlikely that a single mechanism is responsible for all the carcinogenic effects of TCDD in all tissues and species. However, it is now accepted by the scientific community that most, if not all, of TCDD's toxic and biochemical effects, including tumor promotion, are AhR dependent and that TCDD provides an example for evaluating the issues relevant to risk assessment for receptor-mediated carcinogens.

The list of biochemical effects produced by TCDD in humans, experimental animals, and cell systems is expanding. These effects include those that may alter normal cell regulatory processes, such as cell proliferation and differentiation, metabolic capacity, and hormonal pathways. Potentially the effects of TCDD on the endocrine system and tissue differentiation may play a role in susceptibility to carcinogenesis induced by other compounds, that is distinct from effects on metabolism of procarcinogens. Brown and co-workers showed that prenatal exposure of female rats to TCDD resulted in an increased susceptibility to DMBA-induced mammary adenocarcinomas. This was likely due to an increase in mammary gland terminal end buds as a result of prenatal exposure (Brown et al., 1998).

6.4.3. Cell Replication/Apoptosis and Tumor Promotion

One mechanism that has been proposed for the reduced tumor promotion capacity of TCDD in ovariectomized rats is the effect of TCDD on cell proliferation. TCDD did not stimulate cell proliferation rates in ovariectomized rats, whereas a mean increase of tenfold was apparent in intact rats receiving 100 ng TCDD/kg for 30 weeks (Table 6-5) (Lucier et al., 1991). There was considerable interindividual variation in both cell proliferation rates and enzyme-altered foci in the DEN/TCDD groups. Comparisons of the two data sets revealed a strong positive correlation between enzyme-altered foci and cell proliferation, although the importance of this finding is diminished by the fact that cell proliferation was quantified in nonlesioned hepatocytes. The mechanism whereby ovarian hormones and TCDD interact to produce cell proliferation in hepatocytes may involve growth factor pathways. Consistent with this idea, TCDD induced a loss of plasma membrane epidermal growth factor receptor (EGFR) in intact rats but not in ovariectomized rats (Sewall et al., 1993) EGF is thought to provide a

mitogenic stimulus in hepatocytes and to play a key role in hepatocarcinogenesis (Vickers and Lucier, 1991; Velu, 1990; Shi and Yager, 1989; Eckl et al., 1988). A schematic representation of a plausible mechanism for the role of estrogen in TCDD-mediated liver cancer in rats is given in Figure 6-2.

These observations of the ovarian hormone-dependent increase in hepatocyte replication following chronic exposure to TCDD (Lucier et al., 1991) parallel the observed sex-dependent induction of liver tumors in rats. This observation has led to the hypothesis that the induction of cell replication by TCDD may be a critical event in the mechanism of hepatocarcinogenesis. This hypothesis was supported by the observation that hepatocyte replication was dose-dependently increased after chronic exposure to TCDD (Maronpot et al., 1993)(Table 6-8).

Other studies, however, have failed to observe any effect of TCDD on nonfocal hepatocyte replication (Buchmann et al., 1994; Stinchcombe et al., 1995). More recently, it was shown that induction of hepatocyte replication is exposure-duration dependent and is only observed following 30 weeks of exposure to TCDD (Walker et al., 1998). Indeed, after 14 weeks of exposure, hepatocyte replication is lower in TCDD-treated animals than in controls. These data indicate that the induction of hepatocyte replication is not an early event in tumor promotion by TCDD and likely represents a secondary response to the induction of putatively preneoplastic AHF. However, data are insufficient to conclude that induction of hepatocyte replication is not involved in development of liver tumors.

Although cell replication is not seen after subchronic exposure to TCDD, it was observed that there was a suppression of hepatocyte apoptosis following TCDD treatment (Stinchcombe et al., 1995). The suppression of UV-inducible apoptosis by TCDD has also been observed in vitro (Worner et al., 1996), suggesting that this suppression may be an early event in tumor promotion. The suppression of apoptosis by TCDD in AHF may provide a growth advantage to these preneoplastic lesions, and therefore may be involved in the mechanism of hepatocarcinogenesis.

6.4.4. Thyroid Cancer–Proposed Mechanism of Action

TCDD causes a dose-related increase in thyroid follicular cell adenomas and carcinomas in rats and mice. One hypothesis for the induction of thyroid tumors involves the disruption of thyroid hormone homeostasis via induction of phase II enzymes UDP-glucuronosyltransferases (UGTs) (Hurley, 1998; Hill et al., 1998). Dioxin-like compounds induce the synthesis of UDP-glucuronosyltransferase-1 (UGT1) mRNA by an AhR-dependent transcriptional mechanism (Bock et al., 1998; Nebert et al., 1990). It is proposed that dioxin-like compounds increase the incidence of thyroid tumors through an extrathyroidal mechanism. Dioxin-like compounds induce hepatic UGT resulting in increased conjugation and elimination of thyroxine (T4),

leading to reduced serum T4 concentrations. T4 production is controlled by the thyroid stimulating hormone (TSH) which is under negative and positive regulation from the hypothalamus, pituitary, and thyroid by the thyrotrophin-releasing hormone (TRH), TSH, T4, and triiodothyronine (T3). Consequently, the reduced serum T4 concentrations would lead to a decrease in the negative feedback inhibition on the pituitary gland. This would then lead to a rise in the secreted TSH and stimulation of the thyroid. The persistent induction of UGT by dioxins and subsequent prolonged stimulation of the thyroid would result in thyroid follicular cell hyperplasia and hypertrophy of the thyroid, thereby increasing the risk of progression to neoplasia. In support of this hypothesis, Kohn et al. modeled the effect of TCDD on UGTS and thyroid hormones in female rats within the framework of a pharmacologically based-pharmacokinetic (PBPK) model (Kohn et al., 1996). This mathematical model described release and uptake of thyroid hormones, metabolism, TCDD induction of UGT1, regulation of TSH release from the pituitary by T4 and feedback on TRH and somatostatin which inhibits TSH release. The model successfully reproduced the observed effects of TCDD on serum T3, T4, and TSH, and UGT1 mRNA and enzyme activity, suggesting that this is a plausible mechanism for an indirect role of TCDD on the thyroid. This model is supported by the more recent experimental work of Schuur et al. which demonstrated the extrathyroidal effects of TCDD on thyroid hormone turnover (Schuur et al., 1997).

6.4.5. Mechanisms of Reduced Spontaneous Tumor Incidence

In the Kociba study, there was a significant reduction in the incidence of spontaneous benign tumors of the uterus, benign neoplasms of the mammary gland, mammary carcinomas, and pituitary adenomas in female rats, and pheochromocytoma of the adrenal gland and pancreatic adenomas in male rats. It is likely that the reduction in body weight gain as a result of TCDD exposure is responsible for the reduced incidence in these spontaneous lesions. Studies by the National Toxicology Program (Haseman and Johnson, 1996; Seilkop, 1995) indicate that chemical exposures resulting in a reduction of body weight by 10%-20% is correlated with a decrease in incidence of both mammary tumors and anterior pituitary tumors. This phenomenon may be related to a homeostatic growth suppression in reproductive organs during periods of reduced nutritional status. In addition, reduction in pancreatic adenomas (Kociba et al., 1978) has been observed in diet-restricted animals, and consequently, this reduction in incidence may be due to TCDD induced body weight reduction. The reduction in pheochromocytoma in male rats does not appear to be a consequence of changes in body weight, yet it exhibited a dose-dependent reduction in TCDD exposed males. The mechanism for the reduction in pheochromocytoma is unknown. The decrease in hormone-dependent cancers also may be related to the ability of TCDD to alter estrogen metabolism and/or its ability to act in some

tissues/cell systems as an antiestrogen. Increased estrogen metabolism may result from increased expression of CYP1 cytochromes P450, UGT, and GST. Decreased estrogen action could result from effects on the estrogen receptor (ER) levels or ER transcriptional function. TCDD may also induce the inactivation of estrogen in target cells by metabolism by TCDD inducible cytochromes CYP1A2, CYP1B1, or conjugating enzymes such as UGT1/GST without altering circulating estradiol concentrations.

6.5. BIOCHEMICAL RESPONSES

This section will summarize some of the changes produced by TCDD, including discussion of (1) possible relevance of the response to TCDD-mediated cancer, (2) whether the response is AhR mediated, (3) whether information is available on the role of transcriptional activation, (4) dose-response relationships, and (5) whether animal models are consistent with human responses. This chapter will not attempt to evaluate all of the biochemical and molecular responses to TCDD, but will focus on the ones that are either the most relevant to carcinogenic responses or have received the most study. The responses include induction of P4501A1 (CYP1A1), cytochrome P4501A2 (CYP1A2), EGFR, estrogen receptor (ER), and UDP-glucuronosyltransferase (UDPGT). Table 6-9 lists many of the biochemical changes affected by TCDD in in vivo and/or in vitro systems and some information on mechanisms of action.

6.5.1. Cytochrome P450

The most studied response to TCDD has been induction of cytochrome P450 isozymes (Whitlock, 1990; Silbergeld and Gasiewicz, 1989; Poland and Knutson, 1982). The first reports of P450 induction in vivo and in vitro appeared in 1973 (Lucier et al., 1973; Greig and DeMatteis, 1973; Poland and Glover, 1973), and hundreds of papers have been published on the subject since that time. These papers have dealt with various aspects of TCDD-mediated induction of P450, such as isozyme specificity, time course, structure-activity relationships, molecular mechanisms of transcriptional activation of the CYP1A1 gene, identification of transcriptional activating factors, tissue and cell specificity, and dose-response relationships. The molecular mechanisms responsible for enzyme induction are described elsewhere in this volume.

The mechanistic relationship of CYP1A1 and 1A2 induction to cancer or any other toxic endpoint following dioxin exposure has not yet been demonstrated, yet considerable controversy exists on this subject (Roberts, 1991). Because CYP1A1 catalyzes the metabolic activation of many chemicals, such as the PAHs, to DNA-reactive metabolites, it has been postulated that induction of CYP1A1 might enhance the carcinogenic actions from a given exposure level to

many PAHs. Recently it has been shown that benzo(a)pyrene is not carcinogenic in transgenic mice that are AhR deficient (Shimizu et al., 2000). The lack of carcinogenicity is presumably due to the lack of induction of CYP1A1 by B(a)P in these animals, supporting a proposed role for CYP1A1 in the carcinogenicity of B(a)P. Usually, however, preinduction of CYP1A1 diminishes the carcinogenic potency of PAHs such as 3-methylcholanthrene, benzo(a)pyrene, and 7,2-dimethylbenzanthracene if exposure to an inducing agent (such as TCDD) is short term (Parkinson and Hurwitz, 1991; Wattenberg, 1985; Cohen et al., 1979; Wattenberg, 1978; Miller et al., 1958). Induction also protects against the carcinogenic actions of aflatoxin, diethylnitrosamine, arylamines, and urethane. Protection occurs at numerous cancer sites, including liver and lung. Several lines of evidence support the idea that enzyme induction is the mechanism responsible for the protective effect. First, treatment of mice deficient in AhR with inducers does not protect against PAH-mediated cancer (Kouri et al., 1978). Second, the ability of inducing agents to protect against cancer is positively correlated with their potency as inducing agents (Wattenberg and Leong, 1970; Arcos et al., 1961). Third, the inducing agent must be administered at least 1 day prior to treatment, which allows sufficient time for the inducer to produce elevated levels of CYP1A1 (Parkinson et al., 1983; Wheatley, 1968).

The most probable mechanism for the protective effect of enzyme induction is that it leads to decreased concentrations of promutagenic DNA adducts in target tissues. These findings appear to contradict the knowledge that CYP1A1 is required for the metabolism of PAHs, aflatoxin, and several other carcinogens to DNA-reactive arene oxides (Guengerich, 1988; Levin et al., 1982; Conney, 1982). For example, the promutagenic DNA adduct of benzo(a)pyrene appears to be a 7,8-diol-9,10 epoxide metabolite adducted to deoxyguanosine, and formation of this metabolite requires two separate actions of CYP1A1. The contradiction can be resolved by analysis of all the metabolic pathways for chemical carcinogens whose potencies are decreased by pretreatment with inducing agents. In addition to CYP1A1-mediated increases in metabolic activation, CYP1A1 also converts PAHs to inactive metabolites (Thakker et al., 1985; Pelkonnen and Nebert, 1982). Moreover, induction of uridine diphosphoglucuronyltransferase also occurs concurrently with CYP1A1 induction (Lucier et al., 1986). This enzyme also detoxifies metabolites of PAHs and other carcinogens and facilitates their excretion from the body (Thakker et al., 1985; Nemoto and Gelboin, 1976). Therefore, it appears that TCDD-mediated enzyme induction increases the rate of detoxification of some carcinogens to a greater extent than it increases the rate of formation of DNA-damaging metabolites.

Increased frequency of sister chromatid exchanges was observed in lymphocytes of people exposed to pentachlorinated dibenzo-*p*-dioxins (PCDFs) in Taiwan when those lymphocytes were challenged with beta-naphthoflavone (Lundgren et al., 1986, 1988). This may

be because the PCDFs cause increased rates of metabolic activation of beta-naphthoflavone to DNA-reactive metabolites (Lundgren et al., 1987). These findings are consistent with the idea that TCDD's ability to induce drug-metabolizing enzymes (CYP1A1 and 1A2) may lead to an increased rate of formation of DNA-reactive metabolites of some carcinogens, most notably the PAHs and aromatic amines. However, there is evidence that the opposite effect occurs in some cases, because in vivo exposure to CYP1A1 inducers actually leads to a decrease in DNA adducts in target tissue following in vivo exposure to PAHs such as benzo(a)pyrene (Cohen et al., 1979; Parkinson and Hurwitz, 1991). It can reasonably be concluded that TCDD exposure may increase the rate of DNA adduct formation for some carcinogens but decreases the rate for others, and that predictions should not be made without experimental data on DNA adduct concentrations in control and TCDD-treated animals.

Although there is no clear mechanistic link between CYP1A1 induction and cancer, it is important to note that many CYP1A1 inducers are themselves carcinogens when encountered in chronic dosing regimens; therefore, the protective effect of inducing agents appears to be limited to short-term exposure. For example, benzo(a)pyrene, 3-methylcholanthrene, and TCDD are CYP1A1 inducers and multisite carcinogens (Vanden Heuvel and Lucier, 1993; Levin et al., 1982; Slaga et al., 1979; Sims and Glover, 1974).

The relationship of CYP1A2 induction to the carcinogenic actions of other compounds is less clear than it is for CYP1A1. For example, CYP1A2 catalyzes the formation of catechol estrogens from 17-beta-estradiol (Graham et al., 1988). The catechol estrogens are considered to be possible toxic metabolites because they could lead to increased free radical damage to cellular macromolecules such as DNA (Li and Li, 1990; Metzler, 1984; Yager and Liehr, 1996). This mechanism could be responsible, in part, for the findings that TCDD is a hepatocarcinogen in female rats but not male rats, and that ovariectomy protects against the hepatocarcinogenic actions of TCDD. Also consistent with the hepatocarcinogenicity data is the observation that CYP1A2 is induced in liver but not in extrahepatic organs, with the possible exception of the nasal mucosa (Goldstein and Linko, 1984). In contrast, CYP1A1 induction occurs in virtually every tissue of the body, which is consistent with the observation that the AhR is found in a wide variety of cell types.

In addition to the well-characterized induction of CYP1A1 and CYP1A2, TCDD also induces another cytochrome P450, CYP1B1, that has been identified in humans and rodents (Bhattacharyya et al., 1995; Savas et al., 1994; Sutter et al., 1994; Walker et al., 1995). CYP1B1 is expressed in a variety of human tissues and is inducible by TCDD in numerous human cell and rodent tissues including liver, lung, and kidney (Hayes et al., 1996, Sutter et al., 1994; Walker et al., 1995). CYP1B1 is active in the metabolism of numerous polycyclic aromatic hydrocarbons and arylamines (Otto et al., 1992; Shimada et al., 1996; Crofts et al., 1998) and can catalyze the

4-hydroxylation of 17-beta-estradiol in humans cells (Hayes et al., 1996). The potent carcinogenicity of 4-hydroxyestradiol in Syrian Golden hamsters (Liehr et al., 1986) and the observed elevation of 4-hydroxylase activity in human tumors (Liehr et al., 1996) suggest that the estradiol hydroxylase activity of CYP1B1 may play a critical role in tumorigenesis. This implication has been further extended to suggest that the induction of CYP1B1 in rat liver may play a role in the ovarian hormone-dependent hepatocarcinogenicity of TCDD (Yager et al., 1996). However, there are no reports in the literature that CYP1B1 in rodents has any significant estradiol hydroxylase activity, and therefore it is not clear if CYP1B1 is involved in the mechanism of hepatocarcinogenesis in rats.

CYP1B1 in both humans and rodents is active in the metabolism of PAHs and arylamines, and therefore, like CYP1A1, CYP1B1 may play a role in modulating the carcinogenicity of procarcinogens in both humans and experimental models. A recent report indicates that CYP1B1-dependent DMBA metabolism is required for the induction of DMBA-induced lymphomas in mice (Buters et al., 1999).

There are a number of studies on dose-response relationships for TCDD's effects on CYP1A1 and 1A2 (DeVito et al., 1991; Lin et al., 1991a; Kedderis et al., 1991; Harris et al., 1990a; Goldstein and Safe, 1989; Abraham et al., 1988; Lucier et al., 1986; Vecchi et al., 1983; Kitchin and Woods, 1979; Poland and Glover, 1973). These studies (Tritscher et al., 1992; Graham et al., 1988; Sloop and Lucier, 1987) include single and chronic dosing, time-course evaluations, and species comparisons. Dose-response relationships have been evaluated by quantitation of CYP1-dependent enzyme activities, quantitation of mRNA levels by Northern blot analysis, and quantitation of CYP1 protein by radioimmunoassay and immunolocalization in tissue sections. Dose-response modeling of these studies is described in detail in Chapter 8 of this document. Evaluations of various data sets for TCDD-mediated dose-response relationships have revealed some interesting information. One way of analyzing data for linearity or nonlinearity of dose-response for receptor-mediated events is the Hill equation (Hayashi and Sakamoto, 1986). A Hill coefficient of 1 suggests a linear relationship between exposure and dose throughout the experimental dose range, and would predict a proportional relationship between target tissue concentration of TCDD and biological response at all dose levels. This would imply that the response had no practical threshold or “no effect level.” Hill coefficients greater than 1 would indicate sublinearity in dose-response, whereas a Hill coefficient of less than 1 would indicate supralinearity for response in the low-dose region. Analyses of single-exposure and chronic exposure data for CYP1A1 and CYP1A2 induction in rat or mouse liver indicate a Hill coefficient of slightly greater than 1 for CYP1A1 and slightly less than 1 for CYP1A2 (Portier et al., 1992; Kohn et al., 1993). Although these analyses involve an extrapolation beyond the range of experimental data, they are consistent with the hypothesis that

there is no threshold for TCDD-mediated induction of CYP1A1 and 1A2. Time-course and dose-response analyses indicate that CYP1B1 is expressed at significantly lower levels than either CYP1A isozyme and is induced only at higher doses than those required for CYP1A1 or CYP1A2 (Santostefano et al., 1997; Walker et al., 1999). Furthermore, the Hill coefficient for CYP1B1 induction is greater than that for CYP1A1 (Walker et al., 1999). A more detailed analysis of dose-response relationships for cytochrome P450 induction and other dioxin-inducible responses can be found in Chapter 8 of this volume.

Immunological detection of induced CYP1A1 and 1A2 in liver sections obtained from rats exposed chronically to TCDD indicates hepatocyte heterogeneity in response to TCDD (Tritscher et al., 1992; Bars and Elcombe, 1991). For example, relatively low doses of TCDD (1 ng/kg/day) appear to maximally induce some cells around the centrilobular region. Increasing doses of TCDD increase the number of cells responding, rather than the amount of induction in responding cells. Like CYP1A1 and CYP1A2, CYP1B1 is also induced by TCDD in the rat liver in a centrilobular pattern of expression (Walker et al., 1997). It has been suggested that the heterogeneous pattern of expression may be due to differences in expression of the AhR across the acinus (Lindros et al., 1997) or to differences in binding affinity (Andersen et al., 1997). Alternatively, the observation that CYP1A2 is responsible for hepatic sequestration of TCDD (Diliberto et al., 1999) suggests that the heterogeneity in expression of the CYPs may be in part due to a heterogeneity in distribution of TCDD across the liver acinus. In support of this theory, the concentration of TCDD in periportal hepatocytes is higher than that seen in centrilobular hepatocytes (Santostefano et al., 1999). These data, which document cell differences in sensitivity to induction, complicate evaluation of dose-response relationships. For example, some hepatocytes appear to be maximally induced by low doses of TCDD, whereas other hepatocytes exhibit no detectable P450 induction response at the same doses. As discussed earlier, a mechanistic link between P450 induction and cancer has not been established. Evaluations of P450 induction and TCDD-mediated cell proliferation by immunocytochemical methods in rat liver reveal that cells expressing CYP1A1 and 1A2 are different from those exhibiting TCDD-mediated increases in DNA replication (Lucier et al., 1992).

Placentas from Taiwanese women exposed to rice oil contaminated with polychlorinated dibenzofurans have markedly elevated levels of CYP1A1 (Lucier et al., 1987; Wong et al., 1986). Comparison of these data with induction data in rat liver suggests that humans are at least as sensitive as rats to the enzyme-inductive actions of TCDD and its structural analogues (Lucier, 1991). Consistent with this contention, the in vitro EC_{50} for TCDD-mediated induction of CYP1A1-dependent enzyme activities is approximately 1.5 nM when using either rodent or human lymphocytes (Clark et al., 1992). Also, binding of TCDD to the AhR occurs with a higher affinity in rat cellular preparations compared with humans (Lorenzen and Okey, 1991;

Okey et al., 1989). This difference may be related to the greater lability of the human receptor during tissue preparation and cell fractionation procedures, or to an inherent property of the human AhR (Manchester et al., 1987). In any event, it does appear that humans contain a fully functional AhR (Cook and Greenlee, 1989), as evidenced by significant CYP1A1 induction in tissues from exposed humans, and this response occurs with sensitivity similar to that observed in experimental animals.

6.5.2. Epidermal Growth Factor Receptor

EGF is a potent mitogen and stimulates the generation of mitotic signals in both normal and neoplastic cells (Stoscheck and King, 1986; Carpenter and Cohen, 1979). Several lines of evidence suggest that the EGF receptor and its ligands, including transforming growth factor-alpha, possess diverse functions relevant to cell transformation and tumorigenesis (Velu, 1990; Marti et al., 1989; Mukku and Stancel, 1985). In fact, the mechanism of action for several tumor promoters, such as phenobarbital and the phorbol esters, is thought to involve the EGF receptor pathway (Stoscheck and King, 1986). A schematic representation of the proposed mechanism for EGF-stimulated mitogenesis is given in Figure 6-3.

Several studies have shown that TCDD decreases the binding capacity of the plasma membrane EGF receptor for its ligand without a change in K_d (Clark et al., 1991a; Lin et al., 1991a; Abbott and Birnbaum, 1990; Astroff et al., 1990; Sunahara et al., 1989; Stoscheck and King, 1986; Hudson et al., 1985; Madhukar et al., 1984). One study used a range of TCDD doses (3.5 to 125 ng/kg/day) for 30 weeks to evaluate the effects of TCDD exposure on EGF receptor in rat liver plasma membranes. There was a clear dose-response relationship for TCDD's effects on the total binding capacity of the EGF receptor, although TCDD did not produce a change in binding affinity of the receptor. The maximal effect was a threefold decrease in the concentration of plasma membrane EGF receptor; the ED_{50} was ~10 ng/kg/day based on administered dose and ~2 ppb TCDD based on liver TCDD concentration. These values are similar to the ED_{50} for induction of CYP1A1 and CYP1A2 for 30-week exposures. The dose-response data, like the data for CYP1A1 and CYP1A2 induction, were subjected to curve-fitting analyses using the Hill equation (Portier et al., 1992). This analysis indicated that a Hill coefficient of 1 provided the best fit, suggesting that there is a linear relationship between target tissue dose and response for effects on the EGF receptor. Although Hill analyses of dose-response data for TCDD's effects on the EGF receptor, CYP1A1 induction, and CYP1A2 induction are inconsistent with the idea of a threshold, the lowest dose used in these experiments was 100 pg/kg/day, so the possibility exists that dose-response relationships are different in the very low-dose region (1 to 10 pg/kg/day) encountered as background human exposures.

Dose-response data on EGFR were compared with dose-response relationships for TCDD-mediated increases in cell proliferation and growth of preneoplastic lesions within the framework of a two-stage model for hepatocarcinogenesis in rats (Lucier et al., 1992, Sewall et al., 1993, 1995a). Results indicate that cell proliferation and the growth of preneoplastic lesions are less sensitive responses to TCDD than is loss of plasma membrane EGF receptor. Therefore, the EGF receptor may be involved in the hepatocarcinogenic actions of TCDD, but dose-response relationships for this effect may be different from dose-response relationships for liver cancer in rats. These data reflect the knowledge that several steps and/or several genes are involved in the modulation of coordinated biological responses.

The mechanism by which TCDD alters EGF receptor-binding capacity is not fully understood, although TCDD does not appear to decrease EGF receptor mRNA (Lin et al., 1991a; Osborne et al., 1988). By using congenic mice deficient in the high-affinity AhR, TCDD's effects on the EGF receptor were shown to require the AhR (Lin et al., 1991a). In control animals, the EGF receptor is distributed on the surface of the plasma membrane and is composed of an external ligand-binding domain, a transmembrane domain, and an intercellular domain (Velu, 1990; Carpenter, 1987). Ligands for the EGF receptor (EGF or TGF-alpha) in the intracellular space bind the EGF receptor, producing a conformational change that stimulates the intercellular region to catalyze phosphorylation of the receptor itself as well as other proteins involved in cell regulation. The process results in internalization of the receptor, characterized by an increase in cytosolic EGFR coupled with a decrease in membrane-bound receptor. The effects of TCDD and CDFs on the number of binding sites for the plasma membrane EGF receptor are correlated with a concomitant decrease in EGF-stimulated autophosphorylation of the EGF receptor, indicating that TCDD produces a true functional change in the EGF receptor (Clark et al., 1991a; Sunahara et al., 1989; Nelson et al., 1988; Sunahara et al., 1988). Importantly, the addition of EGF to hepatocytes or several cell lines in culture produces a loss of plasma membrane EGF receptor coupled with a loss of EGF-stimulated autophosphorylation (Velu, 1990; Carpenter, 1987). Therefore, TCDD produces an EGF receptor-like response consistent with the idea that TCDD enhances the generation of cellular mitotic signals.

Although TCDD exposure mimics EGF actions in hepatocytes, TCDD itself does not appear to bind to the EGF receptor. The most plausible mechanism for effects on the EGF receptor involves the finding that TCDD induces production of TGF-alpha in hepatocytes as well as human keratinocytes (Choi et al., 1991). This response could alter control of normal growth patterns because TGF-alpha binds the EGF receptor with high affinity, leading to enhanced production of mitogenic signals. Alternatively, TCDD may affect EGF receptor transcription. In fact, TCDD has been shown to decrease uterine EGF receptor mRNA levels (Astroff et al., 1990). Receptor concentrations may also be altered by other events including posttranslational

glycosylation, increased lysosomal degradation, or alterations in signal transduction pathways such as protein kinases (Madhukar et al., 1988). It is also possible that TCDD alters phosphorylation of the EGF receptor by activation of protein kinase C, resulting in decreased binding capacity of the plasma membrane EGF receptor. This effect occurs following exposure to the tumor promoter TPA and is associated with decreased autophosphorylation rates and EGF receptor internalization (Beguinot et al., 1985; Cochet et al., 1984). In any event, TCDD-mediated alterations in EGF receptor pathways may, in part, be responsible for the tumor-promoting actions of TCDD by enhancement of mitotic signals.

The effects on the EGF receptor system may be mediated by estrogen action, and it has been postulated that the estrogen and EGF receptor pathways are integrated by "cross talk" mechanisms (Ignar-Trowbridge et al., 1992; Astroff et al., 1990). In vivo and in vitro studies have demonstrated that TCDD alters the ER (DeVito et al., 1992; Lin et al., 1991a; Clark et al., 1991a; Umbreit and Gallo, 1988; Romkes et al., 1987) and estrogens can, in turn, alter EGF receptor binding and cellular distribution (Vickers and Lucier, 1991; Vickers et al., 1989; Mukku and Stancel, 1985). Moreover, studies conducted within the framework of a two-stage model for hepatocarcinogenesis have demonstrated that TCDD-mediated decreases in plasma membrane EGF receptor are ovarian hormone dependent (Sewall et al., 1993). These studies concluded that ovarian hormones are essential to the tumor-promoting actions of TCDD because TCDD does not induce hepatocyte proliferation or stimulate the growth of preneoplastic lesions in ovariectomized rats (Section 6.3, Initiation/Promotion Studies).

Evidence indicates that TCDD and its structural analogues produce the same effects on the EGF receptor in human cells and tissues as observed in experimental animals. First, incubation of human keratinocytes with TCDD decreases plasma membrane EGF receptor, and this effect is associated with increased synthesis of TGF-alpha (Choi et al., 1991; Hudson et al., 1985). Second, placentas from humans exposed to rice oil contaminated with polychlorinated dibenzofurans exhibit markedly reduced EGF-stimulated autophosphorylation of the EGF receptor, and this effect occurred with similar sensitivity to that observed in rats (Lucier, 1991; Sunahara et al., 1989). The magnitude of the effect on autophosphorylation was positively correlated with decreased birth weight of the offspring.

6.5.3. UDP-Glucuronosyltransferases

Several studies have shown that TCDD induces synthesis of at least one isozyme of UDPGT (Lucier et al., 1973, 1974, 1986) by a mechanism that requires the AhR (Bock, 1991). The gene UGT-1 regulates synthesis of the UDPGT isozyme, which conjugates numerous substrates including 1-naphthol, p-nitrophenol, and thyroxine (Burchell et al., 1991). This gene contains a TCDD-responsive element that permits transcriptional activation following binding of

the TCDD-AhR complex. Other chemicals that bind the AhR, such as 3-methylcholanthrene and benzo(a)pyrene, also induce UGT-1 (Bock, 1991). UDPGTs are considered a deactivation pathway for numerous environmental chemicals and endogenous compounds, such as steroid hormones, by rendering them water soluble and excretable as a consequence of the catalytic addition of a glucuronide moiety (Tephly and Burchell, 1990). Therefore, induction of UDPGT may be responsible, in part, for the finding that pretreatment with TCDD leads to diminished DNA adducts for PAHs and decreased concentrations of some steroid hormones.

Conjugation of thyroxine by UGT-1 leads to deactivation and elimination of this thyroid hormone (Henry and Gasiewicz, 1987; Bastomsky, 1977). The decreased levels of thyroxine associated with UDPGT induction produce decreased feedback inhibition of the pituitary gland, which responds by secreting increased amounts of TSH (Sanders et al., 1988; Barter and Klaassen, 1992). Several studies have provided evidence that prolonged stimulation by TSH produces an oncogenic effect on the thyroid (Hill et al., 1989). Interestingly, rat liver EGF receptor may, in part, be regulated by thyroid hormones (Mukku, 1984). Increased incidence of thyroid tumors is the most sensitive endpoint in cancer bioassays, as evidenced by a statistically significant increase at a dose of 1.4 ng/kg/day. Consistent with this hypothesis, rodent studies have shown that TCDD and other inducers of hepatic UDPGT decrease thyroxine concentration in blood, which is associated with increased levels of thyroid-stimulating hormone (Barter and Klaassen, 1992; Henry and Gasiewicz, 1987).

Dose-response studies for TCDD's inductive effects on hepatic UDPGT in rats have demonstrated that the single dose ED50 is approximately 0.7 µg/kg, which is similar to the ED50 for CYP1A1 induction (Lucier et al., 1986). Furthermore, the shape of the dose-response curve for both responses is similar. Analysis of the expression of UGT1A1 in rodent liver showed that induction of UGT1A1 RNA was dose dependently increased following a single dose of TCDD (Vanden Heuvel et al., 1994). Further studies showed that chronic exposure of female rats to 0-125 ng TCDD/kg/day for 30 weeks led to a significant increase in UGT and subsequent alterations in thyroid function (Sewall et al., 1995b). A mathematical pharmacokinetic-pharmacodynamic model for TCDD (Kohn et al., 1993) was modified to include effects of TCDD on UGT and thyroid hormone levels (Kohn et al., 1996) (see Chapter 8). Model outcomes accurately predicted changes in thyroid hormone levels in TCDD-treated female rats and lend support to the hypothesis that induction of UGT, and subsequent persistent stimulation of the thyroid by TSH, may be involved in the promotion of thyroid tumorigenesis. It is noteworthy, however, that these data were obtained from female Sprague-Dawley rats and that the thyroid carcinogenicity of TCDD was observed in male but not female Osborne-Mendel rats. Furthermore, in the Kociba study chronic exposure to TCDD did not induce thyroid tumors in female Sprague-Dawley rats. Although gender-specific difference in carcinogenicity may be due

to higher circulating levels of TSH in male rats, the model predictions increase confidence in the hypothesis that the induction of UDPGT by TCDD is directly involved in the mechanism.

Because humans have the dioxin-responsive UDPGT (UGT-1) (Burchell et al., 1991) and TCDD induces UDPGT in human hepatocyte cell cultures, it is reasonable to assume that TCDD and its structural analogues would induce UDPGT in humans, although laboratory data are needed to validate this assumption.

6.5.4. Estrogen Receptor

Several lines of evidence have demonstrated that interactions of TCDD and estrogens are critical to some of the carcinogenic responses to TCDD. Although the precise mechanisms of those interactions have not been established, recent data indicate that TCDD effects on the ER and on estrogen metabolism are involved. The mechanisms for TCDD/estrogen interactions appear to be tissue specific. Of particular interest is the finding that TCDD increases liver tumor incidence in rats, and at the same time decreases tumor incidence in organs such as the mammary gland, uterus, and pituitary (Kociba et al., 1978). Therefore, TCDD/estrogen interactions will be examined separately for liver and other endocrine organs.

The liver contains a fully functional ER that possesses characteristics similar to those identified for ER in the mammary gland and uterus (Mastri and Lucier, 1983; Powell-Jones et al., 1981; Eisenfeld et al., 1976). For example, the liver exhibits high-affinity binding for 17-beta-estradiol and other potent estrogens, liver ER binding is specific for estrogens, the ligand receptor complex interacts reversibly with DNA, and this interaction leads to transcriptional activation of estrogen-responsive genes. Synthesis of hepatic ER, unlike ER in other target tissues, is under pituitary control (Lucier et al., 1981). Treatment of rats with a single dose of TCDD decreases binding capacity of the hepatic ER, and this effect is correlated with a decrease in ER protein (Zacharewski et al., 1991, 1992; Harris et al., 1990b; Romkes and Safe, 1988; Romkes et al., 1987). TCDD also decreases rat hepatic ER in chronic exposure experiments, with a threefold decrease evident following a dose of 100 ng/kg/day for 30 weeks (Clark et al., 1991b). TCDD also decreases hepatic ER binding in C57Bl6 mice, but a much higher dose is needed to produce this effect in congenic mice deficient in the high-affinity AhR, indicating that TCDD-mediated decreases in ER are dependent on the AhR (Lin et al., 1991b). Dose-response studies in mice demonstrate that the single-dose ED50 is ~0.7 µg TCDD/kg, similar to the ED50 for other biochemical end points such as CYP1A1 induction, loss of plasma membrane EGF receptor, and induction of UDPGT. The observation that TCDD decreases hepatic ER is in apparent contradiction to the finding that TCDD increases hepatocyte proliferation, because the ER is thought to produce mitogenic signals. However, quantitation of ER in control and TCDD-treated rats was done using preparations from liver homogenates. Immunolocalization

studies are needed so that the relationship of ER concentrations to cell proliferation in normal and preneoplastic cells can be more carefully evaluated.

In addition to effects on hepatic ER, TCDD may influence estrogen action in another way. CYP1A2 efficiently catalyzes the conversion of estrogens to catechol estrogens in liver (Graham et al., 1988; Dannan et al., 1986). CYP1A2 is not found in extrahepatic tissues, with the possible exception of the nasal cavity, so catechol estrogen formation would be expected to occur only in liver. Catechol estrogens have been postulated to possess macromolecule-damaging properties as a consequence of free radical generation (Li and Li, 1990; Metzler, 1984). Therefore, TCDD may increase the DNA-damaging capacity of estrogens in liver as a function of CYP1A2 induction. This effect may, in part, explain the carcinogenic actions of TCDD in female rat liver, and is consistent with the knowledge that ovariectomy protects against the hepatocarcinogenic actions of TCDD and that male rats do not appear to be susceptible to TCDD-induced liver tumors (Lucier et al., 1991; Kociba et al., 1978). It is important to note that cancer is more than a two-stage process, and the stage-specific actions of TCDD in multistage cancer models are not known, although TCDD-mediated cell proliferation and possible indirect genotoxic effects may be critical at more than one stage. A hypothetical mechanistic scheme for TCDD-mediated liver cancer is shown in Figure 6-2.

The finding that chronic TCDD exposure decreases tumor incidences in the pituitary, mammary gland, and uterus may also reflect TCDD's effects on ER and estrogen metabolism. As discussed above, TCDD decreases uterine ER concentrations in cytosolic and nuclear fractions of rats and mice, and these changes are associated with diminished estrogen action in both in vivo and in vitro studies. TCDD also increases estrogen metabolism, presumably as a consequence of CYP1A2 in liver and UDPGT induction in liver and extrahepatic tissues (Shiverick and Muther, 1982). Likewise, the addition of TCDD to a breast cancer cell line (MCF-7) results in increased estrogen degradation (Gierthy et al., 1988). However, there are only small effects on serum 17-beta estradiol levels following administration of TCDD to either rats or mice (Shiverick and Muther, 1983). Therefore, the effect on serum estradiol is considerably less sensitive than the effects on the uterine receptor. This comparison has led investigators to conclude that the antiestrogenic actions of dioxins are primarily caused by effects on ER levels in reproductive tract tissues. Consistent with this hypothesis, Fernandez and Safe (1992) have shown that TCDD is antimitogenic in human breast cancer cells. Final evaluation of the role of estrogen metabolism awaits data on concentrations of estrogens in responsive cells of control and TCDD-treated rats, which may be different from serum estradiol levels. In any event, it appears clear that TCDD does possess antiestrogenic properties that are likely to be important to decreased tumor incidences in some reproductive tract and endocrine

organs. Numerous studies have documented that the ER is found in virtually every tissue of the body, although the effects of TCDD on human ER in vivo have not been studied.

6.5.5. Other Biochemical Endpoints

TCDD alters a number of other pathways involved in the regulation of cell differentiation and proliferation (see Chapter 3). The specific relationships of these effects to multistage carcinogenesis are not known, but the broad array of effects on hormone systems, growth factor pathways, cytokines, and signal transduction components is consistent with the notion that TCDD is a powerful growth dysregulator (Table 6-9). It is also consistent with the findings that TCDD alters cancer risks at a large number of sites, possibly reflecting multiple mechanisms of carcinogenicity. Biochemical/molecular/endocrine changes produced by TCDD include the glucocorticoid receptor (Sunahara et al., 1989), tyrosine kinase (Madhukar et al., 1988), gastrin (Mably et al., 1990), interleukin-1beta (Sutter et al., 1991), plasminogen activator inhibitor (Sutter et al., 1991), tumor necrosis factor-alpha (Clark et al., 1991b), gonadotropin-releasing hormone (Moore et al., 1989), testosterone (Moore et al., 1985), and luteinizing hormone (Mably et al., 1992). The importance of these responses to the carcinogenic process should not be diminished by the lack of detail presented here. In every case studied, these responses have been shown to be dependent on the AhR.

6.6. SUMMARY AND WEIGHT OF EVIDENCE FROM ANIMAL STUDIES

There have been several long-term studies designed to determine if TCDD is a carcinogen in experimental animals. All of these studies have been positive and demonstrate that TCDD is a multisite carcinogen, is a carcinogen in both sexes and in several species including the Syrian hamster, is a carcinogen in sites remote from the site of treatment, and increases cancer incidence at doses well below the MTD. In two-stage models for liver and skin cancer, it is clear that TCDD is a potent promoting agent with weak or no initiating activity. Of those compounds that make up the bulk of the human body burdens of TEQ, only three of them, namely TCDD and a mixture of two congeners of hexachlorodibenzo-*p*-dioxin (HCDD) (1,2,3,6,7,8 and 1,2,3,7,8,9), have been tested in chronic rodent bioassays. In both cases, there was clear evidence of carcinogenicity. Commercial mixtures of PCBs that have a high TEQ also have been shown to be carcinogenic in rat liver. While many of the other dioxin-like compounds have not been tested in chronic carcinogenicity studies, 1,2,3,7,8-PCDD; 1,2,3,4,6,7,8-HpCDD; 2,3,4,7,8-PCDF; 1,2,3,4,7,8-HCDF; PCB126; and PCB105 all promote the development of putatively preneoplastic altered hepatocellular foci (AHF) within rodent liver suggesting that they also act as tumor promoters like TCDD (see Table 6-5). Together, dioxins and furans comprising 94% of the total dioxin/furan TEQ, and PCBs comprising 85% of the total coplanar

PCB TEQ, have all shown to be positive in either rodent bioassays, rodent liver tumor promotion studies, or mouse skin tumor promotion studies. In addition, complex mixtures of dioxins and furans and commercial PCB mixtures act as promoters of liver AHF. These data suggest that, while the majority of dioxin-like congeners have not been tested for carcinogenicity in chronic rodent bioassays, it is likely that those individual congeners and mixtures of dioxin-like compounds, which comprise the majority of the dioxin-like activity in human tissues, are carcinogenic to rodents. Furthermore, when one considers the impact of current TEF values on compounds that make up the majority of the current TEQ, it is clear that more than 90% of the current TEQ for either dioxins/furans or PCBs is made up of compounds for which the current TEF is supported by data on relative potencies based on tumor promotion or carcinogenic endpoints. More information on this point is provided in Table 6-10.

The finding of weak or no initiating activity is not surprising because TCDD does not form DNA adducts and is negative in short-term tests for genetic toxicity. The general consensus is that TCDD is an example of receptor-mediated carcinogenesis in that (1) interaction with the AhR appears to be a necessary early step, (2) TCDD modifies a number of receptor and hormone systems involved in cell growth and differentiation, such as the epidermal growth factor receptor and the ER, and (3) sex hormones exert a profound influence on the carcinogenic actions of TCDD. Although tumor promotion data for the polychlorinated dibenzofurans and coplanar polychlorinated biphenyls are limited, it appears that these compounds are liver tumor promoters with potencies dependent on their binding affinity to the AhR.

Some of the central issues in the risk assessment of TCDD and its structural analogues are (1) characterization of the shape of the dose-response curve for receptor-mediated events, (2) evaluation of the relevance of animal data in estimating human risks, and (3) the health consequences of background exposures (1 to 10 pg TEQ/kg/day) of dioxin and its structural analogues. With regard to the shape of the dose-response curve, it is clear from animal studies that there are different dose-response curves for different TCDD effects, which is consistent with the generally accepted dogma for steroid receptor-mediated responses. In general, the biochemical/molecular responses such as cytochrome P450 induction do not show evidence for a threshold, although unequivocal conclusions cannot be made about the mechanistic link, if any, between biochemical responses and toxic effects. In fact, coordinated biological responses such as TCDD-mediated cell proliferation and growth of preneoplastic lesions (foci of cellular alterations in liver) appear to be less sensitive endpoints, although evaluation of these responses is complicated by a high degree of interindividual variation: some animals do not exhibit any increase in cell proliferation in response to TCDD exposure.

The mechanistic basis for interindividual variation is unclear, and this lack of knowledge complicates approaches to estimate human risks from experimental animal data. However,

several studies indicate that, for the most part, humans appear to respond like experimental animals for biochemical and carcinogenic effects. However, data from epidemiology studies are difficult to evaluate because the carcinogenic effects, if any, resulting from background TCDD exposures are not known, although biochemical effects such as cytochrome P450 induction may be produced by background exposures.

CHAPTER 7. EPIDEMIOLOGY/HUMAN DATA
PART A: CANCER EFFECTS

7.1. INTRODUCTION

Animal bioassay data provide substantial presumptive evidence of the human carcinogenicity of 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD) (see Chapter 6), but confirmation must come from well-designed human studies. TCDD is a multiorgan carcinogen in animals. Target organs include the liver, thyroid, lung, skin, and soft tissues. There is no assumption of target tissue concordance from animals to humans, although site concordance would add support to a causal interpretation. This chapter reports on the cancer epidemiology evidence of TCDD and its congeners.

This review and analysis of the epidemiologic literature on dioxins and cancer begins by defining the scope of chemical exposures, cancers, and research reports to be considered. Then, following a brief summary of previous EPA assessments of epidemiologic literature, a description is given of the methods used in the present review. The original research reports are then discussed in four groups: (1) follow-up studies of chemical manufacturing and processing workers, (2) case-control studies in general populations, (3) studies of pulp and paper mill workers, and (4) other studies (including studies of pesticide applicators; Vietnam veterans with potential exposure to Agent Orange; residents of Seveso, Italy, exposed to TCDD during an accidental explosion of a phenoxy herbicide factory; and victims of contaminated rice oil poisonings). Because the discussions of the first two groups of studies are relatively lengthy, brief summaries are given at the end of each of those sections. Conclusions are drawn following an overall discussion of all the studies.

7.2. SCOPE

Epidemiologic studies of cancer among persons exposed to TCDD and other polychlorinated dibenzodioxins (PCDDs) and dibenzofurans (PCDFs) are included in this review. Primary emphasis is placed on studies with exposures to TCDD itself, occurring primarily in the manufacture and use of 2,4,5-trichlorophenol, hexachlorophene, and the herbicide 2,4,5-trichlorophenoxyacetic acid (2,4,5-T). Because exposures to 2,4,5-T and 2,4-dichloroacetic acid (2,4-D) often occur among the same groups who manufacture and use these herbicides, some studies of groups exposed only to 2,4-D are also included. Exposure to lower-chlorinated PCDDs (dichlorinated and trichlorinated isomers) may occur in the manufacture and use of 2,4-D. Also included are studies of groups exposed to higher-chlorinated PCDDs (i.e., the hexachlorinated, heptachlorinated, and octachlorinated isomers), occurring primarily in the manufacture and use of pentachlorophenol (PCP) and in the paper and pulp industries.

A major weakness in nearly all of these studies is the lack of good exposure information. Most studies rely solely on interviews and questionnaires of work history to ascertain exposure surrogates. Until recently, there was little, if any, verification of actual internal dose of these compounds. Some studies use chloracne as a surrogate for exposure to TCDD. This presence of chloracne usually indicates a high dose effect. The absence of chloracne does not indicate lack of exposure. Some of the recent cohort studies of chemical production workers (Fingerhut et al., 1991; Becher et al., 1996; Flesch-Janys, et al., 1995, 1996, 1999; Ott et al., 1996; Manz et al., 1991; Zober et al., 1990) do provide estimates of TCDD exposure in cohort samples via serum blood levels taken decades after cessation of exposure. However, these estimates have been chiefly used to provide support for preselected qualitative categories of estimated exposure. But these can also be used to determine possible dose-response trends and estimate the risk of cancer to populations with low-level exposure to TCDD (see Chapter 8). Measures of exposure by individual study have been discussed.

At the time of EPA's last review in 1988, evidence of human carcinogenicity of TCDD and the phenoxy herbicides focused on soft tissue sarcomas (STSs) and malignant lymphomas. Consequently, this report will update the strengths and weaknesses of the evidence pertaining to these cancers. But emerging as a more important topic are evaluations of the evidence of cancer at other sites. The case-control studies reviewed for EPA's last analysis generally considered herbicide applicators with potential exposures to both 2,4-D and 2,4,5-T. Recent case-control studies of U.S. farmer groups in which exposure to 2,4-D and 2,4,5-T can be separated (Hoar et al., 1986; Zahm et al., 1990; Cantor et al., 1992) provide a validation mechanism to separate potential effects of these herbicides and, possibly, their different PCDD contaminants. Thus, these and other recent studies (Hardell and Eriksson, 1988; Eriksson et al., 1990; Woods et al., 1987) will be reviewed and compared with those discussed in EPA's earlier reports.

Five recent cohort mortality studies (Steenland et al., 1999; Fingerhut et al., 1991; Becher et al., 1996; Flesch-Janys et al., 1995, 1998, 1999; Manz et al., 1991; Ott et al., 1996; Zober et al., 1990; Kogevinas et al., 1997; Saracci et al., 1991; Hooiveld et al., 1996, 1998) totaling more than 23,000 workers potentially exposed to TCDD and/or phenoxy herbicides/chlorophenols provide a more important database for analyzing cancer effects and are discussed in Section 7.5. The first three of these, and especially the large U.S. study of Fingerhut et al. (1991) and its update by Steenland et al. (1999), as well as the Dutch cohort study by Hooiveld et al. (1996, 1998), are considered to be the most important new studies in the field of TCDD cancer epidemiology because of their attention to cohort selection, to TCDD exposures or exposure surrogates (chloracne), and to the fact that exposure to dioxin is associated with an increasing risk of cancer at multiple sites. The fifth study (Saracci et al., 1991; Kogevinas et al., 1997) encompasses all the occupational cohorts that are referenced here. Although it has the largest

cohort, it has less reliable information on the TCDD-exposed subcohort and only a little information that would allow a quantitative estimate of exposure. Two other studies of phenoxy acid manufacturers are included (Lynge, 1985, 1993, 1998; Coggon et al., 1986), but their usefulness is limited because of the low unsubstantiated exposure to TCDD. Also included is a study of occupationally exposed women (Kogevinas et al., 1993) who had probable exposure to TCDD.

Four recent cohort studies of workers in the pulp and paper mill industry are also included (Robinson et al., 1986; Jäppinen et al., 1987; Henneberger et al., 1989; Hertzman et al., 1997) because of potential for worker exposure to higher-chlorinated PCDDs but not hexa-, hepta-, or octaphenoxy herbicides, and one with exposure to hexa-, hepta-, and octochlorinated dioxin isomers. However, none of these studies provide any additional information about which PCDD exposures were likely, and these studies are not given much weight.

Studies of Vietnam veterans potentially exposed to TCDD in Agent Orange are reviewed briefly, with only two (Ketchum et al., 1996, 1999; Michalek et al., 1990, 1998) judged to have sufficient information on potential TCDD exposure to be useful for analysis of cancer. Also, the recent studies of cancer in Seveso, Italy, residents are discussed (Bertazzi et al., 1998, 1997, 1992, 1993, 1989a,b; Landi et al., 1998; Consonni et al., 1999; Mocarelli et al., 1991; Pesatori et al., 1999, 1992); these studies provide some exposure data, but the cancer response analysis is limited because of inadequate follow-up time (maximum of 20 years).

Finally, the studies of the rice oil poisonings of residents in Taiwan and Japan with polychlorinated biphenyl (PCB) and PCDF contaminants are reviewed (Kuratsune et al., 1988, 1975; Chen et al., 1980; Koda and Masuda, 1975; Rogan et al., 1988). Even though these poisoned oils did not contain TCDD, they did contain many TCDD-like congeners currently considered by EPA to have carcinogenic potential that can be compared to TCDD. Also, certain dioxin-like PCBs are suspected human carcinogens on the basis of their receptor-binding characteristics and animal studies. Non-dioxin-like PCBs are known animal carcinogens.

Only follow-up and case-control studies are considered in this review. Case reports, other clinical observations, and prevalence surveys are excluded. The review is restricted to studies that have been published or are about to be published and that are available in the open scientific literature. Prepublication reports and studies published only in abbreviated form (as well as abstracts or letters to editors) are included only where they supplement the published articles. These restrictions limit the review to studies that have received at least a minimum of peer review and that have been described fully enough to permit a thorough assessment of materials, methods, and results.

7.3. PREVIOUS EPA REVIEWS

In the Health Assessment Document for Polychlorinated Dibenzo-*p*-Dioxins, dated September 1985 (U.S. EPA, 1985), the majority of the epidemiology studies pertained to groups of herbicide applicators with potential exposure to phenoxy acids and/or chlorophenols. In that report, the analysis emphasized case-control studies of STSs and non-Hodgkin's lymphoma (NHL). That report concluded that the epidemiologic research available at that time provided "limited evidence for the carcinogenicity of phenoxy acids and/or chlorophenols in humans. However, with respect to the dioxin impurities contained therein, the evidence for the human carcinogenicity for TCDD based on the epidemiologic studies was only suggestive because of the difficulty of evaluating the risk of TCDD exposure in the presence of the confounding effects of phenoxy acids and/or chlorophenols." In its next report, the review draft dated June 1988 of A Cancer Risk-Specific Dose Estimate for TCDD (U.S. EPA, 1988), the focus was essentially the same, and EPA concluded that "the human evidence supporting an association between exposure to TCDD and cancer is considered inadequate."

7.4. REVIEW METHODS

This review will follow the spirit of the EPA Risk Assessment Guidelines of 1986 (U.S. EPA, 1987) by considering alternative explanations for results observed in epidemiologic studies. These explanations fall into the general categories of causality, chance, bias, and confounding. The basic approach is akin to a process of elimination, by which one attempts to determine the direction and to quantify the magnitude of the influence that chance, bias, and confounding may have had on the results of each study. Wherever possible, the results of all studies will be reported in units of relative risk estimates and 95% confidence limits.

Most biases in epidemiologic studies can be placed into one of two categories: biases of classification and biases of selection. Classification biases can result from inaccurate ascertainment of exposure, disease, or confounders. Selection biases can result from nonrepresentative sampling of populations, as in the selection of controls in case-control studies, or from incomplete participation by study subjects. Any bias gains tenability as an explanation for an observed result if empirical evidence can be adduced to buttress the mere suggestion that the bias might have occurred. Only those biases considered to be potentially important will be addressed explicitly in this review.

When imprecise exposure estimates are available, such as with much of the epidemiologic data on dioxin, estimates of risk can be potentially biased toward the null. Misclassification, if random, could potentially lead to a masking of a true effect.

Classification biases are of two kinds: differential and nondifferential. Differential misclassification will lead to either an exaggeration or an underestimation of an effect.

Nondifferential misclassification occurs when the exposure or disease classification is incorrect in a portion of the subjects (cases or controls). This type of bias is generally toward the null, and the risk estimate may reflect this. Such misclassification can happen when some subjects are classified as having exposure to dioxin when they really were not exposed. Similarly, some actually may have had exposure but were classified as not having had it. In studies where few or no effects were seen, researchers must seriously consider the problem of nondifferential misclassification. This can be the reason that nonpositive risk estimates or even disparate risk estimates are seen from different studies of the same effect. On the other hand, in studies with significant results, nondifferential misclassification is not likely to be a cause of a significant finding.

Recall bias may produce the opposite effect. Persons with a disease may tend to remember exposure to a substance better when they know that such exposure might be associated with the disease. This could potentially lead to inflated risk estimates. In fact, it has been suggested that such biases are present in many of the case-control studies on dioxin. The Swedish studies by Hardell and colleagues have been particularly singled out for criticism in this respect. That some recall bias may be present is confirmed in a later case-control study (Hardell and Eriksson, 1988) in which some reduction of risk estimates was produced by the use of cancer controls. But then this result could be the result of a general cancer effect as well.

Confounding bias is a tenable explanation for an association between an exposure and a disease if the hypothetical confounder can be named and if a good case can be made that it is a cause of the disease, that it was associated with the exposure in the study population, and that it was not adequately controlled in the study design or data analysis. This review will explicitly mention only those potential confounders that meet all of these criteria.

As stressed in previous EPA reviews (1985, 1988), concomitant exposures present a special problem of potential confounding in the literature on TCDD and related chemicals. As a noteworthy example, an association between 2,4,5-T exposure and a given cancer, if causal, could be due to 2,4,5-T itself, to TCDD, or to some other contaminant. The problem multiplies when it is recognized that, historically, many phenoxy acid herbicide preparations were mixtures of 2,4,5-T and 2,4-D and that many persons who manufactured, processed, and used these preparations were exposed to other chemicals as well. Nevertheless, it may be possible, by examining studies of persons exposed to different combinations of chemicals, to identify "threads" of commonality and differences in the results, especially when specific cancers are considered separately.

Publication bias, sometimes considered a form of selection bias, is the tendency for the results of a study to influence a judgment as to whether or not it will be published. The direction and magnitude of publication bias is difficult, if not impossible, to quantify. It is expected to be

a much greater problem in literature reviews and in studies relying on existing records than in original research in which substantial resources are devoted to collection of data of relatively high quality. The level of effort required for such studies creates a strong incentive to publish the results. There is a tendency to publish studies with positive results as opposed to studies with nonpositive findings.

Strength of association, as measured by the magnitude of the estimated relative risk, is an important feature of a study's results. The stronger the association, the stronger a bias or confounding factor would have to be to explain it. Because questions of bias and confounding are study-specific, no defensible criteria can be set up in advance to place relative risk values into categories of strength of association.

Trends in increased risk by degree of exposure and by time since first exposure (latency) are also important. Different hypothetical causal mechanisms might predict different exposure-response and latency patterns. Hypotheses of steadily increasing effect with increasing exposure (i.e., monotonic exposure-response functions) and hypotheses of effects early in the carcinogenic process (e.g., for factors that operate at the initiation stage) predict that increases in risk will be greatest among persons with relatively high degrees of exposure and after relatively long latency periods. Hypotheses of tumor promotion and/or initiation will be discussed in the appropriate sections.

Replication of results is important in all scientific research. When several studies have shown a positive association of effect with the same exposure but were conducted under different circumstances, the possibility that an unknown confounder or chance produced the observed elevated effect is minimized. When different investigators working with different populations using different methods confirm an original finding, the results are more believable.

The statistical aggregation of results from different studies (meta-analysis) has become a popular feature of epidemiologic literature reviews. In this review, results from separate studies are aggregated only when all key methodologic features and results are reasonably similar. The method of aggregation used here is to take the ratio of the sum of the cause-specific observed deaths to the sum of the cause-specific expected deaths for the individual studies. Because investigators recognize the value of varying their methods to test methodologic hypotheses, and because results often differ appreciably, aggregation of results is not often indicated and is done here with caution.

7.5. FOLLOW-UP STUDIES OF CHEMICAL MANUFACTURING AND PROCESSING WORKERS

7.5.1. United States

Fingerhut and colleagues (1990, 1991) reported a study of 5,172 males who had worked at 12 plants in the United States in the production of chemicals contaminated with TCDD. Five thousand of the cohort members (97%) were identified in company records as having been "assigned to a production or maintenance job in a process involving TCDD contamination" (Fingerhut et al., 1991). The remaining 172 cohort members were "identified in a previously published study on the basis of exposure to TCDD" (Fingerhut et al., 1991). This cohort subsumed, and thereby supplanted, company-specific cohorts from Dow Chemical USA (Ott et al., 1987; Cook, 1981) and the Monsanto Company (Zack and Gaffey, 1983; Zack and Suskind, 1980) that had been the subject of previous reports. This study was initiated in 1978 to determine whether health effects were apparent in humans who were exposed to 2,4,5-T. In 1978, toxicological, teratogenic, and carcinogenic effects data were released that indicated a cancer effect in animals. There was a concern about the potential effects of exposure to Agent Orange on Vietnam veterans and workers who produced products that were contaminated with dioxin (Fingerhut et al., 1992). Follow-up began in 1940 or on the date of the "first systematically documented assignment to a process involving TCDD contamination" (Fingerhut et al., 1991), whichever was later, and closed at the end of 1987. Comparisons were made with the United States population.

The authors stated that approximately 13% of the cohort of 5,172 workers had records of chloracne. The presence of a significant incidence of chloracne in a group of people is an indicator of relatively intense exposure to TCDD. Chloracne can be caused by higher-chlorinated PCDDs, PCDFs, and PCBs as well (O'Malley et al., 1990) and also by Ah receptor agonists such as brominated congeners and with naphthalenes. It is a highly specific indicator of exposure to these compounds because it virtually never occurs among unexposed persons. It is a nonsensitive indicator, however, because many highly exposed persons do not develop it (Manz et al., 1991; Caramaschi et al., 1981; Mocarelli et al., 1991). Exposure to other dioxin-like chemicals that can be found in the workplace produces a form of chloracne that could be indistinguishable from that produced by dioxin (Ott et al., 1993). These chemicals can be dioxin-like in their effects and act through the aryl hydroxylase (Ah) receptor.

Although all members of the cohort had specific assignments to TCDD exposure areas in common, exposures to multiple chemicals generally occur in the chemical industry. At one plant, for instance, considerable overlap existed among persons involved in the production of chlorophenols, 2,4,5-T, and 2,4-D (Ott et al., 1987; Bond et al., 1988, 1989a), and thus exposed to TCDD and higher- and lower-chlorinated PCDDs. Presumably, many persons throughout the

cohort had contact with other chemicals. Comprehensive surveys of chemical exposures were conducted in plant-specific cohorts and may be available through the authors.

Special attention was paid to results for the 3,036 workers who were followed for at least 20 years after first exposure. This group was again divided into those with less than 1 year (N=1,516) and those with more than 1 year (1,520) of exposure (referred to below as the long duration/latency subcohort). One year was chosen as the criterion for duration of exposure because an analysis of 253 workers from 2 plants showed that every worker with 1 or more years of exposure had a lipid-adjusted serum TCDD level greater than the mean value (7 ppt) in a comparison group of unexposed workers (Fingerhut et al., 1990). Although the average level for all 253 workers was 233 ppt, the average increased to 418 ppt in those 119 who were exposed for 1 or more years (Fingerhut et al., 1991). The average serum TCDD level in those exposed less than 1 year was 69 pg/g. The researchers described a plan, utilized by Steenland et al. (1999), that replaced this duration-based exposure scale by using "a dioxin exposure matrix constructed from historic process descriptions, analytic measurements of TCDD and industrial hygiene data . . . to develop the relative ranking of workers exposed to TCDD" (Fingerhut et al., 1990).

The cohort as a whole experienced an estimated 15% (95% CI = 1.0-1.3) elevation of mortality from all cancers combined, with a 46% elevation (95% CI = 1.2-1.8) among those in the long duration/latency subcohort (Table 7-1). An excess of deaths from cancers of connective and soft tissues (STSs) was apparent in the total cohort (RR = 3.4, CI = 0.9-8.6) and in the long duration/latency subcohort (RR = 9.2, CI = 1.9-27.0), but these results were based on only four deaths and three deaths, respectively, from two different plants. A 40% overall elevation in deaths (CI = 0.7-2.5) from NHL was confined to workers in the total cohort and was not seen in the long duration/latency subcohort. Results for Hodgkin's disease were highly imprecise, based on only three deaths (vs. 2.5 expected) in the total cohort. Lung cancer was elevated by 10% overall but by 40% (CI = 1.0-1.9) in the long duration/latency subcohort. A similar 40% excess of stomach cancer (CI = 0.4-3.5) in this subcohort was based on only four deaths; no excess was seen in the total cohort.

The investigators conducted a special study of connective and soft tissue cancers. A review of all available hospital records and tissue specimens failed to confirm the indications of STSs on two of the four death certificates that had been assigned to this cause-of-death category (Fingerhut et al., 1990). The review also provided evidence that two persons in plant 8 whose deaths had been assigned to other causes of death had actually had soft-tissue sarcomas. Because only the exposed cohort's death certificates were subjected to detailed review, the analytic comparisons with the United States population were required to be based strictly on death certificate information. The basic and well-known rule in such situations is that, absent evidence to the contrary, erroneous information on death certificates must be considered to have been

equally frequent in the two groups being compared. But Suruda et al. (1993), in a study of STS diagnoses in cohorts exposed to dioxins and chlorinated naphthalenes, found that death certificates are "relatively insensitive"for detecting STS and that the power of life-table analysis to detect excess risks of STS may be reduced compared with its utility in correctly estimating the risk of other cancers, such as colon cancer or rectal cancer. However, the correct identification of STS as the underlying cause of death on death certificates appears to be much better (82%), based on medical records, than first thought according to the results of this study. Medical records on the remaining 18% could not be found. If a death certificate gives as an underlying cause of death a STS and it is coded as 171x, it is very likely correctly coded, according to the authors. In an earlier study, this figure was estimated by Percy et al. (1981) to be 55%. This nondifferential misdiagnosis could potentially bias risk estimates downward (underestimate the true risks).

Four of the STSs that are discussed in Fingerhut's study (two are included in Fingerhut's life-table analysis while two others are discussed but did not qualify for inclusion in the life-table analysis) are actually from the Nitro, West Virginia, plant. The remaining two cases that were included in Fingerhut's life-table analysis are from a different plant in the study. One of these cases also suffered chloracne. The four cases from the Nitro, West Virginia, plant are also the subject of a later study by Collins et al. (1993). The two cases included in Fingerhut's life-table analysis had previously suffered chloracne from an incident in which 121 workers developed chloracne as a result of a trichlorophenol process accident on March 8, 1949 (Zack and Gaffey, 1983). Collins et al. (1993) included one more STS not previously discussed by Fingerhut from the same plant. The Collins et al. (1993) study is reviewed later.

If the properly diagnosed STSs were correctly assigned to their appropriate plants and the two incorrectly diagnosed STSs were removed, there would be one STS in plant 9 and three in plant 8. No STSs were found at the other plants. This unusually skewed distribution might possibly be related to the accident that happened in plant 8 in 1949. Or perhaps physicians in Nitro, West Virginia, are more likely to diagnose STS than are physicians in other areas of the country. Because of the rarity of STS, there was inadequate statistical power to expect to see STSs in the other individual plants. If an excess risk is associated with exposure to TCDD, then it might be several more years before this cohort will produce STSs at the other facilities that are part of the study.

Cases of STS include a diverse group of histological entities. All STSs arise only from mesenchymal tissue, and all share common features that make them alike in their basic intercellular and intracellular composition rather than different in their morphology and location. Characterizing them as fundamentally different because they are found in different sites of the body is perhaps inadequate for determination of the risk of cancer (Enzinger and Weiss, 1988).

The histological classification of STS is centered on a dozen distinctly different classes of mesenchymal cells that form six relatively well-defined but widely distributed organ systems. By considering the growth pattern and cell morphology with an evaluation of intracellular and extracellular products of the tumor cells, fairly precise histogenetic classification of STSs is possible (Hajdu, 1981). For human cancer risk assessment, all connective tissues developing from the same mesodermal tissue, expressing the same set of "proto-oncogenes"and surrounded by the same chemical milieu of the extracellular matrix, are expected to develop cancer following exposure to certain carcinogens. The grouping of these end-target organs together is therefore necessary to evaluate the risk from exposure to dioxin.

Confounding by cigarette smoking must be considered in interpreting the approximate 40% excess of lung cancer deaths in the long duration/latency subcohort (Table 7-2). For the United States as a whole, the authors (Fingerhut et al., 1990) computed age-adjusted proportions of 24% never smokers, 19% former smokers, and 57% current smokers in 1965 (roughly midway through the follow-up period). The corresponding proportions were 28% never smokers, 14% former smokers, and 59% current smokers among the 87 workers from the study of serum TCDD levels who were members of the long duration/latency subcohort as well. Assuming relative risks of lung cancer of 4.7 for former smokers and 10.9 for current smokers, the authors used a standard technique (Axelson and Steenland, 1988) to adjust the number of expected lung cancer deaths and found essentially no change in the results. It should be kept in mind that the sample of smoking histories was taken from only two plants but the excess in lung cancer risk was chiefly in two other plants. The generalization of smoking habits of employees in 2 of the 12 participating plants to that of the entire cohort may not be representative of the true smoking impact on the risk of lung cancer to the cohort. Most of the lung cancers (56 of 89 observed lung cancer deaths) came from 3 facilities. The remaining 7 plants contributed the other 33 lung cancers to the total because of the small sizes of the respective subcohorts and insufficient latency. It then would be possible to evaluate the effect of smoking on the risk of lung cancer at each individual plant. It should be remembered that national U.S. rates were used to derive expected deaths in each of the 12 plants. It is possible that local or regional rates may be a more appropriate comparison population for the cancer sites examined by the authors, although local rates may be unstable. In addition, if biomonitoring could be extended to the remaining 10 plants, a better idea could be derived concerning the dose levels associated with those plants experiencing higher lung cancer rates. The authors point out that deaths from other diseases associated with smoking, such as diseases of the heart and circulatory system and emphysema, were either not increased or significantly decreased in this cohort (Fingerhut et al., 1990). Although the possible contribution of factors such as smoking and occupational exposure cannot

be excluded, there is no evidence that smoking patterns in this cohort are entirely the reason for the elevated risk of lung cancer (Fingerhut et al., 1991).

One possible explanation for the increase is that the 87 surviving members of the long duration/latency subcohort did not show the well-known tendency for smoking to be more common among blue-collar workers than in the general population. A possible reason is that because smoking appreciably elevates the overall death rate, fewer and fewer smokers will remain in a fixed group of persons as time goes by. Thus, the use of the 87 *surviving* members of the long duration/latency subcohort may have underestimated the proportions of former and current smokers in the subcohort as a whole over the course of mortality follow-up. However, this same phenomenon is also present in the population from which expected deaths were generated, so the effect is probably nullified. The effect on the lung cancer risk as the proportion of smokers increased in the cohort is shown in Table 7-2. The lack of increased mortality from cardiovascular diseases as well as cancer of the buccal cavity and pharynx in this cohort, however, makes this explanation less likely. Furthermore, as the authors point out, mortality from nonmalignant respiratory disease (standard mortality ratio [SMR] = 96), which is often associated with smoking, was less than expected. This strengthens the argument that exposure to dioxin causes lung cancer.

On the other hand, the authors report a correlation coefficient of 0.72 between length of exposure and serum TCDD tissue level. This negative bias is potentially much greater than the positive bias that could possibly be produced by smoking. And because nondifferential bias is the only type of bias that could occur in the Fingerhut study, risk estimates are more than likely lower than the true risk. The only way that dioxin exposure could have a positive bias is if it prevents cancer and the exposure classification is 100% wrong.

The authors of this study also report that two of these cancer deaths were from mesothelioma, a finding that more than likely indicates exposure to asbestos. Although these two mesotheliomas occurred at plants 9 and 12, it is not known whether these persons were exposed in that job or in some previous job. Only one death from asbestosis was noted in the nonmalignant respiratory deaths, and this occurred in Plant 1. These three asbestos-related deaths were more than likely due to exposure in a previous occupation.

Fingerhut et al. (1991) has been updated by Steenland et al. (1999), of the same research group. The SMR for all cancers combined was 1.13 (95% CI = 1.02-1.25). The SMR for all cancers combined for the highest exposure group was 1.60 (95% CI = 1.15-1.82). Recent analyses support the finding that high exposure to TCDD results in an excess of cancer without any marked specificity. Steenland and colleagues' later analyses differ from Fingerhut's in that the authors applied a "job-exposure matrix"to a subcohort of 3,538 workers from the original 5,172 male workers and followed the entire cohort for 6 more years. This job exposure matrix is

not based upon ambient air levels of TCDD or even blood TCDD serum levels. It is based upon the concentration of TCDD (μg/g) present in the process materials to which the workers are exposed *times* the fraction of the day the worker was employed in that process *times* the "contact"level (meaning the likelihood the product will reach the skin or be inhaled) *times* the period of time the worker worked in proximity to TCDD. Steenland et al. did not consider workers and plants where records on the degree of exposure to TCDD were lacking, a detailed work history was lacking, or there was concurrent exposure to pentachlorophenol contaminated by higher chlorinated PCDDs/PCDFs. They also analyzed a subcohort of 608 workers with frank chloracne without regard for any of the exceptions mentioned above, and analyzed a subset of 393 of the 608 who fell into the subgroup of 3,538 workers above.

The results indicated that as cumulative exposure increased through seven exposure categories based upon their "job-exposure matrix," the calculated risk of overall cancer mortality tended to increase (all sites combined). In the chloracne cohort of 393 men mentioned, in the two highest septiles of cumulative exposure the risk was significant at 1.68 (CI = 1.19-2.30).

In the larger subcohort of 3,538, the results tended to be similar but less pronounced. Utilizing either the life-table analytical method or the Cox regression method, trends tended to be positive, although in an inspection of the seven categories, the increasing trends are not monotonic using either method, lagged or unlagged (Table 7-3).

Although the authors believe that this lack of linear trend in cancer with cumulative exposure as a continuous variable is due to the extreme skewedness of the data, this may have more to do with the way in which cumulative exposure is determined in the job-exposure matrix and the fact that the authors use seven exposure categories to generate risks. The fact that quantity of TCDD in process materials is used, rather than ambient air levels of TCDD or even blood serum levels of TCDD, to determine basic exposure potentially removes the estimation process for exposure even further from the truth. There is likely considerable variability in the cumulative exposure indices calculated for individuals in this cohort. Furthermore, the use of so many categories of exposure also makes individual risk calculations within each septile less stable and perhaps even unreliable, because they are based upon smaller numbers.

Despite these problems the authors were still able to detect significantly positive trends in total cancer, several site-specific cancers such as lung cancer, and even ischemic heart disease, especially when they considered the logarithm of cumulative exposure (the more appropriate test statistic for this kind of distribution of exposures). The finding concerning an increased risk of ischemic heart disease seems consistent with what is known about the interaction of serum dioxin with endogenous cholesterol and high-density lipoproteins. There appears to be an inverse relationship between serum TCDD level and high-density lipoprotein and a positive relationship with total cholesterol (Grubbs et al., 1995; Calvert et al., 1996).

Another observation is the finding that the risk of bladder cancer (16 cases) was increased by exposure to 4-aminobiphenyl at the one plant where 10 cases occurred. This is consistent with the fact that 4-aminobiphenyl is a strong bladder carcinogen. This could potentially bias the elevated overall cancer risk because these deaths are included. However, they will probably not affect site-specific cancers such as lung cancer, except that bladder cancer "competes" with other potential causes for the distinction of being designated the "underlying" cause of death. The authors also point out that exposure-related trends remained unchanged for smoking-related cancers when bladder cancers were omitted. This implies that the findings for all cancers remained unchanged when bladder cancers were omitted. The excess is about eight cases over expected.

The analysis done by Fingerhut in her first paper, showing that there is a high correlation between years of exposure to TCDD and in vivo serum levels of TCDD, based upon 253 workers, is strong evidence of a likely dose-response relationship. Endogenous markers of exposure are superior to exogenous man-made constructs. Although markers of exposure that are closer to the target organ for carcinogenicity are better indicators of the actual dose received by the organism at some given point in time, they still tell us little of what may have occurred by way of exposure in the past and exposures in the future. However, indexes of exposure such as "cumulative exposure" are likely to be more accurate and reliable when based upon actual dose measures.

In summary, Steenland et al. (1999) continues to support the hypothesis that dioxin is causally associated with an increased risk of cancer punctuated by increased selected site-specific risks such as lung cancer, STS, etc. There is a significant positive trend for cancer mortality with increasing exposure, with a 60% excess mortality from cancer in general in the highest exposure group. But in addition, the data suggest a potential for an added risk of ischemic heart disease.

The positive association of lung cancer in male workers observed in this study is also consistent with an excess of pulmonary tumors found in male mice and rats exposed to TCDD (see Chapter 6). These same animal data suggest the possibility of a protective hormonal effect from TCDD and the risk of pulmonary cancer in female rats. Because this study dealt with only male workers, this hypothesis could not be verified in female workers. On the other hand, no elevated risk of liver cancer is evident in male workers even in the long duration/latency subcohort. This is also consistent with rat data, where the tumors were only observed in female rats. If there is a promoting effect on liver cancer in human females due to hormonal effects, as suggested by the rat studies, it could not be verified.

Collins et al. (1993) suggested that there is an association of STS with exposure to 4-aminobiphenyl. The authors reported that workers who developed chloracne from an accident in which a chemical mix containing TCDD was scattered throughout a 2,4,5-trichlorophenol plant
