4. HUMAN EXPOSURES TO CDD, CDF, AND PCB CONGENERS

4.1. INTRODUCTION

The purpose of this chapter is to assess background exposures to the dioxin-like compounds. Recent assessments of background exposures cited in the scientific literature are summarized, and background exposure estimates based on the data presented in this report are presented. Two methods have been used in this chapter to estimate background daily intake of dioxin-like compounds. One method estimates background exposures based on pharmacokinetic modeling using body burden data. The other derives background exposure estimates from dietary intake and contact with other media containing dioxin-like compounds. These two approaches provide comparable estimates of daily TEQ-WHO_{98} intake of dioxin-like compounds.

The primary focus of this chapter is background exposure among the general population. The general population consist of people who are exposed to background levels of dioxin-like compounds in soil and air. Most of their exposure comes from the commercial food supply and they do not have significant occupational exposure. People outside the general population are those living in areas with elevated soil or air levels, or whose dietary exposure is strongly influenced by food outside the commercial food supply (i.e., nursing infants, sports or subsistence fishermen, etc.).

The term "background," as applied to exposure, can be used to represent different concepts. Two common definitions are (1) the level of exposure that would occur in an area without known point sources of the contaminant of concern or (2) the average level of exposure occurring in an area whether sources are present or not. For the purposes of this document, "background" is defined as suggested in the first definition above. To the extent possible, background exposures estimated in this chapter are based on monitoring data obtained from sites removed from known contaminant sources (i.e., food data representative of the general food supply) and body burden data from nonoccupationally exposed members of the general population. Most of the data are based on studies published in the late 1980s and 1990s, but primarily the 1990s. These data are considered to be the most useful for describing background exposure levels.

Chapter 5 also includes information on potentially elevated exposures. It describes the potential for elevated exposures among subpopulations such as nursing infants, sport

and subsistence fishermen, cigarette smokers, and individuals living in areas that may be affected by localized sources of dioxin-like compounds.

4.2. LEVELS OF DIOXIN-LIKE COMPOUNDS IN HUMAN TISSUE

4.2.1. Adipose Tissue and Blood Studies from the 1980s and Early 1990s

The most extensive U.S. study of CDD/CDF body burdens is the National Human Adipose Tissue Survey (NHATS) (U.S. EPA, 1991a). NHATS was designed to estimate national population average levels of CDD/CDFs. The survey analyzed for CDD/CDFs in 48 human tissue samples that were composited from 865 samples. Each composite contained an average of 18 specimens. These samples were collected during 1987 from autopsied cadavers and surgical patients. The sample compositing prevents use of these data to examine the distribution of CDD/CDF levels in tissue among individuals. Also, not all 48 composites were used for all congeners in the statistical analysis of the data because some components did not meet the data quality objectives of the study. However, the study results allowed conclusions to be made in the following areas:

- National Averages - The national population averages for all TEQ congeners were estimated as listed in Table 4-1. Nondetects were treated as half the detection limit for averaging purposes. As shown in this table, all congeners except some CDFs, had a very low frequency of nondetects. Thus, the overall TEQ estimate is not sensitive to how nondetects were treated in the averaging.

- Age Effects - Tissue concentrations of CDD/CDFs were found to increase with age (Orban et al., 1994) (Table 4-2).

- Geographic Effects - In general, the average CDD/CDF tissue concentrations appeared fairly uniform geographically. Only one TEQ congener was found to have a significant difference among geographic regions of the country. This compound, 2,3,4,7,8-PeCDF, was found at the lowest level in the West (4.49 pg/g) and the highest in the Northeast (13.7 pg/g).

- Race Effects - No significant difference in CDD/CDF tissue concentrations was found on the basis of race (Table 4-2).

- Sex Effects - No significant difference in CDD/CDF tissue concentrations was found between males and females (Table 4-2).

- Temporal Trends - The 1987 survey showed decreases in tissue concentrations relative to the 1982 survey for all congeners. However, it is not known whether these declines were due to improvements in the analytical methods or actual reductions in body burden levels. The percent reductions among individual congeners varied from 9 percent to 96 percent.

Patterson et al. (1994) provided additional information on levels of dioxin-like compounds in human tissue. Human adipose from 28 individuals was collected. The individuals studied were ones who died suddenly in the Atlanta area during 1984 or 1986. Their ages ranged from 19 to 78 years and averaged 49 years. 2,3,7,8-TCDD levels varied with the upper end of the range equaling between three and four times the mean concentration. The tissue data are summarized in Table 4-3. This table shows that the mean PCB levels generally exceeded the mean 2,3,7,8-TCDD level and PCB-126 exceeded the 2,3,7,8-TCDD level by over an order of magnitude. The mean TEQ levels for these dioxin-like PCBs summed to about 14 ppt on a lipid basis (using either TEF_P-WHO_{94}s or TEF_P-WHO_{98}s). A complete CDD/CDF congener analysis was conducted on tissues of four of the individuals, resulting in an average of 26 ppt I-TEQ_{DF} (31 ppt TEQ_{DF}-WHO_{98}) on a lipid basis. These tissue samples were also analyzed for PCBs 77, 126, and 169. The lipid-based TEQ_P-WHO_{94} levels for these dioxin-like PCBs summed to 5.4 ppt. Thus, PCBs 77, 126, and 169 contributed between 15 and 20 percent of the total CDD/CDF and PCB TEQs. Patterson et al. (1994) also studied serum collected by the CDC blood bank in Atlanta during 1982, 1988, and 1989. These samples were pooled from over 200 donors. The average levels for 2,3,7,8-TCDD and PCBs are summarized in Table 4-4 in units of ppt on a whole weight basis. The serum data appear to indicate a decrease in exposure to PCBs from 1982 to 1988/1989. The lipid-based TEQ_P-WHO_{94} for the 1988 sample was 14 ppt based on PCBs 77, 126, 160, 105, 118, and 180. In general, the Patterson et al. (1994) data suggest that the dioxin-like PCBs can contribute significantly to body burdens of dioxin-like compounds. The data suggest that the dioxin-like PCBs can increase the total background body burden to over 40 ppt of total TEQ_{DFP}-WHO_{94}. This conclusion is uncertain because the people studied by Patterson et al. (1994) may not be representative of the overall U.S. population.

Schecter et al. (1993) reported on the comparisons of congener-specific measurements of CDDs, CDFs, and dioxin-like PCBs (77, 105, 118, 126, 156, 169, 170, and 180) in whole blood samples of four individuals with known exposures to that of the

general population. In this comparison, the analytical results of separate 450 mL blood samples collected from 50 Michigan residents, and a pooled blood sample from 5 donors at a blood bank in Missouri were used as the control group. Two of the exposed individuals were pulp and paper plant workers with potential exposure to dioxins, and the other two were Michigan residents who had elevated blood PCB levels from consuming contaminated fish. It was found that the control group and the pulp and paper mill workers who had no known exposures to PCBs had relatively high levels of coplanar, mono-ortho, and di-ortho PCBs in their whole blood. On average, the Michigan and Missouri control samples showed mean I-TEQ_{DF} concentrations of 27 ppt and 24 ppt (TEQ_{DF}-WHO_{98}s were 31 ppt and 26 ppt), respectively. These same samples showed TEQ_{P}-WHO_{94} mean concentrations of 17 ppt for the Michigan controls, and 10 ppt for Missouri controls.

Cole et al. (1995) reported on CDD/CDFs and PCBs in 132 serum samples (pooled to 14) from Ontario Great Lakes anglers and control populations. Based on a preliminary survey, anglers from the communities of Cornwall and Mississauga, Canada, were categorized based on the numbers, species, and locations of fish caught and kept for consumption, and on data reflecting the contaminant levels for the fish in these areas. Individuals categorized as having the highest and lowest potential for having elevated body burdens of CDD/CDFs and PCBs were selected for biological sampling. Individuals who did not consume fish served as controls. Study participants were further categorized by age (i.e., $<$38 years, 38-50 years, and $>$50 years). The results indicated that mean CDD/CDF TEQ levels were similar for both eaters and noneaters of Great Lakes' fish in these communities. I-TEQ_{DF}s ranged from 20.8 to 41.2 ppt for fish eaters and 24.7 to 36.8 ppt for noneaters. In general, mean I-TEQ_{DF}s increased with age (Table 4-5). PCBs 77, 126, and 169 were also evaluated in the serum samples collected from Cornwall residents. TEQ_{P}-WHO_{94}s ranged from 2.6 to 17.3 ppt for fish eaters and noneaters combined. Because no statistical differences were observed between fish eaters and noneaters, the data from this study were assumed to represent background exposures and were included in the background tissue level calculations in this chapter.

Schecter et al. (1989a) provided data on PCB levels in adipose samples from three patients from North America with no known chemical exposure history. The mean TEQ_{P}-WHO_{94} level based on PCBs 118, 105, 156, and 180 was 12.2 ppt on a lipid basis (the

TEQ_P-WHO_{98}, recalculated using TEF_P-WHO_{98}s, was 11.5 ppt on a lipid basis). Williams and LeBel (1991) reported on the mean residue levels of PCBs 126 and 169 in 62 adipose tissue samples collected in Canada during 1984. The mean lipid-based TEQ_P for these samples was estimated to be 28 ppt based on TEF_P-WHO_{94} or TEF_P-WHO_{98}s for PCBs.

Kang et al. (1997) reported on the levels of PCBs 77, 126, and 169 in human serum collected from white male paper mill workers (n = 46), as well as residents (n = 16) of a northeastern U.S. community. PCB 77 was not detected in any samples, but PCBs 126 and 169 were detected in most samples. The mean lipid-based concentrations of the two congeners (i.e., PCB 126 and 169) were 25 ppt and 31 ppt, respectively, for paper mill workers, and 18 ppt and 27 ppt, respectively, for community residents. Using TEF_P-WHO_{94}s for these PCBs (PCB 126 - 0.1, PCB 169 - 0.01), the relative contribution of these PCBs to the total CDD/CDF/PCB TEQ (using I-TEF_{DF}s for CDD/CDFs) for all study participants was approximately 10 percent. Kang et al. (1997) also observed that age, body mass index, and consumption of locally caught fish were significant predictors of coplanar PCB concentrations in human serum.

The levels of dioxin-like compounds found in human tissue/blood appear similar in Europe and North America. Schecter (1991) compared levels of dioxin-like compounds found in blood among people from U.S. (pooled samples from 100 subjects) and Germany (85 subjects). Although mean levels of individual congeners differed by as much as a factor of two between the two populations, the total I-TEQ_{DF} averaged 42 ppt in the German subjects and 41 ppt in the pooled U.S. samples. Using TEF_{DF}-WHO_{98}s, these TEQ_{DF}-WHO_{98} concentrations would be 49 ppt and 50 ppt, respectively. In later papers, Schecter et al. (1992a; 1994a) reported human blood levels for the general population from various countries. These data are presented in Table 4-6. Schecter (1991) reported adipose tissue levels in various countries, as summarized in Table 4-7. The adipose tissue data show more variation between countries, but also involved much fewer samples, reducing confidence in the accuracy of the mean.

Gonzalez et al. (1993) reported that the levels and patterns of CDD/CDFs in the adipose tissue obtained from the general population of Madrid, Spain, were similar to those of other industrialized countries. A total of 17 adipose tissue samples were collected from male and female patients ranging in age from 48 to 89 years. The lipid-based mean I-TEQ_{DF} was 42 ppt (46 ppt using TEF_{DF}-WHO_{98}s) and the mean level of

2,3,7,8-TCDD was 3.28 ppt. CDDs were found to be higher than CDFs in these samples with the higher-chlorinated CDDs accounting for the highest portion of the total CDD/CDFs (Table 4-8). The mean lipid-based I-TEQ_{DF} concentration in the blood of 11 individuals from Madrid, Spain, was 15.7 ppt (Jimenez et al., 1995). The higher-chlorinated CDDs (i.e., HpCDD and OCDD) were the dominant congeners observed in these samples.

Schumacher et al. (1999a and 1999b) conducted two studies to analyze background concentrations of CDD/CDFs in blood and adipose tissue from individuals from Tarragona, Spain. In the first study (Schumacher et al., 1999a), blood plasma samples were collected from 20 nonoccupationally exposed subjects living near an area where a hazardous waste incinerator is being constructed. The reported mean blood lipid CDD/CDF concentration was 27.0 ppt I-TEQ_{DF} with a range of 14.8 to 48.9 ppt. The maximum TEQ_{DF} value observed in this study was approximately 1.7 times the mean. CDD/CDF TEQs were higher in women (e.g., 27.7 ppt) than in men (e.g., 25.2 ppt). The results, however, were not statistically significant. Schumacher et al. (1999b) conducted a second study on adipose tissues of 15 autopsied subjects. The arithmetic mean I-TEQ_{DF} was 30.98 ppt (range of 13.4 to 69.4 ppt). The maximum I-TEQ_{DF} value observed in this study was approximately 2.2 times the mean. Unlike their previous study, I-TEQ_{DF}s were statistically higher ($p < 00.1$) in the fat of women (mean value: 45 ppt) than in men (mean value: 24 ppt). Levels of CDD/CDFs were higher for those people that lived in industrialized areas than the residents who lived in the city, but this difference was not statistically significant.

Beck et al. (1994) reported on levels of CDD/CDFs in adipose tissue from 20 males (mean age-50 years) from Germany. I-TEQ_{DF}s ranged from 18 ppt to 122 ppt with a mean of 56 ppt (using TEF_{DF}-WHO_{98}s, the mean TEQ_{DF} would be 65 ppt), on a fat weight basis. The I-TEQ_{DF} maximum concentration in this study was approximately 2.4 times the mean. Beck et al. (1994) also reported on CDD/CDF levels in various organs of the body. In comparison to adipose tissue, the concentrations of CDD/CDFs in brain and placental tissue were found to be low. Accumulation of CDD/CDFs was not found to occur in the thymus, spleen, and liver, based on whole weight concentrations. Schecter et al. (1994a) also reported on I-TEQ_{DF} levels in organs of two autopsy patients from New York. The highest concentrations of CDD/CDFs were found in adipose tissue (28 ppt I-TEQ_{DF}),

adrenal tissue (14 ppt I-TEQ_{DF}), and liver (12 ppt I-TEQ_{DF}), on a whole weight basis. Lower concentrations were observed in spleen (4.6 ppt I-TEQ_{DF}), muscle (2.4 ppt I-TEQ_{DF}), and kidney (0.8 ppt I-TEQ_{DF}). Schecter et al. (1994b) reported PCB levels for these two autopsy patients. Total PCBs in adipose tissue were 280.7 ppb on a wet weight basis and 344.2 ppb on a lipid weight basis.

Beck et al. (1994) also observed that CDD/CDF tissue levels were dependent on the age of the individual. I-TEQ_{DF} concentrations in infants ranged from 2.1 pg/g to 22 pg/g on a lipid basis. 2,3,7,8-TCDD was found to increase at a rate of 0.12 pg/g fat per year, and I-TEQs increased at a rate of 0.77 pg/g fat per year. Schecter et al. (1995a) measured levels of CDD/CDFs in human fetal tissue (N = 10) at 8 to 14 weeks gestational age and observed an average of 5 pg I-TEQ_{DF}/g on a lipid basis. Stillborn liver (N = 3) concentrations averaged 10 pg I-TEQ_{DF}/g on a lipid basis. These levels are considerably lower than those observed in adult tissues (Schecter et al., 1995a). Päpke et al. (1996) also observed that I-TEQ_{DF} levels in human tissues were age dependent. Whole blood samples collected in 1994 indicated that I-TEQ_{DF} concentrations increased with increasing age. Similar age effects were noted for PCBs 77, 126, and 169 (Päpke et al., 1996).

Wuthe et al. (1995) studied body burdens of CDD/CDFs among children in Germany. Three study groups were evaluated: blood from 11 nonexposed children, age 9 to 15 years; adipose and liver tissue from 20 stillborn or otherwise deceased infants, age 0 to 44 weeks, some of whom had been breast-fed; and pooled blood from 10-year-olds from 3 different regions. The total I-TEQ_{DF} concentration for the first study group (i.e., blood from 11 children between the ages of 9 and 15 years) was 10.7 ppt. Based on the other study groups, the authors made the following conclusions: (1) because CDD/CDFs were found in stillborns, a diaplacental transfer of these compounds occurred; (2) breast feeding has an impact on CDD/CDF concentrations (i.e., the mean I-TEQ_{DF} concentration was 12.7 ppt for breast-fed infants and 3.6 ppt for formula-fed infants); and (3) body burdens of CDD/CDFs are lower among children than adults.

Lanting et al. (1998) examined PCBs in adipose tissue, liver, and brain from nine stillborns at varying gestational ages. Of the four PCB congeners examined, only PCB 118 was dioxin-like. The median levels reported for PCB 118 were 20 ppt for adipose tissue, 17 ppt for the liver, and 6 ppt for the brain. The results of the study indicated that there was a significant relationship (correlation coefficient = 0.98; $p < 0.01$) between adipose

tissue concentrations and liver concentrations. Correlation between the levels of PCB congeners in these tissues and gestational age of the infants were not significant; correlation coefficients varied between 0.22 and 0.47.

Kruezer et al. (1997) reported CDD/CDF concentrations from lipids of adipose tissue and livers from cadavers (3 stillborns and 17 infants aged 0.43 to 44 weeks old who died from sudden infant death syndrome). I-TEQ_{DF} lipid-based concentrations were in the range of 1.55 to 29.63 ppt for adipose tissue (n = 20) and 2.05 to 57.73 ppt (n = 19) for liver. TCDD concentrations in lipids of breast-fed infants were higher compared to nonbreast-fed infants.

Nagayama et al. (1995) studied the effect of birth order on the body burdens of CDD/CDFs and PCBs among 50 healthy Japanese women. The concentrations of these dioxin-like compounds in blood were found to be significantly higher among first-born women than among other women. No relationship was found between the method by which these women were fed (i.e., breast-fed, formula-fed, or mix between breast milk and formula) and the blood concentrations of CDD/CDFs and PCBs.

Human breast tissue has also been analyzed for dioxin-like PCBs (Dahl et al., 1994; Petreas et al., 1998). Dahl et al. (1994) examined breast tissue collected from 16 women seeking hospital care for breast tumors in Sweden. PCB levels were observed to increase with age. Based on PCBs 105, 114, 118, 156, 157, 170, 180, and 189, the mean total TEQ_P-WHO_{98} for these samples was 40 ppt. Petreas et al. (1998) studied human breast adipose tissue collected from women undergoing breast surgery at Stanford University in California to determine CDD/CDF and PCB levels. Of the 17 CDD/CDF congeners, only OCDD, HpCDD, HxCDD, and PeCDF were observed to be above the limit of detection. I-TEQ_{DF} lipid-based concentrations, using one-half LOD for non-detects, ranged from 6 ppt to 78 ppt with a mean of 17.8 ppt (n = 62). Based on only the four detected congeners, the I-TEQ_{DF} concentration ranged from 5 ppt to 42 ppt with a mean of 12.6 ppt (the maximum I-TEQ_{DF} value is 3.3 times higher than the mean). Lipid-based PCB levels ranged from 451 ppb to 3,830 ppb with a mean of 1,120 ppb, based on PCBs 153/132, 180, 74, 138, 182/187, 170, 196/203, 194, 199, 156, 118, 206, 183, 99/113, 177, 28, 105/127, 128/162, 157, and 101 (n = 61). The maximum concentration is 3.4 times the mean. Lipid-based TEQ_P-WHO_{94} levels for coplanar PCBs 77, 126, and 169 ranged from 7 ppt to 110 ppt with a mean of 38 ppt (the maximum TEQ_P-WHO_{94} is 2.9 times higher than

the mean). The most prevalent PCB congeners included PCBs 153/132, 180, 74, 138, 182/187, and 170, which, when summed, contributed over 50 percent of the total PCB measure.

Iida et al. (1999) analyzed blood samples from 50 young (i.e., approximately 20 years of age) Japanese women for dioxin-like compounds. The women were described as "normal subjects" who had not yet had children, and the samples were collected in 1993 and 1994. The range if I-TEQ_{DF}s was 7.3 pt to 28.0 ppt with a mean of 16.4 ppt (the maximum value is 1.7 times higher than the mean). The range of TEQ_{P}-WHO_{94}s (based on PCBs 77, 126, and 169) was 1 ppt to 10 ppt with a mean of 4.9 ppt. The total TEQ_{DFP}-WHO_{94} was 21 ppt and the maximum value was 37 ppt. This maximum value is 1.8 times higher than the mean.

4.2.2. Breast Milk Studies from the 1980s and Early 1990s

Schecter et al. (1989b; 1992b) reported that in a study of 42 U.S. women, the average I-TEQ_{DF} was 16 ppt (20 ppt of TEQ_{DF}-WHO_{98}) (3.3 ppt of 2,3,7,8-TCDD) in the lipid portion of breast milk. Schecter et al. (1989b) also reported a total I-TEQ_{DF} of 27 ppt (TEQ_{DF}-WHO_{98} = 31 ppt) for human milk collected in Germany (n = 185). A much larger study in Germany (n = 526) showed an average of 29 ppt of I-TEQ_{DF} (TEQ_{DF}-WHO_{98} = 34 ppt) in lipid portion of breast milk (Fürst et al., 1994). Bates et al. (1994) analyzed breast milk samples from 38 women in New Zealand and reported mean lipid-based I-TEQ_{DF}s of 16.5 ppt for urban women and 18.1 ppt for rural women (average I-TEQ_{DF} = 17.2 ppt; average TEQ_{DF}-WHO_{98} = 21 ppt). The age of the mother was found to be positively correlated with the concentration of CDD/CDFs in breast milk. Beck et al. (1994) reported a mean I-TEQ_{DF} of 30 ppt (TEQ_{DF}-WHO_{98} = 35 ppt) in the milk fat based on 112 human milk samples from Germany. The congeners that contributed the most to the total I-TEQ_{DF} were 2,3,4,7,8-PeCDF (35 percent), total HxCDD (22 percent), and 1,2,3,7,8-PeCDD (21 percent). Beck et al. (1994) observed that CDD/CDF levels decreased with the number of children and the duration of breast feeding, but increased with the age of the mother. Beck et al. (1994) also compared the adipose tissue levels of breast-fed and bottle-fed infants who had died of sudden infant death syndrome. The breast-fed infants had higher tissue levels (5.4 to 22 pg/g fat; n = 4) than the bottle-fed infants (2.1 to 4.4 pg/g fat; n = 2).

Hirakawa et al. (1995) studied differences in CDD/CDF levels in human milk collected from primipara and multipara Japanese women. Human milk samples were taken from seven primiparas and eight multiparas between the ages of 22 and 40 years and analyzed for CDD/CDFs and dioxin-like PCBs. Total lipid-based TEQ concentrations were 34.6 ppt for the primiparas and 30.7 for multiparas, using I-TEF_{DF}s for CDD/CDFs and TEF_P-WHO_{94} for PCBs. Significant differences were observed between the concentrations of 2,3,7,8-TCDD; 1,2,3,7,8-PeCDD; 1,2,3,6,7,8-HxCDD; 1,2,3,7,8,9-HxCDD; 2,3,4,7,8-PeCDF; and 1,2,3,6,7,8-HxCDF in primipara and multipara women. The concentrations of these congeners varied by a factor ranging from 1.3 to 1.8 for the two study groups (Table 4-9). The mean I-TEQ_{DF} plus three standard deviations indicates that the high-end CDD/CDF concentration is approximately 2 times higher than the mean.

Van Cleuvenbergen et al. (1994) observed lipid-based I-TEQ_{DF} levels in human milk ranging from 27 to 43 ppt with a mean of 34 ppt (TEQ_{DF}-WHO_{98} = 40 ppt), based on samples from 9 women living in Belgium in 1992. The maximum I-TEQ_{DF} concentration observed in this study was approximately 1.3 times higher than the mean. OCDD and 1,2,3,4,6,7,8-HpCDD accounted for the highest proportion of total CDD/CDFs, but 2,3,4,7,8-PeCDF accounted for the largest proportion of the total CDD/CDF I-TEQ_{DF} (i.e., approximately 45 percent (Table 4-10)). Similar I-TEQ_{DF} levels have been observed in other countries. Schecter et al. (1989c) collected human milk samples from southern Japan in 1986. The mean lipid-based total I-TEQ_{DF} for two composites, containing three samples each, was 26 ppt. Based on data from Startin et al. (1989), the mean lipid-based I-TEQ_{DF} for a pool of 80 human milk samples from the United Kingdom was 33 ppt (TEQ_{DF}-WHO_{98} was 39 ppt).

Pluim et al. (1994a) studied the influence of short-term dietary changes in fats and carbohydrate intake on CDD/CDF concentrations in human milk. Two different diets were administered to two groups of lactating women in The Netherlands. Sixteen women had a low-fat/high-carbohydrate/low-dioxin diet, and 18 women had a high-fat/low-carbohydrate/low-dioxin diet for 5 consecutive days. At the end of this dietary regimen, milk samples were collected and analyzed for CDD/CDFs. No significant differences between CDD/CDF levels were observed. The mean I-TEQ_{DF} values for mothers using the low-fat/high-carbohydrate/low-dioxin diet were 30.2 ppt and 30.0 ppt before and after the test period, and the mean I-TEQ_{DF} values for the mothers using the high-fat/low-

carbohydrate/low-dioxin diet were 24.4 ppt and 24.0 ppt before and after the test period. Pluim et al. (1994a) concluded that short-term dietary changes were not an effective means of reducing dioxin concentrations in human milk. In another study, Pluim et al. (1994b) measured the levels of CDD/CDFs in breastmilk as part of a study to evaluate relationships between neonatal CDD/CDF exposure via breastmilk and potential physiological effects. CDD/CDFs were measured in the breastmilk of 35 Dutch mothers when their nursing infants were 11 weeks of age. The mean lipid-based I-TEQ_{DF} level in these breastmilk samples was 28.1 ppt (TEQ_{DF}-WHO_{98} = 33.5 ppt).

In 1994 and 1996, Hooper et al. (1998) monitored levels of CDD/CDFs in breast milk samples collected in Kazakstan, a country of the former Soviet Union. The mean reported CDD/CDF levels ranged from 7.2 to 57 ppt I-TEQ_{DF}. The detection limit for the sampling was 1 ppt, and only levels above the detection limit were reported. Approximately 92 breast milk samples were collected in both of these years. The range and mean values of individual and composite samples were similar by region and ethnicity. In addition, this study found that CDD/CDF levels were significantly higher in breast milk samples collected from rural sites (mean 46 ppt I-TEQ_{DF}, n = 23) than from a nonrural site (mean 11 ppt I-TEQ_{DF}, n = 32). Hooper et al. (1998) did not identify the reason for the higher CDD/CDF concentrations in samples from rural women. Several postulations include the high use of a pesticide (Hexachlorocyclohexane) in Kazakstan, the Kazakstan diet may include more contaminated fish from the Ural River, and consumption of cottonseed oil and kefir (a beverage of fermented cow's milk), which has been shown to have high dioxin levels. Consumption of cottonseed oil and kefir is more common in the rural areas than in urban areas.

Recently, Liem et al. (1996) reported on the results of the second round of a human breast milk study conducted by the World Health Organization (WHO). Human milk samples were collected from women in 19 countries during 1992/93 and analyzed for CDDs, CDFs, and PCBs (i.e., non-ortho 77, 126, 169; mono-ortho 105, 118; markers 28, 52, 101, 138, 153, 180). The results were compared to the results of the first round of sampling that occurred among 11 countries in 1987/88 to evaluate trends in exposure to dioxin-like compounds. Based on the 1992/93 results of pooled human milk samples, lipid-based I-TEQ_{DF} concentrations ranged from 3.8 pg/g for the Librazhd area of Albania to 27.1 pg/g for the Liege area of Belgium (Table 4-11). Overall, significantly lower I-TEQ_{DF}s

and PCBs were observed in Albania, Hungary, and Pakistan (Table 4-11). The highest I-TEQ_{DF} levels were observed in Belgium and The Netherlands (Table 4-11), and the highest TEQ_P-WHO_{94} levels were observed in Canada's Hudson Bay region and in regions of the Czech and Slovak Republics. An analysis of individual samples from The Netherlands and Denmark indicated a high level of variability among individuals (i.e., levels varied by a factor of 3 to 5). Comparison of the 1992/93 data to the 1987/88 data indicated that the levels of CDD/CDFs and marker PCBs in breast milk have declined in some countries with concentrations decreasing up to 50 percent in some areas (Table 4-12). Liem et al. (1996) estimated an overall annual decrease in CDD/CDFs of 7.2 percent over the 5-year time period evaluated.

Vartiainen et al. (1997) reported CDD/CDF and PCB levels in the human milk of 167 women collected in 1987 from an urban area and a rural area in Finland. The average CDD/CDF levels were significantly higher ($p < 0.001$) in the urban area (26.3 pg I-TEQ_{DF}/g fat; $n = 47$) than in the rural area (20.1 pg I-TEQ_{DF}/g fat; $n = 37$) for all primiparae individuals. Similarly, the total PCB concentrations were higher ($p < 0.01$) among urban primiparae (496 ng/g fat; 36.8 pg TEQ_P-WHO_{94}/g; n-47) than among rural primiparae (396 ng/g fat/ 26.3 pg TEQ_P-WHO_{94}/g; $n = 37$). The CDD/CDF and PCB levels in the milk of these women decreased with the increasing number of children breast-fed by them. Vartiainen et al. (1997) estimated that a woman's third child would be exposed to about 70 percent of the CDD/CDF and PCB levels that her first-born child was exposed to, and the eighth to tenth child would be exposed to only about 20 percent of the levels of the first-born. In addition, Vartiainen et al. (1997) observed a possible correlation between average I-TEQ_{DF} levels and total PCB concentrations (correlation coefficient (R) was 0.84 for the urban area and 0.71 for the rural area).

Kiviranta et al. (1999) coordinated a study from 1992-1994, which was designed as a follow-up of the Vartianen et al. (1997) study, measuring CDD/CDF and PCB levels in human milk in Finland. One round of 20 samples focused on urban areas (Helsinki, Finland) and the second round of 64 samples focused on rural areas (Koupio, Finland, and surroundings). Samples were divided into groups based on the number of children the mother has nursed. The groups included women who have had 1, 2, 3, 4, 6, or 13 children. The average CDD/CDF levels reported were 13.6 pg I-TEQ_{DF}/g fat for rural areas and 19.9 pg I-TEQ_{DF}/g fat for urban areas for all primiparae women. The average total

PCB concentrations were 198 pg/g fat from rural areas, and 296 pg/g fat for urban areas. The conclusions of the Kiviranta et al. (1999) study were identical to the Vartianen et al. (1997) study. The differences between the breast milk I-TEQ_{DF}s and PCB concentrations for rural and urban women remain and I-TEQ_{DF}s and PCB concentrations in breast milk also decreased proportionally when women had two or more children. It was also evident that there was a marked decrease in I-TEQ_{DF} and PCB levels when comparing to the values reported in 1992-1994 to those in 1987.

Tuinstra et al. (1994) evaluated the CDD/CDF and dioxin-like PCB content of human milk from The Netherlands. Samples were collected 10 and 42 days after delivery from about 200 mothers. Based on these data, the mean total I-TEQ_{DF} was 31 ppt (TEQ_{DF}-WHO_{98} = 36 ppt) (Tuinstra et al., 1994), and the mean TEQ_P-WHO_{94} for PCBs 77, 126, 169, 105, 118, 156, 170, and 180 was 36 ppt (TEQ_P-WHO_{98} = 31 ppt) (Tuinstra et al., 1994; Koopman-Esseboom et al., 1994).

Similar estimates of the dioxin-like PCB content of human milk have been obtained for North America and Europe. Hong et al. (1992) analyzed human milk samples from upstate New York for PCBs 77, 105, 114, 118, 123, 126, 156, 157, 167, 169, and 189. PCB 118 accounted for the highest proportion of the total PCB concentration. The mean lipid-based TEQ_P-WHO_{94} and TEQ_P-WHO_{98} for these samples was 13 ppt. The total TEQ_P-WHO_{94} for 96 pooled human milk samples from Canada was also 13 ppt (TEQ_P-WHO_{98} = 10 ppt) (Dewailly et al., 1994). She et al. (1995) analyzed 12 human milk samples for PCBs 77, 118, 105, 126, 156, 169, 170, and 180. The total TEQ_P-WHO_{94} for these samples was 16 ppt (TEQ_P-WHO_{98} = 14 ppt).

For European countries, the lipid-based TEQ_P-WHO_{94} levels were 22 ppt (TEQ_P-WHO_{98} = 18 ppt), based on 1990/91 data for PCBs 118, 156, 170, and 180 from 68 German women (Georgii et al., 1995) and 32 ppt (TEQ_P-WHO_{98} = 30 ppt), based on data for PCBs 77, 126,169, 105, 118, 114, 156, 170, and 180 from 28 Norwegian mothers (Johansen et al., 1994). Noren et al. (1990) and Noren and Lunden (1991) analyzed human milk samples from Sweden in 1989 (n = 2) and in every 4 years between 1972 and 1988/89, respectively. Total TEQ_P-WHO_{94}s based on Noren et al. (1990) were 29 ppt (TEQ_P-WHO_{98} = 27 ppt) (PCBs 118, 105, 156, 180, 77, 126, and 169). Noren and Lunden (1991) observed that the concentrations of PCBs in human milk declined between 1972 and 1984/85, but that the 1988/89 samples had similar concentrations as the

1984/85 samples. Based on the 1988/89 sampling period, the total TEQ_P-WHO_{94} was 19 ppt (TEQ_P-WHO_{98} = 18 ppt) based on PCBs 105, 156, 180, 77, 1216, and 169 (n = >100).

Van der Velde et al. (1994) compared the levels of PCBs 77, 126, and 169 in cow's milk and human milk from The Netherlands. The concentrations of these compounds were found to be higher in human milk than in cow's milk collected from a background location (Table 4-13). Based on these data, the total TEQ_P-WHO_{94} and TEQ_P-WHO_{98} for human milk was 9.4 ppt for these three dioxin-like PCBs.

Abraham et al. (1998) measured CDD/CDF and coplanar PCBs in blood of four mothers before and after delivery and during lactation. Abraham et al. (1998) also examined their breast milk and their infants blood for concentrations of CDD/CDF and coplanar PCBs. CDD/CDF and coplanar PCBs were also quantified in the cord blood, meconium, and transit stool. Table 4-14 presents a summary of the TEQ_{DF}s of mothers' milk and blood, and infants' blood. For two of the mothers (mother 1 and mother 2), the data were associated with their second delivery, and data were also available for their first-born infants at the age of 11 to 12 months. Mother 3 was the only subject that did not fully breastfeed her infant for at least 17 weeks. The results of this study suggest that CDD/CDF and coplanar PCB TEQs in the blood of the second infants were only about half as much as in the first born children (at the same age). This is likely a result of reductions in CDD/CDF concentrations in breast milk as a result of previous lactation. In addition, the infant that was not fully breast-fed had a lower l-TEQ_{DF} concentration in the blood than the fully breast-fed infants. Lipid-based CDD/CDF concentrations in the infants' tissues appeared to increase during the 11 months after birth, based on the comparison of infants' blood CDD/CDF concentrations at 11 months and CDD/CDF concentrations in cord blood concentrations.

Schecter et al. (1998) analyzed blood and milk from a mother that nursed twin babies over a 38-month period. In this study, a woman gave birth to twins on December 15, 1992. Blood and milk samples were taken each month starting in February 1993 and ending in September 1995. Overall, CDD levels in milk decreased from 309 ppt to 173 ppt, CDF levels dropped from 21 ppt to 9 ppt, and total coplanar PCB levels decreased from 151 to 21 ppt during that time period. Schecter et al. (1998) estimated that the mother reduced her dioxin body burden from 310 to 96 ng TEQ_{DFP}-WHO_{98}, or

approximately 69 percent during that time period. Overall, the CDD/CDF/PCB concentrations in the maternal whole blood dropped from 698 ppt to 262 ppt in lipids during that time period. The twins' consumption of CDD/CDF and coplanar PCBs from breast feeding was estimated to be approximately 115 ng TEQ_{DFP}-WHO_{98} per twin.

The levels of dioxin-like compounds in human breast milk can be predicted on the basis of the estimated dioxin intake by the mother. Such procedures have been developed by Smith (1987) and Sullivan et al. (1991). The approach by Smith assumes that the concentration in breast milk fat is the same as in maternal fat and can be calculated as:

$$C_{milk\ fat} = \frac{m\ h\ f_1}{0.693\ f_2} \qquad \text{(Eqn. 4-1)}$$

where:

$C_{milk\ fat}$ = Concentration in maternal milk (pg/kg of milk fat);
m = Average maternal intake of dioxin (pg/kg of body weight/day);
h = Half-life of dioxin in adults (days);
f_1 = Proportion of ingested dioxin that is stored in fat; and
f_2 = Proportion of mother's weight that is fat (kg maternal fat/kg total body weight).

This steady-state model assumes that the contaminant levels in maternal fat remain constant. Though not described here, Smith (1987) also presents more complex approaches that account for changes in maternal fat levels during breast feeding. The model developed by Sullivan et al. (1991) is a variation of the models proposed by Smith (1987). The Sullivan model considers changes in maternal fat levels and predicts chemical concentrations in milk fat as a function of time after breast feeding begins. The model proposed by Smith assumes that infant fat concentration at birth is zero; whereas, Sullivan assumes that the infant fat concentration at birth is equal to the mother's fat concentration.

Flesch-Janys et al. (1996) estimated the half-life of 2,3,7,8-TCDD in humans to be approximately 7 years. For the purpose of this preliminary analysis, it is assumed that a 7-year half-life applies to all of the dioxin-like compounds. Smith (1987) suggests values of 0.9 for f_1 and 0.3 for f_2. Using these assumptions and a background exposure level of

1 to 3 pg of TEQ_{DFP}-WHO_{98}/kg-d (derived from diet analysis, see Section 4.4.2 and previous assessments of background exposure), the concentration of dioxin-like compounds in breast milk fat is predicted to be about 10 to 30 ppt of TEQ, which is slightly lower than the measured values.

Uncertainty is introduced into this estimate by the assumption that the assumed half-life rate and partitioning factors apply to all the dioxin related compounds. Although these properties are likely to be similar among the various congeners, some variation is expected. It is unknown whether the net effect of these uncertainties would lead to over or under estimates of dose. However, the simple model appears to provide reasonable predictions of background levels found in breast milk and was judged adequate for purposes of a preliminary analysis. For detailed assessments, readers should consider using the more complex models and developing chemical-specific property estimates.

Travis et al. (1988) presented an alternative approach to estimating breast milk contaminant levels. They proposed a biotransfer approach:

$$C_m = B_m I \qquad \text{(Eqn. 4-2)}$$

where:

C_m = Contaminant concentration in breast milk fat (mg/kg);
B_m = Biotransfer factor for breast milk fat (d/kg); and
I = Maternal intake of contaminant (mg/d).

Travis et al. (1988) also argued that the biotransfer factor is primarily a function of the octanol-water partition coefficient (K_{ow}) and developed the following geometric mean regression:

$$B_m = 6.2 * 10^{-4} K_{ow} \qquad \text{(Eqn. 4-3)}$$

This regression was derived from data on six lipophilic compounds (log K_{ow} range: 5.16 to 6.5), but did not include any dioxins or furans. Assuming a log K_{ow} of 6.6 for 2,3,7,8-TCDD, a B_m of 3,700 d/kg is predicted. Combining this value with a maternal intake of 6

pg/d, a breast milk concentration on a fat basis of 22 ppt is predicted. This prediction is about 7 times higher than what has been measured for TCDD in breast milk in the United States. Thus, this approach appears to overpredict TCDD levels while the approach suggested by Smith (1987) appears to underpredict total TEQ levels.

4.2.3. The Blood Studies of the CDC Collaboration (1995-1997)

The Centers for Disease Control (CDC) has compiled data on blood concentrations of dioxins, furans, and coplanar PCBs from individuals in the United States with no known exposures to dioxins (CDC, 2000). These data come from site-specific studies (with permission from principle investigators in those studies), and CDC has provided the laboratory analyses of all the blood samples. All the samples were collected between 1995 and 1997. There are a total of 316 individuals included in their compilation from six locations: 1) Manchester, Missouri (n = 61), 2) Times Beach, Missouri (n = 67), 3) Jacksonville, Arkansas (n = 57), 4) Oregon (n = 9), 5) Wisconsin (n = 93), and 6) North Carolina (n = 29). CDC is preparing manuscripts for peer literature publication of statistical summaries and interpretations of this data. They have provided EPA with an overall statistical summary of the congener-specific and overall TEQ results from this compilation (Patterson, 2000), and those results will be described shortly. EPA judges these data to be the best representation of current background concentrations of dioxin-like compounds in the blood of US citizens, for these reasons: 1) all individuals were evaluated by the CDC analysis group as appropriately representing US background conditions and EPA concurs with this evaluation - that is, all individuals were judged to be exposed only through background exposures, including inhalation of background ambient air (i.e., not impacted by nearby high dioxin stack emitters), consumption of animal food products not known or expected to be contaminated, no occupational exposures, and so on, 2) the blood was analyzed using a consistent, high resolution, mass spectrometry state-of-the-art protocol (Patterson and Turner, 1997) which included 4 dioxin-like coplanar PCBs, 3) the data represent a wide range of adult ages, from 20 to over 70 years of age, and 4) the sampling was of relatively recent origin - 1995 to 1997, more recent than other studies reviewed in this chapter. Prior to describing this overall profile, information on four of the six study sites have been made available to EPA, and these will be described first.

With the assistance of the Agency for Toxic Substances and Disease Registry, the Missouri Department of Health (MDOH, 1999) conducted an exposure study to evaluate the potential impact of incinerating contaminated soil from Times Beach. Approximately 265,000 tons of soil and other materials containing 2,3,7,8-TCDD from 27 eastern Missouri sites were burned at the Times Beach Superfund site during the period March 17, 1996 through June 20, 1997. MDOH (1999) undertook a study to evaluate the impact of emissions from this incineration. Their approach was to take blood samples from a target and a comparison population before, during, and after the incineration, and evaluate the differences in blood levels of dioxin-like compounds between the populations and over time. MDOH (1999) selected a target population based on air dispersion and deposition modeling. This population resided within a 4-kilometer radius of the incinerator. A comparison population from Manchester was located about 16 kilometers from the incinerator. From a list of over 650 individuals from both populations, totals of 76 and 74 individuals were selected from the target and comparison groups, respectively, for blood sampling. These selections considered demography, whether or not a woman was pregnant or breast feeding (neither was selected), and other critical factors. Blood samples were taken from all participants in September 1995, July 1996, and June 1997, and questionnaires were administered each time. Mean concentrations of each of 15 dioxin and furan congeners, and 4 coplanar PCB congeners were determined assuming non-detects were equal to one-half the detection limit. These detection limits, on a lipid basis, were: 0.8 ppt for the tetra- and penta-CDD congeners and the tetra- through octa-CDF congeners, 1.2 ppt for the hexa- through hepta-CDD congeners, 3.8 ppt for the coplanar PCB congeners, and 15.4 ppt for OCDD. Concentrations for two hexa-CDD congeners, 1,2,3,4,7,8-HxCDD and 1,2,3,6,7,8-HxCDD, and one hexa-CDF congener, 1,2,3,7,8,9-HxCDF, were not reported, and concentrations of one hepta-CDD congener which is not assigned a TEF value, 1,2,3,4,6,7,9-HpCDD, was reported. The mean concentrations for each congener for each testing period and study group, is shown in Table 4-15. Further details on this study can be found in MDOH (1999).

The CDC compilation included only the data from 1997. For that year, 67 of the 76 individuals from Times Beach had available measurements for their compilation, and 61 of the 74 individuals from the comparison site, Manchester, had available measurements.

MDOH (1999) concluded that there was no statistically significant differences between the target and comparison groups for all the analytes measured except for PCB 126, which was slightly higher in the comparison group. MDOH (1999) concluded that the values measured were some of the lowest values ever recorded on a human population. As seen in Table 4-15, the TEQ_{DFP}-WHO_{98} for the target group was 11.7 ppt while for the comparison group it was 12.6 ppt (averaged over all sampling dates). However, the actual TEQ concentrations would be higher than these since this study did not report on measurements for the three congeners noted earlier. Other data suggest that the hexa-CDD congeners not reported on in this study, mainly 1,2,3,6,7,8-HxCDD, comprise in the range of one-fourth to one-third of the total body burden of TEQ. MDOH (1999) also observed that there appeared to be a decrease in concentrations from pre- to post-incineration for most analytes. Of all factors examined through questionnaires, only two appeared to be important for dioxin body burdens: smoking and age. Combining both populations, the average TEQ for participants living in homes with cigarette smokers as 12.8 ppt (I-TEQ_{DF} + TEQ_{P}-WHO_{94}), compared to 9.4 ppt (I-TEQ_{DF} + TEQ_{P}-WHO_{94}) in homes that do not have smokers. No age-specific results were presented in MDOH (1999), but a Pearson correlation of 0.525 for average TEQ concentration (statistical significance <0.001, two-tailed) was found for age. The average age of participants in both populations was about 43 years.

The Arkansas Department of Health (ADH) and the Agency for Toxic Substances and Disease Registry (ATSDR) cooperated on the design and implementation of a study to evaluate the exposure of individuals to dioxin-like compounds and other contaminants manufactured and then disposed of through incineration at the Vertac/Hercules Superfund Site (abbreviated the Vertac Site) in Jacksonville, Arkansas (ADH, 1995). The site had been used from the 1950s to manufacture herbicides such as 2,4,-D, 2,4,5-T, and 2,4,5-TP. It had changed hands several times until being abandoned by Vertac in 1987. Incineration occurred between 1992 and 1994. One component of the study was to sample and then analyze blood from three target groups of individuals: 1) residents living near the Site for more than 15 years as of 1991 - 72 individuals recruited, 2) residents living between 1 and 5 years as of 1991 - 36 recruited, and 3) residents living in a comparison area - 72 recruited; 71 participated. The comparison area chosen was in Mabelvale, Arkansas, a demographically similar community approximately 25 miles south

of Jacksonville. Study participants ranged in age from 18 to 65 years old. The average age of the comparison group at the first sampling in 1991 was 40 years. Blood samples were taken in March, 1991, and participants also filled out an extensive questionnaire at that time. Subsets of individuals from all three populations were sampled once again in 1994 and 1995 after the incineration had been completed.

The CDC compilation used only the data from 1995 in their compilation. This data set included individuals who lived both in Jacksonville and in Mabelville - most of the individuals followed into 1995 lived in Jacksonville. The number of individuals sampled in 1995 included in the CDC compilation is 57.

The 1991 and 1994 sampling were described in a draft report released by the Arkansas Department of Health for public comment in 1995 (ADH, 1995). This report has never been finalized. However, the blood data has been available and even used by one researcher citing results from the Mabelville population sampled in 1991 as a comparison group to his own study of dioxin-like compounds in the blood of a Great Lakes sport-fishing population (Anderson et al., 1998). Individual results that are summarized here have been provided to EPA via personal communication (Cranmer, 1996). The data supplied for each dioxin-like congener was either: identified as a quantified concentration (in serum, on a lipid basis), identified as "not detected" (ND), or identified as "not reported"(NR). Detection limits were not specified. Therefore, for purposes of the calculation of means, non-detects were assumed equal to zero. Measurements identified as NR were not included in the calculation of means.

Table 4-16 summarizes the results from the comparison population only. This table shows the results for the entire set of 71 individuals sampled in 1991. It also shows the results for subsets of these individuals that were sampled in 1994 and 1995. For comparison, the 1991 means for these same subsets are also provided. Unlike the target population of the Times Beach study described earlier, there appeared to be measurable impacts on the blood levels of dioxin-like compounds in the target populations at Vertac, as evidenced by the 1991 sampling. However, these impacts have not been tied directly to activities at Vertac. For example, in groups 1 (15 years residence near the site) and 2 (between 1 and 5 years residence), the mean lipid-based concentrations of 2,3,7,8-TCDD were 8.5 and 4.2 ppt, while the mean for the background population was 2.5 ppt. The high means for groups 1 and 2 were driven by a small number of very high concentrations

(the three high concentrations from group 1 were 29.7, 84.9, and 94.8 ppt). However, if these high values are excluded, the overall concentrations from these groups are still higher than for the comparison group. The average TEQ_{DFP}-WHO_{98} from the comparison population in 1991 was 25.2 ppt. The select group of 18 individuals who were targeted for resampling in 1994 were individuals whose lipid-based concentration of 2,3,7,8-TCDD ranged from 2 to 5 ppt. Table 4-16 suggests that the average blood TEQ_{DFP}-WHO_{98} level for this group decreased between 1991 and 1994, from 26.8 to 22.6 ppt. However, when evaluating the average CDD/CDF/PCB concentration of the 14 individuals resampled in 1995 (a further subset of the 18 who provided samples in 1994), there appears to be little evidence of a decline in TEQ_{DFP}-WHO_{98}. The TEQ_{DFP}-WHO_{98} concentrations were 25.0 ppt in 1991 and 24.0 ppt in 1995 for this group. As with other studies, ADH (1995) also reported on an important age effect - the levels of dioxins and furans increased with age.

Grassman et al. (1999) developed a method to evaluate inter-individual variation in dioxin responsiveness among humans. Specifically, they developed a system that measures dioxin-responsive biomarkers in peripheral blood lymphocytes challenged *in vitro* with 10 nM TCDD during cell culture. Grassman et al. (1999) evaluated the capabilities of this method by obtaining blood samples from 3 populations widely variable in the magnitude and duration of their exposure to dioxin. One was a group of plant workers in a German chemical manufacturing plant, one was comprised of men, women, and children living in the vicinity of Seveso, Italy, during the accidental release of 2,3,7,8-TCDD in 1976, and the third was comprised of adult North Carolina volunteers, with no known occupational or unusual exposures to dioxin. This third group is comprised of 29 individuals, with ages ranging from 21 to 52 years, mean of 34.5 years, and it is the results from their analyses that are considered here as a U.S. background population. Grassman et al. (1999) reported that their average lipid-based TEQ_{DFP}-WHO_{94} was 14.2 ppt. Results of the study comparing the three study groups are reported in Grassman et al. (1999).

The North Carolina participants were sampled in 1996. EPA was provided the congener specific data for the 29 individuals of this study (Masten, 2000). Average congener concentrations from this group are provided in Table 4-17. Interferences were found in the analysis for 1,2,3,6,7,8-HxCDD, so this congener was not reported for any of the individuals, and TEQs were calculated without this congener. Other body burden data

suggests that this congener could comprise in the range of one-fourth to one-third of the body burden of TEQ_{DFP}, so the overall TEQ for this population is underestimated. A small number of additional measurements from other congeners were not reported, and these were not considered in the generation of mean congener values. The mean values were calculated by assuming that non-detects were equal to one-half the detection limit. With this procedure, the lipid-based TEQ_{DFP}-WHO_{98} was calculated to be 15.0 ppt. Assuming that non-detects are equal to zero would not change these results by much; the lipid-based TEQ_{DFP}-WHO_{98} in this case was calculated as 13.0 ppt.

The CDC compilation includes these same data from the 29 North Carolina individuals. The congener profile for the overall compilation done by CDC is shown in Table 4-18. These averages were derived assuming non-detects were equal to ½ the detection limit. These average congener concentrations were derived only using data from the overall set where these congeners were reported. As noted in the above discussions, there were some studies where congeners were not reported, such as 1,2,3,6,7,8-HxCDD. Therefore, the number of observations that went into calculating overall averages for each congener was less than or equal to the total number of individuals (n = 316) in the study. These congener profiles were not used to generate TEQ concentrations for the overall data base. Instead, Patterson (2000) supplied statistical results for the TEQ_{DFP}-WHO_{98} concentrations that were generated using substitution methods for each individual included who had "not reported" (NR) for some of the congeners. Each time a congener was NR in an individual's congener profile, the average concentration from other individuals in the same study set was substituted for the individual who had the missing data. When that congener was missing from an entire study set, then the average for that congener from all other data sets where it was reported was substituted for all individuals in the data set with the missing congener. With these substitution techniques, every individual included in the overall data base had a complete set of congener results including quantified concentrations, non-detects with known detection limits, and substituted values. Then, each individual's TEQ_{DFP}-WHO_{98} lipid-based concentration was derived (assuming non-detects equal ½ detection limit), and from these TEQs, means and percentiles were generated. By this discussion, it should be clear that one cannot derive the TEQ concentrations in Table 4-18 from the congener profiles in Table 4-18, although they will be close.

As seen in Table 4-18, the average lipid-based TEQ_{DFP}-WHO_{98} concentration was 22.1 ppt. It was found that the substituting ND = ½ LOD did not influence the TEQ results. At ND = 0, the average TEQ concentration was only 1 ppt lower at 21.1 ppt TEQ_{DFP}-$WHO_{98.}$ However, this TEQ_{DFP}-WHO_{98} concentration included only 4 of the 12 coplanar PCB congeners. The overall compilation of literature data on coplanar PCB concentrations in human tissues, other than this CDC compilation, shown later in this chapter in Table 4-21, includes data on 11 of the dioxin-like coplanar PCBs. That data suggests a weighted mean TEQ_P-WHO_{98} concentration in blood of 15.6 ppt TEQ_P-WHO_{98}, of which these four congeners comprise 5.9 ppt. Therefore, the congeners missing from the CDC data base account for 62% [(15.6-5.9)/15.6 * 100%] of the total PCB TEQ estimated in the early 1990's for blood. From the congener profile in Table 4-18, it is calculated that the 4 PCB congeners add about 2.0 ppt TEQ to the overall mean concentration of 22.1 ppt. Assuming that the missing congeners from the CDC study data contribute the same proportion to the total PCB TEQ as in earlier data, they would increase the estimate of current PCB blood concentrations by another 3.3 ppt TEQ_P-WHO_{98} lipid for a total PCB TEQ of 5.3 pg/g lipid and a total TEQ_{DFP}-WHO_{98} of 25.4 ppt lipid. This will be the TEQ lipid concentration assumed to represent current background conditions in the United States.

4.2.4. Additional Recent Tissue Studies

Petreas, et al. (2000) reported on the analysis of breast adipose tissue samples for the seventeen dioxin-like CDD/F congeners. Samples were taken in 1998 from women in San Francisco area hospitals undergoing breast surgery for suspected breast cancer. l-TEQ_{DF} concentrations were reported for 45 of these women who were found to be cancer-free. The range of l-TEQ_{DF} concentrations found in this study population was 10 to 60 ppt lipid-basis, with a median concentration of 19 ppt. This was calculated assuming non-detects were equal to ½ the detection limit. When assuming non-detects were equal to zero, this dropped slightly to 16 ppt l-TEQ_{DF}. When recalculating TEQs using the WHO_{98} TEF scheme, Petreas et al. (2000) found the concentrations to increase by 2-3 ppt. These concentrations compare well to the mean concentration of WHO_{98}-TEQ_{DF} of approximately 21.6 ppt lipid-basis found in the 316 samples of the CDC compilation (Patterson, 2000) reported on earlier. These results were compared to a set of 17 adipose

samples from other women patients undergoing surgeries for other reasons 10 years earlier in 1988. From 17 samples, the range was similar at 13 to 63 I-TEQ_{DF}, but the median was higher at 27.3 pg/g I-TEQ_{DF} lipid-basis. Other analyses by Petreas demonstrate the apparent downward trend in body burdens in these adipose tissues.

4.2.5. Summary of Human Tissue Levels

Tables 4-19 and 4-20 present summaries of the TEQ_{DF} concentrations in human tissues from North America, and Europe and Japan, respectively, as reported in the literature. In general, these data represent studies conducted in the late 1980s and early 1990s. These data on human adipose tissue, blood, and breast milk indicate that mean tissue concentrations of CDD/CDFs ranged from 20 to 50 ppt TEQ_{DF}-WHO_{98} on a lipid basis, with a midpoint of 35 ppt TEQ_{DF}-WHO_{98} during that time period. The mean TEQ_{DF}-WHO_{98} from the U.S. studies was 32.7 ppt, and the mean from the European and Japanese studies was 41.0 ppt. The assumption is made here that levels in all three tissues are similar (on a lipid basis) and that levels in all of these tissues can be considered representative of overall body burden. Van den Berg et al. (1994) reported that (on a lipid basis) the serum-to-blood tissue ratio for 2,3,7,8-TCDD is approximately one and this ratio increases with higher chlorinated CDD/CDFs. Van den Berg et al. (1994) also compared lipid-based concentrations for all CDD/CDF congeners reported in human milk, blood, and adipose, and concluded that the levels are strikingly similar across tissues.

It should be noted that all available human tissue studies have uncertainties that prevented a precise, statistically-based estimate of the national mean. Except for NHATS, the number of people in the available studies of CDD/CDFs in human tissues is relatively small, and participants are not selected in a statistically based manner. Other biases may have also been present in NHATS, as well as in other studies. Thus, it is uncertain how representative these data were of the general population.

Tables 4-21 and 4-22 present summaries of PCB TEQ concentrations in human tissues from North America and Europe, respectively, based on data from the 1980s and early 1990s. The average tissue level of dioxin-like PCBs for the general U.S. population was probably within the range of 10 to 30 ppt TEQ_{P}-WHO_{98} on a lipid basis, with a midpoint of about 20 ppt. The mean TEQ_{P}-WHO_{98} from these U.S. studies was 16.7 ppt. The mean from the European studies was 31.9 ppt. This indicates that on a TEQ_{P}-WHO_{98},

PCB levels were between one-half and two-thirds that of CDD/CDFs. Inclusion of dioxin-like PCBs raised the estimate of U.S. human tissue levels to approximately 30 to 70 ppt TEQ_{DFP}-WHO_{98} (midpoint = 55 ppt) for the late 1980s and early 1990s.

As discussed above, the representativeness of these PCB studies for the general population is unknown. The toxic equivalency factors for PCBs are not as well established as the CDD/CDFs and increase uncertainty in these estimates. Uncertainty is also increased by the high background levels of PCBs found in many laboratories, which can create analytical difficulties. In addition, not all studies presented data for the same set of PCB congeners. Therefore, studies were combined to calculate a total TEQ_P-WHO_{98} based on all PCB congeners for which TEF_P-WHO_{98}s have been established. Total TEQ_P-WHO_{98}s were calculated by summing weighted mean TEQ_P-WHO_{98} concentrations (based on one or more studies) for each toxic PCB congener.

The CDC data base includes 316 individuals from 6 sites in the time frame of 1995-1997. These data form the basis of the estimates of current background tissue levels in the United States. The mean TEQ tissue level from the study data alone is 22.1 ppt TEQ_{DFP}-WHO_{98}. Because this concentration does not include important dioxin-like PCB congeners, this average has been increased to 25.4 ppt TEQ_P-WHO_{98} using information from earlier studies of dioxin-like PCBs in blood. This concentration will be used to represent current background conditions in the United States. This use includes an overall conclusion for body burdens of dioxin-like compounds in this chapter, as well as an assumption for mother's milk concentration in an evaluation of the impacts of nursing on infants in Chapter 5.

It is important to note that the 95th percentile concentration from this study data base is 38.8 ppt TEQ_P-WHO_{98}, which is nearly twice the mean of 22.1 ppt TEQ_P-WHO_{98} from this study. Later in this chapter, variation in background dose is investigated using data on dietary consumption of fats. Using statistical surveys on food consumption, it was found that the 95th percentile of fat consumption was about twice the mean (and the 99th percentile is about 3 times the mean). Knowing that dioxins are transmitted primarily through consumption of dietary fat, this result from the CDC blood compilation is consistent with the dietary result; the 95th percentile consumption of dietary fat appears to lead to the 95th percentile in body burden of dioxin-like compounds.

A portion of the CDC blood data were plotted as a function of age. This plot is shown in Figure 4-1. This figure was generated as part of a site-specific study conducted by the Agency for Toxic Substances and Disease Registry at Mossville, Louisiana (ATSDR, 1999). The data shown in Figure 4-1 encompass the control population that was to be compared against measurements in Mossville. This comparison population is a subset of the full CDC (2000) population. Figure 4-1 shows that blood levels generally increase with age, and also that the variability in blood levels increase with age. An age trend such as this one has been observed in other studies, such as the NHATS tissue data described earlier (U.S. EPA, 1991a).

4.2.6. Body Burden Profiles

The profiles for CDD/CDF concentrations in human adipose tissue, blood, and human milk are presented in Figure 4-2 and Table 4-23 based on the literature studies from the 1980s and early 1990s. These profiles were generated by calculating the ratio of the mean concentrations of the 2,3,7,8-substituted congeners to total concentration of 2,3,7,8-substituted CDD/CDFs when nondetects were set to one-half the detection limit. In addition, it should be noted that some studies (i.e., adipose tissue - Schecter, 1991 and U.S. EPA, 1991a; blood - Schecter et al., 1994a and Cole et al., 1995) reported total 2,3,7,8-substituted HxCDD/F and HpCDD/F concentrations instead of reporting concentrations for the individual HxCDD/F and HpCDD/F congeners. Thus, in order to provide a complete profile based on all 17 of the 2,3,7,8-substituted congeners, the concentrations of total HxCDDs, HxCDFs, HpCDDs, and HpCDFs from these studies were apportioned among the individual HxCDD/F and HpCDD/F congeners based on the ratios of individual congeners to total HxCDD/Fs and HpCDD/Fs reported in studies providing data for the individual 2,3,7,8-substituted HxCDD/F and HpCDD/F congeners (i.e., adipose tissue - Patterson et al., 1994; blood - Schecter et al., 1993). The profiles generated for these three body tissues appear to be similar. In general, higher-chlorinated CDDs dominate with OCDD accounting for over 65 percent of the total 2,3,7,8-substituted CDD/CDFs. CDFs account for a relatively small portion of the total 2,3,7,8-substituted CDD/CDFs.

The profile of 2,3,7,8-CDD/CDF congeners in human blood from the more recent (i.e., 1995-1997) CDC blood data set was also generated. This profile is shown in Figure

4-3 and is based on the data in Table 4-18. The profile is similar to that generated from earlier human tissue data (Figure 4-2).

4.3. INTAKE ESTIMATES BASED ON TISSUE LEVELS AND PHARMACOKINETIC MODELING

4.3.1. Steady State Approach

Examination of human tissue data provides a way to estimate exposures of humans to CDD/CDFs. Average daily intake of CDD/CDFs may be estimated using human tissue data and pharmocokinetic modeling as follows:

$$D = \left[\left(\frac{\ln 2}{t_{1/2}}\right) V * CF_1 (C) CF_2\right] / (A) \qquad \text{(Eqn. 4-4)}$$

where:

D	=	Daily intake of CDD/CDF (pg/day);
$T_{1/2}$	=	Half-life of CDD/CDF (years);
V	=	Volume of body fat (kg);
C	=	Concentration of CDD/CDF in tissue (pg/g)
CF_1	=	Conversion factor (1,000 g/kg);
CF_2	=	Conversion factor (year/365 days); and
A	=	Fraction of dose that is absorbed.

The level of 2,3,7,8-TCDD found in human adipose tissue averages about 5.5 ppt in the United States based on data from a variety of studies from the 1980s and mid 1990s, and 2.1 pt based on the CDC data set. These values may be used to estimate the associated exposure levels using a simple pharmacokinetic model that back calculates the dose needed to achieve the observed tissue levels under the assumption of steady-state exposure/dose, as given above. (See Equation 4-4.) This model requires an estimate of the fraction of the dose that is absorbed, the elimination rate constant, and body fat volume.

A complete summary of the literature on gastrointestinal, dermal, transpulmonary, and parenteral absorption is provided in Part II - Health Assessment of 2,3,7,8-Tetrachlorodibenzo-*p*-dioxin and Related Compounds, Chapter 1 - Disposition and Pharmacokinetics. The summaries there pertaining to oral absorption justify the selection of 0.8 as an absorption fraction for dioxin TEQs in simple exercises conducted in this section on pharmacokinetic modeling. Most of the gastrointestinal absorption research has been conducted on 2,3,7,8-TCDD and laboratory animals. Results suggest that 2,3,7,8-TCDD is absorbed at a rate greater than 50% in oil or in diet, with several studies reporting average absorption at 70% or more: Rose, et al. (1976) found an average of 84% in rats where the vehicle was a mixture of acetone and corn oil; Piper, et al. (1973) found an average of 70% on rats with the same vehicle; Diliberto et al. (1996) reported 88% in rats in a vehicle of vegetable oil, ethanol, and water; and Olson, et al (1980) reported 70% in hamsters in a vehicle of olive oil. Similar and even higher absorption was found for 2,3,7,8-TCDF, 1,2,3,7,8-PCDD, 2,3,4,7,8-PCDF, and 3,3',4,4'-TCB. Lower absorption at 2 to 15% was found for OCDD (Birnbaum and Couture, 1988), but since background TEQ doses are dominated by the lower chlorinated congeners, the low absorption of OCDD may be less critical. In limited studies and evaluations of oral absorption on humans, it is concluded that the more soluble congeners, such as 2,3,7,8-TCDF are almost completely absorbed, whereas the extremely insoluble OCDD is poorly absorbed. In one experiment, Poiger and Schlatter (1986) found that >87% of the oral dose of TCDD in corn oil in a 42 year-old man was absorbed from the gastrointestinal tract. Like some of the experiments on rats, the amount absorbed in some cases was dose dependent, with lower absorptions at higher doses. Again, low absorption at high doses is less critical for the current exercises, which focus on low background dose of TEQs.

Flesch-Janys et al. (1996) estimated the half-life of 2,3,7,8-TCDD (and other CDD/CDFs) based on blood levels of a group of occupationally exposed individuals. The median half-life for 2,3,7,8-TCDD (n=48) was estimated to be 7.2 years. Half-lives for other CDD/CDF congeners ranged from 3.0 to 19.6 years. Van der Molen et al. (1998) estimated the elimination rate constant of 2,3,7,8-TCDD using data on the TCDD blood lipid levels of Vietnam veterans who had been involved in the spraying of Agent Orange. The Van der Molen et al. (1998) model predicted half-lives ranging from 5.5 years in

young adults to 11 years in elderly men. The model accounted for age-dependent body composition, and age- and time-dependent background intake.

Ryan et al. (1997) reported the elimination rate constant of 2,3,7,8-TCDD by back calculating from the levels in 1992 and 1996 blood samples collected from six of the 2,4,5-trichlorophenoxyacetic (2,4,5-T) workers in Russia. The elimination rate constants of four of the six samples ranged from 6.9 to 17 years (6.9, 9.7, 9.7, and 17, respectively), while those of two of the six samples were incalculable. Ryan et al. (1997) stated that these four values were in the range reported by other investigators. However, no supporting references were provided. Due to the large variability of values, the small sample sizes (one single value for each sample), and a potential inconsistency in sample analysis (samples were analyzed by two different laboratories at two different times), there is uncertainty in these values. Therefore, these values require further consideration.

Based on available data, the elimination rate constant (i.e., half-life) for 2,3,7,8-TCDD was assumed to be about 7.1 years, and the fat volume was assumed to be 17.5 kg (i.e., 70 kg body weight * 0.25 fat) which yielded a background TCDD dose of about 32 pg/day using the TCDD tissue estimate from the 1980s to mid 1990s (5.5 ppt), and 12 pg/day (0.18 pg/kg/day) using the TCDD tissue concentration from the CDC data set (2.1 ppt). These estimates agree well with the background exposure estimates (to 2,3,7,8-TCDD only) of 35 pg/day by Travis and Hattemer-Frey (1991) and 25 pg/day by Fürst et al. (1991), but are somewhat higher than the current background exposure estimate of 5.6 pg/day from this assessment (see Section 4.4.2), as derived using typical media levels and contact rates. Using the current CDD/CDF TEQ body burden data presented in Table 4-18 and the pharmacokinetic model presented in Equation 4-4, the average daily intake of total CDD/CDFs is estimated to be 126 pg TEQ_{DF}-WHO_{98}/day. This estimate assumes a half-life of TEQ_{DF}-WHO_{98}s in the body of 7.1 years, a fat volume of 17.5 kg, a concentration in the body fat of 21.6 ppt (i.e., the approximate mean TEQ concentration for CDD/CDFs only, as calculated from the data in Table 4-18), and steady-state conditions. This value is also three times higher than the current background exposure estimate of 41 pg TEQ_{DF}-WHO_{98}/day from this assessment, as derived using typical media levels and contact rates. If PCBs are included in this exercise (i.e., using the current TEQ_{DFP}-WHO_{98} background tissue concentration of 25.4 ppt) the estimated TEQ_{DFP}-WHO_{98} dose would be 146 pg/day. This estimate is approximately 2.2 times higher than

the direct estimate from the dietary data of 65 pg TEQ_{DFP}-WHO_{98}/day. Because this model was originally developed for use with 2,3,7,8-TCDD, the effect of using it to model CDD/CDFs introduces uncertainty into these estimated values.

An important uncertainty in the modeling exercise described above was the assumption that the half-life estimate for 2,3,7,8-TCDD (7.1 yr) would apply to TEQ_{DF}-WHO_{98}s. Thus, the same pharmacokinetic model was applied to average human tissue levels for each congener, using half-lives that are specific to each congener, and then summing the estimated intakes for each congener. This approach yielded an estimated intake of 87 pg TEQ_{DF}-WHO_{98}/day (Table 4-24). This value is approximately 2 times higher that the current background estimate of 41 pg TEQ_{DF}-WHO_{98}/day.

Another, perhaps more important, uncertainty in using this approach to estimate current dose is that the dose is assumed to be constant over time. If, in fact, the dose which has resulted in current average body burden were constant over the past several decades, than use of this steady-state PK model would provide quite reasonable estimates of current dose. The only uncertainty in this case (beside the simplistic nature of it being a one-compartment PK model) is the use of 7.1 years as the half-life (as described above). If the dose regime instead was characterized by very low doses in the middle of the twentieth century only to rise significantly in the latter part of the century, than this model would, by definition, provide an underestimate of current dose. If, on the other hand, doses were very much higher in the mid-portions of the twentieth century only to drop towards the end of the century, than this steady state model would, by definition again, provide an overestimate of the current dose. The steady-state model only provides an average dose over time that could account for a given body burden - it obviously doesn't address the possibility of changes in dose over time. As will be described in the next section, there is a very large amount of evidence suggesting that doses were higher in the mid-decades of the twentieth century, and may be significantly higher, as compared to the latter decades. The tissue levels representing the "current average body burdens" included a significant number of individuals living in this middle decades of the twentieth century. This being the case, it is concluded that the steady state approach will overestimate current dose.

4.3.2. Non-Steady State Approach

Chapter 6 describes evidence supporting temporal trends in CDD/CDF/PCB concentrations in environmental media, foods, and associated doses. It appears that the levels of dioxin-like compounds have increased in the environment starting from the 1930s through the 1960s, and loadings began to decline perhaps starting in the 1970s to the present. Recent evidence collected on animal food products in the United States (Winters, et al., 1998), combined with body burden data, provide evidence that human exposures to dioxins may have followed the same trends. (See Chapter 6.)

Pinsky and Lorber (1998) used a non-steady state approach to reconstruct the pattern of past exposure and estimate current exposure to 2,3,7,8-TCDD, using a simple pharmacokinetic model that included a time-varying TCDD dose. A first order, one-compartment PK model was used to compute an individual's body lipids TCDD concentration through time. Key inputs for that model include: (1) a time-varying dose of TCDD (expressed in units of pg/kg-day), (2) a fraction of dose absorbed into the body lipid compartment (assumed to be constant), (3) the volume of the body lipid compartment (assumed to be time varying), and (4) a rate of TCDD loss from the lipid compartment (modeled as a function of the percent of body fat). In order to calculate the rate of TCDD loss, a model of how body lipid volumes vary over time, in addition to a model of how overall body weight varied over time, was required.

In this modeling exercise, all inputs were fixed, except the time-varying dose of TCDD. Using Bayesian statistical approaches, the non-steady state dose was "calibrated" to best-fit a set of data on TCDD concentration in body lipids from the 1970s to the 1990s. The results of this exercise indicated that the dose appears to have increased from the 1940s through the 1960s, and began to drop through the 1970s, with a baseline level being reached by the 1980s. The results suggest that TCDD exposures may have been 20 times higher during the 1960s than the 1980s. Over a 10-year peak period in the 1960s and early 1970s, daily exposures could have been as high as 1.5 to 2.0 pg/kg-day, possibly dropping as low as 0.10 pg/kg-day (7 pg/day) and less into the 1980s. This estimate of current dose of 7 pg 2,3,7,8-TCDD/day is quite similar to the estimate of 6.1 pg 2,3,7,8-TCDD/day made using typical media levels and contact rates. In another test, Pinsky and Lorber (1998) used the same modeling structure to test the steady state assumption by forcing the dose to be constant over time. In that test, Pinsky

and Lorber (1998) solved for a 'best-fit' dose of 0.35 pg/kg-day. This is higher than the 1980s calibrated 'current dose' of 0.10 pg/kg-day, derived by allowing the dose to vary over time. As described in the previous section, if much higher doses of dioxin occurred in the middle part of the twentieth century, than a steady state model will provide an overestimate of current dose; in other words, this Pinsky and Lorber (1998) result is to be expected. In addition, the steady-dose 'best-fit' solution provided a significantly poorer fit to the data as compared to the non-steady dose solution, providing even more evidence that doses have not been steady during the twentieth century. (See Chapter 6 for a complete description of this modeling approach.)

4.4. INTAKE ESTIMATES BASED ON EXPOSURE MODELING

4.4.1. Previous Assessments of Background Exposures

Several researchers have published quantitative assessments of human exposures to CDDs and CDFs. Some of the more recent assessments are discussed below (Travis and Hattemer-Frey, 1991; Fürst et al.,1990; Fürst et al., 1991; Henry et al., 1992; Theelen, 1991; Schuhmacher et al., 1997; Gilman and Newhook, 1991; Schrey et al., 1995; MAFF, 1995; and Jacobs and Mobbs, 1997; Himberg, 1993; and Liem et al. 2000a, 2000b). It is generally concluded by these researchers that dietary intake is the primary pathway of human exposure to CDDs and CDFs. Over 90 percent of human exposure occur through the diet, with foods from animal origins being the predominant sources.

Travis and Hattemer-Frey (1991) estimated that the average daily intake of 2,3,7,8-TCDD by the general population of the United States is 34.8 pg/day. Ingestion exposures were estimated by multiplying the concentration of 2,3,7,8-TCDD in beef, milk, produce, fish, eggs, and water (estimated using the Fugacity Food Chain model) times the average U.S. adult consumption values for these products reported by Yang and Nelson (1986). The calculations assume that 100 percent of the 2,3,7,8-TCDD ingested are absorbed through the gut. Intake via inhalation was estimated by multiplying the concentration in air times the amount of air inhaled per day (20 m^3) assuming that 100 percent of inhaled 2,3,7,8-TCDD are absorbed through the lung. The results of their assessment, summarized in Table 4-25, indicate that foods from animal origins comprise

95 percent of the estimated total daily exposure. These foods include milk and dairy products, beef, fish, and eggs. Exposure resulting from consumption of vegetables and other produce was estimated to account for 3.4 percent of the total intake. Exposure from ingestion of water, ingestion of soil, and inhalation of air together accounted for about 1 percent of the total daily intake.

Fürst et al. (1990) estimated human exposure to CDD/CDFs based on the analysis of 107 food samples collected in the Federal Republic of Germany. The average daily I-TEQ_{DF} intake was estimated to be 85 pg/person/day or 1.2 pg/kg body weight/day. Fürst et al. (1990) concluded that foods of animal origin contribute significantly to the human body burden of CDD/CDFs. In a subsequent study, Fürst et al. (1991) assessed human exposure to CDDs and CDFs from foods using data from more than 300 randomly selected food samples and food consumption data reflective of consumption habits of the German population. These authors estimated that the German population's average daily intake of CDDs and CDFs from food is 158 pg I-TEQ_{DF} per person of which 25 pg is 2,3,7,8-TCDD. Dairy products, meat and meat products (primarily beef), and fish and fish products each contribute about 32 to 36 percent of the daily intake of I-TEQ_{DF}. Based on the levels of CDD/CDFs observed in human samples, the average daily intake via food was estimated to be in the range of 1 to 3 pg I-TEQ_{DF}/kg body weight.

Henry et al. (1992) of the U.S. Food and Drug Administration estimated the average exposure to the U.S. population from 2,3,7,8-TCDD through the food supply using the following assumptions: (1) all dairy products have background lipid 2,3,7,8-TCDD levels equivalent to those found in milk and half-and-half, i.e., about 55 ppq (whole dairy food levels were estimated using percent fat in each food); (2) levels averaging 35 ppq in beef tissue are present in all meat products; (3) ocean fish with tissue levels equal to half of the detection limit (about 0.5 ppt) are the sole fish source in the diet; (4) average food consumption figures (total-sample-basis) available from nationally representative data bases were used for frequency of eating (Market Research Corporation of America's (MRCA) Menu Census VI (1977-78)) and for serving sizes (U.S. Department of Agriculture's 1977-78 National Food Consumption Survey). The concentration assumptions used in the Henry et al. (1992) study were based on previously published data. For example, most of the food data were based on La Fleur et al. (1990), and the fish data were based on U.S. EPA (1992). These studies are described in Sections 3.7.2

and 3.6.1, respectively. FDA's estimates of 2,3,7,8-TCDD intake were derived by multiplying the food dioxin levels by the average amounts of food consumed per day. The results of the FDA assessment, summarized in Table 4-26, indicate an average daily exposure of 15.9 pg/day of 2,3,7,8-TCDD of which 4 percent are due to dairy and milk products, 41 percent are due to meats, and 54 percent are due to ocean fish.

Theelen (1991), of The Netherlands National Institute of Public Health and Environmental Protection, estimated the average daily intake of 2,3,7,8-TCDD and total I-TEQ_{DF} by residents of The Netherlands for various possible routes of exposure. The results, summarized in Table 4-27, indicate an average intake of 20 pg/day of 2,3,7,8-TCDD and 115 pg/day of total I-TEQ_{DF} from food and 0.08 pg/day (2,3,7,8-TCDD) and 3.2 pg/day (I-TEQ_{DF}) from combined direct air and soil exposure. Milk and dairy products make up about one-third of the total daily exposure. Animal fat in meat, poultry, and fish (i.e., fish oil) also contribute about one-third. Fish consumption represents 18.5 percent of total daily exposure. In a later study, Theelen et al. (1993) reported a median daily intake for adults of 1 pg I-TEQ_{DF}/kg body weight, and a 95th percentile rate of 2 pg I-TEQ_{DF}/kg body weight. These values were based on CDD/CDF residue levels in food products and food consumption survey data.

Becher et al. (1998) estimated dietary intake of CDD/CDFs and dioxin-like PCBs in the Norwegian population. Average food consumption data obtained from the 1992-1994 Norwegian consumer survey of 4,033 households was analyzed in conjunction with measured CDD/CDF and dioxin-like PCB concentrations in basic foodstuffs to determine dietary intake. Becher et al. (1998) investigated pooled samples from 20 to 25 seafood samples and 10 to 15 samples of other foodstuffs. Average CDD/CDF dietary intake ranged from 71 to 85 pg I-TEQ_{DF}/day and average PCB dietary intake ranged from 86 to 106 pg TEQ_{P}-WHO_{94}/day. Fish and fish products constituted the largest contribution to the dietary intake of CDD/CDFs and PCBs. PCBs contributed more to the total dioxin related toxicity (i.e.,TEQ_{DFP}-WHO_{98}) than CDD/CDFs in the following food groups: milk, meat, eggs, and cod liver oil; while CDD/CDFs were the higher contributor in the fats food group.

Buckland et al. (1998) estimated dietary intake of CDD/CDFs and PCBs in the population of New Zealand. The estimate was based on 19 food group composites from 51 individual food samples purchased from retail outlets in four major cities and one

provincial center. Estimated dietary intake was calculated based on two typical diets, an average exposure diet of an adult male and a high-end exposure diet of an adolescent male. Total dietary levels of all CDD/CDF congeners ranged from 14.5 to 30.6 pg I-TEQ_{DF}/day (whole weight). Total dietary PCB levels ranged from 12.2 to 22.7 pg TEQ_P-WHO_{94} (whole weight). Total PCB concentration was based on levels of the following PCBs: 28, 31, 52, 77, 101, 99, 123, 118, 114, 105, 126, 153, 138, 167, 156, 157, 169, 187, 183, 180, 170, 189, 202, 194, and 206. These calculations were made by setting concentrations less than the LOD at one-half the LOD. Vegetable fats/oils, cereals, cooked potatoes and hot chips, and processed meats constituted the largest contribution to I-TEQ_{DF}s in the adolescent diet. Butter, processed meats, and milk constituted the largest contribution of TEQ_P-WHO_{94}s to the adolescent diet. The authors noted that while it is difficult to compare these total dietary TEQ results to countries with different dietary patterns, the results appear to indicate that estimated dietary intake of CDD/CDFs and PCBs is lower in New Zealand than in other countries that have conducted similar studies (e.g., USA, UK, Spain, The Netherlands, Federal Republic of Germany, and Norway).

Schuhmacher et al. (1997) and Domingo et al. (1999) estimated dietary intake of CDD/CDFs based on the analysis of 35 food samples from local supermarkets in Catalonia, Spain. Most of the results are in agreement with the recent data reported elsewhere; however, the levels in whole milk, vegetables, lentils and beans, and cereals are higher than those reported in previous studies. The average intake per adult was estimated as 210 pg I-TEQ_{DF}/day. The contributions from vegetables and cereals were relatively high (8.13 percent and 23.09 percent, respectively, of total intake) compared to previous studies where the vegetable and cereal contributions are almost negligible. The high contributions may be explained by high consumption of these foods in the Mediterranean diet. Schuhmacher et al. (1997) stated that since the Mediterranean diet is typical throughout most Spanish regions, the results reported could be a representative of the dietary intake of CDD/CDFs in Spain.

Gilman and Newhook (1991), of the Canadian Department of National Health and Welfare and the Ontario Ministry of the Environment, respectively, estimated an average lifetime daily intake of 140 to 290 pg of I-TEQ_{DF} for the typical Canadian. Their results, summarized in Table 4-28, indicate that between 94 and 96 percent of the estimated

intake are from food sources. No breakdown of intake by food type was provided in the report.

Schrey et al. (1995) estimated dietary intake of CDD/CDFs using the duplicate method. A total of 14 food samples that were duplicates of the food eaten by seven German men and seven German women (age 24-64 years) were collected and analyzed for CDD/CDFs. The 3-day sampling period included both weekdays and weekends. All samples contained detectable levels of 2,3,7,8-substituted CDD/CDFs, but OCDD had the highest concentrations. Daily intake was estimated to range from 3.3 to 14 pg/day (0.026 to 0.26 pg/kg-day) for 2,3,7,8-TCDD and 23 to 96 pg/day (0.18 to 1.7 pg/kg-day) for I-TEQ_{DF}s. These values are slightly lower than those observed in earlier German studies conducted by Beck et al. (1991), even though the dietary intake of fat was similar.

Recently, the United Kingdom's Ministry of Agriculture, Fisheries, and Food (MAFF, 1995) analyzed Total Diet Study samples collected during 1982 and 1992 for CDD/CDFs to analyze trends in dioxin intake over recent years. Samples of 11 food groups collected from 24 locations in the United Kingdom were analyzed. The average intake of dioxins from each food group was calculated by multiplying the CDD/CDF residue concentration in the food group by the average daily intake of the food based on data from the United Kingdom's National Food Survey. Average daily intake of I-TEQ_{DF}s was estimated to be 240 pg/day in 1982 and 69 pg/day in 1992 (Table 4-29). These values represent upper bound exposures because I-TEQ_{DF}s were calculated by setting nondetects to the limit of detection. Based on these results, the authors concluded that the relative contributions of the various food groups to total dioxin intake in the United Kingdom have changed over the years. In the most recent study, the proportion of total exposure attributable to cereal products increased, while exposures from fats, oils, and milk products decreased.

Jacobs and Mobbs (1997) conducted a reassessment of human dietary exposure to CDD/CDFs in the UK. Based on the data of the UK Total Diet Survey (TDS) in 1992, the levels of CDD/CDFs in 11 fat-containing food groups were recalculated. Instead of using the food consumption data from the UK's National Food Survey as in the MAFF study, Jacobs and Mobbs (1997) obtained individual dietary intake data from three other surveys that included adults, children (aged 1.5 to 4.5 years), and infants (aged 6 to 12 months) in the UK. Combining the dietary intake data with the data of CDD/CDF levels in foods, Jacobs and Mobbs (1997) reported an adult daily dietary intake of CDD/CDF as 175.5 pg

I-TEQ_{DF}/day (2.93 pg TEQ/kg/day), a value that is more than twice that estimated by MAFF (1995). The levels for young children ranged from 54.19 pg I-TEQ_{DF}/kg/day at 6 months of age, to 0.25 pg TEQ_{DF}/kg/day at 4.5 years of age. It should be noted that for infants (under 1 year of age), breast milk is the largest contributing source. Estimation of the cumulative dietary I-TEQ_{DF} intake indicated that the levels peak sharply between age 0 and 1 year at about 80 pg I-TEQ_{DF}/kg/day, decrease until 10 years of age, and then rise to about 15 pg TEQDF/kg/day at 22 years of age.

Dioxin-like PCBs can also contribute to TEQ exposures. Himberg (1993) evaluated exposures to dioxin-like PCBs 77, 15, 126, and 169 in Finnish foods. Based on fish, beef, pork, poultry, and inner organs, total TEQ_P-WHO_{94} intake was estimated to be 118 pg/day, calculated using TEQ_P-WHO_{94} concentrations in foods and consumption data from Finland's 1990 household survey. PCB congeners 105 and 126 contributed the most to total TEQ_P-WHO_{94} intake. Intake of PCBs in fish products accounted for the greatest proportion (i.e., approximately 70 percent) of the total TEQ_P-WHO_{94} intake from these foods.

Currado and Harrad (1997) measured air concentrations of PCBs from 9 different indoor environments, including two laboratories, two offices, and five residential houses in the United Kingdom (UK). The results indicated that the total PCB levels found in indoor air (1.4 to 19.1 ng/m^3, mean = 7.1 ng/m^3) were between 2 and 19 times higher than the levels in outdoor air (0.77 to 0.87 ng/m^3, mean = 0.82 ng/m^3). Currado and Harrad (1997) also calculated the daily human intake of PCBs via inhalation. The estimate ranged from 36.9 to 176.5 ng/person/day (mean = 103.5 ng/person/day), and represented between 10 and 33 percent of overall exposure to PCBs for a typical UK individual with a 340 ng/day dietary intake of PCBs (estimated by the UK Ministry for Agriculture, Fisheries and Food (MAFF) in 1992). Currado and Harrad (1997) suggested that, compared to the dietary intake of 340 ng/person/day of PCBs, inhalation of indoor air might be a significant pathway for PCB exposure. It should be noted that the study did not focus on dioxin-like PCBs; only concentrations of four dioxin-like PCB congeners were reported for indoor and outdoor areas.

Liem et al. (2000a) reported on a European cooperative study coordinated by the National Institute of Public Health and the Environment in the Netherlands, and the Swedish National Food Administration. Ten countries, including Belgium, Denmark,

Finland, France, Germany, Italy, The Netherlands, Norway, Sweden, and the United Kingdom, delivered available data on the occurrence of PCDDs, PCDFs, and dioxin-like PCBs in food products and human milk. When available, these countries also delivered data on the consumption of these foods and other data on the dietary exposures of the general populations of these countries. Consumption data were combined with concentration data to arrive at exposure doses in pg TEQ_{DFP}-WHO_{94}. Concentrations and doses expressed in terms of the more recent WHO 1998 TEF scheme are generally higher than these earlier TEF schemes, by about 5-10%, in American food and environmental media. Some countries also provided consumption data representative of the 95th, or 97.5, percentile of the population. These consumption data were combined with mean concentration data from the countries to evaluate higher end exposures of the general population. Liem et al. (2000) concluded that data were reasonably available for dioxins and furans, but limited for the dioxin-like PCBs.

Based on the short summary of this effort in Liem et al. (2000a), it appears that trends in European CDD/F food concentrations and exposures are consistent with those from the United States, although dioxin-like PCB concentrations may be somewhat higher in Europe. National average concentrations of CDD/Fs in eggs, fats and oils, meat products, and milk products are generally less than 1 up to 2-3 pg/g fat, I-TEQ_{DF} basis. Concentrations in fruits, vegetables and cereals were found to be generally close to the limits of detection. Some of the data suggested reductions in concentrations over time, but the available information was insufficient to draw general conclusions. Limited data on dioxin-like PCBs suggest average TEQ_P-WHO_{94} that are between 1 and 2 times higher than I-TEQ_{DF} concentrations in all food products, more so in fish. PCB TEQ concentrations in fish were between 0.25 and 10-20 pg/g fat WHO_{94}-TEQ_P. In contrast, in the United States, TEQ concentrations of dioxin-like PCBs are roughly comparable, if not lower, than TEQ concentrations of CDD/Fs in foods of terrestrial origin Some data on dioxin-like PCBs in fish suggest higher concentrations than CDD/Fs, particularly from a recent study of several fish species from the Great Lakes (Kolic et al., 2000a).

Given the limitations of the available data, Liem et al. (2000a) reported that for eight countries and for the period after 1995, the average adult dietary intakes of CDD/Fs ranged between 29 and 97 pg I-TEQ/day. This compares well to the estimate of 45 pg TEQ_{DF}-WHO_{98}/day developed in this assessment. The upper percentiles estimates of

dietary exposures, where 95 and 97.5% of consumption rates were combined with average concentrations, was 2-3 times the mean intake. This analysis was only available from data on consumption supplied by the Netherlands and the United Kingdom. This also compares well to evaluations done in this assessment based on dietary fat (and total diet) intake, which suggest that the TEQ intakes at the 95th (2 standard deviations above the mean) and 99th (3 standard deviations above the mean) percentiles would be 2 and 3 times the mean intakes, respectively.

Their limited data on dioxin-like PCBs suggest perhaps more of an impact than developed in this assessment. Their average daily intake estimates ranged between 48 and 110 pg TEQ_P-WHO_{94}, compared to the 25 pg TEQ_P-WHO_{94}/day calculated for the US in this evaluation. For countries where data were available for both CDD/Fs and PCBs, the dioxin-like PCBs contributed between a roughly equal amount (Finland, Netherlands, Sweden, United Kingdom) to approximately 4 times (Norway) the TEQ contributions of the CDD/Fs.

Other findings of interest include:

1) Based on concentrations in foods taken in the 1970s and 1980s, calculated doses were much higher, ranging from 127 to 314 pg I-TEQ/day.

2) Similar to findings in this assessment, the highest dietary contributions were made by milk and dairy products (between 16 and 39% of total TEQ intakes), meat and meat products (6-32%), and fish and fish products (2-63%).

3) The intake to breast-fed children was estimated to be between 1 and 2 orders of magnitude higher than adults, on a body weight basis. This is similar to the finding in this assessment that the average infant dose of a year's worth of breast-feeding would be about 77 pg TEQ_{DFP}-WHO_{98}/kg-day.

According to Liem et al. (2000b), "Countries that started to implement measures to reduce dioxin emissions in the late 1980s, such as The Netherlands, United Kingdom, and Germany, clearly show decreasing PCDD/PCDF and PCB levels in food and consequently a

significantly lower dietary intake of these compounds by almost a factor of 2 with the past 7 years".

As reported in Section 3.7.1, CDD/CDFs can migrate from bleached paper packaging and paper food-contact articles to foods. Some investigators have included this pathway in estimates of background exposure. U.S. EPA (1990) estimated that I-TEQ_{DF} intake due to leaching from paper products into food from paper packaging was in the range of 5.5 to 12.7 pg/d. Henry et al. (1992) estimated that daily intake of 2,3,7,8-TCDD due to migration from paper to food could amount to 12 pg/d, almost as much as the daily intake from unaffected food of 16 pg/d. (See Table 4-26.) As shown in Table 4-27, Theelen (1991) estimated that out of a total of about 120 pg of I-TEQ_{DF}/d, 9 pg of I-TEQ_{DF}/d could be due to migration from paper. These estimates are based on levels in paper before recent changes in industry practices that are expected to substantially reduce dioxin levels in paper. As discussed in Section 3.7.1, these reductions are expected to have significantly lowered the CDD/CDF levels currently found in food due to any leaching of dioxin-like compounds from paper.

Horstmann and McLachlan (1994) measured CDD/CDF levels in human skin using an adhesive tape stripping method. Skin samples of the stratum corneum were collected from the backs of eight volunteers of varying age and sex. Two additional layers of increasing depth were collected from five people. All showed a decrease in CDD/CDF levels with depth. The concentration in the first layer ranged from 1,000 to 7,800 pg/g on a total CDD/CDF basis. The second layer was an average of 43 percent lower, and the third layer was an average of 33 percent lower. OCDD was the dominant congener in all three layers. Also, non-2,3,7,8 substituted congeners were identified, congeners which are not normally present in human tissue. In addition, samples of the epidermis and subcutis were analyzed. These analyses indicated that levels of the non-2,3,7,8 substituted congeners were much higher in the stratum corneum than in the epidermis, and none were identified in the subcutis. The authors argue that because these congeners could not be transported from inside the body to the stratum corneum, the CDD/CDF in the stratum corneum must originate from external sources. Horstmann and McLachlan (1994) hypothesized that textiles could be the source of skin contamination. Thirty-five new textiles, primarily cotton products, were analyzed and found to have a total CDD/CDF

level that was generally less than 50 ng/kg; however, several colored T-shirts had high levels, with concentration up to 290,000 pg/g. The homolog patterns in the textiles were similar to the patterns found in the skin. Experiments were then conducted measuring the CDD/CDF levels in human skin before and after wearing T-shirts. Significant increases in CDD/CDF levels in the skin occurred after wearing the highly contaminated shirts for 1-2 weeks, and significant decreases in CDD/CDF levels in the skin occurred after wearing the uncontaminated shirts for 1-2 weeks. This work strongly suggests that dermal exposure to textiles may be contributing to background exposures to CDD/CDFs. Horstmann and McLachlan (1994) comment that although the levels of most CDD/CDF congeners in humans can be explained on the basis of diet, the origins of OCDD in humans is less clear. Because OCDD was found to be the dominant congener in textiles and skin, they speculate that the human body burden of this congener may result from dermal absorption. Horstman and McLachlan (1994) further discuss that human scale (stratum corneum) contributes to house dust and could lead to exposure via inhalation.

Klasmeier et al. (1999) further studied the transfer of CDD/CDFs from textiles to human skin. Spatial variability, variability among individuals, and the percent transfer from different cotton textiles was examined. Spatial variability in transfer to the skin was measured by placing 7 and 10 cm^2 patches of contaminated and uncontaminated (for background determination) textiles on the upper back of human volunteers for 8 hours. The four samples collected from the outermost layers of the skin of the back of 12 volunteers contained similar concentrations of all detected congeners. The results indicated that the skin surface properties determining the transfer of CDD/CDFs from cotton textiles to the stratum corneum of the human back did not vary. An additional volunteer wore a similarly contaminated cotton t-shirt for 72 hours. The mean percent transfer for the 72 hour exposure was 1.6 to 2.5 times higher than for the 8-hour exposure.

Matsueda et al. (1995) measured CDD/CDFs and PCBs in skin lipids from the faces of eight Japanese men between the ages of 21 and 73 years. Skin lipids were collected in the morning before washing the face, using facial wipes containing 70 percent alcohol. The I-TEQ_{DF} concentrations in the samples ranged from 8.8 ppt to 22.3 ppt with a mean of 15.3 ppt. I-TEQ_{P}-WHO_{94} concentrations ranged from 7.3 ppt to 22.5 ppt. Matsueda et

al. (1995) also collected serum samples from these same subjects. Blood I-TEQ_{DF}s ranged from 13.5 ppt to 36.5 ppt, and TEQ_{P}-WHO_{94} ranged from 7.1 ppt to 22.7 ppt.

4.4.2. Updated Assessment of Background Exposures on the Basis of Media Levels and Contact Rates

Background exposures to CDD/CDFs and dioxin-like PCBs in North America were estimated using: (1) the arithmetic mean TEQ_{DFP}-WHO_{98} levels in environmental media and food from Table 3-61; (2) the standard contact rates for ingestion of soil, water, and food, and inhalation of ambient air; and (3) the appropriate unit conversion factors. The general equation used to estimate background exposures is as follows:

$$\text{Intake (pg WHO98-TEQ/kg-day)} = \frac{\text{Daily Contact Rate x Concentration x Unit Conversion Factors}}{\text{Body Weight}} \qquad \text{(Eqn. 4-5)}$$

where:

Contact Rate = inhalation or ingestion rate (m^3/day, mg/day, L/day, or g/day); and

Concentration = residue level in media of concern (pg/m^3, ppt, or ppq).

These background exposure estimates represent administered doses and not absorbed doses.

The estimated exposures and assumptions made for adults concerning ingestion or contact rates are presented in Table 4-30 for CDD/CDFs and Table 4-31 for PCBs. Standard intake rates representative of the adult general population were used. The background exposure estimates reported here do not account for individuals with higher consumption rates of a specific food group (e.g., subsistence fishermen, cigarette smokers, and individuals with exposures from localized impacts--these are discussed in Chapter 5). The estimates are assumed to represent typical (i.e., "central tendency") U.S. background exposures, and do not account for these types of variations in the population as a result of differences in intake rates of the various food groups. Average contact rates for ingestion of soil, water, beef, pork, poultry, other meats, and eggs, and inhalation were derived from the revised Exposure Factors Handbook (U.S. EPA, 1997). The intake

rate for other meats represents total meat intake minus the intake rates for beef, pork, and poultry. Other meats could include lamb, game, etc. It should be noted that the concentration of dioxin-like compounds in other meats was assumed to be similar to that observed in beef, pork, and poultry, because data were not available for these other meats. Thus, the TEQ_{DFP}-WHO_{98} for other meats was estimated as the average of TEQ_{DFP}-WHO_{98} concentrations for beef, pork, and poultry. Mean fish ingestion rates were derived from U.S. EPA (2000). Contact rates for milk, dairy, and vegetable fats were derived from USDA (1995). The contact rate for dermal contact with soil was calculated as the skin surface area that contacts the soil (cm^2/day) x the soil adherence rate (mg/cm^2) x the dermal absorption fraction for CDD/CDFs (0.03) (U.S. EPA, 1999). The age-specific surface areas and adherence factors were based on data and estimation methods recommended in U.S. EPA (1997) and U.S. EPA (1999) for adult and child residents. The soil ingestion rates used here are those recommended by U.S. EPA (1997). Soil ingestion occurs commonly among children during activities such as mouthing of toys and other objects, nonsanitary eating habits, and inadvertent hand-to-mouth transfers. In addition to normal soil ingestion activities, some individuals exhibit behavior known as pica which involves intentional soil ingestion. Soil ingestion rates associated with pica are probably much higher. Some limited data suggest rates as high as 5 to 10 g/day for deliberate soil ingestion rates for pica children. The current Exposure Factors Handbook (U.S. EPA, 1997) suggests a central tendency value for non-pica children of 100 mg/day. To a lesser extent, soil ingestion also occurs among adults from activities such as hand-to-mouth transfer when eating sandwiches or smoking, and other inadvertent ingestion of soil, such as that in household dust. Data on soil ingestion are even more scarce for adults. Based on limited data, a central tendency value of 50 mg/day is suggested by U.S. EPA (1997), which is used here.

It should be noted that the contact rates used in this assessment for some food products (e.g., meats) are lower than those used in an earlier 1994 draft (U.S. EPA, 1994) of this document. The values in the earlier draft were based on the average of food disappearance rates and intake rates. The intake rates were 1-day diary data derived from the 1987/1988 USDA National Food Consumption Survey (NFCS) (USDA, 1995). This type of survey is considered to be the best indicator of food consumption patterns, and statistical designs used by USDA optimized the ability to correctly account for factors

such as seasonality, geography, age of recipients, and other factors. The intake data derived from the 1987/1988 USDA NFCS in the 1994 draft used assumptions to allocate meat mixtures among the various meat groups. These assumptions were required because the meat consumption rates available at the time did not account for meats consumed as mixtures. These assumptions over-estimated intake for the various individual meat groups because it was assumed that intake rates for the NFCS meat mixture category included intake of foods made up of mixed meat items only. For example, it was assumed that meat mixtures were made up of 40 percent beef, 17 percent pork, 32 percent poultry, and 11 percent fish. However, meat mixtures actually included food items that had dietary components (i.e., grains, vegetables, etc.) other than meats. Therefore, the individual meats accounted for a much smaller fraction of the mixtures than assumed in 1994. "Disappearance rates" are derived as the total amount of food that disappears (i.e., is used) from the U.S. commercial food supply divided by the number of people in the U.S., corrected for removal of bone and fat, food that goes into pet foods, and food that is imported (USDA, 1993). These rates are expected to overestimate average daily intakes because they do not account for uneaten portions, spoilage, or waste. In 1994, EPA used the USDA's report on Food Consumption, Prices, and Expenditures between 1970 and 1992 (USDA, 1993) to derive disappearance rates for each food type.

The intake data used in this current assessment are derived from a newer set of USDA intake data. EPA recently conducted a statistical analysis of the USDA food data from the 1989-1991 Continuing Survey of Food Intake among Individuals (CSFII) for inclusion in the Exposure Factors Handbook (U.S. EPA, 1997). The USDA CSFII is a 3-day survey that provides national data on the amount of food eaten by individuals over the survey period. During 1989 through 1991, over 15,000 individuals participated in the CSFII (USDA, 1995). Using a stratified sampling technique, individuals of all ages living in selected households in the 48 coterminous states and Washington, D.C., were surveyed. Individuals provided 3 consecutive days of data, including a personal interview on the first day followed by 2-day dietary records. The survey uses a statistical sampling technique designed to ensure that all seasons, geographic regions of the U.S., and demographic and sociodemographic groups are represented (USDA, 1995). EPA's analysis of the CSFII data tabulated intake rates for the major food groups, as well as individual food items. The

analysis allocated intake of meat mixtures among the various meat groups and other applicable food groups according to the percentages provided by USDA (1995), as described in U.S. EPA (1997). For example, according to USDA (1995), meat mixtures contained 20 percent beef, 2 percent pork, and 8 percent poultry. Intake of other food groups (i.e., grains, vegetables, etc.) accounted for the balance of meat mixture intake. These meat mixture fractions are considerably lower than those assumed for the 1994 draft.

As an example of the difference in the 1994 and the current food consumption rates, the 1994 pork consumption rate, 47 g/day, was derived as the average of the disappearance rate of 62 g/day and the intake rate of 32 g/day. (The intake rate of 32 g/day was estimated as the intake rate for pork of 14 g/day plus an assumed 17 percent of meat mixtures.) The resulting value, 47 g/day, is higher than the intake rate used in this current draft, 0.22 g/kg-day, or approximately 15 g/day assuming a 70 kg adult. Other differences are also significant: 77 g/day beef (1994) versus 50 g/day (currently), 68 g/day poultry (1994) versus 35 g/day, and 67/251 dairy/milk g/day (1994) vs. 55/175 g/day (currently). Also, contact rates for some of the other media are lower (e.g., soil), based on the revised Exposure Factors Handbook (U.S. EPA, 1997).

Another reason that current estimates of exposure are lower than in the 1994 document is that the estimated TEQ_{DF}-WHO_{98} concentrations for several food items (i.e., beef, pork, poultry, milk, and dairy) are also lower in this assessment than in the earlier (1994) draft. Estimates in the earlier draft were based on limited data sets for these foods, whereas the current assessment uses data from the more recent statistically-based national analyses of several food categories, as described in Chapter 3. Some of the older studies had nondetectable congener concentrations and higher detection limits than the newer studies, resulting in higher TEQ concentrations. For example, the beef concentration assumed in the 1994 assessment was 0.48 pg I-TEQ/g whole weight basis, while the current estimate is 0.18 pg TEQ_{DF}-WHO_{98}/g whole; poultry was 0.19 pg I-TEQ/g, while here it is 0.068 pg TEQ_{DF}-WHO_{98}/g. Table 4-32 compares the contact rates, TEQ concentrations, and background exposure estimates from the 1994 draft and this assessment. It should be noted that the previous draft estimated I-TEQ_{DF}s, while TEQ_{DF}-WHO_{98}s are used in the current assessment.

Background exposure levels are also presented for Germany, based on data from Fürst et al. (1990; 1991). The current total background TEQ_{DF}-WHO_{98} exposure shown in Table 4-33 is approximately 43 pg/day for North America. Based on Fürst et al. (1990; 1991), the estimated total CDD/CDF I-TEQ background exposure from food consumption for Germany is 79 pg/day (Table 4-33). However, it should be noted that the estimated background level for the United States and Germany are based on limited data, and exposure to all food groups was not considered. Also, the addition of TEQs for multiple pathways presumes that individuals are exposed by all pathways, and assumes that the fraction absorbed into the body is the same for all ingestion and inhalation pathways (i.e., 100 percent absorption in the gut and lungs is assumed). The dermal absorption pathway assumes that 3 percent of the CDD/CDFs in soil that adheres to the skin surface is dermally absorbed. The following sections present observations about CDD/CDF exposures in North America, comparisons between exposure estimates from this and previous studies, and comparisons between North American and European exposures to CDD/CDFs.

Based on the data presented in this report, the adult general population total background TEQ_{DF}-WHO_{98} exposure for North America was estimated to be 0.61 pg/kg-day (or 43 pg/day assuming a 70 kg adult), for all media combined. Exposure to 2,3,7,8-TCDD accounts for approximately 13 percent (5.5 pg/day) of the total TEQ exposure. Estimated exposures based on total TEQ_{DF}-WHO_{98} from the various exposure pathways are presented in Figure 4-4. The highest exposures were estimated to occur via ingestion of CDD/CDFs in fish and shellfish (0.12 pg/kg-day) and beef (0.13 pg/kg-day), which accounted for about 20 and 21 percent of the total TEQ_{DF}-WHO_{98} exposure, respectively. The ingestion of foods accounted for approximately 95 percent of the total TEQ_{DF}-WHO_{98} exposure. Exposure to CDD/CDFs via ingestion of water appears to be very low. Exposure via inhalation, soil ingestion, and dermal contact with soil are 0.023 pg/kg-day, 0.0063 pg/kg-day, and 0.0015 pg/kg-day, respectively. These exposures account for approximately 5.0 percent of the total CDD/CDF TEQ exposure in North America.

Adult general population TEQ_{P}-WHO_{98} exposure for North America was estimated to be 0.33 pg/kg-day (or approximately 23 pg/day, assuming a 70 kg adult), for all foods combined. This estimate is based on data on dioxin-like PCBs for food items and soil; PCB congener data were not available for urban air or water. For CDD/CDFs, these

environmental media accounted for about 3.8 percent of the overall TEQ_{DF}-WHO_{98} exposure. Assuming that these media account for a similar percentage of dioxin-like PCB exposure, total PCB exposure would be approximately 0.34 pg/kg-day (i.e., 0.33 pg/kg-day x 1.038). Thus, TEQ_{P}-WHO_{98} exposures from PCBs are approximately three quarters the TEQ_{DF}-WHO_{98} exposures from CDD/CDFs.

4.4.3. Assessment of Background Exposures Among Children

Exposures among other age groups of the U.S. population were also estimated using the same media TEQ-WHO_{98} concentrations that were used to estimate adult exposures. However, age-specific contact rates and body weights were used. These values were derived from data presented in U.S. EPA (1997) and USDA (1995). Background exposures were estimated for three age groups (i.e., 1-5 years, 6-11 years, and 12-19 years). Table 4-34 compares the contact rates and estimated CDD/CDF exposures for these age groups to adult contact rates and exposures. Table 4-35 makes similar comparisons for TEQ_{P}-WHO_{98}s. As shown in these tables, the dose per unit body weight (pg/kg/day) decreases with increasing age, but the daily dose (pg/day) increases with age. On a pg/kg-day basis, adult TEQ_{DF}-WHO_{98} doses were 3.6 times lower than those of 1 to 5 year old children and 2.1 times lower than those of 6 to 11 year old children. Likewise, for PCBs, TEQ_{P}-WHO_{98} adult doses were 3.3 times lower for 1 to 5 year old children and 1.8 times lower for 6 to 11 year olds. Table 4-36 presents the percentage contribution of each environmental media and food group to total TEQ dose for each age group. Figure 4-5 depicts these percentages for CDD/CDFs, grouped as meat/fish/eggs, dairy, and other, for the four age groups.

Milk and dairy products accounted for approximately 56 percent of the total TEQ_{DF}-WHO_{98} and TEQ_{P}-WHO_{98} exposures in 1 to 5 year old children, but only approximately 22 percent in adults. In contrast, meat and fish intake accounted for a much smaller portion of total exposure in 1 to 5 year olds, and a higher portion in adults.

Patandin et al. (1999) observed similar results using data for adults and children in The Netherlands. Data on CDD/CDF and PCB residues in foods were combined with food consumption data for various age groups to model dietary intake of dioxin-like compounds in the following age groups: 1 to 5 years, 6 to 10 years, 10 to 15 years, 16 to 20 years, and 20 to 25 years. The doses, on a body weight basis, were higher than those

estimated for the United Sates population, but the ratio of adult to child doses were similar to those described above. For example, Patandin et al. (1999) estimated a daily TEQ_{DFP}-WHO_{94} dose of 6.5 pg/kg-day for male children, age 1 to 5 years; 3.9 pg/kg-day for male children, age 6 to 10 years; and 2.4 pg/kg-day for adults, age 20 to 25 years. The adult value is 2.7 and 1.6 times lower than the values for 1 to 5 year old males and 6 to 10 years old males, respectively. Patandin et al. (1999) also reported on the contributions of various food group to total dietary intake of CDD/CDF/PCBs for various age groups. The results are consistent with those described above for the U.S. population.

4.4.4. Variability in Intake Estimates

The background adult daily intake values presented in Tables 4-30 and 4-31 are representative of mean exposures among the adult general population because they are based on mean TEQ_{DF}-WHO_{98} and TEQ_{P}-WHO_{98} concentrations and mean contact rates. They do not account for individuals with higher contact rates for foods or environmental media, or individuals who may be exposed to higher concentrations of dioxin-like compounds such as those affected by localized contamination.

Exposures to dioxin-like compounds were estimated as the product of media concentrations of CDD/CDF/PCBs times contact rates for these media with food ingestion accounting for the vast majority of the dose. Assuming that, over the long-term, all individuals in the general population are exposed to the mean TEQ_{DFP}-WHO_{98} media concentrations, variability among this population can be assessed by evaluating variations in contact rates. The assumption that long-term media concentrations to which the general population are exposed are represented by mean values is reasonable if temporarily elevated concentrations are offset by lower concentrations during other time periods, and if no regional trends are assumed (e.g., foods with varying CDD/CDF/PCB concentrations are equally distributed in the market place). Also, because food intake accounts for such a large percentage of the total dose, variations in long-term average food contact rates (i.e., ingestion rates) are likely to have the greatest impact on long-term average dose.

Some sense of the variability in general population exposures to TEQ_{DFP}-WHO_{98} can be gained by evaluating either the variability in fat intake among the general population (i.e., because fatty foods account for a high percentage of total exposure), or by

evaluating the variability of specific dietary components (i.e., food groups of the total diet). Published data on the variability in fat intake among the general population are somewhat limited. However, Cresanta et al. (1988), Nicklas et al. (1993), and Frank et al. (1986) analyzed dietary fat intake data as part of the Bogalusa heart study. The Bogalusa study "is an epidemiologic investigation of cardiovascular risk-factor variables and environmental determinants in a population that began 20 years ago" (Nicklas et al., 1995). Among other things, the study collected fat intake data for children, adolescents, and young adults. According to Nicklas (1995), "the diets of children in the Bogalusa study are similar to those reported in national studies of children." Thus, these data are useful in evaluating the variability in fat intake among the general population for the purposes of evaluating variability in exposure for dioxin-like compounds among this group. Based on data for 6 month old to 17 year old individuals during 1973 to 1982, maximum total fat intakes are 2.5 to 5 times higher than mean fat intakes. Maximum animal fat intakes for this group are 3 to 7.6 times mean animal fat intakes (Frank et al., 1986). Based on the mean total fat intake plus three standard deviations for 10-year old children during 1992 to 1994 and young adults (i.e., 19 to 28 years) during 1988 to 1990, upper-range fat intake is between two to three times that of mean intake (Nicklas et al., 1993; Nicklas et al., 1995). (Three standard deviations around the mean should represent approximately 99 percent of the population.) These data are presented in Table 4-37. Based on the assumption that variability in intake is the key contributing factor to variability in exposure to dioxin-like compounds, and that the fat intake data from these studies is representative of the general population of the United States, upper-range exposures to dioxin-like compounds would be expected to be two to three times higher than the mean background exposures estimated in this chapter.

Block (1992) and Norris (1997) estimated dietary fat intake among the adult general population using data from National Health Interview Surveys (NHIS) conducted by the National Center for Health Statistics (NCHS). Block (1992) used data for 20,143 men and women, ages 18 to 80+ years, from the survey. The mean and standard deviation fat intakes from this analysis are presented in Table 4-38. Assuming that the mean value plus three standard deviations represents the upper end of the range of fat intake, maximum fat intake is approximately two to three times higher than the mean. Norris (1997) used data for 10,827 men and women from the 1992 NHIS. The mean fat intake

was 64.4 g/day and the standard deviation was estimated to be 41.6 g/day. Using the same assumption as stated above (mean plus three standard deviations), the upper end of the range of fat intake wold be 189.2 g/day. This value is 2.9 times higher than the mean. Thus, these data from a nationally representative sample of adults are consistent with the data for children and young adults from the Bogulusa study. This variability is also supported by the ranges of tissue CDD/CDF/PCB levels, as described in Section 4.2. These data show that maximum tissue levels of dioxin-like compounds are typically two to three times the mean values.

Another way to assess variability in CDD/CDF/PCB background doses among the general U.S. population is to evaluate variability in total dietary intake and the contribution of specific dietary components to total dietary intake. Recently, EPA conducted an analysis of USDA's 1994-1996 CSFII data set to estimate total dietary intake as well as the contribution of the major food groups (i.e., total dairy, total fish, total meats, total fats, eggs, etc.) to the total diet. Intake data from this analysis were used in conjunction with average CDD/CDF/PCB concentrations in foods to evaluate variability in background dose of dioxin-like compounds.

The procedure used to evaluate variability in CDD/CDF/PCB doses from total dietary intakes derived from the CSFII was developed as follows. First, estimates of "total dietary intake" for individuals in the CSFII were determined as the sum of all food intakes reported by the individuals included in the survey. For purposes of this exercise, specific food items reported by each individual in the CSFII were grouped into classes, including total dairy, total meats, total fish, total vegetables, total eggs, and total fats. Once these total dietary intakes were compiled, CSFII survey adult individuals were ranked from lowest to highest based on total dietary intake, and intake rates at specific percentiles, such as the 50th or 90th percentile were examined. From these percentiles, subsets were defined including a "central" group of adults, which were those in the 45-55th percentile of total intake, and an upper percentile group of adults, which were defined as those above the 90^{th} percentile of total intake. For the purposes of evaluating variability in CDD/CDF/PCB doses that extend above the average doses reported in this chapter, intake rates for the upper percentile group of adults was of interest. To calculate upper percentile doses of CDD/CDF/PCBs, point estimates of the intake rates for each of the major food groups were calculated as the mean intake rate for the individuals within the upper percentile of

total food intake (i.e., above the 90th percentile). As noted above, these intake rates represented intakes for major food groups only (e.g., total meats) and not specific food items (e.g., beef, pork, poultry). Therefore, to complete this exercise, it was necessary to convert the intake rates of the major food groups to intake rates for the categories of individual foods for which CDD/CDF/PCB concentration data were available. To do so, it was assumed that the proportions of individual foods (e.g., beef, pork, poultry, and other meats) making up a food group (e.g., total meats) were the same for the upper percentile groups as for the average background individual assessed in Tables 4-30 and 4-31. Finally, average concentrations of CDD/CDF/PCBs in the various individual food items (as shown in Tables 4-30 and 4-31) were combined with the upper percentile intakes rates for individual food items to arrive at the doses to an upper percentile adult. The results for this exercise for the "upper percentile" intake rates are shown in Tables 4-39 and 4-40, which also include the average non-food exposures associated with soil, water, and air. As shown in Table 4-39 the estimated TEQ_{DF}-WHO_{98} dose among adults in the "upper percentile" of total food intake is 1.1 pg/kg/day or 77 pg day. This dose is 1.8 times higher than the mean TEQ_{DF}-WHO_{98} dose estimated in Table 4-30. The estimated TEQ_{P}-WHO_{98} dose for "upper percentile" adults is 0.65 pg/kg-day or 45 pg/day (Table 4-40). This dose is 1.9 times higher the mean dose estimated in Table 4-31.

The variability in current dose of about 2 to 3 times above the mean is similar to the range of tissue CDD/CDF/PCB levels, as described in Section 4.2. These data show that maximum tissue levels of dioxin-like compounds are typically two to three times the mean values. However, it was also discussed that important factors such as the age of the individual and their past history of exposure also contributed to variability in tissue levels, perhaps more so than their current dose. Therefore, this variability in tissue data, while similar to the variability in intakes based on the dietary data discussed here, should not be considered as important supportive evidence to a finding that elevated intakes of dioxin-like compounds range up to 3 times higher than the average dose. Also of note is that the 1994 Dioxin Reassessment documents developed an estimate of variability of intake of between 3 and 7 times the mean intake rates. This variability estimate was based on statistical extrapolations from a relatively small study measuring CDD/CDFs in blood. The new variability estimates presented here are considered more strongly

supported because they are based on larger studies, do not involve extrapolations, and more directly reflect consumption.

4.4.5. Comparison of Previous North American Studies to This Study

Previous studies of CDD/CDF exposures in North America were presented in Section 4.4.1 of this report. These studies reported CDD/CDF exposures based on the most toxic congener, 2,3,7,8-TCDD, and not on the total TEQ_{DF} value for all congeners combined. For the purposes of comparison, mean background levels of 2,3,7,8-TCDD in North America from this assessment were used to calculate exposure via various pathways. Background exposures were calculated using background environmental levels of 2,3,7,8-TCDD, standard contact rates, and appropriate unit conversion factors, as described previously. Total 2,3,7,8-TCDD exposure among adults for all pathways combined was 5.5 pg/day for the current assessment compared to 15.9 and 34.8 pg/day for the two previous studies of 2,3,7,8-TCDD exposure in North America (Henry et al., 1992; and Travis and Hattemer-Frey, 1991). Figure 4-6 depicts the comparisons of the percent contribution of various exposure pathways to total exposure to 2,3,7,8-TCDD for the current assessment and for previous North American studies. Figure 4-6 indicates that exposure via ingestion of meats accounted for a large portion of the exposure in all three studies. However, fish accounted for a higher percentage, and dairy products accounted for a lower percentage of the total 2,3,7,8-TCDD exposure in the Henry et al. (1992) study and in the current assessment than in the Travis and Hattemer-Frey (1991) study. These differences reflect differences in assumptions for food ingestion rates as well as in TCDD levels. All three studies indicate that beef, dairy products, and fish comprise over 93 percent of the total exposure. Because of the data base weaknesses noted earlier, it is not known if these differences can be considered significant.

European CDD/CDF exposure studies may also be compared to the exposures estimated in U.S. reports and in the current assessment. Comparisons may be made based on the 2,3,7,8-TCDD congener or on total TEQ_{DF} exposures (Table 4-41). Adult general population exposures to 2,3,7,8-TCDD in North America range from 5.5 pg/day to 34.8 pg/day based on the current assessment and two other U.S. studies. These values are comparable to the 2,3,7,8-TCDD exposures reported in Germany and The Netherlands by Fürst et al. (1991) and Theelen (1991). Fürst et al. (1991) reported an estimated

2,3,7,8-TCDD exposure of 25 pg/day based on ingestion of dairy products, meat, and fish; Theelen (1991) reported an estimate of 20 pg/day based on dairy, meat, poultry, and fish intake. Total TEQ_{DF} background exposure estimates for North America range from approximately 43 pg TEQ_{DF}-WHO_{98}/day for the current assessment to 140 to 290 pg I-TEQ_{DF}/day based on Gilman and Newhook's (1991) Canadian study. For Europe, total I-TEQ_{DF} exposure estimates range from 79 pg/day based on Fürst et al. (1990) to 158 pg/day based on Fürst et al. (1991).

4.4.6. Relative Contribution of Exposure Pathways to Total Intake

Figure 4-7 depicts the contributions of various exposure pathways to total background TEQ exposures for North America, Germany, the United Kingdom, and The Netherlands based on data from the current assessment (Fürst et al., 1990; MAFF, 1995; and Theelen, 1991). For all three geographic regions, over 90 percent of the exposures were attributed to ingestion of CDD/CDFs in foods. For the United States and Germany, intake of meat, fish, and eggs account for over 60 percent of the daily exposure, while milk and dairy consumption account for less than 30 percent, and soil ingestion, inhalation, etc. account for less than 7 percent of the total exposure. For The Netherlands and the United Kingdom, the meat/fish/eggs group accounts for somewhat less of the total intake, while milk/dairy and the "other" category account for more of the exposure. In particular, approximately 30 percent of the total exposure came from breads and cereals in the United Kingdom. These food groups were not evaluated in the United States estimates.

Based on the data presented in Figure 4-7, it is reasonable to expect that the CDD/CDF body burden in vegetarians would be lower than the body burden in nonvegetarians because vegetarians avoid the consumption of meat and fish and their derivative products. Welge et al. (1993) tested this hypothesis by comparing the CDD/CDF levels in the blood of 24 German vegetarians with the blood levels of 24 nonvegetarians, matched for age, sex, body weight, and height. With the exception of two individuals, all vegetarians had practiced a diet without meat and fish for at least 3 years. The CDD/CDF levels in the vegetarian group ranged from 14.64 to 52.85 pg I-TEQ_{DF}/g (lipid basis) with a mean of 32.60 pg I-TEQ_{DF}/g. In the nonvegetarian group, the CDD/CDF levels ranged from 14.26 to 97.98 pg I-TEQ_{DF}/g (lipid basis) with a mean of

34.32 pg I-TEQ_{DF}/g. There was no significant difference (α = 0.05) between the vegetarian and nonvegetarian group in the mean levels of any of the 2,3,7,8-substituted congeners, in the total CDD levels, in the total CDF levels, in the total CDD/CDF levels, or in the total I-TEQ_{DF} levels (each on a lipid and on a whole weight basis). Welge et al. (1993) suggested several reasons why no differences were found. First, all tested vegetarians had at one time been nonvegetarians. The higher levels of exposure during this nonvegetarian period coupled with the long biological half-life of CDD/CDFs may be responsible for the apparent similarity in body burdens using blood as the measure of body burden. Second, the vegetarians may have a higher level of consumption of dairy products than the nonvegetarians and thus have a similar CDD/CDF exposure even without consumption of fish and meat.

Schecter and Papke (1998) collected blood samples from two individuals (one male and one female) who had been vegans for over 20 years and analyzed them for CDD/CDFs and coplanar PCBs. These individuals were strict vegetarians, consuming no milk, cheese, eggs, or other animal products. Total CDD/CDF and PCB concentrations, as well as I-TEQ_{DF} and TEQ_{P}-WHO_{94} concentrations among these vegans were compared to the levels in two pooled samples from 100 men and 100 women from the general population. Total concentrations of CDD/CDF/PCBs were 244 ppt and 330 ppt for male and female vegans, respectively. These values were considerably lower than those observed in pooled samples from the general population; 643 ppt and 906 ppt for male and female subjects, respectively. Likewise, the TEQ_{DFP}-WHO_{94} concentrations were lower among the vegans (4.4 ppt and 8.7 ppt for males and females, respectively) than the general population (24.2 ppt and 29.3 ppt for males and females, respectively). Both the total concentrations and TEQ levels of CDD/CDFs and PCBs were higher in the samples collected from those taken from males.

4.4.7. Geographical Contributions to Dietary Exposure

As indicated in the previous sections, dietary intake appears to be the primary pathway of human exposure to dioxin-like compounds. Over 90 percent of the background dose is obtained through the diet, with foods of animal origin being the predominant sources. Aside from some episodes of localized contamination that may result in elevated exposures among individuals who consume foods from contaminated

areas (see Chapter 5), the general population of the United States is assumed to consume foods, over the long-term, that contain average background concentrations of dioxin-like compounds, resulting in background exposures that are similar across all regions of the United States. Except for some of the more perishable foods (i.e., milk and eggs) most foods are widely distributed in commerce. Thus, the general population of the United States may consume foods from a wide variety of geographic locations. In addition, the concentrations of foods grown in the various geographic regions may not vary widely. The national studies of beef, pork, and poultry, conducted jointly by EPA and USDA (Winters et al., 1996a; Winters et al., 1996b; Lorber et al. 1997; Ferrario et al., 1997), indicated that there was little variation in the concentrations of dioxin-like concentrations, based on geographic location. The milk study (Lorber et al., 1998) suggested the possibility of a geographic trend, with CDD/CDF concentrations being somewhat higher in the southeastern United States than in the southwestern United States.

Based on the distribution of foods in commerce, and the similarities of concentrations in many foods, variations in dietary exposure on the basis of geography would not be likely to be significant and the general population would be expected, over the long term, to be exposed to similar concentrations of dioxin-like concentrations in foods. However, the total amount of dioxin-like compounds entering the food supply may vary geographically because of the predominance of certain types of food production in certain regions of the country. For example, food such as pork is produced primarily in the northern midwest and some areas on the southeastern part of the United States; whereas poultry is produced primarily in the southeast.

The purpose of this section is to present the results of a study of the geographic variability of dioxin production as indicated by variability in production of animal fats. EPA conducted an analysis to determine the geographic origin (within the 48 contiguous United States) of several food groups that are likely to contain dioxin-like compounds (e.g., meats and dairy products). Cattle, chicken, and hog producer sales figures from the 1997 Census of Agriculture (USDA, 1997), enumerated by county, were converted to an equivalent dioxin TEQ using data in Putnam and Allshouse (1999). The 1997 food disappearance data for beef, pork, and chicken in this reference were used to convert the USDA production data, expressed in units of individual animals sold, to grams of animal fat entering the food chain. Food disappearance is the total supply at the start of the

year, plus imports, minus exports and shipments to U.S. territories, minus stock at the end of the year. It therefore includes all food eaten in the home, wasted by spoilage in the home, lost in preparation, or left uneaten on the plate. The food disappearance data were expressed as a boneless weight assuming a standard conversion factor for each animal type (Putnam and Allshouse, 1999). This total weight was converted to dioxin TEQs using CDD/CDF/PCB concentration values from the EPA meat/milk surveys and WHO_{98} TEFs. The total dioxin value was then divided by the total number of animals to yield ng TEQ per animal. This value was multiplied by the county-level USDA data to yield ng TEQ per year for every county.

Production figures for dairy products are not included in the Census of Agriculture, but the number of dairy cows is provided for each county. State-level data on milk fat production were apportioned among each state's counties on the basis of the number of dairy cows in each county. This approach assumes that all milk cows in a given state are equally productive. In a similar way, where only state-level egg production data are available, county values were calculated by apportioning the state-level data among the counties on the basis of the number of layers and pullets in each county. Examples of the county-level production data are shown in Figures 4-8 and 4-9 for pork and dairy products, respectively. Similar maps were produced for the other products (i.e., beef, poultry, and eggs) and for the total TEQ_{DF}-WHO_{98} over all five products. It should be noted that the geographic variability in this analysis is based on variability in food production only, and not in the concentration of dioxin-like compounds in the foods. Thus, it does not indicate that the concentrations of dioxin-like compounds are higher in some regions than in others. Instead it indicates that the production of dioxin-containing foods is higher in some regions than in others. The relative contributions of the five food products included in this study compare favorably with EPA's current estimates of total TEQ_{DF}-WHO_{98} dose based on 1989-91 CSFII food intake data (Figure 4-10).

This analysis may be useful, in conjunction with source analyses, in identifying important food production areas where dioxin-like compounds are also being released. To that end, major contributors to the total dioxin TEQ for the 48 contiguous states were identified. The 3,048 counties in the database were sorted in descending order and divided into four groups, with each group encompassing 25 percent of the 48-state total. The resulting map (Figure 4-11) shows that the top 65 counties account for 25 percent of

the total TEQ. The second, third, and fourth quartiles encompass 212, 498, and 2,303 counties, respectively. Assuming that the dominant pathway resulting in dioxin exposure for domestic meat and dairy animals is air deposition onto feed crops, it necessarily follows that the dioxin sources that dominate general population exposure have to be those sources that dominate ambient air concentrations in the areas flagged by this analysis. Future work is aimed at identifying these dioxin sources.

4.4.8. Contribution of CDD/CDF Congeners to Background Dose and Body Tissue Concentration

The purpose of this section is to evaluate the contribution of individual congeners to background dose and tissue concentrations. This section also evaluates whether the congeners that are the primary contributors to dietary dose are consistent with those that dominate the body burden. Section 4.4.2 derived a background dose of approximately 1 pg TEQ_{DF}-WHO_{98}/kg-day, which included doses of 0.61 pg TEQ_{DF}-WHO_{98}/kg-day for CDD/Fs and 0.33 pg TEQ_{DF}-WHO_{98}/kg-day for coplanar PCBs. These doses were calculated assuming average exposure media concentrations and contact rates for several pathways. Food consumption made up most of this total dose, with the food consumption pathways of beef, pork, chicken, fresh fish, marine fish, dairy, and milk totaling 0.90 pg TEQ_{DFP}-WHO_{98}/kg-day. This exercise will focus on these pathways alone. Section 4.2 examined body tissue concentrations of the dioxin-like congeners. The average TEQ_{DF}-WHO_{98} lipid concentration in blood was calculated at 21.6 pg TEQ_{DF}-WHO_{98}/g. For dioxin-like PCBs, the average lipid concentration in blood was 2.0 TEQ_{P}-WHO_{98}/g. These data were based on the CDC blood data, as described previously, and represent recent body burdens. It should be noted, however, that PCB data were only available for four congeners (i.e., PCBs 77, 81, 126, and 169). The exercise in this section determines the percentage TEQ_{DFP}-WHO_{98} contribution of each toxic CDD, CDF, and dioxin-like PCB congener to the daily total background dose of TEQ_{DFP}-WHO_{98} s. It also determines the percentage TEQ_{DFP}-WHO_{98} contribution of each toxic congener to the body tissue TEQ_{DFP}-WHO_{98} concentrations. The exercise concludes with a comparison of the two sets of percentages.

The following general rules were applied in developing the information for this exercise:

1) *The food surveys used to calculate average concentrations for background dose calculation of TEQ-WHO_{98}s were also used to calculate TEQ-WHO_{98} congener profiles, when possible.*

For all food groups except two, the same data used in calculating background doses were used in this analysis. The total TEQ_{DF}-WHO_{98} for these data are summarized in Table 3-59 and the total TEQ_{P}-WHO_{98} are summarized in Table 3-60. For freshwater and marine fish, it was not possible to derive a CDD/CDF congener profile using the same data as that used to calculate a background dose because the individual congener concentrations were not provided in the core reference. Thus, data from Schecter et al. (1995b) were used. These data represent a sampling of 10 freshwater fish from supermarkets. For marine fish, data from Fiedler et al. (1997) were used.

2) *Average concentration profiles for food were calculated assuming non-detects are equal to one-half detection, which was the same procedure for calculating body tissue concentration profiles.*

This was the assumption used to calculate the background dose. However, it should be noted that this could be problematic for some data, specifically when the detection limits were high. The determination of the food concentration profiles in Chapter 3 was accomplished assuming nondetects were equal to zero for this reason.

3) *When more than one survey was used to determine the average representative concentration profile in food or body tissue concentration, all samples were pooled and assumed equally weighted for dioxins. However, for coplanar PCBs, the data in the literature studies were developed by compositing methods that did not allow for the calculation of weighted averages. Because of this, one concentration per study was derived for each congener, and then the average concentration was assumed to be the average over the number of studies.*

Since many of the studies reporting CDD/CDF concentrations, particularly the food studies, were grab sample studies, it seems most reasonable to simply treat all samples equally. Also, mean food concentrations, for purposes of background dose derivation of the CDD/CDFs, were calculated giving all samples equal weight. Therefore, the determination of the representative profiles was made consistent with the dose

calculation. The background dose calculation for the dioxin-like PCBs was done slightly differently. In these cases, two of the principal studies, Mes and Weber (1989) and Mes et al. (1991) composited several samples. In one study, nondetected congeners on composite samples were set to one-half the detection limits for calculating mean congener concentrations. However, in the other study, mean congener concentrations were based on positive composites only. Thus, there was no simple method for calculating a weighted mean for these studies.

4) *For the dioxin-like PCBs, not all the studies evaluated the same coplanar congeners. This occurred in both the food data and the tissue data. Therefore, this analysis is incomplete with regard to estimating the full dose of dioxin-like PCBs as well as the percentage of dose/body tissue* TEQ_P-WHO_{98} *that can be attributed to each congener. This appears to be an issue for two of the dioxin-like PCBs. However, inclusion of the full information of these two congeners will unlikely change the important qualitative finding in the dioxin-like PCB analysis - that PCB 126 dominates both tissue and body burden concentration.*

There are 11 dioxin-like PCBs with some dioxin-like toxicity, based on the TEQ_P-WHO_{98} scheme (Younes, 1998). Using the TEF_P-WHO_{98} scheme, 13 PCB congeners were considered to have dioxin-like toxicity. The CDC data set included data for only four of the dioxin-like PCBs for human tissues (i.e., PCBs 77, 81, 126, and 169). There were no reported concentrations in food for two of the congeners, PCBs 123 and 167. PCB 114 had some impact on total tissue concentrations and was included in some of the food survey data. However, this congener was not included in the USDA/EPA national studies on pork, beef, poultry, and milk. Other food studies also measured PCB 189, which was not included in the USDA/EPA studies, but contributed an insignificant amount to coplanar TEQ_P-WHO_{98} concentration, so its exclusion in the USDA/EPA studies was not critical. The net effect for exclusion of PCB 114 in these food groups is that the contribution of PCB 126 to TEQ_P-WHO_{98} was overestimated while the contribution from PCB 114 was underestimated. Likewise for human tissues, the contribution of PCB 126 to TEQ_P-WHO_{98} is likely overestimated.

Further details on the procedures used in the forward dose calculations and the body tissue concentrations are presented below.

4.4.8.1. *Background Dose*

Approximately 90 percent of the background daily TEQ_{DFP}-WHO_{98} dose is derived from the following foods: freshwater fish, marine fish, milk, dairy, beef, pork, and poultry. For CDDs/CDFs/PCBs, the total daily dose from these pathways is estimated to be 58 pg TEQ_{DFP}-WHO_{98}/day. The remaining dose comes from: soil ingestion, marine shellfish ingestion, inhalation, water ingestion, egg ingestion, and vegetable fat ingestion. For ease of calculation, this exercise focuses on the higher contributing food groups rather than on all routes of exposure. Further, when calculating the percentage of the total TEQ_{DFP}-WHO_{98} dose which can be attributed to each congener, it is assumed that the 58 pg TEQ_{DFP}-WHO_{98}/d represents 100 percent of the daily dose. For ease of understanding, the CDD/CDF and PCBs are tabulated separately in the tables and figures. The TEQ_{DF}-WHO_{98} dose from CDDs/CDFs is 38 pg/day and the dose for coplanar PCBs is 20 pg TEQ_{P}-WHO_{98}/day. The congener contributions from the dietary intake calculation is characterized in terms of the percentage each congener contributes to the TEQ_{DFP}-WHO_{98}. This will be compared to the congener contributions to body burdens, which are also compiled on an individual percentage basis.

The procedure for doing the dietary intake calculations is described in the following four steps:

1. **Determine the representative congener concentrations in the food product.** These were determined as the average concentrations of the individual congeners from available survey data, given the rules stated above. Based on the way in which the data were reported in the literature, the basis for food concentrations was either on a lipid basis or on a whole weight basis. Most of the CDD/CDF food data were reported on a lipid basis, while most of the coplanar PCB data were reported in the literature on a whole food basis. Although the basis for the food concentrations is important for calculating a dose because the concentration data must be consistent with the intake data (i.e., if concentrations are reported on a whole weight basis, whole weight intake rates must be used), it was not important for calculating the fractional contribution of each congener to the total TEQ since the same values would be calculated using either lipid-based or whole weight concentrations. Therefore, lipid-based CDD/CDF concentrations were used for all foods, and whole weight PCB concentrations were used for all foods.

2. **Determine the toxic equivalent concentrations in the food product.** These were easily determined as the product of the average congener concentration and the appropriate TEF.

3. **Determine the TEQ-WHO_{98} congener profiles as the fractional contribution of each congener to total TEQ-WHO_{98} concentration.** This was determined as the ratio of the toxic equivalent concentration of each congener to the total TEQ-WHO_{98}.

4. **Determine the TEQ-WHO_{98} congener profile of the dietary dose by multiplying the TEQ-WHO_{98} fractional contribution of each congener by food intake rate for that food product.** A multiplication of each food product's overall TEQ-WHO_{98} concentration, in pg/g, and the corresponding food consumption rate, in g/day, gives the pg TEQ-WHO_{98} consumed per day by that food product. Further multiplication of this pg TEQ-WHO_{98}/day and each congener's fractional contribution gives the pg TEQ-WHO_{98}/day contributed by each congener. The representative food TEQ-WHO_{98} concentrations described in Section 4.4.2 to determine background dose were expressed on a whole weight basis, to be consistent with the consumption rates of the food products, which were also on a whole weight basis. The whole concentration, in pg TEQ_{DF}-WHO_{98}/g for CDD/CDFs and TEQ_{P}-WHO_{98}/g for coplanar PCBs for all food products were: beef - 0.18 pg/g CDD/CDFs and 0.084 pg/g PCBs; pork - 0.28 pg/g CDD/Fs and 0.012 pg/g PCBs; poultry - 0.068 pg/g CDDs/CDFs and 0.026 pg/g PCBs; dairy - 0.12 pg/g CDD/CDFs and 0.058 pg/g PCBs; milk - 0.018 pg/g CDDs/CDFs and 0.0088 pg/g PCBs, freshwater fish - 1.2 pg/g CDD/CDFs and 1.2 pg/g PCBs; and marine fish - 0.36 pg/g CDD/Fs and 0.25 pg/g PCBs. The consumption rates for this exercise were expressed in g/day, which were calculated using the g/kg-day consumption rates given in Section 4.4.2 multiplied by a 70 kg adult: beef - 49.7 g/day, pork - 15.4 g/day, poultry - 35 g/day, dairy - 55 g/day, milk - 175 g/day, freshwater fish - 5.9 g/day, and marine fish - 9.6 g/day.

The results of this four-step procedure are demonstrated in Table 4-42 for the beef consumption pathway for CDDs/CDFs. Tables 4-43 and 4-44 show the average congener concentrations of CDDs/CDFs and PCBs, respectively, derived for the food groups, the total TEQ-WHO_{98} concentration for each food group from this profile, and the TEQ-WHO_{98} percentage contributions for each congener and food group. Tables 4-45 and 4-46 show

the final results of this exercise for CDDs/CDFs and PCBs, respectively. Results suggest that 72 percent of the total TEQ_{DF}-WHO_{98} background dose of CDDs/CDFs comes from four congeners: 1,2,3,7,8-PCDD (33 percent), 2,3,4,7,8-PCDF (17 percent), 2,3,7,8-TCDD (10 percent), and 1,2,3,6,7,8-HxCDF (12 percent). PCB 126 comprises 61 percent of the TEQ_P-WHO_{98} dose of dioxin-like PCBs. When adding the doses of the CDDs/CDFs to the coplanar PCBs, PCB 126 and 1,2,3,7,8-PCDD are the largest contributors at 21 percent, followed by the three CDD/CDF congeners at 2,3,4,7,8-PCDF (11 percent), 2,3,7,8-TCDD (7 percent), and 1,2,3,6,7,8-HxCDD (8 percent).

4.4.8.2. *Background Tissue Concentrations*

For the purposes of this exercise, the tissue concentrations from the CDC studies reported in Table 4-18 were used. For coplanar PCBs, the main issue was that data for only four PCB congeners were included (i.e., PCBs 77, 81, 126, and 169). As a result of the exclusion of the other PCBs, their percent contribution to the TEQ tissue concentration could not be calculated.

Once the concentrations were derived, the TEQ-WHO_{98} contributions of individual congeners to the total TEQ-WHO_{98} were derived in a manner similar to the food results. Tables 4-47 and 4-48 show the final results of this exercise for CDDs/CDFs and coplanar PCBs, respectively, giving the derived actual congener concentrations, and the percentage contribution to TEQ-WHO_{98} for each congener. The studies used in this exercise are the same as those used in Section 4.2.3 to estimate recent (i.e., 1990s) body burden levels.

Table 4-47 indicates that four congeners contribute 82 percent of CDD/CDF TEQ_{DF}-WHO_{98}: 1,2,3,6,7,8-HxCDD (34 percent), 1,2,3,7,8-PCDD (24 percent), 2,3,4,7,8-PCDF (14 percent), and 2,3,7,8-TCDD (10 percent). These are the same four congeners contributing the most to background dose. From Table 4-48, it is seen that PCB 126 overwhelms all other congeners, and for all tissue types. PCB 126 comprises 90 percent of the dose of dioxin-like PCBs. Figures 4-12 and 4-13 compare the fractional TEQ-WHO_{98} contributions of each congener to the total TEQ-WHO_{98} background dose of CDD/CDFs (Figure 4-12) and coplanar PCBs (Figure 4-13), to the TEQ-WHO_{98} contributions of each congener to average body tissue TEQ-WHO_{98} concentration of CDD/CDFs (Figure 4-12) and coplanar PCBs (Figure 4-13). The match between the

highest contributors is noteworthy from this figure, as is the lack of contribution from other congeners. Some key observations that can be gleaned from this exercise include:

1) As noted, five congeners dominate the TEQ-WHO_{98} body burden as well as the TEQ dose. These are, 1,2,3,7,8-PCDD, 1,2,3,6,7,8-HxCDD, 2,3,4,7,8-PCDF, and 2,3,7,8-TCDD from the CDD/CDFs, and PCB 126 from the coplanar PCBs.

2) For the four dominant CDD/CDF congeners combined, the body burden had a higher TEQ-WHO_{98} contribution than the food: contributions from the four congeners to body burden TEQ-WHO_{98} equaled 82 percent while for food they equaled 72 percent.

3) While 2,3,7,8-TCDD has been the focus of past exposure and health studies, it would appear that the other CDD/CDF congeners found to be high contributors in this exercise may also be important from an exposure and health standpoint.

4.5. Comparison of Assessment Approaches and Best Estimates of Intake

Two approaches were used in this chapter to estimate background exposures to dioxin-like compounds among the general population of the Unites States. The first approach used pharmacokinetic modeling to calculate a dose from tissue concentrations. This was done using either a steady state or non-steady state approach. Using the steady state approach, the TEQ_{DF}-WHO_{98} dose was estimated to be 126 pg/day, when the half life for TCDD (i.e., 7.1 years) was assumed to apply to the total TEQ, and 87 pg/day, when congener specific half-lives were used. PCB doses could not be estimated in this way because of the lack of congener-specific half-life information. The advantage of modeling doses from tissue concentrations is that all pathways of exposure are accounted for. However, because the half-lives of dioxin-like compounds in the body are relatively long (i.e., 7.1 years for TCDD), modeled doses may reflect the cumulative effect of previous doses and not current doses. This was demonstrated by a non-steady state model used to reconstruct past doses of 2,3,7,8-TCDD. The results of the modeling exercise indicated that current doses would be expected to be less than past doses. Assuming that these results would apply to all dioxin-like congeners, and not just 2,3,7,8-TCDD, the current total TEQ_{DF}-WHO_{98} dose would be expected to be somewhat lower than 88 pg/day, as estimated using the steady state approach.

The second approach used for estimating background doses to dioxin-like compounds was to evaluate dioxin-like compounds in various dietary components (i.e.,

meats, dairy products, fish, etc.) and environmental media (i.e., air, soil, water) to which humans are exposed. By combining TEQ_{DFP}-WHO_{98} concentrations in foods and these media with the contact rates (i.e., ingestion, inhalation, dermal contact rates) for these foods and media, CDD/CDF and PCB doses were calculated. Using this approach, the daily TEQ_{DF}-WHO_{98} dose was estimated to be 43 pg/day and the TEQ_{P}-WHO_{98} was estimated to be 23 pg/day. The advantage of using this approach is that, if current media concentrations and intake estimates are used, the estimated doses should reflect current exposures. In this analysis, the most recent data on the concentrations of dioxin-like compounds in beef, pork, poultry, milk, and vegetable oil, collected by EPA, have been used. Recent data from the published literature have also been used for freshwater and marine fish and shellfish. Likewise, intake rates are based on EPA's recently published *Exposure Factors Handbook* (U.S. EPA, 1997)which presented data from USDA's 1989-1991 Continuing Survey of Food Intake Among Individuals (USDA, 1995) (a more recent USDA data set has been released since the *Exposure Factors Handbook* was published, but EPA has not yet completed its analysis of these data), and the most current data for establishing contact rates for other media. It should be noted, however, that the dose component approach may underestimate current doses if important pathways of exposure are not accounted for in the component analysis. For example, in this assessment, fruits and vegetables have not been considered as significant contributors to the overall dose. Data for the concentrations of dioxin-like compounds in fruits and vegetables are limited, but it expected that the concentrations would be lower in these foods than in fatty foods such as meat, fish and dairy products. Thus, a fruit and vegetable component has not been included in this analysis. If fruits and vegetables actually account for a more significant portion of the exposure than expected, the dose estimated here may be lower than that experienced by the general population of the United States. Other uncertainties introduced by this approach include the use of soil ingestion rates that may or may not account for all types of inadvertent soil ingestion (e.g., outdoor soil, household dust), the lack of PCB residue data for soils and air, and non-representative sampling data for air. For example, the adult soil ingestion rate cited in the *Exposure Factors Handbook* (U.S. EPA, 1997) is based on a limited data set, but is used as a reasonable surrogate for all forms of soil ingestion. The accuracy of this assumption is difficult to assess; however, because soil ingestion accounts for a small percentage of the overall dose, this uncertainty

is not expected to significantly affect one's confidence in the dose estimates. Likewise, the lack of PCB soil and air data, and the non-representative nature of the CDD/CDF air data would be expected to have little effect on the overall dose estimate, because these pathways account for a small percentage of the overall dose.

Despite these uncertainties, the dose component approach is believed to provide the best estimate of the mean current background dose to the general U.S. population. Variability was evaluated using dietary fat data, high-end intake rates, and by evaluating variability in body burden. In general, these data indicate that the high-end dose of dioxin-like compounds is likely to be 2 to 3 times higher than the mean.

[a] Results from the second round of WHO-coordinated exposure studies on levels of PCBs, PCDDs, and PCDFs (on fat basis) in human milk. In calculating sums of the six marker PCBs and levels of PCDDs, PCDFs, non-*ortho*, and mono-*ortho* PCBs expressed in TEQ, both data are shown when non-detect values are equal to zero and non-detect values are equal to the limit of detection. If no differences appeared, a single value is presented.

I-TEF_{DF}s used in calculating TEQ_{DF}s for CCD/CDFs; TEF_P-WHO_{94}s used in calculating TEQ_Ps for PCBs.

Source: Liem et al. (1996).

NOTE: Results are expressed on a fat basis. ∑ (marker PCBs) and TEQs are calculated assuming non-detect values are equal to zero.

[a] Analyzed using packed column technique.
[b] Calculated using Nordic TEF-model.
[c] Ontario-1988 denotes proportional mean of two pooled samples analyzed in the first round.
[d] To compare results between first and second round, samples from 1992/93 have been reanalyzed using (old) packed column technique (Becher and Skåre, personal communication).
[e] Dioxin levels in human milk samples from North Rhine-Westphalia collected in 1992 as reported by Fürst[19]).

* PCBs 77 and 81 were not detected in any sample, so the concentrations shown are the average of ½ detection limit for the 29 samples. PCBs 126 and 169 were detected in most of the samples, so the average concentrations calculated at ½ detection limits reported above are very similar to average concentrations calculated at ND = 0.

TOTAL TEQ_{DF}-WHO_{98}		21.6	87

[a] Represents the mean half-life for all 2,3,7,8-substituted congeners in this class.
[b] Half-life for this congener not available; half-life assumed to be the same as for the CDD with the same chlorination pattern.
[c] No half-life data available for this congener; assumed to be the same as for 1,2,3,6,7,8-HxCDF
[d] Half-life data from Flesch-Janys et al. (1996).
[e] Assumes a body fat volume of 17.5 kg.
[f] Dose = [(ln2/T 0.5 yrs)*17.5 kg*Conc. (pg/g)*(1,000 g/kg)*(1 yr/365 days) / (0.8 absorption).

Table 4-25. Predicted Average Daily Intake of 2,3,7,8-TCDD by the General Population of the United States

Media	Predicted Media Concentration[a]	Media Intake (person/day)	Daily Intake of 2,3,7,8-TCDD (pg/day)	Percent of Daily Intake

Table 4-27. Daily Exposure to 2,3,7,8-TCDD and I-TEQ_{DF} from Air, Soil, Food, and Nonfood in The Netherlands

Media	Media Intake (g/person/day)	Daily Intake of 2,3,7,8-TCDD (pg/day)	Daily Intake of I-TEQ_{DF} (pg/day)
Air inhaled	20[a] m^3	0.05	2
Air ingested (particulates)	[b]	0.025	1
Soil dermal	150 mg	0.004	0.15
Soil ingested		0.003	0.10
Uptake from air and soil		0.08	3.2
Leafy vegetables	27 g	0.2-2	1.8-7
Pork	15 g fat	0.45	4.2
Beef	5 g fat	3	13
Chicken and eggs	2.5 g fat	0.6	4.8
Milk	8 g fat	3.2	17
Cheese, butter	12.5 g fat	5	26
Sea fish	0.4 g fat	2	14
Freshwater fish	0.4 g fat	4	10
Fish oil	5.5 g	1.1	7.2
Vegetable oil	40 g	NDA	14
Intake from food		19.5-21.3	112-117
Intake from paper food packaging		NDA	9.1
TOTAL INTAKE		19.6-21.4	121-126

[a] Intake rate could not be determined from Theelen (1991).

[b] Assumes exposure of 2,000 cm^2 of skin to 1 mg of soil/cm^2. Soil concentrations assumed to be 7,000 mg I-TEQ_{DF}/kg and 175 mg of 2,3,7,8-TCDD/kg. Dermal absorption of 1 percent assumed.

NDA = No data available.

Source: Theelen (1991).

Table 4-28. Estimated Lifetime Average Daily Exposure of Canadians to Dioxin I-TEQ_{DF}

Media	Daily Intake of Dioxin[a] (I-TEQ_{DF}) (pg/day)		
	Adult A[b]	Adult B[c]	Adult C[d]
Food	132 - 282	291 - 441	132 - 282
Air	3.5	3.5	12
Soil	1.75 - 1.90	1.75 - 1.90	1.75 - 1.90
Water	<0.7 - 3.5	<0.7 - 3.5	<0.7 - 3.5
Consumer Products	<0.7	<0.7	<0.7
Total Estimated Lifetime Intake[e]	140 - 290	300 - 450	150 - 300

[a] These estimates represent the lifetime average daily intake calculated by dividing the total estimated intakes for each life stage (i.e., adult, child, infant, neonate) by the 70-year exposure period. The estimates in this table are based on the upper range of average national values and conservative assumptions that overestimate rather than underestimate exposures. These estimates are only approximations and not absolute values.

[b] Adult a is an average 70-kg adult consuming average amounts of air (20 m^3/day), water (1 liter/day), and soil (20 mg/day). Food intakes based on Nutrition Canada 1977 survey.

[c] Adult B is similar to Adult a except that consumption of fish contaminated with CDDs and CDFs is in excess of current Canadian guidelines.

[d] Adult C is similar to Adult a except that he/she lives in close proximity to an incineration/combustion source.

[e] These estimates have been rounded off because of the uncertainty in the data.

Source: Gilman and Newhook (1991).

Other meat ingestion	0.18 ppt[g]	0.35 g/kg/day[h]	6.2×10^{-11}	6.2×10^{-2}	10.1
Vegetable fat ingestion	0.056 ppt[e]	17 g/day	1.4×10^{-11}	1.4×10^{-2}	2.2
	Total		6.1×10^{-10}	6.1×10^{-1} [d]	100.0

[a] Values from Table 3-64.

[b] Values for adult soil ingestion, inhalation, water ingestion, and eggs, beef pork, and poultry ingestion from Exposure Factors Handbook (U.S. EPA, 1997). Contact rates for milk, dairy, and vegetable fats are based on data from USDA (1995). Contact rates for fish from U.S. EPA (2000).

[c] Daily intake (mg/kg-day) = [Contact rate (g/day; m^3/day; L/day; mg/day) x Conc. TEQ x Unit Conversion (soil unit conversion = 10^{-12}, all other media unit conversion = 10^{-9})/Body Weight (kg)] or Contact rate (g/kg-day) x Conc. TEQ x Unit Conversion.

[d] Approximately equivalent to 43 pg/day, assuming an adult body weight of 70 kg.

[e] Calculated by setting nondetects to zero.

[f] Calculated as the surface area of the body that contacts the soil (5,700 cm^2/day) x the rate that soil adheres to the skin (0.07 mg/cm^2) x the fraction of CDD/CDFs absorbed through the skin (0.03); exposure factors based on recommendations in U.S. EPA (1999) for an adult resident, which assumes that the lower legs, forearms, hands, and head are exposed to the soil.

[g] Estimated as the average of beef, pork, and poultry.

[h] Calculated as the total meat intake rate minus the intake rates for beef, pork, and poultry (U.S. EPA, 1997).

[i] This concentration is a species-specific ingestion-weighted average value.

Table 4-31. Estimated Dioxin-Like PCB Mean Background Exposures for Adults in the United States

Beef ingestion	0.084 ppt	0.71 g/kg/day	6.0×10^{-11}	6.0×10^{-2}	18.2
Pork ingestion	0.012 ppt	0.22 g/kg/day	2.6×10^{-12}	2.6×10^{-3}	0.8
Poultry ingestion	0.026 ppt	0.50 g/kg/day	1.3×10^{-11}	1.3×10^{-2}	4.0
Other meat ingestion	0.041[g]	0.35 g/kg/day[h]	1.4×10^{-11}	1.4×10^{-2}	4.3
Vegetable fat ingestion	0.037 ppt	17 g/day	9.0×10^{-12}	9.0×10^{-3}	2.7
	Total		3.3×10^{-10}	3.3×10^{-1} [d]	100.0

[a] Values from Table 3-64.

[b] Values for adult soil ingestion, eggs, beef pork, and poultry ingestion from Exposure Factors Handbook (U.S. EPA, 1997). Contact rates for milk, dairy, and vegetable fats are based on data from USDA (1995). Contact rates for fish from U.S. EPA (2000).

[c] Daily intake (mg/kg-day) = [Contact rate (g/day; m^3/day; L/day; mg/day) x Conc. TEQ x Unit Conversion (soil unit conversion = 10^{-12}, all other media unit conversion = 10^{-9})/Body Weight (kg)] or Contact rate (g/kg-day) x Conc. TEQ x Unit Conversion.

[d] Approximately equivalent to 23 pg/day, assuming an adult body weight of 70 kg.

[e] Calculated by setting nondetects to zero.

[f] Calculated as the surface area of the body that contacts the soil (5,700 cm^2/day) x the rate that soil adheres to the skin (0.07 mg/cm^2) x the fraction of CDD/CDFs absorbed through the skin (0.03); exposure factors based on recommendations in U.S. EPA (1999) for an adult resident, which assumes that the lower legs, forearms, hands, and head are exposed to the soil.

[g] Estimated as the average of beef, pork, and poultry.

[h] Calculated as the total meat intake rate minus the intake rates for beef, pork, and poultry (U.S. EPA, 1997).

Table 4-32. Comparison of Adult Contact Rates, TEQ_{DF} Concentrations, and Background Exposure Estimates from the 1994 Draft and Current Version of This Document

Media	Previous I-TEQ_{DF} Concentration	Current TEQ_{DF}-WHO_{98} Concentration	Previous Contact Rate	Current Contact Rate	Previous Daily Intake Rate (pg/kg-day)	Current Daily Intake Rate (pg/kg-day)

c 58 kg body weight assumed
d 70 kg body weight assumed
e Dermal contact rates based on the calculation: skin surface area contacting soil (cm^2/day) x soil adherence rate (mg/cm^2) x absorption fraction (0.03). Exposure factor values based on recommended data and procedures in U.S. EPA (1999) for adult and child residents. For all ages it was assumed that the head, hands, lower legs, and forearms were exposed to soil. Adherence factors for ages 1-5 years and 6-11 years were calculated using data for children playing in dry soil. For ages 12-19 years and adults, a gardening scenario was assumed. Surface areas were assumed to be 2,400, 3,500, 5,300, and 5,700 cm^2/day for ages 1-5 years, 6-11 years, 12-19 years, and adults, respectively. Adherence factors for these age groups were estimated to be 0.03, 0.03, 0.07, and 0.07 mg/cm^2, respectively.
f Fish intake rates for children based on data in Table 10-46 of EPA's Exposure Factors Handbook (U.S. EPA, 1997). Total fish intake values apportioned among various fish categories based on the proportions for adults.
g Calculated by setting nondetects to zero.
h This concentration is a species-specific ingestion-weighted average value.

NOTE: Contact rates derived from U.S. EPA (1997) except for milk, dairy, and vegetable fats which were derived from USDA (1995). Dairy intake is assumed to be intake of total milk and milk products minus fluid milk intake.

Vegetable fat ingestion	0.056 ppt[e]	28.8 g/day	2.3×10^{-11}	2.3×10^{-2}	2.1
	Total		1.1×10^{-9}	$1.1 \times 10^{+0}$ [d]	100.0

[a] Values from Table 3-64.

[b] Values for adult soil ingestion based on data in U.S. EPA (1991b). Inhalation rate based on data for males in Exposure Factors Handbook (U.S. EPA, 1997). Water ingestion rate based on high-end value in U.S. EPA (1997). Contact rates for fish, milk, dairy, eggs, meats, and vegetable fats are based on data from an unpublished analysis of USDA's 1994-1996 CSFII data conducted by EPA.

[c] Daily intake (mg/kg-day) = [Contact rate (g/day; m^3/day; L/day; mg/day) x Conc. TEQ x Unit Conversion (soil unit conversion = 10^{-12}, all other media unit conversion = 10^{-9})/Body Weight (kg)] or Contact rate (g/kg-day) x Conc. TEQ x Unit Conversion.

[d] Approximately equivalent to 77 pg/day, assuming an adult body weight of 70 kg.

[e] Calculated by setting nondetects to zero.

[f] Calculated as the surface area of the body that contacts the soil (5,700 cm^2/day) x the rate that soil adheres to the skin (0.30 mg/cm^2) x the fraction of CDD/CDFs absorbed through the skin (0.03); exposure factors based on recommendations in U.S. EPA (1999) for an adult resident, which assumes that the lower legs, forearms, hands, and head are exposed to the soil.

[g] This concentration is a species-specific ingestion-weighted average value.

Table 4-40. Estimated Dioxin-Like PCB Upper Percentile Background Exposures for Adults in the United States

Media	Conc. WHO98-TEQ[a]	Contact Rate[b]	Daily Intake[c] (mg/kg-day)	Daily Intake (pg/kg-day)	% of Total
Soil ingestion	2.3 ppt[e]	100 mg/day	3.3×10^{-12}	3.3×10^{-3}	0.5
Soil dermal contact	2.3 ppt	51.3 mg/day	1.7×10^{-12}	1.7×10^{-3}	11.1
Freshwater fish and shellfish ingestion	1.2 ppt	10.3 g/day	1.8×10^{-10}	1.8×10^{-1}	28.5
Marine fish and shellfish ingestion	0.25 ppt	16.7 g/day	6.0×10^{-11}	6.0×10^{-2}	9.6
Inhalation	--	--	--	--	--
Water ingestion	--	--	--	--	--
Milk ingestion	0.0088 ppt	421 g/day	9.6×10^{-11}	9.6×10^{-2}	15.5
Dairy ingestion	0.058 ppt	132 g/day	1.1×10^{-10}	1.1×10^{-1}	17.6
Eggs ingestion	0.10 ppt	0.39 g/kg/day	3.9×10^{-11}	3.9×10^{-2}	6.3
Beef ingestion	0.084 ppt	0.93 g/kg/day	7.8×10^{-11}	7.8×10^{-2}	12.6
Pork ingestion	0.012 ppt	0.30 g/kg/day	3.6×10^{-12}	3.6×10^{-3}	0.6
Poultry ingestion	0.026 ppt	0.68 g/kg/day	1.8×10^{-11}	1.8×10^{-2}	2.9
Other meats ingestion	0.041 ppt	0.48 mg/kg/day	2.0×10^{-11}	2.0×10^{-2}	3.2
Vegetable fat ingestion	0.037 ppt	28.8 g/day	1.5×10^{-11}	1.5×10^{-2}	2.5
	Total		6.2×10^{-10}	6.2×10^{-1} [d]	100.0

[a] Values from Table 3-64.

[b] Contact rates for fish, milk, dairy, eggs, meats, and vegetable fats are based on data from an unpublished analysis of USDA's 1994-1996 CSFII data conducted by EPA.

[c] Daily intake (mg/kg-day) = [Contact rate (g/day; m^3/day; L/day; mg/day) x Conc. TEQ x Unit Conversion (unit conversion = 10^{-9})/Body Weight (kg)] or Contact rate (g/kg-day) x Conc. TEQ x Unit Conversion.

[d] Approximately equivalent to 43 pg/day, assuming an adult body weight of 70 kg.

[e] Calculated by setting nondetects to zero.

[f] Calculated as the surface area of the body that contacts the soil (5,700 cm^2/day) x the rate that soil adheres to the skin (0.07 mg/cm^2) x the fraction of CDD/CDFs absorbed through the skin (0.03); exposure factors based on recommendations in U.S. EPA (1999) for an adult resident, which assumes that the lower legs, forearms, hands, and head are exposed to the soil.

Table 4-41. Comparisons of Predicted Average Daily Intake of 2,3,7,8-TCDD and Total TEQ_{DF}s

Location	Daily Intake of 2,3,7,8-TCDD (pg/day)	Daily Total TEQ_{DF} intake (pg/day)	Media
United States[a]	34.8	--	beef, milk, produce, fish, eggs, water, inhalation
United States[b]	15.9	--	dairy, meat, fish
North America[c]	5.5	43	dairy, eggs, meat, poultry, fish, inhalation, soil ingestion, soil dermal contact
Canada[d]		140-290	air, water, soil, food
Germany[e]		85 (79)	dairy, meats, fish
Germany[f]	25.0	158	dairy, meat, fish
Netherlands[g]	20.0	121-126	dairy, meat, poultry, fish
United Kingdom[h]	--	69	meat, fish, dairy, poultry, eggs, milk products, breads, and cereals
United Kingdom[i]	--	175.5	meat, fish, dairy, poultry, eggs, milk products, breads, and cereals
Spain[j]	--	210	vegetables, lentils and beans, cereals, fruit, fish, meat, eggs, dairy, milk, and oil

OCDF	1.9	0.00019	0.00018	0.0016
TOTAL		1.06	1.00	8.9

[1] This is calculated as the picograms TEQ_{DF}-WHO_{98} contributed by each congener divided by the total TEQ_{DF}-WHO_{98} concentration. For example, the 0.049 for 2,3,7,8-TCDD is calculated as 0.052/1.06.

[2] Picograms contributed by each congener = (0.18 pg/g) (0.71 g/kg/day) (70 kg) (TEQ_{DF}-WHO_{98} fraction), where 0.18 pg/g is whole weight beef concentration as derived in Section 4.4.2, 0.71 g/kg/day is the consumption rate, 70 kg is the average adult body weight, and the TEQ_{DF}-WHO_{98} fraction is shown in the fourth column above, just preceding this final column of results.

5.0. POTENTIALLY ELEVATED EXPOSURES

5.1. INTRODUCTION

Certain groups of people may have higher exposures to the dioxin-like compounds than the general population. The following sections discuss higher exposures that may result from dietary habits, localized impacts, and cigarette smoking. Other population segments can be highly exposed due to occupational conditions or industrial accidents. For example, several epidemiological studies have evaluated whether elevated dioxin exposure has occurred to certain workers in the chemical industry, members of the Air Force who worked with Agent Orange, and residents of Seveso, Italy, who were exposed as a result of a pesticide plant explosion. These epidemiological studies are fully discussed in the Epidemiology Chapter of the Dioxin Health Reassessment Document (U.S. EPA, 1996) and should be consulted if further details are desired. This chapter, however, does not address occupational or accidental exposure. Instead, it focuses on elevated exposures among the general population from dietary habits such as breast feeding or high rates of fish ingestion, localized sources, or cigarette smoking.

5.2. NURSING INFANTS

Nursing infants may be exposed to dioxin-like compounds via consumption of breast milk. These compounds are deposited in the fatty tissues (i.e., adipose tissue, blood lipids, and breast milk) of the mother and may be transferred to the infant during nursing. Based on data from 1989, approximately 52 percent of U.S. mothers initiate breastfeeding with their newborn infants, and 40 percent continue breastfeeding for 3 months or longer (NAS, 1991). At 5 to 6 months of age, only about 20 percent of infants are breast-fed (NAS, 1991). This section will show how breast milk ingestion exposures, which are higher during breast-feeding, on a body weight basis, than during any other period in an individual's life, impact lifetime exposures and body burdens. First, data showing the impact of breast milk ingestion to the infant body burden of CDD/CDF/PCBs are reviewed. Then, an estimate of the dose (average daily dose, ADD, and lifetime average daily dose, LADD) to the infant via breast milk is made. The section will close by developing, testing, and applying a model on the impact of breast-feeding to body burdens for growing infants.

5.2.1. The Impact of Breast Feeding on Infant Body Burden

Abraham et al. (1994, 1995) studied CDD/CDF/PCB levels in the blood of a breast-fed and a formula-fed infant at 11 and 25 months of age. Sampling of blood showed that the body burden of dioxin-like compounds was more than an order of magnitude higher for the breast-fed infant than the formula-fed infant during both time periods, with CDD/CDF ranging from 34.7 (11 months) to 43.9 (25 months) ppt TEQ_{DF}-WHO_{98} lipid-basis in the breast-fed infant compared to 2.7 to 3.3 ppt TEQ_{DF}-WHO_{98} for the formula-fed infant. Dioxin-like PCB concentrations were similarly an order of magnitude different, with the breast-fed infant having a concentration of 31.4 ppt TEQ_{P}-WHO_{98}, compared to 2.5 ppt TEQ_{P}-WHO_{98} for the formula-fed infant at 11 months (PCB 126 not measured at 25 months, so a comparison for that age is not informative). The full congener profiles for these results are shown in Table 5-1. The increase in the lipid-based CDD/CDF TEQ concentration in the blood of the breast-fed infant at 25 months was attributed to the relative decrease in body fat mass during the period between sampling and slight increases in body burden concentrations.

Abraham et al. (1994) also analyzed mother's milk at 1 month and mother's blood along with the infants' blood at 11 months. They found mother's milk to contain 23.5 ppt TEQ_{DF}-WHO_{98} at 1 month and mother's blood to contain 14.2 ppt TEQ_{DF}-WHO_{98} at 10 months. If blood and milk concentrations in a mother during lactation are the same at any given time, then these data suggest a reduction of about 40 percent in TEQ concentration in the mother between the 1st and 10th month of lactation. The reduction in mother's milk concentration of dioxins during nursing is discussed further in Section 5.2.3 below.

Kreuzer et al. (1997) developed and tested a toxicokinetic model of human lifetime body burden of TCDD, starting with a model for breast-feeding. To support their model, they presented adipose tissue and liver data on 3 stillborn and 17 infants who had died from sudden infant death syndrome (SIDS). Nine of the 17 infants had spent some portion of their lives breast-feeding, while the other 8 infants were formula-fed. Average congener and TEQ concentrations for these three groups are shown in Table 5-2. The highest TEQ concentrations were found in the infants who had some breast-feeding, with adipose concentrations at 15.9 ppt TEQ_{DF}-WHO_{98}, as compared to formula-fed infants who had concentrations at 4.3 ppt TEQ_{DF}-WHO_{98}. The breast-fed infants' concentrations included four infants who were weaned several weeks prior to their death from SIDS.

This may have generally led to reductions in their body burdens as their higher daily intake from breast-feeding was reduced after weaning. The average TEQ concentration for the five infants who died while still breast-feeding was 20.1 ppt TEQ_{DF}-WHO_{98}. The highest concentration found was for the infant who was breast-fed the longest at 19 weeks, and who died at that time; the TEQ concentration was 35 ppt TEQ_{DF}-WHO_{98}. Other breast-fed infants, however, did not have as much impact - infants who died while breast-feeding at 12 and 16 weeks had concentrations of 9 and 7.5 ppt TEQ_{DF}-WHO_{98}. While Kreuzer et al. (1997) concluded that breast-fed infants had elevated concentrations compared to formula-fed infants, they also observed that breast-fed infants had adipose TEQ concentrations that were within the range or lower than the values published for adults.

Abraham et al. (2000) reported on a study in Germany in which the blood of 80 breast-fed infants between the ages of 4 and 11 months were analyzed for the 17 CDD/CDFs . Of these 80 infants, 27 were from a region where a copper recycling plant led to elevations in the mother's milk. The I-TEQ_{DF} blood concentration in this group of 80 children at 11 months ranged between 2.0 and 107 pg/g lipid-basis, with a median of 25.3 ppt. Of these children, 6 had I-TEQ_{DF} concentrations greater that 50 ppt, and 5 of these 6 were from the region impacted by the copper recycling plant. From a control group of 21 children who had been formula-fed, individual dioxin measurements were performed in 5 children. Concentrations were found to range narrowly from 1.9 to 3.2 ppt I-TEQ_{DF} lipid-basis at 11 months. With several measurements over time, Abraham et al. (2000) found the blood concentrations of the breast-fed infants to increase over time. Infant or time-specific concentration data were not presented in Abraham et al. (2000). However, they did show the ratio between the concentration of specific compounds, as well as the I-TEQ_{DF} concentrations, in the children's blood and the blood of the mothers. When the ratio exceeded 1.0, this meant that the child's concentration was higher than the mother's. Abraham et al. (2000) showed the I-TEQ_{DF} ratio to increase from 1.12 at 16-24 weeks (n = 11 meaning there were 11 paired measurements at that time) to 2.12 at 25-32 weeks (n = 29) to 3.20 at 33-40 weeks (n = 33) to 3.73 at 41-48 weeks (n = 7). This was the most comprehensive data set found in the literature, although it was not fully described in the Abraham et al. (2000) abstract.

Patandin et al. (1997) looked at the plasma levels of four polychlorinated biphenyls (PCBs) in 173 Dutch children 3.5 years of age, 91 of which had been breast-fed and 82

of which had been formula-fed. Children in the breast-fed group had significantly higher median PCB levels in plasma ($p < 0.0001$) than children in the formula fed group. The four PCBs measured were 118, 138, 153, and 180. The median sums of these four PCBs in the two groups of children were 0.75 µg/L in the breast-fed group versus 0.21 µg/L in the formula fed group. By means of an extensive questionnaire on dietary history, combined with data on the concentrations of dioxin and PCBs in foods provided by the Dutch National Institute of Public Health and the Environment, Pantadin et al. (1997) were able to determine that the TEQ intake via the diet was virtually indistinguishable in the two groups. They found that PCB levels in the breast-fed children were significantly correlated with the period of breast-feeding ($r = 0.63$), milk PCB levels ($r = 0.39$), and the total TEQ in breast milk ($r = 0.36$). They concluded that the plasma PCB levels in Dutch children were the result of exposure through breast milk and in utero exposure, and that the influence of dietary intake of PCBs after weaning is small compared to the intake during breast-feeding.

5.2.2. Calculation of an Average Daily Dose from Breast-Feeding

Using the estimated dioxin concentration in breast milk, the administered dose to the infant can be estimated as follows:

$$ADD_{infant} = \frac{C_{milk\ fat} * f_3 * IR_{milk} * ED}{BW_{infant} * AT} \qquad \text{(Eqn. 5-1)}$$

where,

ADD_{infant} = Average daily dose to the infant (pg/kg-d);
$C_{milk\ fat}$ = Concentration in milk fat (pg/g);
IR_{milk} = Ingestion rate of breast milk (kg/d);
ED = Exposure duration (yr);
BW_{infant} = Body weight of infant (kg);
AT = Averaging time (yr); and
f_3 = Fraction of fat in breast milk.

The administered dose can be converted to an absorbed dose by multiplying by the fraction of ingested contaminant that is absorbed.

This approach assumes that all pertinent parameters, including the body weight of the infant, the infant ingestion rate of breast milk, and perhaps most importantly, the contaminant concentration in milk, represent the average over the breast feeding time period.

Smith (1987) reported that a study in Britain found that the breast milk ingestion rate for 7- to 8-month old infants ranged from 677 to 922 mL/d and that a study in Houston measured the mean production of lactating women to range from 723 to 751 g/d. Smith (1987) also reported that breast milk ingestion rates remain relatively constant over an infant's life. For purposes of estimating the dose to breast feeding infants, a milk ingestion rate of 800 mL/d was assumed in the analysis presented in this section. Smith (1987) also assumed that mother's milk has a 4 percent fat content, and that 80 percent of the ingested contaminant are absorbed. The infant weight varies with time. For example, a typical infant (average of male and female data) weighs about 3.3 kg at birth, 7.9 kg at 6 months, and 10.2 kg at 1.0 year (U.S. EPA, 1997; Walker and Watkins, 1997).

The concentration of dioxin in the mother's milk is also expected to change, since lactation provides a significant avenue of depuration. Lakind et al. (2000) cite several references where measurements of breast milk concentrations of lipophilic compounds (PCBs, DDE, DDT, CDD/CDFs) were shown to decline during the course of lactation. They fit available data on 2,3,7,8-TCDD to a curve, and their resulting relationship showed an 86 percent loss over 6 months. This is comparable to a modeling effort by Kreuzer et al. (1997), who modeled a 70 percent decline in TCDD concentrations after 6 months. Their model was more mechanistic, and added the loss by breast milk to an overall female body burden model which included inputs by food consumption and outputs by metabolic and non-metabolic pathways. Patandin et al. (1999), in their modeling of dioxin exposures from infancy to adulthood, cited data from Germany and England to conclude that breast milk concentrations of TCDD decline by 20 percent every 3 months. The data described in the previous section by Abraham et al. (1994) suggest a decline of 40 percent of TEQs from 1 month to 10 months of lactation.

For assignment of $C_{milk\ fat}$ in Equation 5-1, therefore, one would have to assign a concentration at birth and consider a decline in that concentration over time. For purposes of this discussion, a concentration of 25 ppt TEQ_{DFP}-WHO_{98} on a lipid basis is assumed for mother's milk when lactation begins (which is the average tissue concentration derived from recent studies of dioxins in blood in background settings of the US, reviewed in Chapter 4). It is then assumed to linearly drop by 50 percent after 6 months, with an additional linear drop of 50 percent by the end of 12 months, for a total decline of 75 percent from initial concentrations. These assignments in concentration decline are in the middle of the range reported above. They translate to concentrations of 12.5 ppt TEQ_{DFP}-WHO_{98} after 6 months and 6.3 ppt TEQ_{DFP}-WHO_{98} after a year, given a starting concentration of 25 ppt TEQ_{DFP}-WHO_{98}.

The proper way to derive an average dose to the child is to integrate Equation 5-1 over the time period of interest. At birth, for example, with a mother's milk concentration of 25 ppt TEQ_{DF}-WHO_{98}, an infant body weight of 3.3 kg, an average ingestion rate of 800 g/d breast milk, the administered dose is predicted to be 242 pg TEQ_{DF}-WHO_{98}/kg bw/day [(25 pg/g x 0.04 x 800 g/d) / (3.3 kg) = 242 pg/kg-d]. Table 5-3 shows infant body weights, as well as doses of dioxin TEQ_{DF}-WHO_{98} expressed in terms of pg/day for each of the first 12 months of life. These body weight data are the averages for male and female infants (U.S. EPA, 1997; Walker and Watkins, 1997), and along with other data, were used in the pharmacokinetic exercise described in the next section. Calculating monthly doses on the basis of body weight for each of the first twelve months of life and then dividing by 12, results in an average dose to the infant of 87 pg TEQ_{DF}-WHO_{98}/kg bw/day.

This value is much higher than the estimated average background TEQ_{DFP}-WHO_{98} dose for adults of approximately 1 pg TEQ_{DFP}-WHO_{98}/kg-d. However, if a 70 year averaging time is used for this one-year nursing scenario, then the LADD (Lifetime Average Daily Dose, calculated as ADD * ED/LT where LT is lifetime typically assumed to be 70 years) is estimated to be 1.2 pg TEQ_{DFP}-WHO_{98}/kg-d ([87 pg/kg-d] * 1 yr/70 yr). This is close to the adult background dose of 1.0 pg TEQ_{DFP}-WHO_{98}/kg-d. However, this can be misleading because it ignores the difference in daily intake during potentially sensitive stages in development. Also, it does not consider any exposures past the first year of life. In order to calculate a true lifetime average daily dose, one needs to incorporate the

changes in dose over various life stages. Using the estimates of dose derived in Chapter 4 for various ages in children: 1-5: 3.3 pg TEQ_{DFP}/kg-d, 6-11: 1.9 pg TEQ_{DFP}/kg-d, and 12-19: 1.1 pg TEQ_{DFP}/kg-d, the following calculates the LADD for lifetime background exposures considering one year of breast-feeding:

$$\text{LADD} = 87 \frac{1\text{yr}}{70\text{yrs}} + 3.3 \frac{4\text{yrs}}{70\text{yrs}} + 1.9 \frac{6\text{yrs}}{70\text{yrs}} + 1.1 \frac{8\text{yrs}}{70\text{yrs}} + 1.0 \frac{51\text{yr}}{70\text{yr}} \quad \text{(Eqn. 5-2)}$$

$$\text{LADD} = 2.45 \frac{\text{pg TEQ}_{DFP}}{\text{kg- day}} \quad \text{(Eqn. 5-3)}$$

On a mass basis, the cumulative dose to the infant after a year is about 238 ng TEQ_{DFP}-WHO_{98} (87 pg/kg-d x 7.5 kg x 365 d x ng/1,000 pg; 7.5 kg is an average annual weight based on the average of 12 monthly body weights). Using the age-dependent doses derived in Chapter 4 with assumed body weights, a dose from year 1 to year 70 in a 70-year lifetime is estimated to be about 1,687 ng TEQ_{DFP}-WHO_{98}, so that a total lifetime dose is 1,925 ng TEQ_{DFP}-WHO_{98} (1,687 + 238). This suggests that about 12 percent of lifetime dose (238/1925 * 100 percent) may occur as a result of breast feeding, if that feeding occurred for one year.

This exercise describes accumulated dose over a lifetime, given a year of breast-feeding. It was found that about 12 percent of lifetime dose came from breast-feeding. It was also found that the LADD for this scenario, including average dioxin doses after the first year until year 70, was 2.45 pg TEQ_{DFP}-WHO_{98}/kg-day. The issue of accumulative dose is explored in more detail in the next section, where the quantity, "area under the curve" is defined and used to assess overall exposure during a lifetime, or portions of a lifetime, under different breast-feeding scenarios as well as a formula-only scenario where the infant experiences only background exposures.

5.2.3. Modeling the Impact of Breast-Feeding on Infant Body Burden

The previous section described an approach to estimate doses received by an infant due to breast-feeding, which included a starting concentration in mother's milk, a decline of that concentration over time (and the resulting decline in dose delivered to the child),

and the child's changing body weight. That information will be used in this section to evaluate the impact of breast feeding on an infant's body burden of dioxins.

To better evaluate the impact of nursing on infants, a one-compartment non-steady state pharmacokinetic model was used to evaluate dioxin tissue levels. As described below, this model was validated using paired mother/child data on breast milk and infant blood concentrations of TEQ_{DF}-WHO_{98}. Following this validation, several breast-feeding scenarios were modeled and compared with a formula-feeding only scenario. Specifically, changes in infant TEQ_{DFP}-WHO_{98} tissue concentration over time were modeled for these scenarios: formula only, 6 weeks nursing, 6 months nursing, 1 year nursing, and 2 years nursing. The section closes with sensitivity analyses exercises which describe the model response to changes in the key parameters describing the dose received by the infant via breast milk and the rate of dissipation of dioxin TEQs in the infant.

5.2.3.1. *Description of the Model*

The pharmacokinetic model was based on the following differential equation describing the mass balance of dioxin in lipids (Pinsky and Lorber, 1998):

$$da(t)/dt = f\,D(t) - k(t)\,a(t) \qquad \text{Eqn. (5-4)}$$

$$c(t) = \frac{a(t)}{1000\,V(t)} \qquad \text{Eqn. (5-5)}$$

where:

- a(t) = total mass of dioxins in lipid (pg) at time t;
- c(t) = concentration of dioxins in lipid (pg/g) a time t;
- D(t) = ingested dose of dioxins (pg/yr) at time t;
- V(t) = lipid weight (kg) at time t;
- k(t) = elimination rate constant (yrs^{-1}) at time t;
- t = time (yrs); and
- f = fraction of ingested dose absorbed into lipid compartment (unitless).

The lipid weight, V(t), is calculated as the product of the percent body lipid and the full body weight of the infant, both of which are provided in Walker and Watkins (1997) for infant boys and girls. This section demonstrates the approach using the average for infant boys and girls. The dose regime for tested scenarios in this section, the body weight, lipid fraction, and assumed half-lives of TEQ_{DFP}-WHO_{98}, are shown with other model parameters in Table 5-3. The body lipid and body weight are also shown graphically in Figure 5-1, for the 70 year life span and in more detail for the early years of life.

One key assumption of this simplistic framework is that dioxins are instantaneously distributed to all body lipids. This is a common assumption for TCDD PK modeling in humans, adopted by the multi-compartment model of van der Molen et al. (1996), and the single-compartment models in Kreuzer et al. (1997), Campbell et al. (1996), and Lakind et al. (2000). The model of Carrier et al. (1995a,b) alternately has a nonlinear response to doses, with different partitioning to the liver and other body lipids as a function of body concentration; when the overall body concentration is high, more of the dioxin dose is partitioned to the liver, whereas at lower body concentrations, the partitioning to the liver is lower.

The other key and important assumption for the model is that the TEQ_{DFP}-WHO_{98} behaves as a single compound in humans, and can be described by a single dissipation half-life. Ayotte et al. (1994) modeled TEQ body burdens from infancy to adulthood, but it was unclear whether they modeled individual congeners or TEQs as one compound. Campbell et al. (1996) used a framework similar to the one used here and modeled individual congeners for an industrial exposure study.

The elimination rate constant, k(t), was developed in similar fashions by Pinsky and Lorber (1998), Michalek et al. (1996), and Flesch-Janys et al. (1996), for 2,3,7,8-TCDD. All three research groups derived a relationship in which the elimination rate constant was a function of percent body fat. All three also curve-fit their empirical algorithms for k(t) on data from adult individuals, whose percent body fat was about 25 percent. With body fat percent increasing over time, particularly in older individuals, the elimination rate constant decreased (equivalently, the half-life increased) significantly. Given a range of body fat over time, from about a low of 15 percent to a high over 40 percent (for elderly females), the relationship in Pinsky and Lorber (1998) results in a half-life of 2,3,7,8-TCDD ranging from about 6 to over 20 years.

None of these efforts, however, identified processes or factors critical for infants, other than percent body fat. With a body fat of around 15 percent at birth, the half-life is calculated to be about 6.4 years using the relationship in Pinsky and Lorber (1998). Kreuzer et al. (1997), however, developed a procedure for modeling the elimination half-lives for 2,3,7,8-TCDD in infants which considerd metabolic, t_m (breakdown by enzymes), and non-metabolic, t_f (fecal elimination) processes. Kreuzer et al. (1997) combined these two half-lives to solve for an overall half-life, $t_{1/2}$. Other key parameters included total body lipid mass and liver volumes, which change over time, and a reference half-life for an adult. For their "reference adult" at age 40, they cited an overall half-life of 5 years, based on information in Geyer et al. (1986). The Kreuzer et al. (1997) model showed a rise in half-lives from a low of less than 0.5 years at birth to a high of 5 years at the total body lipid mass of 20 kg. With their parameter assignments, perhaps most importantly this assignment of a 5 year half-life for a reference adult, the half-life will not go far beyond 5 years (as a function of body lipid mass, it would exceed 5 years when body lipid mass exceeds 20 kg), which makes the model of Kreuzer et al. (1997) importantly different than that of Pinsky and Lorber (1998), Michalek et al. (1996), and Flesch-Janys et al. (1996), all of whom have half-lives varying from a value of 6 to over 20 years. In short, the model of Kreuzer et al. (1997) has half-lives which mostly never exceed 5 years, while the other approaches have half-lives for TCDD which never go below 6 years.

As noted, the model of Kruezer et al. (1997) suggests relatively short half-lives for infants. For infants, the overall half-life is driven by non-metabolic processes and the resulting half-life for newborns is calculated to be about 0.4 years. It rises to about 2.0 years when the total body fat weight is about 5 kg, which occurs around ages 8-10 years (25-35 kg overall body weight, about 20 percent body fat). Very clearly, this rapid a half-life of dioxin intake will have an important impact on the accumulation of dioxin residues during breast-feeding as compared to a model showing a 6 year or higher half-life. Lakind et al. (2000) adopted the Kruezer et al. (1997) approach in their evaluation of the impacts of breast-feeding on the 2,3,7,8-TCDD body burdens of infants.

For purposes of this assessment, it was assumed that the overall half-life for the early years of life more closely follows the trend as derived in the modeling exercises by Kruezer et al. (1997). For later years, it was felt that the empirical data upon which Pinsky and Lorber (1998), Michalek et al. (1996), and Flesch-Janys et al. (1996) derived

the half-life relationship for 2,3,7,8-TCDD is more valid. Therefore, a hybrid of these assumptions, as shown in Figure 5-2, was adopted for this effort. The half-life at birth starts at the low value of 0.4 yr and then slowly rises to the levels as modeled by Pinsky and Lorber (1998) by about age 20. It is noted that had Kreuzer et al. (1997) established reference half-lives for 40 year-olds more in the 6-20 year range, they would still have had very low half-lives at birth, rising to these higher half-lives with age. The half-life assumptions remain an obvious uncertainty for this type of modeling approach. Not only is there a disparity in the literature with regard to this critical assumption, but the literature is also only specific to 2,3,7,8-TCDD, not TEQ_{DFP}-WHO_{98}. The impact of this assumption is examined later in the sensitivity analysis exercises.

The final assumption for the model is the initial lipid concentration in the infant. It was assumed to be 10 ppt TEQ_{DFP}-WHO_{98}, which was reasonably similar to the 11.9 ppt TEQ_{DF}-WHO_{98} found in stillborn adipose tissue in Kreuzer et al. (1997). All other assumptions and parameter assignments for this modeling exercise, including the half-life change over time, are shown in Table 5-3, and Figures 5-1 and 5-2.

5.2.3.2. *Validation of the Model*

While demonstrating the impact of breast-feeding, the studies reviewed in Section 5.2.1. do not contain the type of information needed for model validation. What is needed are breast milk concentrations that are taken at the same time infant body burden measurements are taken. The breast milk concentrations are used to provide the "independent" model driving term, the dose term, and the body burden measurements provide the "dependent" model prediction, the infant body lipid concentration.

One study had a set of this kind of data. Abraham et al. (1998) studied CDD/CDF/PCB levels in the blood of 6 breast-fed infants as well as the breast milk of the mothers of these infants. A portion of this data set had been reported in their earlier articles (Abraham et al., 1994; 1995). This analysis will focus on the TEQ_{DF}-WHO_{98} concentrations reported in Abraham et al. (1998), since PCB concentrations were not uniformly available for mother's milk and infant blood for all six mother/child pairs.

Two of the infants were the second children from mothers whose first child was also tracked by Abraham and colleagues. It was interesting to note that, for these two second children, both the mothers' milk and the infants' body burdens were significantly

lower. Specifically, the comparison of first and second children, respectively, were: 34.7 ppt TEQ_{DF}-WHO_{98} lipid compared to11.9 ppt TEQ_{DF}-WHO_{98}, and 44.2 ppt TEQ_{DF}-WHO_{98} compared to 18.8 ppt TEQ_{DF}-WHO_{98}. The comparison of the mothers' milk from the first to second children was similarly disparate: the first mother had concentrations ranging from 14 to 24 ppt TEQ_{DF}-WHO_{98} lipid for the first child, but 13 to 14 ppt TEQ_{DF}-WHO_{98} lipid only for the second child. The other mother showed a range of 15 to 27 ppt TEQ_{DF}-WHO_{98} lipid for the first child, but only 13 to 18 ppt TEQ_{DF}-WHO_{98} lipid for the second. Apparently, breast-feeding of the first child resulted in a higher body burden for this infant as compared to the second infant, and a lower body burden for the mother when the second infant was breast-fed.

Table 5-4 shows the observed data that were available in Abraham et al. (1998) for this model validation exercise. There were two concentrations measured in breast-milk for each of 5 of 6 children. The one child whose mother had only one measurement was only breast-fed for 7 weeks; all other children were breast-fed for periods ranging narrowly from 26 to 32 weeks. Concentrations within the breast-feeding period were linearly extrapolated from the two available data points. For example, for the first mother/child pair listed in Table 5-4, mother's milk was analyzed during month 2 and month 11. TEQ concentrations were 23.5 and 14.0 ppt TEQ_{DF}-WHO_{98} lipid, respectively. These concentrations were extrapolated backwards to give an estimated concentration at birth of 24.6 ppt TEQ_{DF}-WHO_{98}. Likewise, forwards extrapolation gave an estimated concentration for month 3 of 22.4 TEQ_{DF}-WHO_{98}, assuming linear decline. The infant body burden was ascertained by blood measurements at about 1 year of age for each child. The amount of time of full breast-feeding was supplied by Abraham et al. (1998), and this is also listed in Table 5-4.

Other assumptions for modeling the infant body burden were outlined above, and these include the intake rate of mother's milk (IR = 800 ml/d), the fraction of fat in mother's milk (0.04), the rate of absorption of dioxins (0.80), and the changing infant body weight and lipid fraction (and hence lipid volume, V(t); Table 5-3). After weaning, the dose to the infant was assumed to be 50 pg TEQ_{DF}-WHO_{98}/d. This is the dose developed for the age range of 1-5 in Chapter 4. The dose by formula feeding or other foods the infants may be consuming after weaning may be lower or higher, as little

information is available on the dioxin content of baby formula or baby food. The assumed initial body burden of the infant was 10 ppt TEQ_{DF}-WHO_{98}, as noted above.

The rate of dissipation of dioxin residues was identified as a principal uncertainty for this model. Two lines of thought discussed above include the rapid dissipation (half-life < 1 year) of TCDD residues in infants modeled in Kreuzer et al. (1997) and later adopted by Lakind et al. (2000), and the much longer dissipation (half-life around 7 years) of TCDD in adults described in Pinsky and Lorber (1998), Michalek et al. (1996), and Flesch-Janys et al. (1996). The model validation exercise described in this section tested the appropriateness of the lower infancy half-life approach adopted in this model, as shown in Figure 5-2, against an assumption of a constant 7 year half-life for TEQ_{DF}-WHO_{98} during the first year of life.

Table 5-4 shows the final results of this exercise. As seen, the model predictions at the selected and more rapid dissipation rate were significantly nearer to observations as compared to the predictions with the longer half-life. The average predicted concentration for the rapid dissipation rate for the 6 infants was 26 ppt TEQ_{DF}-WHO_{98} lipid, compared to the average observed concentration of 23.5 ppt TEQ_{DF}-WHO_{98} lipid. With a longer 7-year half-life, the predicted concentrations were all higher, with an average of 39 ppt TEQ_{DF}-WHO_{98} lipid. The model also seemed very adequately responsive to lower or higher infants' exposures. For the infant who was breast-fed for only 7 weeks with a low concentration in the mother's milk, the blood concentrations measured 5.0 ppt TEQ_{DF}-WHO_{98} lipid at 13 months, compared to a predicted 10 ppt TEQ_{DF}-WHO_{98} lipid (with the rapid dissipation assumption). The infant exposed to the highest mother's milk concentration had the highest body burden measurement at 44.2 ppt TEQ_{DF}-WHO_{98} lipid and also the highest predicted concentration at 36 ppt TEQ_{DF}-WHO_{98} lipid.

In summary, it appeared that, even with the key uncertainties identified above, including the use of a simple, one-compartment pharmacokinetic model and the modeling of TEQ_{DFP}-WHO_{98}s as though they were a single compound, this approach appears to predict infant TEQ_{DFP}-WHO_{98} body burdens within the range observed, and is adequately responsive to the different conditions of high and low exposure via breast-feeding.

5.2.3.3. *Scenario Evaluation*

The scenarios evaluated include: formula only, 6 weeks of breast-feeding, 6 months of breast-feeding, 1 year of breast-feeding, and 2 years of breast-feeding. These scenarios encompass current trends. In comprehensive documentation of statistics for children born between 1990 and 1993, CDC (1997) reported that 55 percent of all babies breastfed, with about half of those breastfeeding beyond 5 months. The average duration of breastfeeding was 28.7 weeks. In a policy statement, the American Academy of Pediatrics (1997) stated that exclusive breastfeeding is ideal nutrition and sufficient to support optimal growth and development for 6 months after birth. They recommend that breastfeeding continue for at least 12 months, and thereafter for as long as mutually desired. Ryan (1997) documented a resurgence in breastfeeding between 1989 and 1995. In comprehensive surveys conducted in 1989 and 1995, he found a 14 percent increase in the number of mothers who breastfed in the hospital, rising from 52 percent in 1989 to 59 percent in 1995. He also found a 19 percent increase in mothers who continued to breastfeed at 6 months, rising from 18 percent in 1989 to 22 percent in 1995.

The specifics of these scenarios are:

Scenario #1: Formula Only: In this scenario, the dose to the infant was assumed to be 50 pg TEQ_{DFP}-WHO_{98}/d. This is the dose developed for the age range of 1-5, as described in Chapter 4. The dose by formula feeding may be lower or higher, as little information is available on the dioxin content of baby formula. TEQ_{DFP}-WHO_{98} doses among individuals from 6 to 11, 12 to 18, and greater than 18 years of age were 54, 65, and 66 pg TEQ_{DFP}-WHO_{98}/d, respectively, as developed for these age ranges in Chapter 4.

Scenario #2: Six-Week Nursing: The dose to the infant was assumed to be a function of the starting concentration of dioxins in the mother's milk, 25 pg TEQ_{DFP}-WHO_{98}/g lipid, and other assumptions that have been described in this section: 800 g/day milk ingestion, 4 percent lipids in milk, resulting in an initial dose of 800 pg TEQ_{DFP}-WHO_{98}/d. This drops to 733 after 1 month, and then to 667 pg TEQ_{DFP}-WHO_{98}/d, when nursing stops. Doses from then are as in Scenario #1.

Scenario #3: Six-Month Nursing: It was assumed that the dose drops linearly from 800 to an ending dose of 400 pg TEQ_{DFP}-WHO_{98}/day at month 6. From there, doses are as in Scenario #1.

Scenario #4: It was assumed that the doses drop linearly from 800 to 400 at 6 months and then linearly again to 200 pg TEQ_{DFP}-WHO_{98}/day at the end of one year. From there, doses again are as in Scenario #1.

Scenario #5: The 1 year dose of 200 pg TEQ_{DFP}-WHO_{98}/day assumes a mother's milk concentration of 6.25 ppt TEQ_{DFP}-WHO_{98} lipid, which represented a drop from an initial concentration of 25 ppt TEQ_{DFP}-WHO_{98} lipid. For purposes of this demonstration, it was assumed that the mother's milk concentration stays at 6.25 ppt TEQ_{DFP}-WHO_{98} lipid for the second year of breast-feeding. From there, doses again are as in Scenario #1.

The results from this exercise are shown in Figures 5-3 and 5-4, which show the lipid concentrations and the body burdens from birth up to 70 years of age (on Figure 5-3), and then these two quantities for the narrower time frame of from birth to 10 years of age (Figure 5-4). The body burden, defined as the whole body concentration, is simply calculated as the lipid concentrations times the lipid fraction. Other results for these 5 scenarios are provided in Table 5-5, including the peak TEQ_{DFP}-WHO_{98} concentrations in the infant, the time when the peak occurred, the "area under the curve" (AUC), corresponding to different times, and the ratio of that AUC for the breast-feeding scenarios and the AUC for formula feeding only. The AUC is defined as:

$$\mathbf{AUC} = \mathbf{\Sigma\ c(t)} \qquad \text{Eqn. (5-6)}$$

where:

AUC = area under the curve, ppt TEQ_{DFP}-WHO_{98}-day

c(t) = lipid-based concentration in the infant each day, ppt TEQ_{DFP}-WHO_{98}

The AUC is a measure of accumulated exposure. For example, a year at a lipid-based concentration of 10 ppt TEQ_{DFP}-WHO_{98} would yield an AUC of 3,650 ppt TEQ_{DFP}-WHO_{98}-day (10 ppt * 365 days). A lifetime at an average body lipid concentration of 10 ppt would yield an AUC of 255,500 ppt TEQ_{DFP}-WHO_{98}-day (10 ppt * 70 yrs * 365 days/yr). The AUC provides a parameter to compare accumulated exposure for different scenarios. For that reason, the ratios of the AUCs of the various breast-feeding scenario and the formula-only scenario are provided in Table 5-5. A ratio for a particular breast-feeding scenario of 6, for example, would mean that the accumulated exposure for that scenario is 6 times that of the breast-feeding only scenario. This can easily be translated to a

corresponding measure of percent above or below the baseline scenario of formula feeding only. For example, if the ratio is 6, this is equivalent to saying that the accumulated exposure for the breast-feeding scenario is 500 percent higher than the formula-only scenario ((6-1)*100 percent); if the ratio is 0.7, this is equivalent to saying that the accumulated exposure for the breast-feeding scenario is 30 percent lower than the formula-only scenario (-(0.7-1)*100 percent).

The lipid concentrations are predicted to rise to about 44 ppt TEQ_{DFP}-WHO_{98} for the 6-month,1-year, and 2-year scenarios. The time that these peaks occur is uniformly at 9 weeks. For the 6 week breast-feeding scenario, the peak is at 34 ppt and it occurs at the 6 week mark. Body burdens follow a similar trend, rising to about 9 ppt TEQ_{DFP}-WHO_{98} for both the 6-month, 1-year, and 2-year scenarios at 9 weeks. The body burdens decline for these breast-feeding scenarios, but the decline is slower as the duration of time for breast-feeding increases. For the 2-year scenario, the body lipid concentration stays near 40 ppt past 2 years of age (Figure 5-4). The six-week scenario shows a rise in infant body burden to above 30 ppt TEQ_{DFP}-WHO_{98}, but then shows a rapid decline, tracking the formula-only scenario fairly well after about age 2. From Figure 5-3, it appears that all four scenarios begin to merge at about age 10 years. The rise in concentrations seen in the later years in Figure 5-3 is due to the rise in body fat percent and the subsequent rise in half-life as predicted by elimination rate model of Pinsky and Lorber (1998).

The AUC results in Table 5-5 show how the accumulated exposure is higher for each of the breast-feeding scenarios as compared to the formula-only scenarios. This exceedance after one year is about a factor of 6 for breast-feeding for 6 months or more. Even for the first 10 years of life, the accumulated exposure is about 2 times higher for these breast-feeding scenarios as compared to formula feeding only. After a lifetime, the ratios suggest that breast feeding results in a lifetime exposure only 1.03-1.18 times higher than formula feeding, or expressed in terms of a percentage, from 3 to 18 percent higher than formula feeding only.

5.2.3.4. *Sensitivity Analysis*

A brief sensitivity analysis was conducted to study the impact of key parameters and assumptions on this exercise. Sensitivity analysis exercises typically focus on the parameters with these two characteristics: those that are the most uncertain and those

that have an important impact on the results. It was ascertained that the parameters: absorption, body weight, and lipid fraction, while important, are reasonably well known and assigned appropriate mid-range values for this exercise. The initial concentration in the infant at birth of 10 ppt TEQ_{DFP}-WHO_{98} lipid is an unknown, but testing showed that infant concentrations rapidly declined to about 5 ppt regardless of the initial concentration. Therefore, this parameter does not appear to influence results like peak concentrations or accumulated exposures. The two most important parameters, or groups of parameters, were those used to determine dose to the infant - mother's milk concentration initially and over time, and the dissipation rate of dioxin-like compounds in the infant. To test the influence that these parameters have on results, six sensitivity analyses were devised. These were all variations on a baseline scenario selected to be the 6-month breast-feeding scenario. The six scenarios were:

Scenario #1: Use of the Pinsky and Lorber (1998) lipid-based function for dissipation rate instead of the hybrid function used. The Pinsky and Lorber (1998) lipid-based function is shown in Figure 5-2. This is expected to result in an increase in the predictions of infant and childhood body impacts.

Scenario #2: Use of the Kreuzer et al. (1997) modeled dissipation rate throughout life instead of the hybrid function used. The Kreuzer et al. (1997) function is shown in Figure 5-2. This is expected to result in a decrease in predictions of infant, childhood, and adult impacts.

Scenario #3: Use of the assumption that mothers' milk concentrations do not decline from 25 ppt TEQ_{DFP}-WHO_{98} lipid during the 6 months of breast-feeding. This will obviously result in an increase in the impact to the infant.

Scenario #4: Use of the assumption that mothers' milk concentrations begin at 15 ppt TEQ_{DFP}-WHO_{98} and decline to 7.5 ppt TEQ_{DFP}-WHO_{98} after 6 months (instead of using concentrations that begin at 25 ppt TEQ_{DFP}-WHO_{98} and decline to 12.5 ppt TEQ_{DFP}-WHO_{98} after 6 months). The assignment of an initial concentration of 25 ppt TEQ_{DFP}-WHO_{98} is based on the finding that this represents a reasonable average of adult body concentrations of the sum of dioxin, furan, and dioxin-like PCB TEQs, described in Chapter 4. However, this average includes a wide age range of populations, including older individuals. As will be discussed in the next chapter on trends, higher exposures in the past have resulted in higher concentrations in older adults compared to today's younger

adults. It may be more reasonable to assume a woman of child-bearing age today would have concentrations closer to 15 ppt TEQ_{DFP}-WHO_{98} rather than the full adult population average of 25 ppt TEQ_{DFP}-WHO_{98}. Also, for children after the first-born, reduction in a woman's body burden of dioxin-like compounds could occur from prior breast-feeding.

Scenario #5: For this scenario, both assumptions that would lead to a higher impact - use of the Pinsky and Lorber (1998) lipid-based function for dissipation rate and the assumption of mother's milk concentration not declining from 25 ppt TEQ_{DFP}-WHO_{98} lipid - were used.

Scenario #6: In contrast to Scenario #5, both assumptions that would lead to a lower impact - the use of the Kreuzer et al. (1997) modeled dissipation rate and the assumption of mothers' milk concentrations beginning at 15 ppt TEQ_{DFP}-WHO_{98} and declining to 7.5 ppt TEQ_{DFP}-WHO_{98} after 6 months - were used.

Results from this sensitivity analysis exercise are shown in Table 5-6 and Figure 5-5. It is seen that all results range from a reduction of 40 percent (AUC ratio of 0.6) from baseline or an increase of 160 percent (AUC ratio of 2.6). The peak concentration can rise as high as 54 ppt TEQ_{DF}-WHO_{98}, as seen in Table 5-6 for Scenario #5 or as low as 28.5 ppt TEQ_{DF}-WHO_{98} for Scenario #6. Perhaps the biggest impact is seen in assuming the higher dissipation rate (lower half-life) for the childhood years. This is seen in Scenarios #4 and #6, with the lowest peak concentration and the steepest reduction from baseline: 30-40 percent. While the results displayed on Table 5-6 focus on the difference between the baseline 6-month scenario and sensitivity analysis scenarios, also of note is the difference between the two extremes as modeled by Scenarios #5 and #6. The peak concentration predicted for Scenario #5 (infant impact maximized) is about twice that of Scenario #6 (infant impact minimized): 54.0 versus 28.5 ppt TEQ_{DFP}-WHO_{98}. More importantly, the accumulated exposure from Scenario #5 is significantly higher than from Scenario #6. This can be seen In Figure 5-5, where the body concentrations are higher in Scenario #5 than #6 throughout the modeled lifetime, particularly for the first 10 years of life. After 10 years, the accumulated exposure, as measured by AUC, is about 4 times higher for Scenario #5 as compared to #6 (this results from the 10-year ratios of 2.6 and 0.7 displayed on Table 5-6, divided by each other; 2.6/0.7 = 3.7).

In short, when using this modeling approach to evaluate exposure-related impacts to infants from breast feeding, the assessor needs to be aware that assumptions relating

to the dissipation of dioxin-like compounds from infants, and the dose they receive through breast milk, are the two most important inputs. Data should be sought to further validate the selected modeling procedure and parameters, if possible.

5.3. SPORT AND SUBSISTENCE FISHERS

The possibility of high exposure to dioxin as a result of fish consumption is most likely to occur in situations where individuals consume a large quantity of fish from one location where the dioxin level in the fish is elevated above background levels. Most people eat fish from multiple sources, and even if large quantities are consumed, they are not likely to have unusually high exposures. However, individuals who fish regularly for purposes of basic subsistence are likely to obtain their fish from one source and have the potential for elevated exposures. Such individuals may consume large quantities of fish. U.S. EPA (1997) presents studies that indicate that Native American subsistence fishermen consume 59 g fish/day (as a mean) and 170 g fish/day (as an upper estimate). Wolfe and Walker (1987) found Native American subsistence fish ingestion rates up to 770 g/day in a study conducted in Alaska. Assuming that subsistence fishermen consume 59 to 170 g of freshwater fish per day as their primary source of protein (i.e., no meat or eggs are consumed) adult daily intake of CDD/CDFs/PCBs would be 2.2 to 5.7 pg/kg-day (Table 5-7). This estimate is based on the same CDD/CDF/PCB media concentrations exposure assumptions, and exposure algorithms as those presented in Chapter 4. The estimated values for subsistence fishermen are two to six times higher than the adult general population mean daily intake from all food sources of 0.94 pg/kg-day, as estimated in Chapter 4. It should be noted that fish ingestion rate data for subsistence fishermen are limited. The ingestion rate values used here pertain only to Native American subsistence populations (U.S. EPA, 1997), but are used to demonstrate the potential for elevated exposures among groups of individuals whose diets are known to consist of higher proportions of fish than the general population. Fish ingestion rates for sports fishermen would generally be lower than for the Native American subsistence population, but higher than for the general population.

Studies are underway to evaluate whether Native Americans living on the Columbia River in Washington have high dioxin exposures as a result of fish consumption. These Tribes consume large quantities of salmon from the river. As cited in U.S. EPA (1997), a

study conducted by the Columbia River Intertribal Fish Commission (1994) suggested that these individuals have an average fish consumption rate of 59 g/day and a 95th percentile rate of 170 g/day. These data were used in the estimated dietary intake calculations for subsistence fishermen, as shown above. Currently, studies are underway to measure dioxin levels in fish from this region.

Svensson et al. (1991) found elevated blood levels of CDDs and CDFs in high fish consumers living near the Baltic Sea in Sweden. Three groups were studied: nonconsumers (n = 9), moderate consumers (n = 9, 220 to 500 g/wk), and high consumers (n = 11, 700 to 1,750 g/wk). The high consumer group was composed of fishermen or workers in the fish industry who consumed primarily salmon (30 to 90 pg I-TEQ_{DF}/g) and herring (8 to 18 pg I-TEQ_{DF}/g) from the Baltic Sea. The I-TEQ_{DF} blood level was found to average about 60 pg I-TEQ_{DF}/g lipid among the high consumers and 20 pg I-TEQ_{DF}/g lipid for the nonconsumers. This difference was particularly apparent for the PeCDFs.

Asplund et al. (1994) also found elevated plasma levels of dioxin-like PCBs in Swedish fishermen who consumed large amounts of fish. A total of 37 individuals with varying intake rates of fish from the Baltic Sea was studied. These individuals were categorized as high-fish eaters, moderate fish-eaters, and nonfish-eaters. The estimated weekly intake of fish correlated positively with plasma PCB levels among this group (Table 5-8).

Cole et al. (1995) reported on CDD/CDFs and PCBs in 132 serum samples (pooled to 14) from Ontario Great Lakes anglers and control populations. Based on a preliminary survey, anglers from the communities of Cornwall and Mississauga, Canada, were categorized based on the numbers, species, and locations of fish caught and kept for consumption, and on data reflecting the contaminant levels for the fish in these areas. Individuals categorized as having the highest and lowest potential for having elevated body burdens of CDD/CDFs and PCBs were selected for biological sampling. Individuals who did not consume fish served as controls. Study participants were further categorized by age (i.e., <38 years, 38-50 years, and >50 years). The results, however, indicated that mean I-TEQ_{DF} levels were similar for both eaters and noneaters of Great Lakes' fish in these communities. I-TEQ_{DF}s ranged from 20.8 to 41.2 ppt for fish eaters and 24.7 to 36.8 ppt for noneaters. In general, mean I-TEQ_{DF}s increased with age (Table 5-9). PCBs 77, 126, and 169 were also evaluated in the serum samples collected from Cornwall

residents. Mean TEQ_P-WHO_{98}s ranged from 2.6 to 17.3 ppt for fish eaters and noneaters combined. Again, significant differences between the two groups were not observed and the serum CDD/CDF and PCB levels are within the range of values observed for the general population, as presented in Chapter 4.

Health departments of five Great Lakes states: Wisconsin, Michigan, Ohio, Illinois, and Indiana, formed a consortium to study blood levels of chemical residues in fish consumers of three Great Lakes: Michigan, Huron, and Erie. Anderson et al. (1998) reported on a feasibility study to determine which compounds might be found in very frequent Great Lakes sport fish consumers. Anderson et al. (1998) selected 32 angling enthusiasts who reported eating at least one sport fish meal per week from one of three Great Lakes (i.e., 11 Lake Huron anglers, 11 Lake Erie anglers and 10 Lake Michigan anglers). The analysis included examination of serum levels of 7 CDDs, 10 CDFs, 4 coplanar PCBs (i.e., 77, 81,126, and 169), and 32 other PCB congeners. One individual was excluded from the data summary due to unusually high occupational/environmental exposures. The blood CDD/CDF/PCB levels for these anglers were compared to CDD/CDF/PCB blood levels for a comparison group (n = 70) from Jacksonville, Arkansas. Data for this Arkansas population are discussed in Chapter 4. The comparison groups represented the general population with no known exposure to the contaminants of concern (Anderson et al., 1998). The mean CDD/CDF lipid adjusted serum concentrations for both the sport fishing populations and the comparison group used by Anderson et al. (1998) are shown in Table 5-10. The mean coplanar and other PCB lipid adjusted serum concentrations are reported in Table 5-11. The average lipid-based I-TEQ_{DFP} concentration for Great Lakes fish consumers was calculated at 56.8 ppt, with the breakdown as follows: I-TEQ_D = 27.5 ppt; I-TEQ_F = 11.9 ppt, and TEQ_P-WHO_{94} = 17.4 ppt. Anderson et al (1998) suggested that these values were higher than the background population used in the comparison.

The Anderson et al. (1998) study led to a larger study, in which the blood of 100 additional sport fishers were sampled, and a comparison population of 100 other individuals were sampled. Falk et al. (1999) reported on the results of the blood sampling from 96 (of the 100) additional sport fishers. Results for the 100 comparison population were not provided. Falk et al. (1999) presented results in terms of I-TEQ_{DF} and TEQ_P-WHO_{94} (congener-specific data were not provided), and also examined relationships

between the CDD/CDF/PCB measurements in blood and factors such as: age, gender, which Great Lakes the fish came from, the type of sport fish consumed, and amount of sport fish consumed, as reported by the participants. The median lipid-based TEQ_{DFP}-WHO_{94} from the 96 participants was 21.3 ppt, with the breakdown as follows: I-TEQ_D = 9.6 ppt; I-TEQ_F = 7.4 ppt, and TEQ_P-WHO_{94} = 4.3 ppt. This finding of 21.3 ppt TEQ_{DFP}-WHO_{94} appears significantly lower than the original finding of 56.7 TEQ_{DFP}-WHO_{98}. One reason for this is that the lower finding from the 96 participants was a *median*, while the finding from the 31 individuals in the pilot study was a *mean*. It also appears that the smaller population had a few individuals with very high levels of dioxins which resulted in a higher mean concentration. Other differences that could be identified from Anderson et al. (1998) and Falk et al. (1999) include: 1) the time of sampling of the two studies; 2) the age of the participants; and 3) the sport fish consumption rates. Anderson et al. (1998) reported that sampling of the initial 31 individuals in the pilot study occurred in 1993. Although Falk et al. (1999) did not identify the date at which the followup study occurred, it appears likely to have been in 1995 or 1996. Although not expected to be a large factor explaining the differences in the populations, it is possible that average body burdens within the population decreased during this time period. The mean age of the 31 participants in the pilot study was 52 years (range 36 to 76), while the mean age in the second population of 96 participants was 46 years (range 27-67). A clear age relationship has been demonstrated in other studies, showing that older individuals have higher body burdens of dioxins. The followup study population of 96 individuals clearly showed lower consumption of Great Lakes fish as compared to the pilot population of 31 individuals, as evidenced by questionnaire response data. The followup study population reported an average of 52 fish meals consumed per year, while the pilot group reported an average of 77 fish meals per year. Likewise, consumption of Great Lakes fish was lower for the followup group than the pilot group: 43 Great Lakes fish meals per year and 49 Great Lakes fish meals per year, respectively. Also, the followup group reported a lower number of years consuming Great Lakes sports fish (26 years) than the pilot group (33 years). In summary, while the larger population of 96 sport fishers in the full survey appeared to show a much lower body burden of dioxin-like compounds as compared to pilot population of 31 sport fishers, the differences could be explained by factors of data description (median vs. mean), year of sampling, age of participants, and exposure to dioxins in fish.

Another observation from the Anderson et al. (1998) study was that Lake Erie sport fish consumers had consistently lower CDD/CDF/PCB serum concentrations than consumers of sport fish from Lakes Michigan and Huron. Serum levels observed for the Lake Michigan and Lake Huron fish consumers were similar and higher than those observed in consumers of Lake Erie sport fish. These interlake differences parallel the pattern observed in previously reported EPA sport fish tissue monitoring data from the respective lakes (Anderson et al., 1998) and indicate that serum concentrations may also be affected by variations in fish concentrations among the lakes.

Kolic et al. (2000) reported on sampling of fish for dioxin-like CDD/F/PCBs conducted by the Ontario Ministry of the Environment between 1996 and 1998 in the Ontario Great Lakes region. Table 5-12 presents the data on this sampling effort as it was reported in Kolic et al. (2000). A total of 193 samples are reported on in Table 5-12. TEQ concentrations were calculated using the WHO 1998 TEF scheme, with zero values used for non-detects. When no congeners were detected in the sample, the value was reported as zero. Fish were sampled for the Ontario Sports Fish Program. This program monitors sport fish in the Ontario fresh water lakes and issues consumption advisories through its biannual guide. Because of this purpose, the fish sampled are typically larger and from suspect areas in order to obtain positive results and therefore be able to set consumption advisories (Reiner et al., 1995). An initial set of data on CDD/CDFs from this program were reported on in Reiner et al. (1995). Sampling reported there occurred between 1991 and 1994. Kolic et al. (2000) examined the data taken between 1996 and 1998 for purposes of studying the relationship between dioxin-like PCBs and CDD/CDFs in the fish. They observed PCB TEQ concentrations substantially greater that CDD/CDF TEQ concentrations in most locations, as is evident from Table 5-12. Over all lakes, they observe an average ratio of 6.5 (omitting the large value of 86 from the Welland River, as well as all circumstances when CDD/CDF TEQ concentrations are zero).

Also noteworthy is that the concentrations reported for these fish are substantially higher than the fish concentrations used for background exposure calculations in Chapter 5. CDD/CDF concentrations for marine and freshwater sources were 1.0 and 0.26 pg/g whole weight TEQ_{DF}-WHO_{98}, respectively. PCB concentrations were 1.2 and 0.25 pg/g whole weight TEQ_{P}-WHO_{98}, respectively. In contrast, the overall concentrations for this Great Lakes data set were 5.4 and 26.6 TEQ_{DF}-WHO_{98}/g whole weight for CDD/CDFs and

PCBs, respectively. As observed by Kolic et al. (2000), CDD/CDF concentrations appeared to be declining since their earlier reporting in 1995. At that time, Reiner et al. (1995) reported on 198 samples, and the average I-TEQ_{DF} concentration was 11.5 pg/g whole weight.

Hong et al. (1994) analyzed PCBs in human milk from Mohawk and control women to evaluate the potential effect that relatively high levels of environmental contamination may have had on the body burdens of lactating Mohawk women in New York. PCBs were found to be present in fish and wildlife in the vicinity of the Mohawk Reservation, and the Mohawk people formerly depended on local fish and wildlife for food. However, no significant differences were observed between the mean total dioxin-like PCB levels in milk from 30 Mohawk women and the 20 control women. The mean PCB concentrations for these women were 49 ppb and 55 ppb, respectively. The age of the mother, the length of the nursing period, and the number of breastfed children were found to influence PCB levels in human milk. Older women, mothers of first born children, and smokers had higher levels of PCBs. PCB levels were also higher at the onset of lactation and in earlier samples during a breastfeeding session.

Dewailly et al. (1994) observed elevated levels of dioxin-like PCBs in the blood of fishermen on the north shore of the Gulf of the St. Lawrence River who consume large amounts of seafood. Of the 185 study samples, the 10 samples with the highest total PCB levels were analyzed for dioxin-like PCBs. Samples from Red Cross blood donors in Ontario served as controls. Dioxin-like PCB levels were 20 times higher among the 10 highly exposed fishermen than among the controls (Table 5-13). Based on these results of the 10 highest samples, Dewailly et al. (1994) estimated that for the entire fishing population studied, dioxin-like PCB levels would be eight to ten times higher than the control group. Dewailly et al. (1994) also observed elevated levels of dioxin-like PCBs in the breast milk of Inuit women of Arctic Quebec. The principal source of protein for the Inuit people is fish and sea mammal consumption. Breast milk samples were collected from 109 Inuit women within the first 3 days after delivery and analyzed for di-ortho-dioxin-like PCBs during 1989 and 1990. Subsets of 35 and 40 randomly selected samples were analyzed for mono-ortho dioxin-like and non-ortho dioxin-like PCBs, respectively. Samples from 96 Caucasian women from Quebec served as controls. The levels of non-ortho dioxin-like PCBs for Inuit women ranged from 24.7 to 220.9 ppt.

These values were three to seven times higher than those observed in the control group. For mono-ortho and di-ortho dioxin-like PCBS, the levels among the Inuit women were three to ten times higher than in the control group.

Humphrey et al. (2000) reported on an elevation in the PCB concentrations in serum of humans consuming Great Lakes fish. They described a careful identification of "sport fish eaters" and "non-sport fish eaters," or controls, from 11 Lake Michigan shoreline communities during the years 1979 and 1982. Sport fish eaters were defined as those individuals who consumed 26 or more pounds of sport-caught fish annually, while non-sport fish eaters consumed less than 6 pounds of sport-caught fish annually. This cohort was revisited a second time in 1992 for a study of individuals over the age of 50. Blood sampling occurred in 1993-1995 for 101 fish-eaters and 78 controls. These samples were measured to 90 PCB congeners, including dioxin-like PCB congeners 77, 105, 118, 123, 157, 169, and 180. They found that sport fishers had significantly higher PCB concentrations as compared to controls. The mean concentration of total PCBs (sum of the 90 measured) in the fish-eaters was 14.26 ppb whole weight, while for the controls, the concentration was 4.56 ppb. They found that 22 of the congeners explained most of the concentration, and dioxin-like PCBs 105, 118, and 180 were among those 22. The whole weight concentrations (ppb) of these three PCBs in sport and control fishers were 2.00 (fishers) vs. 0.79 (control) for PCB 180; 0.26 vs. 0.02 ppb for PCB 105; and 0.83 vs. 0.06 for PCB 118.

5.4. LOCALIZED IMPACTS

Data have been collected that demonstrate that localized impacts may occur from emissions of dioxins from incinerators and other potential sources. "Localized impacts" are defined as measurements of CDD/CDFs in environmental (air, soil) or biotic (vegetation, animal tissue) samples near incinerators or other sources that show elevation above typical background levels for the area being studied. Therefore, "impacts," as used below, refer to elevation above background. These localized impacts may result in elevated exposure among some members of the population. Most of the data on localized impacts originate from studies conducted outside the United States, specifically from the European countries of England, Switzerland, Germany, Austria, The Netherlands, Belgium, and France. Data collected include concentrations of dioxins in air and soil, biota including

grass and cow's milk, as well as human blood and hair samples. This section reviews several of these studies, primarily discussing results in terms of TEQs from CDD/CDFs only. Following a review of the studies, the principal findings with regard to localized impacts are summarized.

Goldman et al. (2000) compared serum concentrations of CDD/CDFs among residents of 2 homes where contaminated home-produced eggs and beef were consumed to residents of a similar rural area that did not consume home-produced eggs and beef. The contaminated eggs and beef originated from a residence located near the site of a 1987 fire at a wood preservative plant. The chicken eggs had an I-TEQ_{DF} mean concentration of 10 pg I-TEQ_{DF}/g; beef fat contained 27 pg I-TEQ_{DF}/g. These concentrations are 10- to 100-fold higher than the results observed in samples of commercial foods. The soil near the home where contaminated eggs were observed contained CDD/CDF levels ranging from 30 to 40 pg I-TEQ_{DF}/g, and the soil CDD/CDF profile was similar to that observed in the eggs. Serum samples were collected from 9 individuals residing in homes where contaminated eggs and beef were consumed. I-TEQ_{DF} concentrations in serum were 26.7 ppt for the 4 individuals who had consumed eggs from the contaminated site over a 2-year period and 63.7 ppt for the 5 individuals who had consumed both eggs and beef from the contaminated site for up to 15 years, compared to 17.0 ppt for the comparison group.

Beck et al. (1990) sampled milk from a rural and an industrial area in Germany, and from dairies near a metals reclamation plant in Austria. Beck et al. (1990) observed average lipid-based concentration of 0.9 pg I-TEQ_{DF}/g in rural, background milk, 2.5 pg I-TEQ_{DF}/g in "industrial milk," and 9.6 pg I-TEQ_{DF}/g in the milk obtained from dairies near the metals reclamation plant. The dairy nearest the metals reclamation plant was located about a kilometer in the downwind direction and had the highest milk concentration (i.e., 14 pg I-TEQ_{DF}/g).

The Austrian metals reclamation plant described above has also been studied for impacts to air, soil, vegetation, and human blood by another research team (Riss et al., 1990; Riss, 1993). The plant was located in a rural Alpine river valley in Tyrol, Austria, in a mostly agriculture area. Although emissions data were unavailable, air concentrations measured near the incinerator were 1.2 to 2.3 pg I-TEQ_{DF}/m^3 (Riss, 1993). These data suggest very high emissions, because typical urban air concentrations are approximately

0.10 pg/m^3 in Europe as well as in the United States, and rural air concentrations are typically less than 0.05 pg I-TEQ_{DF}/m^3. (See Chapter 3.) Soil concentrations averaged 420 pg I-TEQ_{DF}/g at the site of the incinerator, 170 pg/g within 200 meters of plant, and 46 ppt about 2 km in the downwind direction (Riss et al., 1990). This compares with typical urban soil concentrations of approximately 10 to 20 pg I-TEQ_{DF}/g in both Europe and the United States and rural soil concentrations of less than 5 pg I-TEQ_{DF}/g. (See Chapter 3.)

A dairy farm was located between 1,400 and 2,100 meters from the same metals reclamation site in the downwind direction, and members of that farming family consumed milk from their own cows. Samples of the cows milk ranged from 20.1 to 69.5 pg I-TEQ_{DF}/g on a lipid basis. Given a general background level of milk in the low to sub ppt level on a lipid basis, it is clear that the milk showed elevated dioxin levels. (See Chapter 3.) Samples in the grass and hay from that farm were also elevated at 13 to 36 pg I-TEQ_{DF}/g dry weight. This compares to typical grass samples found in rural areas at the low to sub ppt levels (Reed et al., 1990; Kjeller et al., 1991; 1996). Blood samples from two farmers who consumed this milk were also elevated. Their blood CDD/CDF concentrations were 152 and 946 pg I-TEQ_{DF}/g on a lipid basis. Subsequent samples from three additional family members were also slightly elevated above typical levels at 41, 66, and 77 pg TEQ_{P}-WHO_{94}/g lipid.

The Austrian samples described above were taken in the late 1980s, before emission controls and other practices (i.e, removal of some plastics) were undertaken to reduce emissions from these plants. Riss (1993) reported on reductions in both cow's milk and fodder from this nearby farm in the early 1990s and speculated that they resulted from reductions in incinerator emissions. CDD/CDF concentrations in cows' milk dropped steadily from a high in 1987/88 samplings, averaging 49 pg I-TEQ_{DF}/g fat, to an average of 5 pg I-TEQ_{DF}/g fat in the 1992/93 sampling. Grass concentrations similarly dropped from 33 pg I-TEQ_{DF}/g dry weight to 4 pg I-TEQ_{DF}/g dry weight between the two sample dates. This trend demonstrates an important expectation with regard to environmental responses to reductions in emissions from tall industrial stacks. Specifically, vegetation appears to respond immediately to reduced air concentrations, and if dairy cows are being fed with vegetation that has reduced concentrations, cow's milk should similarly respond in a rapid manner. Fries and Paustenbach (1990) stated that a

steady state is reached in cow's milk with a constant dietary input of dioxins after about 30 to 60 days. Therefore, reductions in emissions will result in both a reduction in vegetation and cow's milk concentrations almost simultaneously.

Another study was conducted in Austria by Moche and Thanner (1997). The study evaluated ambient air patterns and CDD/CDF concentrations in a vicinity of steel production plants in Leoben/Donawitz. Samples were collected from sites in the immediate vicinity of the production plants, in an area that was expected to be impacted by the production plants, and in an area that was shielded by mountains in the northwest. Sampling occurred over four periods to address the potential influence of the summer and winter fluctuations in CDD/CDF concentration. The CDD/CDF concentrations in these samples were compared to previous data collected in the three Austrian conurbations Graz, Linz, and Wien. The previous data suggested average summer levels of CDD/CDFs in the range of 20 to 40 fg I-TEQ_{DF}/Nm^3 and winter levels in the range of 50 to 220 fg I-TEQ_{DF}/Nm^3. The data collected at Leoben/Donawitz indicated higher ambient air levels of CDD/CDF concentrations. Only the levels in the area shielded by mountains fall within the levels of the previously reported data. In addition, the CDD/CDF profiles of the Leoben/Donawitz sites indicated a high contribution of the lower chlorinated CDFs (tetra- through hexachlorinated CDFs as the most abundant). The patterns were in good agreement with emission profiles of metallurgical processes reported by Hagenmaier et al. (1994) (Moche and Thanner, 1997).

Liem et al. (1991) reported on the analysis of over 200 samples of cow's milk that were taken in various regions in The Netherlands, including some that were near municipal solid waste incinerators and metals reclamations plants, and some identified as background sites. Background levels ranged from 0.7 to 2.5 pg I-TEQ_{DF}/g lipid. The highest levels were found approximately 2 km from the largest municipal solid waste incinerator identified at the time, with concentrations ranging from 2.8 to 12.6 pg I-TEQ_{DF}/g lipid. Higher than background levels were also found in samplings near other incinerators. The researchers did a principal component analysis on congener profiles in the milk samples to determine if there were any discernable differences among groupings of samples. Liem et al. (1991) observed a distinct pattern for samples around the metals reclamation plant compared to samples around municipal solid waste facilities. A higher CDF/CDD ratio was found around the metals reclamation plant (i.e., higher furan

concentrations were in the milk near the metals reclamation plant than near the municipal solid waste incinerator). Liem et al. (1991) speculated that metals reclamation plants process cables that contain PVC, and according to Christmann et al. (1989), furans are predominantly formed in the combustion of PVC. Subsequently, the higher levels of furans would be taken up into vegetation and then into cow's milk. Liem et al. (1991) also found distinct patterns in samples associated with other facilities, as characterized by the relative amounts of lower and higher chlorinated congeners. Two of the incinerators were closed in April of 1990, and a marked decrease in sample concentrations associated with these two incinerators was noted between the February and August 1990 sampling. This supports the expectation described above regarding the response of vegetation and milk to changes in nearby source emissions.

A limited sample from six cows in Switzerland showed similarly elevated CDD/CDFs in association with incinerators or manufacturing sites. Higher CDD/CDF concentrations were observed in milk samples that were within 1,000 meters of an incinerator (two samples) and those that were within 1,000 meters of a production site for various chlorinated samples (one sample) than samples from a background farm (one sample) and from local dairies that pooled milk from several farms (two samples) (Rappe et al., 1987). Insufficient information was available in this report to calculate I-TEQ_{DF} concentrations.

De Fre and Wevers (1998) evaluated paired CDD/CDF deposition and cow's milk data from several locations in Belgium to evaluate the relationship between deposition rates and milk levels, and the potential impact that elevated deposition rates may have on local milk supplies. CDD/CDF deposition ranged from approximately 2 ng I-TEQ_{DF}/m^2/year to 45 ng I-TEQ_{DF}/m^2/year, and CDD/CDF concentrations in milk fat ranged from approximately 1 pg I-TEQ_{DF}/g to 19 pg I-TEQ_{DF}/g. The correlation coefficient (R) for CDD/CDF deposition rates and milk fat concentrations was 0.69. The results of a regression analysis using these data indicated that milk fat concentrations of I-TEQ_{DF}s could be predicted from deposition rates using the equation $y = 0.3332x$, where y is the milk fat concentration of CDD/CDFs in units of pg TEQ_{DF}/g and x is the CDD/CDF deposition rate in units of ng TEQ_{DF}/m^2/y.

In France, the Ministry of Agriculture and Fisheries investigated CDD/CDF concentrations in cow's milk sampled from farms in a downwind direction within 11 km, but mostly within 5 km, of 26 industrial facilities (Defour et al., 1998). These industries

included: steel manufacturing, secondary lead and aluminum smelting, copper refining, chemical and oil refining industries, electricity production, and municipal waste incinerators. Of the 49 milk samples analyzed, 46 samples had CDD/CDF concentrations that were less than 3 pg I-TEQ_{DF}/g fat with an average of 1.53 pg I-TEQ_{DF}/g on milk fat basis. One milk sample collected from a site near a chemistry industry was found to contain 3 to 5 pg I-TEQ_{DF}/g fat, and two milk samples collected 250 m and 1 km downwind of incinerators had concentrations higher than 5 pg I-TEQ_{DF}/g fat. The average concentration in milk and diary products in France assessed through a 1996 survey conducted by the Ministry of Agriculture and Fisheries was 1.33 pg I-TEQ_{DF}/g fat (Defour et al., 1998).

Abraham et al. (1998) reported on the levels of CDD/CDFs in the human milk of 10 mothers who lived within a radius of 8 km of Ilsenburg, Germany. The town was identified as an area highly contaminated with CDD/CDFs reportedly resulting from emissions from a copper plant. At the time of sample collection (i.e., 1997) the plant had been closed for approximately 6 years, Abraham et al. (1998) compared the findings to the results of a previous study of human milk levels conducted in 1990/1991 when the plant was still in operation. The 1990/1991 human milk samples contained a mean I-TEQ_{DF} of 59 ppt, lipid based (n = 9). The 1997 human milk samples contained a mean I-TEQ_{DF} of 41 ppt, lipid based (n = 10). Abraham et al. (1998) documents that this decrease in CDD/CDFs is lower than the decline reported in general background concentrations in human milk from Western Germany in recent years. These values are somewhat higher than the values reported in Chapter 4 for the general population of the United States.

An extensive study was undertaken in the Pontypool environment of South Wales (Ball et al., 1993; Ball et al., 1994a; Ball et al., 1994b; Ball et al., 1995). Evidence of the impact of emissions from waste incineration at Rechem International Ltd. (a chemical company) prompted extensive investigations into impacts from emissions of PCBs and CDD/CDFs to nearby and regional media including soil, grass, water, air, fruit/vegetables, cow's milk, duck meat, and eggs from chicken and ducks. The region has a combination of residential and industrial uses, with very little agricultural uses. The greatest impact was found at a residence adjacent to the site, located only about 100 meters away. The soil at Rechem International averaged 810 pg I-TEQ_{DF}/g (n = 4), while at this nearby

residence, the concentration averaged 66 pg I-TEQ_{DF}/g (n = 8). Other areas evaluated ranged from 4 to 24 pg I-TEQ_{DF}/g. Data were not available on CDD/CDF emissions, but air measurements at this residence suggested high emission rates. For five air samples taken at the residence, air concentrations ranged from 1.6 to 14.8 pg I-TEQ_{DF}/m^3. This compares to air concentrations ranging from 0.02 to 0.68 pg I-TEQ_{DF}/m^3 taken from a site about 2,500 meters away in the same direction from the Rechem site. The researchers also compared these air concentrations to average air concentrations ranging from 0.21 to 0.67 pg I-TEQ_{DF}/m^3 in four other UK urban areas. Concentrations of CDDs/CDFs in grass were found to be elevated at the same residence, but described as more typical for other grass sampling sites. Perhaps most importantly, samples of duck and bantam eggs from this residence showed concentrations that exceeded other duck and bantam egg samples in the area by a factor of 10. Duck and bantam egg concentrations in the area, but not at this residence, were described as typical of background. Duck meat at the impacted residence was not described as elevated compared to duck meat from nearby settings. Sampling of sediments in a nearby reservoir did not indicate elevated concentrations of dioxins or PCBs. There was no sampling of human blood or tissue. However, a simple exposure exercise showed that consumption of duck eggs, duck meat, apples, inhalation, and incidental soil ingestion at this impacted residence would result a daily intake of 165 pg I-TEQ_{DF}/day, compared to a background intake from these pathways of 43.2 pg I-TEQ_{DF}/day (consumption rates described as typical derived from consumption data from the Ministry of Food and Fisheries in the UK).

Foxall et al. (1997) also reported geographical variations in environmental levels and human exposure to CDD/CDFs and PCBs of the above study. The data indicated a particular impact in a 200-meter wide strip of land around the boundary of the incineration plant owned by Rechem International Ltd. This location is predominantly downwind from the incinerator and there had been evidence suggesting that fugitive emissions from the plant contributed to the environmental impacts. Marked differences were noted between the CDD/CDF and PCB content of samples (i.e., air, soil, and foods) collected at the impacted site and those collected at rural background locations. Intakes of CDD/CDFs (pg I-TEQ_{DF}/day) and PCBs (μg/day) were estimated using mean daily food consumption rates, inhalation and soil ingestion rates of 20 m^3/day and 100 mg/day, respectively, and the median concentrations of CDD/CDFs and PCBs found in the samples. These estimates

indicated that exposure to CDD/CDFs and PCBs at the impacted site was much higher than for background levels and the main contributors to these higher levels were residues in bantam and duck eggs. The estimated intake of CDD/CDFs from ingestion of bantam or duck eggs at the impacted site were 204 pg I-TEQ_{DF}/day and 103 pg I-TEQ_{DF}/day, respectively; levels that are substantially higher than the average UK dietary intake of 88 pg I-TEQ_{DF}/day from all food sources. Based on a body mass of 60 kg, these egg intakes (i.e., 3.4 and 1.7 pg I-TEQ_{DF}/kg body mass/day) would represent 34 and 17 percent of the WHO (World Health Organization) TDI (Total Dietary Intake) value of 10 pg I-TEQ_{DF}/kg body mass. Similarly, the corresponding PCB intake of 7.3 and 6.3 μg/day would represent 73 and 63 percent, respectively, of an average dietary intake (10 μg/day) of PCBs.

Lovett et al. (1998) performed additional analysis of chicken, bantam, and duck eggs; and also duck meat collected from the vicinity of the Rechem incinerator and compared the results to PCB and CDD/F levels of comparable foodstuffs collected from rural areas in the same Welsh district. Poultry produced at the impacted residence displayed a congener profile with noticeable variations compared to those collected from nearby rural sites. A prominence of higher chlorinated congeners in the egg and duck meat samples for the residence located near the incinerator was observed. Analysis of 46 PCB congeners resulted in a median fresh mass total PCB concentration in duck eggs of 191 μg/kg (n = 2), 341 μg/kg in bantam eggs (n = 2), and 43 μg/kg in duck meat (n = 2) from samples collected in the impacted area. Observations from rural areas showed fresh mass based total PCB concentrations of 14 μg/kg for duck eggs (n = 6), 22 μg/kg for bantam eggs(n = 4), and 25 μg/kg for duck meat (n = 6).

A second location in the United Kingdom, the Derbyshire area in central England, has shown elevations in cow's milk and other animal tissues. Initially, samples of cow's milk were taken by the Ministry of Agriculture, Fisheries, and Food (MAFF) from individual farm tanks on 11 farms in 1990. When 2 of the samples showed high concentrations of 40 and 42 ng I-TEQ_{DF}/kg fat (the other 9 showed more typical concentrations in the 1.1 to 7.1 ng I-TEQ_{DF}/kg fat), the sampling was expanded to 30 farms. These original two farms, plus an additional farm, continued to show high concentrations in the milk. Testing continued in milk through 1994. Milk concentrations dropped at one farm, but overall concentrations appeared to remain high (i.e., 29 ng I-TEQ_{DF}/kg) for the most recently

reported sampling in July of 1994 (Harrison et al., 1996). As a result of these findings, MAFF tested animal tissue from the three farms. Calves from one of the three farms had extremely elevated levels of dioxins and furans, with concentrations ranging from 2.5 to 6.9 ng I-TEQ_{DF}/kg whole weight (i.e., not lipid basis) in muscle tissue (MAFF, 1992a). This compares, for example, with I-TEQ_{DF} concentrations approximately 0.20 ng I-TEQ_{DF}/kg in the United States beef supply (from the national study on beef back fat, assuming 19 percent fat in whole beef (Winters et al., 1996). Egg samples were taken from one of the three farms and a second "free range" supplier. The concentrations found were reported as 2.2 and 2.1 ng I-TEQ_{DF}/kg in whole eggs. A second sample from one of the farms taken a year later showed a lower concentration of 0.8 ng I-TEQ_{DF}/kg whole weight. These would appear to be elevated, considering that eggs found in a background setting in Mississippi (Cooper et al., 1995), had concentrations less than 0.10 ng I-TEQ_{DF}/kg whole weight.

MAFF (1992b) also sampled leafy herbage (grass, hay, etc.) from the three farms described above. Concentrations ranged from about 2 to 14 ng I-TEQ_{DF}/kg dry weight. This appears elevated, considering that samplings of background grass in England showed 0.89 ng I-TEQ_{DF}/kg dry weight, as reported in 1991 (Kjeller et al., 1991) and 0.57 ng I-TEQ/kg dry weight in 1996 (Kjeller et al., 1996). The evidence suggests that the impacts were due to nearby industrial emissions from a fuel plant and chemical waste incineration. Her Majesty's Inspectorate of Pollution (HMIP) conducted additional studies to evaluate this possibility. These included stack testing of the Coalite Fuels, Ltd. and the Coalite Chemicals, Ltd. (which were adjacent to one of the farms and near the other two), air dispersion modeling, and soil monitoring. No results were available to evaluate the stack testing, but the air dispersion modeling predicted that the three impacted farms would be in the sectors having the highest air concentrations. The soil sampling on the three farms showed concentrations ranging from 10 to 90 ppt. This can be considered elevated above typical rural background and in the range or even higher than typical urban concentrations. Specifically, this compares with typical urban soil concentrations of 10 to 20 pg I-TEQ_{DF}/g in both Europe and the United States, and rural soil concentrations typically less than 5 pg I-TEQ_{DF}/g. (See Chapter 3.) Also, these concentrations are similar to concentrations found near incinerators emitting very high concentrations of dioxins in Tyrol, Austria, as described above, and in Columbus, Ohio, as described below. The

National Rivers Authority sampled sediment upstream and downstream of the effluent discharge pipe of the Coalite Chemicals, Ltd site. Samples collected about 1.5 km downstream of the discharge site had CDD/CDF levels that were 1,000 times greater than background samples collected 1.5 km upstream of the discharge point (these studies reported in MAFF, 1992a).

Another interesting finding associated with the samplings of foods and environmental media in the Derbyshire area were the congener profiles. Compared to background milk samples, the samples from the three impacted farms had proportionally higher concentrations of lower chlorinated dioxins, particularly 2,3,7,8-TCDD and 1,2,3,6,7,8-HxCDD. The background samples of milk tended to be dominated by OCDD (MAFF, 1992b). Blood samples were also collected from residents of these three impacted farms and analyzed for CDD/CDFs (Startin et al., 1994). The I-TEQ_{DF} concentrations for the 10 individual blood samples ranged from 49 pg/g to 291 pg/g on a lipid basis. In contrast, the two control samples had I-TEQ_{DF} concentrations of 16 pg/g and 26 pg/g on a lipid basis. The Derbyshire samples were dominated by OCDD, followed by 1,2,3,4,6,7,8-HpCDD, 2,3,7,8-TCDD, and 1,2,3,6,7,8-HxCDD.

Sandalls et al. (1998) analyzed soil concentrations around the site of a chemical waste incinerator near Bolsover, Derbyshire, United Kingdom. At each of 46 sites, five surface soil samples were collected, at varying depths up to a depth of 5 centimeters, every 1 square meter. All 46 sample sites had total TCDD concentrations exceeding background concentrations. Higher concentrations of TCDD were observed at locations closer to the incinerator and there was a strong correlation between the TCDD concentration in a given quadrant and the amount of time that the wind was blowing in that direction. At four quadrants around the site, TCDD soil concentrations were reported as 603 ppt for the northeast (approximately 42 percent of the total deposition); 315 ppt for the southeast (22 percent of the total); 269 ppt for the southwest (19 percent of the total); and 244 ppt (17 percent of the total) for the northwest. The results of the spatial distribution of CDD/CDFs implicated the incinerator as the likely source, and the correlation between deposition and wind direction suggested that these compounds reached the ground via the atmosphere. Also, 42 of the 46 sample sites showed similar CDD/CDF congener ratios to the flue gas of the waste incinerator. Soil concentrations were well in excess of background concentrations, up to 5 kilometers around the site.

Ohta et al. (1997) studied levels of CDD/CDF and non-ortho coplanar PCBs in soil at a high cancer-rate area close to a batch-type municipal solid waste (MSW) incinerator in Japan. Sixty-one soil samples were collected around the MSW incinerator. Among them, 52 samples were radially collected within 2 km from the center of the MSW incinerator, and 9 samples were collected across the high cancer-rate area. High concentrations of CDD/CDFs and coplanar PCBs were observed in all the soil samples from the leeward side of the MSW incinerator. Total concentrations ranged from 5,303 to 32,167 pg/g; mean = 13,934 pg/g. On the other hand, all but one sample on the windward site showed high contamination. Among the 61 samples analyzed, the total concentration was greater than 2,000 pg/g in 45 of the 61 samples and the TEQ_{DFP}-WHO_{94} concentration was over 10 pg/g in 39 of the 61 samples. In addition, the levels of CDD/CDFs and coplanar PCBs at a distance of 0 to 1.1 km from the MSW incinerator was compared with that of the area 1.1 to 2.0 km from the MSW incinerator. The area closer to the incinerator contained a higher ratio of samples with contamination over 5,000 pg/g (63.2 percent) than in the area further away from the MSW incinerator (38.5 percent). Similarly, the area closer to the incinerator had a higher percentage of samples with CDD/CDF/PCB levels over 30 pg TEQ_{DFP}-WHO_{94}/g (26.3 percent) than the area further away from the incinerator (15.3 percent).

Miyata et al. (1998) collected blood samples from residents living within 2 km from a batch-type municipal solid waste incinerator in Japan where soil concentrations of CDD/CDFs and PCBs were shown to be elevated. Eighteen blood samples were collected from 13 men, aged 23 to 63 years old (average age = 45 years), and 5 women, aged 30 to 72 years old (average age = 46 years) in March 1996. The results indicated that the average lipid-based TEQ_{DFP}-WHO_{94} concentrations found in blood samples ranged from 34 pg/g to 200 pg/g with a mean of 81 pg/g for men, and from 22 pg/g to 463 pg/g with a mean of 149 pg/g for women. These mean TEQ_{DFP}-WHO_{94} values are higher than those reported for the general population of various countries (the mean value estimated in Chapter 4 of this document is 55 pg/g).

Local impacts around a waste-to-energy municipal solid waste incinerator in Columbus, Ohio, were undertaken by the Ohio Environmental Protection Agency, and the U.S. Environmental Protection Agency (Lorber et al., 1998). This incinerator operated between 1983 and 1994. A stack test was taken in 1992, and when the results were

extrapolated to typical operation of the incinerator, annual emissions were calculated at 985 g I-TEQ/yr. This is a very high emission rate, and compares to total emissions from several European countries. It is about one-tenth of the national emissions estimated for all United States sources. (See Volume 1.) Process modifications were undertaken in the winter of 1993/94. A stack test was conducted which indicated that annual emissions were reduced to 267 g I-TEQ_{DF}/yr. The U.S. EPA undertook a soil testing program in December of 1995. Results showed a definite impact to soils at the site of the incinerator, with an average concentration of 356 pg I-TEQ_{DF}/g (n = 4). Of the four samples collected, three of the samples averaged 458 pg I-TEQ_{DF}/g and the fourth was much lower at 50 g I-TEQ_{DF}/g. Just offsite in the downwind direction, a cluster of four samples within 1,000 meters also showed some elevation of CDD/CDFs with an average concentration of 49 pg I-TEQ_{DF}/g. Fourteen additional samples, generally within 2 miles of the site, averaged 10 pg I-TEQ_{DF}/g. Three soil samples at a background site 28 miles away in the upwind direction averaged 1 pg I-TEQ_{DF}/g. These latter two clusters of urban and background samples have concentrations that are typical of urban and background situations. The urban results suggests that, despite large emissions from this source, soil impacts above typical levels appeared to be restricted to within 1,000 meters of the incinerator.

The Ohio EPA conducted air monitoring in 1994 and 1995 (OEPA, 1994; Lorber et al., 1998). Monitoring in 1994 occurred after process modifications were undertaken to reduce dioxin emissions. A stack test conducted just prior to the air sampling showed reductions of 75 percent from the levels measured in 1992. Wind rose data were taken on an hourly basis during the 1994 sampling. This showed that two samples from a sampler located about 2 miles away were in the downwind direction during the 48-hour sampling period. Eight other samples from four samplers (which were between 1 and 2 miles from the incinerator) were clearly not in the downwind direction. The two downwind samples averaged 0.26 pg I-TEQ/m^3 CDD/CDFs, while the eight upwind samples averaged 0.05 pg I-TEQ_{DF}/m^3. The incinerator shut down in December 1994. Five samples taken in 1995 showed an average of 0.05 pg I-TEQ_{DF}/m^3 CDD/CDFs. This air sampling suggests the following: (1) the typical background urban air CDD/CDF concentration in Columbus is probably around 0.05 pg I-TEQ_{DF}/m^3; and (2) when the incinerator is emitting dioxins typical of the rate measured in the 1994 stack test (not the

1992 stack test), air concentrations about 2 miles away are higher, perhaps by a factor of 5. Other media, including vegetation, agricultural products, or human blood were not sampled.

Schecter and Papke (1998) examined CDD/CDFs and PCBs 77, 126, and 169 in blood sampled from 10 residents living near a PCB manufacturing facility in Alabama in 1997, and compared these concentrations to a pooled sample from a control group representing 100 adults. The results showed that, for the 10 residents, total lipid-based CDD/CDF concentrations ranged from 825 ppt to 6,422 ppt. The corresponding total CDD/CDF concentrations from the pooled control sample was 1,112 ppt. Total PCB concentrations ranged from 240 ppt to 5,216 ppt for the 10 nearby residents, compared to 1,112 ppt for the pooled control sample. PCB-77 was only detected in the blood of 5 of the 10 residents, ranging from 41 ppt to 713 ppt. PCB-126 concentrations ranged from 104 ppt to 4,050 ppt in residents, compared to 48 ppt found in the control sample. PCB-169 concentrations ranged from 136 ppt to 2,807 ppt for the 10 residents, compared to 35 ppt for the control sample. In terms of TEQ, the total I-TEQ_D and I-TEQ_F concentrations ranged from 16.3 ppt to 38.9 ppt, and from 6.7 ppt to 131 ppt, respectively, compared with 18.5 ppt and 8.3 ppt from the control blood. TEQ_P-WHO_{94}s ranged from 34 ppt to 360 ppt compared to 32 ppt for the control blood.

There were also studies conducted in Asia to address localized impacts. Luksemburg et al. (1997) reported, in a preliminary study, that high levels of CDD/CDFs were observed in soil and sediment samples collected inside and outside a sodium pentachlorophenate plant in Tianjin, China. The plant is situated in a wetland with rivers emptying into the nearby Pacific Ocean and close to several large housing developments. Human hair samples collected from barber shops in the housing developments near the plant were also collected and CDD/CDFs were detected in these samples. The I-TEQ_{DF} concentrations in soil ranged from 15 ppt at a site upstream of the plant to 740,000 ppt within the plant, and was 1,800 to 2,200 ppt at sites outside the plant. The I-TEQ_{DF} concentrations in sediment ranged from 150 ppt at a site 50 km away from the site to 110,000 ppt in a drainage canal located just southwest of the plant. Hair samples contained I-TEQ_{DF} concentrations ranging from 12 to 120 ppt. According to Luksemburg et al. (1997), "the isomer profiles of all the samples were consistent with the

pentachlorophenol sources." However, it should be noted that no background information on the test subjects (time of residence, health records, etc.) were collected in this study.

The major findings and conclusions based on this review of localized sources include:

- Localized impacts, meaning elevated concentrations of CDD/CDFs above background, have been found in the vicinity of some CDD/CDF sources.

- Localized impacts appear to be limited to an area within 5 km of an incinerator source, perhaps only within 2 to 3 km of the source, and in some cases, only within a few hundred meters of the source. One study noted elevations in grass, cow's milk, and human blood on a farm located 2 km from an incinerator presumed to be emitting high amounts of CDD/CDFs. Not all of the studies described in the literature discussed distance from the source, as the surveyed areas were simply identified as "industrial."

- Several studies continued environmental samplings after efforts were made to reduce emissions or after the sources were shut down. In these cases, reductions in CDD/CDF concentrations were noted for various media including, cow's milk, vegetation, and air. As discussed below, vegetation has been found to respond rapidly to reductions in air concentrations, and the time to reach steady state in cow's milk given a steady input of CDD/CDFs is also relatively short. In other cases, such as in the accumulation of CDD/CDFs in soils or in body fat, the benefits may not be as immediate. Soil and body fat are reservoirs in which the residence time of these compounds are measured on the order of years.

The available data reviewed above suggest that measurable impacts near incinerators only occur if the incinerator emits very high amounts of dioxins, in contrast to emissions that are known to be within regulatory limits. However, two key descriptors here, including "measurable impacts" and "very high amounts of emissions" cannot be rigorously defined. The data suggest that "measurable" impacts can be defined as

elevations in dioxin concentrations in environmental or biotic media on the order of 5-10 times higher than typical background. "Very high amounts" of releases is less well defined. The Columbus incinerator is the only incinerator reviewed above for which emission data were available, and the stack test of 1992 showed emissions that were about 200 times higher than the 1995 proposed regulatory limit for solid waste incinerators of 30 ng of total dioxins per m^3. By comparison of environmental media sampling, one could surmise that the metals reclamation plant in Tyrol, Austria, and the incinerators in the Derbyshire area of Central England, if not others noted above, were also emitting unusually high amounts of dioxins.

Also, it is important to understand that elevations in air, soil, vegetation, and animal products do not automatically translate to higher exposure levels. This document (and several other efforts worldwide) have concluded that the bulk of exposure to dioxins occurs via the diet, and specifically animal fats. Higher exposure to an individual would only result if an individual subsisted on animal food products from animals raised near incinerators (meaning also that the animal's diet was comprised of vegetation grown where the animal is raised), and perhaps only incinerators emitting high amounts of dioxins. As described above, there are limited human tissue data for individuals where localized environmental contamination has been demonstrated. In one study in Austria of a farming family consuming home-grown milk near the metals reclamation plant, both the milk and the blood of the family were shown to have elevated levels of dioxins. In the vicinity of a municipal solid waste incinerator in Japan where CDD/CDF and PCB concentrations in soil were elevated, nearby residents also had elevated blood levels of CDD/CDF/PCBs. In the U.S., there have been no studies to evaluate the prevalence of subsistence behavior near sources, in general, and near high emitting incinerators, in particular. Even if there is a sparsity of subsistence behaviors near sources in the U.S., it is reasonable to assume that animal fats produced near high emitting incinerators would likely have elevated CDD/CDF levels and be consumed. If incinerators are meeting regulation limits, they would not be high emitters, and the likelihood of localized impacts would be small.

In addition to the localized contamination resulting from incinerator emissions, as described above, there have been several incidents involving contamination of commercial food supplies from natural and accidental sources in various parts of the world. For

example, ball clay was found to be the source of elevated CDD/CDF levels in animal food products in the United States (Ferrario et al., 2000). Ball clay from a mine in Mississippi, which was used as an anti-caking agent in soy-based animal feeds, was found to be the source of contamination after poultry and catfish samples collected in the same region of the United States were found to have concentrations of CDD/CDFs that were significantly elevated above background concentrations. The incident, which occurred in 1998, involved less than 5 percent of the national poultry production. Subsequently, the use of ball clay in animal feeds was discontinued. In Germany, dairy products were found to be contaminated in 1998 (Malisch, 1998). The concentration of CDD/CDFs in milk was 1.38 pg I-TEQ_{DF}/g fat (N = 43) in 1998, compared to 0.62 pg I-TEQ_{DF}/g fat (N = 76) in 1997. After intense investigation, contaminated citrus pulp obtained from Brazil, which was used as a feed ingredient for dairy cows in certain regions of Germany in 1998, was found to be the source of contamination of the food supply. In 1999, similar contamination of the commercial food supply occurred in Belgium when 500 tons of animal feed was inadvertently contaminated with approximately 50 kg of PCBs and 1 g of dioxins in transformer oil (Van Larebeke et al., 2001). The feed was delivered to poultry farms (and to a lesser extent rabbit, cow, and pig breeding facilities), primarily in Belgium. This contaminated feed represented a "limited percentage" of the feed produced in Belgium, but was delivered to hundreds of farms in the country. The mean TEQ_{DFP}-WHO_{94} concentrations were 170 pg/g fat in poultry, 2.3 pg/g fat in eggs, and 2,320 pg/g fat in animal feed. Once discovered, animal products with excessive levels were destroyed, including approximately 2 million chickens.

5.5. CIGARETTE SMOKERS

As discussed in Volume 1, cigarette smoking has been found to be a source of CDD/CDFs. As a result, individuals who smoke cigarettes, and nonsmokers who are exposed to second-hand smoke, may experience higher levels of exposure to dioxin-like compounds than the general population. Matsueda et al. (1994) reported that the mean I-TEQ_{DF} content of a pack of U.S. cigarettes was 8.6 pg. This estimate is based on analytical data from seven brands of U.S. cigarettes. Assuming that a pack of cigarettes contains 20 cigarettes, the I-TEQ_{DF} content of a single cigarette would be 0.43 pg. This value represents about half of the I-TEQ_{DF} value reported for a mainstream cigarette smoke from a Swedish brand of cigarettes (Löfroth and Zebühr, 1992) and is about five times higher than the I-TEQ_{DF} level in mainstream smoke from German cigarettes (Ball et al., 1990). The daily intake of CDD/CDFs by smokers can be estimated by multiplying the CDD/CDF content of a single cigarette by the mean number of cigarettes smoked per day by current smokers. According to U.S. EPA (1992), 25.5 percent of the adult U.S. population were smokers in 1990. The average daily number of cigarettes smoked by this population was 19.1. Thus, mean CDD/CDF exposures via cigarette smoking are estimated to be 8.2 pg I-TEQ_{DF}/day for smokers. This level of exposure represents over 10 percent of the average daily background dose of CDD/CDFs from soil, air, water, and foods, as described in Chapter 4. The use of data on the total I-TEQ_{DF} content of a cigarette from Matsueda et al. (1994) results in uncertainties as to the estimate of exposure to smokers because the approach assumes that all of the dioxin in the unburned cigarette is inhaled. It is likely that some of the dioxins are released with the sidestream smoke rather than being inhaled. It is also possible that dioxins are destroyed and/or formed during the combustion process. Thus, it is unclear if these factors would lead to a net increase or decrease in the amount of dioxins inhaled. However, as described above, the I-TEQ_{DF} value reported by Matsueda et al. (1994) is less than that in mainstream (i.e., inhaled) smoke reported by Löfroth and Zebühr (1992) and greater than that of Ball et al. (1990) and provides the best estimate of CDD/CDFs in cigarettes to which smokers may be exposed.

Nonsmokers may also be exposed to CDD/CDFs from environmental tobacco smoke. Although the data on the frequency, magnitude, and duration of exposure to environmental tobacco smoke are limited, an idea of the magnitude of exposure to

CDD/CDFs can be gained by assuming that nonsmokers receive a fraction of the CDD/CDF TEQ received by smokers. Based on data for nicotine, the dose to nonsmokers exposed to environmental tobacco smoke is estimated to be 0.1 to 0.7 percent that of smokers (U.S. EPA, 1992). For 4-aminobiphenyl, nonsmokers exposed to environmental tobacco smoke were estimated to receive a dose that was 10 to 20 percent that of smokers (U.S. EPA, 1992). Assuming that nonsmokers receive 0.1 to 20 percent of the dose of CDD/CDFs from second-hand smoke that smokers receive, the estimated daily dose of CDD/CDFs for nonsmokers would range from 0.008 pg I-TEQ_{DF}/day to 1.6 pg I-TEQ_{DF}/day. It should be noted, however, that individual exposure to sidestream smoke is highly variable, depending on a person's proximity to smokers, how often they are near smokers, and the ventilation rate in these areas.

7 months	11.5	8.4	0.25	1.00	50	50	50	367	367
8 months	10.4	8.8	0.24	1.05	50	50	50	333	333
9 months	9.4	9.2	0.24	1.08	50	50	50	300	300
10 months	8.3	9.4	0.23	1.10	50	50	50	267	267
11 months	7.3	9.8	0.23	1.12	50	50	50	233	233
1 year	6.3	11.3	0.23	1.14	50	50	50	200	200
2 years	--	13.3	0.20	1.39	50	50	50	50	200
5 years	--	19.7	0.15	2.12	54	54	54	54	54
11 years	--	41.1	0.15	3.60	65	65	65	65	65
18 years	--	65.1	0.13	5.33	66	66	66	66	66
34 years	--	71.5	0.21	7.70	66	66	66	66	66
55 years	--	73.8	0.27	9.76	66	66	66	66	66

a Dose = TEQ_{DFP}-WHO_{98} concentration in milk fat (pg/g) x lipid fraction in milk (0.04) x ingestion rate of milk (800 g/day).

Table 5-4. Model Validation Data and Results (all concentrations in ppt TEQ_{DF}-WHO_{98} lipid basis)

Description	Observed Data				Model Predictions	
	Milk TEQ_{DF}-WHO_{98}/month	Milk TEQ_{DF}-WHO_{98}/month	Child TEQ_{DF}-WHO_{98}/month	Weeks Breast-Fed	Child TEQ_{DF}-WHO_{98} @ Selected k(t)*	Child TEQ_{DF}-WHO_{98} @ Long k(t)
1st Mother, 1st child	23.5 / 2	14.0 / 11	34.7 / 11	26	34	51
1st Mother, 2nd child	13.7 / 2	12.7 / 5	11.9 / 11	29	27	39
2nd Mother, 1st child	26.5 / 2	15.2 / 11	44.2 / 12	30	36	56
2nd Mother, 2nd child	18.3 / 2	13.1 / 6	18.8 / 12	32	27	41
3rd Mother, only child	13.7 / 2	NA	5.0 / 13	7	10	16
4th Mother, only child	12.7 / 2	13.0 / 6	26.5 / 12	30	21	32
Average, pg/g TEQ_{DF}-WHO_{98}			23.5		26	39

* Predicted child TEQ_{DF}-WHO_{98} at the time of measurement (between 11 and 13 months) using the more rapid dissipation rate, k(t), selected for this model in comparison to the slower k(t) (longer half-life of 7 years) shown in the last column.

Table 5-5. Results of PK Modeling for Formula Feeding and 4 Breast Feeding Scenarios

Description of Model Output	Formula	6-wk BF	6-mo BF	1-yr BF	2-yr BF
Peak concentration, pg TEQ_{DFP}-WHO_{98}/g lipid	13.0	34.1	44.3	44.3	44.3
Time after birth of peak	9 yr	6 wk	9 wk	9 wk	9 wk
AUC[1] after 1 year	2,168	5,989	12,129	13,645	13,645
AUC after 10 years	39,433	46,516	62,696	73,183	86,370
AUC after 70 years	27,5419	282,654	299,304	310,210	324,202
AUC (bf) / AUC (formula)[2] - 1 yr	---	2.8	5.6	6.3	6.3
AUC (bf) / AUC (formula) - 10 yr	---	1.2	1.6	1.9	2.2
AUC (bf) / AUC (formula) - 70 yr	---	1.03	1.09	1.13	1.18

[1] AUC = measure of accumulated exposure defined as, "area under the curve", equal to lipid-concentration, ppt TEQ_{DFP}-WHO_{98} * days. For example, a lifetime at 10 ppt TEQ_{DFP}-WHO_{98} lipid would yield an AUC of 10 ppt TEQ_{DFP}-WHO_{98} * 70 years * 365 d/yr = 255,500 ppt TEQ_{DFP}-WHO_{98}-day.

[2] AUC (bf) / AUC (formula) = ratio comparing the accumulated exposure difference between the breast-feeding scenario and the formula. A result of 6.0 means that the accumulated exposure for the breast-feeding scenario being evaluated is 6 times more than a formula only scenario.

Table 5-6. Sensitivity Analysis Testing of PK Model for Breast-Milk Impacts[3]

Description of Model Output	6-mo baseline	Dissipation Tests		Dose Tests		Extremes	
		Sc #1	Sc #2	Sc #3	Sc #4	Sc #5	Sc #6
Peak concentration, pg TEQ_{DFP}-WHO_{98}/g lipid	44.3	49.8	44.3	48.1	28.5	54.0	28.5
Time after birth of peak	9 wk	9 wk	9 wk	9 wk	9 wk	10 wk	9 wk
AUC[1] (sa) / AUC (6-mo)[2] - 1 yr	—	1.3	1.0	1.2	0.6	1.6	0.6
AUC (sa) / AUC (6-mo) - 10 yr	---	2.2	0.8	1.1	0.8	2.6	0.7
AUC (sa) / AUC (6-mo) - 70 yr	---	1.4	0.7	1.03	0.96	1.5	0.6

[1] AUC = measure of accumulated exposure defined as, "area under the curve", equal to lipid-concentration, ppt TEQ_{DFP}-WHO_{98} * days. For example, a lifetime at 10 ppt TEQ_{DFP}-WHO_{98} lipid would yield an AUC of 10 ppt TEQ_{DFP}-WHO_{98} * 70 years * 365 d/yr = 255,500 ppt TEQ_{DFP}-WHO_{98}-day.

[2] AUC (sa) / AUC (6-mo) = ratio comparing the accumulated exposure difference between the sensitivity analysis scenario and the 6-month breast-feeding baseline scenario. A result of 6.0 means that the accumulated exposure for the sensitivity analysis scenario being evaluated is 6 times more than the 6-month baseline scenario.

[3] Scenario definitions:

Sc #1: Use of the Pinsky and Lorber (1998) lipid-based function for dissipation rate
Sc #2: Use of the Kreuzer, et al. (1997) modeled dissipation rate
Sc #3: Assumption of mother's milk concentration not declining from 25 ppt TEQ_{DFP}-WHO_{98} lipid
Sc #4: Assumption of mother's milk concentration beginning at 15 ppt TEQ_{DFP}-WHO_{98}, declining to 7.5 ppt TEQ_{DFP}-WHO_{98} after 6 months.
Sc #5: Use of Pinsky and Lorber (1998) lipid-based function for dissipation rate and the assumption of mother's milk concentration not declining from 25 ppt TEQ_{DFP}-WHO_{98} lipid.
Sc #6: Use of Kreuzer, et al. (1997) modeled dissipation rate and the assumption of the mother's milk concentration beginning at 15 ppt TEQ_{DFP}-WHO_{98}, declining to 7.5 ppt TEQ_{DFP}-WHO_{98} after 6 months.

Table 5-7. Estimated CDD/CDF/PCB Exposures for Adult Subsistence Fishermen

Media	Conc. TEQ_{DFP}-WHO_{98}[a]	Contact Rate[b]	Daily Intake (pg/kg-day)[c]
Soil ingestion	11.6 ppt[e]	50 mg/day	8.2×10^{-3}
Soil dermal contact	11.6 ppt	12 g/day[f]	1.9×10^{-3}
Freshwater fish ingestion	2.2 ppt[g]	59 to 170 g/day	$1.9 \text{ to } 5.3 \times 10^{+0}$
Marine fish ingestion	0.51 ppt[g]	12.5 g/day	9.1×10^{-2}
Inhalation	0.12 pg/m^3	13.3 m^3/day	2.3×10^{-2}
Water ingestion	0.00056 ppq	1.4 L/day	1.1×10^{-5}
Milk ingestion	0.027 ppt	175 g/day	6.8×10^{-2}
Dairy ingestion	0.18 ppt	55 g/day	1.4×10^{-1}
Vegetable fat ingestion	0.093 ppt[e]	17 g/day	2.2×10^{-2}
	Total		$2.2 \text{ to } 5.7 \times 10^{+0}$ [d]

[a] Values from Table 3-64.

[b] Values for adult soil ingestion, inhalation, water ingestion, and subsistence fish ingestion from Exposure Factors Handbook (U.S. EPA, 1997). Contact rates for milk, dairy, and vegetable fats are based on data from USDA (1995).

[c] Daily intake (mg/kg-day) = [Contact rate (g/day; m^3/day; L/day; mg/day) x Conc. TEQ x Unit Conversion (soil unit conversion = 10^{-3}, all other media no unit conversion needed)/Body Weight (kg)] or Contact rate (g/kg-day) x Conc. TEQ x Unit Conversion.

[d] Approximately equivalent to 77 to 186 pg/day, assuming an adult body weight of 70 kg.

[e] Calculated by setting nondetects to zero.

[f] Calculated as the surface area of the body that contacts the soil (5,700 cm^2/day) x the rate that soil adheres to the skin (0.07 mg/cm^2) x the fraction of CDD/CDFs absorbed through the skin (0.03); exposure factors based on recommendations in U.S. EPA (1999) for an adult resident, which assumes that the lower legs, forearms, hands, and head are exposed to the soil.

[g] This concentration is a species-specific ingestion-weighted average value.

Table 5-8. Levels of Different PCB Congeners in Blood Samples from Three Groups of Men with Different Fish Consumption Habits

Congener (UIPAC)	Fish Intake					
	None		Moderate		High	
	Plasma (n = 9)	Lipid (n = 8)	Plasma (n = 14)	Lipid (n = 7	Plasma (n = 14)	Lipid (n = 11)
Non-ortho-PCBs

6. TEMPORAL TRENDS

6.1. INTRODUCTION

Small amounts of dioxin-like compounds may be formed during natural fires, suggesting that these compounds may have always been present in the environment. However, it is generally believed that greater amounts of these compounds have been produced and released into the environment in association with human industrial and combustion practices. As a result, environmental levels are likely to be higher in modern times than in earlier times. The trend of increasing levels may now be reversing (i.e., releases and environmental levels may be gradually decreasing), however, with changes in industrial practices. As discussed in Volume 1, the potential for environmental releases of dioxin-like compounds has been reduced as a result of the switch to unleaded automobile fuels and associated use of catalytic converters and reduction in halogenated scavenger fuel additives (remaining uses of leaded fuel include chain saws, logging machinery, and mowers), process changes at pulp and paper mills, improved emission controls for incinerators, and reductions in the manufacture and use of chlorinated phenolic intermediates and products.

This chapter describes trends in the levels of dioxin-like compounds that have been observed in various environmental media and foods, as well as evidence of downward trends in exposure to dioxin-like compounds in humans. The downward trend in human exposure is supported by a modeling exercise that reconstructs the most likely past doses of dioxin-like compounds contributing to observed body burdens. Reviews of several studies and the modeling exercise are followed by several observations with regard to temporal trends of dioxin-like compounds.

6.2. SEDIMENT CORE STUDIES OF TEMPORAL TRENDS

Questions regarding the contribution made by natural sources to the overall environmental burden of CDDs and CDFs can be partially addressed using the results from analyses of the temporal distribution of CDD/CDFs in sediment core samples. Sediment cores provide a historical record of contaminant inputs into the environment and have been used by several researchers to study temporal trends in CDD/CDF deposition. Studies at various sites in the United States and Europe suggest that environmental

concentrations of CDD/CDFs began to increase rapidly in the 1930s and peaked around the 1970s.

Czuczwa and Hites (1984) analyzed sediment core samples taken in Lake Huron by the University of Michigan's Great Lakes Research Station. Sedimentation rates within the core samples were determined using Cs-137 and Pb-210 techniques. Those rates were used as a basis for relating depth of core sample to time of deposition. CDD/CDFs were detected in the core samples with no appreciable degradation over time. The most abundant CDD/CDFs were OCDDs and HpCDD/CDFs. Analysis of sample depth showed that the concentration of CDD/CDFs increased steadily beginning in approximately 1940 and leveled off around 1960. Correlations were observed over time between the levels of CDDs and CDFs in the sediment cores and the total volume of synthetic chloro-aromatics produced by the petrochemical industry in the United States. However, coal consumption did not show a good correlation with CDD/CDF concentrations over time. Czuczwa and Hites (1984) concluded that the history of sedimentation rates of CDD/CDFs in core samples from Lake Huron reflected of atmospheric deposition from the combustion of synthetic chloro-aromatics.

In a similar study, Czuczwa et al. (1985a) reported on the temporal variability of CDD/CDFs in sediment core samples taken from a wilderness lake, located in an uninhabited and undeveloped island (Siskiwit Lake, Isle Royale) in Lake Superior. The only mechanism of contaminant input into the lake was believed to be atmospheric transport and deposition. The historical record of CDD/CDF concentration in the core samples showed that CDD/CDFs were virtually absent from the sediments until around 1940. All CDD/CDF homologue groups were detected in sediment samples near the surface, with HpCDDs and OCDDs accounting for the highest percentage of total CDD/CDFs. Comparisons were made between the congener profiles found in the lake sediments and congener profiles found in urban air particles. A correlation coefficient of 0.997 was observed, leading to the conclusion that CDD/CDFs entered the lake system from aerial transport and deposition.

Smith et al. (1992, 1993) analyzed sediment core layers from Green Lake, located near Syracuse, New York, to determine temporal trends in the deposition of CDDs and CDFs since the beginning of the industrial era (circa 1860). This deep lake (200-foot depth) is thought to be affected only by atmospheric deposition because no industrial

inputs are present and motorboats are not allowed. Relatively low concentrations of CDDs and CDFs (10 pg/g or less) were observed in sediments deposited from 1860 to 1930. However, concentrations increased rapidly thereafter, reaching a peak in the mid-1960s when total CDD concentrations exceeded 1,300 pg/g and total CDF concentrations exceeded 250 pg/kg. The concentrations of CDDs and CDFs have declined rapidly since the mid-1960s and, in 1986–1990, were measured at 750 pg/g as total CDD/CDF. In the most recent samples, HpCDD and OCDD dominated the mixture of CDD/CDFs. This observation is consistent with that of Czuczwa et al. (1985a). The authors speculated that the decline in CDD/CDF concentrations over time may be due to the switch to unleaded fuels for vehicles.

Sediment cores from the Hudson River were analyzed by Smith et al. (1995). The results indicated that the subsurface sediment layers, dated between 1950 and 1980, had the highest concentrations of CDD/CDFs. OCDD, HpCDF, and OCDF accounted for the highest percentage of total CDD/CDFs in these cores. Pearson et al. (1995) studied sediment cores collected from the Great Lakes (i.e., Lakes Superior, Michigan, and Ontario) and remote inland lakes. The researchers calculated CDD/CDF accumulation rates as the product of concentration (pg/g) and sedimentation rate (g/cm^2-yr). The results of this study indicated that CDD/CDF accumulation began in the 1930s–1940s and peaked in the early to mid-1970s. Lake Ontario (350 to 575 pg/cm^2-yr) and Lake Michigan (25 to 100 pg/cm^2-yr) were found to have higher CDD/CDF accumulation rates than Lake Superior and the remote inland lakes (5 to 10 pg/cm^2-yr). CDD/CDF profiles for these lakes indicated that OCDD dominated. However, the homologue profile for Lake Ontario differed from the other lakes, leading the authors to speculate that different nonatmospheric sources were responsible for the CDD/CDFs found in this lake. MacDonald et al. (1992) observed similar temporal results in Canada. MacDonald et al. (1992) observed that OCDD and PCB-77 concentrations in sediments collected from the Strait of Georgia, British Columbia, began to increase in about 1940, reaching a maximum in about 1970. However, 2,3,7,8-TCDF concentrations did not begin to increase until about 1965 as a result of discharges of chlorine bleach effluent from local pulp mills.

Lebeuf et al. (1995) observed decreasing dioxin-like PCB (i.e., PCBs 77, 126, and 169) trends in sediments from the Lower Estuary and Gulf of St. Lawrence, Canada. Two sediment cores were collected from sites approximately 50 km apart and sliced into 25

samples. PCB concentrations were found to increase with increasing depth. These results indicate that recent inputs to this water body have decreased substantially (Lebeuf et al., 1995).

Rappe et al. (1997) analyzed sediment core samples from five lakes in southern Mississippi. The sediment cores were collected from five man-made recreational lakes with no known industrial point source of CDD/CDFs and low atmospheric deposition rates. Cores were subdivided into sections to evaluate temporal trends in deposition of CDD/CDFs. No observable trend for levels of CDDs, homologues, or I-TEQs correlating to the age of the strata could be identified.

Recently, EPA/DOE conducted a time-trend study of dioxin-like compounds in sediment cores (Cleverly et al., 1996; Versar, 1996). Cores from 11 lakes/reservoirs were collected, sectioned, and dated using ^{137}Cs and ^{210}Pb dating techniques, and analyzed for CDD/CDFs and PCBs. The lakes were located in various geographic locations throughout the United States (10 within the continental United States and 1 in Arctic/Alaska) and were selected to represent background conditions (i.e., no known CDD/CDF sources). For several of the lakes, dated samples were available for time periods ranging from the 1700s to the present. The results of the study indicated that CDD/CDF and PCB inputs to U.S. lakes have increased over time, with significant increases occurring after the 1930s. This is consistent with the findings of other researchers. In general, a minimum of one order of magnitude increase in concentration occurred from the pre- to post-1930s timeframe. With few exceptions, this observation was consistent for all 2,3,7,8-substituted CDD/CDF congeners, CDD/CDF homologue groups, and PCBs. The observed temporal trends were consistent across lakes (except the Arctic/Alaska lake), especially for lakes within the same geographic region. For some lakes, a downward trend appeared to exist for the most recent periods. The point of inflection for this downward trend varied across lakes, but appeared to occur between the 1950s and 1970s. Figure 6-1 depicts the changes in concentration over time for Beaver Lake, Washington. The data also indicate that the CDD/CDF and PCB profiles in these lakes were similar across all periods and across all lakes. This may suggest that the relative congener-specific inputs from the atmosphere have remained consistent over time and are similar across all geographic regions. Relationships also were observed between CDD/CDF and PCB trends and indicators of anthropogenic activities (i.e., PCP production, leaded gasoline sales, carbon monoxide

emissions, and PCB releases) that may be associated with production of CDD/CDFs or PCBs. However, it should be noted that correlations between these variables do not necessarily reflect causal relationships.

Several studies have also evaluated sediment cores from European lakes. Czuczwa et al. (1985b) studied temporal trends in three Swiss lakes (Lakes Zurich, Lugano, and Baldegg). No CDD/CDFs were detected in the sediments prior to 1945, but increasing levels were observed in subsequent time periods. The most abundant congeners found in the uppermost sediment samples were OCDD, HpCDD/CDFs, and OCDF. Using sedimentation rates and CDD/CDF surface sediment concentrations, the estimated accumulation rates were 300 pg/cm^2-yr for Lake Zurich, 270 pg/cm^2-yr for Lake Lugano, and 190 pg/cm^2-yr for Lake Baldegg. The authors noted that the similarities in congener profiles and fluxes of CDD/CDF in Switzerland and the United States may be indicative of similar sources of CDD/CDFs. Similar trends were noted by Beurskens et al. (1993, 1994). These researchers evaluated sediment cores from Lake Ketelmeer, a sedimentation area of the Rhine River in The Netherlands. CDD/CDF concentrations were shown to increase after the 1940s and peak between 1960 and 1980. Similar results were obtained for coplanar PCBs.

Sediment cores from two lakes in the Black Forest region of Germany were analyzed for temporal trends in CDD/CDF deposition by Schramm et al. (1994). CDD/CDFs were found to have increased by a factor of 13 since the 1930s. Recently, Hagenmaier and Walczok (1996) evaluated CDD/CDF levels in dated sediment core samples collected from Lake Constance, Germany. Cores were collected in December 1995 and April 1996. Based on a preliminary dating scheme, the results indicated that the I-TEQ$_{DF}$ concentrations for these samples began increasing around 1940, reached their peak around 1970 to 1975, and then began decreasing. The homologue profiles for the 1940s sediments were similar to those in recent deposition samples.

Using dated sediment core analyses, Alcock et al. (1997a) reported that CDD/CDF concentrations in a remote lake in Scotland began increasing in the 1860s and 1870s and peaked in the 1950s and 1960s. According to Alcock et al. (1997a), concentrations appear to have decreased in recent years. Brzuzy and Hites (1995) reported on changes over time in the CDD/CDF homologue profile for Lake Windermere in the United Kingdom. CDFs accounted for a significant fraction of the total CDD/CDF concentration in sediment

core sections dated 1946–1950. In contrast, sections dated 1988-1992 had a significantly lower fraction of CDFs, and the profile was dominated by OCDD and HpCDD. These results provide evidence that the sources of CDD/CDF deposition have changed over time, with CDFs accounting for a much higher percentage of inputs during the earlier period.

Sediment core samples from the Baltic Proper, near Sweden, showed detectable levels of CDD/CDFs dating back as early as 1882 (Kjeller and Rappe, 1994). CDD/CDFs increased slowly in the sediment strata dated between 1882 (92 pg/g) and 1962 (233 pg/g) and then increased rapidly in the 1970s. Total CDD/CDFs were estimated to be 520 pg/g in 1970 and 1,803 pg/g in 1978. CDD/CDFs decreased to a concentration of 1,454 pg/g in the most recent layer, dated 1985. DeWit et al. (1990) also observed that CDD/CDF concentrations were higher in deeper sediment layers from the Baltic Sea. I-TEQ_{DF} concentrations in surface sediments (i.e., most recently deposited) were approximately 20 times higher than in sediments collected at depths of 22 to 28 cm.

Sediment cores were collected to a depth of 5–18 m at three locations near Osaka Bay, Japan, and analyzed for CDD/CDFs (Sakai et al., 1998). CDD/CDFs found at Yodo River, which is influenced by urban activities, increased slowly from 1980, reached a peak in 1993, and then dropped to a lower concentration before stabilizing. Comparison between the southern and northern parts of Lake Biwa, representing areas more and less affected by human activities, respectively, showed that CDD/CDF concentrations at the southern part of Lake Biwa began increasing around 1955 and increased dramatically in 1964, reaching a peak in 1973. At the northern part of Lake Biwa, CDD/CDF concentrations increased dramatically in the late 1960s and continued to increase until the 1980s, when they leveled off. Homologue profiles for the sediment core sampled from the northern part of Lake Biwa showed that OCDD was the dominant congener since 1842, followed by TCDD after 1935. The concentrations of OCDD and TCDD continued to increase after 1935. The sources of these two congeners were suspected to be herbicides, preservatives, and municipal solid waste incinerators (Sakai et al., 1998).

CDD/CDFs have also been detected in remote Arctic sediment core samples, but at very low concentrations (Tan et al., 1993; Vartiainen et al., 1995). Tan et al. (1993) analyzed a sediment core collected from Wonder Lake, Alaska. With the exception of 1,2,3,4,6,7,8-HpCDF and OCDF, which had concentrations of 13 and 15 pg/g,

respectively, in all sediment sections dated between 1590 and 1790, CDD/CDF concentrations were less than 8 pg/g. The authors suggest that these results support *de novo* synthesis of CDD/CDFs. Vartiainen et al. (1995) found total CDD/CDF levels of 2.29 pg/g in sediments dated 1890 and 55 pg/g in sediments dated 1994. OCDD dominated in these samples, followed by the hepta- and hexa-chlorinated congeners.

The results of these sediment core studies provide evidence that deposition of dioxin-like compounds began increasing dramatically after the 1930s and continued throughout the 1960s. Decreases appear to have occurred only during the most recent periods. In all of these studies, the higher chlorinated compounds dominated the homologue profiles. These observations are consistent among cores collected in various locations throughout the United States and Europe. CDD/CDFs have been observed both in relatively remote lakes, as well as in lakes close to industrialized areas. This suggests that atmospheric transport and deposition may be an important mechanism of entry into these lakes.

6.3. TEMPORAL TRENDS IN SOIL, VEGETATION, AND AIR

Temporal trends in CDD/CDF and PCB deposition have also been studied in other types of environmental media including soil, vegetation, and air samples. Kjeller et al. (1991) analyzed archived soil samples dated from 1846 to 1986 from semirural plots in the United Kingdom. Herbage samples dated from 1891 to 1988 that originated from a grassland area were also tested for CDD/CDFs (Kjeller et al., 1991, 1996). All CDD/CDF homologue groups were detected in soil and herbage samples from all time periods, and the CDD/CDF concentrations increased over time beginning at about 1900 (Kjeller et al., 1991). The concentrations of total CDDs in soil increased from 31 to 92 pg/g between 1893 and 1986. CDD/CDFs in the vegetation samples remained essentially constant between 1861 and 1945, increased to peak levels in the early 1960s, declined, and then reached a second peak in the late 1970s (Kjeller et al., 1996). CDD/CDFs were about 7 to 8 times higher in the 1960s to 1980s than in the sample from 1891 to 1900. In the most recent sample (1991 to 1993), total CDD/CDFs declined to levels similar to those observed in pre-1946 samples (Kjeller et al., 1996).

In a similar study, Alcock et al. (1997b) presented evidence that CDD/CDFs were present in UK soils before the widespread development of chloroaromatics (around

1930s). A previously unopened bottle of soil, collected in 1881 from Rothamsted Experimental Station as part of an agricultural experiment, was analyzed for CDD/CDFs. The soil sample contained 0.7 ppt I-TEQ_{DF}, with OCDD, 1,2,3,4,6,7,8-HpCDD, and 1,2,3,4,6,7,8-HpCDF as the dominant congeners. Great care was taken to avoid contamination with modern air and dust for the initial analysis, and the sample was subsequently exposed to laboratory air for 32 days to determine whether current air concentrations would alter the CDD/CDF concentrations detected in the archived soil. The results indicated that such exposure did not alter the soil concentration of CDD/CDF. Modern soil samples collected from the same field plot were found to contain 1.4 ppt I-TEQ_{DF}. The authors speculated that the increase was presumably a result of cumulative atmospheric deposition of CDD/CDFs. The results also indicated that although the soils from 1881 had lower concentrations of CDD/CDFs, they contained similar congener profiles of CDD/CDF as modern soil. This may indicate long-term persistence of CDD/CDFs in soil, and similarities in source inputs over time (Alcock et al., 1997b). Alcock et al. (1997a) also summarized temporal trends in sediments, archived vegetation, soil, food groups, and direct air measurements from the United Kingdom. They suggested that concentrations in UK media were the highest between the 1950s and the 1970s and were directly related to human activities. Since the 1970s, CDD/CDF concentrations have shown a consistent decline. According to Alcock et al. (1997b), current herbage concentrations are similar to pre-1946 levels, and ambient air monitoring data from London and Manchester indicate that CDD/CDF air concentration have steadily declined since the 1970s. Archived soil, herbage, and air samples collected in the United Kingdom between 1942 and 1992 were used to evaluate changes in PCB emissions over time (Harner et al., 1995). The concentrations of PCB congeners 28, 52, 138, and 153 in these samples rose from near zero in 1935 to a maximum in the late 1960s and then fell steadily to their present levels.

Hiester et al. (1995) observed a decrease of CDD/CDF concentrations in Germany's ambient air over a 6-year period. Ambient air samples were collected over 12 sampling intervals from four sites in the heavily industrialized Rhine-Ruhr region of Germany during 1987–1988 and 1993–1994, and analyzed for CDD/CDFs. Total I-TEQ_{DF}s for these sites ranged from 0.13 pg/m^3 to 0.33 pg/m^3 during 1987–1988, and from 0.04 pg/m^3 to 0.12 pg/m^3 during 1993–1994. Reductions in CDD/CDF I-TEQ_{DF}s at these sites ranged from 46

to 69 percent over the 6-year period (i.e, from 0.22 pg/m^3 to 0.13 pg/m^3 at Dortmund, and from 0.13 pg/m^3 to 0.04 pg/m^3 at Köln). These reductions were attributed to abatement actions taken since 1989 (Hiester et al., 1995).

6.4. TEMPORAL TRENDS IN WILDLIFE

Temporal trends in CDD/CDFs and PCBs have also been studied in wildlife, including fish and bird eggs. Hebert et al. (1994) analyzed pooled herring gull eggs for CDDs annually between 1981 and 1991. The eggs were collected from colonies in the Great Lakes and the Gulf of St. Lawrence River. Analyses results indicate that CDD levels declined between 1981 and 1984, but that CDD levels have remained relatively constant since 1984. DeWit et al. (1994) evaluated temporal trends in the levels of CDD/CDFs and coplanar PCBs in the biota of Sweden. Guillemot eggs were collected from the Island of St. Karlso in the Baltic Proper (Sweden) between 1969 and 1992, and pike samples were collected from Lake Storvindeln in Lapland, Sweden, between 1968 and 1992. During these time periods, the concentrations of CDD/CDFs and PCBs decreased in both species. Roos et al. (1998) confirmed that PCB concentrations decreased significantly in the Baltic Sea between 1989 and 1997 at an annual rate of 2–4 percent by analyzing samples from 54 juvenile grey seals caught off the Swedish coast. Roos et al. (1998) also found that the PCB concentrations in herring, cod, and guillemot eggs caught from the Baltic Sea during the period 1969–1996 decreased over time by 9–10 percent annually. Decreases in PCBs since the 1970s were also observed in fish from Finland (Korhonen et al., 1995). Pike samples from both inland lakes and coastal areas of Finland had significantly lower total PCB concentrations in 1994 (1.7 to 2.1 μg/g) than in 1971 (>7 to 10 μg/g).

U.S. EPA (1994a) reported a decline in PCB concentrations in lake trout from Lake Michigan since the late 1970s; however, PCB concentrations currently appear to be approaching equilibrium in the Great Lakes system. U.S. EPA (1994a) attributed the decline in tissue concentrations to reductions in pollutant loadings to the water column. The levels of PCBs in coho salmon also declined during the early 1980s, but have remained relatively constant since that time. According to U.S. EPA (1994a), the leveling off of PCB concentrations in the Great Lakes is related to "(1) historically contaminated sediments; (2) tributaries inputs resulting from point sources, spills, and runoff from both

urban and rural areas, and resuspension from contaminated sediments; and (3) atmospheric deposition of pollutants."

Hilbert et al. (1997) analyzed cod livers collected from Danish waters between 1973 and 1996 for total PCBs (Aroclor 1260). The results indicated that PCB levels in cod livers decreased during the past three decades. Total PCBs ranged from approximately 4 to 8 mg/kg (fresh weight) in 1973 at five locations in Danish waters to less than 1 mg/kg (fresh weight) in 1996 in those same waters.

Huestis et al. (1997) examined the temporal and age-related trends of CDD/CDFs and coplanar PCBs in Lake Ontario lake trout. Archived samples of 4-year-old lake trout, collected between 1977 and 1993 from the eastern basin of Lake Ontario at Main Duck Island (MDI), were analyzed for CDD/CDF/PCBs. Three- to 9-year-old trout were collected from the western end of the basin at Port Credit. The results of the temporal trends analysis indicated that CDD/CDF/PCB concentrations were at their highest levels in 1977 and lowest in 1987. The total TEQ_{DFP}-WHO_{94} was 583 ppt in 1977, compared to 124 ppt in 1993. The most important contributor to the total TEQ_{DFP}-WHO_{94} was PCB 126. This PCB congener contributed between 40 to 50 percent of the total TEQ_{DFP}-WHO_{94}, depending on the year examined. The contribution of 2,3,7,8-TCDD accounted for 15 to 20 percent of the total TEQ_{DFP}-WHO_{94}. CDD/CDF contaminant profiles for 1977, 1982, and 1991 suggest an increase of the proportion of 2,3,7,8-TCDF as the proportion of 2,3,7,8-TCDD decreases. The study also evaluated age-related effects of CDD/CDF/PCB concentrations. The results of the analyses of 3- to 9-year-old fish indicate that as the age of the fish increases, the level of contamination also increases.

Boumphrey et al. (1998) examined 10 gannet eggs taken from Ailsa Craig, a colony in the northern part of the Irish Sea, every 2 years from 1977 to 1992 to analyze temporal trends in total PCB and PCB congener concentrations. The results indicated that the average total PCB concentration was 6.08 μg/g in 1977 and 2.5 μg/g in 1992 with an annual rate of decline of approximately 0.25 μg/g. Individual PCB congeners declined at various rates, which resulted in different congener profiles between 1977 and 1992.

6.5. TEMPORAL TRENDS IN FOOD PRODUCTS

Recent studies have evaluated trends in concentrations of dioxin-like compounds in food by analyzing levels of PCBs and CDD/CDFs in food products from different time

periods. The United Kingdom's Ministry of Agriculture, Fisheries, and Food (MAFF) compared the levels of CDD/CDFs found in commercially available cows' milk in 1990 to the levels in samples collected in 1995 (MAFF, 1997a). The 1995 samples were collected from 12 locations in England and corresponded, where possible, to the 1990 sampling locations. Analysis of the 1995 samples was performed on a pool of 105 pints of full fat milk from each location. As shown in Table 6-1, the lipid-based I-TEQ_{DF} concentrations in 1990 ranged from 1.1 to 3.3 ppt, while the 1995 I-TEQ_{DF} levels decreased to between 0.67 and 1.4 ppt. Table 6-1 also reports PCB levels for the 1995 samples. Lipid-based TEQ_{P}-WHO_{94} levels ranged from 0.75 to 2.2 ppt. No PCB analysis for the 1990 cows' milk samples was presented.

Fürst and Wilmers (1995) compared the levels of CDD/CDFs found in German dairy products in 1990 to the levels in 120 dairy samples collected in 1994. Over the 4-year period, mean I-TEQ_{DF} concentration in milk fat decreased by almost 25 percent from 1.35 ppt to 1.02 ppt. Similar reductions were noted in human milk fat (Fürst and Wilmers, 1995).

To examine trends in CDD/CDF and PCB concentration in American food products, Winters et al. (1998) analyzed 14 preserved food samples from various decades of the 20th century for 7 dioxin-like coplanar PCBs and the 17 2,3,7,8-substituted dioxin and furan congeners. The authors compared the concentrations found in historical samples to the current dioxin concentrations observed in the national food surveys for beef (Winters et al., 1996a; 1996b), pork (Lorber et al., 1997), poultry (Ferrario et al., 1997), and milk (Lorber et al., 1998). As shown in Table 6-2, all 10 samples, dated from 1957 to 1982, had I-TEQ_{DF} concentrations higher than the current mean concentrations (when nondetects were set to one-half the limit of detection). Similarly, mean TEQ_{P}-WHO_{94} concentrations were higher than current mean concentrations for 12 of the 13 samples taken between 1945 and 1983. If these samples are indicative of past CDD/CDF concentrations, normalized I-TEQ_{DF} results suggest CDD/CDF levels 2 to 3 times higher, and PCB levels over 10 times higher during the 1950s, 1960s, and 1970s than current concentrations. As shown in Figures 6-2 and 6-3, I-TEQ_{DF} and TEQ_{P}-WHO_{94} concentrations in food products began to increase with the 1957 sample and continued to increase throughout the 1960s and 1970s. The peak concentration was observed in the 1968 poultry sample. This trend in CDD/CDF and PCB concentrations in food products is consistent with the

pattern observed in sediment cores, as discussed in Section 6.2 (Cleverly et al., 1996; Versar, 1996; Smith et al., 1992, 1993, 1995; Czuczwa et al., 1984, 1985a).

6.6. TEMPORAL TRENDS IN HUMAN EXPOSURE

Several studies have examined trends in the dietary intake of CDD/CDFs and PCBs. In 1995–1996, MAFF reported on its analysis of Total Diet Study samples collected in 1982 and 1992 from 24 locations in the United Kingdom (UK) (MAFF, 1995, 1996, 1997b). Of the 11 food groups examined, 10 groups represented the major dietary contribution to intake of dioxins and PCBs, and 1 group represented bread because it is a dietary staple. The results indicated that total dietary intake of PCBs and CDD/CDFs by consumers in the United Kingdom decreased dramatically between 1982 and 1992. Dietary intake of CDD/CDFs and PCBs for specific food items was estimated by multiplying the TEQ concentration of CDD/CDFs and PCBs in the food item (calculated by setting nondetects to the limit of detection) by the average daily intake for that food item, as estimated in the UK's National Food Consumption Survey. Total dietary intake was calculated by summing the dietary intakes for all food groups. The estimated upper bound dietary intakes of CDD/CDFs and PCBs by the average adult UK consumer in 1982 and 1992 are presented in Table 6-3. The total dietary intake of CDD/CDFs was estimated to be 240-pg/day I-TEQ_{DF} in 1982 and 69-pg/day I-TEQ_{DF} in 1992. The total dietary intake of PCBs decreased from 156-pg/day TEQ_{P}-WHO_{94} in 1982 to 46-pg/day in 1992 (MAFF, 1997b). Harrison et al. (1998) also reported on composite human milk samples collected as part of the MAFF study. Lipid-based CDD/CDF I-TEQ levels in Birmingham, England, were 37 ppt in 1987–1988 and 21 ppt in 1993–1994. I-TEQ levels were 29 ppt in Glasglow in 1987–1988 and 21 ppt in 1993–1994.

Liem et al. (1997) analyzed duplicate portions of 24-hour diet samples collected in The Netherlands in 1978, 1984 to 1985, and 1994. This study was conducted to estimate the dietary intake of CDD/CDFs and PCBs in the Dutch population 18 years of age and older to evaluate trends in dietary exposures. Dietary intake was estimated by combining the results of the chemical analyses of foods with data on consumption rates from the Dutch National Food Consumption Survey. Liem et al. (1997) reported a significant reduction of CDDs and CDFs in the diet over the three time periods. The mean daily dietary intake of CDD/CDF decreased from 4.2 pg/kg I-TEQ_{DF} in 1978 to 1.8 pg/kg I-

TEQ_{DF} in 1984–1985 and 0.5 pg/kg I-TEQ_{DF} in 1994. When PCBs were included in the TEQ calculation, the daily dietary intake was 11 pg/kg TEQ_{DFP}-WHO_{94} in 1978, 4.2 pg/kg TEQ_{DFP}-WHO_{94} in 1984–1985, and 1.4 pg/kg TEQ_{DFP}-WHO_{94} in 1994. The percentage decrease in 1994 samples was consistent for all the measured CDD/CDF/PCBs. The results of this study suggest that a reduction in dietary ingestion of CDD/CDFs and PCBs occurred in The Netherlands beginning in the late 1970s.

In a study similar to the United Kingdom's MAFF (1995, 1996, 1997b) study, FÜrst and Wilmers (1997) found that CDD/CDF dietary levels also dropped in Germany in recent years. Several hundred food samples were randomly collected and analyzed for CDD/CDFs during 1989 and 1995. Fish products showed the greatest decline in CDD/CDF food concentrations over this period. Significant decreases also were noted for meats. Samples of more than 300 dairy products were collected in 1990 and 1994 from several dairies in North Rhine and Westphalia and analyzed for CDD/CDFs. The results indicate that from 1990 to 1994, CDD/CDF levels in cows' milk decreased approximately 25 percent. To test whether the reduction of CDD/CDF concentrations in food had a positive effect on human exposure, dietary intake of CDD/CDFs was estimated using the results of the food sample analysis described above and standard food consumption data. This analysis indicated that in the past few years, CDD/CDF intake by humans decreased by approximately 50 percent. The current average daily intake is estimated to be 69.6 pg I-TEQ_{DF} compared to a daily average intake of 127.3 pg I-TEQ_{DF} in 1990. This decrease in daily intake was also reflected in a decrease in breastmilk concentrations (Fürst and Wilmers, 1997). A study of more than 1,000 individual breastmilk samples from the North Rhine-Westphalia region showed a decrease from 34 ppt I-TEQ_{DF} in milk fat in 1989 to 14.2 ppt I-TEQ_{DF} in milk fat in 1996. This represents a 60 percent reduction since 1989.

6.7. TEMPORAL TRENDS IN HUMAN BODY BURDENS OF DIOXIN-LIKE COMPOUNDS IN THE UNITED STATES

Long-term, nationally representative environmental monitoring for dioxin-like compounds has not been conducted. However, this section reviews various dioxin body burden monitoring studies which have been conducted in the United States in past decades. Studies which sampled either blood or adipose tissue were compiled; studies on

other matrices such as breast milk were not included. Also, this compilation only included dioxin and furan congeners; dioxin-like PCBs were not included. Other characteristics of studies included in this compilation are:

1. All or a toxicologically significant subset of the 17 dioxin-like dioxins and furans were measured and individual-specific or overall study average concentrations of these congeners were available (this was needed in order to calculate TEQ_{DF} - WHO_{98} concentrations).
2. All results were reported on a lipid-basis.
3. Although not possible for all studies, data were obtained which had reported detection limits so that average congener concentrations could be derived assuming non-detects (NDs) equal one-half detection limit (½ DL). When detection limits were not supplied, NDs were assumed to equal zero. In only one study from the 1970s (Kang et al., 1991; U.S. EPA, 1990), NDs were reported as zero and detection limits were not supplied. In this case, it made no difference in the calculation of TEQ_{DF} -WHO_{98} concentrations.
4. All measurements were on background populations. The first study described below included Vietnam Veterans, non-Vietnam Veterans, and civilians. All three groups were included in this analysis as the concentrations in the three were indistinguishable - the civilian population had, in fact, the highest concentrations. Another reason to include all three populations was that this was the only study available with the full suite of congener concentrations in the 1970s. Two other studies (Schecter et al., 1989; Schecter et al., 1993) were comprised of blood samples taken from Vietnam Veterans only. In both of these, small subsets of individuals appeared to have elevated concentrations of 2,3,7,8-TCDD and TEQ. Congener-specific averages, not including these individuals, could be developed with the information in the articles, so these amended profiles were included in this compilation.
5. Only studies which sampled adult populations were included; data on children or infants were not included. Studies on "average adult populations" which included demographic information were comprised of approximately the same number of males and females and the average age was usually in the 40s. Studies on

Vietnam Veterans were all male populations and the maximum age was in the 40s, and one study that sampled breast adipose tissue was on females alone.

Twelve studies were found for this compilation. A summary of the results from these studies is shown in Table 6-4. Table 6-5 provides the congener-specific average concentrations from each of the years in this compilation. Figure 6-4 shows the TEQ concentrations collected from these studies as a function of year. Figure 6-5 shows the age trend for three studies. This trend refers to the common finding for surveys in the 1980s and 1990s that older individuals had higher dioxin concentrations as compared to younger individuals. Following now are study-by-study summaries.

Study 1: Dioxins and Dibenzofurans in adipose tissue of US Vietnam veterans and controls

This study was undertaken by the U.S. Department of Veterans Affairs and the U.S. EPA (Kang et al. 1991; U.S. EPA, 1990). They used EPA's National Human Adipose Tissue Survey (NHATS) Repository to collect samples. In the repository at the time of the study were approximately 8,000 tissue samples, with up to a 1000 a year collected annually starting in 1970. The target population for NHATS was all non-institutionalized persons in the US. Due to the invasive nature of adipose tissue sampling, the population was actually derived from individuals who died from external causes (90%) and surgical patients (10%). From that repository, they were able to identify samples from 494 males who potentially served in Vietnam, those born between 1936 and 1954. These 494 samples were taken between 1972 and 1981. Searching through military records, they were able to identify 134 veterans from this potential population of 494, 40 of whom served in Vietnam. They selected all of these 40, as well as 80 of the remaining 94 veterans who had not served in Vietnam (these 80 selected randomly from the population of 94). They matched each of the 40 Veterans with 2 civilians in terms of age and sex from the potential population of 494. The final population of this study was, therefore, 200 individuals: 40 Veterans serving in Vietnam, 80 non-Vietnam Veterans and 80 civilians. Five samples were discarded as inappropriate (not enough lipid, records of individuals not certain with regard to military status, etc.), for a final sample count of 195.

While a comprehensive set of data, this was not a good background representation because the oldest individual was no older than 45 years old (the last year sampled, 1981, minus the earliest birth date, 1936), and they were all males. Still, it was the only data set from these years which measured all the 17 CDD/CDF congeners, and results suggest that these individuals were not influenced by unique high exposures.

The results from these three sample sets were indistinguishable - TEQ_{DF} -WHO_{98} concentrations were 71.9, 65.4, and 72.0 pg/g lipid for the Vietnam Veterans, the non-Vietnam Veterans, and the civilians, respectively. The 2,3,7,8-TCDD concentrations followed the same trend, with concentrations of 13.4, 12.5, and 15.8 pg/d lipid for the same three groups. For this reason, these study populations were merged for further analysis here. These full study summaries can be considered to represent the years 1972 to 1981, for this limited male population. It would be desirable to compile concentrations by sampling year, to see if there was a temporal trend in the data. However, the full sample-specific study results in U.S. EPA (1990) did not indicate the year in which each of the samples were taken. This information was retrieved from EPA's files by personal communication (personal communication, J. Remmers, Office of Prevention, Pesticides, and Toxic Substances, U.S. EPA, to M. Lorber, Office of Research and Development, U.S. EPA, 2000), which allowed for the year-by-year compilations shown in Table 6-4. Only 178 of the 195 samples could be identified by year of sample collection.

As seen in Table 6-4, there appears to be a clear trend, with concentrations (in ppt) declining from the 80s to the 50s between 1972 and 1981. The 5 samples averaging 129 ppt TEQ in 1976 appear to be anomalous. There were other samples with concentrations above 100 ppt, such as a sample at 151 ppt TEQ_{DF} -WHO_{98} from 1981, at 166 ppt TEQ_{DF} -WHO_{98} from 1978, and at 179 ppt TEQ_{DF} -WHO_{98} from 1973, but 4 of 5 samples in 1976 ranged from 99 to 215 ppt TEQ_{DF} -WHO_{98}. There is no reason to believe that the high average in 1976 is indicative of any exposure for that year.

Data from 1976 notwithstanding, these data are the earliest that could be found and seem to clearly suggest a declining trend of TEQs throughout the 1970s, starting as high as in the 80s ppt TEQ lipid during the early 1970s, and declining to the 50s ppt TEQ lipid by the late 1970s.

Study 2. Control samples taken to compare to individuals exposed to a PCB transformer fire in a building in upstate New York

Schecter et al. (1986) sampled intra-abdominal and subcutaneous adipose tissue in five individuals in Binghamton, during 1983 and 1984 (these samples were assumed to be taken in 1983 for tabular and figure display). One individual had been exposed to fumes from a PCB transformer fire in an office building, but that individual is not included here. Two of the remaining 4 individuals had died from unknown causes - two types of adipose tissue were sampled and averaged for purposes here. Subcutaneous adipose tissue samples were taken from an additional two controls. No information was available as to the age and sex of these four individuals. Schecter et al. (1986) reported the concentrations of 14 of 17 of the CDD/CDF congeners; 1,2,3,7,8-PCDF; 2,3,4,6,7,8-HxCDF; and 1,2,3,7,8,9-HxCDF were not reported. The average of the four control samples was 34 ppt TEQ_{DF} -WHO_{98} lipid.

Study 3. Background population of St. Louis, Missouri

Graham et al. (1986) reported on the analysis of adipose tissues from autopsy patients who had died suddenly or violently out of the hospital during 1985. It was unclear as to whether to include the results from this study in this compilation, since only these 6 CDD/CDF congeners were measured: 2,3,7,8-TCDD; 1,2,3,7,8-PCDD; 1,2,3,6,7,8-HxCDD; 1,2,3,4,6,7,8-HpCDD; OCDD; and 2,3,4,7,8-PCDF. However, a comparison between these results and the results from the previous two studies suggests that these six congeners comprise over 90% of total TEQ_{DF} -WHO_{98}. For this reason, TEQ_{DF} -WHO_{98} concentrations were calculated and included in this compilation. Graham et al. (1986) also listed age and sex in the tabular summary of results. Of the 35 samples, 16 were male and 19 were female, and the age range was from 21 to 88 years, with an average age of 43. The average (congener limited) TEQ_{DF} -WHO_{98} concentration from this population was 47 ppt lipid. Figure 6-5a shows the results from this study, with concentrations displayed as a function of age. There is a clear age trend, with concentrations ranging from less than 20 ppt TEQ_{DF} -WHO_{98} lipid for the youngest sampled individual to over 100 ppt TEQ_{DF} -WHO_{98} lipid for the oldest sampled individual. The highest sample was about 140 ppt TEQ_{DF} -WHO_{98} lipid for a 60 year-old individual.

Study 4: Four background individuals from Atlanta, Georgia

Patterson et al. (1994) reported on the analysis of mono- and di-ortho substituted polychlorinated biphenyls, dioxins, and furans in serum and adipose tissue samples collected in Atlanta. The results included from this study for the present purposes were adipose tissue samples from four individuals who had died suddenly. These four included 2 men and 2 women, ages 19, 25, 35, and 55 years. Patterson et al. (1994) reported on 13 of 17 congeners, not evaluating 2 hexa- and 1 hepta-furan congeners. As above, the reported results comprised the bulk of the TEQ. Therefore, these data were included in the current compilation. The average TEQ concentration from this small set was 31 ppt TEQ_{DF} -WHO_{98} lipid.

Study 5: NHATS 1987

The National Human Adipose Tissue Survey of 1987, FY87 NHATS, was undertaken, in part, for comparison with a very similarly designed survey in 1982, FY82 NHATS. For both surveys, composite samples of adipose tissue from individuals characteristic of average background conditions were analyzed for the full suite of dioxin and furan congeners. FY82 NHATS was not included in this temporal trend compilation because there appears to have been unexplained high findings of 1,2,3,7,8-PCDD. Table 6-6 compares average congener concentrations of selected dioxin congeners from FY82 NHATS and FY87 NHATS for the 15-44 year age group. As seen in Table 6-6, all dioxin congeners had reasonably comparable concentrations, except 1,2,3,7,8-PCDD. The finding of 125.0 ppt for 1,2,3,7,8-PCDD is much higher than results for that congener for any of the studies found here, even the highest ones in the 1970s. The overall average 1,2,3,7,8-PCDD concentration for FY82 NHATS at 73.6 is itself significantly higher than ever found anywhere. For that reason, FY82 NHATS was not included in this compilation.

Results from 38 of the 48 composite samples from NHATS '87 were used. These were results for the adult population, described in the age groups: 15-44 and >45 years. The 10 composites representing the <15 year age group were not included. The 38 samples represented 666 individuals (the 48 samples represent 865 individuals). According to the 1980 census, these two age groups comprised 46 and 31% of the population, respectively. Average congener concentrations for these age groups presented in U.S. EPA (1991) were weighted to calculate the adult average concentrations

shown in Table 6-5. Again, not all congeners were reported, but those that were reported comprised over 90% of TEQ concentrations, as suggested by other studies which had results for all congeners. The overall adult average concentration was 37 ppt TEQ_{DF} - WHO_{98} lipid. Like other studies, there appears to be an age trend, with the older set having an average of 53 ppt TEQ_{DF} -WHO_{98}, while the younger age range had an average that was almost half that at 28 ppt TEQ_{DF} -WHO_{98}.

Study 6. Vietnam Veterans in Massachusetts in 1988

Schecter et al. (1989) reported on a study in which blood was taken from 28 Vietnam Veterans from the state of Massachusetts. The year in which the sampling occurred was not provided. Therefore, it is assumed to have occurred one year prior to the year of study publication. Of the 28 individuals sampled, it appeared as though 2 individuals had been exposed to Agent Orange in Vietnam or to another source of 2,3,7,8-TCDD. The concentration of this congener in their blood was 34 and 29 ppt lipid, and the TEQ_{DF} -WHO_{98} concentrations were 54 and 62 ppt lipid. The other congeners in the blood of these two individuals did not appear elevated. For the other 26 individuals, the average 2,3,7,8-TCDD concentration was 4.8 ppt and the average TEQ_{DF} -WHO_{98} concentration was 29.6 ppt lipid.

Study 7: San Francisco and Los Angeles residents in the late 1980s

This study was undertaken by the California Air Resources Board for the purpose of determining a preliminary estimate of the body burden levels of CDD/CDFs in the California population, so that future efforts evaluating the impact of specific air sources could use the knowledge gained, both in terms of survey design, implementation, and analysis, as well as the background levels found (Kramer et al., 1989). A total of 57 adipose tissue samples, from an initial target population of 60, were taken from surgical patients who were in surgery for reasons other than cancer. Samples were selected based on the following stratification variables: 1) age - three age groups of 12-34, 35-49, and >50 years were sampled, 2) location - San Francisco and Los Angeles were targeted, 3) sex - half of the samples were sought from each sex. The average age of the respondents was about 50 years. The average concentration found was 31 ppt TEQ_{DF} -WHO_{98} lipid. Figure 6-5b shows the results as a function of age. Again, a trend is suggested showing higher

concentrations with age. However, the trend is not nearly as well defined as in the Missouri study. Concentrations ranged from <10 ppt TEQ_{DF} -WHO_{98} lipid for the youngest individuals sampled (about 21 years old) to approximately 80 ppt TEQ_{DF} -WHO_{98} lipid for an individual over 60 years old.

Study 8: Pooled blood sample from blood bank donors in upstate New York

In a survey article describing various sampling efforts in the United States and around the world, Schecter (1991) presented the results of a pooled blood sample comprised of the blood from 100 individuals. This same profile was identified in Schecter et al. (1991) as the control population for an AIDS study, and having originated from a Syracuse Red Cross Blood Bank. Schecter et al. (1991) claims that this control population contained samples collected from approximately an equal number of males and females. No additional demographic information was available for these individuals. The average concentration reported was somewhat higher at 50 ppt TEQ_{DF} -WHO_{98} lipid, compared to other values presented for the 1980s in this compilation.

Study 9: Fifty Michigan Vietnam Veterans

Blood samples from 50 Michigan Vietnam Veterans were collected by Schecter et al. (1993) in 1991. The purpose of this collection was to compare impacts of exposure to Agent Orange in these veterans to levels of dioxin in Vietnamese exposed to Agent Orange. The average age of the 50 veterans at the time of sampling was 48 years, with a range of 41 to 66 years. Levels of 2,3,7,8-TCDD and other dioxins were elevated in 6 of these 50 Vietnam veterans. The average TEQ_{DF} -WHO_{98} concentration in these 6 veterans was 85 ppt lipid. The average TEQ_{DF} -WHO_{98} concentration in the other 44 veterans was much lower at 29.1 ppt lipid. The difference in 2,3,7,8-TCDD concentration was more striking: 46 ppt in the 6 veterans versus 4.1 ppt in the other 44 veterans. The average of the 44 veterans was used for this compilation.

Study 10: Pooled blood sample from Binghamton

Schecter et al. (1997) reported on the result of a pooled blood sample representing 100 adult men and women. The samples were collected at a Binghamton hospital laboratory from specimens ready to be discarded after having been used for routine

medical purposes. The average TEQ concentration from this pooled sample was 32 ppt TEQ_{DF} -WHO_{98} lipid.

Study 11: Blood samples from 6 study sites around the country

This is the extensive compilation prepared by the Centers for Disease Control (CDC, 2000) that forms the basis of this Reassessment's representation of current background body burdens in the United States. Details on this compilation are provided in Chapter 4, Section 4.3.2 and are not included here. Briefly, these were background populations from site-specific studies. Sites and populations were: Manchester, Missouri (n = 61); Times Beach, Missouri (n = 67); Jacksonville, Arkansas (n = 57); Oregon (n = 9); Wisconsin (n = 93); and North Carolina (n = 29). The average TEQ_{DF} -WHO_{98} concentration is 20 ppt lipid. The age of the individuals sampled were available for 214 individuals located in Missouri, Arkansas, and North Carolina. The average age was 45 years, with a range of 20-70 years. The concentrations of these individuals are graphed in Figure 6-5c. While an age trend is evident, it does appear as though that the trend is much less marked, as compared to earlier years.

Study 12. Breast adipose tissue in San Francisco

Petreas et al. (2000) presented a summary of results of analyses of breast tissue samples taken from women undergoing breast surgery during 1998. These 45 individuals comprised the control group in a breast cancer case-control study in the San Francisco Bay area. Specific results from each individual were not available in Petreas et al. (2000), but were supplied by personal communication (personal communication from M. Petreas, Hazardous Material Laboratory, California EPA, to M. Lorber, Office of Research and Development, U.S. EPA, 2000). The average age of these women was 45 years, with a range of 28-67 years. The average TEQ_{DF} -WHO_{98} concentration was 25 ppt lipid.

Two important trends that can be ascertained from these data are:

1) While certainly not a statistically collected set of data, these studies suggest a downward trend in average adult body burdens of CDD/CDFs from the 1970s through the 1990s. The adult concentrations appear to be in the range of 70 - 90 ppt TEQ_{DF} -WHO_{98} in the early 1970s; in the range of 30 - 50 ppt TEQ_{DF} -WHO_{98} in

the 1980s; below 30 ppt in the 1990s; and perhaps approximately 20 ppt by the year 2000.

2) An age trend that has been identified by others in the literature is displayed is discussed here and displayed in Figure 6-5. Specifically, older individuals appear to have higher body burdens as compared to younger individuals. Based on an examination of three studies in the 1980s (NHATS FY87 and the two studies graphed in Figure 6-5), and one from the 1990s (Figure 6-5c), one might speculate that the age trend is less pronounced through the 1990s. This is probably due to a dose trend discussed earlier in Section 6.7 (i.e., that doses to CDD/CDFs, as exemplified by 2,3,7,8-TCDD, were possibly higher in the 1960s and 70s, declining to current background levels). With lower exposures through the 1990s, older individuals could be in a period of depuration - body burdens are actually declining as they age. For example, individuals who were in their 30s and 40s in the 1970s and 80s may have had concentrations above 40 ppt TEQ_{DF} -WHO_{98}, but may have had concentrations less than 30 ppt in the 1990s, as lower background doses could not sustain the higher body burdens.

6.8. ADDITIONAL EVIDENCE OF TEMPORAL TRENDS IN BODY BURDENS

Schecter (1991) analyzed liver tissues estimated to be 100 to 400 years old recovered from the frozen bodies of two Native American (Eskimo) women. The women died in their igloo in Point Barrow, Alaska, when they were trapped and frozen by an ice overflow. Oil was used for cooking and heating, and ventilation was poor. One woman had soot-laden lungs. The results indicated that dioxin levels were much lower in these ancient tissues than in livers of people currently living in industrial areas. Tong et al. (1990), as cited in Schecter (1991), found a lipid-based total I-TEQ_{DF} level of 0.24 ppt in one of the ancient liver samples. I-TEQ levels (i.e., CDD, CDF, and total) were nondetectable in the other ancient sample. Analysis of two liver samples from modern times showed lipid-based total I-TEQ_{DF} levels of 13.3 ppt (Ryan et al., 1986, as cited in Schecter, 1991).

Recently, Päpke et al. (1997) analyzed 180 whole blood samples collected in Germany in 1996 for CDD/CDFs. The samples were taken only from individuals who had no known exposure to CDD/CDFs (i.e., their only exposure would be through food

ingestion). The results of this study were compared to a similar study conducted in 1994. The results indicated that concentrations declined from 19.1 ppt I-TEQ_{DF} in blood lipids in 1994 to 16.5 ppt I-TEQ_{DF} in blood lipids in 1996. These results suggest human exposure to CDD/CDFs have decreased over the past several years.

Wittsiepe et al. (1998) measured CDD/CDFs in 507 blood samples collected in Germany between 1991 and 1996. The samples were intended to represent the general population (i.e., the individuals were not exposed to dioxin-like compounds as a result of occupational or accidental contacts). The results indicated that blood levels of CDD/CDFs declined significantly between 1991 and 1996, with the more recent concentrations representing approximately one-half the earlier concentrations. The mean lipid-based total CDD/CDF concentrations were 71.8 pg/g in 1991 and 334.4 pg/g in 1996 (Table 6-7).

Liem et al. (1996) detected downward trends in the levels of CDD/CDFs in human breastmilk between 1987–1988 and 1992–1993. Breastmilk samples were collected from women in 11 countries as part of a World Health Organization (WHO)-coordinated exposure study. Protocols were developed to ensure that the samples collected during the two periods were comparable. The protocols included criteria for selection of donors, sampling areas, etc. The samples were analyzed for the 17 CDD/CDF congeners, as well as 6 marker PCBs (IUPAC numbers 28, 51, 101, 138, 153, and 180). The results indicated that CDD/CDF levels are decreasing in some countries (Table 6-8). Liem et al. (1996) estimated an overall annual CDD/CDF decrease of 7.2 percent, based on the data from those countries.

In a similar study, Schecter et al. (1997) assessed CDD/CDF concentrations in blood and breastmilk samples collected in Germany and the United States during two time periods. More than 100 blood samples were collected in Germany during the years 1989 and 1994 from "persons for whom there was concern about dioxin exposure but abnormal dioxin blood levels were not found." American blood samples were collected in 1984–1989 (male veterans with no dioxin abnormalities) and 1996. The German milk samples were collected in Westphalia in 1991 and 1995, and American samples were two pooled samples from 1988 (Binghamton, NY, and Los Angeles, CA), five individual analyses from the period 1995-1996 (Binghamton, NY), and one pooled sample from 1997 (Binghamton, NY). The results of the study indicated that from 1989 to 1994, the CDD/CDF concentrations in German blood declined from 43 ppt I-TEQ_{DF} to 19 ppt I-TEQ_{DF}.

CDD/CDF concentrations in United States blood samples declined from 28 ppt I-TEQ_{DF} in 1984–1989 to 25 ppt I-TEQ_{DF} in 1996. The results of the German breastmilk analyses indicated a decline from 23 ppt I-TEQ_{DF} in 1991 to 16 ppt I-TEQ_{DF} in 1995. American milk samples showed a reduction from 17 ppt I-TEQ_{DF} in 1988 to 9 ppt I-TEQ_{DF} in 1995–1997.

Kiviranta et al. (1998) measured the concentrations of the 17 toxic CDD/CDF congeners and 6 PCB congeners (IUPAC 28, 52, 101, 138, 153, and 180) in human milk samples from primiparae mothers in Finland. Samples were collected from women in both rural and urban areas between 1992 and 1994 and compared to data from 1987 (Table 6-9). Total lipid-based CDD/CDF concentrations declined from 339 ppt (n = 37) to 217 ppt (n = 28) in rural areas between 1987 and 1992–1994; urban concentrations were similar: 375 ppt (n = 47) and 381 ppt (n = 14) for the two sample periods, respectively. I-TEQ_{DF} values decreased from 20.1 ppt to 13.6 ppt in rural areas, and 26.3 ppt to 19.9 ppt for urban areas between 1987 and 1992–1994. Total lipid-based PCB concentrations declined from 396 ng/g (n = 37) to 198 ng/g (n = 28) in rural areas, and from 496 ng/g (n = 47) to 296 ng/g (n = 14) in urban areas for the same two sample periods.

6.9. A MODELING EFFORT TO RECONSTRUCT PAST DOSES OF 2,3,7,8-TCDD

Previous sections in this chapter describe evidence supporting temporal trends in environmental concentrations and human exposure to CDD/CDF/PCBs. Levels of dioxin-like compounds appeared to increase in the environment starting from the 1930s through the 1960s, and loadings began to decline perhaps starting in the 1970s to the present. Recent evidence collected on animal food products in the United States (Winters et al., 1998), combined with body burden data, are the best evidence that human exposures to dioxins may have followed the same trends. (See Sections 6.5 and 6.6.) This section describes a third way of evaluating past exposures to dioxins. Pinsky and Lorber (1998) described an effort to statistically reconstruct the pattern of past human exposure to the most toxic dioxin congener, 2,3,7,8-TCDD (abbreviated TCDD), through use of a simple pharmacokinetic (PK) model that included a time-varying TCDD exposure dose. This section summarizes the procedure and presents some key results from this modeling exercise. The original reference (Pinsky and Lorber, 1998) should be obtained for further detail.

A first-order, one-compartment PK model was used to compute an individual's body lipids' TCDD concentration over time. Key inputs for that model include: (1) a time-varying dose of TCDD (expressed in units of pg/kg-day), (2) a fraction of dose absorbed into the body lipid compartment (assumed to be constant), (3) the volume of the body lipid compartment (assumed to be time varying), and (4) a rate of TCDD loss from the lipid compartment (modeled as a function of the percent of body fat). To calculate the rate of TCDD loss, a model was needed to predict how body lipid volumes vary over time, in addition to a model of how overall body weight varied over time.

In this modeling exercise, all inputs were fixed except the time-varying dose of TCDD. Using Bayesian statistical approaches, the dose was "calibrated" to best fit a set of data on TCDD concentration in body lipids. These data, shown in Table 6-10, were obtained from studies that focused on persons with no known direct exposure to dioxins and, as such, measured background exposure levels. In terms of this modeling exercise, the most important data from this set, were from the 1970s, suggesting that body lipid concentrations of TCDD were above 10 ppt during those years (VA/U.S. EPA, 1988). Current data from the 1980s into the 1990s show TCDD concentrations below 10 ppt (U.S. EPA, 1991; Michalek et al., 1998; Andrews et al., 1989).

The feature of the Bayesian approach that is most relevant to this calibration modeling exercise was the use of constraints on the input functions. In other words, much of the evidence described earlier in this chapter suggests an expected trend on the dose function that was being calibrated in this modeling exercise (i.e., that the TCDD dose may have increased from the 1930s to the 1970s and declined thereafter). An examination of the existing trend data suggests, specifically, the following for the current dose modeling purposes: (1) a peak in environmental levels appears to have occurred in the 1960s or 1970s, (2) early century levels are from 2 to >33 times lower than the peak, (3) late 1980s levels are from 1 to 20 times lower than the peak, and (4) late 1980s levels are higher than early century levels; in all cases, the ratio of peak to 1980s levels is lower than the ratio of peak to early century levels. Also, and importantly for this modeling exercise, the estimate of TCDD exposure dose based on the 1994 release of this dioxin reassessment document (U.S. EPA, 1994b) was 0.17 pg TCDD/kg-day. Using these trends, the following Bayesian "plausibility criteria" were established for calibration modeling purposes:

1. A range of 0.0 to 0.50 pg TCDD/kg-day for the exposure dose in 1990. The same plausible range was used for the 1900 dose.
2. Ranges of 2 to 200 for the ratio of peak to 1900 dose, and 1 to 100 for peak to 1990 dose.
3. Peak year set between 1945 and 1980.

Finally, to ensure a smooth exposure curve, a limit of 20 percent was set on the rate of decrease from the peak exposure level going forward or backward 1 year.

Pinsky and Lorber (1998) detailed how well the calibrated doses duplicated the measured body burdens shown in Table 6-10. In general, several slightly different calibrated dose functions fit the data equally well. An example of a family of similar dose curves is shown in Figure 6-6. In that figure, the dose appears to increase from the 1940s through the 1960s, then begins to drop through the 1970s, with a baseline level being reached by the 1980s. This qualitatively fits some of the trend data described previously. However, while the calibrated model fits the data reasonably well, it does not fit the data perfectly. Obviously, the lack of a perfect model fit beginning in the 1970s could be partially attributed to the lack of observed body concentrations of 2,3,7,8-TCDD. As seen in Figure 6-6, the dose curves appear to converge after the 1970s, when there were observed data, while the dose curves seem to diverge prior to 1970, when there were no data on which to base the calibration. Also, some data were inconsistent, particularly the National Human Adipose Tissue Study (NHATS) data from 1982 and 1987 (U.S. EPA, 1991). Specifically, in a comparison of the NHATS 1982 and 1987 data, the mean TCDD concentration increased considerably from 1982 to 1987 in the oldest age group (45+), but decreased considerably in the two younger age groups. Further, the NHATS 1982 data do not display the trend of increasing TCDD concentrations by age that is seen in most other studies done in the 1980s (mean was 6.9 pg/g in the 15–44 age group and 5.5 pg/g in the 45+ age group), while the age trend in NHATS 1987 data (mean of 4.4 pg/g in the 15–44 age group versus 9.4 pg/g in the 45+ age group) seems exaggerated. These trends are difficult to explain with the current modeling structure; subsequently, all models with a good data to model fit overpredicted the 1982 mean and underpredicted the 1987 mean in the highest age group. More data from prior to and during the 1970s would have provided a much more useful database from which to

calibrate the model; however, no other TCDD body concentration data could be found from those time periods.

Despite the lack of a perfect fit of the model to the data, several informative findings resulted from this exercise.

1. The model calibration exercise was regenerated using two changes to the initial Bayesian constraints on the shape of the exposure/dose curve. One change essentially dropped all constraints in order to test whether the imposition of the constraints restricted how well a calibrated dose curve could fit the data. It was found that a best-fit solution for exposure with no constraints provided only an insignificant improvement. The second change was to constrain the exposure dose, making it constant over time. Results showed that the temporally varying dose provided a significantly improved fit to the data, as compared to the constant dose. Further, the best-fit constant dose in this exercise was 0.35 pg TCDD/kg-day, compared with the current average adult dose of 0.17 pg TCDD/kg-day, as determined by the previous version of this dioxin reassessment (U.S. EPA, 1994b), and with the revised 0.09 pg TCDD/kg-day of this current reassessment. The result provides strong evidence that past doses were, in fact, higher than current doses.
2. The exposure/dose curves in Figure 6-6 suggest that dioxin exposure followed a sharp bell curve, with a precipitous drop to a flat baseline in dose before 1980. This drop is counterintuitive and probably more the result of the simplicity of the pharmacokinetic model than a real-world trend. However, it may be reasonable to treat some generalizations from these calibrated dose curves as reasonable hypotheses. For example, the late 1960s were estimated as years of peak TCDD exposure, an observation that coincides with peaks found in sediment core studies. The estimates derived suggest that TCDD exposures may have been 20 times higher during the 1960s than the 1980s. Over a 10-year peak period in the 1960s and early 1970s, daily exposures could have been as high as 1.5 to 2.0 pg/kg-day, possibly dropping to as low as 0.10 pg/kg-day and below into the 1980s. Without body burden data, it may be difficult to go much further with the model results.

3. In addition to an exposure dose, the results of this exercise also include temporal body burden levels, as described by body lipid concentrations of TCDD. An example of these results is shown in Figure 6-7. The "specimen year" on the x-axis refers simply to the year in which a cross-section of the population can be examined. For example, in 1986, young individuals have a body burden of about 2 pg/g lipid; whereas older individuals have a body burden exceeding 5 pg/g lipid. The modeled build-up of TCDD in an individual's body can be ascertained by following a curve corresponding to the individual's birth year, shown on the z-axis, and progressing to the left. This figure displays two important trends: (a) body burdens in general tend to be dropping (Schecter, 1991; U.S. EPA, 1991; MAFF, 1995), and (b) body burdens are higher in older individuals than younger individuals (Orban et al., 1994; Andrews et al., 1989; Van der Molen et al., 1996). As seen from specimen years after approximately 1970, body concentrations in individuals of all ages appear to be dropping. At the same time, the cross section of all birth-year populations after about 1970 suggests that concentrations are higher in older individuals. Interestingly, this trend may not have been present in the U.S. population in the mid-1970s and earlier. In the mid-1970s, peak body concentrations appear to have peaked for individuals in their 20s (roughly), with a constant body burden for older individuals. In the 1960s and earlier, differences in body burden do not appear to be a function of age.
4. This model also had a breastmilk feeding component. To search for the best-fit exposure/dose curve, it was arbitrarily assumed that half the population was breast fed and the other half was bottle fed. Therefore, the average concentration for all individuals was calculated as the midpoint of body lipid concentrations modeled with and without breast-feeding. Breast-fed infants were exposed to milk concentrations modeled to occur in 25-year-old females (where breastmilk lipid concentrations were assumed to equal body lipid concentrations). Infants were assumed to be breast fed for 4 months, and their consumption of breastmilk lipids was 26 g/day. Bottle-fed infants were assumed to be exposed to the general exposure dose, which as can be expected, turned out to be much lower than the breast-feeding dose. Model predictions were compared to a limited subset of the available body burden data, specifically to the under-15 age groups for the two

NHATS data sets, where the mean concentrations were 4.2 pg/g lipid (NHATS 1987) and 2.0 pg/g lipid (NHATS 1982). For the under-15 age group in 1982, the predicted mean concentrations in one possible solution were 3.8 pg/g in breast-fed children versus 0.3 pg/g in bottle-fed children; in 1987, the expected means in this age group were 1.8 pg/g for breast-fed and 0.2 pg/g for bottle-fed individuals. Assuming a 50 percent breast-fed rate, predictions yielded averages of 2.0 pg/g and 1.0 pg/g for the 1982 and 1987 NHATS, respectively. Two observations could be made. First, the modeling exercise shows the impact of breast-feeding since modeled predictions of bottle-fed body concentrations were much lower than breast-fed body concentrations (i.e., 0.3 and 0.2 pg/g lipid for bottle fed versus 3.8 and 1.8 pg/g lipid for breast fed). Therefore, if the low body burden found for bottle-fed infants reflects reality, then the NHATS data showing 4.2 and 2.0 pg/mL also show the influence of breast-feeding on the body burden of children. Second, both the model and the data show a drop in the body concentrations of the under-15 age group between 1987 and 1982, suggesting a trend toward declining exposures through the 1980s.

Table 6-1. Lipid Based Concentrations of CDD/CDFs and PCBs in Samples of Pooled Retail Milk Purchased in the United Kingdom During 1990 and 1995

Location	Concentrations (ppt) TEQ (lipid)			
	CDD/CDFs (1990)[a]	CDD/CDFs (1995)	PCBs (1995)	CDD/CDF/PCBs[b] (1995/1996)
Bristol	2.0	0.92	2.2	3.1
Cambridge	1.4	0.84	1.5	2.3
Carlisle	1.1–1.4	0.67	0.75	1.4
Central London	1.4–3.3	0.99	1.7	2.7
Commuter London[c]	1.7–2.1	0.88	1.7	2.6
Crewe	—	1.4	2.1	3.5
Exeter	1.1–3.3	1.3	1.7	2.9
Northallerton	—	1.1	1.7	2.8
Norwich	—	1.1	2.1	3.2
Nottingham		1.1	2.3	3.5
Slough		0.80	1.6	2.4
Worchester	—	1.0	2.3	3.4

Note: I-TEF_{DF}s were used in calculating I-TEQ_{DF}s; TEF_P-WHO_{94}s were used in calculating TEQ_P-WHO_{94}s.

ppt = parts per trillion

a Some locations were sampled twice in 1990. Samples were also purchased from Beverley, Leeds, and Preston in 1990. Fat contents were not measured for the 1990 samples, and the whole milk concentrations were converted assuming 4 percent fat content, which is typical for UK whole milk.
b The combined concentrations of CDD/CDFs and PCBs were calculated before rounding.
c The individual pints forming this pool were purchased in outer London and the home counties.

	Glasgow	29.1		15.2	23			131	23

NOTE: Results are expressed on a fat basis. ∑ (marker PCBs) and I-TEQ$_{DF}$s are calculated assuming non-detect values are equal to zero.

a Calculated using Nordic TEF-model.
b Ontario-1988 denotes proportional mean of two pooled samples analyzed in the first round.
c Analyzed using packed column technique.
d To compare results between first and second round, samples from 1992/93 have been reanalyzed using (old) packed column technique (Becher and Skåre, personal communication).
e Dioxin levels in human milk samples from North Rhine-Westphalia collected in 1992 as reported by Fürst (1993).

Footnote References

[a] Values are presented as they appeared in the referenced article. Values in ( ) are either estimated or are calculated/extrapolated from experimental values.

[b] [R] is the ranking of the value from the cited reference.

[c] For several PCB congeners, subcooled liquid values were converted to solid values using the melting points presented in this table and the conversion methodology presented in Eitzer and Hites (1988) and Mackay et al. (1992).

[d] The selected vapor pressure value for PCB-169 is the midpoint of the range of calculated values.

$$\ln (P_{sc}/P_s) = 6.79 (T_m\text{-}T)/T$$

where: P_{sc} = subcooled value
P_s = solid value
T_m = melting point (°K)
T = ambient temperature (°K)

[a] P-chem properties with two ranks indicates that some of the values for the chemicals in the reference had been verified by another laboratory, and some values have not been verified yet. It also indicates that more than one methodology may have been used in the reference to determine the p-chem property.

Footnote References

NOTES: Summary statistics provided in or derived from references; when reference did not compute mean, it was computed using one-half the detection limit for non-detects if congener-specific detection limits were given; when detection limits were not given, zero was used for nondetects.
NA = Not applicable.
ND = Non-detect.
NR = Not reported.
Detection limits varied by study and as was different for different compounds, but generally were 1 to 5 ng/kg (ppt). Descriptions provided were those given by reference or surmised from study description when not given.

Footnote References

NOTES: Summary statistics provided in or derived from references; when reference did not compute mean, it was computed using one-half the detection limit for non-detects if congener-specific detection limits were given; when detection limits were not given, zero was used for nondetects.
NA = Not available.
NR = Not reported.
ND = Non-detect.
Detection limits varied by study and were different for different compounds, but generally were 1 to 5 ng/kg (ppt). Descriptions provided were those given by reference or surmised from study description when not given.

[a] Key: A LOD (Ref. 1)=20 to 50 ppt, LOD (Ref. 6)=1,000 ppt, LOD (Ref. 16)=500 ppt.
B Dry Surface Sediments from 18 lakes.
C All collected samples not analyzed.
D Superfund/Michigan "Area of Concern" Site.

NOTES:

NR = Not Reported
NA = Not Applicable
ND = Not Detected
ppt = Parts per trillion

Footnote References

[a] Ch. = Channel; Y. = Yellow; Sm. M. = Small Mouth; Str. = Striped; Br. = Brown; Rb. = Rainbow; P. = Pole.

[b] Various, Netherlands = samples taken from six locations around Ijsselmeer Lake; Various, Michigan = samples taken from Tittabawassee River, Grand River, Saginaw River, Saginaw Bay, and Lake Michigan; Various, Sweden = samples taken from Grenlandsfjord and Frierfjord; Various US = samples taken from 314 sites across the US, including industrial and background sites.

[c] Species were taken from both bottom feeders and open water feeders, and then composited.

[d] Whole fish samples and fillet samples were combined during analysis.

Table B-11. Environmental Levels of Dioxins in Fish (ppt) (continued)

NOTES: Summary statistics provided in or derived from references; when reference did not compute mean, it was computed using one-half the detection limit for non-detects;
NA = not applicable;
ND = non-detected (limit of detection);
NR = not reported;
Descriptions provided were those given by reference or surmised from study description when not given;
One half the detection limit was used in calculating means. Therefore, it is possible to have mean concentrations greater than the range (e.g., reported detection limit for nondetects greater than the positive sample).

Footnote References

[a] Br. = Brown; Smk. = Smoked; Str. = Striped; Lg. M. = Large Mouth; Rb. = Rainbow; P. = Pole; Y. = Yellow.

[b] Various, Netherlands = samples taken from six locations around IJsselmeer Lake; Various, Sweden = samples taken from Grenlandsfjord and Frierfjord; Various US = samples taken from 314 sites across the US, including industrial and background sites.

[c] Species were taken from both bottom feeders and open water feeders, and then composited.

[d] Whole fish samples and fillet samples were combined during analysis.

NOTES: Summary statistics provided in or derived from references; when reference did not compute mean, it was computed using one-half the detection limit for non-detects;
NA = not applicable;
ND = non-detected (limit of detection);
NR = not reported;
Descriptions provided were those given by reference or surmised from study description when not given;
One half the detection limit was used in calculating means. Therefore, it is possible to have mean concentrations greater than the range (e.g., reported detection limit for non detects greater than the positive sample).

Footnote References

[a] Blk. = Black; Lg. M. = Large Mouth; Wh. = White; Y. = Yellow; Br. = Brown; Rb. = Rainbow
[b] US = samples taken from 362 sites across the US, including industrial and background sites.
[c] Species were taken from both bottom feeders and open water feeders, and then composited.
[d] Whole fish samples and fillet samples were combined for analysis.

NOTES: Summary statistics provided in or derived from references; when reference did not compute composite, it was computed using one-half the detection limit for non-detects;
NA = not applicable;
ND = non-detected (limit of detection);
NR = not reported;
Descriptions provided were those given by reference or surmised from study description when not given.

Footnote references

[a] Samples were obtained from grocery stores unless stated otherwise. Milk samples were obtained from dairies or transport trucks. No cooked samples from the references were used.
[b] For ND values 1/2 LOD was used in calculating the mean. Therefore, it is possible to have mean concentrations greater than the range (e.g., reported detection limit for nondetects greater than the positive sample).
[c] For ND values the detection limit was used in calculating the mean.
[d] Value in reference was reported as total 2,3,7,8-TCDD toxic equivalents.

NR = not reported
NA = not applicable

Footnote references

[a] Samples were obtained from grocery stores unless stated otherwise. Milk samples were obtained from dairies or transport trucks. No cooked samples from the references were used.
[b] For ND values 1/2 LOD was used in calculating the mean. Therefore, it is possible to have mean concentrations greater than the range (e.g., reported detection limit for nondetects greater than the positive sample).
[c] For ND values the detection limit was used in calculating the mean.

NR = not reported.
NA = not applicable.

APPENDIX C. BIOAVAILABILITY OF DIOXIN

Page

APPENDIX C. BIOAVAILABILITY OF DIOXINS

C.1 Bioavailability Data

Umbreit et al. (1985, 1986a,b) conducted experiments in guinea pigs, administering 2,3,7,8-TCDD in corn oil, 2,3,7,8-TCDD added to chemically decontaminated soil, or soil from two industrial sites in Newark, New Jersey (a manufacturing site and a salvage site) contaminated with CDDs. 2,3,7,8-TCDD was the principal lower chlorinated isomer (dioxin or furan) present in the soil from the manufacturing site (for which a chemical analysis was presented). Soil from the manufacturing site was found to have 1,500 to 2,500 ppb 2,3,7,8-TCDD under soxhlet extraction; release under ambient temperature manual solvent extraction was much lower, reported as "$>$2.5 ppb." The soil from the salvage site was reported as approximately 180 ppb 2,3,7,8-TCDD under soxhlet extraction.

In this study, groups of two or four male and two or four female guinea pigs received single gavage doses of the test materials and were observed until death or sacrifice at 60 days. 2,3,7,8-TCDD in corn oil or in recontaminated soil (6 g/kg in both) proved highly toxic, without similar toxicity being observed in animals treated with up to twice this dose of 2,3,7,8-TCDD in the soil from the manufacturing site. The limited data on 2,3,7,8-TCDD levels in the liver showed much higher levels following administration of recontaminated soil versus contaminated soil from the manufacturing site.

Umbreit et al. (1986a) thus demonstrated that gavaged 2,3,7,8-TCDD containing soil from the manufacturing site was substantially less toxic than equivalent doses of 2,3,7,8-TCDD in corn oil. However, quantitative comparison of the effective doses in this study is difficult. Approaches to a quantitative comparison are outlined below.

(1) Guinea pigs receiving 12 ug/kg 2,3,7,8-TCDD in contaminated soil experienced no deaths, while five out of eight guinea pigs receiving 6 ug/kg 2,3,7,8-TCDD in corn oil died, with no groups tested having lower doses in corn oil. Other authors have provided data on the toxic effects of 2,3,7,8-TCDD in corn oil which could aid in the comparison.

McConnell et al. (1984) observed one out of six animals dying at 1 ug/kg and six out of six animals dying at 3 ug/kg. Silkworth et al. (1982) observed three out of six animals dying at 2.5 ug/kg and no deaths out of six at 0.5 ug/kg. Comparing these data directly with the Umbreit et al. results would suggest that the 2,3,7,8-TCDD in the Newark manufacturing site soil was less effective, by a factor of 10 or greater, in producing

toxicity than 2,3,7,8-TCDD in corn oil.

(2) Umbreit et al. reported a "slightly reduced" weight gain in guinea pigs receiving 6 ug/kg of 2,3,7,8-TCDD in Newark manufacturing site soil, and a "greater reduction" at the 12 ug/kg dose. No other signs of toxicity were noted in these groups. The animals receiving 6 ug/kg 2,3,7,8-TCDD in corn oil, in contrast, exhibited a marked loss of body weight and showed toxicity and mortality. Silkworth et al. (1982) also provided data on weights of guinea pigs receiving 2,3,7,8-TCDD in corn oil. Those receiving 2.5 ug/kg exhibited a marked reduction in weight gain among three out of six survivors, while those receiving 0.5 ug/kg showed a weight gain comparable to vehicle controls. Comparison of this weight data with that of Umbreit et al. suggests that the 2,3,7,8-TCDD in corn oil was more than 5 times but less than 25 times as potent as 2,3,7,8-TCDD in the Newark soil. This comparison assumes that the effect of the Newark manufacturing site soil on weight gain was due to 2,3,7,8-TCDD as opposed to other compounds in the soil. Numerous other dioxin and furan compounds and other chemicals have been identified in this soil (Umbreit et al., 1987a). It has not been established that 2,3,7,8-TCDD is the sole or prime source of toxicity in the soil.

(3) Umbreit et al. presented liver concentrations of 2,3,7,8-TCDD after death or sacrifice at 60 days following gavage. Much lower concentrations of 2,3,7,8-TCDD were found in the livers of animals receiving soil from the manufacturing site compared with those receiving the dose in corn oil. There are, however, two factors that limit the conclusions than can be drawn from this comparison.

First, the corn oil group experienced major toxicity and weight loss, particularly complete loss of body fat. These changes may have affected the partitioning of 2,3,7,8-TCDD within the body, leading to a higher concentration in the livers of the animals experiencing toxicity. Second, the animals gavaged with corn oil died early--half were dead by 26 days, while all of the guinea pigs treated with soil survived to 60 days (with the exception of one gavage death). The U.S. EPA (1985c) reported a half-life for 2,3,7,8-TCDD elimination of 30 $\pm$ 6 or 22 to 43 days from two studies in guinea pigs. Additionally, the U.S. EPA (1985c) stated that elimination in the guinea pig may follow zero-order kinetics. Differences in elimination due to differences in periods of survival are likely to have affected the relative quantities of 2,3,7,8-TCDD found in the livers of the test groups.

Perhaps a more appropriate comparison can be made with the four animals receiving 0.32 ug/kg of 2,3,7,8-TCDD in contaminated soil from the Newark salvage site. These animals experienced no reported toxic signs (weight data not presented) and survived the full 60-day experiment. Approximately 6% of the gavage dose was found in the liver of these animals, while only about 0.06% of the gavage dose was found in the livers of guinea pigs in the 12 ug/kg group receiving the Newark manufacturing site soil. This would suggest that the 2,3,7,8-TCDD in the manufacturing site soil was 100 times less bioavailable. However, given the different doses used and the fact that only a single pooled sample was analyzed for 2,3,7,8-TCDD in each group, caution must be used in interpreting this comparison.

The 2,3,7,8-TCDD in soil from the salvage site was substantially bioavailable, based on the single liver tissue analysis. Approximately 6% of the administered dose was recovered from the livers of these animals at 60 days. This can be compared with data on hamsters given 2,3,7,8-TCDD in corn oil by McConnell et al. (1984), where approximately 8% of the 2,3,7,8-TCDD could be recovered in the 1 ug/kg dose group among survivors at 30 days.

McConnell et al. (1984) treated Hartley guinea pigs (2.5 weeks old) with single gavage doses of either 2,3,7,8-TCDD or dioxin contaminated soil from two sites in Missouri. The 2,3,7,8-TCDD concentrations from the two sites were reported at 700 and 880 ppb respectively; total tetrachlorodibenzofurans (TCDF) concentrations in the soil were 40 to 80 ppb, and polychlorinated biphenyls (PCB) concentrations were 3 to 4 ppm. Taking into account the relative toxicities, the authors concluded that toxicity from the other compounds was likely to be small compared with that from 2,3,7,8-TCDD. Livers were analyzed for 2,3,7,8-TCDD at death or sacrifice at 30 days following treatment. Treatment deaths occurred between 5 and 21 days post-gavage.

Guinea pigs that died exhibited severe loss of body fat, markedly reduced thymus and testicle size, and adrenal hemorrhage. No adverse affects were noted in animals treated with decontaminated soil. For 2,3,7,8-TCDD in corn oil and for both contaminated soils, there were clear dose-responses in mortality. The calculated LD_{50} values for the two soil types were lower than the LD_{50} for 2,3,7,8-TCDD in corn oil by a factor of three to four.

There was a dose-response between the liver concentration of 2,3,7,8-TCDD and the gavage dose; the details of this relationship are complex. Animals dying during the experiment had liver concentrations a factor of 1.4 to 3.2 higher than animals in the same dose groups who survived 30 days. This observation makes quantification of the dose-response relationships difficult (all or most of the animals in the low-dose groups

survived the experiment, while all of the animals in the high-dose groups died). When the liver concentrations of 2,3,7,8-TCDD in animals dying early at the middle and high-dose groups are compared, there appears to be a greater-than-linear increase in liver concentration with dose for the Times Beach and Minker Stout soil groups, with a 3.3-fold increase in dose producing a 10- to 13-fold increase in liver concentration.

Liver concentrations of animals in the different dosing groups can best be compared among groups that experienced similar mortality.

(1) Animals in dose groups in which all animals died within 30 days: 2,3,7,8-TCDD in corn oil, approximately 20% of the administered dose was in the liver. For the soil-treated groups, 13% and 11% of the doses, respectively, were in the liver. Comparison of these data suggest that 2,3,7,8-TCDD was approximately twice as available through corn oil as through soil.

(2) Animals surviving the 30-day experiment (in groups where at least 4 out of 6 survived): For 2,3,7,8-TCDD in corn oil, 7.5% of the administered dose was in the liver. For soil-treated animals < 3.6, 1.3, < 4.2, and 2.0% of the doses, respectively, were in the liver. Comparison here would suggest that 2,3,7,8-TCDD was approximately four times as available through corn oil as through soil.

The authors note that the differences in liver concentrations observed in the study may reflect varying partitioning of the 2,3,7,8-TCDD among internal organs, since dying animals suffered major loss of body weight and fat content. In addition, surviving animals would have had greater opportunity to metabolize and excrete 2,3,7,8-TCDD due to a longer lifetime.

Umbreit et al. (1986a) reported additional chemical analyses of the Times Beach soil. Soxhlet extraction of the Times Beach soil yielded a similar quantity of 2,3,7,8-TCDD to the solvent extraction reported by McConnell et al. (1984). This is in contrast to the Newark manufacturing site soil used in the Umbreit et al. (1987a) experiments, where only a small fraction of soxhlet-extractable 2,3,7,8-TCDD was extractable by the solvent extraction methodology used by McConnell et al. (1984).

McConnell et al. (1984) also reported an experiment in which groups of six Sprague-Dawley rats were given single gavage doses of 2,3,7,8-TCDD in corn oil or dioxin-contaminated soil from the Minker site. Induction of aryl hydrocarbon hydroxylase (AHH) in the rat livers was measured at sacrifice 6 days after dosing. Experimental doses ranged from 0.4 to 5.0 ug/kg 2,3,7,8-TCDD. Measured AHH induction was similar for groups receiving 2,3,7,8-TCDD in corn oil or receiving contaminated soil containing nearly equal doses of 2,3,7,8-TCDD. For example (based on the rate of formation of 3-

hydroxybenzo[a]pyrene), AHH activity was measured at 1,269 pmole min^{-1} mg^{-1} for the group receiving 5 ug/kg 2,3,7,8-TCDD in corn oil and at 1,230 pmole min^{-1} mg^{-1} for the group receiving 5.5 ug/kg 2,3,7,8-TCDD in contaminated soil. For the five dose groups, the AHH activity for the soil group ranged from 50% to 110% of the activity in the corn oil group.

The McConnell et al. (1984) rat data indicate that the bioavailability of 2,3,7,8-TCDD from the Minker site soil was at least 50% of that of equivalent doses of 2,3,7,8-TCDD in corn oil.

Lucier et al. (1986) provided additional information on the induction of hepatic enzymes in rats by the 2,3,7,8-TCDD contaminated soil from the Minker site tested by McConnell et al. (1984). AHH induction was similar for the groups of rats receiving 2,3,7,8-TCDD in corn oil and contaminated soil (within a factor of two) over a broader range of doses (0.015 ug/kg to 5 ug/kg) than reported by McConnell et al. (1984). In a second enzyme assay using the same animals, UDP glucuronyltransferase activity was found to be slightly higher in groups receiving 2,3,7,8-TCDD in corn oil than groups receiving equal doses in contaminated soil.

Liver concentrations of 2,3,7,8-TCDD for the rats were also reported. For the corn oil vehicle the liver concentrations were 40.8 $\pm$ 6.5 ppb at the 5 ug/kg dose and 7.6 $\pm$ 2.5 ppb at the 1 ug/kg dose. Assuming that the liver comprises 4.0% of body weight, the retention rates for the 5 and 1 ug/kg doses were 33% and 30%, respectively. In rats receiving 2,3,7,8-TCDD in contaminated soil, the 5.5 ug/kg group had liver concentrations of 20.3 $\pm$ 12.9 ppb, and the 1.1 ug/kg group had concentrations of 1.8 $\pm$ 0.3. Thus, retention rates for the 5.5 and 1.1 ug/kg groups are estimated at 14% and 7%, respectively. These data indicate that liver retention in the soil group was 20% to 40% of that in the corn oil vehicle groups.

Umbreit et al (1986b) report additional studies of mortality in guinea pigs treated with soil containing 2,3,7,8-TCDD from Newark (manufacturing site) and Missouri (Times Beach) previously tested by Umbreit et al (1985, 1986a) and McConnell et al. (1984), respectively. Guinea pigs received a single gavage dose of a soil suspension and were observed for 60 days. After autopsy, deaths were classified as whether or not they appeared to be due to TCDD toxicity. Substantial mortality (25% overall) from conditions not attributed to TCDD was observed across all groups.

The data for both the Newark and Missouri sites are similar in trend for the previous data on these sites; and clearly indicate the greater toxicity of the Newark soil for given equal administered doses of 2,3,7,8-TCDD. With larger groups of guinea pig studied, a toxicity-related death was observed in both the 5 and 10 mg/kg dose groups for

Newark soil while no deaths were observed in corresponding dose groups (6 and 12 mg/kg) with fewer animals in Umbreit et al. (1986a).

Comparing groups within this study, similar mortality (1 or 2 deaths in 10 to 16 animals) was seen in both the 5 and 10 ug/kg Newark groups and the 1 and 3 ug/kg Missouri groups. These results suggest that the toxicity of these materials differs by an order of magnitude or less. As noted above, the degree to which toxicity from these soils can be attributed to 2,3,7,8-TCDD in the presence of numerous other related toxic compounds is not known. 2,3,7,8-TCDD tissue concentrations were not reported in this work.

In another comparative study Umbreit et al. (1987b) compared the Newark manufacturing site and Times Beach soils in the induction of aryl hydrocarbon hydroxylase (AHH) in rats. While the use of only single dose levels prevents detailed analysis, the two soils proved quite similar in their ability to induce AHH. The explanation for the difference in this finding from those observed in the toxicity studies discussed above is not clear, but may relate to the presence of other toxic and/or AHH inducing compounds.

Umbreit et al. (1987a) report a reproductive toxicity study with soils from the Newark manufacturing site and salvage yard previously studied by Umbreit et al. (1986a). Female mice were treated thrice weekly with soil from these sites, with treatment continuing through fertilization to weaning of pups. The total doses of 2,3,7,8-TCDD received by the mice were 720 ug/kg in manufacturing site soil, and 86 ug/kg in salvage yard soil. A corn oil vehicle group and a recontaminated soil group received a total of 225 ug/kg.

Deaths in animals showing "classic signs" of TCDD toxicity were observed in the corn oil and recontaminated soil groups, and indicate appreciable bioavailability of 2,3,7,8-TCDD. Deaths were also observed in animals receiving manufacturing site soil but the authors did not observe "classic signs" of TCDD toxicity. Fewer live pups born and fewer pups surviving until weaning were observed in the manufacturing site soil group compared with those receiving decontaminated soil. TCDD completely blocked reproduction in the corn oil and recontaminated soil groups. The results of this study demonstrate acute and reproductive effects occurred in animals receiving manufacturing site soil. However, these effects were of a lesser magnitude than those seen in animals treated with 2,3,7,8-TCDD in corn oil at a dose three fold lower. The authors note the presence of substantial quantities of other toxic substances in the manufacturing site soil (chemical analyses presented). No toxic effects were noted in animals treated with salvage site soil, who received a much smaller 2,3,7,8-TCDD dose. The data does not allow a quantitative evaluation of the bioavailability of 2,3,7,8-TCDD.

Kaminski et al. (1985) and Silkworth et al. (1982) reported the results of a series of studies on the toxicity of soot containing dioxin and furan compounds from a fire involving transformer fluid containing PCBs. Hartley guinea pigs (500 to 600 g) received single oral doses of soot in an aqueous vehicle, a soxhlet extract of the soot in the same vehicle, or 2,3,7,8-TCDD in either an aqueous vehicle or corn oil.

The soot was reported to contain 2.8 to 2.9 ppm 2,3,7,8-TCDD and 124 to 273 ppm 2,3,7,8-TCDF. The total polychlorinated dibenzofuran content was estimated at 5,000 ppm. Animal weights and mortality were recorded for 42 days, at which point the survivors were sacrificed and LD_{50} values were calculated. Blood chemistry and a pathologic examination were performed at sacrifice.

Silkworth et al. (1982) noted that the LD_{50}s for contaminated soot and soot extract were similar at 410 and 327 equivalent ug/kg, indicating that the matrix had only a small effect on toxicity. If expressed in terms of the content of 2,3,7,8-TCDD, the LD_{50} from soot is 2.5 ug/kg, which is a factor of seven below the LD_{50} for 2,3,7,8-TCDD in an aqueous vehicle, suggesting that other compounds contributed to the toxicity of the soot and soot extract.

The authors stated that they adopted an aqueous vehicle in these experiments because it was nontoxic and provided a stable suspension of soot; they regarded this vehicle as more appropriate for modeling of human exposure conditions than an oil vehicle. The data from these experiments also demonstrate that use of an oil vehicle leads to substantially greater 2,3,7,8-TCDD toxicity than does an aqueous vehicle.

Comparison of mortality and weight loss in groups of female guinea pigs receiving 500 ug/kg of soot or the equivalent amount of soot extract suggests that the extract may be somewhat more toxic; however, all six animals died in the 1,000 ug/kg soot group, while four out of five died in the 500 ug/kg extract group. Taken together, these data indicate that the soxhlet extract of soot in an aqueous vehicle was between one and two times as toxic as the soot itself. It is likely that a larger difference in toxicity would have been observed if the soot extract was in an oil vehicle.

Van den Berg et al. (1983) fed small groups of male Wistar rats fly ash from a municipal incinerator (pretreated with HCl) containing dioxins and furans, a soxhlet extract of the fly ash, or a purified extract of the ash that was obtained using column chromatography. 2,3,7,8-TCDD was present as 3.3% of the TCDD isomer group in the fly ash extract. (The authors did not specify whether this reference was to crude or purified extract.) 2,3,7,8-TCDF was present as 17.9% of the tetra-CDF isomer group in the extract. The rats were fed 2 g/d fly ash mixed with diet or the residual from 2 mL/d extract after the extract was mixed with diet and the solvent was evaporated. The animals

were exposed to the treated diet for 19 days, and then sacrificed, and the liver tissue was analyzed for the presence of dioxins and furans.

Approximately 1% of the 2,3,7,8-TCDD dose from fly ash was retained in the liver, and approximately 4% of the dose of this isomer from fly ash extract was so retained. The corresponding percentages for 2,3,7,8-TCDF are 0.3 and 1.0. Data on the retention of isomer groups in adipose tissue were presented for the extract-treated groups but not for the fly ash-treated group. The concentrations of the various isomers in adipose tissue are comparable to, or less than, the concentrations in liver tissue.

The U.S. EPA (1985b) reported a half-life for elimination of 2,3,7,8-TCDD in the rat of 20 days at high dose. If a similar half-life is assumed in this experiment, the quantities of 2,3,7,8-TCDD in the animals at the end of the 19-day feeding experiment would be significantly less than the absorbed dose, but still of the same order of magnitude. However, the recovery percentages in this study are low for both the fly ash and fly ash extract groups in comparison with other studies in which 2,3,7,8-TCDD was administered to rats. Fries and Marrow (1975) fed rats diets containing 7 or 20 ppb of 2,3,7,8-TCDD for a period of up to 42 days. After 14 days of feeding, the rat livers contained an average of 32% of the cumulative administered dose; at 28 days, 21% of the dose; and at 42 days, 18% of the dose. Thus, in the van den Berg et al. (1983) study, the liver retention of 2,3,7,8-TCDD for the fly ash extract group is a factor of five to eight below what could be anticipated for the Fries and Marrow (1975) data, and the liver retention in the van den Berg et al. (1983) group fed soot is a factor of 20 to 30 lower than that seen by Fries and Marrow (1975). Data from Kociba et al. (1976), Rose et al. (1976), and Kociba et al. (1978) lead to similar conclusions to those from the Fries and Marrow (1975) data regarding the fraction of cumulative 2,3,7,8-TCDD dose retained in the rat liver.

An explanation of the low level of recovery for the animals receiving the soxhlet extract of soot is not apparent. It is possible that the presence of multiple compounds affected absorption or metabolism in the rats fed soot and soot extract.

A second approach to the van den Berg et al. (1983) data is to compare the ratios of liver concentrations for dioxins in fly-ash-treated animals to the concentrations in extract-treated animals. These ratios, based on measurements in small numbers of animals, indicate a substantial bioavailability of dioxin and furan compounds from the tested fly ash. This availability varied among the different isomers with the value of 0.3 for 2,3,7,8-TCDD, indicating that this isomer was three times as available from fly ash extract as from fly ash.

Van den Berg et al. (1985) fed fly ash (pre-treated with HCl) to Wistar rats, guinea pigs, and Syrian golden hamsters. Fly ash was mixed with standard laboratory diet at

2.5% by weight, and animals were allowed to eat ad libitum. The amount of fly ash consumed by each group of five rodents was determined by the authors. For each species there were three groups of animals each fed fly ash for approximately 32 days (group I), 60 days (group II), or 94 days (group III). Concentrations of dioxin and furan isomer groups in the food were presented, and include 1.4 ng/g TCDD compounds and 2.1 ng/g TCDF compounds.

The authors presented calculated recovery percentages for the cumulative dose of specific isomers in the rodent liver. For 2,3,7,8-TCDD in guinea pigs, 3.7%, 0.9%, and 1.4% of the administered dose was recovered in the liver in groups I, II, and III, respectively. The 32-day (group I) recovery percentage is somewhat higher than seen in the lower dose groups receiving 2,3,7,8-TCDD contaminated soil in McConnell et al. (1984). The value in hamsters was approximately 2% (only reported for group II), and analytical problems prevented this determination in rats. No other TCDD compounds were quantified. Similarly, for 2,3,7,8-TCDF, guinea pigs showed retention of 4.7%, 2.2%, 2.5% of the administered dose in groups I, II, and III, respectively. For both 2,3,7,8-TCDD and 2,3,7,8-TCDF the recovery percentages in guinea pigs at 32 days were approximately a factor of 4 to 15 higher than that observed in the van den Berg et al. (1983) study in rats.

Other TCDD compounds that were present showed comparable or somewhat lower retention, averaging 1% to 2% over the animals groups. No TCDD or TCDF compounds were detected in hamster liver or analyzed for in rat liver. Higher chlorinated congeners most typically showed retention in the range of 2% to 5% in rat liver and 1% to 3% in guinea pig liver, with the exception of 2,3,4,7,8-PeCDF (9.8%, 8.3%, and 11.3% in the hamster groups). Few other compounds were found in hamster liver, but 2,3,4,7,8-PeCDF was found with a recovery of 5% to 8% and 2,3,4,7,8-HxCDD was found at 3% to 7%.

As with other experiments in which the retention of dioxins in the liver has been determined, these percentages place a lower bound on the bioavailability of the dioxins but, because not all dioxin is localized in the liver, do not permit bioavailability to be estimated without knowledge of the elimination of the administered dose over time and the quantity of dioxins in the remainder of the organism. No positive control group receiving 2,3,7,8-TCDD was included for comparison.

Poiger and Schlatter (1980) conducted several experiments in Sprague-Dawley rats (180 to 220 g) in which liver concentrations of tritium label from 2,3,7,8-TCDD were determined using various doses and vehicles. All experiments consisted of a single gastric intubation of 2,3,7,8-TCDD-containing material, followed by animal sacrifice at

predetermined times. The doses used were well below the LD_{50} in the rat (the maximum dose applied was 5 ug/kg), and no deaths or toxic effects were reported.

In a preliminary experiment, rats were treated with 14.7 ng/rat 2,3,7,8-TCDD in ethanol. The results indicate substantial localization of 2,3,7,8-TCDD in the rat liver, with a decrease of a factor of two in the fraction of the dose in the liver between 1 and 4 days. Poiger and Schlatter (1980) conducted all further studies with sacrifice at 24 hours to maximize the recovery of 2,3,7,8-TCDD from the liver.

In a second experiment, the authors administered 2,3,7,8-TCDD doses in ethanol ranging from 15 to 1,070 ng/rat to groups of six rats. They found a graded increase in percentage retained in the liver from 37% $\pm$ 1% at the 15 ng dose to 51% $\pm$ 4% at 280 ng. At the high-dose point, the percentage may have fallen (42% $\pm$ 10% at 1,070 ng).

In a further experiment, 2,3,7,8-TCDD was administered at low dose in a series of vehicles. These data demonstrate that administration of 2,3,7,8-TCDD in soil reduced the retention of the dose in the liver to 66%, or 44% of the retention seen with 2,3,7,8-TCDD
in ethanol. The lower value, 44%, was obtained for soil that was aged for 8 days at 30-40 °C following addition of 2,3,7,8-TCDD. This observation is consistent with the findings of other studies reported here that 2,3,7,8-TCDD from environmental soil (naturally aged) was generally less available than 2,3,7,8-TCDD freshly added to clean samples of these soils. The aqueous suspension of 2,3,7,8-TCDD in activated carbon showed little evidence of bioavailability; this is supported by the authors' measurements showing that 2,3,7,8-TCDD was only slightly extractable from the activated carbon matrix by various solvents. In contrast, 58% to 70% of 2,3,7,8-TCDD could be recovered from soil samples by washing with hexane/acetone (4:1 v/v).

Poiger and Schlatter (1980) also presented results from several skin application experiments with TCDD-containing materials using rats and rabbits (not reviewed here).

Bonaccorsi et al. (1984) reported the results of a study of gut absorption of 2,3,7,8-TCDD from soil taken from the Seveso, Italy accident site. Soil containing 81 $\pm$ 8 ppb 2,3,7,8-TCDD from the "highly contaminated" area in Seveso was administered to albino male rabbits (2.6 $\pm$ 0.3 kg) in daily gavage doses for seven days. Additional samples of clean soil were spiked with 2,3,7,8-TCDD in the laboratory to yield 10 and 40 ppb contamination levels and were administered to rabbits following the same protocol. For comparison, rabbits were also treated with 2,3,7,8-TCDD in solution in acetone-vegetable oil (1:6) or alcohol-water (1:1). Rabbits were sacrificed on the day after treatment stopped and liver concentrations of 2,3,7,8-TCDD were measured. The authors did not remark on the presence or absence of toxicity in the treated rabbits. EPA (1985a)

reports values for the single dose LD_{50} of 2,3,7,8-TCDD in rabbits of 115 and 275 ug/kg. The total doses received by the rabbits in this study were approximately 54, 107, and 215 ug/kg over seven days. Based on this comparison, there is a likelihood that toxic effects occurred in the Bonaccorsi work, and as noted above, toxicity has the potential to affect the tissue concentrations of 2,3,7,8-TCDD. For this reason, the most appropriate comparisons among these data are between groups showing similar liver concentrations of 2,3,7,8-TCDD, which may then be inferred to have experienced similar toxic effects.

That this method of comparison is desirable can also be seen from the Bonaccorsi et al. (1984) data, where both solvent vehicle groups and the spiked soil groups show an increase of the fraction of the dose in the liver at the higher administered doses. However, it should be mentioned that use of two different solvent vehicles complicates interpretation. Similar liver concentrations of 2,3,7,8-TCDD were seen in the 40 ug/d solvent vehicle and 80 ug/d Seveso soil groups. Comparing the percentage of liver retention in these two groups indicates absorption from Seveso soil was 40% of that from the solvent vehicle. Using the same approach, comparison of the 80 ug/d solvent vehicle and 160 ug/d Seveso soil groups indicates that absorption from the soil was 41% of that from the solvent.

The same approach can be used to compare absorption from the solvent vehicle and from the spiked soil. In this case the 40 ug/d solvent vehicle group had the liver concentrations closest to either the 40 or 80 ug/d spiked soil groups. Comparison of the percentage of dose in the liver indicates absorption from spiked soil is 68-73% of that from the solvent vehicle. Bonaccorsi et al. (1984) conducted work with either aged or non-aged spiked soil but do not present data to allow a comparison of these groups.

Shu et al. (1987, as cited by Leung and Paustenbach, 1987) studied 2,3,7,8-TCDD from the Missouri site tested by McConnell et al. (1984). Their paper reports an oral bioavailability of approximately 43% in the rat dosed with environmentally contaminated soil from Times Beach, Missouri. This figure did not change significantly over a 500-fold dose range of 2 to 1450 ng 2,3,7,8-TCDD per kg of body weight for soil contaminated with approximately 2, 30 or 60 ppb of 2,3,7,8-TCDD. The data from this study is not now available to the Exposure Assessment Group of EPA for review.

C.2 Summary of Bioavailability

Table C-1

summarizes data that are pertinent to the bioavailability of 2,3,7,8-TCDD from environmental matrices. Studies of bioavailability, which examined soil samples, soot, and fly ash, have utilized three methodologies: measuring acute toxicity, retention of 2,3,7,8-TCDD in the liver, and induction of hepatic enzymes.

Among the five samples of soil from contaminated sites that have been tested, three have shown substantial bioavailability, e.g., 25% to 50%, when compared with 2,3,7,8-TCDD in corn oil gavage. A fourth soil sample was compared with 2,3,7,8-TCDD administered in a solvent vehicle, and fell in this range. The fifth soil, tested by Umbreit et al. (1986a,b; 1987a,b) showed bioavailability substantially less than the other soils tested. While difficult to gauge quantitatively, dioxin from this fifth soil may be an order of magnitude less available than from the other soils.

Additionally, three samples of soil spiked with 2,3,7,8-TCDD have been tested for bioavailability, including one sample in which the 2,3,7,8-TCDD was incubated with soil at

an elevated temperature. The 2,3,7,8-TCDD added to these soil samples proved to be highly available (e.g., 40% to 70%).

In one study, soot from a transformer fire containing dioxins and furans proved similarly toxic to a soxhlet extract of the soot in an aqueous vehicle. However, the soot extract may have proved more toxic if delivered in corn oil, as was 2,3,7,8-TCDD in the soil studies. The availability of 2,3,7,8-TCDD and other dioxins and furans from incinerator fly ash have been addressed by van den Berg et al. (1983, 1985) in extended feeding studies. In these studies, liver retention of 2,3,7,8-TCDD from either fly ash or fly ash extract proved low, with availability from fly ash being approximately 25% of that from the extract.

The individual studies reviewed have a variety of limitations, as discussed in the preceding text. A notable limitation was that some experiments were conducted using highly toxic doses of 2,3,7,8-TCDD, so that determination of bioavailability was complicated by wasting and early death of the test animals. It should also be noted that, while the relative retention of 2,3,7,8-TCDD in the liver can serve as an appropriate indication of differences in bioavailability between samples, the percentage of dose found in the liver only places a lower bound on absorption. This is particularly relevant to experiments where animals have been maintained for many weeks after dosing and an undetermined quantity of 2,3,7,8-TCDD has been excreted.

Finally, toxicity data for mixtures for which both toxicity and bioavailability of individual compounds may vary are difficult to interpret quantitatively in terms of bioavailability.

As presented in U.S. EPA (1985c), Rose et al. (1976) determined gut absorption of 2,3,7,8-TCDD in a 1:25 mixture of acetone to corn oil (by volume) in the rat. In both single dose and multiple dose experiments, measured absorption was approximately 85%. Assuming that absorption from pure corn oil is similar to that from this mixture, and assuming that absorption in other species for which data are not available is similar, the 85% factor can be applied to the data presented here to obtain an approximate range for typical 2,3,7,8-TCDD absorption from soil. Using this factor, the estimated relative bioavailability of 2,3,7,8-TCDD from soil is 25% to 50% and, when compared with corn oil, provides an estimate of gut absorption of 20% to 40% of ingested 2,3,7,8-TCDD in soil. This estimate is comparable with the 20% to 26% absorption from 2,3,7,8-TCDD treated soil from the work of Poiger and Schlatter (1980).

Recognizing these limitations, the weight of evidence indicates that 2,3,7,8-TCDD is often highly available from environmental materials. However, in one tested soil sample the compound was substantially less bioavailable. While the data are too sparse to allow

a prediction as to whether a particular environmental sample will prove more or less bioavailable, one important suggestion has emerged. In the two samples that have proved least bioavailable (the Umbreit et al. (1986a) manufacturing site soil sample, and 2,3,7,8-TCDD on activated carbon tested by Poiger and Schlatter (1980)) the 2,3,7,8-TCDD was largely resistant to solvent extraction. This was not the case for more bioavailable materials.

Further research, using short-term experiments in which animals are handled under identical conditions and are fed dioxins in different media, is needed for an improved comparison of absorption between different environmental samples. Acutely toxic doses should be avoided to ensure that tissue concentrations are directly interpretable. Experiments studying both tissue retention and enzyme induction should prove valuable for this research. Whole-body levels of 2,3,7,8-TCDD need to be related to liver concentrations, and the effects of metabolism need to be addressed. The vehicle of administration has been shown to affect acute 2,3,7,8-TCDD toxicity, and vehicle effects need to be considered in designing experiments.

C.3 Distribution

Ryan et al. (1985) examined the distribution of 2,3,7,8-TCDD in two humans at autopsy. On a weight basis, there were 6 ppt of TCDD in fat, 2 ppt in liver and below levels of detection in kidney and muscle. They reported that on a per lipid basis the levels were similar between tissues. It is important to note that one of these subjects suffered from a fatty liver syndrome, possibly resulting in higher levels in the liver than might normally be found in healthy individuals.

Poiger and Schlatter (1986) estimated that about 90% of the total body burden of 2,3,7,8-TCDD was sequestered in fat. Levels of 2,3,7,8-TCDD averaging 5-10 ppt have been reported for background populations in St. Louis, MO, by Graham et al. (1986), and in Atlanta, GA, and Utah by Patterson et al. (1986). These data are consistent with the lipid bioconcentrations assumptions made in calculations of daily intakes (*vidae supra*).

Patterson et al. (1987) developed a high resolution gas chromatographic/high resolution mass spectrometric analysis for 2,3,7,8-TCDD in human serum. A high correlation was reported between adipose tissue and serum concentrations when adjusted for total lipid content. The reader is referred to other documents (U.S/ EPA, 1993; Schlatter, 1991; Schecter, 1991) for more details on the distribution and elimination.

1. BACKGROUND AND SUMMARY

1.1. BACKGROUND

This reassessment is comprised of three reports:

Part 1. *Estimating Exposure to Dioxin-Like Compounds* (EPA, 2000a) (which expanded upon a 1988 draft exposure report titled, *Estimating Exposure to 2,3,7,8-TCDD* [EPA, 1988]);
Part 2. *Health Assessment of 2,3,7,8-Tetrachlorodibenzo-p-Dioxin (TCDD) and Related Compounds* (EPA, 1994; EPA, 2000b); and
Part 3. *Dioxin: Integrated Summary and Risk Characterization for 2,3,7,8-Tetrachlorodibenzo-p-Dioxin (TCDD) and Related Compounds* (EPA, 2000c).

Throughout the remainder of this document, these three parts as a whole will be abbreviated as the Reassessment Documents, and the individual parts will be referred to as the Exposure Reassessment Document, the Health Reassessment Document, and the Risk Characterization. The Exposure Reassessment Document has expanded to three volumes, as discussed below. Volumes 1 and 2 of the Exposure Reassessment Document are summarized in Section 4 of the Risk Characterization.

The process for developing the Reassessment Documents has been open and participatory. Each of the documents has been developed in collaboration with scientists from inside and outside the Federal Government. Each document has undergone extensive internal and external review, including review by EPA's Science Advisory Board (SAB). In September 1994, drafts of each document were made available for public review and comment. This included a 150-day comment period and 11 public meetings around the country to receive oral and written comments. These comments, along with those of the SAB (EPA, 1995a), have been considered in the drafting of this final document. The Dose-Response Chapter of the Health Document underwent peer review in 1997 (EPA, 1997a); an earlier version of the Integrated Summary and Risk Characterization underwent development and review in 1997 and 1998, and comments have been incorporated. In 1998, EPA released a workshop review version of the sources inventory (EPA, 1998), one of the three volumes of the Exposure Reassessment Document. In addition, as requested by the SAB, a chapter on Toxic Equivalency has been developed and underwent external peer review in parallel with the Integrated Summary and Risk Characterization in July, 2000. The November, 2000, review by the SAB of the Dose-Response Chapter, the Toxic Equivalency Chapter and the Integrated Summary and Risk Characterization

was the final step in this open and participatory process of reassessment. The full set of background documents and the integrative summary and risk characterization replace the previous dioxin assessments as the scientific basis for EPA decision-making.

The final Exposure Reassessment Document reflects changes made as a result of both review comments and analyses of a variety of other types of information that has come available. These include relevant information obtained from published peer-reviewed literature, EPA program offices, and other Federal agencies. This version of the Exposure Reassessment Document is current in this regard through 2000.

The purpose of the Exposure Reassessment Document is threefold: 1) to inventory the known sources of release of dioxins into the environment, 2) to develop an understanding of dioxins in the environment, including fate and transport properties, environmental and exposure media concentrations, background as well as elevated exposures, and temporal trends in exposure, and 3) provide site-specific procedures for evaluating the incremental exposures due to specific sources of dioxin-like compounds. Following this structure, the Exposure Reassessment Document is presented in three volumes:

Volume I - Sources of Dioxin-Like Compounds in the United States

This volume presents a comprehensive review of known sources of environmental releases of dioxin-like compounds in the United States. It includes an inventory of known source activity in terms of estimates of annual releases of dioxin-like compounds into the U.S. environment (i.e., air, water and land). This inventory is specific for two reference years, 1987 and 1995. From these data, it is possible to compare and contrast releases of dioxin-like compounds among the sources and between the reference years.

Volume II - Properties, Environmental Levels, and Background Exposures

This volume presents and evaluates information on the physical-chemical properties, environmental fate, environmental and exposure media levels, background and elevated human exposures, and temporal trends of dioxin-like compounds in the U.S. environment during the 20^{th} century.

Volume III - Site-Specific Assessment Procedures

This volume presents procedures for evaluating the incremental impact from sources of dioxin release into the environment. The sources covered include contaminated soils, stack emissions, and point discharges into surface water. This volume includes sections on: exposure parameters and exposure scenario development; stack emissions and atmospheric transport modeling; aquatic and terrestrial fate, and food chain modeling; demonstration of methodologies; and uncertainty evaluations including exercises on

sensitivity analysis and model validation, review of Monte Carlo assessments conducted for dioxin-like compounds, and other discussions.

The primary technical resource supporting the development of the inventory of sources of dioxin-like compounds discussed in Volume I (above) is the Database of Sources of Environmental Releases of Dioxin-Like Compounds in the United States (EPA/600/C-01/012. March, 2001). This database includes congener-specific CDD and CDF emissions data extracted from original engineering test reports. It has been published independently from the Reassessment and is available on Compact Disk -Read only Memory (CD-ROM), without cost, from EPA's National Service Center for Environmental Publications (NSCEP) in Cincinnati, Ohio (telephone: 1-800-490-9198, or 513-489-8190; fax: 513-489-8695). In addition, it can be downloaded from the web page of the National Center for Environmental Assessment, www.epa.gov/ncea/dioxin.htm.

1.2. DEFINITION OF DIOXIN-LIKE COMPOUNDS

This assessment addresses specific compounds in the following chemical classes: polychlorinated dibenzo-*p*-dioxins (PCDDs or CDDs), polychlorinated dibenzofurans (PCDFs or CDFs), polybrominated dibenzo-*p*-dioxins (PBDDs or BDDs), polybrominated dibenzofurans (PBDFs or BDFs), and polychlorinated biphenyls (PCBs), and describes this subset of chemicals as "dioxin-like." Dioxin-like refers to the fact that these compounds have similar chemical structure, similar physical-chemical properties, and invoke a common battery of toxic responses. Because of their hydrophobic nature and resistance towards metabolism, these chemicals persist and bioaccumulate in fatty tissues of animals and humans. The CDDs include 75 individual compounds; CDFs include 135 different compounds. These individual compounds are referred to technically as congeners. Likewise, the BDDs include 75 different congeners and the BDFs include an additional 135 congeners. Only 7 of the 75 congeners of CDDs, or of BDDs, are thought to have dioxin-like toxicity; these are ones with chlorine/bromine substitutions in, at a minimum, the 2, 3, 7, and 8 positions. Only 10 of the 135 possible congeners of CDFs or of BDFs are thought to have dioxin-like toxicity; these also are ones with substitutions in the 2, 3, 7, and 8 positions. This suggests that 17 individual CDDs/CDFs, and an additional 17 BDDs/BDFs, exhibit dioxin-like toxicity. The database on many of the brominated compounds regarding dioxin-like activity has been less extensively evaluated, and these compounds have not been explicitly considered in this assessment.

There are 209 PCB congeners. Only 12 of the 209 congeners are thought to have dioxin-like toxicity; these are PCBs with 4 or more lateral chlorines with 1 or no substitution in the

ortho position. These compounds are sometimes referred to as coplanar, meaning that they can assume a flat configuration with rings in the same plane. Similarly configured polybrominated biphenyls (PBBs) are likely to have similar properties. However, the database on these compounds with regard to dioxin-like activity has been less extensively evaluated, and these compounds have not been explicitly considered in this assessment. Mixed chlorinated and brominated congeners of dioxins, furans, and biphenyls also exist, increasing the number of compounds potentially considered dioxin-like within the definitions of this assessment. The physical/chemical properties of each congener vary according to the degree and position of chlorine and/or bromine substitution. Very little is known about occurrence and toxicity of the mixed (chlorinated and brominated) dioxin, furan, and biphenyl congeners. Again, these compounds have not been explicitly considered in this assessment. Generally speaking, this assessment focuses on the 17 CDDs/CDFs and a few of the coplanar PCBs that are frequently encountered in source characterization or environmental samples. While recognizing that other "dioxin-like" compounds exist in the chemical classes discussed above (e.g., brominated or chlorinated/brominated congeners) or in other chemical classes (e.g., halogenated naphthalenes or benzenes, azo- or azoxybenzenes), the evaluation of less than two dozen chlorinated congeners is generally considered sufficient to characterize environmental "dioxin."

The chlorinated dibenzodioxins and dibenzofurans are tricyclic aromatic compounds with similar physical and chemical properties. Certain of the PCBs (the so-called coplanar or mono-ortho coplanar congeners) are also structurally and conformationally similar. The most widely studied of this general class of compounds is 2,3,7,8-tetrachlorodibenzo-*p*-dioxin (TCDD). This compound, often called simply "dioxin," represents the reference compound for this class of compounds. The structure of TCDD and several related compounds is shown in Figure 1-1 . Although sometimes confusing, the term "dioxin" is often also used to refer to the complex mixtures of TCDD and related compounds emitted from sources, or found in the environment or in biological samples. It can also be used to refer to the total TCDD "equivalents" found in a sample. This concept of toxic equivalency is discussed below.

1.3. TOXIC EQUIVALENCY FACTORS

CDDs, CDFs, and PCBs are commonly found as complex mixtures when detected in environmental media and biological tissues, or when measured as environmental releases from specific sources. Humans are likely to be exposed to variable distributions of CDDs, CDFs, and dioxin-like PCB congeners that vary by source and pathway of exposures. This complicates the human health risk assessment that may be associated with exposures to variable mixtures of dioxin-like compounds. In order to address this problem, the concept of toxic equivalency has

been considered and discussed by the scientific community, and TEFs have been developed and introduced to facilitate risk assessment of exposure to these chemical mixtures.

On the most basic level, TEFs compare the potential toxicity of each dioxin-like compound comprising the mixture to the well-studied and understood toxicity of TCDD, the most toxic member of the group. The background and historical perspective regarding this procedure is described in detail in Part II, Chapter 9, Section 9.1, 9.2, and in Agency documents (EPA 1987, 1989a,b, 1991). This procedure involves assigning individual TEFs to the 2,3,7,8-substituted CDD/CDF congeners and "dioxin-like" PCBs. To accomplish this, scientists have reviewed the toxicological databases along with considerations of chemical structure, persistence, and resistance to metabolism, and have agreed to ascribe specific, "order of magnitude" TEFs for each dioxin-like congener relative to TCDD, which is assigned a TEF of 1.0. The other congeners have TEF values ranging from 1.0 to 0.00001. Thus, these TEFs are the result of scientific judgment of a panel of experts using all of the available data and are selected to account for uncertainties in the available data and to avoid underestimating risk. In this sense, they can be described as "public health conservative" values. To apply this TEF concept, the TEF of each congener present in a mixture is multiplied by the respective mass concentration and the products are summed to represent the 2,3,7,8-TCDD Toxic Equivalence (TEQ) of the mixture, as determined by Equation (1-1):

The TEF values for PCDDs and PCDFs were originally adopted by international convention (EPA, 1989a). Subsequent to the development of the first international TEFs for CDD/CDFs, these values were further reviewed and/or revised and TEFs were also developed for PCBs (Ahlborg et al., 1994; van den Berg et al., 1998). A problem arises in that past and present quantitative exposure and risk assessments may not have clearly identified which of three TEF schemes was used to estimate the TEQ. This reassessment introduces a new uniform TEQ

$$TEQ \cong \sum_{i-n}\left(Congener_i \times TEF_i\right) + \left(Congener_j \times TEF_j\right) + ...\left(Congener_n \times TEF_n\right) \quad (1\text{-}1)$$

nomenclature that clearly distinguishes between the different TEF schemes and identifies the congener groups included in specific TEQ calculations. The nomenclature uses the following abbreviations to designate which TEF scheme was used in the TEQ calculation:

1. I-TEQ refers to the International TEF scheme adopted by EPA in 1989 (EPA, 1989a). See Table 1-1.
2. TEQ-WHO_{94} refers to the 1994 WHO extension of the I-TEF scheme to include 13 dioxin-like PCBs (Ahlborg et al., 1994). See Table 1-2.

3. TEQ-WHO_{98} refers to the 1998 WHO update to the previously established TEFs for dioxins, furans, and dioxin-like PCBs (van den Berg et al., 1998). See Table 1-3.

The nomenclature also uses subscripts to indicate which family of compounds is included in any specific TEQ calculation. Under this convention, the subscript D is used to designate dioxins, the subscript F to designate furans and the subscript P to designate PCBs. As an example, "TEQ_{DF}-WHO_{98}" would be used to describe a mixture for which only dioxin and furan congeners were determined and where the TEQ was calculated using the WHO_{98} scheme. If PCBs had also been determined, the nomenclature would be "TEQ_{DFP}-WHO_{98}." Note that the designations TEQ_{DF}-WHO_{94} and I-TEQ_{DF} are interchangeable, as the TEFs for dioxins and furans are the same in each scheme. Note also that in this document, I-TEQ sometimes appears without the D and F subscripts. This indicates that the TEQ calculation includes both dioxins and furans.

This reassessment recommends that the WHO_{98} TEF scheme be used to assign toxic equivalency to complex environmental mixtures for assessment and regulatory purposes. Sections in the Health Reassessment Document, and summarized in the Risk Characterization, describe the mode(s) of action by which dioxin-like chemicals mediate biochemical and toxicological actions. These data provide the scientific basis for the TEF/TEQ methodology. In its 20-year history, the approach has evolved, and decision criteria supporting the scientific judgment and expert opinion used in assigning TEFs has become more transparent. Numerous states, countries, and several international organizations have evaluated and adopted this approach to evaluating complex mixtures of dioxin and related compounds. It has become the accepted methodology, although the need for research to explore alternative approaches is widely endorsed. Clearly, basing risk on TCDD alone or assuming all chemicals are equally potent to TCDD is inappropriate on the basis of available data. Although uncertainties in the use of the TEF methodology have been identified (which are described in detail in the Health Reassessment Document, Chapter 9, Section 9.5), one must examine the use of this method in the broader context of the need to evaluate the potential public health impact of complex mixtures of persistent, bioaccumulative chemicals. It can be generally concluded that the use of TEF methodology for evaluating complex mixtures of dioxin-like compounds decreases the overall uncertainties in the risk assessment process as compared to alternative approaches. Use of the latest consensus values for TEFs assures that the most recent scientific information informs this "useful, interim approach" (EPA, 1989a; Kutz et al., 1990) to dealing with complex environmental mixtures of dioxin-like compounds. As stated by the U.S. EPA Science Advisory Board (EPA, 1995a), "The use of the TEFs as a basis for developing an overall index of public health risk is clearly justifiable, but its practical application depends on the reliability of the

TEFs and the availability of representative and reliable exposure data." EPA will continue to work with the international scientific community to update these TEF values to assure that the most up-to-date and reliable data are used in their derivation and to evaluate their use on a periodic basis.

A chemical is assigned a TEF value based on all the available data comparing the chemical to either TCDD or PCB 126. In addition, there are weighting criteria that place more emphasis on chronic and subchronic studies examining toxic endpoints (van den Berg et al., 1998). There is a broad range in the quantity and quality of the data available for individual congeners. For example, the TEF for PCB 126 is based on over 60 in vivo endpoints examining responses as diverse as enzyme induction, developmental toxicity, immunotoxicity, hepatic toxicity, alterations in hormones and tumor promotion, while the TEF for 3,4,4',5-tetrachlorobiphenyl (PCB 81) is based on in vitro CYP1A induction and QSAR calculations. Fortunately, PCB 81 does not significantly contribute to human TEQ exposures. There are 5 congeners that contribute approximately 80% of the total TEQ in humans: 2,3,7,8-TCDD, 1,2,3,7,8-PCDD, 1,2,3,6,7,8-HxCDD, 2,3,4,7,8-PCDF, and PCB 126 (See Part I, Volume 3 and Section 4.4.3 of this document). With the exception of 1,2,3,6,7,8-HxCDD, the TEFs for these chemicals are based on a number of different endpoints from multiple studies performed in different laboratories. The TEF for 1,2,3,6,7,8-HxCDD is based on a two-year bioassay in which rats were exposed to a mixture of 1,2,3,6,7,8-HxCDD and 1,2,3,7,8,9-HxCDD. The TEFs for 2,3,4,7,8-PCDF and PCB 126 are similar to the mean REP value for all in vivo endpoints and are similar to their REPs for tumor promotion. The TEF for 12378-PCDD is based largely on its REP for tumor promotion in rats. From these data, it is clear that the chemicals that contribute approximately 80% to the total human TEQ are well studied and the assigned TEFs provide reasonable estimates of the relative potency of these chemicals. In contrast, while there are some chemicals in the TEF methodology which have minimal data sets to reliably assess their relative potency, these chemicals do not contribute substantially to the human blood TEQ.

The ability of the TEF methodology to predict the biological effects of mixtures containing dioxin-like chemicals has been evaluated in a number of experimental systems. These studies generally demonstrate that the assumption of additivity provides a reasonable estimate of the dioxin-like potential of a mixture (described in the Health Reassessment Document, Chapter 9, Section 9.4). In addition, there are examples of non-additive interactions between dioxins and non-dioxins. Both greater than additive and less than additive interactions have been observed in these studies. In general the non-additive interactions between the dioxins and non-dioxins have been observed at doses that are considerably higher than present background human exposures.

There are a number of natural chemicals that bind and activate the AhR and induce some dioxin-like effects. It has been proposed by some scientists that these chemicals contribute significantly to the total TEQ exposures and that these exposures far out weigh those from PCDDs, PCDFs and PCBs (Safe, 1995). While this hypothesis is intriguing, there are several limitations to these analyses. The in vivo data on the natural AhR ligands is limited to enzyme induction and a single developmental study. Few, if any, toxicology studies demonstrating clear dioxin-like toxicities have been published. The natural AhR ligands are rapidly metabolized and result in both transient tissue concentrations and transient effects. The natural ligands also have significant biological effects that are independent of the AhR and it is not clear as to the role of the AhR in the biological effects of these chemicals. Clearly this issue requires further research in order to better understand the relative potential health effect of dioxin and related chemicals as compared to natural AhR ligands.

One of the limitations of the use of the TEF methodology in risk assessment of complex environmental mixtures is that the risk from non-dioxin-like chemicals is not evaluated in concert with that of dioxin-like chemicals. Another limition of the TEF methodology is their application to non-biological samples. The fate and distribution of PCDDs, PCDFs and PCBs are not necessarily related to their TEF. Thus, the use of the TEF for non-biological media must be done cautiously. Future approaches to the assessment of environmental mixtures should focus on the development of methods that will allow risks to be predicted when multiple mechanisms are present from a variety of contaminants.

1.4. OVERALL COMMENTS ON THE USE OF VOLUME III OF THE DIOXIN EXPOSURE DOCUMENT

Users of the dioxin exposure document should recognize the following:

1. This document does not present detailed procedures for evaluating multiple sources of release. However, it can be used in two ways to address this issue. Incremental impacts estimated with procedures in Volume III can be compared to background exposure estimates which are presented in Volume II. This would be a way of comparing the incremental impact of a specific source to an individual's total exposure otherwise. Assuming the releases from multiple sources behave independently, it is possible to model them individually and then add the impacts. For example, if several stack emission sources are identified and their emissions quantified, and it is desired to evaluate the impact of all sources simultaneously, then it is possible with ISCST3 to model each stack emission source individually and then sum the concentrations and depositions at points of interest in the surrounding area.

2. The demonstration of the site-specific procedures presented in this exposure document best serve as general examples for evaluating exposures to dioxin-like compounds, rather than specific assessments. This demonstration scenarios in Chapter 5 of this document were not generated for purposes of supporting any specific regulation. Rather, they were only intended to demonstrate the procedure described earlier in Chapters 2 through 4. Certainly, the goal of developing “high end” and “central” is consistent with Agency policy, and even assignment of many of the exposure and fate parameters can be adopted for other assessments. Therefore, assessors may find even the specifics of the demonstration scenarios useful for other purposes.

3. The understanding of the exposure to dioxin-like compounds continues to expand. Despite being one of the most studied groups of organic enivronmental contaminants, new information is generated almost daily about dioxin-like compounds. This document is considered to be current through 2000.

Numerous parameter values are used in this document and it is important to understand their degree of "endorsement" by EPA. The parameters can be divided into the following four classes for purposes of addressing this issue:

1) **First Order Defaults:** As defaults, these parameters are independent of site specific characteristics and can be used for any assessment. Also, as first order defaults, it is felt that the values selected for the demonstration scenarios carry a sufficient weight of evidence from current literature such that these values are recommended for other assessments. Several of the chemical specific parameters, such as the Henry's Constant, H, and the organic carbon partition coefficient, Koc, fall into this category. The qualifier above, "current literature", indicates that new information could lead to changes in these values.

2) **Second Order Defaults:** Like the above category, these parameters are judged to be independent of site specific characteristics. However, unlike the above category, the current scientific weight of evidence is judged insufficient to describe values selected for demonstration purposes as first order defaults. Parameters of principal note in this category are the bioconcentration parameters specific to the chemicals, such the Biota Sediment Accumulation Factor, or BSAF. This parameter translates a bottom sediment concentration to a fish tissue concentration. The science is evolving for this parameter, including thought on the extent to which BSAFs generated for one species at one site can be generalized to other sites and/or species, the differences in BSAF between column and bottom feeders, the differences between past and ongoing contamination, and so on. Users should carefully review the justification for the SOD values selected for the demonstration scenarios before using the same values.

3) **Site Specific:** These parameters should or can be assigned values based on site-specific information. The information provided on their assignment for the demonstration of methodologies in this document can be useful where site specific information is unavailable. A key class of site specific are the source strength terms - the soil concentrations, effluent discharge rates, and stack emission rates. Others include physical properties (organic carbon contents of soil and sediment, climate variables, areas, distances, and volumes) and parameters for bioconcentration algorithms (yields of vegetation, cattle raising practices, fish lipid contents).
4) **Exposure Parameters:** The exposure parameters have not been categorized as have the contaminant fate and transport/transfer parameters. Assignment of these values are critical as Lifetime Average Daily Dose (LADD) estimates are linearly related to parameter assignments - doubling exposure duration assumptions double LADDs, and so on. Some exposure parameters are appropriately described as first order defaults. These include: lifetime, body weights, water ingestion rates, inhalation rates, and an exposure duration for a childhood pattern of soil ingestion. All of the other exposure parameters are better described as either second order defaults or site specific parameters. All exposure parameters were developed based on information and recommendations in EPA's *Exposure Factors Handbook* (EPA, 1997b) and *Dermal Exposure Assessment: Principles and Applications* (EPA, 1992a).

The end products of the exposure assessment procedures presented in this document are estimates of potential dose expressed in mass (pg, ng, etc.) of dioxin-like compound/body weight (usually kg)-day. The procedures for converting these dose estimates to risk estimates, both cancer and non-cancer, are described in Chapter 2 and demonstrated in Chapter 5.

The scope of each chapter in Volume III is summarized below.

Chapter 2, Estimating Exposure and Risks, presents overall framework for conducting exposure assessments. It provides procedures for identifying exposure pathways, estimating contact rates and resulting exposure levels. Approaches for defining exposure scenarios are presented. Procedures for converting exposure dose to lifetime cancer risk estimates are provided, and procedures for evaluating non-cancer risk are also discussed.

Chapter 3, Evaluating Atmospheric Releases of Dioxin-Like Compounds from Combustion Sources, provides procedures to estimate the emission rates of dioxin-like compounds from combustion processes and further atmospheric transport modeling procedures from the stack to the surrounding land surface. This chapter describes and demonstrates the use of the ISCST3 model on a hypothetical incinerator and lists the associated atmospheric dispersion and deposition estimates from that model exercise.

Chapter 4, Estimating Exposure Media Concentrations, provides procedures for estimating concentrations of the dioxin-like compounds in exposure media (soil, air, water, biota) resulting from soil contamination, effluent discharges, and stack emissions.

Chapter 5, Demonstration of Methodology, develops hypothetical scenarios and generates exposure and risk estimates to demonstrate the methodologies of this document.

Chapter 6, User Considerations, discusses key issues for users of the methodologies. All model parameters are listed and categorized according to the scheme noted above. Sensitivity analysis is conducted on the algorithms estimating exposure media concentrations. An exercise on estimating the releases from a bounded area of soil contamination is presented. The purpose of this exercise is to determine whether a reservoir of soil contamination would be depleted prior to an assumed duration of exposure.

Chapter 7, Model Comparisons and Validations, presents extensive information aimed at gaining confidence and establishing credibility for the use of the fate models of this assessment to predict the fate, movement, and resulting exposure media concentrations near sources of dioxin release. One section of this chapter presents alternate fate models, and where possible, generates results from these models to compare with results from the models selected for this assessment. The second major section presents several model validation exercises, where the models are paramterized to predict exposure media concentrations, and the results are compared with appropriate real world observations.

Chapter 8, Uncertainty, discusses the sources and possible magnitude of uncertainty in the exposure assessment procedures. Uncertainty and variability of fate and transport, and exposure parameters, are discussed. Monte Carlo and similar numerical methods to quantify variability and uncertainty are discussed, and several literature examples of these types of exercises conducted for dioxin-like compounds are summarized.

1.5. EXECUTIVE SUMMARY OF VOLUME III

Volume III describes procedures for conducting site specific exposure and risk assessments to estimate potential dose, cancer, and non-cancer risks from exposure to dioxin-like compounds from a nearby source of release. Sections below summarize the key issues and results from each chapter of this volume.

1.5.1. Exposure Equation

A potential dose is defined as a daily amount of contaminant inhaled, ingested, or otherwise coming in contact with outer surfaces of the body, averaged over an individual's body

weight and lifetime. The general equation used to estimate potential dose normalized over body weight and lifetime is as follows:

$$\text{Lifetime Average Daily Dose (LADD)} = \frac{(\text{exposure media concentration} \times \text{contact rate} \times \text{contact fraction} \times \text{exposure duration})}{(\text{body weight} \times \text{lifetime})} \quad (1\text{-}2)$$

This procedure is used to estimate dose in the form needed to assess cancer risks. For non-cancer risks, an ADD term is instead derived. ADD is calculated as above except that exposure duration and lifetime are taken out of the equation above. Each of the terms in this exposure equation is discussed briefly below:

- **Exposure media concentrations:** These include the average concentrations in the media to which individuals are exposed. Media considered in this assessment include soil, air, water, vegetables/fruits, fish, beef, milk, and poultry.
- **Contact rate:** These include the ingestion rates, inhalation rates, and soil contact rates for the exposure pathways.
- **Contact fraction:** This term describes the distribution of total contact between contaminated and uncontaminated media. This assessment describes exposures which occur at homes, so the contact rate translates to time spent at home for air, soil, and water exposures, and fraction of total food product produced at home (vegetables/fruits, beef, milk, and poultry) or obtained recreationally (fish) from an impacted water body. This assessment assumes time at home fractions of 0.70 and 0.90 for central and high end scenarios, respectively, and home food production factors, or food contact fractions, of about 0.50 and less.
- **Exposure duration:** This is the overall time period of exposure, mostly pertinent to adult exposures. Central and high end durations of 9 and 30 years, respectively, are assumed in this assessment. Another exposure duration considered in this methodology is one associated with a childhood pattern of soil ingestion. The exposure duration in this case is 5 years.
- **Body weight:** For all the pathways, the human adult body weight of 70 kg is assumed. Although the United States population average is closer to 60 kg (EPA, 1997b), the value of 70 kg has been more traditionally used. The body weight for child soil ingestion is 17 kg.
- **Lifetime:** Following convention, and because cancer slope factors are derived based on a 70-year human lifetime, the average adult lifetime assumed throughout this document is 70 years.

1.5.2. Procedures for Evaluating Cancer and Non-Cancer Risk

Although the focus of the site-specific methodology is to estimate exposures to dioxins, procedures are also presented and demonstrated for estimating cancer and non-cancer risk. The usual procedure used to calculate an upper-limit incremental cancer risk is as follows:

$$R = 1 - e^{-q_1^* \, LADD} \approx q_1^* \, LADD \qquad (1\text{-}3)$$

when q_1^* LADD < 10^{-3} and where q_1^* is the 95% upper confidence limit of the linearized cancer slope factor of the dose-response function (expressed in inverse units of the dose quantity, such as kg-day/pg, or equivalently, $(pg/kg\text{-}day)^{-1}$) and LADD is the dose (which needs to be in units appropriate to cancel those of q_1^*, pg/kg-day). This assessment uses the simplified q_1^* LADD since the exposures and risks demonstrated are generally less than 10^{-3}. The slope factor, q_1^*, for 2,3,7,8-TCDD has been previously estimated by EPA as 0.000156 $(pg/kg\text{-}d)^{-1}$ (EPA, 1984; 1981), but has been reevaluated as 0.001 $(pg/kg\text{-}d)^{-1}$ in this Reassessment. Also, it is being applied to a TEQ dose in this Assessment.

This selected cancer slope factor was based primarily on the meta analysis of the human epidemiology studies where exposure was estimated from dioxin concentrations in blood in occupationally exposed cohorts. The dose estimates used to derive the slope factor were obtained by using a PK model to convert the blood concentrations to an administered, or potential, dose. An administered dose is defined as the dose which contacts the body boundary surfaces, such as the skin as in dermal exposure or the dose ingested prior to absorption. This administered dose was derived by first calculating an absorbed dose and then dividing by 0.8 - i.e., an absorbed dose was assumed to be 80% of an administered dose. Because the potency factor was derived based on an administered dose, the new slope factor can be applied to an administered dose without any adjustment for absorption as long as the absorption is approximately 80%. Although the data are limited, this is probably a reasonable assumption for most types of food ingestion and inhalation. For soil pathways, however, an additional adjustment factor has to be added to account for significantly less absorption. Data suggests that the dose of dioxins absorbed from soil ingestion is about 30% and about 3% from soil dermal contact. For soil dermal contact, an absorbed dose is already calculated; thus the dermal contact pathway yields an absorbed dose already. Therefore, for these two pathways, Equation (1-3) needs an additional adjustment factor equal to 0.3/0.8, or 0.375, for soil ingestion and 1.00/0.8, or 1.25, for soil dermal contact. A full discussion on absorption of administered dioxin through

the various pathways can be found in Chapter 1. Disposition and Pharmacokinetics, of the Health Reassessment Document (EPA, 2000b).

To evaluate incremental non-cancer effects in a risk assessment, EPA uses established Reference Doses (RfDs) for most contaminants. An RfD is defined as an estimate, with uncertainty spanning perhaps an order of magnitude, of a daily exposure of the human population, including sensitive subgroups, that is likely to be without an appreciable risk of deleterious non-cancer effects during a lifetime. The incremental dose from a particular source is compared with the RfD. However, an RfD has not been established for dioxin-like compounds. It was concluded in the Risk Characterization that setting an RfD using traditional Agency approaches would result in an RfD that would likely be 2-3 orders of magnitude below current background intakes and body burdens. For this reason, EPA concluded that establishing an RfD for assessing the potential for non-cancer effects would not be helpful to risk managers. Instead, it was suggested in the Risk Characterization that risk managers compare the increment of exposure to a specific source with background exposures for assessing the potential for non-cancer effects. For this reason, a "ROIE", or Ratio of Incremental Exposure, was developed. The ROIE was defined as a ratio between the increment of daily exposure from the source in question, the term defined by ADD as noted above, to background daily exposure. A ROIE equaling 1.0 suggests that the increment of exposure from the source in question is equal to background exposure.

Background exposure could be considered to be a national average background exposure, or it could a quantity specifically developed for the site in question. The latter would be appropriate if certain behaviors, such as subsistence fishing or farming, or certain environmental conditions, such as a high local background of dioxin in soil or air due to industrial practices, were present in the vicinity of the specific source being evaluated.

1.5.3. Procedure for Estimating Exposure

Before making exposure estimates, the assessor needs to gain a more complete understanding of the exposure setting and the contamination source. The approach used for this assessment is termed the exposure scenario approach. There are 7 steps in this approach:

Step 1. Identify Source: Three principal sources are addressed in this document: contaminated soils, stack emissions, and effluent discharges.

Step 2. Estimate Release Rates: Estimating the release of contaminants from the initial source is the first step towards estimating the concentration in the exposure media. Releases from soil contamination include volatilization, and wind and soil erosion. Stack emissions and effluent discharges are point source releases into the environment.

Step 3. Estimate Exposure Point Concentrations: Contaminants released from soils, emitted from stacks, or discharged into surface waters move through the environment to points where human exposure may occur, and/or to impact environmental media to which humans are exposed. Various fate, transport, and transfer models are used to predict exposure media concentrations given source releases.

Step 4. Characterize Exposed Individuals and Exposure Patterns: Exposed individuals in the scenarios of this assessment are individuals who are exposed in their home environments. They are residents who breathe air at their residence, fish recreationally, have a home garden, farm, and are children ages 2-6 for the soil ingestion pathway. Exposures which occur at the workplace or other locations are not discussed in this assessment, although the procedures could be adapted for other exposure sites. Each pathway has a set of exposure parameters including contact rates, contact fractions, body weights, exposure durations, and a lifetime. An individual's total exposure is the sum of the exposures from individual pathways.

Step 5. Put It Together in Terms of Exposure Scenarios: A common framework for assessing exposure is with the use of "settings" and "scenarios." Settings are the physical aspects of an exposure area and the scenario characterizes the behavior of the population in the setting and determines the severity of the exposure. A wide range of exposures are possible depending on behavior pattern assumptions. An exposure scenario framework offers the opportunity to vary any number of assumptions and parameters to demonstrate the impact of changes to exposure and risk estimates.

Step 6. Estimate Exposure: The end result of having followed the above 5 steps are estimates of individual exposures to a characterized source of contamination.

Step 7. Assess Uncertainty: Uncertainties should be considered when applying procedures in this document to a particular site. Pertinent issues explored in this assessment include: 1) model predictions of exposure media concentrations compared to field measurements in a series of model validation exercises, 2) similarities and differences for alternate models for estimating exposure media concentrations, 3) sensitivity of model results to a range of values for methodology parameters, 4) mass balance checks, and 5) qualitative and quantitative discussions on the uncertainties with the model parameters and exposure estimates generated for the demonstration scenarios.

1.5.4. Estimating Exposure Media Concentrations

Literally hundreds of fate and transport models have been published which differ widely in their technical sophistication, level of spatial or temporal resolution, need for site specific

parameterization, and so on. This makes selection of the most appropriate one for any particular situation very difficult. For this assessment, relatively simple, screening level models are used to model fate, transport, and transfer of dioxin-like compounds from the source to the exposure media. Simple assumptions are often made in order to arrive at the desired result, which is long-term average exposure media concentrations. Perhaps the most critical of the assumptions made is that the source strength remains constant throughout the period of exposure.

It is important to understand that EPA is not endorsing the algorithms of this assessment as the best ones for use in all dioxin assessments. They are suggested as reasonable starting points for site-specific or general assessments. All assumptions for the models and selection of parameter values are carefully described. If these assumptions do not apply to a particular situation, or where assessors require more spatial or temporal resolution, more complex models should be selected. Finally, it cannot be overemphasized that measured concentrations are generally more reliable than modeled ones. Assessors should use measured concentrations if available and if such measurements can be considered spatially and temporally representative for the exposed populations.

Chapter 4 provides algorithms used to evaluate the fate, transport, and transfer of dioxin-like compounds from contaminated soil, stack emissions, and effluent discharge. These three sources of dioxin release are referred to as "source categories" in this document. Algorithms are presented which link each of these sources to estimated concentrations in a number of media which may be contaminated as a result, and are therefore potential "exposure media": 1) surface soils, 2) surface-water associated media: suspended and bottom sediment and dissolved phase concentrations, 3) air including the vapor phase and in particulate form, and 4) biota including beef, milk, poultry, fruit and vegetables, and fish. The remainder of this section describes how each potential exposure medium can be affected by each source, and the algorithms used to make this link.

- **Surface soils:** Exposure to contaminated soil may be a result of direct contact with soil on the site of the contamination, or indirectly after the contaminated soil has been transported off the site of contamination and onto a nearby site of exposure. These cases are termed "on-site": the site of contamination and the site of exposure are the same, and "off-site": the site of exposure is distant from the site of contamination. In either case, soil concentrations are specified for the contaminated source. For the off-site case, dioxins reach the site of exposure via erosion. Mixing of contaminated and uncontaminated exposure site soil is into either a "tilled" 20-cm depth or a "non-tilled" 2-cm depth. The tilled concentrations are used to estimate concentrations in underground vegetables, and for outdoor dermal contact. The non-tilled concentrations are used for indoor dermal contact events, for childhood soil ingestion in

residential and farm settings, and for cattle soil ingestion (used in estimation of beef and milk concentrations).

Exposure site soils can also be impacted from stack emissions due to air transport of particle-bound dioxins from the stack to the exposure site. Deposition modeling for dioxin-laden particles allows for estimation of tilled and non-tilled soil concentrations. When stack emissions are the source, the nontilled depth of mixing is again assumed to be 2 cm.

A key assumption for evaluating the exposure site as a result of both off-site erosion and stack emissions is that contaminants impact a thin layer of soil and do, in fact, dissipate; no dissipation is assumed if the site of contamination is also the site of exposure. A soil dissipation half-life of 25 years is assumed for all dioxin-like congeners for the shallow 2 cm depth and 100 years is assumed for the residues tilled to 20 cm.

- **Surface Water:** The principal assumption driving the solutions for the soil and stack emission source categories is that the suspended and bottom sediments of water bodies originate as watershed soils, which are subsequently eroded. For the stack emission source category, a portion of the sediments also originates from directly-depositing dioxins. The process of erosion transports soils within the watershed to the water body. Unit rates of erosion along with watershed size determine the total potential amount of soil which could be delivered to the water body. Sediment delivery ratios reduce that potential amount. A mass balance assures that soil eroding on an annual basis becomes either suspended or bottom sediment within an annualized volume of surface water. "Enrichment" of eroded soil is assumed, which means that eroded soil from a contaminated source is assumed to be higher in concentration of dioxin-like compounds than *in situ*, off-site soils. Once in the water body, a standard partitioning model based on the organic carbon partition coefficient, Koc, determines the concentration of contaminant in the water in truly dissolved form and the concentration on suspended sediments. The organic carbon normalized concentrations of suspended and bottom sediment are assumed to be equal. Watershed soil concentrations are model input parameters for determining the effect on surface water from contaminated soils. For stack emissions, a total (dry + wet) deposition rate of contaminant which represents average depositions onto the watershed is specified as an input parameter, as well as a mixing depth representing the watershed. In this way, average watershed soil concentrations are calculated for the stack emission source category.

For effluent discharges as sources, watershed soils are not considered. An amount of contaminant is discharged into an annual flow volume to obtain a simple dilution concentration. This total concentration is partitioned into a truly dissolved phase and a phase sorbed to suspended sediments using the organic carbon partition coefficient, the Koc. Bottom sediments are not considered for effluent discharges.

- **Soil to Air:** From contaminated soils, residues become airborne via the processes of volatilization and wind erosion. For on-site soil contamination, these vapor and particle phase fluxes are translated to ambient air concentrations using a near-field dispersion model. For the off-site scenario, the same approach is used to estimate ambient air exposure site concentrations, except that a far-field dispersion model is used. These airborne reservoirs are the basis for inhalation exposures, and are also used to estimate plant concentrations for vegetable ingestion and in grass and feed for estimating beef and milk concentrations.

- **Stack emissions and atmospheric transport modeling :** Air dispersion/deposition models consider the basic physical processes of advection, turbulent diffusion, and removal via wet and dry deposition to estimate the atmospheric transport, resulting ambient air concentration, and settling of particles. The ISCST3 model is used for air dispersion and deposition modeling. Besides discussions in Chapter 3 on theoretical underpinnings and parameter assignment, further discussions on the ISCST3 model can be found in EPA (1995b).

Application of the ISCST3 model follows these steps:

Step 1. Emission factors: The first step in the use of the ISCST3 model is to determine "emission factors" for dioxin-like congeners. These factors are defined as the μg (or other mass unit) congener emitted per kg (or other mass unit) feed material combusted. Once assuming a rate of feed material combusted in appropriate units, kg/day, these emission factors can be translated to the units appropriate for atmospheric transport modeling, μg/sec. This assessment promotes the generation of specific congener emission factors, rather than emission factors for TEQ or homologue groups. Emission factors for the demonstration of stack emission sources in Chapter 5 were generated from actual test data from an incinerator burning organic wastes (source otherwise unspecified). Emission estimates for this example incinerator are similar to emissions that are known to be emitted from combustors employing sophisticated air pollution control devices (e.g., scrubbers combined with fabric filters).

Step 2. Vapor/particle (V/P) partitioning: The second step in atmospheric transport modeling is to determine the percent of totally emitted dioxin-like congener which is in a vapor phase, and the percent which is in the particle phase. The partitioning of stack emissions into these two phases was examined by reviewing stack testing data, ambient air sampling data, and a theoretical approach developed in Bidleman (1988). From this review, it was generally concluded that the most appropriate representation of partitioning of dioxins for purposes of fate modeling and exposure assessing was provided by the modeling approach, and the V/P partitioning scheme for dioxins and furans shown in Table 1-4 is the one adopted for this Assessment.

Step 3. Two runs of the ISCST3 model: In order to provide estimates of vapor and particle phase concentrations of dioxin-like compounds, as well as estimates of wet/dry particle deposition flux, it is necessary that to run the ISCST3 model twice. Both model runs should assume a "unit emissions release rate", e.g., 1 g/s. Results from these unit runs can easily be transformed to final outputs given the total emission rate of the congener and vapor/particle partitioning. A vapor phase run involves turning wet/dry deposition switches to the "off" position. This inactivates a plume depletion equation that subtracts out losses in ambient air concentration due to particle deposition. What is left are the Gaussian dispersion algorithms. The vapor phase concentrations are used for inhalation exposures and also for vapor transfers onto vegetation for food chain modeling. A second run of ISCST3 with wet/dry deposition switches turned to the "on" position is considered a simulation of particle-bound contaminant. Outputs from this run include wet and dry deposition rates, and air concentrations of contaminants in the particulate phase. The depositions are used in soil and food chain modeling, and the concentrations are added to the vapor phase concentrations from the first ISCST3 run to arrive at the total air-borne reservoir for inhalation exposures.

- **Biota:** Simple bioconcentration/biotransfer approaches are used to estimate biota concentrations in this assessment. Specifics for each biota considered are:

1. Fish - The soil contamination and stack emission source categories estimate the concentration of contaminant on bottom sediments of water bodies. A fish lipid concentration is estimated based the organic carbon normalized bottom sediment concentration and a BSAF, or Biota Sediment Accumulation Factor. Whole fish concentrations for exposure estimation then equal this lipid concentrations times a whole fish lipid content (or a fillet lipid content). For the effluent discharge source category, fish lipid concentrations are estimated as a function of organic carbon normalized concentrations and the closely related BSSAF, or Biota Suspended Solids Accumulation Factor. This recently introduced bioaccumulation factor (EPA, 1993) is analogous to the BSAF, and it is suggested in EPA (1993) that, as a first estimate, it take on the same chemical-specific numerical value as the BSAF.

2. Vegetation - Concentrations in three types of vegetation are considered in this assessment: below ground vegetables (carrots, potatoes, e.g.), above ground vegetables/fruits (tomatoes, apples), and above ground grass and cattle feed which are required for estimation of beef and milk concentrations. Assumptions critical to all three include: above ground vegetation is impacted by vapor phase transfers and particle deposition - there is no root to shoot translocation, outer portions of the vegetation are only impacted with minimal within plant translocation, particle bound contaminants deposit onto and mix in a vegetative reservoir and are subject to a fourteen-day dissipation half-life which represents particle washoff, and

vegetables/fruits which have an outer protective layer (peas, citrus e.g.) are unimpacted by dioxin-like compounds. Below ground vegetable concentrations are estimated from soil water concentrations and a Root Concentration Factor, or RCF. Above ground concentrations in plants due to atmospheric vapor concentrations are modeled using a "biotransfer" approach, where the vapor concentrations are simply multiplied by an air-to-leaf transfer factor, B_{vpa}, and a surface area to volume reduction factor, VG, which is equal to 1.00 for grasses and other leafy vegetation and less than 1.00 for bulky vegetation. This B_{vpa} was found to be one of the most critical parameters for not only vegetation concentration modeling (i.e., above ground vegetations were found to be dominated by vapor transfers over particle phase depositions), but for subsequent terrestrial animal food chain models. The B_{vpa} was developed for the dioxins in a field calibration exercise.

3. Beef and Milk - Weighted average concentrations of dioxin-like compounds in the diets of cattle raised for beef or lactating cattle are multiplied by a congener-specific bioconcentration factor, BCF, which yields the concentrations in the fat of beef or milk. The same congener-specific BCF is used for beef and milk. This presumes that dioxin-like compounds bioaccumulate equally in body fat and milk fat of beef and dairy cattle. The difference between the two food products is mostly a function of the diets presumed for beef cattle and lactating cows. A set of BCFs for all dioxin-like congeners for this assessment were based on a set of data on a lactating cow (i.e., dietary intakes of dioxin congeners, concentrations in milk, and other pertinent quantities; McLachlan, et al., 1990). A later feeding experiment by Fries, et al. (1999) found BCFs very similar to the McLachlan, et al. (1990) single cow BCFs adopted for this assessment. Beef and dairy cattle diets are described in terms of proportions in pasture grass, cattle feed (silage, grains), and soil. Models described above estimate concentrations in these cattle intakes.

4. Chicken and Eggs - The algorithm to estimate the concentration of contaminant in chicken and/or eggs is essentially the same algorithm as in beef/milk above: the concentration in the lipid of chicken/eggs is a function of the weighted average concentration in the chicken diet (comprised of vegetation and soil) and chicken/egg bioconcentration factors. The experiments used to develop the chicken and egg bioconcentration factors were conducted by the Hazardous Materials Laboratory at the California EPA (Stephens, et al. 1995). Three key differences in the application of the chicken/egg bioconcentration model and beef/milk model were: 1) data was available and robust enough to assign different bioconcentration factors for chicken and eggs, 2) chickens, both layers and non-layers, were assumed to "free range" in the demonstrations of this pathway in Chapter 5, which translated to a higher exposure to soil in their diet - 10% for free range chickens vs. 4% for beef cattle and 2% for dairy cattle, and 3) based on information in

Stephens, et al. (1995), chicken feed was assumed to originate from protected vegetation and was therefore assumed to be dioxin-free.

1.5.5. Demonstration of Methodology

EPA (1992b) states, "In exposure scenario evaluation, the assessor attempts to determine the concentrations of chemicals in a medium or location and link this information with the time that individuals or populations contact the chemical. The set of assumptions about how this contact takes place is an exposure scenario." These assumptions can be made many different ways producing a wide variety of scenarios and associated exposure levels. The number of people exposed at different levels form a distribution of exposures. Ideally assessors would develop this entire distribution to fully describe the exposed population. Since the necessary information for developing a population distribution is rarely available, EPA (1992b) recommends developing a central and high end scenario to provide some idea of the possible range of exposure levels.

1.5.5.1. Description of the Demonstration Scenarios

The basic setting for which the methodologies are demonstrated is a rural setting which contains both farms and non-farm residences. The three principal sources of contamination, soil, stack emissions, and effluent discharges, are assumed to exist in such a setting. "Central" scenarios are based on typical behavior at a residence and "high end" scenarios are comprised of a farm family that raises a portion of its own food. Key distinguishing features between the high end and central scenarios include: 1) individuals in high end scenarios are assumed to be at their home a greater proportion of the day than the central scenarios (which impacts assignment of contact fraction), 2) individuals in high end scenarios are exposed to impacted beef from cattle which they raise on their farm while these exposures are not considered for the central scenarios, 3) in contrast, individuals in the central scenario recreationally fish, 4) the exposure duration for individuals in the high end scenario is 30 years compared to 9 years for the central scenario, and 5) certain exposure parameters, such as water ingestion rate which is 1.4 L/day for the central scenarios and 2 L/day for the high end scenario, are different.

The example scenarios were carefully crafted to be plausible and meaningful, considering key factors such as source strength, fate and transport parameterization, exposure parameters, and selection of exposure pathways. However, it should be clearly understood that the purpose of the demonstration scenarios is to provide users of this methodologies with a comprehensive example of their application. The demonstration exposure scenarios were:

Scenarios 1 and 2: Background conditions, Residence and Farm

Surface soils within the watershed are initialized to soil concentrations of the 17 dioxin-like congeners (no dioxin-like PCBs) which have been found in an actual rural setting. Also, air concentrations of the 17 congeners are initialized to air concentrations which have been found in this same rural setting. Scenario 1 is the central residential scenario, and Scenario 2 is the high end farming scenario. The exposure pathways for Scenario 1 are: water ingestion, air inhalation, fish ingestion, fruit/vegetable ingestion, soil dermal contact, and soil ingestion. The exposure pathways for Scenario 2 are: water ingestion, air inhalation, beef ingestion, fruit/vegetable ingestion, soil dermal contact, and soil ingestion. It is noted that for a background condition, it could be argued that all exposure is to background concentrations in exposure media. In other words, all contact fractions would be 1.00. However, if an assessor wished to compare the incremental impacts from a specific source of dioxin release with impacts an individual would receive by contact with the same exposure media which has only background concentrations of dioxins, than the assessor would assume all the same exposure behaviors (rates of contact, contact fractions). This demonstration takes this approach.

Exposure Scenario 3: Soil Contamination, Farm

A 40,000 m^2 rural farm is located 150 m (500 ft roughly) from a 40,000 m^2 area of bare soil contamination; an area that might be typical of contaminated industrial property. The surface soil at this property is contaminated with three example dioxin-like compounds to the same concentration of 1 part per billion (ppb). These compounds are: 2,3,7,8-TCDD, 2,3,4,7,8-PCDF, and 2,3,3',4,4',5,5'-HPCB. The 1 ppb soil concentration is reasonable for industrial sites of contamination of dioxin-like compounds, and generally about three orders of magnitude higher than the concentrations of these congeners in background settings. As in the above and all scenarios, bottom sediment in a nearby river is impacted, which impacts the water and fish. The exposure pathways include: water ingestion, air inhalation, beef ingestion, fruit/vegetable ingestion, soil dermal contact, and soil ingestion.

Exposure Scenarios 4 and 5: Stack Emissions, Residence and Farm

A 4,000 m^2 rural residence (Scenario 4) is located 5000 meters from an incinerator, and a 40,000 m^2 (Scenario 5) rural farm is located 500 meters downwind from an incinerator. Emission data of the suite of 17 dioxin-like dioxin and furan congeners (no dioxin-like PCBs) is available from stack testing of an actual incinerator. This allows for estimation of impacts from each congener individually, and estimation of WHO_{98}-TEQ_{DF} impacts. The exposure pathways for Scenario 4 are: water ingestion, air inhalation, fish ingestion, fruit/vegetable ingestion, soil dermal contact, and soil ingestion. The exposure pathways for Scenario 5 are: water ingestion, air inhalation, beef ingestion, fruit/vegetable ingestion, soil dermal contact, and soil ingestion.

Exposure Scenario 6: Effluent Discharge into a River

Exposure parameters associated with central behaviors for the water and fish ingestion pathways were chosen to demonstrate this source category. The source strength was developed from data on pulp and paper mill discharges of 2,3,7,8-TCDD. The discharges of the other two example compounds are assumed to be the same for purposes of demonstration. Obviously, however, there is less of a tie to real data for the discharge rate for these other two example compounds.

Food pathway analyses outside of the scenario framework: The food consumption pathways of fish, milk, chicken, and eggs are demonstrated using source strength characteristics of the three high end scenarios above: Scenarios 2 (background conditions), 3 (soil contamination), and 5 (stack emission). These food pathways were not modeled in the scenarios themselves. In these analyses, exposure media concentrations are calculated for each source and the pathway exposure estimates are provided. The purpose of these external pathway analyses was to provide further demonstration and to compare impacts from the various food pathways where methodologies have been provided in this assessment.

1.5.5.2. Results from the Demonstration Scenarios

For brevity, only a subset of results from the demonstrations will be summarized. Table 1-5 gives the exposure media concentrations for WHO_{98}-TEQ_{DF} for Example Scenarios #1 and #2, demonstrating a background setting, and Scenarios #4 and #5, the central and high end scenarios for the stack emission source category. Table 1-6 gives the estimated Lifetime Average Daily Doses, LADDs, and the cancer risk for Scenarios #2 and #5, the high end scenarios for the background setting and stack emission source.

Much of the differences between exposure pathways and scenarios is due to differences in exposure media estimation. Following are some of the observations on exposure media concentrations, LADDs, cancer and non-cancer risks for the background and stack emission scenario demonstrations:

1) Concentrations in environmental and exposure media for the stack emission central and high end scenario were about 3 and 2 orders of magnitude lower than the central and high end scenarios demonstrating background conditions, respectively. For example, the background WHO_{98}-TEQ_{DF} air concentration was 0.021 pg/m^3. In contrast, the WHO_{98}-TEQ_{DF} air concentration for the stack emission source was 2 orders of magnitude lower at 500 meters from the stack, at 0.00024 pg/m^3, and was lower still at 5000 meters from the stack, at 0.000085 pg/m^3. This suggests that the example stack emission source, which was a single emission source with a high level of pollution control, would contribute little to overall background exposure levels.

2) For both the background scenarios, 1 and 2, and the stack emission scenarios, 4 and 5, WHO_{98}-TEQ_{DF} soil concentrations were over an order of magnitude higher than 2,3,7,8-TCDD concentrations. The difference in 2,3,7,8-TCDD and WHO_{98}-TEQ_{DF} impacts to all media mirrors the difference in stack emissions of 2,3,7,8-TCDD and stack emissions of WHO_{98}-TEQ_{DF}. This trend in differences between 2,3,7,8-TCDD and TEQ impacts occurs in all exposure media estimations for both the background scenarios and the stack emission scenarios.

3) Within each demonstration scenario, there appears to be a reasonably narrow range of predicted lipid concentrations among beef, milk, chicken, and egg fat. The difference is about a factor of 3 to 4. The lowest concentrations are noted for the stack emission demonstration scenarios, in the 10^{-3} to 10^{-2} pg WHO_{98}-TEQ_{DF}/g (ppt) range, lipid basis. The background concentrations were next highest, about two orders of magnitude higher in the 10^{-1} to 10^{0} ppt range. The average concentration of WHO_{98}-TEQ_{DF} in lipids of terrestrial animal food products measured in US food products, as described in Volume II of the Exposure Reassessment Document, is similar to the background concentration predictions. This is not unexpected since concentrations of dioxins in terrestrial food animals in the background scenarios were modeled based on a profile of dioxins and furans found in air in an actual rural setting.

4) Table 1-6 shows the percent of total scenario exposure which is accounted for by each pathway. The total scenario LADD was calculated simply as the sum of the pathway LADDs in the scenario, without accounting for any differences in body absorption. As discussed above, inhalation and food/water ingestion pathways have an absorption in the range of 80%, soil ingestion has an absorption of 30%, and soil dermal contact has absorption already considered, so LADD estimates are already at 100% absorption. From Table 1-6, it is seen that the beef pathway dominates the scenarios. For the central scenarios (not summarized in this section), which included fish ingestion but not beef or milk ingestion, the fish ingestion dominated. Interestingly, the beef ingestion pathway LADD was over an order of magnitude higher than the fish ingestion pathway LADD. This was more due to differences in the exposure parameters including the ingestion and contact rates, and the differences in the lipid content of the full product, rather than lipid concentrations themselves since the fish lipid concentrations tended to be higher than the beef lipid concentrations for a given source.

5) Differences between analogous "central" and "high end" exposure pathway estimates for the background demonstration scenarios, 1 and 2, were near or less than an order of magnitude (inhalation exposure for the central background scenario and the inhalation exposure for high end on-site scenario are analogous exposures). This is because the exposure parameters used to distinguish typical and high end exposures, the contact rates, contact fractions, and exposure durations, themselves did not differ significantly, and these were the only

distinguishing features for analogous pathways in the background demonstrations. For the total exposure, however, there was a difference of a factor of 20 between high end and central exposure in the background demonstration scenarios. This is because the high end scenario included consumption of beef, which was the highest exposure pathway and exceeded the fish pathway of the central scenario by over an order of magnitude.

6) In the stack emission scenarios, placing exposed individuals either 500 or 5000 meters away from the incinerator did significantly impact the results. The order of magnitude difference in distance added about an order of magnitude difference in exposure media concentrations and hence LADD estimates. Therefore, the full difference in analogous pathways between the central and high end was closer to 2 orders of magnitude for the stack emission demonstration scenarios.

7) The LADD of 0.093 WHO_{98}-TEQ_{DF}/kg-day for the background high scenario is about an order of magnitude lower than the adult background dose of 0.64 pg WHO_{98}-TEQ_{DF}/kg-day generated in Volume II, Chapter 4. The reasons for this difference are: 1) the Volume II background exposure estimate was an average daily dose, ADD, not an LADD calculated in the demonstration scenarios here. The LADD estimated in this chapter assumes 30 years of exposure. The ADD during the exposure period would be just over twice, or 70/30, as high as the LADD; 2) the Volume II background exposure estimate considered additional pathways including fish, dairy ingestion (milk and otherwise), eggs, pork, and poultry. If one adds the additional pathways for the background high scenario - milk, chicken, egg, and fish, the LADD (and ADD) roughly doubles; 3) the exposure factors are different, with the most important difference being that in the exposure scenarios considered in this chapter, contact fractions of less than 1.0 were assumed - less than 0.5 for the terrestrial animal pathways, in fact.

Some of these differences between the Volume II background exposure estimate and the LADD estimates for the background high scenario also are relevant for the procedures demonstrated here to characterize non-cancer risk. As described earlier, a “ratio of incremental exposure”, or ROIE, is the current recommended approach for evaluating non-cancer risk. This is defined as the ratio of the incremental dose due to the source being evaluated and the background dose, multiplied by 100%. The background dose can be a generic US background dose, or a site-specific dose. The generic adult background dose of WHO_{98}-TEQ_{DF}, as noted above, is 0.64 pg TEQ/kg-day. A background dose for the specific site being evaluated here has not yet been developed. All of the exposures and risks displayed in previous tables assumed a less-than-lifetime exposure, a limited set of exposure pathways, and contact fractions less than 1.0 (meaning that a fraction of their total consumption was from home-produced and impacted food). Producing a site-specific background exposure requires an assessor to estimate the total

exposure of an individual (or individuals) to dioxins if the nearby source were not in existence. In that circumstance, the family would be still be consuming home produced foods. But they would also be consuming store bought or restaurant bought foods. The "total" exposure would include all pathways considered in the scenarios of this chapter, but other pathways as well.

For the purposes of the demonstration in Chapter 5, it was assumed that the farming family in the background scenario consume foods at similar rates whether or not they are consuming home produced or store bought food products, and that their exposure is characterized by all the pathways in the formal demonstration scenarios, as well as the additional scenarios that were demonstrated in Chapter 5, including milk, chicken, eggs, and fish. To estimate their average background daily dose over a lifetime, the exposure duration will increase from 30 to 70 years, and the contact fractions will all rise to 1.00. The resulting daily exposure is 1.16 pg WHO_{98}-TEQ_{DF}/kg-day. This 1.16 pg WHO_{98}-TEQ_{DF}/kg-day will be used here as the "site-specific background dose" against which one can develop ROIEs for the incinerator source.

As discussed in Chapter 2, a pertinent issue for generation of ROIEs is the use of LADDs or ADDs. Chapter 2 recommends the use of ADD for ROIEs, but this demonstration will show a ROIE calculation for both LADD and ADD. The total LADD for the stack emission high end scenario, as displayed in Table 1-7, is $1.01 * 10^{-3}$ pg WHO_{98}-TEQ_{DF} /kg-day. The ADD can be simply calculated as this LADD times 70/30, or $2.36 * 10^{-3}$ pg WHO_{98}-TEQ_{DF}/kg-day. The ROIEs are then easily calculated as:

using LADD: $[(1.01*10^{-3})/(1.16)] * 100\% = 0.09\%$
using ADD: $[(2.36*10^{-3})/(1.16)] * 100\% = 0.20\%$

As seen by these two calculations, the ROIE is less than 1%. If the generic US background dose of 0.64 pg WHO_{98}-TEQ_{DF}/kg-day were used instead of the site-specific background dose of 1.16 pg WHO_{98}-TEQ_{DF}/kg-day, the ROIEs would not be significantly different: 0.16% using LADD and 0.37% for ADD.

1.5.6. Sensitivity Analysis

This section discusses three sensitivity analysis issues pertinent to use of the site-specific methodologies promoted in this document: 1) the appropriate use and categorization of model parameters, 2) a sensitivity analysis exercise on the parameters required for algorithms estimating exposure media concentrations, and 3) the issue of mass balance with regard to the source strength terms of the four source categories.

1.5.6.1. Categorization and Use of Model Parameters

Table 6.1 in Chapter 6 lists all the parameters, including names, definitions, and units, that are required for the methodologies of this assessment except the exposure parameters. Exposure parameters are given in Table 2.1 in Chapter 2. Table 6.1 also gives four additional pieces of information for each parameter listed. Three are numerical values which were used in the sensitivity analysis exercises that are described below. One of those parameters is labeled "selected", which were the ones used in the demonstration exposure scenarios. High and low values of parameters selected for sensitivity analysis were carefully developed and might be considered a reasonable range of values for other uses of the methodology (with obvious exceptions such as areas of contamination, distances from contaminated to exposure site, and so on). The fourth piece of information is a qualitative judgement on the part of the authors of this document as to the appropriateness of using the "selected" parameter values for other assessments. This judgement is categorized in three ways:

1) **First Order Defaults:** As defaults, these parameters are independent of site specific characteristics. As first order defaults, it is felt that the values selected for the demonstration scenarios carry a sufficient weight of evidence from current literature such that these values are recommended for other assessments. Several of the chemical specific parameters, such as the Henry's Constant, H, and the organic carbon partition coefficient, Koc, fall into this category. The qualifier above, "current literature", indicates that new information could lead to changes in these values.

2) **Second Order Defaults:** Like the above category, these parameters are judged to be independent of site specific characteristics. However, unlike the above category, the current scientific weight of evidence is judged insufficient to describe values selected for demonstration purposes as first order defaults. Parameters of principal note in this category are the bioconcentration parameters specific to the chemicals, such as the Biota Sediment Accumulation Factor, or BSAF. This parameter translates a bottom sediment concentration to a fish tissue concentration. Users should carefully review the justification for the SOD values selected for the demonstration scenarios before using the same values.

3) **Site Specific:** These parameters should or can be assigned values based on site-specific information. The information provided on their assignment for the demonstration scenarios, and for selection of high and low values for sensitivity analysis testing, is useful for determining alternate values for a specific site. A key class of SS parameters which are the source strength terms - the soil concentrations, effluent discharge rates, and stack emission rates. If users are unable to obtain site-specific information, or their use of the methodologies is for general purposes, they should review the justification for selection of values for methodology

demonstration, as well as information provided giving ranges of likely values for model parameters.

The exposure parameters can be categorized as have the contaminant fate and transport/transfer parameters. Assignment of these values are critical as LADD estimates are linearly related to parameter assignments - doubling exposure duration assumptions double LADDs, and so on. Some of the exposure parameters are appropriately described as first order defaults. These include: lifetime, body weights, water ingestion rates, inhalation rates, and an exposure duration for a childhood pattern of soil ingestion. All of the other exposure parameters are better described as either second order defaults or site-specific. All exposure parameters were developed based on information and recommendations in EPA's *Exposure Factors Handbook* (EPA, 1997b) and *Dermal Exposure Assessment: Principals and Applications* (EPA, 1992c). Attaining site-specific information is recommended for exposure parameters.

1.5.6.2. Sensitivity Analysis

Sensitivity analysis was undertaken in order to evaluate the impact to exposure media concentration estimations with changes in fate and transport/transfer model parameters. Figure I-5 shows an example of sensitivity analysis conducted. This figure describes the impact of key factors for the stack emission source category for determining impacts to beef. The x-axis contains the names of the parameters evaluated. The key below the figure gives the definition of the parameters and the values selected for the demonstration scenarios. The y-axis shows the fractional change to the key model result, in this case, beef fat concentrations, to the changes made in the parameter. These actual changes in model predictions are noted above and below the bars. For example, beef fat concentrations increase by about a factor 2 with a 10-fold increase in the soil concentration. In contrast, there appears to be almost a linear relationship between an increase in vegetation concentration with beef fat concentration, as shown by the sensitivity test displayed next to the soil concentration test. There, a 10-fold increase in grass and other feed concentration resulted in a 10-fold increase in beef fat concentration. This was not the same trend that was tested for the soil contamination source category. There, soil dioxin provides the source term for vegetation and cattle impacts, not the air source of the stack emission category. In the soil contamination source category, the soil-to-cattle pathway dominates the prediction of beef fat concentration, whereas in the stack emission source category, the air-to-plant-to-cattle dominates. The right side of Figure 1 shows how the beef fat predictions are effected by changes in the assumptions regarding how the beef cattle are exposed, as expressed in the exposure parameters BCSDF (beef cattle soil diet fraction), BCFDF (beef cattle feed diet fraction), and the others listed in Figure 1-2. When....

Following are key overall observations from the several sensitivity analysis exercises undertaken in Chapter 6:

1) Source terms are the most critical for exposure media impacts. Source terms include soil concentrations, stack emission rates, and effluent discharge rates. In all cases, the impact to exposure media is linear with changes to source terms. Proximity to the source term can be important as well, as demonstrated with differences in distance from the stack emission source.

2) Chemical-specific parameters, particularly the bioconcentration/biotransfer parameters, are the second most critical model inputs. Some of these have lesser impacts within the range tested, such as the organic carbon partition coefficient, Koc, for surface water impacts. Generally, at least an order of magnitude in range in possible media concentrations is noted with the range of chemical-specific parameter ranges tested. The impact of changes to bioconcentration/biotransfer parameters is mostly linear. This is because these transfer factors estimate media concentrations as a linear transfer from one media to another. For example, fish lipid concentrations are a linear function of the organic carbon normalized concentration of contaminants in sediments. These transfer parameters are also identified as uncertain parameters. Tested ranges sometimes spanned over an order of magnitude for 2,3,7,8-TCDD.

3) All other parameters had less of an impact as compared to source strength and chemical specific parameters; nearly all impacts were within an order of magnitude for the range of tested values. Part of the reason for this trend is that there is a reasonably narrow range for many of the non-chemical specific or source term parameters - soil properties, wind speeds, vegetation yields, and others.

4) The sensitivity analysis exercises unearthed a dichotomy in model performance, and likely therefore behavior in the real world, when soil is the source of dioxins as compared to when stack emissions are the source of dioxins. The on-site soil source category was demonstrated with a 1 ppt soil concentration of 2,3,7,8-TCDD, a concentration similar to measured concentrations of 2,3,7,8-TCDD in rural settings. Air concentrations are estimated to be $4*10^{-5}$ pg/m^3 (vapor+particle phases summed). Atmospheric transport modeling in the demonstration of the stack emission source category resulted in an exposure site air concentration (vapor+particle phases summed also) at 500 meters from the stack to be $1*10^{-5}$ pg/m^3. With similar air concentrations predicted to occur at the exposure site for the demonstration of the soil and stack emission categories, one might hypothesize that all subsequent impacts would be similar. That was not the case. The stack emission source algorithms deposited particulates onto soil to estimate a soil concentration that was in the 10^{-3} ppt range for the 1-cm untilled depth and the 10^{-5} range for the 20-cm tilled depth. This

compares to the 1 ppt concentration for the on-site soil source category demonstration. With similar air concentrations but a 3+ order of magnitude difference in soil concentrations in the demonstration of the soil and the stack emission sources, the following trends were noted: 1) below ground vegetables had much higher concentrations for the soil source demonstration scenario; 2) soil-related exposures (dermal contact and soil ingestion) were much higher for the soil source demonstration scenario; 3) soil was significantly more critical in predicting beef and milk fat concentrations in the soil source category. The following shows the relative impact of soil versus vegetation (grass and cattle feed) for the on-site soil demonstration and the stack emission demonstration:

	Percent impact due to ingestion of:		
Description	Soil	Grass	Feed
Soil contamination, beef	90	7	3
Soil contamination, milk	87	2	11
Stack emission, beef	5	59	32
Stack emission, milk	3	15	82

Subsequently, beef and milk concentrations were almost two orders of magnitude higher for the soil source category as compared to the stack emission source category, 4) because above ground vegetation are driven by air concentrations, above ground vegetables/fruit and grass/cattle feed concentrations were similar for both demonstrations.

1.5.6.3. Mass Balance

A mass balance exercise was undertaken to evaluate whether a principal of mass balance will be violated with the models and parameters used for the demonstration of the soil source category - that principal being that dioxin releases from a site cannot exceed the original amount at the site (assuming no replenishment). A simplifying assumption for the soil source category was that the soil concentration remained constant over the period of exposure - there was not a systematic depletion of the reservoir over time due to modeled dissipation processes.

First, an estimate of the "reservoir" of 2,3,7,8-TCDD that is implied with the demonstration parameters was made. Then, an estimate of the rate at which this reservoir dissipated using the solution algorithms for dissipation: volatilization and wind erosion flux from

soils, soil erosion, the soil ingestion by cattle and children, losses in runoff and leaching, the loss via dermal contact, and the removal via harvest of below ground vegetation. The premise examined was that, if it takes substantially more time than the exposure period to dissipate the reservoir, then the assumption of a constant soil concentration may be suitable for purposes of exposure assessments. On the other hand, complete dissipation within a time period less than or even near to the period of exposure would mean that exposures and risks are being overestimated. This analysis led to a conclusion that the reservoir modeled in the exercise above would take more than 90 years to dissipate.

This was not a definitive exercise, by any means, but it does lend some confidence that a principal of mass balance may not have been violated for the soil source categories, and for the assumption of 30 years exposure duration.

1.5.7. Model Comparisons and Model Validations

Chapter 7 contains a series of tests of the fate models, including comparisons with other available models and model validation exercises. Brief summaries of these exercises providing an overview and qualitative statement about the results are provided below; Chapter 7 provides all the detail and the quantitative results. Overall, model comparison and validation tests in Chapter 7 showed that: 1) the empirical models selected for this methodology compared well with most other models, many of them empirical as well, 2) since many of the key models of this assessment, in particular the bioconcentration models relating a biota concentration (vegetation, terrestrial animal lipid concentration) to an adjacent media concentration (air, animal feeds), were developed from field data, it is not surprising that when tested against other field data, they were shown to reproduce the field data reasonably well. It can be concluded that, with careful parameter assignment, model predictions of environmental/exposure media concentrations of dioxin-like compounds should be reasonably realistic for most uses. Nonetheless, it should be understood that model testing is an ongoing process. The model comparisons and validations summarized here are, by no means, expected to establish model validity beyond any doubt. Users of this methodology are encouraged to subject the models to any number of tests, validation or otherwise, as they use the models described in this document to conduct site-specific assessments for dioxin-like compounds.

1.5.7.1. Model Comparisons

1. Evaluation of alternative air-to-leaf modeling approaches Three empirical air-to-leaf models for estimating grass concentrations from air concentrations are described and tested against two field data sets. Both field data sets contained simultaneous air concentration and grass concentration measurements of dioxin-like congeners. One set was in a rural and the other in an industrial setting in the United Kingdom. Therefore, this test was both a model comparison test as well as a validation of the air-to-plant modeling developed in this methodology. A principal finding of this exercise was that the model selected for this assessment provided the best fit of the data to the model.

2. Estimating water concentrations given a steady input load from overland sources

The WASP4 model, a substantially more complicated aquatic fate model than the one developed in this methodology, was tested in a dynamic and a steady-state mode for Lake Ontario (EPA, 1990a). Conditions in the steady state run were duplicated for the simple dilution model used in the effluent discharge source category of this assessment. Results suggest that the simple dilution model of this assessment produces reasonably similar results as the more complicated WASP4 model.

3. Estimating fish tissue concentrations based on water column concentrations rather than bottom sediment concentrations A water column measure of the potential for a contaminant to accumulate in fish tissue is termed the Bioaccumulation Factor, or BAF. Bioaccumulation refers to the net accumulation of a chemical from exposure via food and sediments as well as water, and is calculated as the ratio of the chemical concentration in the fish to that in the water. A $ssBAF_l^t$ and a $ssBAF_l^d$ (defined respectively as the steady state BAF, lipid- and total water concentration-based, and steady state BAF, lipid- and dissolved water concentration-based) were developed for lake trout, 2,3,7,8-TCDD, and for Lake Ontario 1987 contamination conditions (EPA, 1990a). WASP4 model runs assuming steady loadings to Lake Ontario were duplicated using the watershed modeling approach of this assessment, where water body concentrations were a function of soil erosion loading, followed by simple partitioning and dilution algorithms.

The prediction of whole fish tissue concentrations using $ssBAF_l^t$ and $ssBAF_l^d$ in the WASP4 modeling exercise was similar to fish concentrations predicted using the simple dilution model and the use of the BSAF of this assessment. Differences were further studied using changes in key modeling parameters including sediment organic carbon fraction and others.

4. Other modeling approaches and considerations for air concentrations resulting from soil volatilization For the soil contamination source category, air concentrations result from volatilization of vapor phase dioxins and suspension of particle-bound dioxins. Dioxins released in these two ways disperse over the soils using simple dispersion models. Two alternate modeling approaches for soil volatilization were tested, and one alternate air dispersion model was tested. One of the alternate volatilization approaches was developed by Jury and co-workers (Jury, et al., 1983, 1984a,b). If one assumes that the contaminant moves through the soil column in only the vapor phase, a simplification of the fundamental equations used by Jury offers another option for modeling soil volatilization. This model comparison test showed that the volatilization model chosen for this methodology predicted an average flux over 30 years roughly four times higher than the average flux predicted by the Jury model. The exact reason for this four-fold difference was not ascertained, and could lie in differences in assumed boundary conditions. In any case, it is judged that both models predict comparable volatilization fluxes. On the other hand, the vapor diffusion model predicted volatilization rates that were 100 times less than the Jury models and about 250 times lower than the model of this methodology. The reason for this discrepancy also could not be ascertained.

The alternate approach to estimating on-site dispersion is the "box-model" approach. This is a simple dilution approach similar to the dilution model used to model the dispersion of dioxins emitted from a pipe effluent discharge. Model testing showed that the box model predicted air concentrations above a soil that was 10 times higher than the near-field dispersion model used in this methodology and 100 times higher than the far-field solution.

5. An alternate model for estimating plant concentrations from soil concentrations For plants grown in contaminated soils, plant concentrations are modeled as a two-step process: vapor and particle-phase releases from soil disperse in the air and settle (particle-bound) or

transfer (vapor-phase) to the vegetation in the models of this assessment. An alternate and simpler approach was developed from field data on above ground vegetation concentrations correlated to soil concentrations of contaminants and the octanol water partition coefficient in Travis and Arms (1988). This correlation led to an empirical bioconcentration factor for vegetation, B_v, regressed against the contaminant log Kow, and defined by the authors as the concentration in above ground plant parts divided by the concentration in soil. The B_v calculated for 2,3,7,8-TCDD is 0.0041. This compares with two plant:soil ratios calculated using the soil-to-air-to-plant algorithms of this assessment: they were in the range of 10^{-5} for bulky vegetables and 10^{-3} for leafy vegetation.

6. Alternate modeling approaches for estimating beef and milk concentrations

Webster and Connett (1990) compared five models which estimated the 2,3,7,8-TCDD content of cow's milk from 2,3,7,8-TCDD air contamination. All five models have the same basic framework. Particulate-bound 2,3,7,8-TCDD deposits onto the ground and vegetation, cattle feed and pasture grass, to which the cattle are exposed. Algorithms to estimate soil concentrations in these models are the same ones used in this approach, but the vegetation algorithms importantly do not consider vapor phase dioxins. Model validation exercises done in Chapter 6, and model sensitivity analysis exercises done in Chapter 5 both show that neglecting the vapor phase will result in a significant underprediction in vegetation impacts for the lower chlorinated dioxins.

These models use a “biotransfer factor” approach to estimating dioxin concentrations in cow’s milk. This approach converts a daily dosage of dioxin, in units of mass/day, into a dioxin concentration. The “bioconcentration” approach in this assessment first calculates an average dioxin concentration in the whole diet, considering fractions of the diet in vegetation and soil and the concentrations in these diet components, and then multiplies this average concentration by a bioconcentration factor. The most sophisticated biotransfer factor was developed by Travis and Arms (1988), who developed a beef and a milk biotransfer factor, B_b and B_m, as a function of the log Kow of the contaminant. Given a log Kow of 6.8 for 2,3,7,8-TCDD (assumed in this assessment), B_b is solved for as 0.16 and B_m is solved for as 0.03. The beef/milk bioconcentration factors of this document were developed from a data in a study by McLachlan,

et al. (1990). This same data can be used to calculate biotransfer factors. The 2,3,7,8-TCDD B_m from that data set is calculated at 0.01. While this 0.01 looks similar to the 0.03 calculated using the empirical relationship developed by Travis and Arms (1988), this does not imply that the Travis and Arms relationship is valid for dioxin-like compounds. In fact, the Travis and Arms relationship calculates a larger B_m as log Kow increases, while the McLachlan data suggest that B_m decreases as the degree of chlorination increases. It was concluded that the Travis and Arms relationship is not valid for compounds with high log Kow, and definitely not valid for dioxin-like compounds.

1.5.7.2. Model Validations

1. The impact of dioxin soil contamination to nearby soils The demonstration of the "soil source" category in Chapter 5 suggested that the concentration at a site of exposure 100 meters away would be 40% of the concentration at the contaminated site for the 2 cm depth and 6% for the 20-cm depth. The literature contained several, somewhat anecdotal, information on elevations of dioxin in soils near a contaminated site, and these were reviewed, including derivation of a similar percentage when possible. One of those sites was the Dow Chemical site in Midland, MI, and percentages derived with their data ranged from 3.5% to 15%, depending on what soil concentration was assumed to represent contamination and what represented impacted.

2. Background soil concentration to bottom sediment concentration ratio A "sediment enrichment ratio" of 3.00 in the model increases the concentration of dioxins in eroding soil as compared to the concentration in the basin draining into a water body. The concentrations of dioxins in the water body will be predicted to be higher than watershed soils, but not necessarily three times higher. Other factors, particularly the organic carbon partition coefficient of the dioxin compound and organic carbon fraction of the water body sediments, also influence the prediction of water body sediment concentration. In the demonstration of background conditions in Chapter 5, the ratio of the concentration of 2,3,7,8-TCDD in water soil to the water body sediment was 2.8. A set of data on 2,3,7,8-TCDD in bottom sediment and background soil concentration from several water bodies and nearby soils was used to derive several similar

ratios. Although there was variability among the various water bodies, the average ratio derived using all soil samples (n = 77) and all sediment concentrations (n = 346) was also 2.8.

3. Soil-to-Air and Air-to-Soil Modeling Air and soil measurements of the 17 dioxin congeners at a rural site were available for model testing. Two tests were conducted - one assumed air was the source of dioxins in the soil and soil concentrations were predicted based on deposition of dioxins from the air, and the other assumed that soil was the source of dioxins in the air and modeled the release and dispersion of dioxins. It was found that, when air dioxin was assumed to be source of dioxin in the soil, a good match between predicted and observed soil concentrations were found. When soil was instead assumed to be the source of dioxins in the air, it was found that air concentrations were underpredicted by about three orders of magnitude. This supports findings described earlier in the fate and transport overview of Volume III that long range transport of dioxins by air is the cause for widespread dispersal of dioxins in the environment.

4. Soil to Below Ground Vegetation A laboratory test in which carrots and potatoes were grown in soil at various 2,3,7,8-TCDD levels provided a test for the soil-to-below ground vegetation model. In that model, an RCF (root concentration factor) is multiplied by soil water concentration to predict root concentration. For bulky below ground vegetables, an additional VG_{bg} reduced the concentration predicted only with RCF since this RCF was developed from experiments on barley roots grown in solution. It was found that the measured concentrations in the carrots and potatoes exceeded the predictions made using the RCF and a VG_{bg} initially set at 0.01. It was found that the measured peel concentrations were similar to model predictions without the VG_{bg}. This suggested that the dioxins translocated more than expected into the carrots and potatoes, and on the basis of these tests, the VG_{bg} was increased from 0.01 to 0.25 for application of this model to below ground vegetables.

5. Paper and Pulp Mill Discharges and the Subsequent Impact to Fish Emissions of 2,3,7,8-TCDD measured in the 101 mill study (EPA, 1990b) were combined with average streamflow data from the rivers and streams into which the paper mills discharged. Predictions

of 2,3,7,8-TCDD in fish were compared with measurements of TCDD in fish from EPA's National Bioaccumulation Study (EPA, 1992c). These fish were known to be downstream of the pulp and paper mills. First, it was found that the model significantly underpredicted fish concentrations when the mill discharged into the largest water bodies where paired data was available - those with streamflows averaging $2.8 * 10^{10}$ L/hr, with a narrow range of 1 to $4 * 10^{10}$ L/hr. The predicted concentrations were about two orders of magnitude lower than measured. It was speculated that there were many more sources of dioxin input to the rivers in these larger systems; this modeling exercise assumed that the pulp mill was the only source of dioxins to impact the fish. The predictions of TCDD in fish were much better in other paired data sets when the streamflows averaged $5.4 * 10^{8}$ L/hr, with a range of 10^{7} to 10^{9} L/hr. These lower streamflows characterized 38 of 47 mills used in this model validation exercise. The average of 38 mills and 74 fish for modeled and observed fish concentrations is 7 ppt and 15 ppt, respectively. Also of note and perhaps not ironically, the highest observed fish concentration of 143.3 ppt is matched by the highest predicted fish concentration of 89.2 ppt, for these lower streamflow conditions. The average of 9 mills and 21 fish associated with large receiving water bodies for modeled and observed fish concentrations is 0.7 and 5.3 ppt, respectively.

6. ISCST3 Modeling of the Release of Large Amounts of Dioxin from a Municipal Solid Waste Incinerator and the Subsequent Impacts to Air and Soil Measurements of dioxin TEQ emissions at nearly 1 kg/yr from a municipal solid waste incinerator in Columbus, OH, in 1994 caused EPA's Region 5 to issue an Emergency Order requiring operators of this incinerator to install MACT, Maximum Achievable Control Technology, pollution devices on an accelerated basis. The incinerator had been in operation 11 years at this time, and a soil study clearly showed elevations of dioxins in soils to about 3 km from the incinerator. Air measurements taken at the same time additional stack measurements were taken were also available, and the stack, air, soil, and obtained meteorological data allowed for a comprehensive test of the ISCST3 model to predict short-term air concentrations, and with predicted depositions, long-term soil concentrations. It was found that the prediction of highest 48-hour air concentrations were generally in the same direction and magnitude as was found in the air monitoring program. With specific congener differences, the model also showed the highest soil

concentrations near the incinerator, with reduced concentrations in both measured and modeled concentrations as the distance increased. An important observation was that the modeled soil concentrations retained a similar relative profile as the stack-emitted dioxins. Differences between the soil and stack profiles were only due to vapor/particle partitioning - there was no modeling of air degradation (there was plume depletion due to deposition), and all congeners were modeled to dissipate in soil at a similar half-life of 25 years. On the other hand, the measured soil concentrations, while unambiguously and significantly elevated near the incinerator, had a relative profile very similar to dioxin profiles found in a typical background urban or rural soil profile, where concentrations are much lower. This shows that, while high emissions clearly resulted in high soil concentrations near the Ohio incinerator, differential dissipation mechanisms for the congeners in the soil and/or in the air resulted in a very typical profile that was not modeled by ISCST3 and the soil concentration model. Future modeling exercises for dioxins in air and depositing to soil using the ISCST3 or similar models should focus on this disparity.

1.5.8. Uncertainty

Some discussion of the issues commonly lumped into the term "uncertainty" is needed at the outset. The following questions capture the range of issues typically involved in uncertainty evaluations:

(1) How certain are site specific exposure predictions that can be made with the methods?

(2) How variable are the levels of exposure among different members of an exposed local population?

(3) How variable are exposures associated with different sources of contamination?

The emphasis in Volume III is in providing the technical tools needed to perform site-specific exposure assessments. For the assessor focusing on a particular site, question (1) will be of preeminent importance. Therefore, the emphasis of the uncertainty evaluation is to elucidate those uncertainties inherent to the exposure assessment tools presented. This chapter examines the capabilities and uncertainties associated with estimating exposure media concentrations of the dioxin-like compounds using the fate, transport, and transfer algorithms, and also identifies

and discusses uncertain parameters associated with human exposure patterns (contact rates and fractions, exposure durations, etc.).

A site specific assessment will also need to address the variability of risks among different members of the exposed population, the second key question above. The level of detail with which this can be done depends on the assessors knowledge about the actual or likely activities of the exposed population. In this document, one approach to evaluating this variability is demonstrated. Separate "central" and "high end" scenario calculations are presented to reflect different patterns of human activities within a hypothetical rural population.

A key issue with regard to intra-population variability is that it is best (if not only) addressed within the context of a specifically identified population. If such information is available, a powerful tool that can be used to evaluate the variability within a population is Monte Carlo Analysis. Three recent Monte Carlo studies which have been done for exposure to 2,3,7,8-TCDD were reviewed. Assumptions on distributions of exposure patterns and fate and transport parameter distributions are described, as are the results of their analyses.

With regard to question (3), this document does not present a detailed evaluation of how exposure levels will vary between different sources of release of dioxin-like compounds into the environment. While Volume III does demonstrate the methodologies developed for sources of release of dioxin-like compounds into the environment with source strengths and environments crafted to be plausible and meaningful, there is still a great deal of variability on both the source strengths and on the environments into which the releases occur. For example, the frequency with which farms and rural residences are near stack emissions of dioxin-like compounds is not addressed. Such analysis is beyond the scope of this document.

Chapter 7 identifies some of the key uncertainties, as well as the key supporting evidence, for the procedures and parameters associated with all the pathways. A summary of discussions from the uncertainty evaluation is now presented. First is a summary of three exposure parameters common to all pathways:

1. Lifetime, Body Weights, and Exposure Durations: Of these three parameters, the exposure duration is the most uncertain. The estimates of 9 and 30 years were made in this assessment for non-farming residents in rural settings, and farming residents in rural settings.

An adult body weight of 70 kilograms and a lifetime of 70 years are standard assumptions for exposure and risk and, although variability is recognized for these parameters, these variations are not expected to add significant uncertainty in exposure estimates. The same is true for the 17 kg child body weight in the childhood exposure pattern of soil ingestion.

2. Soil Ingestion and Soil Dermal Contact: Soil ingestion for older children and adults were not considered, which may have underestimated lifetime soil ingestion exposures. Pica soil ingestion patterns were not evaluated in this assessment. The ingestion rates (100 mg/day for central scenarios and 600 mg/day for high end scenarios, during ages 2-6) considering this appear reasonable. For the soil dermal contact pathway, key uncertain parameters include the contact rate, (0.005 and 0.1 mg/cm^2-event for indoor and outdoor events for the high end farming scenario) and the absorption fraction (0.03 for dioxin-like compounds).

A major area of uncertainty for both pathways is the estimation of soil concentrations where the source of contamination is located distant from the site of exposure. For this assessment, this includes the off-site soil source category and the stack emission source category. Validation exercises described above seem to suggest that prediction of soil concentrations from airborne depositions or from soil erosion appear reasonable. Key uncertain parameters identified include the dissipation rate (0.0693 yr^{-1}), the mixing depth (2 cm), and the use of an enrichment ratio (equal to 3.0) which increases the concentration of dioxin-like compound on eroded soil relative to in-situ soil.

3. Ingestion of Water: A comparison of alternate modeling approaches for estimating water concentrations showed similar results to the models adopted for this assessment. There also does not appear to be a wide range of possible values for water ingestion rate (1.4 L/day for central scenarios and 2.0 L/day for high end scenarios) and contact fraction (0.75 for central scenarios and 0.90 for high end scenarios), and these are not expected to introduce significant uncertainty into water ingestion exposure estimates.

4. Inhalation: The inhalation rate assumed for both central and high end scenarios was 20 m^3/day. The distinction in the scenarios was in the contact fractions: central scenarios assumed a contact fraction of 0.75 and high end scenarios had a 0.90 contact fraction. These

fractions correspond to time at the home environment. These fractions and the inhalation rate are not expected to add significant uncertainty in inhalation exposure estimates.

Sensitivity analysis showed air concentrations resulting from soil emissions to be sensitive to Koc and H, and also to key source strength and delivery terms such as areas of contamination and wind speed. Assuming these non-chemical specific parameters can be known with reasonable certainty for site-specific applications, the most uncertainty lies with chemical specific data.

Alternate approaches for volatilization and air dispersion tested included the volatilization approach developed by Jury, et al. (1983, 1984a,b) and the box model for dispersion calculations. The Jury model predicted about 1/3 as much volatilization flux (given the selection of parameters, made equal to or most analogous to the models of this assessment) as the Hwang, et al. (1986) model of this assessment. The box model predicted about 6 times higher air concentrations than the near-field dispersion approach of this assessment. This reasonable comparison lends some credibility to the models selected.

Approaches to estimate particulate phase concentrations are empirical and based on field data. They are based on highly erodible soils but are specific to inhalable size particles, those less than 10 μm. As such, they may overestimate inhalation exposures, but may underestimate the total reservoir of particulates, which becomes critical for the particle deposition to vegetation algorithms. Another area of uncertainty is the assumption that volatilized contaminants do not become sorbed to airborne particles - this is also critical because vapor phase transfers dominate plant concentration estimation. A final key area of uncertainty is that transported contaminants from a contaminated to an exposure site via erosion are assumed not to volatilize or resuspend at the exposure site or from soils between the contaminated and the exposure site - air borne exposure site concentrations may be underestimated as a result.

5. Fruit and Vegetable Ingestion: All ingestion parameters assumed are evaluated as reasonable for general exposure to broad categories of fruits and vegetables. However, great variability is expected if using these procedures on a specific site where home gardening practices can be more precisely ascertained. Concepts of below and above ground vegetations were developed to accommodate soil to root algorithms and soil to air to vegetation algorithms.

Protected vegetation - those with outer inedible protections such as citrus or corn - were assumed not to be impacted by dioxin-like compounds.

A key assumption in the vegetation algorithm, that dioxin-like compounds do not translocate from root to shoot, was verified by two experiments. Vapor-phase contributions to vegetation dominated the contaminated soil and stack emission source categories, with one exception. Particle depositions were more important for above ground fruit/vegetable concentrations for the stack emission source.

Critical empirical parameters were the above and below ground correction factors, VG_{ag} and VG_{bg}, which were set at 0.01 and 0.25, respectively, for fruits and vegetables. The VG_{ag} was justified based on the fact that the above-ground transfer algorithm was based on experiments for the azalea leaf, and this leafy vegetation would differ for fruits such as apples where translocation into the fruit would be minimal; the VG_{ag} for grass was 1.00 for this same reason. Support for this VG_{ag} for bulky above ground vegetation came from independent experiments by McCrady (1994). The VG_{bg} was given a value of 0.25 based on the testing of the root transfer algorithm on experiments on carrots and potatoes.

Important experimentally derived empirical factors describing the transfer of dioxin-like compounds from one media to plants include the RCF, the soil to below ground vegetables transfer factor, and B_{vpa}, the vapor-phase to above ground plant transfer factor. Validation exercises described above on both of these factors lent a degree a credibility to the independent use of these transfer factors.

6. Ingestion of Fish: The key exposure parameter for this pathway was the fish ingestion rate. The rates assumed in the demonstration scenarios were low in comparison to estimates given for subsistence fisherman or others who live near large water bodies where fish are commercially caught. The justification for the lower ingestion rate for demonstration purposes was that the setting demonstrated was described as rural, containing farms and non-farm residences, where the emphasis is on agriculture. A relatively small watershed with a small impacted water body was assumed. Daily ingestion rates of 8 (central) and 25 (high end) g/day were assumed, based on data from recreational fisherman surveys summarized in EPA (1997b) and on subsequent recommendations for these values in EPA (1997b).

Other models for estimating fish concentration based on water column concentrations, rather than suspended sediment concentrations, were described in EPA (1993) and demonstrated in this assessment. Results indicated that the water column approaches would predict similar whole fish concentrations compared with the sediment concentration approaches of this assessment. A key uncertain parameter for estimating fish tissue concentrations is the Biota Sediment Accumulation Factor, or BSAF, and the Biota Suspended Sediment Accumulation Factor, or BSSAF. A range of 0.03 to 0.30 for 2,3,7,8-TCDD is hypothesized for column feeding fish, while the Connecticut data (CDEP, 1992) and some other data on bottom feeding fish indicate higher BSAFs ranging up to 0.86 for 2,3,7,8-TCDD. A value of 0.09 for 2,3,7,8-TCDD for BSAF and BSSAF is used in this assessments. A "Bioequivalency Factor", or BEF, approach is used to assign values to other dioxin-like congeners. In this approach, a relative rating scheme provides factors to multiply the 2,3,7,8-TCDD bioconcentration parameter to get this same factor for the other dioxin congeners. Another key parameter is the fish lipid content, which can vary from below 0.05 to above 0.20. The model estimates a fish lipid concentration. Multiplying fish lipid concentration by fish lipid content arrives at a whole fish concentration or an edible fish concentration, depending on the user's assignment and characterization of the fish lipid content variable. For this assignment, the fish lipid content was assigned a value of 0.07 for the demonstration scenarios, based on lipid content of fish in EPA's Lake Ontario study (EPA, 1990a).

7. Beef and Milk Ingestion: The rates of beef and milk fat ingestion are 2.45 and 14.0 g/day, respectively. Beef fat and milk fat contents are assumed to be 22% and 3.5%, respectively. An additional factor of 0.55 accounts for cooking and post cooking loss of beef. The assumptions for contact fractions for beef and milk (fractions of their total consumption that comes from home supplies) was 0.48 and 0.21, respectively. Since exposure estimates from these pathways are linearly related to ingestion rate and contact fraction, these are critical exposure parameters for site specific applications.

Comparison with earlier modeling approaches showed that the current approach to estimating beef and milk concentrations is the same as earlier approaches, although mathematically formulated differently. Early efforts in the literature did not consider vapor transfers to vegetation; one later assessment did include vapor transfers, and a key result in that

assessment, as well as this one, is that vapor transfers are critical for beef impacts. Finally, earlier assessments considered the practice of fattening beef cattle prior to slaughter by feeding them residue-free grains. These efforts estimated over a 50% reduction in beef concentration due to residue degradation or elimination and/or dilution with increases in body fat. The demonstration scenarios in this assessment did not consider this practice. However, this practice was considered in the air-to-beef food chain validation exercise. There, a 50% reduction in beef concentrations due to feedlot fattening was assumed.

Key uncertain and variable parameters for beef/milk concentrations include: 1) the beef and milk fat bioconcentration factor, BCF, 2) the beef cattle and dairy cow exposure assumptions (fractions of their feed in which feed categories), 3) the assumptions concerning vapor/particle partitioning for the stack emission source category, and 4) the air-to-leaf transfer parameter, B_{vpa}, for vapor phase contaminants.

BCFOD	beef cattle fraction of contaminated feed	1.00

2. ESTIMATING EXPOSURES AND RISKS

2.1. INTRODUCTION

In this chapter, the framework for assessing exposure and risk to 2,3,7,8-TCDD and related dioxin-like compounds will be described. Section 2.2 introduces the exposure equation and its key terms. Section 2.3 describes how cancer risk and non-cancer risk estimates are generated, given exposure estimates. Section 2.4 summarizes procedures for calculating exposure and risk for dioxin toxic equivalents. Section 2.5 provides the overview of the procedures used in this document. Section 2.6 describes the development of exposure scenarios for this assessment. Finally, Section 2.7 discusses the exposure pathways and exposure parameters chosen for this assessment.

The development of exposure assessment methods, scenarios and associated parameter values raises many issues which are generic to all chemicals. In order to keep the scope of this document reasonable, the decision was made to focus on issues specific to dioxin-like compounds and to avoid evaluating generic issues. Thus, priority is given to addressing issues such as fish bioconcentration, dermal absorption, degradation, and other chemical/physical properties of these compounds. The approach used to address generic issues such as soil ingestion rates, inhalation rates and other behavior parameters is based on published Agency documents, primarily the Exposure Factors Handbook, published first in 1989 (EPA, 1989). The current version of the Exposure Factors Handbook was published in 1997 (EPA, 1997a). Exposure factors used in this chapter are based on this version.

Another generic issue which has been raised in connection with this document is the use of Monte Carlo procedures to define exposure scenarios. These procedures require distributions for the input parameters used in the assessment. Such distributions are now being addressed in the Exposure Factors Handbook. However, this document has not demonstrated Monte Carlo and related procedures on the scenarios developed in this chapter. Individuals outside of the Agency have published assessments which applied Monte Carlo procedures to problems involving dioxin-like compounds. In recognition of the high interest in this area, a general description of this technique and summaries of assessments which applied it to dioxin-like compounds are included in Chapter 8 of this Volume.

2.2. EXPOSURE EQUATION

This document describes procedures for conducting exposure assessments to estimate either potential or internal dose. A potential dose is defined as a daily amount of contaminant

inhaled, ingested, or otherwise coming in contact with outer surfaces of the body, averaged over an individual's body weight. An internal dose is defined as the amount of the potential dose which is absorbed into the body. Section 2.3 below discusses the relevancy of this distinction for dioxin-like compounds.

The general equation used to estimate potential dose normalized over body weight and lifetime is as follows:

$$\text{Lifetime Average Daily Dose (LADD)} = \frac{(\text{exposure media concentration} \times \text{contact rate} \times \text{contact fraction} \times \text{exposure duration})}{(\text{body weight} \times \text{lifetime})} \quad (2\text{-}1)$$

The LADD is used to assess cancer risks. Non-cancer risks from exposure to dioxin-like compounds can be assessed using the Average Daily Dose, or ADD. This is calculated as in Equation (2-1), but without the exposure duration in the numerator and the lifetime in the denominator. Each of the terms in this exposure equation is discussed briefly below:

- **Exposure media concentrations:** These include the concentrations in soil for the dermal contact and soil ingestion exposure pathways, in the vapor and particulate phases in air for the inhalation exposure pathway, in water for the water ingestion pathway, and in food products such as fish, fruits and vegetables, and beef and milk, for the food ingestion pathways. The concentrations used should represent an average over the exposure period. Chapter 4 provides models for estimating exposure media concentrations.
- **Contact rate:** These include the ingestion rates, inhalation rates, and soil contact rates for the exposure pathways. These quantities are generally the total amount of food ingested, air inhaled, etc. Only a portion of this material may be contaminated. The next term, the contact fraction, which is 1.0 or less, reduces the total contact rate to the rate specific to the contaminated media.
- **Contact fraction:** As noted, this term describes the distribution of total contact between contaminated and uncontaminated media. For example, a contact fraction of 0.8 for inhalation means that 80% of the air inhaled over the exposure period contains dioxin-like compounds in vapor form or sorbed to air-borne particulates. The contact fractions for the exposure pathways of air inhalation and water ingestion are related to the time individuals spend at home. Other pathways such as fish ingestion or ingestion of home grown foods are not related to time at home. Similarly, contact fractions for individuals exposed at work places relate

largely to time spent at the work place. EPA (1997a) discusses several time use studies which can be used to make assumptions about time spent at home (and outdoors at the home environment) versus time spent away from home. Generally, these time use studies asked participants to keep 24 hour diaries of all activities. Studies summarized were national in scope, involved large numbers of individuals, cross-sections of populations in terms of age and other factors, and up to 87 categories of activities. Results from different studies reviewed in EPA (1997a) consistently indicate that the average adult spends between 68 to 73% of time at the home environment.

- **Exposure duration:** This is the overall time period of exposure. Values of 9 years and 30 years are used in the example scenarios described in Chapter 5. EPA (1997a) describes several population mobility studies. A recent study by the U.S. Bureau of the Census (1993) covered a national sample of 55,000 interviews. The 50th and 90th percentile values of values for years living in current residence were determined to be 9.1 and 32.7 years, which are rounded here simply to 9 and 30 years. The 9 years will be used in a residential scenario and the 30 years for the farming scenario. The fact that farmers tend to live longer in their residents than average individuals was supported by a second study (Isreali and Nelson,1992) described in EPA (1997a) which categorized respondents in a number of different ways. The average time living in current residence for individuals in farms was 17.3 years, while it was 7.8 years for individuals in rural settings and 4.6 years for all households (Isreali and Nelson,1992). Another exposure duration demonstrated in Chapter 5 is one associated with a childhood pattern of soil ingestion. The exposure duration in this case is 5 years.
- **Body weight:** The human adult body weight of 70 kg is assumed. While the average adult (males and females) body weight is closer to 60 kg (EPA, 1997a), 70 kg has been traditionally used by the Agency and will be used in this assessment where appropriate. This document has chosen to use consumption rate data that are in terms of g food consumed/kg body weight/day, rather than g food consumed/day. Therefore, body weight drops out as an exposure factor for these pathways; it is still required in this assessment for the inhalation, soil ingestion, soil dermal contact, and the water ingestion pathways. The fish consumption pathway still uses the g/day convention since most fish consumption survey data, and the data used in this assessment, are in that form. As such, this pathway also

uses the 70 kg body weight assumption. The average of male and female average body weights at ages 1 through 6 was 16.6 (EPA, 1997a). This was used to assume an average body weight of 17 kg for the childhood pattern of soil ingestion. The 70 kg adult body weight will be used in some, but not all of the pathways.

- **Lifetime:** Following traditional assumptions, the average adult lifetime assumed throughout this document is 70 years. Even though actuarial data indicate that the United States average lifetime now exceeds 70 years, this convention is used to be consistent with other Agency assessments of exposure and risk.

2.3. CANCER AND NON-CANCER RISK ASSESSMENT

The primary source of information on the health risks of the dioxin-related compounds is the Health Document of this Reassessment, Part II of the Reassessment Documents (Part I are the Exposure Documents and Part III is the Risk Characterization). While that remains the principal source of information on potential health effects resulting from dioxin exposures, some general procedures for using exposure estimates in support of cancer and non-cancer risk assessments are summarized here.

The Risk Characterization emphasizes that risk assessments for dioxin-like compounds must consider background exposures when evaluating the impact of increments that are due to specific sources:

> *When evaluating incremental exposures associated with specific sources, knowing the increment relative to background may help to understand the impact of the incremental exposure. For instance, it would be misleading to focus on incremental exposure in evaluating the potential impact on human health when a relatively large background body burden of dioxin already exists in the exposed population. In these circumstances, the incremental exposure needs to be evaluated in the context of these background levels. This has led us to suggest that perhaps the best information for a decision-maker to have is: (1) a characterization of effects noted in the low dose range; (2) a characterization of the range and average of "background" exposures, including a discussion of MOE; (3) a characterization of the incremental percent increase over background of individuals or subpopulations of interest; and (4) guidance on when contributions from incremental exposures adding to average "background" become significant for the decision.*

The Risk Characterization as well as the Health Document provide detailed discussions of the effects of dioxin exposure in the low dose, or background, range, and those discussions are not repeated here. These documents also discuss in great deal the Margin Of Exposure, MOE, concept and the MOE associated with current background exposures. The MOE is calculated by dividing a "point of departure" dose or exposure at the low end of the range of observation in human or animal studies by the comparable surrogate of human exposure at a "level of interest". These points of departure could include the human-equivalent lowest observed adverse effect level (LOAEL), the no observed adverse effect level (NOAEL), the benchmark dose (BMD), or the effective dose (ED) at some percentage; ED_{01} is the effective dose for 1% of the population. Points of departure could also be body burden levels associated with health effects. The comparable "level of interest" for dioxin-like compounds are defined here as terms relating to background exposures, or perhaps, background exposures plus incremental exposures due to a specific source being evaluated. The Risk Characterization provides this general guidance regarding interpretation of MOEs:

> *Generally speaking, when considering either background exposures or incremental exposures plus background, MOEs of 100 or more are considered adequate to rule out the likelihood of significant effects occurring in humans based on sensitive animal responses or results from epidemiologic studies and traditional factors used in safety assessment. Conversely, as MOEs approach the range of observation of effects, reaching any conclusion regarding the certainty of no harm is much more difficult.*

The Risk Characterization concludes that the MOE for background exposures are well below 100 and even below 10:

> *One of the difficulties in assessing the potential health risk of exposure to dioxins is that background exposures are often a significant component of total exposure when based on TEQ. The average levels of background intake and associated body burdens of dioxin-like compounds in terms of TEQs in the general population (1 pg TEQ/kgBW/day and 5 ng TEQ/KgBW, respectively) are well within a factor of 10 of human-equivalent levels associated with NOELS, LOAELs, BMDs, or ED_{01} values derived from studies in laboratory animals exposed to TCDD or TCDD equivalents. Therefore, in many cases, the MOE compared to background using these endpoints is a factor of 10 or less....*

The Risk Characterization provides tabular summaries of these health endpoints that show that the MOEs for certain endpoints are even below 5. With MOEs below 10 for background exposures alone, a calculation of an MOE based on background plus incremental exposure may not be of benefit in a site-specific risk assessment. For example, if an MOE for a particular toxicological endpoint of interest is calculated to be 5 for background exposures (5/1), and it were determined that a source resulted in an incremental exposure that is 10% of background, than a resulting MOE considering background plus incremental exposure would be about 4.5 (5/1.1). While this kind information does not appear to be of benefit to decisionmakers, it may be useful to know that a particular source adds 10% more exposure than an individual would get by background exposures alone. This is identified in the third recommendation provided in the first quote above from the Risk Characterization: *"...(3) a characterization of the incremental percent increase over background of individuals or subpopulations of interest"*.

The first section below discusses the quantification of "background exposures" to dioxin-like compounds, from both a dose and body burden standpoint. The second section introduces the "increment above background", or IOB, ratio, which is a ratio that describes the percent increase over background a specific source contributes. The IOB concept is suggested as a way of evaluating non-cancer risk. The final section will discuss the traditional approach to estimating cancer risk, based on an incremental exposure and a slope factor. These approaches will be demonstrated in Chapter 5.

2.3.1. Background Exposure Doses and Body Burdens

The second volume of the Exposure Document, Volume II: Properties, Environmental Levels, and Background Exposures, describes United States background exposures to dioxin-like compounds, both from the perspective of exposure doses and body burden. Combining average adult contact rates (inhalation rate, food consumption rates, etc.) with average concentrations of these compounds in the contact media (air, food, etc.), the current adult background dose to dioxin-like compounds is quantified as 1.0 pg WHO_{98}-TEQ_{DFP}/kg-day. This Volume further provides similar background estimates for children of various ages, and these estimates are: 1-5 yrs: 3.3 pg WHO_{98}-TEQ_{DFP}/kg-day, 6-11 yrs: 1.9 pg WHO_{98}-TEQ_{DFP}/kg-day, and 12-19 yrs: 1.1 pg WHO_{98}-TEQ_{DFP}/kg-day. In addition, background exposures of infants to dioxins in breast milk is also addressed in the Volume II of the Exposure Document.

The average adult body burden of dioxin-like compounds, expressed on a lipid basis, was estimated as 25 pg WHO_{98}-TEQ_{DFP}/g (ppt). This was based on measurements of dioxins in blood of specifically selected "background" populations in six site-specific studies conducted by, or

with the assistance of, the Agency for Toxic Substances and Disease Registry between 1995 and 1997, with the blood analyzed by the Centers for Disease Control (CDC, 2000). A total of 316 adults ranging in age from 20 to 70 years were measured in these studies. The individuals sampled were all U.S. residents with no known exposures to dioxin other than normal background. While the samples in this data set were not collected in a manner that can be considered statistically representative of the national population and lack wide geographic coverage, they are judged to provide the best available indication of current tissue levels in an average adult population in the United States. The Risk Characterization has estimated a national background body burden of 5 pg WHO_{98}-TEQ_{DFP}/g, on a whole weight basis.

An important issue associated with the use of this national body burden estimate is that it represents the average for the wide range of adult ages from 20 through 70. As discussed in Volume II, there is an age trend associated current body burden data - older individuals have higher body burdens. An in-depth analysis of this trend in Lorber (2002) concludes that this trend is due to two factors: 1) that exposures were higher in past, such that older individuals have been exposed to much more dioxin during their lives compared to younger individuals, and 2) that dioxins are long-lived in the human body, such that an individual's body burden will rise as they age if they receive a steady input dose during their life. Lorber (2002) concluded that higher past exposures was much more responsible for this trend than build-up over time in an individual's body. They explored this trend using simple pharmacokinetic modeling. Figure 2-1 shows one result of their analysis. These are modeled populations distributions of body burdens of dioxin and furan TEQ lipid-based concentrations (Lorber's examination didn't include dioxin-like PCBs) corresponding to the hypothetical sampling years 1965, 1985, 1995, and 2030.

There are a few important observations to make regarding the information in this figure. It shows that the average population body burdens are declining, and that by 2030, the average body burdens of WHO_{98}-TEQ_{DF} will be 9 pg/g lipid, or about 2.3 pg/g whole weight basis (assuming 25% body lipids). This trend for 2030 is essentially identical to the trend of how an individual's body burden would very slowly rise through adulthood if they are exposed to a constant dose. This result was derived by assuming that today's dose of dioxin and furan TEQs stayed constant throughout the early decades of the 21st century. It also simplistically modeled dioxin TEQs as though they were a single compound with a single half-life. If one were to redo this to include dioxin-like PCBs, again modeling TEQs as though they were a single compound, it would show that the average adult body burden at the steady intake of 1.0 pg WHO_{98}-TEQ_{DFP}/kg-day would be about 13 pg WHO_{98}-TEQ_{DFP}/g-lipid, or about 3.3 pg WHO_{98}-TEQ_{DFP}/g whole weight. This figures also shows that today's background body burdens (as estimated by

the population distribution for 1995) of younger individuals is lower than the population average: the population average is 28 ppt lipid while the concentrations for the under 30 age group is below 20 ppt lipid. This means that if one were to conduct an analysis of the incremental impact to specific individuals who might comprise the younger portion of an adult population, such as women of child-bearing age, it might be more appropriate to assume a lower average background body burden than the 25 pg WHO_{98}-TEQ_{DFP}/g lipid that characterizes the full range of today's population.

In site-specific assessments, the assessor has the option of using information on current national average daily intakes or body burdens as the "background" against which to compare incremental exposures. In this case, the assessor needs to make it clear that he is comparing incremental exposures and/or body burdens to national background estimates. In certain circumstances, it may be preferable to have an understanding of the "local", or "regional", background rather than the national background. A local background dose or body burden for a site-specific assessment, where a specific source of dioxin release is being evaluated, can be thought of as the overall dose or body burden that an individual potentially impacted by that source of release would experience, or would have, if the source in question were not in existence. Local background exposures for one setting may be higher than in another because, for example, one setting may have more sources of industrial dioxin release (other than the one being evaluated) within it. Another site-specific consideration would be the behaviors of exposed individuals. There may be a water body for fishing in one site, while agriculture may dominate another site. If there is reason to consider a subsistence behavior for a particular setting that could lead to elevated exposures, it may be appropriate to derive a local background exposure to dioxin based on that subsistence behavior, rather than on general behaviors.

While it may be important for risk assessors or risk managers to consider local backgrounds rather than national backgrounds, it should be emphasized that this document will not provide guidance, such as a hierarchy of recommendations, on how to assign background quantities for any quantitative evaluation of the incremental exposures using the increment above background, or IOB, approach described below. Obviously, this choice can be important. If a particular area is likely to have a higher background as compared to a national background, this would influence the numerical value of a ratio such as an IOB ratio. For example, if local background is twice as high as a national background, than an incremental exposure that is equal to 10% of national background would be equal to 5% of a local background. Similarly, if an area is thought to be have lower exposures as compared to background exposures, say half as much for example, than an incremental exposure equal to 10% of national background would be equal

to 20% of a local background. Risk managers could evaluate incremental exposures differently if they are told that the incremental is 5% of background as compared to 20% of background. Perhaps the best general advice that can be offered in this procedures document is to recommend that a risk assessor supply the risk manager with this type of information: 1) the incremental exposure from a specific source, 2) how that compares to the national background exposure, and 3) information on how local exposures may relate to national exposures, if this information is available.

A local background body burden can be ascertained through monitoring. A comprehensive discussion of monitoring approaches of human matrices (blood, adipose tissue, mother's milk) is beyond the scope of this document. However, some key generalizations can be noted here that are relevant to site-specific assessments for dioxin-like compounds:

1) Whether the source is in operation or not: Some site-specific assessments are conducted to evaluate the potential impact of an industrial facility not yet operating. In that case, sampling of the representative population that could be impacted by emissions from the facility would be appropriate. If the facility has been operating, it becomes necessary to sample a population that is not impacted by the facility, but one that is comparable with regard to demographics. Dioxin body burdens are a function of many factors including age, nursing practices, dietary preferences and possibly occupational history. Ideally, the population of concern around a site should be characterized in terms of these factors. If the source is ongoing, and it becomes necessary to locate and sample a different population to characterize background, then a comparison population with similar characteristics should be chosen.

2) How to interpret differences in the study and a comparison population: Since dioxin body burdens reflect contributions from all sources, the portion due to releases from the site of concern cannot be definitively established. Sometimes measurements from a comparison population can be difficult to interpret; the better the demographic match between the study and comparison populations, the more likely it is that any differences between the groups can be attributed to the site or source of concern.

3) Body matrix to sample: As noted above, the background body burden of 25 ppt WHO_{98}-TEQ_{DFP} lipid-basis was determined from sampling of blood in background populations from several site-specific evaluations. Blood is the recommended matrix for sampling in that the entire population can be sampled in a relatively easy, non-invasive manner. In can be costly, however, and obtaining volunteers for a background blood sampling program can be an issue. Mother's milk can be considered and it does have certain advantages over blood: 1) it may be easier to obtain volunteers for a mother's milk sampling program in contrast to a blood sampling

program, 2) mother's milk has a higher lipid content (3-4 %) than blood (<1%), and therefore less milk would be required for analysis than blood, with a greater possibility of being able to quantify concentrations of the lipophilic dioxin-like compounds, and 3) useful information would be gained on potential infant impacts in addition to population exposures. However, mother's milk concentrations should be interpreted carefully, given these considerations: 1) needless to say, these programs monitor only half the population, and 2) proper interpretation of data for the female population can also be an issue. Evidence has shown that breast-feeding provides an avenue of depuration of dioxin-like compounds in the lactating female: breast milk concentrations decline while the mother is breast-feeding and female body burdens are lower for the second and subsequent children as compared to first children. As a matrix for screening studies, mother's milk can be more expedient than blood monitoring. Certainly, important implications exist when unusually high concentrations of dioxin-like compounds are found in breast milk, and general differences between populations can easily be identified in a breast milk monitoring program.

Other issues exist when deriving a background dose rather than a background body burden. A background dose estimate requires two quantities: contact rates and exposure media concentrations. Two options for contact rate assignment could be contact rates derived for a specific site (i.e., subsistence fishing consumption rates), or national average contact rates. National average contact rates were used to develop the 1 pg WHO_{98}-TEQ_{DFP}/kg-day. Four options are available for estimating exposure media concentrations:

1) National average exposure media concentrations: Combining site-specific contact rates with national average exposure media concentrations could provide the assessor with useful information at minimal cost, and would be quite acceptable in most cases where the assessor has no reason to believe that local concentrations are substantially different than national average concentrations. In other circumstances, it might be most appropriate to conclude that local concentrations are different than national average concentrations, necessitating a different approach for estimating concentrations.

2) Measurement of Local Exposure Media Concentrations: Measurement of concentrations of dioxin-like compounds in all relevant exposure media associated with a site would be the most accurate way to characterize a site-specific exposure media, but it would prove costly and, in fact, it may not be useful if the source in question has been in existence for several years. For example, a measurement of dioxins in air and soil in the vicinity of an operating incinerator source would reflect the impacts of the incinerator. Measurements in environmental/exposure media in the vicinity of an incinerator, even if it was shut down, could

still be influenced by past emissions from the incinerator. This would be the case if measuring soil around a closed incinerator. It would not be the case, however, for measuring air concentrations in a vicinity around a closed incinerator. In this case, the measured air concentrations would be appropriate reflections of background air concentrations for that site (although small contributions to that measured air concentration could come from releases of dioxins from soils; evidence suggests that these contributions would be small). The measurement of exposure media concentrations is mostly feasible (but still costly) if the assessment is prospective in nature - i.e., that it evaluates a new source not yet emitting dioxins. Another possibility is to use existing measurements or take new measurements in a nearby area which is matched as closely as possible to the study area, but doesn't have a similar dioxin source present. EPA's National Dioxin Air Monitoring Network, NDAMN, has been collecting air concentrations in background areas of the United States on a quarterly basis (4 samples/yr) since 1998 (Cleverly, et al., 2001). These concentrations could be used as background air concentrations for a site-specific assessment. However, the purpose of this network is to measure background air concentrations in settings where no apparent sources are present, such as in national parks. For this reason, NDAMN measurements might be lower than would exist in urban or suburban settings where a source of release is being evaluated with the methodologies of this document. Lorber, et al. (1998) showed how concentrations of dioxins in soil in Columbus, OH, approached a local urban background about 12 kilometers away from an incinerator. Soil or air measurements on the order of 10 kilometers or more from an air source being evaluated, but still within a very similar urban or rural setting, might be reasonable surrogates for background concentrations for specific sites.

3. Modeling of Exposure Media Concentrations: There are at least two ways in which background exposure media concentrations could be estimated with the use of models alone. One is to model the impacts from all major sources in the area being evaluated except for the source in question and then adding impacts at points of interest. This assumes that the impacts from all modeled sources are independent. The model ISCST3 used in this site-specific methodology document does, in fact, have the capability of combining inputs from multiple sources. In a complex setting, this option may be more costly and difficult than can be justified given the uncertainty in the exercise and the output. Specifically, the assessor must consider issues such as, have all sources been identified?, how accurate are source emission estimates?, and so on. Another possibility, for some time in the future, is to use results from studies now underway to develop multiple source, large-scale air dispersion/deposition models specific to dioxin. As an example, EPA is developing an application of the RELMAP model, which is the

model originally developed for acid rain assessments by EPA's Office of Air Quality and Planning Standards, and was also used to predict national fate of mercury emissions in EPA (1997b). This model takes, as input, emissions into the air from specifically defined sources in the United States, and predicts, for any location (on a 40 km grid) in the United States, deposition rates and air concentrations for modeled contaminants. Air concentrations and depositions could then serve as the input for modeling impacts to the terrestrial and aquatic environment using the steady state models discussed in this assessment. The uncertainties involved in using RELMAP and similar models to predict impacts of dioxin sources are not well quantified at the present time. EPA initiated a study in 2001 to compare modeled to measured air concentrations, and to compare RELMAP outputs to outputs generated with other similar regional models. These comparisons will help to reduce the uncertainty and to refine/calibrate these models for future possible site-specific applications involving dioxin-like compounds. Exposure media concentrations modeled by RELMAP or other aggregate source models would represent the "background" concentrations. The source in question is modeled separately and any predicted concentration would be in addition to the "background" concentration predicted by the aggregate modeling.

4. A combination of modeling and limited monitoring: This may be a reasonable way to estimate background exposure media concentrations for a specific site, if useful site-specific monitoring is available. For example, if an incinerator were no longer operating, then air concentrations measured in the vicinity of the shut down incinerator could give an estimate of the background air concentrations for that site. These air concentrations could then be routed through the terrestrial and aquatic fate models to predict soil and food concentrations for background exposure estimation. Careful monitoring of soil and air concentrations in the vicinity of the source while it is still operating is another possibility. Specifically, if several air monitors in all directions from an incinerator source were sampled on several days, during which time wind rose data were also taken, then one could probably identify air concentrations most and least likely to be impacted by the source in question by a careful examination of the wind rose data. Soil concentration data several miles away from an incinerator source, or a soil contamination source, may be an appropriate measure of dioxin impacts to soils not including the source in question. An example of careful monitoring around an incinerator emitting large amounts of dioxin allowed Lorber, et al (1998) to distinguish background air and soil concentrations from impacted air and soil. Again, these intermediate exposure media concentrations could be used with the steady-state models described in this assessment to estimate the full range of terrestrial and aquatic impacts.

A demonstration of a site-specific background scenario is presented in Chapter 5. Specifically, this scenario uses site-specific exposure factors and option 4 above to derive exposure media concentrations. Actual air and soil measurements in a background setting are used for the inhalation and soil related pathways. These measured concentrations are routed through the terrestrial and aquatic food chain models to predict concentrations in food products. Background dose estimates are calculated using these site-specific exposure factors and these hybrid exposure media concentrations. As such, the "background doses" in this example scenario in Chapter 5 can be thought of as specific to the region in which the source in question exists.

2.3.2. The Increment Over Background Concept for Non-Cancer Risk Assessment

EPA's Office of Solid Waste (OSW) has evaluated the potential for non-cancer impacts from individual sources of dioxin release based on an "increment above background", or IOB, approach. They have recommended that assessments conducted for hazardous waste incinerators use, on a provisional and site-specific basis, an IOB calculated as the ratio of the incremental exposure dose divided by the background exposure dose for dioxins, and then multiplying by 100%, so that the IOB is expressed in terms of a percentage. Some of the experience using this approach in OSW has been compiled and reported upon in Canter, et al. (1998). OSW has termed this ratio the margin of incremental exposure, or MOIE. That terminology and acronym will not be used here as it is similar to the MOE, or margin of exposure, which is used here and has a specific meaning in Agency risk assessing.

The other important difference is that the IOB approach developed here will be used to characterize the incremental increase to body burden and not to dose. The Risk Characterization concludes that non-cancer health effects due to dioxin exposure are best correlated to body burden and not to dose. If a dose has been occurring for a long period of time such that the body burden approaches a steady state, than of course dose and body burden are related. A percent increase in dose over background dose will be similar to a percent increase in body burden over background body burden in this circumstance. If an incremental dose has been occurring for a short amount of time, than the body burden will not rise to the level it would reach at steady state from that incremental dose. Therefore, a percent increase over background in terms of dose could be significantly higher than a percent increase over background in terms of body burden for short duration exposures. For that reason, the IOB approach developed here will be focused on body burden.

The IOB equation for body burden is given as:

$$IOB_{bb} = \frac{IBB}{BB_{bk}} * 100\% \quad (2\text{-}2)$$

where:

IOB_{bb}	=	increment over background ratios for body burden (bb), %
IBB	=	increment of body burden increase due to the incremental exposure, pg/g whole weight
BB_{bk}	=	background body burden, pg/g whole weight basis

To use this equation, a background body burden needs to be assigned, and an approach needs to be developed to estimate the increment of body burden that is due to the source being evaluated. Discussions in the previous section address the assignment of the background body burden. As discussed above, issues to consider include: whether to use a national or a local background body burden, whether to consider the background body burden for younger adults rather than the full range of adult ages (younger adults would have a lower background body burden), whether to consider specific populations such as women of child-bearing age (which again might imply a lower concentration as compared to a full population average), and so on.

The focus on the procedures in this volume are on predicting exposure media concentrations and estimating site-specific intake doses. A simple procedure is recommended here to estimate body burdens given intake doses to dioxin-like compounds. Specifically, the simple one-compartment, first-order pharmacokinetic model is recommended. The non steady-state form of this model to predict body burden from a constant intake dose is given by:

$$L \frac{dC_L}{dt} = D - kLC_L \quad (2\text{-}3)$$

where:

C_L	=	concentration in lipid, pg/g;
L	=	lipid mass, g
	=	BW * F_{lipid} (= body weight * fraction lipid)
D	=	steady-state absorbed dose, pg/day (* 365 d/yr = pg/yr)
k	=	first-order dissipation rate constant, 1/day (or 1/yr, if D is in 1/yr units)

= $0.693/t_{1/2}$

$t_{1/2}$ = half-life, days (or years)

t = time period of interest, most often the full duration of exposure

The closed form solution for Equation (2-4) is given as:

$$C_L(t) = C_L(0)\, e^{-kt} + \frac{D}{kL}\,(1 - e^{-kt}) \qquad (2\text{-}4)$$

The first term on the right hand side of Equation (2-4) describes the decline in an initial body burden. If using Equation (2-4) to solve for the full body burden after a period of exposure denoted by "t", than one has to also assign a value of "D" equal to the incremental dose plus the ongoing background dose times an absorption fraction. However, if using this solution to estimate the incremental body burden due to the incremental dose only, than the first term drops out and the equation for solving IBB is:

$$IBB = \frac{ADD\ AF}{kL}\,(1 - e^{-kt}) \qquad (2\text{-}5)$$

where the term "D" has been replaced by ADD * AF, where ADD is the average daily incremental dose, and AF is the absorption fraction. The Risk Characterization has assumed a value of 0.8 for the absorption fraction, 70 kg for the body weight (BW) and 7.1 years for the half-life ($t_{1/2}$), when using this model for WHO_{98}-TEQ_{DFP} in a backwards mode to estimate a steady-state dose that is associated with a body burden. For site-specific assessments, the assessor can assign values to these parameters based on whether they intend to model individual dioxin-like compounds (which could influence the assignment of $t_{1/2}$ or A) and/or whether they intend to consider different sexes and/or stages of life (which could influence the assignment of BW).

2.3.3. Traditional Agency Cancer Risk Assessment Procedures

The usual procedure used to calculate an upper-limit incremental cancer risk is based on an assessment of lifetime average daily dose, LADD, and a slope factor, as follows:

$$R = 1 - e^{SF*LADD} \approx SF * LADD \quad (2\text{-}6)$$

where SF is the slope factor, or more precisely, the 95% upper confidence limit of the linearized cancer slope factor of the dose-response function (expressed in units of the probability divided by dose, or probability/[mg/kg-day], which is most often simply shortened to $[mg/kg\text{-}day]^{-1}$) and LADD is the dose (which needs to be in units appropriate to cancel those of SF, mg/kg-day). The estimated R in Equation (2-6) can be understood as the 95% upper confidence probability of incurring cancer during a lifetime as a result of the exposure defined by LADD; the true probability may be less than the quantity R, and may even be zero. The simplified form of the risk equation shown above is reasonably accurate for risks less than 10^{-2}. This assessment uses the simplified SF * LADD form of this equation since the exposures and risks demonstrated are generally less than 10^{-3}. The slope factor, SF, for 2,3,7,8-TCDD has been previously estimated by EPA as $1.56*10^{5}$ $[mg/kg\text{-}day]^{-1}$ (EPA, 1984; 1981), but has been reevaluated as $1.0*10^{6}$ $[mg/kg\text{-}day]^{-1}$ in this Reassessment. Also, it has been recommended in the Risk Characterization that it be applied to a TEQ dose, in addition to a 2,3,7,8-TCDD dose. As detailed in the Risk Characterization, a current estimate of lifetime cancer risk from background exposures to dioxin-like compounds is about 10^{-3}. This is calculated simply as the background exposure dose of 1 pg WHO_{98}- TEQ_{DFP}/kg-day times the slope factor of $1*10^{-3}$ (converted to [pg WHO_{98}-TEQ_{DFP}/kg-day]$^{-1}$ to be consistent with the dose units).

Similar to the estimation of lifetime cancer risk demonstrated above showing a risk of 10^{-3} due to background exposure to dioxin-like compounds, assessors can also estimate the incremental cancer risk in these probability terms. The LADD of Equation (2-6) would simply be $LADD_{ss}$. These LADDs can be for individual exposure pathways assessed, or all exposure pathways combined.

When using Equation (2-6) for estimating incremental cancer risk, the assessor needs to be aware that adjustments may be required for particular pathways. Adjustments are necessary for the soil-related pathways, soil ingestion and soil dermal contact. The selected cancer slope factor was based primarily on the analysis of the human epidemiology studies where exposure was estimated from dioxin concentrations in blood in occupationally exposed cohorts. The dose estimates used to derive the slope factor were obtained by using a pharmacokinetic model to convert the blood concentrations to an administered, or potential, dose. An administered dose is defined as the dose which contacts the body boundary surfaces, such as the skin as in dermal exposure or the dose ingested prior to absorption. This administered dose was derived by first calculating an absorbed dose and then dividing by 0.8 - i.e., an absorbed dose was assumed to be 80% of an administered dose. Because the slope factor was derived based on an administered

dose, the new slope factor can be applied to an administered dose without any adjustment for absorption as long as the absorption is approximately 80%. Although the data are limited, this is probably a reasonable assumption for most types of food ingestion and inhalation.

The absorption from ingested soil or dermal exposure from soil, however, is likely to be less than 80%. Studies have shown that the bioavailability of dioxin from ingested soil is variable depending on properties such as organic carbon content and is best determined on a site specific basis. A full discussion on absorption of administered dioxin through the various pathways can be found in *Chapter 1. Disposition and Pharmacokinetics*, of the Health Document (Part II of these Dioxin Reassessment Documents). Assuming that 30% of dioxin in ingested soil is absorbed, then the slope factor should be multiplied by 30/80 or 0.375 before combining it with the ingested dose to compute risk. For the soil dermal pathway, the absorption of dioxin through the skin has been estimated to range from 0.5 to 3.0% (EPA, 1992a), with assessments typically (conservatively) assuming 3.0%. This assessment adopts the 3% value to calculate the dose of dioxins absorbed through soil dermal contact. As will be described below, this absorption fraction is already considered in the calculation of dioxin dose through soil dermal contact, and the calculated dose is already an absorbed dose. As such, the correction factor is a little different for soil dermal contact - its purpose is to convert a 100% absorbed dose into a dose comparable to other administered doses to which the SF is applied. Specifically, it needs to be adjusted downward to be equivalent to, for example, an inhaled administered dose which is 100% as calculated by the procedures here, but it only 80% (or thereabouts) when absorbed. Therefore, the dermal dose, needs to be adjusted upward by a factor of 1.00/0.8, or 1.25, to be used with the SF. The adjustments for the soil pathways to estimate cancer risk are given as:

$$R_s = SF\ LADD_s\ AF_s \qquad (2\text{-}7)$$

where:

	R_s	=	lifetime excess cancer risk from soil pathways, ingestion and dermal contact
	SF	=	cancer slope factor, $(mg/kg\text{-}day)^{-1}$
	$LADD_s$	=	administered dose from soil ingestion and soil dermal contact, mg/kg-day
	AF_s	=	absorption correction factor for the soil pathways, 0.375 for soil ingestion and 1.25 for soil dermal contact

An assessor can easily apply the IOB concept for cancer risk: simply divide the incremental cancer risk by an appropriate background cancer risk, and then multiply by 100% As noted above and discussed in the Risk Characterization, the current average background cancer risk is 10^{-3}. One can use this national average cancer risk estimate or derive a site-specific background cancer risk by determining a site-specific LADD and multiplying it by the slope factor. For example, if the incremental cancer risk is 10^{-5}, and the national background cancer risk of 10^{-3} is used, then the IOB for cancer risk is estimated as 1%.

2.3.4. Interpretation of Cancer and Non-Cancer Risk Assessment Results for Dioxins

Chapter 5 will demonstrate the procedures for estimating incremental cancer risk and for characterizing non-cancer risk for dioxin-like compounds using the IOB approach. This demonstration will include generation of site-specific background estimates of dose and body burden that are distinct from the national averages above, and the generation of the IOB and incremental cancer risk estimates. However, no interpretations for these results will be provided. Interpretations of risk assessment results is where risk management takes over, and it is beyond the scope of this document to provide risk management guidance for assessing incremental impacts of the dioxin-like compounds from specific sources of release.

Still, some general comments can be provided here as background. For cancer risk for compounds other than the dioxin-like compounds, EPA has based regulatory actions on a wide spectrum of levels, generally in the range of 10^{-6} to 10^{-4} lifetime cancer risk. Estimated lifetime individual risks below 10^{-6} have rarely been found to be sufficient basis for action, while in most cases levels above 10^{-4} result in some form of action, although not necessarily regulation. As described above, the current background cancer risk from exposure to dioxin-like compounds is at 10^{-3}. In performing a site-specific assessment for a specific source of dioxin release, an assessor should assume that an individual's exposure and resulting lifetime cancer risk to dioxin-like compounds are already at 10^{-3} (or a different site-specific lifetime cancer risk) and that the source adds to this impact. For example, if assessing impacts to farmers who live near an incinerator and consume a portion of their agricultural produce, it must be assumed that their produce has dioxin concentrations already at background levels and that the incinerator emissions add to this concentration. The challenge for risk managers in such a circumstance is to determine what level of incremental lifetime cancer risk posed by the specific source warrants concern, when the background lifetime cancer risk is already at a level near where, for other

contaminants and other circumstances, EPA has historically judged that some form of action may be warranted.

Similar issues arise when trying to put the site-specific IOB in perspective. As discussed above, the MOE for background exposures for non-cancer effects is already in a range (<10) that is of concern. An incremental exposure will decrease this margin.

In both cancer and non-cancer risk assessment, therefore, traditional rules-of-thumb may not be of immediate use to the risk assessor, because background levels translate to concern as defined by traditional Agency methods. The Risk Characterization recognizes the difficulty posed by this circumstance, and suggests that the Agency take a broad, long-term view of dioxin risk management:

> *In this case, a strategy might be to bring average "background" exposures down and to also focus on larger incremental exposures or highly susceptible populations. This would be a strategy that would parallel the Agency's approach to control lead exposures. Other parallel science and management issues between dioxin-like compounds and lead are under discussion within the Agency. Providing guidance on the how to judge the significance of incremental increases to background using the MOE approach is beyond the science scope of the reassessment and will have to be addressed elsewhere by EPA.*

2.4. THE TOXIC EQUIVALENCY PROCEDURE

Assessments very rarely focus on 2,3,7,8-TCDD alone, but rather on the suite of 17 dioxin and furan dioxin-like congeners, and also the 12 dioxin-like coplanar PCBs. Chapter 1 describes the "toxicity equivalency factor", or TEF, approach to handling mixtures of dioxin-like compounds. The TEF for a congener of interest is a measure of the potency of that congener divided by the potency of 2,3,7,8-TCDD. As shown in Table 1-1 in Chapter 1, the TEFs for 2,3,7,8-TCDD and 1,2,3,7,8-PCDD are 1 and all other dioxin-like compounds have TEFs less than 1. The combined risk resulting from exposure to a mixture of dioxin-like compounds can be computed using the TEFs and assuming that the risks are additive. This assessment recommends that assessors model the fate of all the congeners individually until the estimate of the exposure media concentration is made. At that point, the Toxic Equivalent exposure media concentration, C_{TEQ}, can be calculated as:

$$C_{TEQ} = \Sigma\ TEF_i\ C_i \qquad (2\text{-}8)$$

where C_i is the concentration of the individual congener. LADDs and ADDs can then be estimated for a TEQ concentration. Cancer risk on a TEQ basis can be assessed using the q_1^* for 2,3,7,8-TCDD in combination with the TEQ-based LADD. Non-cancer risk procedures are similarly driven by TEQ body burdens or increments above background.

2.5. PROCEDURE FOR ESTIMATING EXPOSURE

Section 2.2 described the exposure equation as it applies to dioxin and dioxin-like compounds. Before making exposure estimates, the assessor needs to gain a more complete understanding of the exposure setting and be prepared to estimate exposure media concentrations. The purpose of this section is to provide guidance for the procedures followed in this assessment to define such settings and estimate exposure media concentrations. The approach used here is termed the exposure scenario approach. Brief descriptions of the steps and associated document chapters are presented below.

Step 1. Identify Source

Three principal sources are addressed in this document. The first, identified as "soil contamination", is called a source in that the starting point of the assessment is a bounded area of soil contamination. Of course, the ultimate source for soil contamination is some unidentified cause for the soil to become contaminated. For exposure and risk assessment purposes, the cause for contamination is not relevant except to assume that the cause is not ongoing and that the impact of the "initial" levels is what is being evaluated. For contaminated soils, exposures could occur on the site of contamination or distant from the site of contamination. Examples of on-site exposures include exposures to workers on Superfund or similar sites, or special circumstances such as Times Beach where residential properties become contaminated. A common example of an off-site impact would be impacts to residents who live near a Superfund (or similar) site whose property becomes contaminated due to erosion and whose air contains elevated levels of the contaminant due to dust erosion or volatilization followed by atmospheric transport. The second principal source is called "stack emissions." Unlike the soil source, the contamination is assumed to be on-going. Stack emissions in particulate form are assumed to deposit onto the soil and vegetation at the site of exposure, and emissions in vapor form result in air-borne concentrations which transfer into vegetation at sites of exposure. It is noted that individuals working at the site where stack emissions occur are also exposed. The procedures in this document only apply to residents who are not associated with the site where stack emissions occur. The third principal source is called "effluent discharges". Such discharges represent point

source inputs to surface water bodies. Like the stack emission source, impacts to surface water bodies are assumed to be ongoing during the period of exposure. Unlike either of the above two sources, only the impacts to water and fish are considered for this source category.

Step 2. Estimate Release Rates

Estimating the release of contaminants from the initial source is the first step towards estimating the concentration in the exposure media. Releases from soil contamination include volatilization, and wind and soil erosion. Chapter 4 on estimating exposure media concentrations describes fate and transport modeling procedures for estimating soil releases. Stack emissions and effluent discharges are point source releases into the environment. Background on stack emissions including details on modeling from the stack to a site of exposure are provided in Chapter 3.

Step 3. Estimate Exposure Point Concentrations

Contaminants released from soils, emitted from stacks, or discharged into surface waters move through the environment to points where human exposure may occur. Contaminated soil that is near but not at the site of exposure is assumed to slowly erode and contaminate the exposure site soil, but to a level lower than the level at the contaminated site. The only time when the source concentrations equal the exposure concentrations is for the soil pathways, soil ingestion and dermal contact, when the soil contamination is at the site of exposure. Chapter 3 describes the use of the ISCST3 Model to estimate dispersion of stack plumes to predict air-borne concentrations at the site of exposure as well as deposition rates of dioxins sorbed to stack emitted particulates. Chapter 4 describes how soil and vegetation concentrations are estimated given contaminant concentrations and deposition rates, and also how release rates from soil initially contaminated translate to exposure point concentrations. Chapter 4 also describes a simple dilution model which translates effluent discharges into surface water and fish tissue concentrations.

Step 4. Characterize Exposed Individuals and Exposure Patterns

The patterns of exposure are described in Sections 2.6 and 2.7 of this Chapter. Exposed individuals in the scenarios of this assessment are individuals who are exposed in their home environments. They are adult residents who also recreationally fish, have a home garden, farm, and are children ages 2-6 for the soil ingestion pathway. Each of these pathways is evaluated separately. Although it is unlikely that individuals would experience all of these pathways

simultaneously, quite often exposure assessments do add exposures across pathways. In this document, the doses across pathways are added. Exposure pathways evaluated, which have generally been alluded to in discussions above, include inhalation, ingestion, and soil dermal contact. Each pathway has the set of parameters including contact rates, contact fractions, body weights, and lifetime. These parameters were defined earlier in Section 2.2.

Step 5. Put It Together in Terms of Exposure Scenarios

A common framework for assessing exposure is with the use of "settings" and "scenarios." Settings are the physical aspects of an exposure area and the scenario characterizes the behavior of the population in the setting and determines the severity of the exposure. A wide range of exposures are possible depending on behavior pattern assumptions. An exposure scenario framework offers the opportunity to vary any number of assumptions and parameters to demonstrate the impact of changes to exposure and risk estimates. Exposure estimates for six example scenarios are demonstrated in Chapter 5.

Step 6. Estimate Exposure and Risk

Section 2.2 described the basic equation that estimates exposure for every assumed pathway in an exposure scenario. Chapter 5 demonstrates the methodology on six example scenarios, which includes the generation of exposure estimates for ten different exposure pathways and the suite of 17 dioxins and furans, and one dioxin-like PCB.

Step 7. Assess Uncertainty

Chapter 7 provides a discussion on model validation and provides several exercises where the models of this assessment were validated with real world data. Chapter 8 addresses the issue of uncertainty more generally, identifying possible sources of uncertainty associated with this methodology. These uncertainties should be considered when applying this procedures to a particular site. Chapter 6 on User Considerations includes discussions on other pertinent topics such as sensitivity of model results to parameter selection, and judgements on use of the parameters selected for the demonstration scenarios for other applications.

2.6. STRATEGY FOR DEVISING EXPOSURE SCENARIOS

EPA (1992b) states, "In exposure scenario evaluation, the assessor attempts to determine the concentrations of chemicals in a medium or location and link this information with the time that individuals or populations contact the chemical. The set of assumptions about how this

contact takes place is an exposure scenario." These assumptions can be made many different ways producing a wide variety of scenarios and associated exposure levels. The number of people exposed at different levels form a distribution of exposures. Ideally, assessors would develop this entire distribution to fully describe the exposed population. Such distributions could be defined using Monte Carlo techniques if sufficient input data are available. However, as discussed in Section 2.1 above, generic issues surrounding use of Monte Carlo are not evaluated here. Discussions of how other assessors have applied Monte Carlo to problems involving dioxin-like compounds are presented in Chapter 8. Since the necessary information for developing a population distribution is rarely available, EPA (1992b) recommends developing a central and high end scenario to provide some idea of the possible range of exposure levels. Since that set of guidelines, an additional set of guidelines had been developed (Browner, 1995) which reaffirms this recommendation for central and high end risk descriptors, and adds other recommendation to identify “highly susceptible” or “highly exposed” subpopulations. There have also been instances where an EPA program office has provided guidelines which specify, almost in cookbook fashion, the make-up of exposure scenarios for evaluating a source. EPA’s Office of Solid Waste and Emergency Response provided such guidance for evaluation of hazardous waste incinerators (EPA, 1994b). US EPA’s Region 6 has more recently published similar guidance for hazardous waste incinerators (EPA, 1998).

This section will illustrate the concept of central and high end scenario development as it could be applied to specific sources of release of the dioxin-like compounds. In addition, this section identifies the exposure pathways which are relevant to these compounds, and provides background and justification for the exposure parameters which were selected for the demonstrations in Chapter 5.

For any physical setting, a wide variety of exposure scenarios are possible. The range of exposure levels results from a number of different factors including individual behavior patterns, proximity of individuals to the source of contamination, the fate characteristics of the contaminant, and others. In order to illustrate the possible range, the assessor should try to characterize a central and high end scenario. The general strategy recommended here for defining these scenarios is to first identify and quantify the source of contamination. Next, the assessor should determine the geographic area that is impacted by this source. The contaminant levels are likely to vary widely over this area. Select locations of interest within this area such as the location of the nearest exposed individual or most heavily populated area. For each of these locations, identify behavior patterns which characterize central and high end exposure patterns. Central scenarios correspond to average or median levels and high end scenarios are defined as

levels above the 90th percentile but within the actual range of exposure levels (EPA, 1992b; Browner, 1995).

Statistical data are rarely available to precisely define such scenarios. Instead, judgement is usually required to identify behavior patterns meeting these criteria. For example, most rural areas probably include both farming and nonfarming residents. Farmers who grow or raise a portion of their own food could be selected to represent the high end scenario and those living in typical residential areas could represent the central scenario. Alternatively, if more detail is desired, central and high end scenarios could be defined for both segments of the population, i.e., farmers and residents. For each scenario, determine relevant exposure pathways and assign values for exposure parameters such as contact rate, exposure duration, and so on, which represent a central and/or high end pattern for the type of receptor. Finally, compute the associated exposure level. The resulting range of exposure levels for each location can be used to illustrate the possible range of exposures.

Reference has been made in this chapter to the example scenarios found in Chapter 5, Demonstration of Methodology. Three "source categories", categories of contamination sources described in Chapter 4, are demonstrated in Chapter 5. The stack emission source is assumed to expose a relatively large population in a rural area containing residences and farms. For this source, both central and high end scenarios are defined in the manner outlined above. Specifically, a central scenario is based on typical behavior at a residence and the high end is based on a farm family that raises a portion of its own food. For the soil contamination and effluent discharge sources, only one scenario each will be defined and demonstrated. The soil contamination category will be demonstrated with a high end scenario - a farm is located near the site of contamination. Soil on the farm becomes impacted through the process of soil erosion. Other individuals within a community can also be impacted by a site of high soil contamination. Such individuals would include those visiting or trespassing on the site, volatilized residues can reach their residences, they may obtain water and fish from a nearby impacted water body, and so on. As such, alternate scenarios demonstrating the impact of a site of soil contamination could be developed. For the sake of brevity, and also considering that those residing nearest the contaminated are most impacted, only a high end scenario is developed for the soil contamination source category. The effluent discharge source category is unique in that only the pathways of water ingestion and fish ingestion are considered. For this category, fish and water ingestion patterns will be those adopted for the central scenarios. Again, other patterns of fish and water ingestion could be evaluated for this source category. As a matter of brevity again, only central patterns of behavior with regard to fish and water ingestion are demonstrated.

Two other scenarios, a central and a high end scenario, will be developed for "background" conditions. In this special circumstance demonstrated in Chapter 5, a unique point source such as a tall stack or an effluent pipe, or diffuse source in the case of a large area of soil contamination, is not considered. Rather, all the soil in a hypothetical setting contains dioxins at background levels. Similarly, the air concentration in the hypothetical setting will be initialized to background levels of dioxins. This demonstration will use fate and transport algorithms that have been developed for both the soil contamination source category as well as the stack emission source category. Further details of this structure are described in Chapter 5.

Finally, Chapter 5 will demonstrate some of the pathways outside the scenario structure. These include the chicken and the egg ingestion pathways. These were not included in the central or high scenario because it seems somewhat unlikely to assume that individuals living on farms in rural settings would generate quantities of several food items simultaneously on the farm or homestead. In a real setting, it may be plausible that there are farmers who raise cattle and use a portion of their stock to supply the family with beef and/or milk, farms or residences where chickens are raised that provide the family with eggs and/or chickens, and so on, but it is unlikely that a single farm would raise two or more distinct food animals. Also, if a farm is producing foods that are consumed locally, than a high end scenario could be comprised of individuals who don't live on farms but who do consume local foods. In this document, the high end scenario is defined as a farm raising only one type of terrestrial animal which is used to supply the family with terrestrial animal food products; specifically, the farm family raises cattle and consumes beef and milk from their own stock.

The methodologies used to estimate exposure media concentrations are described in Chapter 4 as screening level in their technical sophistication, but site specific in their application. Defining populations that are typical of central and/or high end exposures is clearly a site specific exercise. Assessors need to make the kinds of assumptions discussed here for their own source and populations of concern. Many acceptable ways could be used to define central and high end scenarios. The approach used here was done for demonstration purposes only. On the other hand, the example scenarios in Chapter 5 were carefully crafted to be plausible and meaningful, considering key factors such as source strength, fate and transport parameterization, exposure parameters, and selection of exposure pathways.

Key source strength terms were carefully developed and defined. These include soil concentrations, effluent discharge rates, and stack emission rates. For the demonstration of the soil contamination category, for example, the concentration of 2,3,7,8-TCDD and two other example compounds were set at 1 ppb, which was a typical concentration of 2,3,7,8-TCDD

found in Superfund-like sites studied in the National Dioxin Study (EPA, 1987). Concentrations in soil in the demonstration of background conditions were characterized as typical of background levels and were based on concentrations found in rural settings. Researchers investigating concentrations of 2,3,7,8-TCDD in "background" or "rural" settings have typically found it in the ppt range or not detected it (with a detection limit generally less than 1 ppt), which contrasts the 1 ppb assumed for 2,3,7,8-TCDD in the demonstration of the soil contamination source category. Introductory sections of Chapter 5 provide a more complete description of the example scenarios.

2.7. EXPOSURE PATHWAYS AND PARAMETERS

The dioxin-like compounds have been found primarily in air, soil, sediment and biota and to a lesser extent in water. Thus, the most likely exposure pathways are:

- Ingestion of soil, water, terrestrial animal food products (beef, pork, chicken, eggs, dairy products), fish, fruit, and vegetables
- Dermal contact with soil
- Inhalation of particulates and vapors.

The following sections describe the selection of central and high end exposure parameters for these pathways. Table 2-1 summarizes all the exposure parameters selected to represent the central and high end demonstration scenarios of Chapter 5.

2.7.1. Soil Related Exposures

The two soil related exposures which will be demonstrated in this assessment include a childhood pattern of soil ingestion and an adult pattern of soil dermal contact. The soil ingestion pathway will involve the assignment of central and high ingestion quantities in units of mg/day and it will assume a child body weight of 17 kg. This contrasts the food pathways described below in Section 2.7.4, where the contact rate is defined in units of g/kg/day. Parameters for the soil dermal contact pathway were developed using the Exposure Factors Handbook (EPA, 1997a). Further details on this pathway can be found in EPA's Dermal Exposure Assessment: Principals and Applications (EPA, 1992a).

2.7.1.1. *Soil Ingestion*

Soil ingestion occurs commonly among children during activities such as mouthing of toys and other objects, nonsanitary eating habits, and inadvertent hand-to-mouth transfers. In addition to normal soil ingestion activities, some individuals exhibit behavior known as pica

which involves intentional soil ingestion. Soil ingestion rates associated with pica are probably much higher. Very limited values for pica patterns have been reported in the literature. Based on some limited data, EPA (1997a) reports that a 5 to 10 g/day for deliberate soil ingestion rates for children may not be unreasonable. This dioxin assessment considers only normal soil ingestion among children.

To a lesser extent, soil ingestion also occurs among adults from activities such as hand-to-mouth transfer when eating sandwiches or smoking. However, the data to estimate the adult rate of soil ingestion is scarce. EPA (1997a) notes that the data available on adult soil ingestion is consistent with a 50 mg/day assumption often used by EPA program offices to model this pathway. Adult soil ingestion is not demonstrated in this assessment. Paustenbach (1987) and Sheenan et al. (1991) have suggested calculating exposures for this pathway (as well as dermal contact and inhalation) separately over three to four age periods to reflect major changes in body weight, surface area and inhalation rates. In general, exposure assessments can be refined by estimating exposures separately over each year of age that is of interest and summing to get the total. Age specific data for body weight, surface area and inhalation rate are presented in EPA (1989, 1992b, and 1997a). These procedures are not presented here, but readers interested in refining exposure estimates are encouraged to check the above references for further guidance.

Based on the review of literature, EPA (1997a) suggests that a child soil ingestion rate of 100 mg/day appears to represent a central estimate of the mean for children under 6 years old. This value will be adopted for the central scenarios. Of the studies which were considered appropriate in EPA (1997a), upper percentile values ranged from 106 mg/day to 1,432 mg/day with an average of 383 mg/day for soil ingestion and 587 mg/day for soil and dust ingestion. On this basis, a value of 600 mg/day will be used for the high end exposure.

In cooler climates where the children may have little exposure to outdoor soils for a significant portion of time, it may be appropriate to develop a time-weighted average daily soil ingestion rate based on indoor and outdoor behaviors. Hawley (1985), for example, assumed that young children ingest 100 mg of housedust per day while spending all their time indoors during the winter months, that they ingest 250 mg/day while playing outdoors during the summer months, and that they ingest 50 mg/day while playing indoors during the summer. His time-weighted annual average, considering this different summer and winter patterns, was calculated at 150 mg/day.

For the soil ingestion pathway, contact fraction refers to the portion of ingestion soil which is contaminated. For the residential setting, the assumption is made here that all soil ingestion by children occurs in and around the home, and that all the soil at the home is

contaminated. Thus, a value of 1 has been adopted in the example scenarios presented in Chapter 5. In situations where the contaminated area is located remote from where children live, and children have some access to these areas (if the areas are parks or playgrounds, e.g.), lower fractions would be appropriate.

Another issue for the soil ingestion, and the soil dermal contact pathway discussed below, is the concentration of dioxin-like compounds to which individuals are exposed. As described later in Chapter 4, two "source categories" discussed in this document include stack emission sources and off-site soil contamination (i.e., a site of soil contamination distant from the site of exposure). Dioxins arrive at the site of exposure either from the air, as in the stack emission source, or via overland erosion, as in the off-site soil contamination scenario. Residues of dioxin mix into either a shallow (2 cm) depth of soil which is "untilled", or a 20-cm depth which is "tilled" (by gardening or farming). Obviously, tilled concentrations are lower than untilled concentrations. Given that ingestion is only modeled for children who are likely not too heavily involved in gardening or farming, it is assumed that their contact is with untilled soils, and the higher concentration associated with these soils is used.

2.7.1.2. *Soil Dermal Contact*

The total annual dermal contact to soil alone, expressed in mg/yr, is the product of three terms: the contact rate per soil contact event, the surface area of contact, and the number of dermal contact events per year. The soil contact rate is also known as the soil adherence rate to reflect that it is not only the amount of soil contacted, but the amount of contact that adheres. Current guidance in the Exposure Factors Handbook (EPA, 1997a) suggest that soil dermal exposure can be divided into components for indoor and outdoor exposures; for indoor exposures, the medium might be better described as "indoor dust", and for outdoor exposures, the medium would be soil. The adherence rate is also a function of the body part - with hands usually having the highest adherence, with other exposed parts such as arms and legs usually having lower adherences. The Exposure Factors Handbook provides details on these factors. A summary pertinent to the applications demonstrated here is:

- Contact rate: <0.002 to >20 mg/cm^2-event. The very high adherence rates were found for the scenario described as, "kids-in-mud", and was from data on children playing by a lakeshore. The lower range was found for an indoor Tae Kwon Do setting. Adherences for a day-care setting ranged from 0.03 for arms and legs to

0.1 for hands. Outdoor adherences for gardeners ranged from 0.005 for legs to 0.02 for arms to 0.2 for hands.

- Body surface area: Average adult and child body surface areas are in the neighborhood of 20,000 and 6500 cm^2 (for a child ages 2-5). The selection of the surface area considered for a dermal contact event depends on the nature of the event and the assumptions about which part(s) of the body are involved in that event. For a child ages 2-5, hands comprise about 5.5% of total body surface area, arms about 13%, and legs about 25%. For adults, hands are similarly about 5%, arms are about 13%, and legs about 32%.
- Event frequency: This is a factor more based on exposure assessment judgement, rather than data, as in the above two factors. Obviously, climate, activity, age, and similar factors play into assignment of this parameter. This factor can be expressed in terms of events per time period, usually events/yr. For consistency in use in the exposure equation, it is usually transformed to an event/day basis.

All other pathways assessed here estimate an "administered" or "potential" dose, which is defined as the dose which comes in contact with the body. For this pathway, however, an "absorbed" dose will be estimated. This is because for all other pathways, a significant amount of the dose that comes in contact with the body is absorbed - about 80% for the inhalation and ingestion pathways (except for soil ingestion, when the fraction absorbed is more like 30%). An absorption fraction, or AF, is added in the calculation of a LADD for the dermal contact pathway. EPA (1992a) reviews the data to conclude that the absorption of dioxin through the skin has been estimated to range from 0.5 to 3.0%. This document will adopt the conservative estimate of 3.0%, or an AF of 0.03, to give the following for LADD for the soil dermal contact pathway:

$$LADD_{dc} = \frac{C_s \; CR \; SA \; EF \; AF \; ED \; 10^{-6}}{AT \; BW} \qquad (2\text{-}9)$$

where:

$LADD_{dc}$	=	lifetime average daily dose due to soil dermal contact, mg/kg-day
C_s	=	concentration in soil, mg/kg
CR	=	contact, or adherence, rate, mg/cm^2-event
SA	=	surface area of contact, cm^2

EF	=	event frequency, events/day
AF	=	absorption fraction, 0.03
ED	=	exposure duration, yr
AT	=	averaging time, 70 yr for LADD
BW	=	body weight, kg
10^{-6}	=	units conversion factor, kg/mg

In this document, soil dermal contact exposures are demonstrated only for an adult for a "gardening" central tendency pathway and a "farming" high end pathway. Indoor activities for both the central and high end scenarios will assume Tae Kwon do-like activities which translate to a contact rate of 0.005 mg/cm^2-event, with dermal contact only with the hands which translates to 1,000 cm^2 (20,000 cm^2 total surface area * 5% surface area for hands) and 1 event per day (or 365 times per year). Outdoor dermal contact will be modeled on a gardening scenario for the central scenarios and a farming scenario for the high end pathways. The gardening scenarios assume 0.03 mg/cm^2 for contact rate, 10,000 cm^2 surface area contact which assumes hands, arms, and legs, and 0.27 events/day (or 100 events/yr). In comparison to outdoor gardening, the farming scenario assumes a greater adherence at 0.1 mg/cm^2, a smaller surface area of 3600 cm^2 which assumes hands and arms only, more frequent events at 0.96 events/day (or 350 events per year).

Another difference between indoor and outdoor activities in this assessment is the concentration to which the individuals are exposed. As described in the previous section on soil ingestion, tilled (lower in concentration) and untilled (higher) soil concentrations are derived for the stack emission and off-site soil contamination sources. In this assessment, outdoor dermal contact events are assumed to occur in association with tilled soils (gardening or farming), while indoor contact events are assumed to occur in association with untilled soils.

2.7.2. Vapor and Dust Inhalation

EPA (1997a) describes the derivation of ventilation rates, which include assumptions regarding number of hours in sleep, hours inactive, and hours in various levels of activity. Several inhalation studies are reviewed. The final recommendation for continuous exposure assessments in which specific activity patterns are not known is 13.3 m^3/day based on Layton (1993). A rate of 13.0 m^3/day (rounded for simplicity) will be adopted in this assessment. EPA (1997a) suggests that a value of 20 m^3/day represents an upper percentile estimate among adults, and this will be adopted in this assessment as a high end.

The contact fraction for this pathway is equal to the fraction of total inhaled air which is contaminated. Thus it relates largely to percent of time spent in the contaminated area. For the demonstration scenarios in Chapter 5, the contaminated area is the home environment. Therefore, information on the time spent at home versus away from home is pertinent. In EPA (1997a), several activity pattern studies are reviewed. Two of the studies reviewed contained information on time spent at home and away from home, and both studies had very similar results for time spent in the home environment. Robinson and Thomas (1991) reviewed and compared data from the 1987-88 California Air Resources Board (CARB) time activity study with a similar 1985 national study titled, "American's Use of Time." In an average day comprising 1440 minutes, Robinson and Thomas (1991) found an average of 954 minutes at home from the national study, or 66% of the time, compared to 892 minutes (62%) for Californians. Sexton and Ryan (1987) reviewed the procedures for assessing inhalation exposures, and in so doing, reviewed two previous studies on time use including information on time at home and away from home. One study showed 69% of the time at home and the second study showed 71%. Based on these, a central estimate for the fraction of time spent at home will be 70%.

EPA (1997a) did not make specific recommendations for a high end contact fraction. Such a fraction should be relevant to the population defined as high end, which in this assessment is a subsistence farm. It seems reasonable to assume that a rural farming family may have more time at home as compared to the general population. Without rigorous justification, a high end contact fraction will be assumed to be 90%.

The two key parameters discussed above, contact rate and contact fraction, when multiplied together, will yield a contact rate for contact with the contaminated media. For the central scenario, the two key quantities are 13.0 m^3/day and 0.70, which yield a contact rate with impacted air of 9.1. For the high end scenario, this calculation is 20.0 m^3/day times 0.90, which is 18 m^3/day. Therefore, the difference between central and high end from behavior assumptions alone is about a factor of two.

An additional assumption needs to be made for the vapor and dust inhalation pathways. This pertains to an assumption concerning the differences in air quality between indoor and outdoor conditions. Algorithms for both particulate and vapor-phase air-borne concentrations of contaminants are specific to outdoor air. Hawley (1985) assumed, based on several other studies in which measurements were made, that the concentration of suspended particulate matter in indoor air is equal to 75% of that outside. Also, his report stated that most household dust is outdoor dust that is transported into the house, and that only a small percentage is developed

from sources within. He then concluded that 80% of the indoor dust is identical in contaminant content to outdoor soil. Refinements to the concentration of contaminants on indoor versus outdoor dust should have a minor effect on exposure estimates. A similar trend is assumed for air-borne vapor phase concentrations. For this reason, differences between indoor and outdoor concentrations are not specifically considered, or equivalently, no distinctions are made for outdoor and indoor air quality.

2.7.3. Water Ingestion

The water ingestion rate of 2 L/day has been traditionally assumed for exposure through drinking water. However, EPA (1997a), after review of several literature sources, concludes that 2 L/day may be more appropriately described as a 84% value, or a value for high end exposure estimates (the 90% value was actually calculated to be 2.34 L/day). For this reason, a water ingestion rate of 2 L/day is assumed only for the high end exposure estimates. Since the high end scenario includes a farm and the farming family, it is also argued that farm labor requirements justify the higher rate of water ingestion. EPA (1997a) recommends a rate of 1.4 L/day as representative of average adult tap water drinking water consumption. This is the rate used for central scenarios in Chapter 5. The difference in central and high end tendencies is also modeled using the contact fraction. Again, this fraction is based on the time spent at home. The value of 0.70 is used to model the central estimate, for the residence setting, and the value of 0.90 is used to model the high end estimate, for the farm setting.

2.7.4. Ingestion of Terrestrial Food Products

This section discusses the consumption rates used in the beef, dairy, chicken, eggs, and vegetables/fruits ingestion pathways. All these pathways are similar in that the food products originate from the land. The high end demonstration scenario in Chapter 5 is a farming family which home produces a portion of its beef consumption. In site-specific assessments, home production of foods is often a scenario of concern, particularly if the home producers are located near the source of contaminant release. An exposure pattern similar to home production/consumption of foods is the consumption of locally produced foods. This would be relevant for individuals who live in a setting where food is produced, a rural setting for example, who do not produce any of their own food but who rely on local foods, such as from farmer's markets.

In order to estimate the contact rates for consumption of home produced foods, analysis of the USDA National Food Consumption Survey (abbreviated NFCS; USDA, 1992) of 1987-88 as

conducted in EPA (1997a) will be used in this dioxin exposure reassessment. Specifically, EPA (1997a) used the household component of this survey. This component collects information over a 7-day period on the socioeconomic and demographic characteristics of households, and the types, values, and sources of foods consumed. Like the use of any survey data, use of this data must be understood by users. EPA (1997a) took from the household survey this information: 1) whether or not the food product was used in the house that week, 2) whether or not the food product used that week was home produced, 3) the quantity (mass, such as pounds or kilograms) of food consumed (home produced or not) in the house that week, 4) the number, age, and body weight of individuals in the household, and 5) the number of weekly meals consumed by each family member. If the household reported consumption that week, than EPA could calculate an individual consumption rate for "consumers only". To do this, EPA (1997a) then assumed that all individuals in the household consumed some of the product, and the amount of individual consumption was based on average serving sizes for each individual (different as a function of the age of the individual) and number of meals consumed by each individual. Then, dividing by 7 (as in days of the week) and the body weights of the individuals, they derived consumer only consumption rates in terms of g/kg/d.

EPA (1997a) also looked at a second major USDA food consumption survey - the Continuing Survey of Food Intakes by Individuals (CSFII). This measured the food consumption patterns of all individuals throughout a 3-day period, whether the food was eaten at home or not, and did not have questions on home production practices. EPA (1997a) used this survey to derive general population per capita consumption rates (see next paragraph for definition of per capita).

In order to understand how the EPA (1997a) analysis of USDA data was used for this dioxin exposure document, it is important first to understand three types of generic food consumption rates: *1) Per Capita Consumption Rate*: This is an average consumption rate and includes all consumers as well as nonconsumers. *2) Consumption Rate for Consumers Only:* This is the consumption rate calculated only for individuals who report consumption of the food product in question. A per capita consumption rate can be calculated as a product of the consumption rate for consumers only and the ratio of those reporting consumption and all respondents including those who reported consumption plus those who didn't report consumption (or equivalently, reported nonconsumption):

$$C_{pc} = C_{co} \frac{N_c}{N_c + N_{nc}} \qquad (2\text{-}10)$$

where C_{pc} is the per capita consumption rate, C_{co} is the consumer only consumption rate, N_c is the number of consumers, and N_{nc} is the number of non-consumers, and *3) Consumption rates, Per Capita or Consumer Only, for Consumers of Home Produced Products:* Home producers/consumers are a critical subpopulation, as noted earlier. EPA (1997a) was able to estimate consumer only consumption rates for home producers/consumers for a variety of food products from the household survey of the NFCS. These consumer only home producer/consumer rates are used in the demonstrations of Chapter 5.

The use of the consumer only consumption rate for home produced foods from the household survey of the USDA NFCS represents a significant departure from earlier versions of the dioxin exposure reassessments (EPA, 1992c; EPA, 1994a). It is the most appropriate type of rate to use when the scenario is a farm where individuals consume the food they produce - that is precisely what the definition of these rates are. Unlike earlier consumption rates, body weights are not used as the consumption rates are derived over the range of individuals including infants and children. It is also important to note that the consumer only consumption rates for the food products appear significantly higher than other consumption rates generated in EPA (1997a). For example, the general population per capita consumption rate for beef using the CSFII was 0.83 g/kg-day. The consumer only consumption rate for home produced beef was 2.45 g/kg/day. The following describes some of the differences in these two beef ingestion rates, 0.83 and 2.45 g/kg/day:

1) The household survey reports on total food product brought into the household, and this data is used directly for the calculation of consumers only consumption rates in EPA (1997a). Their calculation does not include bone and other wastage, trimmable fat, cooking loss, or uneaten foods. By contrast, intake rates developed from data in the 1-day individual consumption survey are defined “as eaten” meaning that these rates do account for cooking loss, wastage, and uneaten food. As will be described below, cooking and post cooking losses will be accounted for the meat product consumption rates developed from household data. The appropriate factor for beef is calculated to be 0.55. While the household data does not account for cooking and post cooking loss (without the correction introduced below), it does not include food eaten away from home, which could lead to underestimation of total consumption rates.

2) The 0.83 g/kg/day rate derived from the CSFII is a per capita consumption, meaning that it is calculated considering non-consumers as well as consumers. The percent consuming beef,

according to the CSFII, is 91%. Therfore, solving for the consumers only rate, using Equation (2-8) above, is 0.91 g/kg/day (0.83 g/kg/day divided by 0.91).

3) It is likely that home producing consumers - ie., only those who reported eating home produced beef which is what the 2.45 g/kg-day rate is - eat a fair amount of their home-produced beef during the weeks in which they reported this behavior. Other weeks they may also eat beef that was not home produced, but it might be smaller amounts so that their overall consumption rate of meat is likely to be lower than is reflected in these home producing consumers only rates. No data was available in EPA (1997a) to evaluate this speculation, but it seems reasonable (isn't it true that when the tomatoes in the home garden are ripe, the family will eat more fresh salad than usual?).

4) Two other differences between the CSFII and the household component of the NFCS which could lead to over or underestimation of actual behaviors include three-day versus week-long information (unclear which direction this would lead to) and individual recall versus head of household recall (again unclear).

To account for cooking and post cooking losses for the meat products which are home produced, information was obtained from USDA (1975). This data is summarized in Table 2-2.

This assessment uses the home producing consumers only consumption rate for home produced beef, milk, chicken, eggs, vegetables, and fruits. The following section describes how the "contact fraction" for these consumption rates is calculated. As has been defined, this describes the fraction of total food category consumption which is home produced. Following a description of this parameter for the dioxin reassessment, sections will describe the derivation of consumers only consumption rates for the various food products.

2.7.4.1. *Derivation of the Contact Fractions for Beef, Milk, Chicken, Eggs, Vegetables, and Fruits*

The home producer consumer-only consumption rate needs to be adjusted downward by consideration of the contact fraction. The average "consumer only" consumption rate for home producers developed from NFCS data will include weeks where only a little of the product in question is eaten and weeks when much of the product is eaten. Most importantly, however, this calculated "average" will only be an average during which consumption of home produced foods actually occurs. It is probably not reasonable to assume that average consumption weeks occur

52 weeks a year; there will be weeks where no consumption of the home produced product occurs. In other words, the contact fraction, or CF, will be less than 1.00.

Means to assign values to CF for site-specific applications will require judgement on the part of assessors. If localized information is available for a site-specific assessment, this could be used. For example, climate or local agronomic practices could assist in the assignment of a CF. One could assume, for example, that home production of dairy does not occur from December through February (13 weeks), and use this information to reduce the consumers only dairy consumption by 25% (13 weeks/52 weeks); i.e., the CF = 0.75. This assumes that a home producer of dairy products is producing at least some dairy during all weeks between February and December. EPA (1997a) did break out the household consumption survey data into seasons and it is clear that there was less consumption of home-produced food products during the winter as compared to the summer. But what is still true regardless of any refinement of this type is that the consumers only analysis of the USDA household survey is still only a reporting of households which did consume during the week.

EPA (1997a) developed data from the NFCS which will be used to assign values of CF for home produced foods. Based on questionnaire responses, EPA (1997a) was able to determine the fractions of total food intake that is home-produced; that is, of all the food product consumed by respondents in the survey, what fraction of that product was home-produced. For example, 3.8% of all beef consumed is home produced. This 3.8% includes, however, both those who raise cattle and then consume it (actual home producers) and those who took part in the survey, but did not raise any animals. Therefore, this 3.8% is not what is needed for current purposes. What is instead needed is the percentage (or fraction) of total beef consumed by people who raise cattle, that comes from their own stock. This could not be ascertained perfectly from the household survey because there was not this direct a question: “Knowing that you raise cattle, what percent of your home consumption is from your own stock?” Still, there were questions that were asked that are close to this. There was the question, “During the past year (1986), did anyone in the household produce any animal products such as milk, eggs, meat, or poultry for home use in your household?” The households which answered yes to this question form the universe of home producers of animal food products. These individuals were also asked questions about whether they consumed home-produced foods the week of the survey. For beef, 48% of households in this universe of home producers said that they did eat home-produced beef that week, while 52% said they did not. Therefore, 0.48 becomes the contact fraction for beef. Other contact fractions that were ascertained using this intersection of questions include: for diary - 0.21, for poultry - 0.15, and for eggs - 0.21. For fruits and vegetables, the universe of

home producers was ascertained by those who answered yes to the question of whether there was gardening in the household. Responses of yes for consumption that week of the category "exposed vegetables" - 0.233, and "root vegetables" - 0.106, was averaged to yield a 0.17 that is used in this assessment as the CF for vegetables. The CF for fruits in this assessment is 0.12, based on a yes response to consumption that week of home produced "exposed fruits".

2.7.4.2. *Beef Ingestion*

The high end farming scenarios include this pathway for purposes of demonstration. Other terrestrial animal consumption pathways are demonstrated separately. EPA (1997a) calculated a consumers only overall (over all ages and regions of the US) average consumption rate for home produced beef of 2.45 g/kg/day. Applying the CF of 0.478 for beef as described above leads to an average consumption rate for home produced beef of 1.17 g/kg/day. This is further adjusted with the use of a preparation term. As shown in Table 2-2, the percent losses during cooking and after cooking is 27 and 24%, respectively. Therefore, the average consumption rate with these considerations is now estimated as, 1.17 g/kg/day * 0.73 * 0.76 = 0.65 g/kg/day.

Consumption rates of terrestrial animal food products are expressed in terms of fat ingested per day for two reasons. One, dioxin-like compounds tend to partition strongly toward lipids and virtually all of such compounds will be found in the fat portion of animal food products. Two, the algorithms to estimate concentrations in these food products estimated fat concentrations and not whole product concentrations. EPA (1997a) reports that USDA's Agricultural Handbook Number 8 (USDA, 1979-1984) lists the fat content of cooked beef, including lean and fat, as 21.54. This will be rounded to 22% in this assessment. Therefore, the ingestion of beef fat for individuals in the high end farming scenarios of Chapter 5 will be 0.143 g/kg/day (0.65 * 0.22).

2.7.4.3. *Dairy Ingestion*

As noted above, this pathway will be demonstrated in Chapter 5, but outside of any defined scenario. EPA (1997a) calculated a consumers only overall average consumption rate for home produced dairy of 14.0 g/kg/day. Applying the CF of 0.207 for dairy as described above leads to a final long term consumption rate of 2.90 g/kg/day. EPA (1997a) reports that USDA's Agricultural Handbook Number 8 (USDA, 1979-1984) lists the fat content of whole milk of 3.16. This will be rounded to 3% in this assessment. Therefore, the ingestion of dairy fat for this pathway demonstrated in Chapter 5 will be 0.087 g/kg/day.

2.7.4.4. *Chicken Ingestion*

Like the diary ingestion pathway, the chicken ingestion pathway will be demonstrated outside of a defined scenario. Furthermore, it will be assumed that the chickens are allowed to free range. A full discussion of predicting the concentration of dioxins in chickens and eggs, including free range chickens, is given in Chapter 4. EPA (1997a) calculates a consumers only consumption rate for home produced chickens of 1.57 g/kg/day. As described above, a CF of 0.151 will be adopted for home-produced chicken consumption leading to a total of 0.24 g/kg/day. As with beef, a preparation factor will be added, and as seen in Table 2-2, this factor will be equal to 0.70 * 0.70, or 0.49. The final consumption rate for chicken is estimated as 0.12 g/kg/day. EPA (1997a) reports that USDA's Agricultural Handbook Number 8 (USDA, 1979-1984) lists the fat content of meat and skin cooked chicken is 13.6. This will be rounded to 14% in this assessment. Therefore, the ingestion of chicken fat for this pathway demonstrated in Chapter 5 will be 0.010 g/kg/day.

2.7.4.5. *Egg Ingestion*

Like the diary and chicken ingestion pathways, the egg ingestion pathway will be demonstrated outside of a defined scenario. EPA (1997a) calculates a consumers only consumption rate for home produced eggs of 0.73 g/kg/day. As described above, a CF of 0.214 will be adopted for home-produced egg consumption leading to a total of 0.156 g/kg/day. EPA (1997a) reports that USDA's Agricultural Handbook Number 8 (USDA, 1979-1984) lists the fat content of eggs as 8.35%. This will be rounded to 8% in this assessment. This is the fat content of the entire egg, as the fat content of the yolk (which has all the egg fat) is about 30%. Therefore, the ingestion of egg fat for this pathway demonstrated in Chapter 5 will be 0.012 g/kg/day.

2.7.4.6. *Vegetable and Fruit Ingestion*

EPA (1997a) analyzed data from the NFCS household survey to estimate the amount of homegrown "exposed above ground vegetables/fruits" and "root vegetables". Protected vegetables/fruits, as opposed to exposed, were defined as vegetables/fruits which have outer protective coverings which are removed prior to consumption such as peas or oranges. No root vegetables were considered to be protected although, of course, it is common to consume some below ground vegetables such as carrots or potatoes after removal of the skin. The overall consumers only average of home grown fruits, above ground vegetables, and root vegetables was

1.49, 1.52, and 1.16 g/kg/d. These data are in fresh weight. These numbers were somewhat influenced by higher consumption rates for younger children of lesser body weight, as the consumption rate for three age ranges less than 5.0 ranged from 1.28 g/kg/day to 5.75 g/kg/day. The fruit and vegetable pathways will be included in both the central and high end scenarios of Chapter 5, and it will be assumed that the behaviors in the central and high end scenarios do not differ. The CF for both above and below ground vegetables will be 0.173 and for fruit (above ground only) will be 0.101, leading to final fresh weight consumption rates of 0.15 g/kg-day for fruit, 0.26 g/kg-day for above ground vegetables, and 0.20 g/kg-day for below ground vegetables.

2.7.5. Fish Ingestion

The procedure to estimate exposure to fish from consumption of fish caught in recreational pursuit will be different than that of the terrestrial food products. This is done because it is most common in exposure assessments to model exposure to fish in terms of a g/day consumption rate rather than a g/kg/day rate, and a wealth of data in the g/day format has been generated from consumption and creel surveys. Therefore, the LADD equation will be used with a separate consumption rate in g/day and an assumed body weight of 70 kg.

EPA (1997a) extensively reviewed the literature on fish consumption. Their analysis of available surveys led them to make recommendations on studies which they considered valid for generation of fish consumption rates. They also categorized available consumption rates from these surveys into: 1) General Population, 2) Recreational Marine Anglers, 3) Recreational Freshwater Anglers, and 4) Native American Freshwater Anglers.

The demonstration scenarios of Chapter 5 assume a rural setting which includes farms and non-farm residents. Also, it is assumed that a major river system cuts through the watershed which is used for recreational fishing and drinking. It is assumed to be a freshwater system, and therefore, the "recreational freshwater angler" consumption rates will be used in this assessment. Three studies were deemed valid for characterizing recreational freshwater angler consumption rates, and these include the mailed questionnaire studies of Ebert et al. (1993) and West, et al. (1989) and the diary study of Connelly, et al. (1996). The arithmetic mean consumption rate from these four studies are 5, 12, 17, and 5, respectively. The 95th percentile consumption rates from these studies were 13 (Ebert et al, 1993) , 39 (West, et al., 1989), and 18 g/day (from Connelly, et al., 1996). From these data, EPA (1997a) recommended a mean and a 95th percentile value for recreational anglers of 8 and 25 g/day. The central scenarios including a fish consumption pathway will assume the 8 g/day rate. The high end scenarios, which were defined as a subsistence beef farm, will not include a fish consumption pathway. This is done for

demonstration purposes - it certainly is plausible for a farming family to partake in recreational fishing. A high end fish consumption pathway will be demonstrated outside of a scenario, however, as with other pathways. The high end pathway demonstration will use the 25 g/day rate as recommended in EPA (1997a).

It should be noted that these consumption rates are for all recreational freshwater fishers, not only those who consumed the fish they caught. Therefore, they could be underestimates for the purposes here - modeling individuals who consume fish they reacreationally catch. It is also noted that these rates are probably best described as, "as eaten" since the respondents were asked to estimate the weight of the fish they consumed, and assistance the respondents were given (choices, photos, etc.) were based on as consumed weights by those conducting the surveys. Because these rates are, "as eaten", there is no preparation factor required. Finally, it is assumed that the fish is 7% lipid. There were no specific recommendations in EPA (1997a) regarding this factor; there were tables showing the percent fat for various fish species. The 7% value selected appears to be a reasonable mid-range from those tables, and it was also the percent assumed in previous versions of this dioxin exposure assessment (EPA, 1994a).

As a point of comparison, the general population recommended mean consumption rate was 20.1 g/day (14.1 marine fish and 6.0 freshwater/estuarine fish). The 95th percentile recommended rate was 63 g/day. These were described as long term average consumption rates. For a Native American subsistence population, EPA (1997a) recommends a value of 70 g/day for mean intake of fish, and 170 g/day for the 95th percentile intake.

The current Exposure Factors Handbook (EPA, 1997a) and its predecessor (EPA, 1989) both emphasize the importance of obtaining site-specific information on the exposure parameters, not the least of which is the fish consumption rate. For smaller water bodies, EPA (1989) recommends that surveys of local fisherman would obtain the most appropriate fish consumption information. Alternately, EPA (1989) recommends using judgement regarding how many fish meals per year an individual could obtain from the contaminated waters and assuming meal sizes of 100 to 200 g. This was the approach adopted in the earlier draft of the Dioxin Exposure Assessment document (EPA, 1994a). With that approach, it was assumed that a "central" pattern of consumption of fish from an impacted water body led to 3 meals/person/year, and that a "high end" pattern led to 10 fish meals/person/year. With a meal size of 150 g (the current Exposure Factors Handbook recommends a mean fish meal size of 129 g, and a 95th percentile fish meal size of 326 g), this led to consumption rates of 1.2 g/day as the central estimate and 4.1 g/day as the high end estimate.

Table 2-1. Summary of exposure pathway parameters selected for the demonstration scenarios of Chapter 5.

Pathway Description	Contact Rates		Contact Fractions	Comments
Soil Ingestion				Only pathway specific to an age-range; 2 to 6 year-old children assumed. Absorption fraction converts potential to absorbed dose for risk estimation.
Central	100 mg/d		1.0	
High End	600 mg/d		1.0	
Absorption fraction	0.30			
Soil Dermal Contact	Indoor	Outdoor		Unlike other pathways, daily contact is not assumed; approach instead estimates exposure in terms of contact/event * events/yr; central pattern based on behavior of non-farming adults, high end behavior based on farming pattern. Absorption fraction converts potential to absorbed dose for risk estimation.
Central			1.00	
CR, mg/cm^2-ev	0.005	0.03		
SA, cm^2	1,000	10,000		
EF, ev/day	1	0.27	1.00	
High End				
CR, mg/cm^2-ev	0.005	0.1		
SA, cm^2	1,000	3600		
EF, ev/day	1	0.96		
Absorption fraction	0.03	0.03		
Vapor/Dust Inhalation				Indoor/outdoor air quality assumed equal; central contact fraction is based on average at-home time from time use surveys
Central	13 m^3/day		0.70	
High End	20 m^3/day		0.90	
Water Ingestion				The more traditional 2.0 L/day was evaluated in EPA (1995) as an high end rather than a central value; 1.4 L/day recommended instead for central assumptions.
Central	1.4 L/day		0.70	
High End	2.0 L/day		0.90	

Table 2-1. (continued)

Pathway Description	Contact Rates	Contact Fractions	Comments
Terrestrial Food Products	All contact rates for the terrestrial food products, including animal food and vegetable/fruit, will be: 1) expressed in terms of g/kg/day thereby not requiring a 70 kg body assumption in the denominator of the LADD equation, and 2) based on the EPA (1997a) analysis of the household part of the USDA National Food Consumption Survey. Fish consumption will be handled in the more traditional way using a g/day fish consumption rate and an assumption of a 70 kg body weight. Central scenarios include fish pathway and veg/fruit ingestion pathway, but no other terrestrial food production; high end scenarios include beef/dairy and veg/fruit ingestion pathway, but no other food production including fish consumption. Chicken and egg pathways will be demonstrated outside the context of an exposure scenario.		
Beef Fat Ingestion Central High End	 NA 2.45 g whole/kg/d	 NA 0.478	2.45 g whole/kg/d is transformed to g fat/kg/d basis assuming 22% fat; additional factor of 0.55 accounts for cooking and post cooking loss
Milk Fat Ingestion Central High End	 NA 14.0 g whole/kg/d	 NA 0.207	14.0 g whole/kg/d is transformed to g fat/kg/d basis assuming 3% fat
Chicken Fat Ingestion Central High End	 NA 0.97 g whole/kg/d	 NA 0.151	0.97 g whole/kg/d is transformed to g fat/kg/d basis assuming 14% fat; additional factor of 0.49 accounts for cooking and post cooking loss
Egg Fat Ingestion Central High End	 NA 0.73 g whole/kg/d	 NA 0.214	0.73 g whole/kg/d is transformed to g fat/kg/d basis assuming 8% fat
Fruit Ingestion Above ground exp. Central High End	 1.47 g fresh/kg/d 1.47 g fresh/kg/d	 0.101 0.101	Central and high end behaviors assumed for residence and farm scenarios, respectively; difference is modeled with contact fractions only.

Table 2-1. (continued)

Pathway Description	Contact Rates	Contact Fractions	Comments
Vegetable Ingestion			Central and high end behaviors assumed for residence and farm scenarios, respectively; both scenarios assume similar behaviors; differences are in other pathways and parameters.
Above ground exp.			
Central	1.52 g fresh/kg/d	0.173	
High End	1.52 g fresh/kg/d	0.173	
Root vegetables			
Central	1.16 g fresh/kg/d	0.173	
High End	1.16 g fresh/kg/d	0.173	
Fish Ingestion			Based on "freshwater recreational angler surveys". Fat content is assumed to be 7%.
Central	8.0 g/day	1.00	
High End	25.0 g/day	1.00	
Exposure Duration, Body Weight, Lifetime: Based on mobility data (EPA, 1997a), a duration of 9 years was assumed for the central residence scenario, and a high end duration was assumed to be 30 years. The childhood soil ingestion pathway had a duration of 5 years. As noted above, a body weight assumption was not used for terrestrial food product pathways. For all others, a body weight of 70 kg was used except for childhood soil ingestion, which used a 17 kg body weight. In all cases, a 70 year lifetime was assumed.			

Table 2-2. Percent weight losses from preparation of various meats.

Meat Type	Mean Net Cooking Loss (%)[a]	Mean Net Post Cooking Loss (%)[b]
Beef	27	24
Chicken	30	30
Lamb	29	34
Pork	28	36
Turkey	31	28
Veal	30	25

[a] Includes dripping and volatile losses during cooking. Averaged over various cuts and preparation methods.

[b] Includes losses from cutting, shrinkage, excess fat, bones, scraps, and juices. Averaged over various cuts and preparation methods.

3. EVALUATING ATMOSPHERIC RELEASES OF DIOXIN-LIKE COMPOUNDS FROM COMBUSTION SOURCES

3.1. INTRODUCTION

Since the late 1970's, it has become well established that the combustion of certain fuels containing both organic material and chlorides can form polychlorinated dibenzo-p-dioxins (CDDs) and polychlorinated dibenzofurans (CDFs). This discovery has prompted world-wide research to identify combustion sources, to characterize the conditions favoring the formation of CDD/Fs within the combustion process, and to characterize the emission of dioxin-like compounds to the air from the stack of the process.

The purpose of this chapter is to provide site-specific procedures for evaluating the emission of dioxin-like compounds from stationary combustion sources. The first step is to characterize stack emissions in terms of mass of CDD/F congener released, and then to partition that release into a vapor and a particle phase. Using atmospheric transport modeling, these releases are translated to ambient air vapor and particle phase concentrations, and wet and dry particulate deposition amounts, in the vicinity of the release. This chapter demonstrates these procedures on a hypothetical incinerator using an air dispersion model called the Industrial Source Complex 3, or ISC3. The short-term version of that model, ISCST3, is used in this document. A second purpose of this chapter, therefore, is to provide the background and justification for the model inputs and key parameters for ISCST3. The final results for this model simulation are vapor and particle phase concentrations, and particulate deposition amounts of the specific dioxin-like congeners, which are then used for the demonstration of the stack emission source category in Chapter 5 of this Volume.

This chapter is structured as follows:

- Section 3.2 describes the generation of CDD/F congener-specific emission factors. These factors are defined as the mass of congener emitted per mass of feed material combusted. Subsections within Section 3.2 discuss: 1) a hierarchy of preferred options for generating such emission factors, starting with site-specific stack testing for specific congeners and ending with engineering evaluations when no other data is available, 2) an approach to estimating congener-specific emission factors using congener profiles generated for a source when only total dioxin (sum of homologue group CDD and CDF concentrations) emissions are available; 3) an approach for estimating congener-specific emission rates from CDD and CDF homologue group emissions data if congener profiles are not available; 4) the emission factors for the example incinerator demonstrated in Chapter 5, and assuming a feed rate into the example incinerator, emissions expressed on a mass per time basis (which is required for transport modeling), 5)

partitioning of emissions into a vapor and a particle phase for atmospheric transport modeling, and 6) a procedure to estimate the mass released and concentrations for a related emission of a combustor, that of ash.

- Section 3.3 describes a general air modeling procedure for evaluating the fate and transport of dioxin-like compounds emitted from stacks. The discussion presents a general review of dispersion theory, a general review of dry particle deposition, and a general review of the wet deposition algorithm employed in this analysis. EPA's ISCST3 air dispersion and deposition model is reviewed. Wherever pertinent, Section 3.3 describes the assumptions, equations, and parameter values that were used in the demonstration of methodologies in Chapter 5 of this Volume.
- Sections 3.2 and 3.3 summarized input data and assumptions (emission rates, vapor/particle partitioning assumptions, etc.) that were made for the demonstration of the methodologies for evaluating stack emissions in Chapter 5 of this Volume. Section 3.4 supplies all other key assumptions for the stack emission demonstration, such as stack height and exit temperatures, meteorological data, and others. This Section also provides the final results from the ISCST3 modeling, including vapor phase air concentrations at various distances in the predominant wind direction, and dry and wet deposition fluxes, also at various distances in the predominant wind direction.
- Section 3.5 closes out the chapter by summarizing critical aspects for making site specific evaluations of stack emission sources.

3.2. ESTIMATING THE EMISSIONS OF DIOXIN-LIKE COMPOUNDS FROM ANTHROPOGENIC COMBUSTION SOURCES

Estimating the emission factor is the first step in assessing a specific stack emission source of dioxin-like compound release. For this assessment, an emission factor is defined as the total mass (in vapor and particulate forms) of dioxin-like compound emitted per mass of feed material combusted. An emission factor is a representative value that attempts to relate the quantity of a pollutant released to the atmosphere with an activity associated with the release of that pollutant. Such factors facilitate estimation of emissions from various sources of air pollution. In most cases, these factors are averages of all available data of acceptable quality, and are generally assumed to be representative of long-term averages for all facilities in the same source category.

The general equation for emission estimation is:

$$E_{yr} = A_{yr} * EF \quad (3\text{-}1)$$

where:

E_{yr}	=	emission dioxin/yr; e.g., g/yr
A_{yr}	=	annual activity level of the subject source; e.g. kg/yr
EF	=	emission factor, mass dioxin emitted/ unit of activity level; e.g., ng/kg

Inherent in Equation (3-1) is the assumption that long-term emissions of dioxin-like compounds from a facility is best represented by the mean emission factor. Emission factors are usually developed from measurements of dioxin releases that are associated with normal operating conditions, not upsets nor industrial accidents.

This assessment recommends the generation of emission factors for individual dioxin-like congeners for a site-specific assessment. Volume I, *Sources of Dioxin-Like Compounds in the United States*, contains congener-specific CDD/F emission factors for specific types or classes of combustion processes. The emission factors were developed from stack gas emission measurements at tested facilities, usually as a result of compliance testing under the Clean Air Act, or in conjunction with the issuance of a State operating permit. The actual facility-specific emission rates and the derivation of emission factors representative of classes of combustors are documented in Database of Sources of Environmental Releases of Dioxin-Like Compounds in the United States (EPA/600/C-01/012. March, 2001). This database includes congener-specific CDD and CDF emissions data extracted from original engineering test reports. It has been published independently from the Reassessment and is available on Compact Disk-Read only Memory (CD-ROM), without cost, from EPA's National Service Center for Environmental Publications (NSCEP) in Cincinnati, Ohio (telephone: 1-800-490-9198, or 513-489-8190; fax: 513-489-8695). Summary files from the database will be available for downloading from the Web page of the National Center for Environmental Assessment, www.epa.gov/ncea/dioxin.htm. Instructions on how to order and obtain the CD-ROM will also be available on the Web page. This compilation of emission factors is the result of entering raw data of stack emissions from engineering reports of tested facilities data into a series of spreads-sheets. Facilities are classified and sub-classified according to similarity of process, design, types of materials processes or combusted and air pollution control equipment. These emissions factors are current through 1995. However, because most combustion processes are generally configured as they were in 1995, EPA believes the database, in most respects, is current with state-of-the-art technologies. This also applies to air pollution control equipment. EPA will, however, provide a periodic update to the database. Currently, EPA is updating this database to be current with the

year 2000. These updates should reflect changes in the improvements in the combustion-related technology and air pollution control equipment with the passage of time.

When evaluating potential human exposure to dioxin-like compounds using an Air Quality Model, EPA has traditionally converted the stack gas concentrations and emissions of CDD/F mixtures into an equivalent concentration of 2,3,7,8-TCDD, or TEQ (Cleverly, et al., 1989, 1991; EPA, 1987; Mukerjee and Cleverly, 1987), when deriving an emission factor. The fate, transport, and transfer parameters of 2,3,7,8-TCDD were applied to model the environmental fate of this TEQ mixture. For the site-specific procedures in this document, individual dioxin congeners are modeled from source to receptor. Only at the interface to human exposure, e.g., ingestion, inhalation, dermal absorption, etc., are the individual congeners recombined and converted into the toxic equivalence of 2,3,7,8-TCDD to be factored into the quantitative risk assessment.

Section 3.2.1 presents a strategy for development of emission factors for conducting a site-specific assessment. Section 3.2.2 describes an approach to estimating congener-specific emission factors when all that is available are homologue group emission factors. Section 3.2.3 summarizes the emission factors for the hypothetical incinerator demonstrated in Chapter 5. Section 3.2.4 presents an in-depth evaluation of the partitioning of emissions between a vapor and a particle phase for further atmospheric transport modeling. This discussion includes subsections on measurements of partitioning at the stack, measurements of partitioning in ambient air, and the theoretical approach used in this assessment for vapor/particle partitioning. Section 3.3.5 closes this section on emission factors by describing procedures to estimate the mass of ash (fly and bottom) produced and the concentration of dioxin-like compounds on ash.

3.2.1. A Strategy for Generating Emission Factors

The following is a hierarchial listing of data collection options for emission factors:

A. *For facilities that are built and operational*, it is preferred that direct stack measurements be used, using EPA recommended congener-specific stack monitoring and analytical protocols (e.g., EPA Method 23 for stack and EPA Method 1613 revision b for laboratory analysis). Stack monitoring provides concentrations and mass release rates of the pollutant, actual volume of stack gas and temperature. Care should be taken to ensure that the emissions characterization reflects a wide range of operating conditions and also accounts for deterioration in emissions output of the facility over its useful life. Procedures to convert data expressed in concentrations or mass release rates to an emission factor are as follows:

1. Test data of emissions are first placed into common units of measurement. English units are converted into metric, and the concentration term (mass of pollutant per unit volume of combustion gas emitted from the stack) should be corrected to the standard temperature and pressure on a dry gas basis, and standard percent carbon dioxide or oxygen within the combustion gas (e.g.,12% CO_2 or 7% O_2). These adjustments may be necessary if more than one test occurred for stack emissions.

2. The next step involves converting the mass emission concentration of the specific dioxin-like congener in units of nanogram per normal cubic meter (at standard temperature and pressure) of combustion gas corrected to 12% carbon dioxide into an equivalent emission factor in units of grams of pollutant emitted from the stack per kilogram of combustible material or feed (g [CDD/F]/kg feed) that was incinerated at the facility during the duration of stack sampling. This is solved in (Equation 3-2) below. In Equation (3-2), it is important that both the concentration of the dioxin-like compound (C_{fg}) and the volume of combustion gas (V_{fg}) be calibrated to the identical oxygen percent, temperature, and pressure.

$$EF = C_{fg} \times V_{fg} \times A$$

$$EF = \left\{\frac{\text{ng dioxin}}{\text{dscm (STP)}}\right\} \times \left\{\frac{\text{dscm (STP)}}{\text{hr}}\right\} \times \left\{\frac{\text{hr}}{\text{kg combusted}}\right\} \qquad (3\text{-}2)$$

where:

EF	=	congener-specific CDD/F emission factor, ng dioxin/kg
C_{fg}	=	concentration in flue gas, ng dioxin/dscm
V_{fg}	=	volume of combustion gas/unit of time, dscm/hr
A	=	combustion activity level, kg/hr

3. As a final step, the average emission factor of each congener is derived by summing the emission factors and dividing by the number of data points used. The average should represent an approximation of long-term emissions (i.e., annual emissions). Many air dispersion models require that emission factors (ng/kg) be translated into units of amount of the pollutant emitted per second of time (ng/s). Therefore the average emission factor must be adjusted accordingly by adjusting the units in Equation (3-2) to a time-scale of one second.

B. *For facilities that have been constructed, but not yet operational, or are in the planning stages of development, the following procedure is recommended:*

1. Refer to the *Database of Sources of Environmental Releases of Dioxin-like Compounds in the United States* (EPA, 2001). This database contains CDD/F emission factors for a variety of combustion sources through 1995:

   a) municipal solid waste incinerators
   b) medical waste incinerators
   c) cement kilns burning hazardous waste
   d) cement kilns not burning hazardous waste
   e) dedicated hazardous waste incinerators
   f) industrial wood burning
   g) residential wood burning
   h) coal and oil-fired utility boilers
   I) secondary aluminum smelters
   j) iron ore sintering
   k) secondary lead smelting
   l) secondary copper smelting
   m) kraft black liquor boilers
   n) sewage sludge incinerators
   o) boilers/industrial furnaces burning hazardous waste

2. Review the listing of air emission sources and combustor types. From this listing, select the closest analogy to the subject technology in terms of design-type, kinds and types of materials processed or combusted, and air pollution control device. Care should be taken to assure that the subject source type and design, controls, and raw material input are those of the source(s) analyzed to produced the emission factor. This fact should be considered, as well as the age of the information and the user's knowledge of technology advances.

3. After selecting the similar technology, go to the area of the *Dioxin Source Database* where average and congener-specific CDD/F emissions factors have been computed.

D. *If no data exist in the National Database that is relevant to a specific facility, then the Compilation of Air Pollution Emission Factors*, Fifth Edition (EPA, 1997; and subsequent

updates), should be used. This compilation was put together and is periodically updated by EPA's Office of Air Quality Planning and Standards (OAQPS), and is commonly referred to as AP-42. Care should be taken to select emission factors which were developed for technologies that best match the facility under consideration. The basic limitation of these of these data is the fact that emission factors are not usually reflective of specific emission control equipment. The AP-42 emission factors can be found in one of six chapters:

Chapter 1, External Combustion Sources
Chapter 2, Solid Waste Disposal
Chapter 3, Stationary Internal Combustion Sources
Chapter 4, Evaporative Loss Sources
Chapter 5, Petroleum Industry
Chapter 6, Organic Chemical Process Industry

Emission factors presented in AP-42 are designed for estimating emissions from a large number of sources over a wide area. They are averages of values determined at one or more individual facilities. The individual values which are used to develop the average may vary considerably. The use of AP-42 emission factors to estimate emissions from any one facility should be done with great care.

3.2.2. Use of Homologue and Congener-Specific Profiles to Estimate Emission Factors

Situations may occur in which CDD/F emissions data of classes of combustor types are reported as either homologue-groups and/or total CDDs plus CDFs. These data may, however, be most relevant to a combustion source under evaluation. Congener-specific emissions data are needed for the analyses of the ambient air impacts and deposition flux of dioxin-like compounds using air dispersion and deposition models. This is because each specific congener will have different physico-chemical properties, and this will greatly affect the modeling result. This section presents guidance on estimating congener-specific emission rates from homologue-specific and total CDD/F emissions data.

The preferred approach is to convert CDD/F homologue and total CDD/F emissions to congener-specific emissions using congener profiles developed for each source. Congener profiles are the fractional distribution of CDD/F congeners in an environmental release, in an environmental sample, or in a biological sample. Congener-specific profiles have been developed for known anthropogenic source activity in the U.S. as part of this assessment, and these profiles can be reviewed at the end of each Chapter in Volume I, *Sources of Dioxin-Like Compounds in the United States*. The following subsection 3.2.2.1 provides guidance for the use

of congener profiles to estimate congener-specific emission rates when only total CDD/F emissions data are available. In some cases no congener-specific profiles may exist for a source. Subsection 3.2.2.2 provides guidance for assuming a congener-specific emissions if at least homologue data are available.

3.2.2.1 *Using Congener Profiles to Convert Total CDD/F*

The assessor may have stack emissions data displayed as the sum of tetra through octa-CDD and CDF congener-groups, i.e., total CDDs plus CDFs. Congener-specific emissions data are needed for the most accurate assessment of potential air and deposition impacts near a source with the application of an air dispersion and deposition model. Congener-profiles derived from stack emissions data of similar combustion sources may assist this effort.

Congener profiles were determined by dividing the mean congener emission factor for the source class by the total tetra through octa-CDD and CDF emission factor for that class. All nondetects were treated as zero values. The result is an average fractional distribution (unitless) of each toxic CDD/F congener. Figure 3-1 is an example of the congener and homologue profile of typical emissions from sewage sludge incineration. In this example, the most prevalent congener in the emissions from sewage sludge incineration is OCDD. When the congener profile is plotted, OCDD is approximately 27% of the total CDD/F emissions. In this example, 2,3,7,8-TCDD is approximately 1% of total CDD/F emissions. Multiplication of the total CDD/F emission factor by the fractional distribution of each congener gives an estimate of the congener-specific emission factor for the source. For example, if it is assumed that the total CDD/F emission factor is 500 ng/kg of waste feed for a sewage sludge incinerator emissions, then the emission factor for OCDD is estimated from the congener profile to be 135 ng/kg (500 ng total CDD/F * 0.27). By this method, 2,3,7,8-TCDD would have an estimated emission factor of 5 ng/kg.

3.2.2.2 *Estimating Congener-Specific Emissions when no Congener Profiles are Available*

In some cases the congener profile may not available for a specific source of interest. This may be due to the general lack of emissions data for that particular source. However, the assessor may have information on homologue emissions from a combustion source. When only homologue emission factors are available, and no congener-specific profile exists for the source, then rough estimates of congener specific emission factors can still be made. First, an equal probability of occurrence of the specific congener is assumed based on relative proportionality. For example, 2,3,7,8-TCDD is one congener out of 22 possible congeners in the TCDD

homologue. Therefore, the probability of occurrence is assumed to be the ratio of 1/22 or 0.045. Multiplication of a total TCDD emission factor by 0.045 gives an approximation of the emission factor for 2,3,7,8-TCDD. Table 3-1 lists the number of dioxin-like congeners within a homologue group and the total number of congeners within that homologue group.

3.2.3. Estimation of Emissions of Dioxin-Like Compounds from the Hypothetical Incinerator

The emission factors for the dioxin-like compounds from the stack of the hypothetical waste incinerator were derived from actual stack monitoring and emissions testing of an incinerator burning a complex mixture of organic waste. The concentrations of the specific CDD/F congeners in units of nanograms per dry standard cubic meter (at 20° C; 1 atm.; 7% O_2) were available, as was the volume of gas escaping from the stack and feed rates for the material being combusted during the stack tests. Using procedures described in Section 3.2.1, this data was converted to emission factors. Such factors for three test runs are shown in Table 3-2. The fourth column is the average of these emission factors converted to g/sec units, which are the appropriate units for the application of the ISCST3 model. The conversion assumed a constant feed rate of 200 metric tons of feed material per day (further details on the hypothetical incinerator are found in Section 3.5). Human exposures to the coplanar PCBs emitted from a combustion source is not demonstrated in Chapter 5. Therefore, an estimation of congener-specific emission factors of coplanar PCBs for the hypothetical incinerator are not provided.

In order to put the emissions from the hypothetical waste incinerator into perspective, they can be compared with emissions from other incineration sources that are similarly controlled, e.g., equipped with scrubbers and/or fabric filters. Such air pollution control devices can reduce the amount of dioxin that is formed within the system by >99% prior to the release from the stack. In this comparison, emissions typical of waste incineration were taken from Volume 2, Chapter 3. The following types of incineration processes were used: medical waste incineration; hazardous waste incineration; sewage sludge incineration; municipal solid waste incineration, and tire incineration. For comparisons, all emissions factors are expressed in units of nanograms I-TEQ emitted from the stack per kg of waste combusted, and are presented as arithmetic mean emission factors. This should not be confused as typical of the incineration source category, but specific only to sources having scrubbers and/or fabric filters. Volume I, Chapter 3 of this assessment gives an overview of dioxin emissions from incineration technologies equipped with a variety of pollution control systems. The emissions from the

hypothetical incinerator is ranked with the other types of waste incinerators that are well controlled with some combination of a scrubber device and/or a fabric filter, as follows:

1. Medical waste incinerator:	70 ng I-TEQ/kg waste combusted
2 .Municipal solid waste incineration:	16 ng I-TEQ/kg waste combusted.
3. Sewage sludge incineration:	6.9 ng I-TEQ/kg sludge combusted
4. **Hypothetical waste incinerator:**	**4.5 ng I-TEQ/kg waste combusted**
5. Hazardous waste incineration:	3.8 ng I-TEQ/kg waste combusted.
6. Tire incineration:	0.3 ng I-TEQ/kg tires combusted.

From these comparisons it appears that the I-TEQ emission factor derived for the hypothetical incinerator lies well within the range of emission factors developed for well controlled sewage sludge and hazardous waste incinerators, but considerably lower than municipal solid waste and medical waste incinerators. The hypothetical incinerator was arbitrarily assigned a waste combustion rate of 200,000 kg waste/day (i.e., 200 tonnes/day). This charging rate conforms to a large medical waste incinerator, an average hazardous waste facility, and moderate sewage sludge and municipal waste incinerators.

3.2.4. Estimation of the Vapor Phase/Particle Phase Partitioning of Emissions of Dioxin-Like Compounds

The first step in the air modeling is the partitioning of total emissions into a vapor and a particle state. This section will review data on partitioning at the point of stack emission, in ambient air, and a theoretical approach to estimating the partitioning of dioxin- like compounds in ambient air. The true vapor/particle partitioning of dioxin under different conditions has not been directly measured, and therefore, is usually implied from these limited data or by theoretical means.

3.2.4.1. *Vapor Phase/Particulate Phase Inferences from Stack Measurements*

While the available literature is weak in this area, various investigators have made inferences on the vapor phase/particulate phase (V/P) partitioning from in-the-stack sampling of CDD/F emissions from combustion sources. Sampling systems which have been used basically consist of a particulate filter followed by a section designed to condense vapors in impinger glassware surrounded by an ice bath, and a resinous material suitable for absorbing vapor phase compounds. Depending on where the congener is distributed within the component parts of the

sampling apparatus, the investigator reports the fraction associated with particulate, and the fraction found in the vapor absorbing material. In order to collect sufficient mass of particulate for accurate analytical determination of the concentration of the recovered congener at sub-part per trillion levels of detection, it is often necessary to sample in stack for periods of four hours or longer. This introduces the possibility of movement of the collected dioxin sample from one part of the sampling train to another through adsorption, desorption, particulate blow-off, or other such phenomena as the sampling train continues to be exposed to the hot combustion gases. No real-time sampling method currently exists to instantaneously measure the concentration and physical state of the various CDD/F congeners in the fluid turbulence of the hot combustion plasma characteristic of gases from combustion traveling up a cylindrical stack. For these reasons, V/P partitioning based on stack test data is highly uncertain. Additional laboratory research is needed that is specifically directed at identifying the physical state partitioning of individual CDD/F congeners at the exit to the stack under varying temperature profiles and conditions of particulate loading and acid gas concentration. Table 3-3 is a summary of the percent distribution of CDD/Fs between the vapor-phase (V) and the particulate phase (P) as interpreted by various stack sampling techniques employed in the measurement of the compounds during incinerator operations.

Cavallaro, et al. (1982) performed a series of stack tests on six municipal solid waste (MSW) incinerators in Italy. He was one of the first investigators to interpret the V/P ratio from where the CDD/F segregated with the sampling train, e.g., the particulate filter and resinous trap. From these data, the percent distribution of congener groups were estimated. Cavallaro observed that the CDD/F emissions from the stack of the tested incinerators seemed to predominate in vapor phase. He attributed this to the possibility that the relatively high temperatures of the combustion gases during sampling (700 to 900° C) may have promoted desorption of CDD/Fs from particulate, although the sampling probe was kept at a constant 150°C.

Benfenati, et al. (1986) describes the stack testing of a modular MSW incinerator in Italy having a combustion capacity of 1500 kg/hour. The purposes of the study were to analyze the concentration of TCDD and TCDF at various points of the incineration process, to estimate the vapor phase versus the particulate phase partitioning at various sampling points corresponding to changes in temperatures, and to estimate the TCDD/F control efficiency of the pollution control device (an electrostatic precipitator). Comparisons were made between the distribution of TCDD/F after the secondary furnace in a region where combustion gas temperature was about 330°C, and the distribution at the stack where combustion gas temperature was 230° C. Benfenati observed that approximately 85% of the TCDD was in the vapor phase at the exit to

the furnace, and approximately 95% of the TCDD was in the vapor phase at the stack. It was concluded that most of the TCDD predominated in vapor phase at the point of release from the stack at the reported temperature of 230°C. However, Benfenati could not exclude the possibility that the TCDD was adsorbed onto ultra fine, submicron aerosol particles.

Tiernan, et al. (1984) reported on the distribution of CDD/Fs recovered in the stack sampling apparatus (EPA Modified Method 5) following the stack testing of a mass burn MSW incinerator operating in Japan. In the Modified Method 5 procedure, the sampling probe is maintained at a temperature of 120°C while the stack gases are isokinetically sampled. The facility was equipped with a dry scrubber combined with a fabric filter as the primary pollution control device. Tiernan observed congener-specific variability in the V/P partitioning inferred from the sampling method. However, greater than 55% of the CDD/Fs were estimated to be in vapor phase at the point of release to the stack. In an earlier stack test (Tiernan, et al., 1982) of an MSW incinerator equipped with an electrostatic precipitator, Tiernan found that 45% to 89% of the CDD/Fs were associated with particulate.

Clement, et al. (1985) stack tested a mass burn MSW incinerator operational in Canada for the emission of CDD/Fs. Three 24-hour stack samples were taken using the EPA Modified Method 5 train with a stack temperature of 230 - 250°C. The components of the sampling train were analyzed separately. Clement observed that more than 95% of the total CDD/Fs detected in the sampling train samples was found in the impingers used to condense vapor phase organic pollutants. Interpretation of this is difficult. However, it is implied from these data that most of the CDD/Fs prevailed in vapor phase.

Hagenmaier, et. al (1986) conducted field tests of two different stack test methods for the accuracy, precision, and comparability of CDD/F measurements. Both instruments were similarly constructed with a glass fiber filter for the capture of particulate-bound contaminants, a series of water or ice-cooled impingers to promote condensation of vapor phase contaminants, followed by an absorbing material to trap vapor phase pollutants. Eight parallel stack sampling experiments were carried out over a three week period using the sampling trains known as the German simple dilution method and the EPA Modified Method 5. Although the two methods reported quite similar total concentrations of CDD/Fs, the distribution of CDD/Fs between the heated glass filter, and ice-cooled impingers and the sorbent trap were remarkably different. In one train, referred to as Train A by Hagenmaier, the temperature in the filter housing was 140° C, and in the second train, Train B, the temperature was 90° C. The stack gas temperature in both cases was 230° C. Hagenmaier found that the percentage of CDD/Fs in the glass fiber filter was markedly greater in Train B than in Train A. Up to 93% of the PCDDs and 90% of the

PCDFs were detected in the particulate filter in Train B. By comparison, 73% and 58% of PCDDs and PCDFs, respectively, were detected in the particulate filter in Train A. Although Hagenmaier's data is used in Table 3-3, Hagenmaier theorized that this difference in the distribution of CDD/Fs in the two sampling trains was due to the differences in the temperature of the glass fiber filter housing.

EPA (1990a) conducted a field validation study for the EPA stack testing Method 23 (the Modified Method 5) for the collection and retention efficiency of CDD/Fs. A carbon-13 labelled congener was metered into the sampling probe just preceding the glass fiber filter using a dynamic spiking system. The validation procedure involved the isokinetic sampling in the stack of a large mass burn MSW incinerator. Sampling *in situ* in the stack while using a dynamic spiking system demonstrated that most of the isotope was recovered in the filter trap and front half of the sampling train designed to capture particulate, and a lower amount was recovered in the XAD resin designed to capture vapor phase organic compounds. In the particular tests in which the overall percent recovery of the dynamic spike were found to be acceptable, the XAD resin and condensor contained about 49% of the isotope, and 51% was associated with carbonaceous particulate.

3.2.4.2. *Discussion of Vapor/Particle Ratios Derived from Stack Testing Methods*

It is apparent that the stack sampling method gives inconclusive and contradictory evidence of the V/P partitioning of CDD/Fs at the stack of incinerators. Although most of the researchers report finding the greatest quantity of CDD/Fs captured within the resinous material having the physical/chemical properties of absorbing vapor phase organic compounds, a few studies have reported the opposite. What is unusual about the V/P distributions in Table 3-3 is the lack of complete consistency despite the similarity of sampling method. Although the stack gas temperatures may vary, the probe and housing to the sampling instrument is usually kept at a standard temperature while traversing the hot flue gas. A more consistent pattern of V/P should have emerged.

Hagenmaier, et al. (1986) has postulated that, depending on the temperature of the glass fiber particulate filter housing, the CDD/Fs might desorb (volatilize) from particulate matter trapped in the filter during the 4 hours of sampling time required of the stack sampling method. Therefore, Hagenmaier does not believe that the distribution of CDD/Fs between the particulate filter, the condensing impingers, and the vapor absorber gives a true indication of the V/P partitioning of these compounds at the stack.

Tests also have been devised by the EPA (1990a) to study the effect a change in temperature of the glass fiber filter housing might have on the distribution of CDD/Fs in the sampling train. During the sampling period, two sampling trains were used: one inlet to the electrostatic precipitator (ESP), and the other placed near the outlet to the ESP. Temperatures of the filter housing were raised from the standard 120° C to 215° C in both sampling trains. In agreement with the observations of Hagenmaier, et al. (1986), an increase in temperature generally resulted in a change in the distribution of the recovered 13-C labelled CDD/F congeners. However, the temperature effect was most apparent within the sampling train inlet to the ESP. In the inlet sampling train, the higher filter box temperature increased the relative percentage of CDD/Fs trapped in the impingers and XAD-2 resin. An amount estimated to be in the vapor phase, based on the segregation of the compounds within the component parts of inlet sampling train, is as follows (with a range listed from low to high temperature): TCDD = 20 - 55% vapor; HxCDD = 10 - 30% vapor; OCDD = 5 - 18% vapor; HxCDF = 18 - 58% vapor; OCDF = 5 - 18% vapor. In the outlet sampling train (characteristic of stack emissions), this dramatic shifting of the congeners from the filter to the XAD-2 did not occur with an increase in temperature. Interpretation of the vapor phase partitioning in the outlet sampling train from low to high temperatures was as follows: TCDD = 90 - 95% vapor; HxCDD = 85 - 90% vapor; HxCDF = 90 - 95% vapor; OCDD = 75 - 90% vapor; OCDF = 78 - 90% vapor. Both these interpretations were developed using a 500 ng CDD/F spiked congener. Notice that the vapor phase to particle phase ratio is significantly different between the inlet and outlet sampling trains: in the inlet train most of the CDD/F congeners seemed to predominate in the particle phase at the standard temperature of the filter housing, whereas in the outlet train most of the CDD/F congeners seemed to predominate in the vapor phase, as interpreted by the distribution within the apparatus.

The temperature-dependent partitioning has recently been observed by Janssens, et al. (1992) during field validation studies involving the sampling of operating incinerators in Belgium. Janssens observed that the fraction of CDD/Fs collected in the heated portion of the particulate glass filter (temperatures in the range of 250 to 300° C) showed an expected partitioning according to the vapor pressures of the compounds. It was found that a very low proportion of the CDD/Fs were found in the particle phase; nearly all the compounds were detected in the vapor phase. Moreover, Janssens observed that higher temperatures seemed to favor the vaporous state of the lower chlorinated congeners (compounds having one to five chlorines on the aromatic ring), and the particulate phase for higher chlorinated congeners (five to eight chlorines). This agrees well with the decrease in vapor pressures that occurs with an

increase in chlorination, and an increase in vapor pressure that occurs with a decrease in chlorination of CDD/Fs. Adding to the theory of Hagenmaier, et al. (1986), Janssens believed that either the sampling apparatus was giving a true distribution of the V/P ratio of individual congeners, or that a significant portion of the congeners were reversibly sorbed onto particulate surfaces and could be eluded to vapor phase by the passage of the volume of sampled combustion gas over a lengthy time interval, neither of which could be proven by his study.

Benfenati, et al. (1986) has suggested that what may be reported as vapor phase may actually consist of nucleated aerosol particles having diameters less than 0.1 micrometers. The impingers in the sampling method are located a few centimeters behind the heated particulate glass fiber filter, and are bathed in an ice bath. The dramatic reduction in temperature within the impinger glassware may cause sublimation from vapor phase to nucleation of aerosol particles. Downstream of the impingers is the vapor absorbing material, usually XAD-2 resin. Although this has been shown to be an excellent trap for semi-volatile organic compounds, the retention of submicron size particles with CDD/Fs adsorbed onto the surfaces, or absorbed into the interior spaces, cannot be ruled out or excluded as a possible explanation for investigators reporting a preponderance of concentration both in the impingers and the vapor trap.

Complicating any meaningful interpretation of the data is the long duration of sampling time required in the stack measurement method. In order to reach a sub-ppt level of detection of CDD/Fs for reliable quantification of specific congeners, sampling proceeds until approximately a five gram mass of particulate is gathered in the particulate filter. This may require *in situ* placement of the sampling apparatus such that samples are taken isokinetically, and the stack interior diameter is traversed for four or more hours. Thus the sampling instrument is continuously exposed to the hot gas plasma over a long sampling moment. In addition the hot gases also contain precursor compounds, chlorides, oxides of sulfur and HCl which may have an effect on the success of accurately sampling CDD/Fs. Although Janssens, et al. (1992), Hagenmaier, et al. (1986), and EPA (1990a) have all but excluded the possibility that sampling under these conditions creates results by producing CDD/Fs or destroying CDD/Fs somewhere within the sampling train, the possibility that the method creates an illusion of the true V/P ratio cannot be excluded.

The above discussions have indicated the variability in the data and the uncertainty with the stack results of vapor/particle partitioning. For these reasons, these data will not be used to infer the V/P distribution of CDD/Fs at the point of release from the stack.

3.2.4.3. *Vapor/Particle Partitioning of CDD/Fs from Ambient Air Sampling*

The measurement of CDD/Fs in air under ambient conditions has only been achieved since the late 1980's. The ambient air sampler which is most often used to estimate particulate and gaseous fractions consists of a glass or quartz fiber filter followed by a sorbent trap such as polyurethane foam (PUF), XAD resins, or a combination of the two. These are active samplers which utilize electric pumps to draw air through the collector at approximately 0.2 - 0.6 m^3/min. This provides sample volumes of 300 - 600 m^3 in a 24-h period, although longer sampling times are not uncommon. The phase distribution is estimated from the segregation of compounds on the filter and sorbent trap, which are assumed to capture compounds that are particulate and gaseous, respectively. PUF is capable of collecting many semivolatile compounds with high efficiency (Bidleman, 1987; Hart and Pankow, 1994; Pankow, 1989; Tashiro et al., 1989; Wagel, et al., 1989), although its usefulness is limited by the vapor pressure of the compound. Examples of compounds for which PUF can be used are the tetrachloro- and higher CDD/Fs, and three-ring and heavier PAHs and PCBs having three or more chlorines. The more volatile members of these classes as well as chlorobenzenes and chlorophenols are collected with greater efficiency by XAD and similar resins (Bidleman, 1987; Hart and Pankow, 1994; Hornbuckle et al., 1993; Patton et al., 1992; Zaranski et al., 1991). The glass fiber filters used in air samplers are rated to collect particles of diameters $\geq$0.3 micrometer, with 99.9% collection efficiency.

Filtration samplers are subject to artifacts which include loss of organic compounds from the particles on the filter by volatilization ("blow-off") (Eatough et al., 1993; Gundel et al., 1995; Lane et al., 1988; Lewis et al., 1991; Subramanyam et al., 1994) and sorption of gaseous compounds to the particle mass collected on the filter and to the filter itself (Cotham and Bidleman, 1992; Hart and Pankow, 1994; McDow et al., 1990; Turpin et al., 1994). The possibility of blow-off losses are recognized and discussed extensively in the literature, but there is disagreement as to how seriously this artifact will bias estimated particle/gas distributions.

Because sampling of CDD/Fs is not instantaneous (i.e., real time measurement), but requires 24+hour air sampling to assure a level of detection of about 0.03 pg/m^3, the V/P ratios described in this section should be considered as “operationally defined”. Operationally defined are relative and not absolute vapor phase and particle bound phase partitioning behavior within the design contraints of the measurment method. The following is a review of ambient air sampling data on the relative V/P partitioning of CDD/F congeners at ambient temperatures. Table 3-4 provides a summary of the particle percentages (vapor percentage = 100 - particle percentage) inferred from these reports.

Oehme, et al. (1986) first described a method sensitive enough for the congener-specific measurement of CDD/Fs at 0.1 pg/m^3 levels of detection in ambient air. Such low levels of detection introduced the possibility of taking ambient air samples in the vicinity of known combustion sources of CDD/Fs to reliably establish an association with stack emissions. Oehme tested the performance and reliability of an ambient air sampler consisting of a glass fiber filter followed by a polyurethane foam plug. Ambient air was sampled over a predetermined period after first spiking the filter with a known concentration of $^{13}C_{12}$ labelled CDD/F standards. This experiment was designed to determine the percent of the initial spiked labelled standard that could be recovered from the sampler after sampling 1000 m^3 of ambient air. The percent recovery of the standard was a measure of the collection and retention efficiency of the sampler. After collecting a sample, the particulate filter and the PUF plugs were extracted and analyzed separately. This was done in order to establish the particle phase and vapor phase partitioning of the CDD/F congeners. Oehme demonstrated that the sampling method was capable of a high degree of reliability in sampling sub-part per trillion concentrations of CDD/Fs as indicated by highly satisfactory recovery of the isotopically labelled standards in the apparatus, e.g., 88 - 102% recoveries. From the results of separately analyzing the filter and the PUF, Oehme postulated on the typical distribution of CDD/Fs between vapor and particles in ambient air. They suggested that TCDF and PeCDF were mainly present in the vapor phase, and HxCDD, HxCDF as well as the less volatile isomers of HpCDF, HpCDD, OCDF, and OCDD, were mainly present in the particle phase. Oehme took over 60 ambient air samples with this device in rural, suburban, and urban areas of Europe.

Eitzer and Hites (1989) reported on the measurement of CDD/Fs in the ambient atmosphere of Bloomington, Indiana while using a similarly configured ambient air sampling method, the General Metals Works PS-1 sampler. Ambient air is drawn through a glass fiber filter followed by a polyurethane foam plug (PUF). This was a long-term study designed to investigate the daily and seasonal variability of the compounds in the ambient air as measured at a single location, and to examine the vapor-phase, particulate-phase partitioning of the chlorinated congeners under ambient conditions. Samples were taken at four different sites over a 2-3 day sampling period until 1500 to 2400 m^3 of ambient air volume had passed through the apparatus. Sampling was conducted monthly from August, 1985 through July, 1986. The quantitative method produced a limit of detection of the individual chlorinated congeners in the range of ~1 femtogram/m^3. Eitzer and Hites (1989) operationally defined the vapor-phase/particle-bound phase of the chlorinated congeners as any compounds found in the PUF plug and the glass fiber filter, respectively. The V/P ratio was subject to certain restrictions of

the sampling method, which the authors identified as: 1. Particles smaller than 0.1 microns would pass through the filter paper of the glass fiber particulate filter and be absorbed into the polyurethane foam; 2. Diurnal temperature variation could cause particle-bound CDD/Fs collected and retained in the filter to vaporize and be "blown-off" to the PUF plug by the passage of the sampled air stream; 3. At these relatively large sampling volumes of ambient air, it is possible that some breakthrough on the PUF plug occurs, and a portion of the CDD/F sample is lost. The investigators were able to rule-out the latter condition through the addition of a XAD-2 resin trap after the PUF. This was one of the first reports on the congener-specific V/P partitioning in the ambient air under variable average ambient temperatures. Although they could find no seasonal effect on the total concentrations of CDD/Fs, seasonal change in temperature did affect the V/P ratio. It was noted that during the warm summer months the V/P ratio was as great as 2:1, and during the cold winter months the V/P ratio could be <0.5. Thus, at warm temperatures most of the lower chlorinated congeners, e.g., mono through penta-chlorinated CDD/Fs, were mostly found in the vapor phase and the hexa - octachlorinated congeners were mostly particulate-bound. The colder winter temperatures produced the effect of causing the lower chlorinated species to partition more onto airborne particles. The higher chlorinated congeners, e.g., hexa-, hepta-, and octa-CDD/Fs, mostly were found to be particle-bound at both the warm and cold temperatures. These quantitative results of the V/P ratio of individual congeners at three ambient air temperatures (3° C, 16 - 20° C, and >28° C) was again reported by Hites (1991), as shown in Table 3-4. Through these analyses, Eitzer and Hites (1989) and Hites (1991) found two dependant variables controlled the V/P ratio in ambient air: 1. the ambient air temperature; and 2. the vapor pressures of the CDD/F congeners. The authors concluded that because the lower chlorinated compounds have higher vapor pressures, they will be found mostly in the vapor phase, and because the higher chlorinated congeners have lower vapor pressures, they will prevail in the ambient air bound to particulate matter.

Wagel, et al. (1989) reported on the performance of the General Metals Works PS-1 sampler for the collection and retention of CDD/Fs while sampling ambient air. This sampler configuration consists of a quartz glass fiber filter followed by a polyurethane foam (PUF) plug, and the investigators added an XAD-2 resin cartridge after the PUF. The addition of the XAD was a check on whether breakthrough of any CDD/F congeners occurred from the PUF during sampling. The PS-1 is the sampler most often used in the U.S. to quantify CDD/Fs in air under ambient conditions. The protocol of this research was to use two samplers co-located. The particulate filter of one sampler was spiked with $^{13}C_{12}$-labelled CDD/F congeners while the second sampler was used to provide background measurements of native (non-labelled) CDD/Fs.

Both units were operated to sample ambient air for 24-hours. The average ambient temperature during the sampling period was 24° C. Following the sampling the filter and PUF were removed and extracted according to published procedures (Wagel, et al., 1989). Performance of the PS-1 sampler was reported as percent recovery of the labeled standards initially spiked onto the particulate filter. The percent recovery was calculated by subtracting the background contributions from the total detected spike concentration and dividing by the concentration of the labeled standard initially added to the filter. The percent recoveries were reported in a range of from 85% to 124%, with an average recovery of 102%. This indicated a high degree of reliability in collecting and retaining CDD/Fs in the sampler during the 24-hr sampling period.

A second series of experiments were conducted to investigate the distribution of CDD/Fs within the sampling apparatus, e.g., the particulate filter versus the PUF plug, by extracting and analyzing the filter and PUF separately. Subject to the caveats previously discussed, the investigators made observations regarding the V/P ratio of CDD/F congeners. It was observed that CDD/Fs having 7-8 chlorines were mostly detected in the particulate filter, and lower chlorinated species were mostly detected in the PUF. Wagel, et al. (1989) suggested that it was possible that the lower chlorinated congeners volatilized from the particulate filter (somewhat affected by the rate of flow of the sampled air volume), and then were retained by the PUF. Furthermore, Wagel, et al. (1989) warned that if results of separately analyzing the filter and PUF are used to derive a vapor phase and particle phase partitioning of the CDD/Fs under ambient conditions, then this may give erroneously high estimates of the amount present in vapor phase.

Harless and Lewis (1992) have quantitatively evaluated the performance of the General Metals Works PS-1 sampler for the trace-level measurement of CDD/Fs in ambient air, adding to the growing evidence that results are actual measurements and not an artifact of the sampling method. In this study, three samplers were used in the same general vicinity, and were operated for a 24-hour period until an air volume of 350 - 400 m^3 had passed through the system. The quartz glass fiber particulate filters of two of the samplers were then spiked with $^{13}C_{12}$ labeled CDD/F congener with a known concentration after the 24-hour sampling period. The three samplers were then operated another 24-hours. The samplers were then shut down, and the filters and PUF plugs were removed and extracted and analyzed for CDD/Fs separately according to prescribed procedures. A separate series of experiments involved precleaning the glass fiber particulate filters, and adding the isotopically labeled CDD/F spike to the filter prior to sampling for seven days until about 2660 m^3 of ambient air had been sampled. Results of this study confirmed the accuracy and reliability of the PS-1 sampler for collecting and retaining

CDD/Fs at sub-ppt concentrations in ambient air. Performance was defined as the percent of the initial concentration of the labelled isotope recovered in the sampling apparatus following the operation over the predetermined sampling period. The average efficiency of recovery of the 0.8 ng $^{13}C_{12}$-1,2,3,4,-TCDD isotope that was spiked onto the filter prior to sampling was 91%, and similar efficiencies were observed for the recovery of the other labeled CDD/Fs. Additionally, Harless and Lewis (1992) used the spiking system to observe the distribution of CDD/Fs in the filter and the PUF after sampling 400 m^3 of ambient air. It was observed that most of the hepta-, and octa-CDD/Fs were retained by the glass fiber filter, indicating that these compounds were retained and not blown off the filter, and most of the tetra-, penta-, and hexa-CDD/Fs volatilized and were collected by the PUF plug. When partitioning was observed on a congener-specific basis, significant differences were observed in the V/P ratio, as shown in Table 3-4.

Hunt and Maisel (1990) reported on the ambient air measurement of CDD/Fs in a northeastern U.S. urban coastal environment during the fall and winter seasons. Isomer-specific sampling was conducted with the General Metal Works PS-1 sampler in and around Bridgeport, Connecticut from November, 1987 through January, 1988. Nine sampling sessions consisting of a total of 43 ambient air samples were taken in this study. Each sampling session was conducted either over a 24-hour or 72-hour period until about 350 m^3 and 600 m^3 of air volume had passed through the sampler. Hunt and Maisel (1990) reported on the typical vapor phase/particle bound partitioning of individual congeners during cold ambient air temperatures. The V/P ratio was based on the results of separately analyzing the PUF plugs and the glass fiber particulate filters for the presence of CDD/Fs. From these data, the investigators concluded that greater than 92% of all the congeners of CDD/Fs were particulate bound (operationally defined as detected in the particulate filter). The 2,3,7,8-TCDD isomer was not detected in any of the 43 collected samples (reported limit of detection was 5-20 fg/m^3). The particulate bound distribution (reported as a percent of the detected concentration) for some of the other congeners were as follows: 2,3,7,8-TCDF = 93%; 1,2,3,7,8-PeCDF = 94%; 2,3,4,7,8-PeCDF = 99%; 1,2,3,4,7,8-HxCDF = 97%; 1,2,3,4,6,7,8-HpCDF = 100%; 1,2,3,6,7,8-HxCDD = 96%; and the 1,2,3,4,6,7,8-HpCDD = 92%. The vapor phase/ particle bound distribution observed in this study is probably controlled by the cold January temperatures from which these observations were derived (average temperature = -5° C).

At a later date, Hunt and Maisel (1992) conducted ambient air monitoring of CDD/Fs in multiple locations in the warm climate of southern California for the State of California Air Resources Board (CARB). Ambient air samplers, e.g., the General Metal Works PS-1 sampler, were primarily placed in areas of high population density that contained known combustion

sources of CDD/Fs, but sites were also sampled that were considered removed from the influences of any local sources. The purpose of the study was to evaluate the congener-specific spacial distribution of CDD/Fs in ambient air near environmental sources of the compounds, and in remote locations, in order to provide a baseline to evaluate population exposures within the region. Monitoring sites were established at eight locations in the South Coast Air Basin in and around the city of Los Angeles. Nine discrete sample sets were collected from December, 1987 through March, 1989. The authors defined a sample set as consisting of five to seven stations at which one or two co-located samplers were operated. Microscale meteorological data was collected during sampling to include wind speed, wind direction, barometric pressure, and temperature. One sampling site was chosen to investigate the distribution of CDD/Fs in ambient air where average ambient temperatures ranged from 16-20°C. This was done by the usual procedure of separately analyzing the filter and the PUF and making the assumption that what is detected in the glass fiber filter is particulate bound, and what is trapped in the PUF is in vapor phase. The authors noted that under these conditions, the V/P partitioning is operationally defined by the ambient air sampling system, and therefore may not be a true indication of the partitioning in the atmosphere. The majority of the hexa through octa CDD/F congeners were detected in the filter, and the authors observed that they were mainly associated with particulate matter. The authors found these observations were consistent with the V/P ratio observed by Eitzer and Hites (1989) in warm climate conditions. In addition, the authors noted that these observations give further evidence that vapor pressures of the specific CDD/F compounds and ambient air temperatures strongly influence the V/P partitioning. Therefore the tetra- and penta-CDD/Fs are expected to predominate in vapor phase during warm seasons. However, during the cold temperatures of the winter season these congeners are expected to be primarily associated with particulate matter in the ambient air.

Bobet, et. al. (1990) reported the results of an ambient air monitoring network operated by Environment Canada to temporally measure CDD/Fs in the ambient air in southwestern Ontario, Canada. The intent of the study was to monitor possible environmental impacts of a large refuse-derived fuel municipal waste combustor operational in the City of Detroit, Michigan. The ambient air monitoring network consisted on two stations, one in Windsor, Ontario, and the other located in the Walpol Island Indian Reservation 18 km to the northeast of Windsor. The former site was considered in an urban area near the expected point of maximum impact from the stack emissions from the MWC, and the other site was considered rural, and away from the influence of any stationary combustion source. CDD/F samples were collected once every 24 days using an high-volume ambient air sampler consisting of a Teflon-coated

glass fiber particulate filter and a PUF adsorbent trap. Ambient air was sampled over a 24-hour period from July, 1987 to August, 1988 with a total sample volume of 800 - 1000 m^3 of air. From August on, the samplers were operated over a 48-hour period, and 1600 - 2000 m^3 of air passed through the sampler. Mean total concentrations of CDD/Fs were compared between the urban and rural sites, and Bobet observed that concentrations measured at the urban site were 4 - 20 times greater than at the rural site. Additionally, the V/P partitioning of CDD/Fs (as operationally defined by detection in the PUF verses detection in the filter) was investigated at both sampling stations. Bobet stated that the V/P may be influenced by "blow-off" of particulate from the filter to the PUF, and/or the passage of particulate matter <0.1 microns from the filter to the PUF, and if this is the case, then the vapor phase partitioning may be too great as interpreted by the method. Under these circumstances the authors suggested that the V/P partitioning should be considered as roughly representative of the vapor/particulate phases in the ambient air. On a total concentration basis, and on a total of 12 separate ambient air samples, the investigators found the following average percent vapor phase versus percent particle phase partitioning of the CDD/F homologues at the Windsor, Ontario station: TCDD = not detected; PeCDD = 100% V/ 0% P; HxCDD = 35% V/ 65% P; HpCDD = 18% V/ 82% P; OCDD = 0% V/100% P; TCDF = 80% V/20% P; PeCDF = 29% V/ 71% P; HxCDF = 0% V/100% P; HpCDF = 0% V/ 100% P; OCDF = 0% V/ 100% P. At the rural Walpole Island station, no TCDD, PeCDD or TCDF - OCDF were detected in any of the 5 separate ambient air samples. All of the detected HxCDD, HpCDD and OCDD was found in the particulate filter indicating a V/P distribution of 0% V/ 100% P for these compounds. The authors did not report the average ambient air temperature at the two stations.

Welsch-Paulsch et al. (1995) presented results of an experiment in Bayreuth, Germany in which grass was grown in a greenhouse and outdoors on soils having different concentrations of CDD/Fs. The purpose of the experiment was to determine the pathways by which these compounds accumulate in the grass. The principal finding of this study was that dry gaseous deposition, rather than particle deposition or soil-to-plant transfer, explained the concentrations of CDD/Fs in the grass. A subset of these data included measurements of CDD/Fs in the particle and gas phases using a glass fiber filter - XAD resin sampler. Samples were collected over two-week integration times during July - August 1991 when the average air temperature was 18ºC. The particulate percentages determined in the study showed a predominance of tetra- and penta-CDD/Fs in the gas phase, approximately equal percentages of the hexa-CDD/Fs in the gas phase and associated with particles, and most of the hepta- and octa-CDD/Fs in the particle phase.

3.2.4.4. *Discussion of the Vapor/Particle Partitioning in Ambient Air Sampling Studies*

The studies that have been reviewed here indicate the following:

• The high-volume ambient air sampler consisting of a glass fiber particulate filter and polyurethane foam absorbent trap is a reliable method for the collection and retention of CDD/Fs in ambient air.

• Current analytical methods assure detection limits, on a congener specific basis, of about 1 - 10 fg/m^3.

• Experiments involving the recovery of isotopically labeled CDD/Fs within the sampler after 24-hours operation indicate that the sampler does not create artifacts representative of either sample losses or the synthesis of dioxin.

• Because the sampler is not artificially heated or cooled, but is allowed to operate at existing ambient air temperatures during sampling sessions, the method can be used to imply the vapor phase and particle bound partitioning of CDD/Fs in ambient air. This is accomplished by separately extracting and analyzing the glass fiber filter and the polyurethane foam for the presence of CDD/F congeners.

• However, the V/P ratio interpreted from these results is operationally defined. This will only give an approximate indication of the V/P ratio since mass transfer between the particulate matter on the filter and the vapor trap cannot be ruled out. The glass fiber filter will collect particles $\geq$ 0.1 microns in diameter, and therefore it is possible that aerosol particles with smaller diameters will pass through the filter and be trapped in the polyurethane foam plug. If this is the case, the percent observed in vapor phase will be overestimated. The method involves ambient air sampling at a relatively high sample volume, around 300-400 m^3 of air, over a 24-hour period. It is possible that a portion of the CDD/Fs that are sorbed to particulate matter captured by the filter may be volatilized by changes in ambient temperature, and carried with the air flow to the PUF sorbent trap (blow-off effect). If this were to occur, the observed vapor-phase fraction of the CDD/Fs would be an over-estimate (or equivalently, the observed particulate fraction would be underestimated). Unfortunately there are no empirical data that have demonstrated that any of these effects may actually occur.

3.2.4.5. *Junge-Pankow Model of Particle/Gas Distribution in Ambient Air*

A relationship first proposed by Junge (1977) and later reviewed and critically evaluated by Pankow (1987) is the most widely used model for estimating the adsorption of semivolatile compounds to aerosols:

$$\phi = \frac{c\,\Theta}{p^{\circ}_{L} + c\,\Theta} \qquad (3\text{-}3)$$

where:

ϕ	=	fraction of the compound adsorbed to aerosol particles
p°_{L}	=	saturation liquid phase vapor pressure of the pure compound at ambient temperature, Pa
Θ	=	the particle surface area per unit volume of air, cm^2 aerosol/cm^3 air
c	=	a constant which is related to the difference between the heat of desorption from the particle surface, Q_d, and the heat of vaporization of the compound, Q_v. The value of c is often estimated at 17.2 Pa-cm

Pankow (1987) argued that different values of Q_d - Q_v (and therefore c) may be appropriate for different classes of compounds.

Although Junge (1977) did not specify the physical state of the sorbing compound in Equation (3-3), field and laboratory studies of the particle/gas distribution of PAHs and organochlorine compounds indicate that the process is better described by using the vapor pressure of the subcooled liquid rather than the solid-phase vapor pressure (p^{o}_{S}) (Bidleman et al., 1986; Cotham and Bidleman, 1992; Foreman and Bidleman, 1987). The two vapor pressures are related by:

$$\ln \frac{p^{\circ}_{L}}{p^{\circ}_{S}} = \frac{\Delta S_f (T_m - T)}{RT} \qquad (3\text{-}4)$$

where:

p°_{L}	=	liquid sub-cooled vapor pressure of the pure compund, Pa
p°_{S}	=	crystalline solid phase vapor pressure of the pure compound, Pa
ΔS_f	=	the entropy of fusion, J/mol-K
T_m	=	the melting point of the compound, K
T	=	is the ambient temperature, K
R	=	ideal gas constant, 8.314 J/mol-K.

Values of ΔS_f have been summarized for CDD/Fs (Rordorf, 1989) and other semivolatile compounds (Hinckley et al., 1990). In the absence of an experimental value, an average $\Delta S_f/R$ = 6.79 is often used (Hinckley et al., 1990), and it is used in this assessment. Liquid-phase vapor pressures have also been estimated for PCBs, PAHs, CDD/Fs and organochlorine pesticides by capillary gas chromatography (Falconer and Bidleman, 1994; Eitzer and Hites, 1988; Eitzer and Hites, 1989; Hinckley et al., 1990; Yamasaki et al., 1984). The hypothesis that p^o_L controls sorption to aerosols is especially significant for CDD/Fs, as many of these compounds have high melting points and thus large differences between p^o_L and p^o_S.

Estimates of θ are given by Bidleman (1988), based on a study by Whitby (1978) of the size distribution of accumulation mode aerosols. Whitby also estimated the average total volume of particles per unit volume of air (V_T = cm^3 aerosol/cm^3 air). Values of θ and V_T are given in Table 3-5. From V_T and an assumed particle density of 1.4 g/cm^3, the average TSP concentrations in urban and average background air are 98 and 42 μg/m^3. These can be compared to average monitored TSP concentrations of 79 and 30 μg/m^3 in 46 U.S. cities and 20 rural locations in 1975 (Shah et al., 1986). Similar calculations using values of θ yield estimates of the aerosol specific surface area (A_{tsp}) of 11 m^2/g in urban air and 3.6 m^2/g in average background air (Bidleman, 1988). Measurements of A_{tsp} from particles collected on glass fiber filters were 1.9 - 3.1 m^2/g in Pittsburgh, Pennsylvania (Corn et al., 1971) and 2.3 - 8.7 m^2/g in Portland, Oregon (Sheffield and Pankow, 1994). The latter authors noted that particles tended to agglomerate to a greater extent on teflon membrane filters than on glass fiber filters, and that experimentally determined specific surface areas were higher on the glass fiber filters. This suggests that values of A_{tsp} measured on filtered particles may be biased on the low side, although more data are needed in this regard.

The particulate fraction can also be expressed by:

$$\phi = \frac{C_p\ (\ TSP\ )}{C_g + C_p\ (\ TSP\ )} \qquad (3\text{-}5)$$

where:

ϕ = fraction of the compound adsorbed to aerosol particles

C_p = the concentration of semivolatile compounds associated with aerosols, ng/μg particles

C_g = the gas-phase concentration, ng/m^3

TSP = the total suspended particle concentration, $\mu g/m^3$

Equation (3-5) is a general relationship that applies to any experimental or model estimate of C_g and C_p. Combining Equations (3-3) and (3-5) yields:

$$Log \frac{C_p}{C_g} = Log\ K_p = Log \frac{c\ \theta}{TSP} - Log\ p^\circ_L \quad (3\text{-}6)$$

Here and in other work (Falconer et al., 1995; Kamens et al., 1995; Hart and Pankow, 1994; Pankow and Bidleman, 1992) C_p/C_g is referred to as the particle/gas partition coefficient, K_p ($m^3/\mu g$). Its inverse, $C_g/C_p = 1/K_p$, has also been used for these correlations (Cotham and Bidleman, 1992). According to Equation (3-6), the expected slope of log K_p vs. log p^o_L is -1 and the intercept is related to the specific surface area of the aerosol A_{tsp} (m^2/g) = $10^8\theta$/TSP. Plots of log K_p vs. log p^o_L for partitioning data obtained with filtration air samplers are usually well correlated and follow the general relationship:

$$Log\ K_p = m\ Log\ p^\circ_L + b \quad (3\text{-}7)$$

It is often the case that m $\neq$ -1 because of kinetic limitations and/or sampling artifacts. In these situations the intercept b is partially dependent on the slope and cannot be used to estimate θ (Pankow and Bidleman, 1992).

3.2.4.6. *Modeling the Vapor/Particle (V/P) Distribution of CDD/Fs*

A portion of the semivolatile compounds found in ambient air appears to be freely exchangeable between the particulate and gaseous phases. A second portion, the "non-exchangeable" fraction, may be irreversibly sorbed or occluded by the aerosols and not in equilibrium with the corresponding gas phase (Bidleman, 1988; Pankow, 1988; Pankow and Bidleman, 1991, 1992). In this procedure methodology document, it is assumed that all compounds emitted from combustion sources are freely exchangeable unless information exists otherwise.

The first step in the modeling of the V/P distribution is to determine the sub-cooled liquid vapor pressure for the CDD/Fs. Eitzer and Hites (1988,1989) used a capillary GC method to

determine liquid-phase vapor pressures for 63 CDD/F congeners. These measured values will be used to develop the V/P partitioning for the dioxin-like compounds in this assessment. The $p°_L$ given in these references are measurements at 25°C. This section will outline a procedure for calculating the $p°_L$ at different temperatures. The V/P calculations of this assessment assume an ambient temperature of 20 °C, necessitating a conversion of $p°_L$ from 25 to 20°C. Finally, this section will also show the calculation of the $p°_L$ based on the crystalline solid phase vapor pressures, $p°_S$. These calculated $p°_L$ will be compared against the measured $p°_L$.

Table 3-6 lists the crystalline solid vapor pressure, p^o_S, at 25°C for the seventeen CDD/F congeners having dioxin-like toxicity. These values of p^o_S were judged as the most appropriate from available reportings in the literature in Chapter 2 of Volume I. They were used in conjunction with Equation (3-4) above to calculate $p°_L$ at 25°C, also shown in Table 3-6. Finally, Table 3-6 gives the p^o_L values at 25°C, which were reported in Eitzer and Hites (1988, 1989).

As seen in Table 3-6, the calculated $p°_L$ were generally less the measured $p°_L$. On the average, the calculated $p°_L$ was 60% of the measured $p°_L$. This assessment will use the measured $p°_L$, which is thought to be preferable to using the modeled values.

These vapor pressures can be corrected to ambient, or any, temperature by the following procedure. The relationship between the liquid sub-cooled vapor pressure and temperature (°K) is (Hinckley, et al., 1990):

$$Log\ p°_L = \frac{-Q_v}{2.303\ R\ T} + b \qquad (3\text{-}8)$$

where:

$p°_L$	=	sub-cooled liquid vapor pressure of the pure compund, Pa
Q_v	=	the latent heat of vaporization, J/mol
R	=	ideal gas constant, 8.314 J/mol-K
T	=	temperature, K
b	=	intercept (related to entropy of vaporization)

The capillary GC method of Eitzer and Hites (1988) provides the temperature coefficient of vapor pressure, expressed by them as the ratio of the heats of vaporization for CDD/Fs to p,p'-DDT: Qv (CDD/Fs)/Qv (DDT). The authors determined these ratios for 14 CDD/F congeners,

including 13 of the ones listed in Table 3-6. For the remaining 4 congeners, it was assumed that Qv (CDD/Fs)/Qv (DDT) were the same as for other members of the same homolog group (e.g., the ratio for 2,3,7,8-TCDD was the same as for 1,2,3,4-TCDD). OCDF was assumed to have the same ratio as OCDD. The value of -Qv/2.303R for p,p'-DDT is -4640 (Hinckley, et al., 1990). This was used with the information given by Eitzer and Hites (1988) to estimate the temperature coefficients of vapor pressure for the CDD/Fs. For example, Eitzer and Hites (1988) give the ratio Qv (2,3,7,8-TCDF)/Qv(DDT) = 0.947. Thus the value of -Qv/2.303R for 2,3,7,8-TCDF = -4640(0.947) = -4394. This quantity can be used as the slope of Equation (3-6) for this congener: log $p°_L$ (2,3,7,8-TCDF) = -4394/T = b.

The next step in the procedure is to estimate the constant, b, of Equation (3-8). This can be accomplished given the slope (as just calculated), and a known (or calculated) $p°_L$, and the temperature associated with that $p°_L$. For example, the measured $p°_L$ of 2378-TCDF at 25 °C, is $1.23*10^{-4}$ Pa (Eitzer and Hites, 1988). Substituting -4394, T = 298 °K, and log p^o_L = -3.910 into Equation (3-6) yields a value for b, 10.83. Therefore, one now has an equation for the vapor pressure of 2378-TCDF as a function of temperature: Log p^o_L (2,3,7,8-TCDF) = 10.83 - 4394/T. In this manner, values of b were derived for all the 17 dioxin-like congeners, and these are shown in Table 3-6. It is importantly noted that all these b were developed from the measured values of the $p°_L$, not the modeled values calculated from the crystalline solid vapor pressure, p^o_S. Therefore, extrapolations to 20 °C are defined as extrapolations from the measured and not the modeled $p°_L$.

At this point, it is now possible to calculate the $p°_L$ as a function of temperature for all the congeners. For estimating the vapor particle partitioning of dioxins, it was assumed that the ambient temperature was 20 °C. The final column in Table 3-6 lists the calculated $p°_L$ at 20°C. Comparing the $p°_L$ at 25 and 20°C, reducing the temperature by 5°C causes the $p°_L$ to be reduced by about a factor of 2.

The Junge-Pankow model, Equation (3-3), was used to estimate particulate percentages for airsheds characterized as clean continental background, average background, background plus local sources, and urban. The particle surface area parameters (θ-values) representative of each airshed were those in Table 3-5. Liquid sub-cooled vapor pressures at 20°C, as derived above, were used, and c = 17.2 Pa-cm was assumed. As an example, the particulate fraction of 1,2,3,7,8-PCDF at 20°C in average background air ($\theta = 1.5 \times 10^{-6}$) is calculated as follows:

a) $p^o_L = 1.98*10^{-5}$ (from Table 3-6)

b) $c\theta = 17.2(1.5 \times 10^{-6}) = 2.58 \times 10^{-5}$

c) $\phi = c\theta/(p^o_L + c\theta) = 2.58 \times 10^{-5}/(1.98*10^{-5} + 2.58 \times 10^{-5}) = 0.57$

Table 3-7 shows the percentage of CDD/Fs predicted to be in the particle phase at 20°C for the seventeen congeners having dioxin-like toxicity.

3.2.4.7. *Comparison of Measured and Modeled Vapor/Particle Distributions for CDD/Fs*

Two factors complicate the comparison of field measurements and predictions of the Junge-Pankow model. One is the problem of sampling artifacts that are inherent with filter-sorbent devices. Parallel collections of PAHs made with filtration samplers and denuders suggest that the more volatile members of a chemical class will be partially lost from the particles on the filter during sampling -- the "blow-off" effect (Gundel et al., 1995; Lewis et al., 1991; Subramanyam et al., 1994). A second difficulty is that very few field measurements of both particulate and gaseous CDD/Fs have been made and presented in such a way that they can be related to model predictions.

The study by Eitzer and Hites (1989) is the best data set for particle/gas partitioning, since a large number of CDD/F congeners were measured on both the glass fiber filter and PUF trap. In their paper, the particle/gas ratios of individual congeners were reported as averages for the entire year, and the average ratios were related to the liquid-phase vapor pressures of the congeners at 25°C. Although their study showed conclusively that vapor pressure controls the distribution of CDD/Fs between the aerosol and gas phases, there is a problem with their method of data treatment. The particle/gas ratio varied greatly with temperature and the average ratio for the year may or may not have been represented by the situation at 25°C.

In his thesis, Eitzer (1989) also presented the particle/gas distributions as functions of the sampling temperature through the equation:

$$Log\ K_p = \frac{Q_d}{2.303\ R\ T} + b \qquad (3\text{-}9)$$

where the heat of desorption, Qd, of individual congeners and the intercept b were estimated by plotting K_p vs. 1/T for all the sampling events. In this form the data allow the particle/gas distributions to be related to event-to-event differences in ambient air temperature.

To relate Eitzer's (1989) data to vapor pressure, his parameters of Equation (3-9) were used to calculate log K_p for individual congeners at 20° C. The K_p values at 20°C were then plotted against the liquid-phase vapor pressures at 20°C according to Equation (3-9) to yield:

$$Log\ K_p = -0.719\ Log\ p^\circ_L - 5.53 \qquad r^2 = 0.962 \tag{3-10}$$

The plot of Equation (3-10) for the 17 dioxin-like CDD/Fs is shown in Figure 3-2a. As seen, there is an excellent correlation between log K_p and log p^o_L. It should be noted that although Equation (3-10) was obtained from values of K_p and p^o_L at 20°C, it applies at any temperature since the variation in partitioning with temperature is accounted for by the temperature effect on vapor pressure. The particulate fraction is related to K_p by:

$$\phi = \frac{K_p\ [\ TSP\ ]}{1 + K_p\ [\ TSP\ ]} \tag{3-11}$$

which follows from Equation (3-5) and the definition of K_p. Comparison of the Eitzer-Hites partitioning data to predictions of the model was done as follows:

a) Field estimates of the particulate fraction (ϕ) were calculated from values of K_p at 20°C by Equation (3-11), scaling to TSP = 60 $\mu g/m^3$ (corresponding to, "background plus local sources", Table 3-5).
b) Model estimates were calculated from Equation (3-3), using $\theta = 3.5 \times 10^{-6}$ (corresponding to, "background plus local sources", Table 3-5).

Plots of measured and modeled particulate percentages vs. log p^o_L at 20°C are shown in Figure 3-2b. Although the Eitzer-Hites partitioning data show a strong dependence on vapor pressure, their measurements fall below the model predictions.

A similar approach was used to evaluate particle/gas distributions for a subset of the other ambient air investigations reviewed earlier. The partitioning data of Hites (1991), Hunt and Maisel (1990, 1992) and Welsch-Paulsch et al. (1995) are given on a homolog basis in Table 3-4. However, because these studies were done at different ambient temperatures, the particulate percentages cannot be directly compared. Therefore, all field data had to be adjusted to a common temperature of 20°C by establishing relationships between the particle/gas distributions and vapor pressure:

a) Values of K_p were calculated from the particulate percentages in Table 3-4 for CDD/Fs which were found to a measurable extent in both the particle and gas phases (i.e., K_p could not be calculated for the 0% and 100% particulate data points). Since these studies were carried out in semi-rural locations, the "background plus local sources" air regime seemed to be the most appropriate, and a value of TSP = 60 $\mu g/m^3$ was assumed in calculating K_p by Equation (3-11).

b) The resulting log K_p values were examined for outliers (only one point was omitted, from the Hites (1991) data set), then regressed against log p^o_L at the ambient sampling temperature (Equations 3-7 and 3-8). The vapor pressure of each homologue group was taken to be the central value for the congeners in that group. Regression parameters of Equation (3-7) are given in Table 3-8 for the various field studies.

c) Values of K_p for each homologue group at 20°C were calculated from the vapor pressure at 20° C, using the regression parameters in Table 3-8.

d) Particulate percentages at 20°C were calculated from K_p by Equation (3-11), assuming TSP = 60 $\mu g/m^3$.

Thus, although the actual field measurements were done under a variety of temperatures, they were normalized to 20°C for comparison. Figure 3-3 shows the particulate percentages from four field studies in comparison to those predicted by the Junge-Pankow model for Whitby's "background plus local sources" air regime. These comparisons are also given in Table 3-9. All of the field data fall substantially below the model curve. For example, the particle-bound percentages of tetrachlorodioxins and furans, which are predicted to be 43-65% at 20°, averaged only 11-18% with the filter-sorbent sampler.

3.2.4.8. *Discussion of Monitored and Modeled Results for CDD/Fs*

The above comparisons show substantial differences between filtration sampling and the Junge-Pankow model for estimating particulate percentages of CDD/Fs. Reasons for these discrepancies may be related to both sampling artifacts and model uncertainties. Blow-off losses during collection are likely to reduce the filter-retained fraction. This artifact is expected to be the most serious for long sampling times, especially if the day-to-night temperature changes are large. However, the Welsch-Paulsch samples, which were collected over two-week integration

times, show only slightly lower particulate values than those of other workers which were obtained over 24-36 h sampling periods. Aside from the Eitzer-Hites data, the measurements of CDD/F vapor/particle distribution in Table 3-4 were based on only a few samples and it is difficult to judge their representativeness. Daily measurements of phase distributions for PAHs and PCBs in Chicago show up to an order of magnitude variation in K_p values, even when normalized for vapor pressure (Cotham and Bidleman, 1995). These variations may be caused by sampling artifacts and kinetic effects, and also by daily differences in aerosol properties.

Limitations of the Junge-Pankow model include uncertainties in the parameters c and θ. Pankow (1987) suggested that optimal values of c might be chosen for different classes of compounds. His reasoning was that the excess heat of desorption (Q_d-Q_v) appeared to be a smaller term for organochlorine compounds than for PAHs. However, this conclusion was based on the very limited field data available at the time Pankow's article was written. It is difficult to extract Q_d information from field data, by plots of Equation (3-7), because such plots involve combining particle/gas distributions for individual air samples which are collected over a range of ambient temperatures, humidities and aerosol properties. Confidence intervals around the Q_d values obtained from such plots are typically large (Pankow, 1991). Moreover, significant differences in Q_d values are obtained by analyzing Equation (3-7) plots by simple linear regression versus regression assuming a constant y-intercept for all compounds (Pankow, 1991). A better approach is to determine Q_d in the laboratory by measuring K_p under equilibrium conditions and at different temperatures, but few of these experiments have been carried out (Cotham and Bidleman, 1992; Falconer and Bidleman, 1994; Storey and Pankow, 1992). The authors of this assessment believe that there is insufficient information at this time to warrant recommending different values of the c-parameter for different compound classes.

The θ-parameter is also subject to uncertainty. It is likely that Whitby's values of θ do not reflect the true surface area distribution, since they were based on the average size spectrum of aerosols and assumed spherical particles. Other limitations of the model are the inability to consider the kinetics of adsorption/desorption (Kamens et al., 1995; Rounds, et al., 1993) and humidity effects (Pankow et al., 1993).

In conclusion, neither the filter-sorbent sampler nor the Junge-Pankow model necessarily give the "correct" vapor/particle distributions. Evidence based on limited field data suggest that the model overestimates the particulate fraction of CDD/Fs relative to the filtration sampler, but it can just as well be stated that the sampler underestimates the particulate fraction relative to the model. Further work needed to improve the state of knowledge of CDD/F partitioning between the aerosol and gas phases includes:

a) Comparative monitoring with filter-sorbent samplers and other speciating devices such as denuders (Coutant et al., 1992; Eatough et al., 1993; Krieger and Hites, 1994; Lane et al., 1988; Lewis et al., 1991; Gundel et al., 1995; Subramanyam et al., 1994; Tang et al., 1994) and diffusion separators (Hornbuckle et al.,1995; Turpin et al., 1993).

b) Laboratory experiments to investigate the kinetics and thermodynamics of the sorption of CDD/Fs and other semivolatile compounds sorption aerosols.

c) Improvements in modeling particle/gas distributions in ambient air.

Despite the differences in the monitored and modeled results, the Junge-Pankow model is the recommended approach for estimating the particle/gas distribution of CDD/Fs at the present time. In addition to reproducing the general trend in partitioning with vapor pressure (Figures 3-2 and 3-3), the Junge-Pankow equation was used in an air-to-beef model validation which is described in Chapter 7. That exercise used the Junge-Pankow model for partitioning dioxins in the air. A key finding of that work was that the transfer of vapor-phase dioxins to plants and subsequently to animals dominated the terrestrial food chain. Also, vapor/particle partition data on other semi-volatile organic compounds are compared in Chapter 7 to model predictions, and the match for these compounds is, in most cases (especially for PAHs), superior to that of the CDD/Fs.

3.2.4.9. *Discussion of Vapor/Particle Partitioning*

This subsection has reviewed stack testing data, ambient air sampling data, and theory rooted in basic physical chemistry that either imply, directly deduce or theoretically calculate the V/P partitioning in the ambient air. From this review it is generally concluded that:

1. Although the sampling methods in use today to characterize stack emissions from combustion sources accurately determine stack gas concentrations of CDD/Fs, these methods do not provide a credible basis for assuming the vapor phase and particle bound partitioning at the point of release. There is no consistent pattern to the interpretation of V/P based on where the CDD/F segregates in the instrument, e.g., the glass fiber filter or the XAD resin. Factors that mostly contributing to this are: (a) The relatively long residence time spent *in situ* during the sampling of stack gases; (b) The fact that the particulate filter housing is kept at a constant temperature, and, (c) The fact that a condensing section (consisting of glass tubing surrounded

by an ice or chilled water bath) is usually located between the particulate trap and the vapor trap to force condensation of vapor-phase organic constituents in the gases.

2. On the other hand, the ambient air sampling methods do give an approximate indication of the V/P ratio that seems to be responsive to changes in temperature, and degree of chlorination of the CDD/Fs. This is in accordance with what would be expected from their individual vapor pressures. There is no artificial heating or cooling of any component of the sampler. The sampler is exposed to actual temperature, pressure, and humidity of the ambient air. This removes the possibility that the vapor phase-particle bound partitioning, operationally defined as the compound segregating to the particulate trap and vapor trap, is actually an artifact induced by artificial heating and cooling within the system. Therefore the methods present a realistic picture of partitioning under variable ambient conditions. However, the method has certain limitations that currently prevent deriving a true measurement of V/P partitioning in the ambient air. Among these limitations are:

a. The glass fiber filter designed to capture and retain particulate matter has filter pours down to 0.1 µm diameter. Particles less than this diameter will pass through the filter and be retained in the polyurethane foam vapor trap downstream. If this is the case, the amount of CDD/Fs observed to be particle bound would be underestimated, and the amount observed to be in vapor phase would be overestimated.

b. The relatively high sampling volume passed through the system (200 to 400 m^3 of air per 24 hours) may redistribute the more volatile congeners from the filter to the absorbent trap by a process known as 'blow-off'.

3. Until sampling methods are improved and modified such that they give results that indicate the true V/P ratio of CDD/Fs in ambient air, the theoretical construct described by Bidleman (1988; and detailed above) is used to calculate the V/P ratio for purposes of air dispersion and deposition modeling of emissions from the hypothetical case demonstrated in Chapter 5. Key advantages to the theoretical approach are that the theoretical construct relies on current adsorption theory, considers the molecular weight and the degree of halogenation of the congeners, uses the boiling points and vapor pressures of the congeners, and uses the availability of surface area for adsorption of atmospheric particles that correspond to a variety of ambient air shed classifications having variable particulate matter densities.

3.2.5. Estimation of the Concentration of Dioxin-Like Compounds in Incineration Ash

The ash that is collected by the particulate matter control device preceding the stack is known conventionally as fly ash. Fly ash is the airborne combustion residue from burning the

fuel. Bottom ash is the ash residue that results from the combustion of the organic solids within the combustion chamber, and usually is collected below a grate system used to convey combustible fuels into the fire zone, or is collected at the bottom of the combustion chamber. In general, there are many factors that may influence the formation of particulate matter known as fly ash from the incineration of organic wastes. Among these factors are: the heating value of the incinerated material (BTU/kg), the percent moisture in the fuel, the furnace temperature and combustion efficiency, and the efficiency of particulate matter capture by the air pollution control device (Brunner, 1984; OTA, 1989). Fly ash, and not the bottom ash, contains most, if not all, the dioxin-like congeners. This can be explained by the synthesis of dioxin that occurs on the reactive surface of fly ash. Therefore, the following estimation of the ash generation rate, and the concentration of dioxin-like compounds in the ash particles, will focus solely on fly ash to the exclusion of bottom ash. Because bottom ash is mostly free of these contaminants, and is about 10 to 100 times the mass of fly ash, the mixing of fly ash with bottom ash will dilute the concentration of dioxin by about a factor of 10 - 100.

Estimation of the mass of fly ash generated, and concentration of dioxin-like compounds can be determined by the following (if no actual data exists):

1. Determine the mass of fly ash generated per day at the facility. This can be estimated from the percent control of particulate matter (PM) of the air pollution control device (APCD) installed at the facility. For example, if a combustor emits 0.5 kg of particulate matter per hour of operation, then 12 kg of PM is released from the stack in one day. If PM is controlled by 99%, then this rate of emission represents one percent of the fly ash generated by the combustion process. The amount of fly ash that is collected by the APCD would be 100 times the amount emitted, or 1200 kg/day.

2. Estimate the congener-specific concentration of CDD/Fs contained in the collected fly ash. This is done by assuming that what is prevented from exiting the stack is contained in the fly ash collected by the pollution control device. If, for example, 10 picograms CDD/F is emitted per gram of PM from the facility per day, and the APCD reduces emissions by 99%, then 100 times more CDD/F concentration, or 1000 picograms CDD/F per gram fly ash, would be in the collected fly ash. If the concentration of dioxin in emitted fly ash and the percent control of dioxin are known, then the concentration of dioxin in the mass of collected fly ash can be estimated. It is important to make such estimations in order to evaluate the potential environmental impact of ash management practices before the operation of the facility, and to select appropriate disposal practices to preclude future adverse conditions from arising.

3. Now estimate total mass, including fly and bottom ash, and final concentrations. If bottom ash mass is estimated at ten times fly ash, than the total ash generated in this example would be 1200 + 1200*10 = 13,200 kg/day. If fly and bottom ash were mixed for disposal, which is common, than the average concentration of the total ash would be one-tenth that estimated for fly ash.

The hypothetical example in Chapter 5 does not assess impacts associated with ash disposal. Section 4.3.5 of Chapter 4 describes procedures for estimating impacts from ash disposal given ash concentrations and mass generated.

3.3. AIR DISPERSION/DEPOSITION MODELING OF THE STACK GAS EMISSIONS OF DIOXIN-LIKE COMPOUNDS

It has been customary for EPA to use air dispersion/deposition models to estimate the atmospheric transport, the deposition flux, and the ambient air concentrations of specific pollutants attributable to smokestack emissions from an industrial combustion source. Air dispersion models are mathematical constructs that approximate the physical and chemical processes occurring in the atmosphere that directly influence the dispersion of gaseous and particulate emissions from smokestacks of stationary combustion sources. These models are computer programs encompassing a series of partial differential and algebraic equations to calculate the dispersion and deposition of the emissions. Concentration and deposition isopleths of the pollutants discharged from the stack are computed at specified distances from the smokestack. These quantities are used to estimate the magnitude of potential exposures to the human receptor.

Numerous dispersion/deposition models have been developed. This document focuses on the Industrial Source Complex 3 Short Term, ISCST3, dispersion model recently developed by EPA to provide modeling outputs useful in the analysis of wet/dry deposition and ambient air concentrations of stack emitted contaminants in all terrain settings (EPA, 1995). The ISC3 was developed as a general replacement to the COMPDEP model first described in EPA (1990b). Modeling enhancements of ISCST3 include more refined small particle dry and wet deposition algorithms than used by the COMPDEP model. The ISCST3 was used to generate the results for the hypothetical incinerator of this assessment. However, the use of ISCST3 is this assessment is not intended to imply that ISCST3 is the only acceptable model to use in the analysis of ambient air concentrations, and wet and dry deposition of dioxin-like compounds.

Subsection 3.3.1 below presents an overview of the dispersion and deposition algorithms in the ISCST3 model. Subsection 3.3.2 discusses dry deposition fluxes, including pertinent

assumptions made in the application of the ISCST3 model for the hypothetical combustor demonstrated in Chapter 5. Subsection 3.3.3 discusses particle size distributions for emitted particles. Subsection 3.3.4 discusses wet deposition, again noting key assumptions for the hypothetical combustor. Subsection 3.3.5. closes the section with guidance indicating that the ISCST3 model should be run with two simultaneous modes of operation: one mode provides estimates of particulate concentrations in air and wet/dry particle deposition flux; the other mode provides for the estimation of vapor phase concentrations of dioxin-like compounds in ambient air.

3.3.1. Basic Physical Principles Used to Estimate Atmospheric Dispersion/Deposition of Stack Emissions

Air dispersion/deposition models mathematically simulate the basic physical processes in the atmosphere to estimate the ground-level air concentrations and deposition flux of contaminants known to be released from the stacks/vents of stationary combustion sources. These processes include advection, turbulent diffusion, and removal of atmospheric particles. Advection describes the physical movement of the air contaminants by the horizontal movement of wind. Turbulent diffusion is the "spreading" of the emissions plume with distance from the stack due to multi-directional fluctuations in air movement. Removal refers to mechanisms which remove emissions from the atmosphere. This can be caused by the force of gravity exerted on the particle mass, Brownian movement of aerosol particles, and scavenging of particles. Scavenging is the removal of particles or vapors by precipitation.

ISCST3 contains modifications of the Industrial Source Complex model (Short-Term version; ISCLT, as described in EPA, 1986b), and COMPLEX I to incorporate algorithms to estimate dispersion, and resulting ambient air concentrations and wet and dry deposition flux. COMPLEX I is a second level screening model applicable to stationary combustion sources located in complex and rolling topography (EPA, 1986a). The ISCST model was developed by EPA to provide estimates of air concentrations and deposition rates of the stack emissions of contaminants from industrial sources located in varied terrain (e.g., from simple to complex terrain). Simple and complex terrain are defined as topography that is either below or above the effective stack height of the source (Turner, 1986). To account for pollutant deposition, the concentration algorithms in COMPLEX 1 were replaced with those from the Multiple Point Source Algorithm with Terrain Adjustments Including Deposition and Sedimentation (MPTER-DS) model (Rao and Sutterfield, 1982). The MPTER-DS algorithms incorporate the gradient transfer theory described by Rao and Sutterfield (1982), and are extensions of the traditional

Gaussian plume algorithms. The dispersion algorithms contained in the ISCST were incorporated to analyze ground-level receptors located below the height of the emission plume (EPA, 1986b). For a steady-state Gaussian plume, the hourly concentrations at downwind distance x (meters) and crosswind distance y (meters) are given by:

$$\chi = \frac{QKVD}{2\pi\mu_s\sigma_y\sigma_z} \exp\left[-0.5\left(\frac{y}{\sigma_y}\right)^2\right] \quad (3\text{-}12)$$

where:

χ	=	the ambient air concentration of the contaminent, $\mu g/m^3$
Q	=	contaminant emissions rate, g/s
K	=	units conversion factor
V	=	vertical term - accounts for the vertical distribution of the Gaussian plume, dimensionless
D	=	plume depletion term relating removal by physical or chemical processes, dimensionless
σ_y, σ_z	=	standard deviation of lateral and vertical concentration distribution, m
μ_s	=	mean wind speed at release height, m/s
y	=	crosswind distance from source to receptor, m

ISCST3 uses the generalized Briggs (1975, 1979) equation to estimate plume-rise and downwind dispersion as a function of wind speed and atmospheric stability. A wind-profile exponent law is used to adjust the observed mean wind speed from the measurement height to the emission height for the plume rise and pollutant concentration calculations. The Pasquill-Gifford curves are used to calculate lateral and vertical plume spread (EPA, 1986a). These curves are based on Pasquill's definitions of atmospheric stability classes, e.g., extremely unstable, moderately unstable, slightly unstable, neutral, slightly stable, and moderately stable, that correspond to various intensities of solar radiation and wind speeds (Seinfeld, 1986). The incorporation of these two basic models into ISCST3 permits analysis of a source located in all types of terrain.

3.3.2. Estimation of Dry Surface Deposition Flux

The dry deposition of particle-bound contaminants is a physical atmospheric removal process that is simulated by the ISCST3 model. Dry deposition refers to the transfer of airborne particulate matter to the Earth's surface (including water, soil, and vegetation) whereby it is removed from the atmosphere. Although the dry gaseous deposition of vapor-phase contaminants is currently considered in the ISCST3 model, this feature has not been calibrated for the estimation of the deposition flux of dioxin-like compounds into vegetation. Until the algorithm has been verified to make reasonably accurate estimates of gaseous deposition of dioxin-like compounds, this guidance will not incorporate examples of it's site-specific application. The focus of the following discussion is directed to the operation of the ISCST3 model to estimate the dry deposition of dioxin-contaminated particles.

The general processes controlling the transfer of particulate from some height above the surface through the surface layer down to the immediate vicinity of the surface are the forces of gravity and turbulent diffusion, followed by diffusion through the laminar sub-layer (defined as a thickness of 10^{-1} to 10^{-2} cm) to the surface (Seinfeld, 1986). The term "deposition flux" is mass concentration of a contaminant sorbed to atmospheric particulates that is delivered to the surface per unit of time by the physical forces of gravity, atmospheric turbulence, and diffusion (Kapahi, 1991). Deposition flux is represented mathematically by F_d. The dry deposition flux, F_d, is defined as the product of the ambient air concentration of the chemical contaminant, C_o, times a deposition velocity(m s^{-1}) of the contaminated particles as in Equation (3-13).

$$F_d = V_d C_o \qquad (3\text{-}13)$$

where:

F_d = dry deposition flux of contaminants sorbed to particles, $\mu g/m^2$-sec
V_d = the particulate depostion velocity, m/sec
C_o = concentration of pollutant on settling particles, $\mu g/m^3$

In general, Chamberlain and Chadwick (1953) first defined the depositon velocity, V_d, as the quotient of the deposition flux, F_d, divided by the airborne concentration, C_o:

$$V_d = - \frac{F_d}{C_o} \quad (3\text{-}14)$$

The value for F_d in Equation (3-14) has a minus sign because the downward flux is negative, whereas the deposition velocity is positive (Sehmel,1980). By this relationship, Chamberlain and Chadwick (1953) first introduced the concept of plume depletion, i.e., as the emission plume is dispersed with downwind distance from the stack, the deposition flux decreases with distance from the source.

The basic dynamics of the physics of modeling dry deposition have not changed significantly since Sehmel's (1980) comprehensive scientific review. The factors that most influence the predicted deposition flux can be divided as being either meteorological influences, or the influences of the properties of the pollutant under analysis. Meteorological influences include the friction velocity, represented as $\mu_{ø}$, and the aerodynamic surface roughness, represented as z_o. These terms are used to describe the wind speed profile above the Earth's surface. In most cases, the analyst uses a graphical procedure to determine values for $\mu_{ø}$ and z_o. If the logarithm of wind speed is plotted for near neutral atmospheric stability as a function of height from the surface, then the values for the constant z_o is fitted to a straight line on a semi-logarithmic scale. This can be described mathematically by Equation (3-15). In most cases, the friction velocity is a percentage of the wind speed.

$$\mu = \left(\frac{\mu*}{\lambda}\right) \ln \left(\frac{z + z_o}{z_o}\right) \quad (3\text{-}15)$$

where:

μ	=	the measured wind speed, cm/sec
μ_*	=	the friction velocity, cm/sec
z	=	the measured height above the surface, cm
z_o	=	surface roughness length, cm
λ	=	von Karman's constant, approx. = 0.4

As a general rule, particles greater than 30 micrometers (μm) in diameter will be removed from the atmosphere primarily by the force of gravity, whereas particles less than 30 μm will be removed primarily by atmospheric turbulence. The deposition flux for the smaller particles is influenced by many factors, including: the distribution of particles by diameter and density; the atmospheric turbulence; the friction of the ground surface and the height of the stack release of emissions. Deposition flux is also affected by the partitioning properties of the pollutant. These properties will determine how much of the pollutant is sorbed to the particle and how much is in the vapor phase. A detailed list of the many factors that can affect dry deposition is shown in Table 3-10.

The ISCST3 estimates dry deposition flux based on empirical associations developed by Sehmel (1980) and Sehmel and Hodgson (1978) relating the deposition flux to the deposition velocity of particles. The downward motion represented by deposition velocity is controlled by the gravitational settling velocity, atmospheric resistance, surface resistance and the atmospheric surface friction layer. This model assumes that a fraction of the particulate comes into contact with the ground surface by the combined processes of gravitational settling, atmospheric turbulence, and Brownian diffusion. The ISCST3 model contains enhancements to calculate dry deposition flux using a dry deposition model developed by Pleim et al. (1984). The Pleim et al. (1984) algorithms represent Sehmel's (1980) empirical relationships for transfer resistances as a function of particle size, density, surface roughness, and friction velocity. In the Pleim et al. (1984) model, integrated resistances to mass transfer are computed within two layers. In the first layer, which extends from one centimeter to one meter above the surface, atmospheric turbulence dominates mass transfer. This is a fully turbulent region where vertical fluxes are nearly constant, and is referred to as the aerodynamic resistance. In the second layer, which lies within one centimeter of the surface, the resistance to mass transfer is derived from particle deposition measurements that were taken in a wind tunnel over various surfaces using mono-dispersed particles (Sehmel,1980; Sehmel and Hodgson,1978). The general approach used by ISCST3 in the resistance methods for estimating the dry deposition velocity of particles is given by:

$$v_d = \frac{1}{r_a + r_d + I_a I_d I_s} + V_g \qquad (3\text{-}16)$$

where:

V_d = the depositon velocity, cm/s

V_g = the gravitaional settling velocity, cm/s
r_a = the aerodynamic resistance, s/cm
r_d = the deposition layer resistance, s/cm

Despite what is currently known about the physical and chemical processes that influence the final deposition flux of particles released from a stationary combustion source, a more thorough understanding of the influence of particle size on deposition velocity is needed. In Sehmel's (1980) review of settling velocities corresponding to particle diameter it was noted that the range of values spanned several orders of magnitude. This complicates efforts to make generalizations of V_d by particle diameter for air modeling purposes. Although dry particle deposition velocities have been estimated from both field studies and laboratory experiments, derived velocities are limited and highly uncertain. This is due largely to the complex and variable array of factors that can influence the rate of deposition (which are summarized in Table 3-10).

In the general classification of particles, particles < 2.5 micrometers (μm) in diameter are referred to a "fine particles", and those > 2.5 μm are "coarse particles". Sehmel (1980) offers the most current review of dry deposition settling velocities for a variety of depositing materials having a broad range of particle diameters. This summary appears in Table 3-11.

For the example application of the ISCST3 model in Chapter 5, particles less than 2 μm were represented by a 1 μm size and were calculated by ISCST3 to deposit at a velocity of $<10^{-2}$ cm/sec. Particles between 2 and 10 μm were represented by a 6.78 μm size and were calculated to deposit at a velocity of < 0.5 cm/sec. Finally, particles greater than 10 μm were represented by a 20 μm size and were calculated to deposit at a velocity of >2.0 < 5.0 cm/sec, although the variable ambient conditions resulted in more variable calculations. The derivation of these particle size representations is given in the next section.

3.3.3. Estimation of the Particle Size Distribution in the Stack Emissions

A distribution of particle size and diameter of the particulate stack emissions must be known before the ISCST3 program can predict deposition flux of the dioxin-like congeners. The diameters of small particles comprising particulate matter in stack emissions are usually measured in units of one millionth of a meter (micrometer, commonly called micron, abbreviated by the letters μm). Unfortunately, few studies have been conducted that describe the distribution of particulate matter entrained in the emissions from various combustion technologies broken down and fractionated by particle diameter. The characterization of particulate matter by

particle diameter will differ from one combustion process to another, and is greatly dependent on such factors as: 1) the efficiency of various air pollution control devices to the remove particles over a broad range of diameters from the gas stream , 2) the composition of the feed/fuel, 3) the design of the combustion chamber, 4) the amount of air used to sustain combustion, and 5) the temperature of combustion. Table 3-12 gives an example of a particle diameter distribution as measured at a stack of an incinerator, and was adopted from USEPA (1980). This example distribution will be assumed for the hypothetical incinerator.

Although the ISCST3 model can simulate up to 10 particle size categories, only three particle sizes are assumed for the model runs of the demonstration in this assessment. These three sizes are generalized from the data in Table 3-12:

- **Category 1:** $\leq$ 2 µm
- **Category 2:** > 2 to $\leq$ 10 µm
- **Category 3:** > 10 µm

After selecting the particle size distribution, it is necessary to calculate the mass emission rate of the particulate-bound congeners of CDD/Fs by particle size category. This is accomplished by calculating the proportion of surface area (available for adsorption of CDD/Fs) for a given particle diameter. The ratio of the surface area to volume is proportional to the ratio of the surface area to weight for a particle with a given radius. Multiplying this proportion times the weight fraction of particles of a specific diameter (µm) gives a value that approximates the amount of surface area available for chemical adsorption. The surface area to volume ratio can be described as follows:

(a) Assume aerodynamic spherical particles.

(b) Specific surface area of a spherical particle with radius,r:

$$S = 4 \pi r^2$$

(c) Volume of spherical particle with radius, r:

$$V = 4/3 \pi r^3$$

(d) The ratio of surface area to volume is:

$$S/V = 4 \pi r^2 / (4/3 \pi r^3)$$

$$S/V = 3/r$$

Dividing the surface area for each particle category by the total available surface area for all particles gives an estimation of the fraction of total area on any size particle. Multiplication of the emission rate of the dioxin-like congener times the fraction of available surface area will estimate the emission rate of the pollutant per particle size. The fraction of total surface area was computed for the three particle size categories. The fraction of total surface areas for the ranges

of particle diameters are summed with each particle size category to represent a single fraction of total surface area for the given particle size category, as follows:

- Particulate category 1: fraction of total surface area = 0.875
- Particulate category 2: fraction of total surface area = 0.095
- Particulate category 3: fraction of total surface area = 0.030

Thus by these assumptions, 87.5% of the emission rate of the dioxin-like congener is calculated to be associated with particles less than $\leq$ 2 µm in diameter, 9.5% of the emission is associated with the particle size of > 2 to $\leq$ 10 µm, and only 3% of the emission is associated with particles greater than 10 µm. To assist in deposition modeling of the emissions from the hypothetical incinerator, the particle size distribution is further simplified by assuming a median particle diameter to represent each broad particle size category, as follows:

- Particulate category 1 = 1 µm particle diameter
- Particulate category 2 = 6.78 µm particle diameter
- Particulate category 3 = 20 µm particle diameter

3.3.4. Estimation of Wet Deposition Flux

Wet deposition occurs by precipitation (rain, hail, snow) physically washing out the chemically contaminated particulate and vapors from the atmosphere. Vapor scavenging is not yet well understood and is not addressed in the ISCST3 model. The remainder of this discussion refers only to the wet deposition of particles.

Wet deposition flux depends primarily on the fraction of the time precipitation occurs and the fraction of material removed by precipitation per unit of time by particle size. Based on these relationships, scavenging coefficients were developed by Jindal and Heinold (1991) for varying types and intensities of precipitation relative to different particle diameters by incorporating the observations of Radke, et al. (1980) in a study of scavenging of aerosol particles by precipitation. The principal assumptions made in computing wet deposition flux are: (1) The intensity of precipitation is constant over the entire path between the source and the receptor; (2) The precipitation originates at a level above the top of the emission plume so that the precipitation passes vertically through the entire plume; (3) The flux is computed on the bases of fraction of the hour precipitation occurs as determined by hourly precipitation measurements compiled by the National Weather Service. The remaining fraction is subject only to dry deposition processes. Thus no dry deposition occurs during hours of steady precipitation, and dry deposition occurs between the periods of precipitation.

Wet deposition flux is estimated by ISCST3 using a scavenging ratio approach. In this approach, the flux of contaminant to the surface (F_w) is the product of the savenging ratio times the contaminant concentration, as in the following equation.

$$F_w = \Lambda \chi \quad (3\text{-}17)$$

where:

F_w = wet deposition flux, g/m^2-sec
Λ = scavenging ratio, sec^{-1}
χ = contaminant air concentration value calculated from the Gaussian plume equation, g/m^3

The scavenging ratio (Λ) is calculated as the product of the scavenging coefficient and precipitation rate (Scire et al., 1990), as follows:

$$\Lambda = \lambda R \quad (3\text{-}18)$$

where:

Λ = scavenging ratio, sec^{-1}
λ = scavenging coefficient, $(sec\text{-}mm/hr)^{-1}$
R = precipitation rate, mm/hr

The scavenging coefficient depends on the size distribution for particles and the nature or form of precipitation, i.e., liquid or frozen.

Across the plume, the total flux to the surface must be approximately equal to the mass lost from the plume. ISCST3 contains a plume wet deposition depletion equation as follows:

$$Q(x) = Q_o e^{-\Lambda x/u} = Q_o e^{-\Lambda t} \quad (3\text{-}19)$$

where:

Q(x) = wet plume depletion factor, dimensionless
Λ = precipitation scavenging ratio, sec^{-1}

t = x/u = the plume travel time, sec

The relationship between the scavenging coefficient, Λ, and the particle size and precipitation intensity was derived from the review of wet deposition studies of aerosol particles by Jindal and Heinold (1991). Table 3-13 displays the scavenging coefficients assigned to the generalized particle size categories and forms of precipitation (liquid rainfall, frozen) used for computing estimates of wet deposition in the application of the ISCST3 for the demonstration scenarios in Chapter 5.

3.3.5. Using ISCST3 to Model Emissions of Particles and Vapors

The ISCST3 model had to be run in two modes in order to provide estimates of ambient air concentrations of vapor-phase and particle-bound dioxins, combined with estimates of wet/dry particle deposition flux. The short-term ISCST3 model can accommodate these estimates in a single run. The user may select any or all of the output types, e.g, air concentration, wet deposition, dry deposition and combined wet and dry deposition, to be generated in a single model run. Instructions for this appear in the User's Guide for the Industrial Source Complex Models (ISC3) (EPA, 1995). To facilitate the modeling exercise, the modeler should assume a "unit emissions release rate" of CDD/Fs from the stack, e.g., 1 g CDD/F congener per second (1 g/s). Results from these unit runs can easily be transformed to final outputs given assumptions on CDD/F emissions in vapor and particle forms. Two assumptions are required. One assumption is the total emission rate of the compound, in units of mass/time (g/s), and the second is the vapor/particle partitioning of this total emission. The two modes are:

- **Mode 1: To estimate vapor-phase concentration of the contaminant in ambient air.**

The first mode assumes that the emissions of dioxin-like compounds are gaseous, e.g., with the wet/dry deposition switches turned to the "off" position. This is to isolate the ambient air concentration of the contaminant in vapor-phase from the calculation of wet and dry particle deposition flux. This inactivates a plume depletion equation that subtracts out losses in ambient air concentration due to particle deposition. What remains is the Gaussian dispersion algorithm to calculate air concentrations.

With the "unitized" emission rate, one can reconstruct the actual predicted ambient air concentration ($\mu g/m^3$) of vapors by multiplying the "actual" vapor-phase emission rate (g/s) by the "unitized" modeling result. For example, let the actual stack gas emission rate of total (vapor

plus particle components) contaminant be $1x10^{-5}$ g/s, and the V/P ratio (expected under ambient conditions) be 60%V/40%P. Then the "actual" emission rate of the vapor-phase portion of the contaminant is calculated to be $6x10^{-6}$ g/s ($1x10^{-5}$ g/s * 0.6). If the "unitized" ambient air concentration at the ground-level receptor is estimated by the ISCST3 model to be $1x10^{-8}$ $\mu g/m^3$ (i.e., this concentration is predicted with a unit emission rate of 1 g/s), then the "actual" predicted air concentration at that receptor can be estimated as:

$$(6x10^{-6} \text{ g/s} \div 1 \text{ g/s}) * 1x10^{-8} \mu g/m^3 = 6x10^{-14} \mu g/m^3$$

- **Mode 2: To estimate wet and dry particle deposition flux, and the ambient air concentration of the contaminant that is particle-bound**.

ISCST3 should be run with the wet/dry particle deposition switches turned to the "on" position, and using a "unit emission rate" of 1 g/s. This second run is considered a simulation of particle-bound contaminant only. Outputs of this run include unitized deposition rate and unitized ambient air concentrations of particles.

Like the vapor-phase run, the "actual" deposition flux (g/m^{-2} -yr) and "actual" particle-phase airborne concentrations can then be determined by multiplying the "actual" emission rate (g/s) of the particle-bound portion of the total contaminant emissions by the "unitized" modeling result at the ground receptor. For example, let the "actual" emission rate of the particle-bound portion of the contaminant be $4x10^{-6}$ g/s, and the "unitized" dry deposition flux at the ground receptor be $1x10^{-5}$ g/m^2-yr. Then the "actual" predicted dry deposition flux is $4x10^{-11}$ g/m^2 ($4x10^{-6}$ g/s ÷ 1 g/s * $1x10^{-5}$ g/m^2-yr). Using this same procedure, this second run provides the airborne concentration of contaminants bound to particles ($\mu g/m^3$).

There are two meteorological preprossesors used by ISCST3 model program to access local conditions necessary to compute model concentrations in both modes of operation: PCRAMMET (Catalano et al., 1987) and MPRM (Irwin and Paumier, 1990). These files contain hourly data for the wind speed, wind direction, stability class, mixing height, ambient air temperature, precipitation, and surface friction velocity.

Inhalation exposures are estimated as the sum of vapor and particle phase concentrations. Air-to-plant transfers require the vapor phase concentrations for vapor transfers and the particle-phase depositions. The air-to-soil algorithm requires particle phase depositions.

3.4. RESULTS OF THE AIR DISPERSION MODELING OF CONGENER-SPECIFIC EMISSIONS FROM THE HYPOTHETICAL ORGANIC WASTE INCINERATOR

The preceding subsections have presented general procedures for conducting air modeling of the emissions of dioxin-like compounds from the stack to the ground, starting with estimation of emission factors, vapor/particle partitioning at the stack, and proceeding to atmospheric dispersion and deposition using EPA's ISCST3 model. Where appropriate, previous subsections have also included discussion on the assumptions and the selection of parameters for the hypothetical incinerator which is demonstrated in Chapter 5. For example, Section 3.2.3 provided the emission factors that were used in this demonstration. This section will provide all other details of the hypothetical incinerator and provide the final results of the ISCST3 model simulations.

To reiterate, the purpose of the hypothetical construct is to help readers understand how to apply these principles to the air dispersion modeling and analysis of dioxin emissions from the source. Therefore, generalizations should not be made on the basis of this example regarding the magnitude of the emissions release and associated environmental impact.

A completely hypothetical incinerator was devised to serve as the example. Accordingly, a hypothetical, but realistic, incineration technology, facility size, stack height, and geographical location was selected. The hypothetical incineration facility has an assumed total daily capacity of 200 metric tons of organic waste materials. The emission rates of specific congeners of PCDD/Fs were derived from the stack testing and monitoring of emissions from a modern incinerator of this size. These emissions are expressed in units of g/sec, and are shown for the hypothetical incinerator in Table 3-14.

In constructing the hypothetical case, the following was defined: stack height; stack diameter; exit velocity of the gaseous emissions from the stack; and temperature of the exhaust gases characteristic of incineration facilities of this size. In order to access historical meteorological data for air modeling purposes, the hypothetical facility was located in a specific geographical area having specific meteorological conditions. To simplify the ambient air modeling and deposition, the hypothetical organic waste incinerator was assumed to exist in a simple terrain setting (e.g., flat terrain). By definition, simple terrain refers to an area where the terrain features are all lower in elevation than the top of the stack of the stationary source under analysis.

The dispersion and deposition computations performed by the ISCST3 model require data on wind speed, wind direction, wind profile above the surface, and hourly precipitation data.

When performing a regulatory analysis, e.g., to set air quality permit conditions, EPA's *Guideline on Air Quality Models* (EPA, 1986a) recommends the use of five consecutive years of representative meteorological data. However, in this example analysis of only one year of meteorological data was used as compiled at the Denver-Stapleton International Airport by the National Weather Service (NWS), because this was not intended as a regulatory analysis. Hourly measurements of wind speed, wind direction, temperature, and precipitation were used as a basis of computing annual average ground-level concentrations of dioxin in ambient air, and as a basis for the estimation of the dry and wet deposition flux. The Pasquill-Gifford (P-G) stability categories, were used as defined in the Modeling Guidelines. The specifications of stability categories depending on wind speed, cloud cover and mixing heights were established by Pasquill (1961), and later modified by Turner (1964). Reference is made here to Tables 9-3 and 9-4 on pages 9-21,22 of the Modeling Guidelines which gives a method for estimating P-G Stability Categories for daytime and nighttime conditions based on surface roughness and the wind speed profiles distributed in the United States.

To summarize, inputs for the ISCST3 model included hourly meteorological data, source characteristics and receptor features. Hourly meteorological data requirements are the mean wind speed, the direction from which the wind is blowing, the wind-profile exponent, the ambient air temperature, the Pasquill stability category, the vertical potential temperature gradient with height, the mixing layer height, and the frequency distribution of hourly precipitation. Source input data requirements included the congener-specific mass emission rate partitioned by vapor and particulate; the physical stack measurements, e.g., diameter, base elevation of the stack, and exit velocity and temperature of the stack gas, and settling parameters for particulate matter for both dry and wet deposition. Table 3-14 is a review of the congener-specific emissions data, and Table 3-15 is a review of the modeling parameters used in the air quality modeling of the hypothetical incinerator.

The output of the ISCST3 model for both surface deposition and ambient air impacts is a concentration array for 160 ground-level receptors around the incinerator, e.g., 10 receptor points along each of the 16 wind directions every 22.5° on the polar azimuth. Vapor and particle phase concentrations are in units of grams per cubic meter of air (g/m^3), and particle-bound depositions are in units of grams per square meter of surface area per year (g/m^2-yr). Results for both ambient air and surface deposition were estimated at concentric radial distances from the incinerator of 0.2, 0.5, 0.8, 0.9, 1.0, 2.0, 5.0, 10, 20, 30, 40, and 50 kilometers. The maximum annual average ground-level vapor and particle-phase air concentrations of all modeled congeners is estimated to occur 900 meters from the center of the stack. Tables 3-16 and 3-17

display the annual average vapor-phase and particle-phase air concentrations of dioxin-like congeners at various distances in the direction of the maximum impact. Tables 3-18 and 3-19 display the dry and wet deposition fluxes of dioxin-like compounds at various distances in the direction of maximum impact. The maximum annual average dry deposition flux occurs 800 meters from the center of the stack, although there is no significant difference from the 900 m distance where the maximum annual average ambient air concentration occurs. The maximum annual average wet deposition occurs 200 meters from the center of the stack, which is what is expected from the algorithm (refer to subsection 3.3.4. Estimation of Wet Deposition Flux).

3.5. REVIEW OF PROCEDURES FOR ESTIMATING SITE-SPECIFIC IMPACTS FROM A STACK EMISSION SOURCE

This chapter has detailed a procedure for evaluating site-specific impacts from stack emission sources. For purposes of demonstration, a hypothetical incinerator was defined, and using the ISCST3 model, estimates of vapor-phase concentrations and particle phase depositions at points around the stack were made. Three major points for estimating impacts of dioxin-like compounds using the ISCST3 or other models are as follows:

1. Characterize the emissions on a congener-specific basis: Although much of the information available on stack emission sources in on a TEQ or a homologue group basis, and not a congener-specific basis, the approach in this assessment, and the recommendation made here, is to conduct site-specific assessments using specific congener emissions. This is because fate and transport parameters, and bioconcentration/biotransfer parameters, are different for the various congeners. Assuming one set of such parameters for TEQ emissions can lead to a different estimated exposure media TEQ concentration than assuming congener-specific parameters and then, given estimated congener-specific concentrations, calculating TEQ exposure media concentrations with the TEF scheme. Emission factors were used in this assessment to describe source and site-specific emissions. These are defined as the mass of contaminant emitted per mass of feed material combusted. Procedures to convert other emission data, such as mass per time emitted or concentration emitted, are presented.

2. Estimate the vapor/particle partitioning for atmospheric transport and deposition modeling: Vapors are dispersed assuming Gaussian plume dispersion algorithms, and particles are transported and deposited via wet and dry deposition. The principal output of the atmospheric transport model, ISCST3, used for further exposure analysis are the vapor and particle phase concentrations, and the wet and dry deposition totals at sites of exposure. There is some thought that the partitioning between the vapor and particle phases at the stack differs from

the partitioning in ambient air. Such a difference might be due to the difference in temperature at the stack versus temperature of ambient air. If so, then deposition and dispersion trends in the close vicinity of the stack may differ from such trends further from the stack. Currently the data to support such a hypothesis is lacking; the earlier review of stack vapor/particle partitioning was inconclusive. Also, modeling approaches for such differences are unavailable. Instead, the approach in this chapter is to assume one partitioning scheme (separate V/P partitioning for individual congeners) for atmospheric transport and dispersion modeling. The scheme adopted in this assessment is based on a theoretical approach described by Bidleman (1988).

3. Conduct atmospheric dispersion and deposition modeling: The ISCST3 model is used in this assessment to estimate vapor and particle-phase concentrations, and wet and dry deposition totals for points around the stack emission source. Key inputs are vapor phase and particulate phase emission rates (rather than emission factor units, atmospheric transport models require emission rates in units of mass/time, or g/sec), stack descriptors (stack height, exit temperature, etc.), atmospheric transport parameters (particle size distributions, dry deposition velocity), meteorological data (hourly rainfall, windspeeds, etc.), and terrain descriptions. Procedures to translate the final model outputs of concentrations and deposition fluxes into exposure media concentrations is given in Chapter 4, Section 4.4.

Table 3-1. The number of dioxin-like and total congeners within dioxin, furan, and coplanar PCB homologue groups.

Homologue Group	n: Number of Dioxin-Like Congeners	N: Number of Total Congeners	1/N
I. Dioxins			
Tetra-CDD	1	22	0.022
Penta-CDD	1	14	0.071
Hexa-CDD	3	10	0.100
Hepta-CDD	1	2	0.500
Octa-CDD	1	1	1.000
II. Furans			
Tetra-CDF	1	38	0.026
Penta-CDF	2	28	0.036
Hexa-CDF	4	16	0.063
Hepta-CDF	2	4	0.250
Octa-CDF	1	1	1.000
III. Mono-ortho coplanar PCBs			
Tetrachloro-PCBs	1	42	0.024
Pentachloro-PCBs	5	46	0.022
Hexachloro-PCBs	4	42	0.024
Heptachloro-PCBs	3	24	0.042

Table 3-2. Emission factors and average emissions used for the hypothetical incinerator.

Congener	Emission Factors, ng/kg			Emissions, g/sec
	Test 1	Test 2	Test 3	
2378-TCDD	0.052	0.031	0.037	$9.3*10^{-11}$
Other TCDD	0.826	0.870	0.913	$2.0*10^{-9}$
12378-PCDD	0.148	0.056	0.048	$1.9*10^{-10}$
Other PCDD	1.390	0.322	0.783	$1.9*10^{-9}$
123478-PCDD	0.104	0.165	0.056	$2.5*10^{-10}$
123678-PCDD	0.157	0.187	0.130	$3.6*10^{-10}$
123789-PCDD	0.148	0.165	0.117	$3.3*10^{-9}$
Other HxCDD	2.440	0.670	1.040	$3.2*10^{-9}$
1234678-HpCDD	2.350	0.957	0.957	$3.3*10^{-9}$
Other HpCDD	4.040	1.650	2.170	$6.0*10^{-9}$
OCDD	4.260	1.390	30130	$6.7*10^{-9}$
2378-TCDF	3.300	2.390	2.170	$6.0*10^{-9}$
Other TCDF	20.00	15.70	14.30	$3.8*10^{-8}$
12378-PCDF	0.435	0.165	0.226	$6.3*10^{-10}$
23478-PCDF	0.243	0.139	0.122	$3.9*10^{-10}$
Other PCDF	6.280	4.480	3.480	$1.1*10^{-8}$
123478-HxCDF	0.478	0.365	0.357	$9.2*10^{-10}$
123678-HxCDF	0.478	0.343	0.313	$8.7*10^{-10}$
123789-HxCDF	0.357	0.165	0.226	$5.7*10^{-10}$
234678-HxCDF	0.243	0.117	0.074	$3.3*10^{-10}$
Other HxCDF	1.490	0.313	0.943	$2.1*10^{-9}$
1234678-HpCDF	0.243	0.565	0.696	$1.2*10^{-9}$
1234789-HpCDF	0.391	0.096	0.165	$5.0*10^{-10}$
Other HpCDF	241.0	2.380	2.180	$5.4*10^{-9}$
OCDF	1.579	0.478	0.971	$2.2*10^{-9}$

Notes: - For references, 1 = Eitzer & Hites (1989) and Eitzer (1989). Average distribution at 20°C based on plots of log Kp vs 1/T from their data; see Section 3.2.4.7. and Figure 3-2a).; 2 = Hites, 1991; 3 = Harless & Lewis, 1992; 4 = Hunt, et al 1990; 5 = Bobet, et al 1990; 6 = Welsch-Pausch, et al, 1995;
- For dioxin columns, 4D = tetra dioxin congener group; 5F = penta furan congener group, etc.
- NR = not reported; ND = not detected; NR and NDs not included in average estimation
- Welsch-Pausch, et al (1995) does not include V/P data, but it was sent by authors
- Harless and Lewis (1992) do not calculate V/P, rather V/P calculated here is based on isotopically labeled CDD/F spiked onto the filter and recovered from the filter and PUF trap.

Table 3-5. Values of θ, V_T, and TSP in different air regimes.

Airshed type	θ cm^2 aresol/cm^3 air	V_T cm^3 aerosol/cm^3 air	TSP $\mu g/m^3$
Clean continental background	$4.2*10^{-7}$	$6.5*10^{-12}$	9
Average background	$1.5*10^{-6}$	$3.0*10^{-11}$	42
Background plus local sources	$3.5*10^{-6}$	$4.3*10^{-11}$	60
Urban	$1.1*10^{-5}$	$7.0*10^{-11}$	98

Column 1: $p°_S$: crystalline solid phase vapor pressure at 25°C, Pa. Assigned based on analysis of available literature; see Volume II, Chapter 2

Column 2: $p°_L$: sub-cooled liquid vapor pressure at 25°C, Pa, calculated from $p°_S$ in Column 1 and the use of Equation (3-2)

Column 3: $p°_L$: l iquid sub-cooled vapor pressure at 25°C, as measured by Eitzer and Hites (1988, 1989)

Column 4: slope: the slope of Equation (3-6), equal to $Q_v/2.303R$

Column 5: b: intercept b of Equation (3-6)

Column 6: $p°_L$: liquid sub-cooled vapor pressure calculated at 20°C using the slope and intercept in Columns 4 and 5, and Equation (3-6)

* numbers without asterisks were based on ratios of Qv (CDD/Fs)/Qv (DDT) measured by Eitzer and Hitest (1989). Numbers with asterisks were assumed to be the same as for other members of the homologue group. OCDF was assumed to have the same ratio as OCDD.

Table 3-7. Particle fractions, ϕ, in four airsheds at 20°C for the dioxin-like congeners.

Congener	Clean Continental	Average Background	Background Plus Local Sources	Urban

Table 3-15. Modeling parameters used in the ISCST3 modeling of CDD/F emissions from the hypothetical incinerator.

Description	Value
General	Modeled after actual organic waste incinerator
Rate of organic waste combustion	200 metric tons per day
Air pollution control system	dry scrubber combined with a baghouse (fabric filters) resulting in 99% reduction of CDDs/CDFs
Model Options: Terrain adjustments	Yes
Stack downwash	No
Gradual Plume Rise	Yes
Buoyancy induced dispersion	Yes
Gravitational settling/deposition	Yes
Wet deposition	Yes
Calm winds processing option	Yes
Building wake effects	No
Stack height	30.48 m
Stack diameter	1.52 m
Anemometer height	10 m
Terrain	simple
Stack temperatre	400 °K
Stack exit velocity	8.9 m/sec
Source elevation	0 m
Z minutes	10 m
Exponents for power law wind increase with height:	0.07, 0.07, 0.10, 0.15, 0.35, 0.55
Particle size categories for dry/wet deposition analysis	
Category 1	$\leq$ 2 µm represented by 1.0 µm diameter
Category 2	>2 - $\leq$ 10 µm represented by 6.78 µm
Category 3	>10 µm represented by 20.0 µm
Particle density	1.4 g/cm^3
Fraction of CDD/F particle bound emission by particle size category: Category 1	0.88
Category 2	0.09
Category 3	0.03
Dry deposition velocities predicted by the CARB algorithm: 1.0 µm	7.11 *10^{-3} cm/sec
6.78 µm	2.87 * 10^{-1} cm/sec
20.0 µm	2.47 cm/sec
Wet deposition scavenging coefficients	Table 3-13
National Weather Service data	Denver-Stapleton Airport: 1989
Grid System	Polar

4. ESTIMATING EXPOSURE MEDIA CONCENTRATIONS

4.1. INTRODUCTION

The purpose of this chapter is twofold. First, it describes the algorithms used to determine exposure media concentrations of the dioxin-like compounds. Discussion of the algorithms are structured around three "source categories." These categories roughly translate to beginning points, or origins, of contamination. The source categories are also the basis for the example scenarios described in Chapter 5. Second, it provides information about all the model parameters and justification for the values selected for the demonstration of methodologies in Chapter 5. Parameter discussions appear immediately following descriptions of modeling methodologies.

Section 4.2 provides an introduction to the type of modeling used in this assessment. Section 4.3 describes the algorithms used for the first source category, soil contamination, where the dioxin-like compounds occur in surface soils. The exposures could occur at the site of contamination or the exposures could occur off the site of contamination. Section 4.3 describes the differences in modeling for these two. Section 4.4 describes algorithms to determine exposure media concentrations resulting from stack emissions, the second source category. Chapter 3 laid the groundwork for this section by describing the use of air dispersion/deposition models as applied to a point source to generate two key quantities: air-borne contaminant vapor phase concentrations at a site of exposure, and particulate phase deposition rates. Section 4.4 describes how modeled concentrations and depositions translate to soil, vegetative, and water concentrations. Section 4.5 concludes the chapter with a discussion of algorithms specific to the third source category, point-source effluent discharges into surface water bodies.

Algorithms are presented which estimate exposure media concentrations for: 1) surface soils, 2) surface water impacts: suspended and bottom sediment and dissolved phase concentrations, 3) air including the vapor phase and in particulate form, and 4) biota including beef, milk, fruit and vegetables, and fish.

4.2. BACKGROUND FOR SOLUTION ALGORITHMS

Literally hundreds of fate and transport models have been published which differ widely in their technical sophistication, level of spatial or temporal resolution, need for site specific parameterization, and so on. This can make selection of the most appropriate one for any particular situation difficult. Relatively simple, screening level models are used to model fate, transport, and transfer of dioxin-like compounds from the source to the exposure media in this

assessment. Simple assumptions are often made in order to arrive at the desired result, which is long-term average exposure media concentrations. Perhaps the most critical of the assumptions made is the assumption that the source strength remains constant throughout the period of exposure: the initial soil concentration of dioxin-like compound remains the same for that exposure period, and stack emissions and effluent discharges remain steady throughout this period.

It is important to understand that EPA is not endorsing the algorithms of this assessment as the best ones for use in all dioxin assessments. They are suggested as reasonable starting points for site-specific or general assessments, and as will be discussed shortly, most multi-media exposure modeling has included similar screening level approaches. The assumptions behind models are described carefully throughout this chapter. If these assumptions do not apply to a particular situation, or where assessors require more spatial or temporal resolution, more complex models should be selected. References to other models are made in this and other sections throughout the chapter. Also, Chapter 7 compares the models of this assessment to alternate models for several of the algorithms.

Finally, it cannot be overemphasized that measured concentrations are generally more reliable than modeled ones. Assessors should use measured concentrations if available and if such measurements can be considered spatially and temporally representative for the exposed populations.

The first examples of similar multimedia compartment modeling were probably the "fugacity" models proposed by Mackay (1979) and Mackay and Paterson (1981, 1982). Fugacity in this context is defined as the tendency for a chemical to escape from one environmental media compartment into another. The fugacity of a chemical present in an environmental media compartment is modeled using common fate and transport parameters such as octanol water partition coefficients, Henry's Constants, water solubilities, and so on. The fugacity concept is based on the fact that at equilibrium, equal fugacities are established in all compartments of a system. Examples of fugacity modeling include the transfer of nonionic organic chemicals between the atmosphere and surface water (Mackay, et al., 1986), between the atmosphere and plants (Riederer, 1990), and for food chain modeling (Travis and Hattemer-Frey, 1987). A regional fugacity model being used in regulatory risk assessment forums is the CALTOX (DTSC, 1993) model. Mackay (1991) authored a comprehensive, though somewhat dated, text on multimedia compartment modeling using the fugacity approach.. A key difference between fugacity modeling and the modeling in this assessment is that for fugacity modeling, movement between compartments is considered for both directions - from compartment A to compartment

B and also compartment B to compartment A. The modeling in this assessment is essentially one way - air to leaf, air to soil, vegetation to terrestrial animal, and so forth. This is thought to be reasonable for dioxins under the circumstances for which the models are being promoted - which is the circumstance of the source strength being constant over the period of exposure. Also, because the persistence and adsorptive tendencies of the dioxin-like compounds, movement from one compartment to another tends to be more one-way than it is for less persistent or more volatile organic compounds.

One possible drawback for the fugacity approach applied to the types of source categories discussed in this assessment is that it does not consider spatial variability of concentrations within a compartment. For example, air concentrations vary depending on the distance from a source of air emissions, such as a stack or a site of soil contamination. The fugacity approach would typically treat air as a single compartment with a uniform concentration. This would be a concern for a regional model such as the CALTOX model.

The transfer of contaminants between compartments and multimedia modeling approaches have been extensively studied at the National Center for Intermedia Transport at the University of California, Los Angeles. Their multimedia compartment model, MCM (Cohen and Ryan, 1985), provides several useful algorithms for intermedia transfer factors that would have application for dioxin-like compounds. Later on, this group introduced the spatial multimedia compartment model (Cohen, et al., 1990), which allows for non-uniformity in some compartments. Such a model would be more suitable for the types of source categories of this assessment, since there is non-uniformity within a compartment as noted above in the air compartment example.

An early approach which merged simplistic multimedia modeling with human exposure was termed the exposure commitment method, developed by Bennett (1981). An exposure commitment is defined as a contaminant concentration in human tissue. Exposure commitments are calculated from transfer factors that are estimated as the ratios of the steady-state concentrations of a contaminant in adjoining compartments of an exposure pathway. An example of adjoining compartments is air to plants to livestock to diet. This method has been applied to both PCBs (Bennett, 1983) and 2,3,7,8-TCDD (Jones and Bennett, 1989). These applications have required measured concentrations of the contaminants in different compartments in order to estimate the transfer factors. The retrospective nature of this approach limits its usefulness for general applications.

One of the early multimedia models which also had human exposure as the endpoint, but did not require retrospective data, was the GEOTOX model (McKone and Layton, 1986). This

model had air (vapor and particle phases), water (surface and ground water, including bottom sediments of surface water bodies), soil (soil gas, water, and solid subcompartments), and biomass (eggs, milk, meat, fish, and vegetation including food crops) compartments. The most recent evolution of this model can be found in McKone and Daniels (1991).

Multimedia modeling approaches have been extensively used to evaluate the exposure to dioxins. Paustenbach, et al. (1992) evaluated the exposure and risk to humans from residential and industrial soil contamination by 2,3,7,8-TCDD. Simple models were used to estimate the concentrations of 2,3,7,8-TCDD in air-borne suspended particulates and fish that reside in nearby streams impacted by the contaminated soil. Together with concentrations in contaminated soil, Paustenbach evaluated human exposures via soil ingestion, dermal contact, particulate inhalation, and fish consumption. They also used Monte Carlo techniques on exposure parameters (in contrast to using Monte Carlo on fate and transport parameters) to determine a range of residential and industrial soil concentrations that would result in a specified risk level. The risk level chosen for their demonstration was 10^{-5}, which was determined by multiplication of the Lifetime Average Daily Doses (LADDs in mg/kg-day) and the cancer slope factor for 2,3,7,8-TCDD of 9700 $(mg/kg\text{-}day)^{-1}$ derived by Keenan, et al. (1991). Residential soil concentrations less than 20 ppb did not pose a lifetime cancer risk greater than 10^{-5}. For industrial sites, concentrations in soil that could pose a 10^{-5} risk ranged between 131 and 582 ppb, depending on the amount of time the industrial worker spend outdoors under typical exposure conditions.

Travis and Hattemer-Frey (1991) evaluated human exposure to 2,3,7,8-TCDD from a broader perspective. The principal assumption of the Fugacity Food Chain model used for Travis' human exposure assessment is that atmospheric concentrations of 2,3,7,8-TCDD can be empirically linked to water, soil, and vegetative concentrations, which in turn are linked to agricultural produce, meat, milk, eggs, and fish concentrations. Simple models for atmospheric depositions onto plants, air-to-leaf transfers of vapor phase 2,3,7,8-TCDD onto plants, transfers to cattle beef and milk, and other models, are presented. They also compared their model predictions of exposure media concentrations to literature values, and concluded that their approaches resulted in concentrations comparable to those found in the literature. This effort by Travis and Hattemer-Frey is examined in more detail in Section 5.6 of Chapter 5.

Exposure to 2,3,7,8-TCDD using simplistic multimedia models has also been assessed for specific sources. Goeden and Smith (1989) evaluated the impact to fish and subsequent human exposure by consumption of fish to dioxins and furans emitted by a resource-recovery facility. Surface water sediment concentrations in a lake were estimated as a simple weighted average of concentrations on three kinds of particles entering the lake: soil via erosion whose concentration

was estimated given contaminated particle depositions onto soil (and considering mixing and soil half-lives), deposition of background uncontaminated suspended particulates directly onto the lake, and direct deposition of contaminated particles onto the lake. Fries and Paustenbach (1990) also evaluated the impact of incinerator emissions of 2,3,7,8-TCDD, but they evaluated human exposure via consumption of food crops, meat, and milk. EPA (1990d) used a simple dilution model to evaluate the impact of pulp and paper mill effluent discharges of 2,3,7,8-TCDD and 2,3,7,8-TCDF into surface water bodies.

The air-plant interface has been the subject of numerous fugacity and related modeling efforts for the dioxin-like compounds. This is because it is recognized that this pathway is critical to the terrestrial animal food chain; little soil-to-plant transfer occurs for these highly sorbed class of compounds. Trapp and Matthies (1995) present a comprehensive air/soil-to-plant modeling system, and in their application of this approach to 2,3,7,8-TCDD, they neglect the soil-to-above ground portion of their model. The importance of the vapor phase dioxins has been recognized in numerous modeling efforts, particularly for the lower chlorinated congeners (Lorber, 1995; McLachlan, et al., 1995). McLachlan, et al. (1995) developed a fugacity approach while the empirical air-to-plant transfer factor approach for vapor-phase dioxins in Lorber (1995) is advocated in the methodology.

This is only a cursory summary of the wealth of multimedia modeling approaches that are available, and the application of such modeling approaches for evaluating human exposure to dioxins. While there are many similarities and differences among the approaches, they all share one characteristic in common - they have all been described as "screening level models". Without attempting a definition of the qualifier, "screening level", such a qualifier for these models seems to imply the following types of common features: assumptions of equilibrium and/or steady state conditions between compartments, lack of substantial (if any) spatial or temporal resolution, the use of biotransfer or bioconcentration concepts which simply relate an environmental concentration (air or water concentration, e.g.) to a biomass concentration (plant or fish concentrations), and so on.

A counterpoint to screening level models might be what are termed "mechanistic" models. Such models are more theoretically sophisticated, contain more spatial and temporal resolution, attempt to simulate actual mechanisms of fate and transport rather than depend on empirical relationships developed from data, could involve complex food chain approaches to model biomass concentrations (to counter the simple biotransfer or bioconcentration approaches), and generally are highly parameterized requiring site-specific data that is often not readily available.

Because of the complexity of the multimedia environment, modeling of contaminant fate in such an environment has tended to remain simple. However, there are complex models which can be applied to smaller subsets of the multimedia environment, and which have been applied to assessments of dioxin-like compounds. One example is the ISCST3 model, which was used in this assessment to evaluate the impact of stack emissions of dioxin-like compounds. That model allows for complexities of terrain, varying weather patterns, vapor/particle partitioning, etc., to be considered. It relies on hourly meteorological data to simulate years of atmospheric transport and deposition, and summarizes the results of its simulation as long term average concentrations and depositions. That model is further described in Chapter 3. Another example of more complex modeling was the use of the WASP4 model in a comprehensive evaluation of bioaccumulation of 2,3,7,8-TCDD in Lake Ontario (EPA, 1990b). That application required a substantial amount of site-specific parameterization. Gobas, et al. (1999) describes the application of EcoFate to 2,3,7,8-TCDD and 2,3,7,8-TCDF pulp and paper mill discharges to the Fraser-Thompson River system in British Columbia, Canada from 1988 to 1995. This is a time-dependent, multimedia mass balance simulation of the environmental distribution and food-chain accumulation of organic contaminants in aquatic ecosystems. In this framework, modeled river systems are segmented, and within each segment, numerous compartments are modeled including the bed sediment (an accessible and an inaccessible bed layer), one or several water column compartments, the atmosphere, and one or more aquatic organism trophic levels (algae/zooplankton, benthic filter filters and detritivores, and fish). They were able to demonstrate a successful application of this model to predicted the two dioxin congener concentrations in bottom sediments, rocky mountain white fish, and rainbow trout.

With the exception of the ISCST3 model, the models used for this assessment are better described as screening level rather than mechanistic. Many of the algorithms used are the same or very similar to the ones found in references above. Except for the effluent discharge source category, which uses a non-spatially resolved dilution model for surface water impacts, the algorithms do consider spatial differences between the source and site of impact or site of exposure. For example, the algorithm estimating surface water impacts from a site of soil contamination, while simple in its framework, does incorporate the following: the area of the site that is contaminated, the area of the watershed which drains into the water body, the erosion rates of the site of contamination as well as the rest of the watershed, the proximity of the site to the water body, the concentration of the contaminant at the site of contamination as well as within the watershed other than the contaminated site, the lipid content of the fish, and the organic carbon fractions of the suspended and bottom sediments of the water body. Assignments

for all these parameters impact water and fish concentrations, and it is certainly arguable that they are all site-specific parameters. From this perspective, it could be argued that most of the algorithms of this assessment are generally screening level in their theoretical sophistication, but site specific in their application.

Sections in other chapters of this volume address key issues relating to the use and credibility of the algorithms described in this chapter. Chapter 5, which demonstrates the methodology, makes observations concerning exposure media concentrations. Chapter 6, on user considerations for use of the models and algorithms of this assessment, discusses categorization of model parameters and conducts sensitivity analysis exercises on key fate, transport, and transfer algorithms. Chapter 7 discusses applications of these models in validation exercises, and also compares the models of this assessment to others available for dioxin-like compounds. Chapter 8 on Uncertainty has critical discussions on parameter assignment and algorithm uncertainties.

Figures 4-1 through 4-3 are flow diagrams showing interim compartment concentrations modeled, and principal processes modeled and assumptions made in the intermedia transfer. Sections 4.3. through 4.5 describe the algorithms for the three source categories considered in this assessment, and background and assignment of parameters for the demonstration scenarios of Chapter 5.

4.3. ALGORITHMS FOR THE SOIL CONTAMINATION SOURCE CATEGORY

As earlier noted, exposures to contaminated soils can occur both at the site of the soil contamination or away from the site of soil contamination. Examples of on-site exposure would be worker exposures to Superfund or similar sites, or unique circumstances such as Times Beach where soil at the site of a residence or a playground becomes contaminated. Examples of off-site exposure include exposures at residences, farms, play or school areas, and so on, that are located near, but not at, the site of soil contamination. There are two primary differences with regard to modeling when exposure is on-site versus off-site. One is in the modeling of the dispersion of dioxin residues which have been suspended via volatilization or dust suspension. Models are presented below for on-site dispersion and off-site dispersion. The second difference is that, for on-site exposures, the initial soil concentration is assumed to remain constant throughout the period of exposure. For off-site exposures, the soil concentration at the site of exposure is assumed to build up over time from an initial level of zero before the site became contaminated to a level when exposure begins and then to a second level when exposure ends. The average soil concentration during the period of exposure is estimated as the midpoint between the two

latter concentrations noted. Otherwise, all other algorithms for the soil contamination source category, including the algorithms for surface water impacts and for biota calculations, are the same whether the exposure to the soil contamination is on-site of off-site.

Sections 4.3.1 through 4.3.4 describe the algorithms for estimating concentrations of the dioxin-like compounds in: bottom sediment, suspended solids, and in the dissolved phase in the water column of surface water bodies (4.3.1), exposure site soil concentrations (4.3.2.), in the air in the vapor and particulate phases (4.3.3), and in biota including fish (4.3.4.1), home-grown vegetables and fruit (4.3.4.2), beef and milk (4.3.4.3), and chicken and eggs (4.3.4.4). Section 4.3.5 describes some key characteristics of specific cases of soil contamination.

4.3.1. Surface Water and Sediment Contamination

The principal assumption in the algorithm estimating the impact to surface water and surface water sediments (suspended and bottom sediments) from an area of contaminated soil is that such an impact is correlated to surface soil concentrations at that site as well as surface soil concentrations within a larger area draining into the water body. This drainage area is commonly referred to as a watershed. Further, the impact to the water body is assumed to be uniform. This tends to be more realistic for smaller water bodies as compared to large river systems. Other key assumptions in the surface water impact algorithm are:

- Soil erosion estimates, coupled with sediment delivery ratios, can be used to describe the impact of a contaminated site relative to other soils in the watershed which contribute sediments to the water body;
- The sorption of dioxin-like compounds onto surface soil, suspended solids and bottom sediments is principally a function of the contaminant's organic carbon partition coefficient, Koc, and the organic carbon content of soils and sediments;
- The concentration of contaminants in soil eroding from a site are initially higher than the concentrations at the site itself - it is "enriched" with contaminants. This enrichment occurs because some processes of transport, such as wind erosion or soil erosion, favor lighter soils (silts and clays) which have higher surface area to volume ratios (more binding sites) as well as higher organic matter contents on the average (which also favors more binding of organic chemicals). Other processes such as volatilization or degradation may counteract the enrichment noted at the edge of a site - concentrations on soil entering a water body may be less than those leaving the site;
- The concentration of contaminants in sediment suspended in the water column exceeds the concentration in bottom sediments. Similar reasoning as the above enrichment

argument applies: particulates which remain in suspension tend to be lighter and more enriched with organic matter as compared to particulates which settle to the bottom of water bodies. It should be noted that suspended solids, in this algorithm, are simply a reservoir into which dioxin-like compounds sorb; more complex models consider sorption onto more than one reservoir of suspended materials including suspended particulates and dissolved organic matter;

- Suspended and bottom sediments originate principally as soil erosion; a mass balance is maintained such that a part of the soil reaching the water body through erosion remains as suspended particulates, and a part settles to bottom sediments.
- A steady state is achieved between concentrations in the dissolved phase in the water column, concentrations in the sorbed phase in the water column, and concentrations in bottom sediments;
- Volatilization out of the water body or degradation of residues in the water body are not modeled. Neglecting these dissipation processes has the net effect of overestimating water body impact. On the other hand, bottom sediment resuspension is not modeled. Not modeling resuspension would have a net effect of underestimating water column impacts; and
- Estimating the average impact to the water body, rather than a localized impact which may be the case if the contaminated soil is very near the water body, is suitable for purposes of this assessment procedure.

Concentrations in bottom sediment are desired because fish concentrations are estimated as a function of bottom sediment concentrations (see Section 4.3.4.1). Concentrations in suspended solids are desired because they are used to estimate bottom sediment concentrations, and dissolved phase concentrations are needed for estimating drinking water exposures.

The solution begins with the mass balance statement:

The mass of contaminant entering the water body	=	An amount which remains as dissolved in the water column + An amount which remains sorbed to suspended materials + An amount which remains sorbed to particles settling to the bottom

This can be described mathematically as:

$$C_{swb}\ ER_{w} = C_{wat}\ V_{wat} + C_{ssed}\ M_{ssed} + C_{sed}\ M_{sed} \quad (4\text{-}1)$$

where:

C_{swb} = concentration on soil entering water body, mg/kg
ER_w = total watershed annual soil erosion, kg/yr
C_{wat} = dissolved-phase concentration in water column, mg/L
V_{wat} = water body annual volume, L/yr
C_{ssed} = concentration on suspended sediment, mg/kg
M_{ssed} = mass of suspended sediment introduced per year, kg/yr
C_{sed} = concentration on sediment settling to bottom, mg/kg
M_{sed} = mass of bottom sediment introduced per year, kg/yr

Other equations based on assumptions stated above and needed for this solution are:

1) mass balance of soil is maintained:

$$ER_w = M_{ssed} + M_{sed} \quad (4\text{-}2)$$

$$M_{ssed} = f_s \, ER_w \quad (4\text{-}3)$$

$$M_{sed} = (1 - f_s) \, ER_w \quad (4\text{-}4)$$

where:

f_s = fraction of annual erosion remaining as suspended materials, unitless

2) equilibrium between sorbed and dissolved phases is maintained; suspended sediments are enriched in comparison to bottom sediments:

$$C_{wat} = \frac{C_{ssed}}{Kd_{ssed}} \quad (4\text{-}5)$$

$$C_{sed} = C_{ssed} \frac{OC_{sed}}{OC_{ssed}} \quad (4\text{-}6)$$

where:

Kd_{ssed} = soil-water partition coefficient for contaminant in suspended sediment, L/kg

OC_{ssed} = fraction organic carbon in suspended sediment, unitless

OC_{sed} = fraction organic carbon in bottom sediment, unitless

Now, Equations (4-2) through (4-6) can be substituted into the right hand side of Equation (4-1) so that this side can be function a one concentration, C_{ssed}, and one erosion amount, ER_w. Factoring out C_{ssed} then gives:

$$C_{swb}\, ER_w = C_{ssed} \left\{ \frac{V_{wat}}{Kd_{ssed}} + f_s\, ER_w + \frac{OC_{sed}}{OC_{ssed}} \left(1 - f_s \right) ER_w \right\} \quad (4\text{-}7)$$

The bracketed quantity in the right hand side of Equation (4-7) can be termed ϕ, so that C_{ssed} can be solved as $(C_{swb}\, ER_w)/\phi$. Now, the numerator in this term can be expanded to describe contaminant contributions by a site of contamination and contaminant contributions by the rest of the watershed. Included in this solution is the assumption made above that soils eroding into water bodies are "enriched":

$$C_{swb}\, ER_w = C_s\, SL_s\, A_s\, E\, SD_s + C_w\, SL_w \left(A_w - A_s \right) E\, SD_w \quad (4\text{-}8)$$

where:

C_{swb} = concentration on soil entering water body, mg/kg

ER_w = total watershed erosion, kg/yr

C_s = contaminated site soil concentration of dioxin-like compound, mg/kg

E = enrichment ratio, unitless

SL_s = unit soil loss from contaminated site area, kg/ha-yr

A_s = area of contaminated site, ha

SD_s = sediment delivery ratio for soil eroding from contaminated site to water body, unitless

C_w = average concentration of dioxin-like compound in effective area of watershed not including contaminated site, mg/kg

SL_w = average unit soil loss for land area within watershed not including contaminated site, kg/ha-yr

A_w = effective drainage area of watershed; the area contributing sediment which mixes with the sediment originating from A_s, ha

SD_w = sediment delivery ratio for watershed, unitless

Finally, the right hand side of Equation (4-8) can be termed, ρ, and the concentration in suspended sediment, C_{ssed}, is equal to ρ/ϕ. All the terms in ρ/ϕ are input parameters or can be solved as a function of input parameters. Other water body concentration terms, C_{wat} and C_{sed}, can now be solved using Equations (4-5) and (4-6). Note that this solution is applicable to both stationary water bodies such as ponds or lakes and moving water bodies such as streams or rivers. The differences in the two water systems can be expressed in the parameters, effective watershed area, A_w, water body volume, V_{wat}, and organic carbon contents of suspended solids and bottom sediments, OC_{ssed} and OC_{sed}. Guidance on these terms and assignment of values for the demonstration scenarios in Chapter 5 is now given.

- **C_s and C_w:** These are concentrations of dioxin-like compounds in the contaminated site soil, C_s, and the average within the effective area of the watershed, C_w. The contaminated site concentrations drive the concentrations assumed for most exposures, and is a principal user input. The simplest assumption for C_w is that it is 0.0. However, examination of soil data from around the world shows that, where researchers have measured concentration in what they described as "background" or "rural" settings, soil concentrations of CDD/Fs are in the non-detect to low ng/kg (ppt) range. Chapter 3 of Volume II of these Dioxin Exposure Reassessment Documents describes studies measuring dioxins in rural parts of America and calculates a TEQ_{DFP}-WHO_{98} of 4 pg/g (ppt). Example Scenarios 1 and 2 in Chapter 5 demonstrate the methodologies in this chapter in what are termed “background” settings. For these example scenarios, the 17 dioxin-like CDD/Fs are initialized to values that have been measured in an actual background setting.

● **E:** Enrichment refers to the fact that erosion favors the lighter soil particles, which have higher surface area to volume ratios and are higher in organic matter content. Therefore, concentrations of organic contaminants, which are a function of organic carbon content of sorbing media, would be expected to be higher in eroded soil as compared to in-situ soil. While enrichment is best ascertained with sampling or site-specific expertise, generally it has been assigned values in the range of 1 to 5 for organic matter, phosphorous, and other soil-bound constituents of concern (EPA, 1977). The enrichment ratio would be expected to be higher in sandy soils as compared to silty or loamy soils because the finer silt particles which erode from a soil generally characterized as sandy are more a deviation from the norm compared to silt particles which erode from a soil generally characterized as silty or loamy. The example scenarios in Chapter 5 modeled mid-range agricultural loam soils (as modeled with organic carbon fractions, soil loss parameters as discussed below). The enrichment ratio will therefore be assigned a value of 3.0 in all circumstances.

Two data bases have been found which justify the use of the enrichment ratio in this context. One is the data base from Connecticut which involved the sampling of surface soils and sediments from several rural locations in Connecticut (CDEP, 1992). Enrichment ratios were calculated from individual sites and for three dioxin-like compounds as the ratio of the concentration measured in sediment to the concentration measured in nearby surface soil samples. Enrichment ratios ranged from 0.33 to 12.3 with overall averages for the three dioxin-like compounds of 1.58 (for 2,3,4,7,8-PCDF), 2.59 (2,3,7,8-TCDF), and 3.86 (2,3,7,8-TCDD). Further details on this data are found in Chapter 7. A first set of results from another research study on the Hudson River was described in Smith, et al. (1995). Using modeling, they concluded that the concentration of dioxins in surficial sediment layers of the Hudson River were principally caused by soil erosion: 76% of the total deposition of CDD/Fs to bottom sediments were caused by surface erosion, with other causes including anthropogenic waste (sewer outflows; 20%), and direct atmospheric input (4%). To model the concentrations in the Hudson river surficial sediments, they used an enrichment ratio of 1.6 (defined as here as the ratio of the sediment concentration to the surficial soil concentration), based on an earlier analysis of particle sources of the Hudson river and its tributaries. The data presented in Smith, et al. (1995) on surface soils and sediments also show the disparity between surface soils and sediments - sediment concentrations are higher than surface soil concentration and sometimes substantially higher. However, since the Hudson River watershed is fairly complex and includes important sources other than soil erosion, it would be inappropriate to estimate enrichment ratios from the data as was done for the Connecticut data.

- **SL_s and SL_w:** These are the unit soil loss, in kg/ha, from the exposure site and the average from the effective land area draining into the surface water body. In the simplest case, the unit losses can be considered equal. In the most complicated solution, the effective drainage area can be broken up into "source areas", where each source area can be unique in terms of the erosion potential, concentration of contaminant, and so on. The total contribution equals the sum of contributions from each source area, as: $\sum C_j * SL_j * A_j * E_j * SD_j$ for the right hand side of Equation (4-8) for j number of source areas not including the exposure site. For direct input into Equation (4-8), the terms C_j, SL_j, A_j, E_j, and SD_j, should be determined and C_w, SL_w, E_w, and SD_w should be estimated as weighted averages over all source areas, A_j. The effective drainage area, A_w, would be the sum of all source areas, A_j.

For the example scenarios in Chapter 5 demonstrating the "background" settings, SL_s and SL_w are assumed equal. This generally assumes that erosion parameters for the site of exposure mirror the averages for the drainage area. Also, the enrichment ratio, E, is assumed to be constant for all watershed soils. For the demonstration of the soil contamination source category, the site of contamination is assumed to have different erosion characteristics. The following is offered as general guidance and background for estimation of unit soil losses in this assessment.

The unit soil loss is commonly estimated using the Universal Soil Loss Equation. This empirical equation estimates the amount of soil eroding from the edge of a field (Wischmeier and Smith, 1965):

$$SL = R\ K\ LS\ C\ P \qquad (4\text{-}9)$$

where:

SL	=	average annual soil loss, Eng. tons/acre-year
R	=	rainfall/runoff erosivity index, t-ft/ac-yr
K	=	soil erodibility factor, t/ac-(unit of RF)
LS	=	topographical factor, unitless
C	=	cover and management practice, unitless
P	=	supporting practices factor, unitless.

Several references are available to evaluate USLE factors for agricultural and non-agricultural settings (EPA, 1977; USDA, 1974; Wischmeier, 1972; Novotny and Chesters, 1981). For this assessment, values for these terms will based on assumptions about contaminated sites and rural

soils. Justification and assumptions are given below. It should be noted that more sophisticated models are available for estimating erosion rates (i.e., CREAMS as described in Knisel, 1980), and should be considered in actual site-specific assessments.

- **Rainfall/erosivity index, R:** The R term represents the influence of precipitation on erosion, and is derived from data on the frequency and intensity of storms. This value is typically derived on a storm-by-storm basis, but it has been compiled regionally for the development of average annual values (EPA, 1977). Annual values range from less than 50 for the arid western United States to greater than 300 for the Southeast. The value used in this assessment will be 160, which is typical of rainfall patterns seen in much of the midwestern United States.

- **Soil erodibility, K:** The soil erodibility factor reflects the influence of soil properties on erosion, with values ranging from less than 0.05 for non-erodible sandy soils to greater than 0.50 for highly erodible silty soils. The value used in this assessment will be 0.30, which is typical of, for example, sandy or silty loam soils with 2% - 4% organic matter contents.

- **Length-slope factor, LS:** The topographic factor reflects the influence of slope steepness and length of the field in the direction of the erosion. Steeper slopes and longer lengths lead to higher LS values, with a range of 0.1 for slopes less than 1.0% and lengths less than 100 ft to greater than 2.0 for slopes generally greater than 10%. The two key considerations for its assignment, therefore, are the size of the field for which erosion estimates are being made, and the slope of that field. The example scenarios in Chapter 5 had field sizes of 0.4 ha (1 ac) for a rural residence, 4 ha (10 ac) for a small rural farm, and 10 ha (25 ac) for a soil contamination site. Guidance for use of the Universal Soil Loss Equation stops short of defining appropriate sizes of field for which unit estimates are to be derived, except that the USLE was developed for agricultural "fields" where cover, slope, soil type, etc. are assumed to be uniform. For purposes of estimating erosion losses in this assessment, a field of 4 ha for estimating the LS factor will be used. In a rural watershed with agricultural and non-agricultural settings, this would be a reasonable average area of uniformity. If square shaped, a 4 ha area translates to a side length of 200 m. For purposes of assignment of the LS factor, it will be assumed that the contaminated site has a 2% slope. EPA (1977) (and other references as noted above) show nomagraphs giving the LS factor as a function of slope length and slope. With a 200 meter slope length and a 2%

slope, the LS factor is approximately 0.20. This factor will be used for all soil loss estimates required in this assessment.

- **Support practice factor, P:** The support practice factor reflects the use of surface conditioning, dikes, or other methods to control runoff/erosion. P can be no greater than 1.0. However, values less than 1.0 should only be assigned when specific practices are employed which are designed to reduce erosion. For the example scenarios in Chapter 5, it will be assumed that no such practices are in place at the site of concern or throughout the watershed to control erosion. Therefore, a value of 1.0 will be assumed.

- **Management practice factor, C:** The final term in the USLE is the cover and management practice factor, C, which primarily reflects how vegetative cover and cropping practices, such as planting across slope rather than up and down slope, influences erosion. C values can be no greater than 1.0, with this value appropriate for bare soils. A C value of 1.0 is an appropriate choice for active landfills or sites of high soil contamination (like Superfund sites) mostly devoid of vegetation. For an inactive landfill with grass cover or any area with dense vegetative cover such as grass, a value of 0.1 or less is appropriate. Values greater than 0.1 but less than 0.7 are appropriate for agricultural row crops, which offer more protection than bare soil, but not as much protection as dense vegetation.

Three erosion estimates are required for scenarios demonstrated in Chapter 5. One is for areas of high soil contamination, or the scenario demonstrating the soil contamination source category. It will be assumed that the contaminated site is largely devoid of vegetation in this case, and a value of 1.0 will be assumed. A second erosion estimate is needed to characterize average unit soil loss throughout a watershed draining into a surface water body. The example scenarios are based on a rural setting which has agricultural and non-agricultural (i.e., rural residences) areas. The C value in this circumstance will be assumed to be 0.3. Finally, a soil erosion estimate is needed in the algorithm transporting contaminated soil from an area of high soil contamination to a nearby site of contamination, as part of the algorithms developed for the soil contamination source category. In this case, the land between a site of soil contamination and the nearby site of exposure will be assumed to be covered with dense vegetation, such as grass. In this case, the C value will be 0.1.

As just described, three unit soil loss estimates are required for this estimates and the difference between the three will be expressed in the C term. Multiplication of the five USLE

terms gives unit soil loss estimates of 9.60 (with C = 1.0), 0.96 (with C = 0.1), and 2.88 (with C = 0.3) t/ac-yr. The value of SL_s and SL_w for the demonstration of the background setting scenarios in Chapter 5 is 2.88 t/ac-yr. Since Equation (4-8) and other uses of unit soil loss estimates are needed in kg/ha-yr, these unit losses are easily converted to 21515, 2152, and 6455 kg/ha-yr.

- **A_s and A_w:** These are the area terms, including the area of the contaminated site, and the effective drainage area of the watershed, both in ha. The scenarios demonstrated in Chapter 5 have assumed 0.4 ha (1 acre roughly) for exposure sites described as rural residences, 4 ha (10 acres) for farms, and 10 ha (25 acres) for the site of soil contamination. If the soil contamination site is at the site of exposure, as in the "on-site" source category, then A_s should be assigned an area equaling the site of exposure (and the concentration term, C_s, should equal the average soil concentration over this site of exposure). If the area of contamination is away from the site of exposure, A_s should equal the total area of contamination (and again C_s should equal the average soil concentration over this area).

The total area impacting a river system has been termed a watershed. For purposes of this assessment, an "effective" drainage area will almost always be less than the total area of a watershed. A "watershed" includes all the land area which contributes water to a river system. For large river systems, this area is in the order of thousands of square miles and includes several tributaries and smaller streams feeding into the main branch of the river. Each stream and tributary has its own sub-basin, whose sediment originates from a land area much smaller than thousands of square miles. If the contaminated site lies within that sub-basin, that it would be appropriate to include only the area within that sub-basin as the effective drainage area. This is one circumstance where an "effective drainage area" would be less than a total watershed area. Another consideration for determining the effective drainage area is the positioning of the contaminated site with respect to the point where water is extracted for drinking and fish are caught for consumption. If these points are significantly upstream in the river system in relation to the contaminated site, there is no reason to conclude that sediments or water near where the water is extracted are impacted by the contaminated site. If these withdrawal points are downgradient of the contaminated site, then there is reason to believe that sediments and water are impacted. However, if they are downgradient from the contaminated site but not at the bottom of the watershed, then sediment and water quality further downgradient from the withdrawal points is not of concern and land draining into these downgradient portions would not be part of the "effective drainage area". One further possible consideration is how far upgradient

in the watershed one should go when determining the size of the effective drainage area. While sediments introduced at the furthest points may eventually work their way down to the mouth of the watershed, this may take geologic time and not recent historic time. Therefore, sediment quality near a site of contamination need not consider these far reaches.

For a standing water body such as a lake or a pond substantially fed by ground water recharge, an assumption that probably should be made using the simple framework of this assessment is that all sediments within the lake/pond are completely mixed. Therefore, the effective area should equal all area around the lake/pond contributing sediment, and, as in the above discussion on river systems, a part of the land area contributing sediments to streams or rivers which may feed the standing water body.

From this discussion, it is clear that determination of an effective drainage area depends on site specific considerations, but it will likely be less than the total watershed area. The demonstrations in Chapter 5 assume a reasonably large watershed area draining into a river that can support a fish population suitable for recreational fishing. The effective drainage area of this watershed, A_w, will be assumed to be 100,000 hectares ($1*10^9$ m^2, $1*10^3$ km^2, 250,000 acres, 385 mi^2). Furthermore, it will be assumed that the water body in question is a river, which mainly impacts the assignment of the total suspended solids parameter, TSS (as discussed below). This assignment is not based on any specific sites that have been studied. As noted , it is justified as being a reasonable size to drain into a river large enough to support recreational fishing

A useful data source for this term and the suspended sediment term below, for specific sites in the United States, is Appendix F in Mills, et al. (1985). This appendix includes a compilation of data from river and reservoir sediment deposition surveys, including total drainage area, water body volumes, and rates of sediment deposition (mass/area-time). A caution in using this and similar data bases when evaluating specific sites is that, again, these total drainage areas are just that, <u>total</u> areas. Water bodies in this data base are located in the 48 conterminous states. An estimate of suspended sediment concentrations can be made using the water volume and the sediment deposition rates from this data, and an assumption on sediment deposition velocity. The specific weight of sediments in the water body, also supplied in this appendix, can be used to estimate sediment deposition velocity.

- **SD_s and SD_w:** These are the sediment delivery ratios applied to the exposure site and the watershed as a whole. Such a ratio is required because not all the soil which erodes from an area deposits into the receiving water body. The following delivery ratio was proposed for construction sites (EPA, 1977):

$$SD_s = (3.28\ DL)^{-0.22} \quad (4\text{-}10)$$

where:

SD_s = sediment delivery ratio for soil eroding from contaminated site to water body, unitless

DL = distance from contaminated site to receiving water body, m

3.28 = converts m to ft (empirical equation was developed for units of ft).

Note that the sediment delivery empirical equation simplifies all land features pertinent to erosion to a function only of length. The equation was developed to estimate sediment loads from construction sites to nearby surface water bodies, and from distances up to 250 m (800 ft, roughly). Without specific information on the sites from which it was developed, it is assumed that the land area between the construction sites and the receiving water body is "average" and this relationship can be used for applications other than construction sites.

As noted in previous bullets, the example scenarios demonstrating the background setting assumed $C_s = C_w$, and $SL_s = SL_w$. The impacted water body was assumed to be 150 meters away from the site of exposure for this demonstration setting. This distance translates to a delivery ratio of 0.26. Site-specific conditions could result in a larger (steeper slope, e.g.) or smaller proportion of the eroded soil being delivered to the water body than would be estimated with this equation.

Figure 4-4 shows a watershed delivery ratio as a function of watershed size. As seen, the ratio decreases as land area increases. The total watershed size, A_w, assumed for the example scenarios in Chapter 5 was 1000 km^2. From Figure 4-4, this translates to a watershed delivery ratio, SD_w, of 0.06. If the watershed is larger than about 2000 km^2, which is the extent of coverage of this figure from Vanoni (1975), the following empirical equation was found to satisfactorily extend the relationship seen in Figure 4-4:

$$SD_w = 0.6\ (A_w)^{-0.125} \quad (4\text{-}11)$$

where:

SD_w = sediment delivery ratio for a watershed, unitless

A_w = effective drainage area of watershed; the area contributing sediment which mixes with the sediment originating from the contaminated site, m^2

- **f_s:** As soil erodes into the water body, it will settle onto the bottom to become bottom sediment. Part of the settled material will become resuspended because of turbulent flow. The finest materials in eroded soil may not settle for a long time, and essentially always be in suspension. One way to arrive at the fraction of annually eroding material which remains in suspension ("remains in suspension" for purposes of discussion - in reality, little, if any, will remain in suspension, but will rather deposit and resuspend) involves complex modeling. A wealth of such models exist, such as those described in Wang (1989). The approach used here is more simple than those in Wang (1989).

If an average level of suspended material in the water were specified, in units of mg/L, what would be known with otherwise required parameters is the total amount of erosion reaching the water body (as discussed above) as well as the annual water volume (discussed below). A required parameter for this assessment will therefore be the level of suspended solids in the water body, TSS. With this parameter and the annual water flow volume, V_{wat}, the total suspended load equals, TSS (mg/L) * V_{wat} (L/yr). The assignment of these two terms are 10 mg/L and $4.8*10^{11}$ L/yr, leading to a total suspended load of $4.8*10^{12}$ mg/yr, or $4.8*10^{6}$ kg/yr. Total erosion into the water body, in similar units, equals, $A_s * SL_s * SD_s + (A_w - A_s) * SL_w * SD_w$. With parameter assignments as discussed above, the total annual erosion equals 1.29×10^{7} kg/yr. Therefore, the fraction of total load that is suspended is 0.36 ($4.8*10^{6}/1.3*10^{7}$).

Given this formulation, the f_s term is not a model input value, but is solved on the basis of the other parameters noted.

- **TSS:** This is the total suspended sediment in the water body. This value will be lower for standing water bodies such as ponds or lakes as compared to streams or rivers. The more turbulent flow in rivers will suspend sediments to a greater degree than a relatively calm lake. A complex modeling exercise evaluating the impact of 2,3,7,8-TCDD to Lake Ontario assumed a suspended sediment concentration of 1.2 mg/L (EPA, 1990b). For use in pond or lake settings, an assumption of a suspended sediment concentration of 1-2 mg/L is reasonable. All example scenarios in Chapter 5 assume that the 100,000 ha watershed drains into a river suitable for supporting fish for consumption and water for drinking purposes. General guidance offered for the potential for pollution problems in rivers and streams as a function of average suspended sediment concentration are: 10 mg/L or less - no problem, 100 mg/L or less - potential problem,

and greater than 100 mg/L - probable problem. A cutoff concentration for protection of aquatic life is 80 mg/L (Mills, et al., 1985). The value assumed for TSS for all example scenarios in Chapter 5 is 10 mg/L, indicating no turbidity problems and a river supportive of fish for consumption.

- **V_{wat}:** The stream in the example scenarios will be assumed to derive its annual flow only from the effective drainage area, A_w. Given the area of drainage, one way to estimate annual flow volume is to multiply total drainage area (in length squared units) times a unit surface water contribution (in length per time). The *Water Atlas of the United States* (Geraghty et al., 1973) provides maps with isolines of annual average surface-water runoff, which they define as all flow contributions to surface water bodies, including direct runoff, shallow interflow, and ground-water recharge. The range of values shown include 5-15 in/yr throughout the Midwest cornbelt, 15-30 in/yr in the South and Northeast, 1-5 in/yr in the desert Southwest, and a wide range of 10-40 in/yr in the far West. For this assessment, an assumed 19 in/yr is used to estimate the annual flow volume. Over a 100,000 hectare drainage area, total flow volume equals 4.8 x 10^{11} L/yr (19 in/yr * 0.0254 m/in * 100,000 ha * 10,000 m^2/ha * 1000 L/m^3).

- **Kd_{ssed}:** This adsorption partition coefficient describes the partitioning between suspended sediment and the water column. For numerous applications for organic contaminants, particularly for estimating the partitioning between soil and soil water, this partition coefficient has been estimated as a function of the organic carbon partition coefficient and the fraction organic carbon in the partitioning media:

$$Kd_{ssed} = Koc \quad OC_{ssed} \qquad (4\text{-}12)$$

where:

Kd_{ssed} = soil-water partition coefficient for contaminant in suspended sediment, L/kg

Koc = organic carbon partition coefficient for contaminants, L/kg or cm^3/gm

OC_{ssed} = fraction organic carbon content of suspended sediment, unitless.

The organic carbon partition coefficient, Koc, can be a measured value or it can be estimated. Chapter 2 of Volume II of this dioxin exposure reassessment reviewed the available

literature on Koc for 2,3,7,8-TCDD. Based on available studies measuring the Koc, a log Koc value of 6.6 was recommended for this congener. Recommendations could not be made for the other dioxin-like congeners because of few measured data points, and when available, the data sometimes showed considerable differences.

In the absence of measured values, the Koc can be estimated from a chemical's octanol water partition coefficient, Kow. Empirical equations relating Kow to Koc are listed in Lyman, et al. (1982). Of six different equations listed in that reference, the following derived by Karickhoff, et al. (1979) is used to estimate the Koc for the example compounds in Chapter 5:

$$\log Koc = \log (Kow) - 0.21 \quad (4\text{-}13)$$

where:

Koc = organic carbon partition coefficient, L/kg
Kow = octanol water partition coefficient, unitless

This equation was empirically developed from a limited number of hydrophobic contaminants (n=10, $R^2 = 1.00$). It implies that Koc is very similar to Kow for strongly sorbed compounds such as the dioxin-like compounds. Using the log Kow of 6.8 recommended in Chapter 2, Volume II of this assessment for 2,3,7,8-TCDD, the estimate of log Koc is 6.59. This is essentially the same as the recommendation for log Koc of 6.6 for 2,3,7,8-TCDD based on measurement studies. This relationship will be used to estimate the Koc for all other dioxin-like compounds.

- **OC_{sed}, OC_{ssed}:** The organic carbon content of solids and sediments of water bodies are generally higher than organic carbon contents of the surrounding lands. Furthermore, organic carbon contents of suspended organic materials and solids are typically greater than those of bottom sediments. A significant sink for strongly hydrophobic contaminants such as the dioxin-like compounds is thought to be suspended, or non-settling, organic material. In modeling 2,3,7,8-TCDD in Lake Ontario (EPA, 1990b) using the WASP4 model, a compartment separate from suspended solids termed "non-settling organic matter" served as a permanent sink. For purposes of this assessment, a single reservoir of suspended materials onto which incoming dioxin-like compounds sorb is principally characterized by OC_{ssed}, and the values selected for OC_{sed} and OC_{ssed} should reflect the relative partitioning behavior of suspended and bottom materials. As noted above, these water body carbon contents are also related to the organic

carbon contents of surrounding soils. The model parameter, OC_{sl}, is the soil organic carbon fraction and is required for modeling of soil contamination by dioxin-like compounds. Foth (1978) lists the organic nitrogen content of several soil types ranging from sand and sandy loam to clay. The range from that list is 0.0002 - 0.0024 on a fractional basis. Assuming a carbon to nitrogen ratio of 10 (Brady, 1984; who notes that C:N ratios vary from 8 to 15, with the typical range of 10 to 12), organic carbon ranges from 0.002 to 0.024. A soil organic carbon fraction, OC_{sl}, is assumed to be 0.01 for all example settings in Chapter 9, which is in the middle of this range. The organic carbon content of bottom sediments, OC_{sed}, will be higher at 0.03. Bottom sediments originate as erosion from surrounding land, but also include decay of organic materials within water bodies. The organic carbon content of suspended materials can approach 0.20, but OC_{ssed} will be assumed to be 0.05 for the example settings in Chapter 5.

4.3.2. Exposure Site Soil Concentrations

If the soil contamination occurs at the site of exposure, than the exposure site soil concentration is simply the soil concentration as initialized by the model user. As described in the Section 4.3.1 above, a key assumption for the simplistic models used in this assessment is that the source strength does not vary over the course of the exposure. Therefore, the soil concentration as initialized remains unchanged during the exposure period. An example of a situation where the contaminated soil is at the site of exposure is a residential property impacted similar to the properties at Times Beach, Missouri, where residential soils were impacted by the spraying of waste oils for dust suppression. Another example would be the analysis of worker exposures on a Superfund site contaminated by dioxin-like compounds.

A more typical application of the methodologies for soil contamination, however, would be the circumstance where sites of exposure are near, but not at, the site of soil contamination. For example, residences or farms near a Superfund site would be the scenario of concern for the contaminated soil source category. This section describes methodologies for estimating the soil concentration at an exposure site near a contaminated soil site.

The key assumptions for the solution strategy estimating exposure site soil concentrations resulting from an off-site soil contamination source are: 1) the exposure site soil becomes contaminated due to erosion of contaminated soil from the source to the exposure site, 2) the amount of soil at the exposure site does not increase, which means that soil delivered to the site via erosion is matched by an equal amount which leaves the site, and 3) not only does soil erode off the contaminated site en route to the exposure site, but soil between the contaminated site and the exposure site also erodes to the exposure site.

The second and third assumption translate to:

$$D_1 + D_2 = SR \quad (4\text{-}14)$$

where:

D_1 = mass of soil delivered from off-site contaminated source, kg

D_2 = mass of soil delivered from land area between contaminated source and exposure site, kg

SR = mass of soil removed from exposure site, kg.

The mass balance equation for exposure site soil concentrations can now be qualitatively stated as (with "ΔC" used as shorthand for change in exposure site soil concentration over time):

ΔC = (the incremental addition to C resulting from the change in erosion of contaminated soil) - (the incremental substraction of C resulting from removal of now contaminated soil from the exposure site) - (the incremental substraction of C resulting from dissipation of residues at the exposure site)

This can be expressed mathematically as:

$$\frac{dC_e}{dt} = \frac{D_1 C_s}{M} - \frac{SR C_e}{M} - k_s C_e \quad (4\text{-}15)$$

where:

C_e = the exposure site soil concentration, mg/kg

D_1 = mass of soil delivered from off-site contaminated source, kg/yr

C_s = contaminated site soil concentration of dioxin-like compound, mg/kg

M = mass of soil at exposure site into which contaminant mixes, kg

SR = mass of soil removed from exposure site, kg/yr

k_s = first order soil dissipation rate constant, 1/yr.

Assuming that the contaminant concentration at the exposure site, C_e, is initially 0, Equation (4-15) can be solved to yield:

$$C_e = \frac{D_1 C_s}{SR + k_s M} \left[1 - e^{-(\frac{SR}{M} + k_s) t} \right] \quad (4\text{-}16)$$

which computes C_e as a function of time, t (in years since k is in years). This can be solved for various increments of time starting from a time when the exposure or contaminated site initially became contaminated, or it can be simplistically assumed that the contamination has existed at the contaminated site for a reasonably large amount of time such that the exponential term approaches zero. The rate at which the exponential term approaches zero is a function of the value of k, the first-order dissipation constant. The smaller the value of k (i.e., the longer the half-life of dioxins transported to a nearby site), the longer it will take for the system to reach steady state. The algorithms of this assessment, such as the surface water algorithms described above and the calculation of the biota calculations as described below, have simplistically assumed that steady state has occurred by the time any exposure has occurred. This simplicity will be continued here. Generally, assuming steady state will lead to conservative results - i.e., overall impacts over time will be less if the systems modeled have not reached steady state (or close enough to it) by the time exposure begins. At steady state, the exponential term drops out, and C is estimated as:

$$C_e = \frac{D_1 C_s}{SR + k_s M} \quad (4\text{-}17)$$

One final note on this solution is that, unlike the solution for estimating water body impacts, there is not an assumption that the eroded soil is enriched in comparison to the soil at the site of contamination; an enrichment ratio was used in the surface water algorithm, but not for this algorithm. The foundation for enrichment of sediments was the arrival of finer textured soils with higher concentrations of constituents of concerns (organic contaminants, inorganic nutrients) at water bodies. This theory is well founded and there is data on the enrichment of dioxin-like compounds in sediments as compared to surface soils. On the other hand, there is no

similar evidence or foundation for assuming enrichment for dioxin-like compounds in soil when the transport is to a nearby site instead of a more distant water body.

Equation (4-17) was used to estimate exposure site concentrations resulting from the erosion of contaminated soil in the demonstration of the soil contamination source category in Chapter 5. Guidance for estimation of these terms including justification for their values as selected in the example settings are:

- **k_s:** For soil residues at the site of soil contamination, the assumption is made that residues do not degrade or dissipate to the point of reducing the concentration of the "initial" soil levels. This was partly based on information indicating generally low rates of biological or chemical degradation for the dioxin-like compounds of this assessment, coupled with the assumption that the soil contamination was sufficiently deep implying a reservoir of contaminant that would remain available during a period of exposure. These assumptions are less likely to be valid for residues which have migrated over the surface to deposit on the exposure site. The deposition is likely to result in only a thin layer of contaminated soil. Though very small, surface-related dissipation mechanisms such as photolysis, volatilization, or degradation, might reduce surface soil contaminant concentrations. For these reasons, a "dissipation" rate constant is assumed to apply to delivered contaminant, where the precise mechanisms of dissipation are not specified, but could include transport (volatilization, erosion) and degradation (photolysis) mechanisms.

Fries and Paustenbach (1990) suggested the use of a half-life of at least 10 years, and used a 15 year half-life in their example scenarios on the impact of air-borne deposition of 2,3,7,8-TCDD originating from stack emissions. In a later publication, Paustenbach, et al. (1992) reviewed the literature on the environmental half-life in soil. For surface soils, they cited the evidence from Eglin Air Force Base (Young, 1983) suggesting a half-life of 10 to 12 years for 2,3,7,8-TCDD, and the work of Cerlesi, et al. (1989), who estimated a soil half-life of 9.1 years for 2,3,7,8-TCDD in Seveso soil. Paustenbach, et al. (1992) also discussed the fact that the loss of TCDD from soil is predominantly through volatilization and photodegradation of residues at the soil surface, and that loss mechanisms are minimal below the soil surface. They suggested that ultraviolet radiation penetrates only about the surface 0.1 cm, which implies that photodegradation could be limited below that depth. They concluded that their review supported the concept that TCDD probably has a half-life of 9-15 years in surface soil and 25-100 years in subsurface soils. McLachlan, et al. (1996) reported on an analysis of soil taken from experimental plots which had been amended with sewage sludge in 1968 and sampled in 1972,

76, 81, 85, and 90. These archived samples were analyzed for all 17 dioxin-like CDD/Fs, and based on an analysis of results, McLachlan and coworkers concluded that half-lives were on the order of 20 years, with dioxin removal from the plots being mainly physical removal processes (overland runoff, wind erosion). Furthermore, their results suggested that all congeners had been removed at roughly the same rate, which is why they concluded that removal processes were mainly physical and very little in-situ degradation appeared to be occurring.

This assessment assumes that residues transported from a site of soil contamination to a site of exposure mix in a soil layer extending 2 cm. This will be discussed below. Therefore, the reservoir of dioxin-like compounds includes a surficial component and what could be considered a subsurface component. This suggests that the average half-life of residues within this depth might be greater than the 9-15 year estimate for surface soils by Paustenbach, et al. (1992), but less than the 25-100 year estimate made by these researchers. This assessment will assume a half-life of 25 years for the 2-cm reservoir of transported dioxins, which translates to a k_s of 0.0277 yr^{-1}. Ideally, half-lives should be assigned to individual dioxin-like congeners as many of the other contaminant-specific parameters such as Kow or bioconcentration parameters. However, the data for 2,3,7,8-TCDD was not definitive, and based on McLachlan's findings with sewage sludge amended soils, it appears reasonable to assign the same half-life to all congeners. The uniform rate of degradation, k_s, for all CDD/Fs, and PCBs, will be 0.0277 yr^{-1}.

- **M:** The delivered contaminant mixes to a shallow depth at the exposure site. The mixing depth depends on activities which disturb the surface, such as construction, plowing, vehicle traffic, movement of cattle or other animals, burrowing action of animals, other biological activity, normal leaching, and raindrop splash. Mixing depths for fallout plutonium have been found to be 20 cm on cultivated land and 5 cm on uncultivated forest and rangeland (Foster and Hakonson, 1987). Fries and Paustenbach (1990) suggested a depth of 15 cm for agricultural tillage, but assumed values of 1 and 2 cm for various sensitivity tests. However, they did not need to make a distinction between tilled and untilled situation because vegetation (pasture grass and forage for estimating beef and milk fat concentration; above ground fruits and vegetables for human consumption) was assumed to be impacted only by particulate deposition and not root uptake. In another assessment on indirect impacts from incinerator emissions, EPA (1990a) estimated vegetation concentrations as a function of particulate depositions, root uptake, and air-to-leaf transfer from the vapor phase. Different mixing depths for untilled and tilled concentration estimation was required. For root uptake estimation for vegetable and other crops, the estimated soil concentrations assuming a tillage mixing depth of 20 cm. For soil

concentrations in untilled situations, they assumed a mixing depth of 1 cm. This mixing depth of 1 cm was retained in a later addendum to this methodology (EPA, 1993a). An earlier version of these dioxin exposure methodologies assumed a 1 cm depth for untilled soils and a 20 cm depth for tilled soils (EPA, 1994).

The methodology of this assessment uses 2 cm for the untilled and 20 cm for the tilled conditions for the off-site soil source category. A principal justification for the increase from the 1 cm depth of the earlier dioxin exposure assessment methodologies (EPA, 1994) to the current 2 cm depth for surface soils comes from Brzuzy and Hites (1995). Their data on soil concentrations of dioxin congener groups as a function of depth show definite migration of residues below the surface. Soil core results were described and concentration versus depth was displayed for 6 cores. The cores were undisturbed, and were taken in background settings with high vegetative cover so that the introduction of dioxins was speculated to be due only to atmospheric depositions - not pesticides or in an oily matrix. Briefly, the results did show a relationship between leaching and percent organic carbon - more residues near the surface soil at higher organic carbon content. For the 6 cores displayed: 1) a peak at the 1-2 cm depth was found in only one core, 2) there was essentially uniform concentrations for 3 cores to 5 cm with dropoffs thereafter, and 3) in two cores which had low organic carbon, there was a steadily rising concentration to peaks at 45 and 55 cm. The authors speculated that downward movement was due to movement of soil particles. They also did suggest that based on their sediment core information that deposition to these soils had been occurring for 60 years. This is not likely to be analogous to the situation of soil eroding from a site of soil contamination both because of the time involved and the mechanism of transport. Still, it would appear from this data that a 1 cm depth may not be justifiable. Based on this evidence, an untilled depth assumed for the soil contamination source will be 2.0 cm.

A tilled depth will be assumed to be 20 cm, as in earlier assessments (EPA, 1990a; EPA, 1993a; EPA, 1994). This assumption is made because tilling gardens is assumed to distribute surface residues to the 20-cm depth. Soil concentrations for dermal contact, soil ingestion, and pasture grass and soil intake for cattle grazing will assume a depth of 2 cm. These activities are assumed to occur on soil which has not been tilled. As will be described in Section 4.5, tilled and untilled depths of mixing are also required for the stack emission source category. For that source category, the untilled and tilled mixing depths are also assumed to be 2 and 20 cm, respectively.

Given the area of the exposure site, the mass of soil into which the eroded contaminant is mixed can be calculated as:

$$M_u = A_{es} B_{soil} d \quad (4\text{-}18)$$

where:

M_u = mass of soil for contaminant mixing per unit depth, kg/m
A_{es} = area of exposure site, m^2
B_{soil} = soil bulk density, kg/m^3
d = depth of mixing, m

- **D_1 and D_2:** The first step in deriving both these amounts of soil is to use the Universal Soil Loss Equation (USLE). This approach was described above. Justification was given for an assumption of unit soil loss from the contaminated site of 9.6 t/ac-yr in Section 4.3.1. D_1 equals this unit loss times the area of contamination times a sediment delivery ratio. The example scenario in Chapter 5 assumed that the exposure site was 150 meters from the contaminated site, and using Equation (4-10), the sediment delivery ratio is 0.26. The unit loss assumed for the area between the contaminated site and the exposure site is 0.96 t/ac-yr. Since this area is adjacent to the exposure site, there is no sediment delivery, and D_2 equals this unit loss times the area between the contaminated and exposure sites.

D_1 and D_2 can now be expressed as:

$$D_1 = 0.224 \; SL_1 \; SD_1 \; A_S \quad (4\text{-}19a)$$

$$D_2 = 0.224 \; SL_2 \; SD_2 \; A_{BLE} \quad (4\text{-}19b)$$

where:

$D_{1,2}$ = mass of soil delivered from off-site contaminated source, D_1, and from the land area between contaminated source and exposure site, D_2, kg/yr,
$SL_{1,2}$ = average annual unit soil loss, Eng. tons/acre-year, equal to 9.6 t/ac-yr for SL_1 and 0.96 t/ac-yr for SL_2
$SD_{1,2}$ = sediment delivery ratios, unitless, 0.26 for SD_1 (with distance = 150 meters) and 1.00 for SD_2

A_S/A_{BLE} = land area of contaminated site, A_S, and of area between contaminated site and exposure site, A_{BLE}, m^2

0.224 = converts t/ac-yr to kg/m^2-yr.

An adjustment is made to the sediment delivery ratio, SD_1, considering the size discrepancies between the contaminated site and the exposure site. For example, if the contaminated site is larger than the exposure site, then the amount of eroded soil delivered 150 meters downgradient would not all mix with soil at the exposure site. On the other hand, if the contaminated site were smaller than the exposure site, than the full amount of eroded soil delivered 150 meters downgradient would be contained within the exposure site. A simple correction factor, equaling the ratio of a side length of the exposure site (assumed square-shaped) and a side length of the contaminated site size (also assumed square shaped), is used to adjust the sediment delivery ratio:

$$SD_{1a} = SD_1 \quad CF_{SD} \tag{4-20}$$

where:

SD_{1a} = adjusted sediment delivery ratio corresponding to SD_1, unitless

SD_1 = sediment delivery ratio reducing the amount eroding from the contaminated site to be delivered to the exposure site, unitless

CF_{SD} = sediment delivery correction factor, unitless

= $A_{ES}^{0.5}/A_S^{0.5}$ if $A_{ES} < A_S$

= 1 if $A_{ES} > A_S$

A_{ES} = area of exposure site, m^2

A_S = area of contaminated site, m^2

Similar considerations are pertinent to the land area between the contaminated and exposure site. Remember that the algorithm assumed that some "clean" (D_2) and some "contaminated" soil (D_1) erodes onto the exposure site, and that a similar amount of soil entering the exposure site (R, which equals $D_1 + D_2$) leaves the exposure site so as to maintain a mass balance. The amount of clean soil eroding from upgradient sources mixing with exposure site soil can be larger than the amount of contaminated soil if the exposure site is larger than the

contaminated site. If the exposure site is smaller than the contaminated, and similar to the solution for SD_{1a} above, then only the small corridor defined by the size of the exposure site contributes clean soil. Either way (i.e., the exposure site is larger or smaller than the contaminated site), the size of the land area contributing clean soil is defined by the size of the exposure site. A_{BLE} can be estimated as the product of the distance between the exposure and contaminated site, and the side length of the exposure site:

$$A_{BLE} = DLCE \quad SLE \tag{4-21}$$

where:

A_{BLE} = land area between contaminated and exposure site, m^2
DLCE = distance from contaminated site to exposure site, m
SLE = side length of exposure site, m
= $(A_{es})^{0.5}$
A_{es} = area of exposure site, m^2

4.3.3. Vapor- and Particle-Phase Air Concentrations

The algorithms for estimating vapor- and particle-phase concentrations of contaminants were presented and derived in Hwang, et al. (1986), EPA (1985b), Hwang (1987), and Turner (1970). The algorithms, in general, entail estimation of the flux of vapor phase and particle bound dioxin-like compounds, and then the estimation of the dispersion of fluxes to arrive at appropriate air concentrations. The flux calculations for emissions of vapor phase and particle bound dioxin-like compounds is the same if the soil contamination occurs at the site of exposure or away from the site of exposure. However, the dispersion algorithms differ, depending on whether the site of exposure is at the site of contamination or away from the site. Discussions below begin with the procedure for calculating the soil fluxes, the volatile flux and the wind erosion flux, of dioxin-like compounds, and then to the two different dispersion algorithms.

The procedures for estimating volatile flux were developed for soil surface and subsurface contamination with polychlorinated biphenyls, PCBs. The models are based on the assumptions that: 1) PCBs move through the soil primarily by vapor phase diffusion, i.e., leaching is not considered, 2) PCB vapor in the soil matrix reaches a local equilibrium with pore air, 3) degradation processes for PCBs were not considered , and 4) the PCB contamination

occurs at the surface and extends down infinitely. These assumptions are similar to the general types of assumptions that have been made for all the algorithms estimating exposure media concentrations in this assessment. The procedures in that PCB assessment were also used for this assessment. Details of the derivation are presented in Hwang, et al. (1986).

The average flux rate over an exposure duration of ED can be estimated as:

$$FLUX_V = \frac{(2)\ (E_{slp})\ (D_{ea})\ (C_s)\ (H)\ (41)\ (10^{-6})}{Kd_s\ [\ (\pi)\ (I)\ (ED)\ ]^{0.5}} \qquad (4\text{-}22)$$

where:

$FLUX_V$ = average volatilization flux rate of contaminant from soil, g/cm^2-s
E_{slp} = soil pore porosity, unitless
D_{ea} = effective diffusivity of contaminant in air, cm^2/s
C_s = contaminant concentration in soil, ppm or mg/kg
H = Henry's Constant of contaminant, atm m^3/mol
Kd_s = soil/water partition coefficient, cm^3/g
ED = exposure duration, s
I = interim undefined term for calculation, cm^2/s
= $[\ D_{ea}\ E_{slp}\ ] / [\ E_{slp} + P_{soil}\ (1\text{-}E_{slp})\ [Kd_s/(41\ H)]\ ]$
P_{soil} = particle bulk density of soil, g/cm^3

The effective diffusivity, D_{ea}, is solved as a function of contaminant diffusivity in air, and soil pore porosity:

$$D_{ea} = D_c\ E_{slp}^{0.33} \qquad (4\text{-}23)$$

where:

D_{ea} = effective diffusivity of contaminant in air, cm^2/s
D_c = molecular diffusivity of contaminant in air, cm^2/s
E_{slp} = soil pore porosity, unitless.

The soil adsorption partition coefficient, Kd_s, is given as:

$$Kd_s = Koc \quad OC_{sl} \tag{4-24}$$

where:

Koc = contaminant organic partition coefficient, L/kg

OC_{sl} = fraction organic carbon in soil, unitless.

It is noted in Hwang, et al. (1986) that this procedure would tend to overestimate emissions and resulting exposures in situations involving small spills which would not involve deep contamination. It is also noted that the average flux rate is inversely proportional to the square root of the duration of exposure - the longer the duration of exposure, the lower will be the average flux rate. Whereas this solution assumes an unlimited reservoir of contaminant, it is an unsteady state solution (unlike most other solution strategies) and is essentially an average flux rate over an amount of time defined by the exposure duration. Inherent in the solution was the consideration that residues dissipate by volatilization at the surface layers, resulting in contaminants diffusing upwards from deeper soil layers over time. With this longer path of diffusion, volatilized amounts decrease, and hence the average flux over time also decreases.

The method for determining the flux of soil particles due to wind erosion for on-site conditions was developed in EPA (1985b) based on Gillette's (1981) field measurements of highly erodible soils. A key assumption for this solution is that the soil surface is assumed to be exposed to the wind, uncrusted, and to consist of finely divided particles. This creates a condition defined by EPA (1985b) as an "unlimited reservoir" and results in maximum dust emissions due to wind only. This solution will, in essentially all cases, overestimate the amount of dioxin-like compounds being emitted by wind erosion. This is because the soil conditions to which it applies, uncrusted and consisting of finely divided particles, are conditions that, at the very least, are disrupted by rainfall or anthropogenic activities (plowing, walking, etc.). The degree of overestimation is less in the situation of most concern - mostly unattended sites of high soil contamination. An alternate, less conservative solution, is one described as a “limited” reservoir solution. This model is presented in EPA (1989). A major problem with this model for application in the current framework is that it requires site-specific daily rainfalls and windspeeds, and it should be run for a period of time, at least a year, in order to estimate average

daily flux. To be consistent with all other methodologies of the soil contamination source category, and to be conservative regarding dust emissions, the "unlimited" reservoir solution is used here. This wind erosion flux for the unlimited reservoir approach is given as (EPA, 1985b):

$$E_e = 0.036 \quad (1 - V) \quad (U_m/U_t)^3 \quad F(x) \qquad (4\text{-}25)$$

where:

E_e	=	total dust flux of <10 μm particle due to wind erosion, g/m^2-hr
V	=	fraction of vegetation cover, unitless
U_m	=	mean annual wind speed, m/s
U_t	=	threshold wind speed, m/s
F(x)	=	a function specific to this model.

EPA (1985b) provides details allowing for the application of this equation under a variety of circumstances. Specific parameter assignments for the application of this equation to the example scenarios in Chapter 5 are given below.

The unit dust flux is easily converted to a contaminant flux by multiplying by soil concentration:

$$FLUX_{WE} = (2.8 \times 10^{-17}) \quad C_s \quad E_e \qquad (4\text{-}26)$$

where:

$FLUX_{WE}$	=	contaminant wind erosion flux from soil, g/cm^2-s
E_e	=	total dust flux of <10 μm particle due to wind erosion, g/m^2-hr
C_s	=	contaminant concentration in soil, ppb or ng/g
$2.8*10^{-17}$	=	converts ng/m^2-hr to g/cm^2-sec.

Like for vapor-phase dioxin-like compounds, the flux is converted to a concentration by the use of a dispersion term. Hwang (1987) describes an algorithm for the dispersion of contaminants emitted from an area source. Vapor- and particle-phase concentrations along the

center (y=0.0) of this area source are used to estimate concentrations when the site of exposure is at the site of contamination:

$$C_{vp} = \frac{(2/\pi)^{0.5} \quad FLUX \quad a \quad 10^{10} \quad erf(e)}{u_m \; S_z} \quad (e^{-0.5\,(z/S_z)^2}) \qquad (4\text{-}27)$$

where:

C_{vp}	=	vapor- or particle-phase concentration of contaminant in air, µg/m^3
FLUX	=	average volatilization or wind erosion flux rate ($FLUX_V$ or $FLUX_{WE}$) of contaminant from soil, g/cm^2-s
a	=	side length of contaminated site parallel to the wind direction, m
U_m	=	mean annual wind speed, m/s
S_z	=	vertical dispersion coefficient in air, m
z	=	height of the exposed individual, m
erf	=	error function
e	=	error function term, unitless
	=	b/(2*(2*S_y)$^{.5}$)
b	=	side length perpendicular to the wind direction, m
S_y	=	horizontal dispersion coefficient in air, m
10^{10}	=	converts g/cm^2-m to µg/m^3.

The dispersion terms, S_z and S_y can be estimated using site-specific wind rose data. In the absence of data, these terms can be estimated assuming the most common stability class, D, as:

$$S_y = 0.1414 \quad X^{0.894} \qquad (4\text{-}28a)$$

$$S_z = 0.222 \quad X^{0.725} \qquad (4\text{-}28b)$$

where:

$S_{y,z}$	=	horizontal and vertical dispersion coefficient, m

X = distance upwind of the contaminated site, m

Estimating the dispersion and resulting exposure site concentrations of air-borne contaminants, originating at a site of contamination which is near but not at the site of exposure, requires a different solution than this solution for the concentrations along the center line of an area source. A simplified solution, given as a virtual point source model, can be found in Turner (1970). This model approximates the dispersion that occurs from an area source by using an imaginary point source. This point is located upwind of the actual source at a distance calculated to create a lateral dispersion at the site equal to its width:

$$C_{vp} = \frac{2.03 \quad FLUX \quad A_{sc} \quad FREQ \quad 10^{10}}{VD \quad S_z \quad U_m} \qquad (4\text{-}29)$$

where:

C_{vp} = vapor or particle phase concentration of contaminant in air, $\mu g/m^3$

FLUX = average volatilization or wind erosion flux rate ($FLUX_V$ or $FLUX_{WE}$) of contaminant from soil, g/cm^2-s

A_s = area of contaminated site, m^2

FREQ = frequency wind blows from source to receptor, unitless

VD = virtual distance, source center to receptor, m

S_z = vertical dispersion coefficient, m

U_m = average wind speed, m/s

10^{10} = converts g/cm^2 to $\mu g/m^2$.

The term, FREQ, in not in the original Turner (1970) solution. It has been added to this equation to appropriately account for changing wind directions, and hence, obtain a more accurate annual average air concentration. The vertical dispersion, S_z, is estimated as an empirical function of the distance from the source center to receptor:

$$S_z = 0.222 \quad x^{0.725} \quad - \quad 1.7 \quad , \quad x \quad < 1000 \ m \qquad (4\text{-}30a)$$

$$S_z = 1.260\ x^{0.516} - 13.0\ ,\ x > 1000\ m \qquad (4\text{-}30b)$$

where:

S_z = vertical dispersion coefficient, m

X = actual distance from source center to receptor, m.

The virtual distance, VD, is an empirical function of the width of the contaminated area and the actual distance from source center to receptor:

$$VD = 2.514\ b + x \qquad (4\text{-}31)$$

where:

VD = virtual distance, source center to receptor, m

b = width of contaminated area perpendicular to wind direction - defined previously as side length for assumed square-shaped contaminated area, m

X = actual distance from source center to receptor, m.

Background on Koc and OC_{sl} were given in Section 4.3.1. above. Guidance for other terms in the four algorithms - volatile flux, wind erosion, on-site dispersion, off-site dispersion, now follow.

- **E_{slp}:** Porosity is defined as the pore space in soils occupied by air and water, and for sandy surface soils show a range of 0.35-0.50. Medium to fine-textured soils (loams, clays, etc.) show a higher range of 0.40-0.60 (Brady, 1984). Soil porosities in the example settings were 0.50.

- **H:** Henry's Constants were discussed in Volume 3, Chapter 2. The values of H used for the three example compounds were: for 2,3,7,8-TCDD - $3.29*10^{-5}$ atm-m^3/mole; for 2,3,4,7,8-PCDF - $4.98*10^{-6}$ atm-m^3/mole; and for 2,3,3',4,4',5,5'-HPCB - $6.65*10^{-5}$ atm-m^3/mole.

- **P_{soil}:** Particle bulk density is defined as the mass of a volume of soil solids. This contrasts the more common parameter, bulk density, which is the mass of a unit of dry soil, which includes both pores and solids. Particle bulk density, P_{soil}, has a narrow range of 2.60 to 2.75, and for general calculation purposes, Brady (1984) recommends a value of 2.65 for average mineral surface soils, the value used for the example settings.

- **ED:** The exposure duration is simply the amount of time individuals are exposed. Two exposure durations were used in the demonstration scenarios, 9 years for "central" and 30 years for "high end" exposures. Used in this algorithm, and as discussed earlier, longer exposure durations translate to lower average volatilization fluxes. This presumes a soil concentration assumed to be uniform over depth starting at time zero, and to become depleted over time. The selected exposure durations of 9 ($2.83*10^8$ sec) and 30 years ($9.46*10^8$ sec) was used.

- **D_c:** Molecular diffusivities in air of the example compounds could not be found in the literature. However, diffusivities of one compound can be estimated from another with the following (Thibodeaux, 1979):

$$\frac{D_a}{D_b} = \left(\frac{MW_b}{MW_a}\right)^{0.5} \qquad (4\text{-}32)$$

where:

$D_{a,b}$ = Molecular diffusivities of compounds a and b, cm^2/s

$MW_{a,b}$ = Molecular weights of compounds a and b, g/mole

Thibodeaux (1979) lists the molecular diffusivity of diphenyl at 25 °C at 0.068. Given the molecular weight of diphenyl of 154 g/mole, the diffusivities of the example compounds are: 2,3,7,8-TCDD (MW = 322) = 0.047; 2,3,4,7,8-TCDF (MW = 340) = 0.046; and 2,3,3',4,4',5,5'-HPCB (MW = 396) = 0.043.

- **U_m:** Mean annual windspeeds vary from between 2.8 and 6.3 m/s (EPA, 1985b). An assumption of 4.0 m/s in the absence of site-specific average wind speeds was made for the example scenarios of this assessment.

- **a, b, z, and x:** Simple assumptions can be made to assign values to the length terms above: a, b, z, and x. Assuming a square-shaped contaminated site, a equals b which equals the square root of the area of the site. A common assumption for z, the height of the exposed individual, is 2 m. The x term can be assumed equal to a side length (a or b), or can equal the side length plus the distance to the exposed individual if the contamination is not on-site and dispersion is modeled as "near field." For the residence and farm setting examples in Chapter 5, where the contamination was on-site, the x term was equal to a side length.

- **FREQ:** Where the wind blows from all directions equally, then it will blow from one compass sector about 15% of the time. On these bases, a FREQ of 0.15 was used in the example scenario demonstrating the soil contamination source category in Chapter 5. In most places, however, wind direction is much less variable, and the appropriate value is best determined with site specific information.

- **V:** Chapter 5 demonstrates “background” conditions for a "residence" and a "farm". In those settings, grass or crops are likely to substantially cover the soil, and the fraction of vegetative cover can range from 0.5 (minimal coverage) to 0.9 (more lush coverage). For the residence example setting in Chapter 5, V was set at 0.9 which assumes a continual grass cover over the contaminated soil. The V for the farm settings was instead 0.5. The area of contamination for the example farm settings was larger than the residence setting, 10 acres to 1 acre. The land where crops were grown was also contaminated; the 0.5 value for V assumes that the cropland is totally or partially bare at some times - perhaps during spring land preparation and fall harvest. For the demonstration of the soil contamination source category, the site of contamination is assumed to be bare, as in an active landfill or an industrial site. With this assumption, V is set equal to 0.0.

- **U_t:** As noted above, the average windspeed, U_m, is assumed to be 4.0 m/s. The threshold wind velocity, U_t, is the wind velocity at a height of 7 m above the ground needed to initiate soil erosion. It depends on nature of surface crust, moisture content, size distribution of

particles, and presence of non-erodible elements. It can be estimated on the basis of the following procedure (EPA, 1985b):

Step 1. Determine the Threshold Friction Velocity

This is the wind speed measured at the surface needed to initiate soil erosion. EPA (1985b) shows how it can be determined as a function of soil aggregate size distribution. However, for the "unlimited reservoir" approach for which Equation (4-25) was developed, soil particles are assumed to be fine at 1.5 mm or less as an average. This translates to a threshold friction velocity of 75 cm/s and less. A value of 50 cm/s might be reasonably assumed to be representative of these types of surfaces, and was assumed for this assessment.

Step 2. Estimate the "Roughness Height"

EPA (1985b) graphically shows the roughness height for a range of possible conditions. Included in this range are a roughness height of 0.1 cm for natural snow, 1.0 cm for a plowed field, 2.0-4.0 cm for grassland, 4.0 cm for a wheat field or for suburban residential dwellings, and up to 1000 cm for high rise buildings. The assumption made for the residence and farm example settings was 4.0 cm, following the information given for a wheat field or a suburban residence. The value assumed for the site of contamination in the demonstration of the soil contamination source category was 1.0 cm, which assumes that the plowed field value is the most analogous to the assumed bare soil site of contamination.

Step 3. Estimate Ratio of Threshold Wind Speed at 7 m to Friction Velocity

A chart provided by EPA (1985b) shows this ratio as a function of roughness height. For a roughness height of 4.0 cm, this ratio is seen to be 13. For a roughness height of 1.0 cm, this ratio is 16.5.

Step 4. Estimate Threshold Wind Speed

This is simply the product of the ratio given in step 3 above and the friction velocity. Using values given above, 50 cm/sec * 13 = 6.5 m/sec for the residential and farm settings, and 8.25 m/sec for the site of soil contamination.

- **F(x):** The model-specific function, F(x), is determined by first calculating the dimensionless ratio x, where $x = 0.886\ U_t/U_m$, and finding F(x) from a chart of F(x) versus x, as

provided in EPA (1985b). For $U_t = 6.5$ and $U_m = 4.0$, x = 1.44 and F(x) = 1.05. For $U_t = 8.25$ and $U_m = 4.0$, x = 1.83 and F(x) = 0.5.

4.3.4. Biota Concentrations

This section summarizes the algorithms to estimate contaminant concentrations in fish, vegetation (including vegetables for human consumption and pasture grass or fodder grown on contaminated soil for beef cattle consumption), beef, and milk. As will be shown, all algorithms are simple empirical equations which relate an environmental media concentration to a biota concentration, using a "biotransfer" or "bioaccumulation" factor.

4.3.4.1. *Fish Concentrations*

The procedure and supportive data for the algorithm to estimate fish tissue concentrations can be found in Cook, et al. (1991), in an assessment of risk of 2,3,7,8-TCDD to aquatic life and associated wildlife (EPA, 1993b) which EPA is conducting as part of its reassessment of dioxin-like compounds, and most recently in a technical support document for the Great Lakes Water Quality Initiative (EPA, 1995). Of those references, only EPA (1995) contains information on the suite of dioxin-like (and other) compounds.

Dioxin-like compounds share a high degree of hydrophobicity that increases as the degree of chlorination increases. Cook, et al. (1991) note that this corresponds in general to an increase in lipophilicity and an increase in ability to bind to organic carbon in sediments and to dissolved organic matter in water. However, these tendencies are not paralleled by an increase in bioaccumulation. Only the 2,3,7,8-chlorine-substituted congeners are substantially bioaccumulated by fish, although large quantities of other CDD/F congeners are found in sediments. This pattern of bioaccumulation results because of higher rates of metabolism of CDD/Fs in fish as compared to the 2,3,7,8-chlorine-substituted congeners (EPA, 1992a; Cook, et al., 1991, with references to Muir et al., 1986; Gobas, 1990). While the highly chlorinated 2,3,7,8-substituted congeners are very slowly accumulated, they have very slow elimination rates.

2,3,7,8-TCDD and other planar polyhalogenated aromatic hydrocarbons often have not been detected in water from aquatic ecosystems even when biota are highly contaminated. Because surface layers of bottom sediments are a good indicator of the relative amount of chemical in the system over the time scale involved for bioaccumulation of super-hydrophobic chemicals, a term known as the Biota to Sediment Accumulation Factor, or BSAF, has been offered as a measure of site-specific bioaccumulation potential. This term was proposed to

replace equivalent terms which were known as the Bioavailability Index, or BI (Kuehl, et al., 1987; Cook, et al., 1991; EPA, 1990b), the Accumulation Factor, AF (Lake, et al., 1990) and the Biota to Sediment Factor, or BSF (Parkerton, et al., 1993; Parkerton, 1991). BSAF is defined as:

$$BSAF = \frac{C_{lipid}}{C_{oc}} \quad (4\text{-}33)$$

where:

BSAF = biota to sediment accumulation factor, unitless
C_{lipid} = concentration of contaminant in lipid of fish, mg/kg,
C_{oc} = concentration of contaminant in bottom sediment organic carbon, mg/kg

The surface water algorithms estimate concentration of contaminant in bottom sediments (see Section 4.3.1 above). This concentration, C_{sed}, can be converted to an organic carbon basis as a function of OC_{sed}:

$$C_{oc} = \frac{C_{sed}}{OC_{sed}} \quad (4\text{-}34)$$

where:

C_{oc} = concentration of contaminant in bottom sediment organic carbon, mg/kg;
C_{sed} = concentration of contaminant in bottom sediment, mg/kg;
OC_{sed} = fraction organic carbon in bottom sediment, unitless

The organic carbon content of bottom sediments was assumed to 0.03; see Section 4.3.1. for the derivation of C_{sed}.

Since the accumulation of contaminant is assumed to occur only in fish lipid, a correction term to estimate the whole fish tissue concentrations is needed since fish consumption in g/day refers to whole fish consumption. The correction term is simply f_{lipid}, and so whole fish concentrations are simply $C_{lipid} * f_{lipid}$.

The BSAF was developed as a measure of bioaccumulation potential rather than as a predictor, as it is being used here. It is uncertain as to whether measured BSAFs are generally applicable to other water bodies. Efforts are underway to evaluate the general applicability of BSAFs (P. Cook, Duluth Environmental Research Laboratory, US EPA, 6201 Congdon Boulevard, Duluth, MN 55804, personal communication). Using the BSAF approach as a predictive tool greatly underplays the complexity of the processes transferring contaminants from aquatic ecosystems to aquatic organisms. EPA (1993b and 1995) provides a comprehensive discussion on aquatic impacts and processes for dioxin-like and related compounds. Following are some of the key issues to consider:

1) **Resident vs. Migratory Species:** Parkerton (1991) applied a bioenergetics-based bioaccumulation model in an attempt to duplicate BSAFs for 2,3,7,8-TCDD found for carp and blue crabs in the Passaic River, New Jersey. He showed nearly a ten-fold difference in 2,3,7,8-TCDD BSAF calculated from data for resident species as compared to migratory species in the Passaic River. This would be expected for fish which also reside part of the time in relatively clean water bodies; migration would enable depuration of residues from fish. The possibility that migration patterns might explain some of the results for fish concentrations of 2,3,7,8-TCDD in the Lake Ontario bioaccumulation study was also raised (EPA, 1990b). That assessment also discussed a related issue of concern - to consider lakewide average sediment concentrations or concentrations near where sampled fish were captured in calculating the BSAF. Even within a large lake, more sedentary populations of fish may be impacted by localized contamination.

2) **Past history of contamination:** If contamination of surface water bodies with hydrophobic compounds like the dioxin-like compounds has occurred principally in the past, then it can be expected that most of the contamination occurs in or near the bottom sediment layer and not within the water column. Furthermore, if inputs to water bodies are declining or low in comparison to past loadings, then sediments would be undergoing depuration - residue levels would be declining, and the system may not be equilibrium. EPA (1990b) noted that very low BAF*s (defined as a fish to sediment ratio not including the sediment organic carbon and fish lipid considerations of BSAFs) and BSAFs for 2,3,7,8-TCDD in Lake Ontario contrasts higher BAF*s for other hydrophobic compounds such as DDE or PCBs. An explanation offered is that loadings to the Lake may be declining, such that there is a substantial disequilibrium between sediments, water, fish, and their prey. One parameter required in the bioenergetics model Parkerton (1991) used (referred to in the above bullet) was a ratio of contaminant

concentration in bottom sediment to that in suspended sediment, rs/rw. In modeling exercises on the Passaic River, he found closer agreement between measured and predicted BSAFs with this ratio equal to 10 in contrast to 1, the only two values tested; a ratio of ten means that the concentration of contaminant in bottom sediment is ten times higher than it is in the suspended sediment. BSAFs predicted by the model were developed as the ratios in modeled fish lipid concentrations divided by modeled bottom sediment organic carbon normalized concentrations. Measured BSAFs used actual Passaic River fish lipid and bottom sediment concentrations of 2,3,7,8-TCDD. BSAFs predicted with this ratio equal to 1 were roughly 4 times as high as measured BSAFs, and BSAFs found with rs/rw equal to 10 were twice as high as measured. A related result of his modeling exercise was that, at best fit between modeled and measured BSAFs where the rs/rw was 10, dietary exposures explained over 50% of the BSAFs for carp and 85% in blue crabs, in contrast to water column exposures. He speculates that prey organisms consist of benthic animals which ingest contaminated bottom sediment. If the food chain begins near bottom sediments, and if food chain exposures are a principal explanation for fish tissue dioxin concentrations, than it follows that a model would perform better when bottom sediment concentrations drive fish tissue concentrations rather than water column concentrations, or equivalently, when rs/rw = 10. Finally, he notes that 2,3,7,8-TCDD contamination in Passaic river largely occurred as a result of historical loadings. The picture that emerges from Parkerton's modeling is as follows: sediments are serving as an internal source of contaminants due to past historical loadings, and the water column is in disequilibrium with bottom sediments and driven only by depuration of bottom sediment concentrations. The bioaccumulation of these compounds in carp and blue crabs appears to be mediated by trophic transfer via the benthic foodweb. In both the Lake Ontario and Passaic River studies, concentrations of 2,3,7,8-TCDD were higher in deeper bottom sediments as compared to surficial bottom sediments - this implies historical loadings and possibly depuration of surficial residues.

This issue is non-trivial for the methodology of this assessment, since an assumption for deriving suspended and bottom sediment concentrations is that the contamination is ongoing, and that the hypothetical water body may be closer to a state of equilibrium as compared to situations where contamination was principally in the past. The BSAF assumed for 2,3,7,8-TCDD in the demonstration scenarios of 0.09 is more in line with data from EPA (1990b) on Lake Ontario and from Parkerton (1991) from data in Passaic River, then with other data (presented later) where historical loadings are not as clear a principal source of bottom sediment contamination. The issue of ongoing versus historical contamination should be considered when assigning site-specific BSAFs.

3) **Variations among fish species, particularly column feeder vs. bottom feeder:** Feeding habits, age, migratory patterns, and lipid contents (including lipid content of edible vs. inedible fish tissues) are just a few of the interacting factors which determine a site-specific BSAF as a function of fish species. Bottom-feeders such as carp or catfish can have BSAF values that could be an order of magnitude higher as compared to column feeders. A calculated 2,3,7,8-TCDD BSAF for carp in Connecticut of 0.86 compares to the 2,3,7,8-TCDD BSAF of 0.03-0.07 calculated for trout by EPA (see Table 4-1). The demonstration of this approach in Chapter 5 assigns a single BSAF to each of the three example contaminants, and the assignment is expected to be more like BSAFs for column feeders. Although not unlike other simplifications of this assessment, such approaches are recognized as oversimplifications.

4) **Study designs to obtain BSAFs:** Although there is some evidence that BSAFs specific to a contaminant may be applicable to other aquatic settings, data to evaluate such a hypothesis is still sparse. Even data sets that do exist need to be carefully evaluated before deriving BSAFs. Such an evaluation should consider sediment as well as fish species data. Critical factors for sediment sampling include location, number, depth of sampling, variability, availability of organic carbon fraction information, and so on. Similar issues are pertinent for fish sampling and analysis.

Following now are guidance for the terms required for estimating fish tissue concentrations.

- **BSAF:** Table 4-1 summarizes literature from which biota sediment accumulation factors for dioxin and furan congeners could be developed. Only six sets of data were found in the literature. The data reported in EPA (1995) for Great Lakes Trout, from the Wisconsin River (Kuehl, et al. 1987), and that from 1 lake in Sweden (Kjeller, et al. 1990) both show decreasing BSAF with increasing chlorination. The BSAF of 2.94 for 2,3,7,8-TCDD determined from a lake in Sweden should be questioned since it is more than an order of magnitude different than any of the other data. Causes for this discrepancy could be manifold. Some observations from Kjeller, et al. (1990) might shed some light on this result. Although sediment data was from three water bodies, 8 of the 9 Pike samples (pike samples were composites of 2-5 fish from one location in the water body) were from one of the water bodies. This is why only data from the one water body was summarized in Table 4-1. This water body, Lake Vanern, was clearly the most contaminated of the three water bodies studied. A paper mill was located at the northern part of this lake and the authors concluded that discharges from this mill impacted the lake. The

average of 2,3,7,8-TCDD and 2,3,7,8-TCDF organic carbon normalized concentrations for five sediment samples from this lake was 297 pg/g; the analogous average concentration for 10 samples taken from another lake, Lake Vattern (6 samples), and a river, Dala (4 samples), was 65 pg/g. A similar disparity between Lake Vanern and the other water bodies is found with the penta-CDD/F concentrations: 205 pg/g vs. 108 pg/g, with similar comparisons for the hexa-, hepta, and octa-CDD/CDF. The sediment and corresponding pike sample nearest this mill had the highest concentrations reported - pike samples were given as 3000 and 833 pg/g lipid normalized 2,3,7,8-TCDF and 2,3,7,8-TCDF (a composite from 5 pike taken at this sampling station), respectively, and sediment was 1800 and 244 pg/g organic carbon normalized for 2,3,7,8-TCDF and 2,3,7,8-TCDD. Note the BSAF for 2,3,7,8-TCDD implied from this data point is 3.41. Another consideration for high BSAFs might be the source of contamination. Speculation from the Lake Ontario and Passaic River field data was that contamination principally occurred in the past, whereas in the Swedish data, contamination appears to have been ongoing at the time of sampling. This might be one indication that BSAFs for aquatic systems where contamination is ongoing might be greater than from systems where the contamination is primarily historical.

The Swedish data also illustrates some of the complexities of interpreting literature data. First, the sediment data was expressed concentrations normalized to "sediment contents of organic material" (sic). This was interpreted as organic matter normalized, not organic carbon normalized. Parkerton (1991) assumed that organic carbon was 45% of organic matter to derive BSAFs when organic carbon data was unavailable; following this lead, organic matter normalized concentrations in Kjeller, et al. (1990) were divided by 0.45 to arrive at organic carbon normalized concentrations. Also, there was not an exact match in "sites" between sediment samples and fish samples; these sites were physical locations within the large lake where samples were taken. There were five sites where sediment samples were taken, and five sites where composited pike samples were taken in Lake Vanern. However, one of the sediment and one of the pike samples were from unique sites; only four sites had both sediment and pike samples. The results in Table 4-1 were derived using average sediment and pike concentrations from only these four sites. Another way to have derived BSAFs would be to average all lake sediment and pike concentrations; since there may be some relationship between sediment and pike concentrations based on lake location, it was decided to include only the four sites with both fish and sediment samples. Finally, there were two sets of results listed for 1,2,3,4,6,7,8-HpCDF as though there were two unique sets of analyses for the same congener; this is why there are two entries for this congener in Table 4-1.

A complete discussion of the data generated by the Connecticut Department of Environmental Protection (CDEP, 1992) is included in Chapter 7. Generally, water bodies tested were mostly in rural/suburban settings rather than urban settings. Concentrations of 2,3,7,8-TCDD in surface soils and bottom sediments were in the low ppt level, indicating background impacts. BSAFs generated with that data ranged from 0.24 to 0.85 for TEQs, 2,3,7,8-TCDD, 2,3,7,8-TCDF, and 2,3,4,7,8-PCDF.

EPA (1995) published BSAFs for lake trout for the 17 dioxin-like congeners based on a reanalysis of the Lake Ontario sediment and lake trout samples originally taken in 1987-88 and reported on first in EPA (1990). It is not clear how many of the samples were reanalyzed and why the 2378-TCDD lake trout BSAF was different in the 1995 report, 0.059, as compared to the 1990 report, 0.07. EPA (1995) also discussed the concept of the "bioequivalency factor", or BEF, which is defined as the ratio between the BSAF of each non 2378-TCDD dioxin-like congener to the BSAF of 2378-TCDD. These BEFs are listed in Table 4-1. They can be used to assign congener-specific BSAFs if all that is known for a specific site is the 2378-TCDD BSAF.

Excluding the Swedish data, there are 43 reported BSAFs for dioxin-like congeners in Table 4-1. These range from 0.00065 to 0.93, with lower BSAFs associated with higher chlorinated congeners. A BSAF of 0.09 will be assumed for 2,3,7,8-TCDD in the demonstration scenarios in Chapter 5. The BSAFs for the other dioxin-like congeners will be assigned based on the BEF for that congener. For example, the BSAF of 2,3,4,7,8-PCDF will be equal to 0.14, which is estimated as the BEF for 2,3,4,7,8-PCDF, 1.6, times the BSAF for 2,3,7,8-TCDD.

EPA (1990b) estimated BSAFs for PCBs and other selected chemicals (DDE, HCB, etc.) for Lake Ontario from several data sets. Later, EPA (1995) reported on BSAFs for subsets of the dioxin-like congeners from three data sets: Oliver and Niimi (1988), a reanalysis of their own sediment and late trout samples from the 1988 Lake Ontario study, and the EPA Green Bay/Fox River Mass Balance Study. Parkerton, et al. (1993) summarizes BSAFs for PCBs and other compounds from other water bodies using other data sets. A selected summary of BSAFs for PCBs taken from the two EPA references and the Parkerton, et al. (1993) reference is given in Table 4-2.

Two trends are apparent. First, the BSAFs for PCBs appear to exceed those of the dioxin and furan congeners by an order of magnitude and more. Second, and from limited data, it would appear that BSAFs increase from dichloro- through hexa- or perhaps hepta-chloro PCBs, and then decrease thereafter. An assignment of a BSAF for 2,3,3',4,4',5,5'-HPCB, which is abbreviated as PCB 189 in the IUPAC system, is not apparent from the data summary below. Two data points from EPA place the value for that congener at 0.71 and 3.45. The data point

from Siskiwit for the single heptachloro-PCB, which was 2,2',3,4',5,5',6-HPCB, was estimated by Parkerton, et al. (1993) as 12.5. The BSAF for the heptachloro-PCB congener group for flounder from New Bedford Harbor estimated by Parkerton, et al. (1993) was 0.84, with BSAFs for lobster and crab as 1.29 and 2.74, respectively. A value of 2.10 is assigned to 2,3,3',4,4',5,5'-HPCB for the example scenarios in Chapter 5, which is the midpoint of the two EPA data points specific to this congener

It should be noted that these assignments are based on data on vertebrate rather than invertebrate aquatic species. It is generally recognized that invertebrates do not possess the enzymatic capability to metabolize hydrophobic compounds as effectively as higher chordates. As a result, invertebrate species such as mussels, clams, oysters, shrimp, crabs and lobsters may have BSAF values much higher than those observed for fish. Parkerton (1991) and Parkerton, et al. (1993) reviewed the literature to estimate BSAFs of 1 to 5 for species including grass shrimp, sandworms, deposit feeding clams, and blue mussel for CDD/Fs and PCBs.

Finally, it should be noted that all bioconcentration or biotransfer parameters, such as the BSAF, are qualified as second order defaults for purposes of general use. Section 6.2. of Chapter 6 discusses the use of parameter values selected for the demonstration scenarios, including a categorization of parameters. Second order defaults are defined there as parameters which are theoretical and not site-specific, but whose values are uncertain in the published literature. The parameter values in this category should be considered carefully by users of the methodology.

- **f_{lipid}:** Lipid contents of edible fish species have been compiled in EPA (1995), and for the sake of brevity, this compilation will not be repeated here. Generally, lipid contents can range from 0.05 to greater than 0.20 (5% - 20%). BSAFs are typically developed on the basis of whole fish lipid content, so estimates of whole fish concentrations should be made with a whole fish lipid content. Parkerton, et al. (1993) cautions, however, that lipid contents of edible portions of fish may be lower than lipid contents of some of the fish portions that were sampled and used to develop BSAFs. Non-edible high lipid content portions include, for example, liver and hepatopancreas. Parkerton, et al. (1993) develops the parameter, β, which is defined as the ratio of the lipid content of the edible portion and the sampled tissue. To demonstrate the impact of this ratio, Parkerton used data from Niimi and Oliver (1989) which included PCB and other halocarbon compound concentration in whole fish and fillets of fish taken from the Great Lakes. The β (defined here as the ratio of lipid in fillet to lipid of whole fish) for these fish, which included brown trout, lake trout, rainbow trout, and coho salmon, ranged from 0.22 to 0.51. The ratio of fillet to contaminant concentrations ranged from 0.20 to 0.54.

In the context of the current model, concentrations in fish for estimating exposure are estimated as the product of: organic carbon normalized bottom sediment concentrations * BSAF * f_{lipid}. BSAFs (in theory) are independent of fish tissue being sampled - they are ratios of the organic carbon normalized concentration and fish lipid concentration. Users should be aware, however, that the f_{lipid} value assigned should correspond to the fish concentration of interest - that could be whole fish if the model is used in validation exercises or edible fish if the model is used for exposure assessment. Cook, et al. (1990) and EPA (1993b) assumed a lipid content of 0.07 for fish in discussions of BSAF and related methodologies for estimating bioaccumulation of 2,3,7,8-TCDD in aquatic ecosystems. This assessment will also assume a f_{lipid} of 0.07, and since its use in this context is in exposure assessment, this value could be thought of as a edible portion lipid fraction.

4.3.4.2. *Vegetation Concentrations*

Vegetation concentrations are required for the estimation of exposure to homegrown fruits and vegetables, and also for the beef and dairy food chain algorithms. Three principal assumptions are made to estimate vegetative concentrations:

- Outer surfaces of bulky below ground vegetation are impacted by soils which contain dioxin-like compounds. Inner portions are less impacted than outer portions, although data has shown some within plant translocation into below ground vegetables.
- Translocation of dioxin-like compounds from roots to above ground portions of plants are negligible compared to other mechanisms which impact above ground portions of plants. As such, translocation into above ground portions will be assumed to be zero.
- Unlike below ground vegetables, data has shown very little impact to inner portions of above ground bulky vegetation. Therefore, it will be assumed that outer and not inner portions of above ground bulky vegetation are impacted.

Concentration of contaminants in below ground vegetation is only required for vegetables (carrots, potatoes, e.g.) grown underground. The basis for the below ground algorithm is the experiments of Briggs, et al. (1982) on uptake of contaminants into barley roots from growth solution, and their elaboration of a Root Concentration Factor. The below ground concentration is given by:

$$C_{bgv} = \frac{C_s \quad RCF \quad VG_{bg}}{Kd_s} \qquad (4\text{-}35)$$

where:

C_{bgv}	=	fresh weight concentration of below ground vegetables, pg/g
C_s	=	contaminant concentration in soil, ppt or pg/g
Kd_s	=	soil-water partition coefficient, L/kg
	=	$Koc*OC_{sl}$
Koc	=	contaminant organic partition coefficient, L/kg
OC_{sl}	=	fraction organic carbon in soil, unitless.
RCF	=	root concentration factor equaling the ratio of the contaminant concentration in roots (fresh weight basis) and the concentration in soil water, unitless
VG_{bg}	=	empirical correction factor for below ground vegetation which accounts for the differences in the barley roots for which the RCF was derived and bulky below ground vegetables, unitless

Two processes, air-borne vapor phase absorption and air-borne particle deposition, are assumed to contribute to above ground vegetation concentrations:

$$C_{abv} = C_{vpa} + C_{ppa} \quad (4\text{-}36)$$

where:

C_{abv}	=	concentration in above-ground vegetation, expressed on a dry weight basis, pg/g or ppt
C_{vpa}	=	contribution of concentration due to vapor-phase absorption or airborne contaminants, pg/g or ppt
C_{ppa}	=	contribution of concentration due to wet plus dry deposition of contaminated particulates onto plant matter, pg/g or ppt

The basis for a vapor-phase transfer factor for various airborne contaminants, including 1,2,3,4-TCDD, from the atmosphere to vegetation was developed by Bacci, et al. (1990, 1992), with amendments suggested by McCrady and Maggard (1993), and McCrady (1994). The final values selected for the 17 dioxin-like CDD/Fs were developed by calibration (Lorber, 1995), and then field validated (Lorber and Pinsky, 1999), as described below. Bacci and coworkers conducted laboratory growth chamber experiments on the vapor-phase transfer of 14 organic

compounds from air to azalea leaves, and developed a generalized model to predict the vapor-phase bioconcentration factor based on a contaminant Henry's Constant, H, and octanol water partition coefficient, Kow. A similar experiment by McCrady and Maggard (1993) conducted for 2,3,7,8-TCDD vapor transfer to grass leaves suggested that the Bacci empirical algorithm to would greatly overestimate the transfer factor for 2,3,7,8-TCDD. The development of the biotransfer factor for vapor-phase dioxins, termed B_{vpa} in this assessment, was based on field data. Further details on these experiments are in the section below on this critical parameter. The algorithm estimating plant concentrations as a function of vapor-phase air concentrations is:

$$C_{vpa} = \frac{B_{vpa} \quad C_v \quad VG_{ag}}{d_a} \qquad (4\text{-}37)$$

where:

C_{vpa} = plant concentration due to vapor-phase absorption or airborne contaminants, pg/g or ppt, dry weight basis

B_{vpa} = mass-based air-to-leaf biotransfer factor, unitless [(pg contaminant/g plant dry)/(pg contaminant/g air)]

C_v = vapor-phase concentration of contaminant in air, pg/m^3

VG_{ag} = empirical correction factor which reduces vegetative concentrations considering that B_{vpa} was developed for transfer of air-borne contaminants into leaves rather than into bulky above ground vegetation

d_a = density of air, g/m^3, 1190

Several exposure efforts for 2,3,7,8-TCDD (Fries and Paustenbach, 1990; Stevens and Gerbec, 1988; Connett and Webster, 1987; Travis and Hattemer-Frey, 1991), have modeled the accumulation of residues in vegetative matter (grass, feed, vegetables) resulting from deposition of contaminated particulates. Key components of their approach, as well as the one for this assessment, include:

- Vegetative concentrations result from particulate deposition onto plant surfaces.
- Vegetative dry matter yield is the reservoir for depositing contaminants; this reservoir varies according to crop.

- Not all particulate deposition reaches the plant, some goes directly to the ground surface; the "interception fraction", less than 1.0, reduces the total deposition rate. This fraction can be related to the percent ground that is covered by the vegetation.
- Weathering processes, such as wind or rainfall, remove residues that have deposited onto plant surfaces via particle deposition, and this process is reasonably modeled as a first-order exponential loss with an associated weathering dissipation rate. All the above references have justified a dissipation rate derived from a half-life of 14 days (based principally on field measurements described in Baes, et al. (1984)); this is the value used for all dioxin-like compounds in this assessment as well. As well, a portion of particles depositing as wet deposition are not retained on the vegetation after the rainfall. A retention factor reduces total wet deposition considering this.
- Vegetative concentrations may not reach steady state because of harvesting or grazing, but a steady state algorithm is used.

The steady state solution for plant concentrations attributed to wet plus dry particle deposition is:

$$C_{ppa} = \frac{F_p}{1000 \; k_w \; Y_j} \qquad (4\text{-}38)$$

where:

C_{ppa}	=	plant concentration due to settling of contaminated particulates onto plant matter, pg/g or ppt, dry weight basis
F_p	=	unit contaminant wet plus dry deposition rate onto plant surfaces, pg/m^2-yr
k_w	=	first-order weathering dissipation constant, 1/yr
Y_j	=	dry matter yield of crop j, kg/m^2
1/1000	=	converts pg/kg to pg/g

The unit contaminant wet plus dry deposition rate, F, is given as:

$$F_p = C_p \; (V_d \; I_j + RN \; R_w \; W_p \; I_j) \qquad (4\text{-}39)$$

where:

F_p	=	unit contaminant wet plus dry deposition rate onto plant surfaces, pg/m^2-yr
C_p	=	air-borne particulate phase contaminant concentration, pg/m^3
V_d	=	deposition velocity, m/yr
I_j	=	fraction of particulates intercepted by crop j during deposition, unitless
RN	=	annual rainfall, m/yr
R_w	=	fraction of particles retained on vegetation after rainfall, unitless
W_p	=	volumetric washout factor for particulates, unitless

Following is brief guidance on assignment of values to the terms in Equations (4-35) to (4-39).

- **C_s and Kd_s:** This is the soil concentration and soil/water partition coefficient, respectively. The soil concentration is specified for the soil contamination source category. When the soil contamination is distinct from the site of exposure, the soil concentration at the site of exposure is modeled. As discussed in Section 4.3.2 above, two soil concentrations including one for a no-till and one for a tilled situation, are modeled in this situation. For modeling below ground vegetable concentration, the tilled concentration is required. The soil partition coefficient is a function of the contaminant organic carbon partition coefficient, Koc, and the soil organic carbon fraction, OC_{sl}, as discussed above in Section 4.3.1. Division of C_s by Kd_s results in the equilibrium soluble phase concentration of the contaminant, in mg/L.

- **RCF:** Briggs, et al. (1982) conducted experiments measuring the uptake of several compounds into barley roots from growth solution. He developed the following relationship for lipophilic compounds tested (lipophilic compounds were identified as those tested that had log Kow 2.0 and higher (n=7, r=0.981):

$$\log RCF = 0.77 \log (Kow) - 1.52 \qquad (4\text{-}40)$$

where:

RCF = root concentration factor equaling the ratio of the contaminant concentration in roots (fresh weight basis) and the concentration in soil water, unitless

Kow = contaminant octanol water partition coefficient, unitless

Since the highest log Kow of the seven for which this relationship was derived is 4.6, and the lowest log Kow for the dioxin-like compounds is above 6.0, this relationship may not hold for the dioxin-like compounds. However, a validation exercise described in Chapter 7 where predictions of dioxin-like compounds in carrots are compared with observations shows this factor to adequately perform for this class of compounds.

Briggs' experiments were conducted in growth solution. Therefore, the RCF is most appropriately applied to soil water in field settings. This is why the C_s was divided by Kd_s in Equation (4-35).

- **VG_{bg}:** This correction factor and the one used to correct for air-to-leaf transfer of contaminants, VG_{ag}, are based on a similar hypothesis. That hypothesis for VG_{bg} is that the uptake of lipophilic compounds into the roots of this experiments is due to sorption onto root solids. High root concentrations were not due to translocation to within portions of the root hairs. Direct use of the RCF for estimating concentrations in bulky below ground vegetation would overestimate concentrations since available data suggests some but little translocation to inner parts of below ground bulky vegetation for the dioxin-like compounds. The experiments of Muller, et al. (1994) showed that the outer portions (peel) of carrots had higher concentrations of dioxin congener groups as compared to inner portions (cortex and stele). However, they also found concentrations within the carrot, suggesting some within plant translocation. Their data is examined below and used to assign a value for VG_{bg} in this assessment.

One set of important soil-to-plant transfer experiments, however, did suggest that certain plants would sorb and translocate dioxins to a significant extent. Hulster, et al. (1994) found that dioxins were sorbed by the roots of vegetables of the cucumber family and made their weight into the above ground portions of these plants. They were unable to explain why this happened and noted that it was a distinctly different trend then they found in several of their other soil-to-plant transfer experiments. For this assessment, it will be assumed that the vegetables of the cucumber family are an anomaly and not typical of vegetation for human or animal consumption.

VG_{bg} converts an outer portion, or skin, concentration, into a whole plant concentration. If inner portions were entirely free of residue, the correction factor could be estimated as the ratio of the mass of the outer portion to mass of the entire vegetable:

$$VG_{bg} = \frac{MASS_{skin}}{MASS_{vegetable}} \quad (4\text{-}41)$$

where:

VG_{bg} = below ground vegetation correction factor, unitless
$MASS_{skin}$ = mass of a thin (skin) layer of below ground vegetables, kg/m^2
$MASS_{vegetable}$ = mass of the entire vegetable, kg/m^2

Simplifying assumptions are now made to demonstrate this ratio for a carrot and a potato. First, it will be assumed that the density of the skin and of the vegetable as a whole are the same, so the above can become a skin to whole vegetable volume ratio. The thickness of the skin will be assumed to be same as the thickness of the barley root for which the RCF was developed. Without the barley root thickness in Briggs, et al. (1982), what will instead be assumed is that the skin thickness is equal to 0.03 cm. This was the thickness of a leaf from broad-leaved trees assumed by Riederer (1990) in modeling the atmospheric transfer of contaminants to trees. The shape of a carrot can be assumed to be a cone. The volume of a cone is given as $(\pi/3)r^2l$, where r is a radius of the base and l is length. Assuming a carrot base radius of 1 cm and a length of 15 cm, the volume is 16 cm^3. The curved surface area of a cone is given as: $\pi r(r^2 + l^2)^{½}$, which equals 47 cm^2, given the r and l assumptions. The volume of the cone surface area is 47 cm^2 * 0.03 cm, or 1.41 cm^3. The skin to whole plant ratio for this carrot is 0.09 (1.41/16). A similar exercise is done for a potato, assuming a spherical shape with a radius of 3 cm. The volume is given as $4/3\pi r^3$, or 113 cm^3. The surface area of a sphere is $4\pi r^2$, or 113 cm^2, and the volume of this surface area is 3.39 cm^3. The skin to whole plant ratio for the potato is 0.03.

This exercise indicates lower bounds for such an empirical parameter. For exposure assessments, other factors which reduce vegetative concentrations should also be considered. Additional reductions in concentration result from peeling, cooking, or cleaning, for example. Wipf, et al. (1982) found that 67% of unwashed carrot residues of 2,3,7,8-TCDD came out in wash water, and 29% was in the peels. A peeled, washed carrot correction factor might instead be, 0.09*0.04, or 0.004 (0.09 from above; 0.04 = 100% - 67% - 29%). A 96% reduction in the estimated VG_{bg} for the potato (the potato is cleaned and the skin is not eaten; additional

reductions possibly when cooking the potato) would equal 0.001. In a site-specific application, the type of vegetation, preparation, and so on, should be considered.

As mentioned above, the Muller, et al. (1994) data did show concentrations in the inner parts of the carrot. They presented concentrations for the cortex and stele, as well as the carrot peel. One interesting trend with this data is that the cortex and stele concentrations are virtually the same with both the control and the contaminated soil. Also, the cortex and stele concentrations for the control carrots are slightly lower, but essentially similar to the peel concentrations for the control group. The authors of this research observed a lack of change in cortex and stele concentrations from the control to the contaminated soil, but offered no explanation. This suggests that the empirical parameter VG_{bg} should not be a constant but should vary, being higher at lower soil concentrations. With a lack of data to develop an algorithm for a varying VG_{bg}, it remains a constant for this assessment.

This data was examined to estimate the VG_{bg}. As noted above, a lower bound assignment of VG_{bg} for the hypothetical carrot was 0.09, and for the potato, was 0.03. This means that if there were absolutely no within plant translocation of dioxin residues - all residues were only in the skin of the carrot and potato - than the VG_{bg} would be 0.09 and 0.03. Muller, et al. (1994) did not include whole carrot concentrations or the necessary information to calculate whole carrot concentrations accurately. Therefore, simple assumptions will be made to do such. It will be assumed that the whole carrot concentration is estimated as 1 part peel concentration, 7 parts cortex concentration, and 2 parts stele concentration. The VG_{bg} is calculated as the whole carrot concentration divided by the peel concentration. Using this procedure, it is found that the VG_{bg} for the control soil varied between 0.38 and 1.00 for the 10 congener groups, with an average of 0.60, and that it varied between 0.14 and 0.39 for the contaminated soil, with an average of 0.24. These estimates are obviously higher than 0.09, indicating, as the data shows, that within plant translocation does occur for carrots. This would suggest a VG_{bg} of between 0.24 and 0.60, absent any consideration of washing or peeling (actually the full range of 0.14 and 1.00, considering differences among congener groups).

Data was sought to do a similar exercise for potatoes. Hulster and Marschner (1991) present concentrations found in potato tubers, both peeled and unpeeled; no data for concentration in peels alone is presented. Like the Muller, et al. (1994) data, simple assumptions need to be made to estimate the peel concentration in order to estimate the VG_{bg} for this data set. As derived above, it will be assumed that the peel is 3% of the entire potato volume. With this assumption, VG_{bg}s of between 0.03 and 0.05 are calculated for potatoes from the data of Hulster and Marschner (1991). This suggests that, unlike carrots, much of the concentration in the

potato, even at low soil concentrations, resides in the peel. Like the carrot, some within plant translocation is indicated for potates.

Another difference between the carrot data in Muller et al. (1994) and the potato data in Hulster and Marscher (1991) is the potential impact of peeling. A ratio of whole vegetable to peeled vegetable was estimated for both these sets of data. For the Muller data on carrots grown in control soils, where the inner carrot concentrations were not substantially different than outer carrot concentrations, the estimated ratio was 0.91, meaning that peeling would not effect the full concentration in these carrots. It should be pointed out that the control soil Toxic Equivalent concentration, 5 ppt, is typical of soils that are considered "background" or "typical". The impact of peeling was more pronounced for the contaminated soil, with an estimated ratio of 0.61. For the potatoes, peeling made a larger difference. The average peeled to unpeeled potato concentration ratio was about 0.20.

For the assessment in this document, "underground vegetables" are not any more defined than just that. Given the data examined in this section, a VG_{bg} of 0.25 will be assigned. This considers that a peeled carrot grown in typical soils could have a VG_{bg} of 0.60 according to the interpretation of the Muller, et al. (1994) data, whereas a peeled potato could have a VG_{bg} less than 0.01.

- **C_v, C_p:** The vapor (C_v) and particle (C_p) phase concentrations of contaminant in air, C_a, used in this algorithm is estimated using procedures described in Section 4.3.3 above.

- **B_{vpa}:** The first version of the air-to-leaf transfer factor used in the dioxin reassessment document (EPA, 1992b) used an empirical algorithm developed by Bacci and coworkers (Bacci, et al. 1990, 1992) who studied the vapor transfer of 14 organic chemicals, one of which was 1234-TCDD (not one of the 17 toxic congeners, but with similar fate properties to 2378-TCDD), to azalea leaves. These chamber experiments did not consider the effect of photodegradation on the transfer of the organic chemicals to the azalea leaves. The empirical relationship these researchers developed determined the volumetric transfer factor, B_{vol}, as a function of the contaminant Henry's Constant and log Kow:

$$\log B_{vol} = 1.065 \log Kow - \log \left(\frac{H}{R_i T}\right) - 1.654 \qquad (4\text{-}42)$$

where:

B_{vol} = Bacci volumetric air-to-leaf biotransfer factor, unitless [(µg contaminant/L of wet leaf)/(µg contaminant/L air)]
Kow = contaminant octanol water partition coefficient, unitless
H = contaminant Henry's Constant, atm-m^3/mol.
R_i = ideal gas constant, 8.205 x 10^{-5} atm-m^3/mol-K
T = temperature, 298.1 K
-1.654 = empirical constant

Then, McCrady and Maggard (1993) conducted chamber experiments on the transfer of 2378-TCDD vapors to grass leaves considering photodegradation. These experiments showed that the transfer of 2378-TCDD to grass leaves was about 40 times less than the transfer as calculated by the Bacci empirical algorithm. In addition to not considering photodegradation, McCrady and Maggard considered the difference in plant species between azalea leaves and grass leaves to be important in explaining the lower rate of transfer in their experiments as compared to Bacci's experiments. McCrady and Maggard's results were used in the next version of the air-to-plant model and the assignment of values to B_{vpa} (EPA, 1994). Specifically, the transfer factor for each dioxin congener was estimated using the Bacci algorithm, but this time all final results were divided by 40. Therefore, the B_{vpa} of the original model was reduced by a factor of 40 for all 17 dioxin and furan congeners for the second version of the air-to-leaf model.

Two key presumptions are inherent in using the Bacci algorithm divided by 40: 1) that the Bacci algorithm is generally appropriate for the dioxin congeners, despite the fact that the physical/chemical properties of the dioxin congeners are generally outside the range of the 14 organic chemicals used by Bacci, and 2) that the factor of 40 derived from one experiment on 2378-TCDD applies to all dioxin-like compounds.

The data of Welsh-Pausch, et al. (1995) will be used to develop an air-to-leaf transfer factor for the third version of the vapor phase air-to-leaf transfer factor described here, and also presented in Lorber (1995). Their data includes grass concentrations and air concentrations. Grass was grown in two flower boxes, with different agricultural soils in each box, beginning in May of 1991. The grass was cut back on July 17 in that year. On August 9, the grass was cut back again and the yield from the two boxes from the growth between July 17 and August 9 averaged 3900 g/m^2 fresh weight. This grass was analyzed for concentrations of dioxin congener groups, and these concentrations were provided on a fresh weight basis (i.e., pg/g fresh weight). On July 18, the first of two week long air samples were taken. These samples were taken very near the boxed grass. The samples were measured for the dioxin congener groups, not the

individual congeners. Representative congener group air concentrations were then determined as the average of the concentrations from the two samples. The concentration of dioxins in air remained relatively constant during the experimental period.

This data was used by McLachlan, et al. (1995) to verify an air-to-plant model based on fugacity concepts. Besides being a different model, McLachlan's modeling differed from the use of the data in this document in that it used to data to validate the model. Here, the data is used to calibrate a B_{vpa}. This was accomplished in the following 3-step procedure:

Step 1: Partition the total concentrations measured into a vapor and a particle phase. McLachlan, et al. (1995) had used the glass fiber filter/XAD trap 2-stage high volume air samplers to estimate vapor and particle fractions from the total reservoir. This apparatus will yield "operationally defined" vapor and particle fractions. The vapor fraction estimated this way will be larger than the vapor fraction estimated using the Junge model as applied and described by Bidleman (1988). The Bidleman model will be used to partition the total air concentration of the Welsh-Pausch, et al. (1995) experiments into a vapor and a particle phase. Whether the Bidleman model is more "correct" than the measurements of the 2-stage sampler is an ongoing technical issue. A full discussion of the issue for dioxins can be found in Chapter 3. Also, model comparisons of predicted and observed vapor/particle partitioning for other organic contaminants, including PCBs, PAHs, and organochlorine pesticides can be found in Chapter 7. Table 4-3 shows the vapor/particle partitioning as developed using the Bidleman model and used here compared against the measured vapor/particle partitioning from the air sampling apparatus. As an example of how the measured and the modeled vapor fractions are different, the air sampling apparatus measures 72% of the PCDD congener group to be in the vapor phase, whereas the Bidleman approach estimates that 13% of the PCDD congener group is in the vapor phase.

The vapor and particle fractions for the congener groups are modeled assuming an air temperature of 20 °C, and a particle density in air corresponding to a condition which Bidleman described as "background plus local sources". The average air temperature between July 17 and August 9 of 1991 was 18 °C (McLachlan et al., 1995), and the "background plus local sources" designation also appears most appropriate for the university city of Bayreuth, described as a typical background situation for this area of Europe by Welsh-Pausch, et al. (1995). Two alternate options instead of background plus local sources appear less relevant for Bayreuth: an "urban" condition (higher particle densities) and a "background" condition (lower particle densities).

Step 2: Model the deposition of particle-bound dioxins to the grass, and subtract out the resulting modeled grass concentration from the total concentration. Since an air-to-leaf vapor phase transfer factor is sought in this exercise, what is needed is the grass concentration due only to vapor transfers. The particle-bound impact to vegetation cannot be measured directly. Therefore, a model will be applied to estimate that part of total grass concentration of dioxin that was due to particle bound depositions. The model that will be applied was described earlier and is shown in Equation (4-38).

Step 3: What is now available after accomplishment of the above two steps is a concentration of vapor phase dioxins in air and a concentration of dioxins in grass due to vapor phase transfers. With appropriate conversions, the air-to-leaf transfer factor is now simply calculated as the vapor-impacted grass concentration divided by the vapor phase air concentration.

As noted, Equation (4-38) is used to estimate the particle deposition impact to the grass. The deposition F can be estimated as the particle bound fraction times a deposition velocity. The velocity of deposition will be assumed to be 0.002 m/sec, which was the velocity of dry deposition of dioxins as measured by Koester and Hites (1992). Wet deposition was not considered for this brief exercise; McLachlan, et al. (1995) indicates that only a small amount of rain fell during this time and that results implied that rain washed off the grass leaves. The interception fraction will be assumed to be 0.59, based on information provided in Baes, et al. (1984). A first-order weathering rate of 0.0495 day^{-1}, corresponding to a 14-day half-life, is used in this model. The experiment occurred between July 17 and August 9, so a time t of 24 days is assumed. Assuming 15% dry matter in grass, the fresh weight yield of 3900 g/m^2 translates to a yield of 0.585 kg/m^2 dry. The final fresh weight concentrations due to particle depositions and vapor transfers are shown in Table 4-3.

Also shown in Table 4-3 in the last column is the percent of total plant concentration that is estimated to be due to vapor transfers. Except for the octa congeners, it would appear that the grass is mostly impacted by vapor transfers. This, of course, is contingent on the validity of the particle impact model.

The volumetric air-to-leaf transfer factor, referred to as B_{vol}, is defined as the volumetric concentration of dioxins in grass due to vapor phase transfers divided by the volumetric concentration of dioxins in air. Appropriate units expressing this ratio are: [pg dioxin/m^3 grass]/[pg dioxin/m^3 air]. The air concentrations are already in the appropriate units. The grass concentrations as given in Table 4-3 are in units of ng dioxins per kg plant fresh weight; these concentrations need to be converted into a volumetric basis. To do the conversion, the denominator in this grass concentration needs to be converted to a volumetric basis. McCrady

and Maggard (1993) use a volumetric factor of 0.77 kg fresh leaf/L volume. Two other conversions necessary are a conversion from L to m^3 and a conversion from ng to pg. The final volumetric plant concentration in appropriate units is given as:

$$GC_{vol}\ \frac{pg\ dioxin}{m^3\ volume} = GC_{fr}\ \frac{ng\ dioxin}{kg\ plant\ fresh}\ \frac{0.77\ kg/L\ \ 1000\ pg/ng}{0.001\ m^3/L} \qquad (4\text{-}43)$$

where GC_{vol} is the volumetric grass concentration desired for calculation of B_{vol}, and GC_{fr} is the fresh grass concentration as reported in McLachlan, et al. (1995).

Table 4-4 now develops the final mass-based transfer factors, B_{vpa}. The volumetric transfer factor needs to be converted to the mass-based transfer factor, B_{vpa}:

$$B_{vpa} = \frac{1.19\ kg/m^3\ B_{vol}}{0.15\ \ 770\ kg/m^3} \qquad (4\text{-}44)$$

The B_{vpa} developed here for congener groups will be applied to all congeners in the congener group. The B_{vpa} for the congener groups calculated in this manner are compared against the B_{vpa} as developed in an earlier version of the Dioxin Exposure Document (EPA, 1994) which, as described above, were developed as function of the Bacci algorithms with an empirical correction factor based on the experiments of McCrady and Maggard (1993).

The B_{vpa} as calculated with the data of Welsh-Pausch, et al. (1995), are lower than the B_{vpa} as calculated in the earlier Dioxin Exposure Document (EPA, 1994). For 7 of the 10 congener groups, the difference is less than an order of magnitude. The exceptions are the two octa congeners and the hepta dioxin congener, where the B_{vpa} calculated from the Welsh-Pausch, et. al (1995) data are two or more orders of magnitude lower for the octa congeners and 1 order of magnitude lower for the hepta dioxin congener. In general, the trend of increasing B_{vpa} from the tetra through the octa congeners is consistent with both approaches.

It may be informative to speculate on why the transfer of vapor phase dioxins appears to be lower in the Welsh-Pausch, et. al (1995) data as compared to the McCrady and Maggard (1993) data. There may be a relevant species difference, such as the lipid content for example, in the grass species used by McCrady and Maggard (1993), Reed canary grass (*Phalaris*

arundinacea L.), and the grass in the Welsh-Pausch, et al. (1995) experiments, Welsh Ray Grass (*Lolium multiflorum*). The climate might have different in Bayreuth, leading to more photodegradative loss in the Welsh-Pausch data. Certainly the experimental designs were different. McCrady and Maggard (1993) used a 2-stage chamber experimental design, including an uptake phase in which the grass was not exposed to sunlight, and a release phase where the grass was kept in sunlight. Uptake and release were occurring simultaneously and in sunlight in the Welsh-Pausch, et al. (1995) experiments. Certainly it seems possible that the net transfer rates might have been lower in the McCrady and Maggard (1993) experiments had the uptake and release phases both occurred in sunlight.

It should be noted that all bioconcentration or biotransfer parameters, such as the B_{vpa}, are qualified as second order defaults for purposes of general use. Section 6.2. of Chapter 6 discusses the use of parameter values selected for the demonstration scenarios, including a categorization of parameters. Second order defaults are defined there as parameters which are theoretical and not site specific, but whose values are uncertain in the published literature. The parameter values in this category should be considered carefully by users of the methodology. However, a model testing exercise published in Lorber and Pinsky (1999) and described in Chapter 7 lends credibility to the use of these CDD/F B_{vpa} for general purposes.

- **VG_{ag}:** The same discussion for this correction factor for below ground vegetation applies here. Fruits such as apples, pears, plums, figs, peaches, and so on, can be approximated by spheres, and upper bound estimates of correction factors would be less than 0.05. Peeling, cooking, and cleaning further reduces residues. The VG_{ag} for unspecified above ground fruits and vegetables in this assessment is assumed to be 0.01. Like VG_{bg}, this value is assigned considering that it should be less than estimated just based on surface volume to whole fruit volume ratios.

Two other VG_{ag} values are required for this assessment. One is for pasture grass and the other for other vegetation consumed by cattle. Both are required to estimate concentrations in these vegetation consumed by cattle in order to estimate beef and milk concentrations. A VG_{ag} value of 1.0 was used to estimate pasture grass concentrations since there is a direct analogy between the grass in the Welsch-Pausch, et al. (1995) experiments for which the B_{vpa} was developed and pasture grass of the cattle diet. However, VG should be less than the other general category of cattle vegetation defined in this assessment, "hay/silage/grain". Pasture grass is considered as a separate diet category because it is a principal component of the cattle diet and most subject to impact by dioxin-like compounds because it is leafy, whereas other cattle

vegetation are lumped together in this second category. As described below, this second general category of non-grass cattle vegetation include some thin leafy (hay) as well as bulky (corn silage and other grains) vegetation to consider. A volume ratio of outer surface to whole surface area to volume vegetation could be used to assign a value to VG, if specific assumptions concerning proportions of each type of vegetative cattle intake were made. An appropriate assumption for a fully protected vegetation such as grain would be zero. Silage can be considered part protected and part leafy. Since specific assumptions concerning hay/silage/grain intake are not being made for this exercise, a simple assumption that VG equals 0.50 for hay/silage/grain is instead made, without rigorous justification.

The only experimental evidence that a VG_{ag} for vapor transfers of dioxin-like compounds is justified came in a study by McCrady (1994). McCrady experimentally determined uptake rate constants, termed k_1, for vapor phase 2,3,7,8-TCDD uptake into several vegetation including kale, grass, pepper, spruce needles, apple, tomato, and azalea leaves. Recall that the similar experimental design of both McCrady and Maggard (1993), and Bacci, et al. (1990; 1992), included an initial phase where vegetation in experimental chambers were exposed to the vapor-phase organic chemicals. The uptake which occurs during this initial phase is described with the rate constant, k_1. A second "elimination" phase then occurs where organic vapors are removed from the chambers and the chemicals allowed to volatilize or otherwise dissipate from the vegetation. The rate constant for this phase is termed k_2. A steady state bioconcentration factor (i.e., B_{vpa}), is then estimated as k_1/k_2. The uptake rate constants from air to the whole vegetation estimated in the McCrady (1994) experiments demonstrate the concept behind the VG parameter. The uptake rate for an apple divided by the uptake rate for the grass leaf was 0.02 (where uptake rates were from air to whole vegetation on a dry weight basis). For the tomato and pepper, the same ratios were 0.03 and 0.08. The VG_{ag} is 0.01 for fruits and vegetables in this assessment, but note above that the simple exercise with a conical carrot and spherical potato estimated a surface volume to whole fruit volume ratio of 0.09 (carrot) to 0.03 (potato); a value of 0.01 for fruits and vegetable empirically considers factors such as washing or peeling which would reduce exposures. McCrady (1994) then went on to normalize his uptake rates on a surface area basis instead of a mass basis; i.e., air to vegetative surface area instead of air to vegetative mass. Then, the uptake rates were substantially more similar, with the ratio of the apple uptake rate to the grass being 1.6 instead of 0.02; i.e., the apple uptake rate was 1.6 times higher than that of grass, instead of 1/50 as much when estimated on an air to dry weight mass basis. The ratios for tomato and pepper were 1.2 and 2.2, respectively. McCrady (1994) concludes, "The results of our experiments have demonstrated that the exposed surface area of plant tissue is an important

consideration when estimating the uptake of 2,3,7,8-TCDD from airborne sources of vapor-phase 2,3,7,8-TCDD. The surface area to volume ratio (or surface area to fresh weight ratio) of different plant species can be used to normalize uptake rate constants for different plant species." McCrady cautions, however, that uptake rates are only part of the bioconcentration factor estimation, and he is unsure of the impact of surface area and volume differences on the elimination phase constant, k_2 (personal communication, J. McCrady, US EPA, ERL-Corvallis, Corvallis, OR 97333). Still, his experiments do appear to justify the use of a VG parameter since the B_{vpa} were developed on an air to whole plant mass basis, and his results are consistent with a VGag of 0.01 for fruits and vegetables.

- **kw:** Fries and Paustenbach (1990) note that this approach may overestimate concentrations because crops can be harvested or pastures grazed before the plant concentrations reach steady state, and that a kw based on a weathering half-life of 14 days may be too long given experimental results of Baes, et al. (1984) which showed a range of 2-34 days, and a median value of 10 days. On the other hand, Umlauf and McLachlan (1994) discuss the phenomena of the transfer of semivolatile organic compounds (SOCs) from depositing particles onto the leaf - the particles themselves may weather off the leaves with a half-life of 14 days, but the SOCs would transfer from the particle and not weather off the leaves. Umlauf and McLachlan (1994) could not find information on the transfer of SOCs from particles to leaves, but they speculated that the lipid covering of the cuticle would facilitate a rapid particle to leaf transfer. In their modeling of several SOCs to spruce leaves, they assumed that the SOCs completely transferred from the particles to the leaves in both wet and dry particle-bound deposition with no subsequent loss of contaminant via weathering or degradation. This is equivalent to assuming an infinite half-life rather than a 14-day half-life. Umlauf and McLachlan (1994) found reasonable model performance when comparing their modeling results with measurements of several SOCs including some PCBs on spruce leaves. Stevens and Gerbec (1988) used a 14-day half-life but did not assume a steady-state concentration is necessarily reached in vegetation. They considered harvest intervals by including the exponential term, $(1-e^{-kt})$, and assigning values of t based on harvest intervals of different crops. This assessment uses a kw of 18.02 yr^{-1}, which is equivalent to a half-life of 14 days. However, based on the discussions of Umlauf and McLachlan (1994), this is recognized as an important area of uncertainty. If their consideration of the transfer of SOCs from particles to leaves is valid, than an assignment of a kw of 18.02 yr^{-1} will significantly underestimate the impact of dry and wet deposition to vegetation.

- **I_j and Y_j:** Interception values and crop yields were determined in the afore-mentioned assessments based on geographic-specific crop yield data provided in Baes, et al., (1984) and the following types of crop-specific relationships estimating interception fraction based on yield (Y), also presented in Baes, et al., (1984):

corn silage: $I = 1 - e^{-0.768Y}$
hay/grasses: $I = 1 - e^{-2.88Y}$
lettuce: $I = 1 - e^{-0.068Y}$

Judgments by Fries and Paustenbach (1990) on high, medium, and low yields of silage, hay, and pasture grass, and the use of the first two interception equations above (the first for silage, and the second for hay and grass), can give some guidance on interception fractions and yields for these crops:

	Yield (kg/m^2)	Intercept Fraction
corn silage	0.30 (low)	0.20
	0.90 (med)	0.50
	1.35 (high)	0.64
hay	0.25 (low)	0.51
	0.45 (med)	0.73
	1.30 (high)	0.98
grass	0.05 (low)	0.13
	0.15 (med)	0.35
	0.35 (high)	0.64

This information can be used for cattle intake of vegetation, and the resulting beef and milk concentrations. The medium values for grass, 0.15 kg/m^2 yield and 0.35 interception, were used for the example setting in Chapter 5. An average of the medium values for hay and silage, 0.63 kg/m^3 yield and 0.62 interception, were used for the second category of cattle vegetation for Chapter 5, the hay/silage/grain category.

Stevens and Gerbec (1988), using yields obtained from the Minnesota State Agricultural Office, derived the following yield and interception estimates, respectively, for vegetables for human consumption in their assessment: lettuce - 8.6,0.72; tomatoes - 12.0,0.55; and beans - 2.7,0.18. Average yields and interception fractions from their exercise: 7.8 kg/m^2 and 0.48, were used in the example setting in Chapter 5. These vegetable yields are fresh weight, so they need

to be converted to a dry weight basis in order to estimate a C_{ppa} appropriate for use in Equation (4-38). Since vegetables are generally 80 ->90% water, a fresh to dry weight conversion factor of 0.15 was used, resulting in an average vegetable dry matter yield of 1.17 (7.8 * 0.15). This was used in the example settings in Chapter 5.

- **V_d:** Particles settle to the ground surface and plant surfaces due to the forces of gravity. Gravitational settling velocity is a function of particle size, with more rapid settling occurring with larger particles. The algorithm used to estimate the concentration of contaminated particulates in air estimates the suspension of particles less than and equal to 10 μm, which is commonly referred to as inhalable size particles. Seinfeld (1986) listed a gravitational deposition velocity of 1 cm/sec for 10 μm size particles. This deposition velocity will be used in this assessment, and in units of m/yr, this equals 315,360 m/y.

- **RN:** Geraghty, et al. (1973) provides a map showing isolines average annual rainfall throughout the United States. This map shows low rates of 5 to 20 inches/year in the desert Southwest, moderate rates of 25 to 40 in/yr in the Midwest cornbelt, 40 to 60 in/yr in the South, and so on. The example scenarios of Chapter 5 were described as rural, with land in agricultural and non-agricultural settings. A rate of 1 m/yr (39 in/yr) will be used in the example scenarios.

- **R_w:** It is assumed that dry depositions fully adhere to plant surfaces; the weathering constant, k_w, models the loss of the vegetative reservoir of particle bound contaminants due to wind, rain, or other weathering process. However, it is not clear that wet deposition should also be assumed to fully adhere during a wet deposition event. Hence, the R_w parameter, or fraction of wet deposition adhering, was introduced. Prior modeling efforts of the impact of depositions of dioxin-like compounds to vegetation are unclear with regard to wet deposition. Stevens and Gerbec (1988), Fries and Paustenbach (1990), Webster and Connett (1990), and Travis and Hattemer-Frey (1991) all model particle deposition impacts of 2,3,7,8-TCDD to vegetation in air-to-beef/milk modeling. None of them discuss the distinction in wet and dry deposition, and model "total deposition" impacts, describing total as wet and dry deposition, total deposition, or simply as deposition. On the other hand, McKone and Ryan (1989) reduce the wet deposition portion of total deposition. They promote use of a "b", which they define as the fraction of material retained on vegetation from wet deposition. They recommend a value between 0.1 and 0.3.

The clearest indication of the fate of wet deposition of particles can be found in Hoffman, et al. (1992). In that field study, simulated rain containing soluble radionuclides and insoluble particles labeled with radionuclides was applied to pasture-type vegetation under conditions similar to those found during convective storms. The fraction of the labeled particles found to remain on the vegetation after the rainfall varied from 0.24 to 0.37. Nine values comprised this range, including particle sizes of 3, 9, and 25 μm, and cover described as clover, fescue, and mixed (a site with old field vegetation including fescue, grasses, weeds, and wild flowers). Based on this work, the R_w will be assumed to be 0.30 for all vegetation and dioxin congeners of this assessment.

- **W_p:** Washout ratios are generally defined as the concentration of contaminant in rain to the concentration of contaminant in air. Concentrations of contaminants in air and rain water can be derived as a mass of contaminant divided by a mass of air/water or a volume of air/water. Mackay, et al. (1986) shows that volume-based washout ratios (mass of contaminant mixing in m^3 air or water, e.g.) exceed mass-based washout ratios (mass of contaminant mixing in kg of air or water) by a factor of 815, which is the ratio of water and air densities. The washout ratio used in this assessment is a volumetric ratio based on methodologies described by Bidleman (1988). Using a volumetric ratio then allows for direct use of contaminant concentrations estimated in this methodology since they are already on a $\mu g/m^3$ volume basis.

  Bidleman (1988) defines the overall washout ratio as: (mass contaminant/volume rain) ÷ (mass contaminant)/(volume air). Bidleman (1988) also discusses that fact that overall washout includes both wet deposition of particulates and scouring of contaminants in the vapor phase. He includes methodologies for estimating the vapor/particulate ratios for semi-volatile organic compounds (abbreviated SOCs) and also for estimating the washout ratios for vapors. However, he claims that if H is sufficiently high, vapor dissolution in droplets is negligible and only the particulate fraction is removed by wet deposition. He claims this to be the situation for n-alkanes, PCBs, chlordane, DDT, and 2,3,7,8-TCDD. Developing overall washout ratios for these and several other SOCs, he estimates that vapor scouring accounts for 1% of the overall washout ratio for 2,3,7,8-TCDD. For PCBs, he estimates similar percentages of 2, 4, and 28% for Aroclors 1260, 1254, and 1248, respectively. Based on this work, it will be assumed that vapor scouring of the dioxin-like compounds is small in comparison to wet deposition and the washout ratio for this assessment will only be applied to the air-borne particulate concentration of dioxin-like compounds.

Bidleman (1988) does not provide a chemical or site-specific equation which estimates the particle-phase washout ratio (which he does for the vapor-phase washout ratio). Rather, he summarizes available data and concludes that there is a wide range of the particle-phase washout ratio, W_p, for SOC: between $2x10^3$ and $1x10^6$. He claims that a typical range is 10^5 to 10^6, and uses a W_p of 2×10^5 in his exercises to estimate the overall washout ratio for several SOCs.

Koester and Hites (1992) list vapor and particle scavenging ratios for congener groups of dioxin-like compounds. To derive these ratios, they used air concentrations for congener groups that were taken at one time period in Bloomington and Indianapolis, Indiana, and rainfall depositions of these compounds at these sites measured during a second period of time. Using the Bidleman vapor/particle partitioning model used in this assessment, they estimate the vapor/split for the air concentrations. With these observations and models, they conclude that the overall washout ratio (sum of vapor and particle ratios) ranges from 10^4 to 10^5, which contrasts the typical range of 10^5 to 10^6 noted above from Bidleman (1988). Also, their calculations indicate that vapor scavenging of dioxin-like compounds is comparable to particle scavenging, also in contrast to the Bidleman analysis summarized above. However, they did not state whether their washout ratios were volume or mass-based. If they were mass-based, then a conversion to volume based would put them in the 10^7 to 10^8 range, which seems improbable given the Bidleman summary above. Therefore, it will be assumed that they are volume-based, and they are appropriate to use for this assessment. Since no clear trend for particle washout ratios with regard to the degree of chlorination increased appears in Koester and Hites' data, the midpoint of their calculated range, $5 * 10^4$, will be used for all example compounds in this assessment.

As a final note, the multiplication of the above terms, $W_p * C_{pa} * RN * R_w$, does result in wet deposition in appropriate units of $\mu g/m^2$-yr, although that is not immediately obvious. First, multiplication of W_p, in (μg contaminant/m^3 rain)÷($\mu g/m^3$ air), and C_{pa}, in μg contaminant/m^3 air, leaves a partial term in units of μg contaminant/m^3 rain. Then, multiplication of this partial term times annual rainfall rate, thought of as m^3/m^2-yr instead of m/yr, gives the final quantity in the appropriate units.

When calculating concentrations in below ground fruit and vegetables using Equation (4-35), C_{bgv} is on a fresh weight basis since the RCF developed by Briggs, et al. (1982) is on a fresh weight basis, and no correction for estimating exposures is necessary. However, C_{abv} as estimated in Equation (4-36) is on a dry weight basis, and should be multiplied by a dry weight to fresh weight conversion factor when applied to above ground fruits and vegetables. A reasonable estimate for this parameter for fruits and vegetables is 0.15 (which assumes 85% water), which

was used in this assessment. When using Equation (4-36) to estimate C_{abv} for the beef and milk food chain algorithm, a conversion to fresh weight is not required, however, since the algorithms were developed assuming dry weight concentrations.

4.3.4.3. *Beef and Milk Concentrations*

The algorithm to estimate the concentration of contaminant in beef and/or milk was based on methods developed by Fries and Paustenbach (1990). They developed the beef bioconcentration factor for 2,3,7,8-TCDD, which is defined as the ratio of the concentration of the contaminant in beef fat to the concentration in the dry matter dietary intake of the beef cattle. They discussed bioavailability, which, as they define it, is the fraction of ingested contaminant which is absorbed into the body. It depends on the vehicle of ingestion - dioxin in corn oil has a bioavailability in the range of 0.7 to 0.8, in rodent feed it has an estimate of 0.5, while in soil it has a range of 0.3 to 0.4. They emphasized the importance of the differences in diet between cattle raised for beef and those which are lactating in explaining different food product concentrations. Although there is likely to be some difference in the bioconcentration tendencies for lactating and non-lactating cattle, Fries and Paustenbach in fact used the same bioconcentration for beef fat and milk fat, and the same will be done here.

The concentration in the fat of cattle products is given as:

$$C_{fat} = BCF\ FF\ (DF_s\ B_s\ AC_s + DF_g\ AC_g + DF_f\ AC_f) \quad (4\text{-}45)$$

where:

C_{fat} = concentration in beef fat or milk fat, pg/g

BCF = bioconcentration ratio of contaminant as determined from cattle vegetative intake (pasture grass or feed), unitless

FF = feedlot factor for beef fat calculation, ≤ 1 for beef fat and =1 for milk fat, unitless

DF_s = fraction of cattle diet that is soil, unitless

B_s = bioavailability of contaminant on the soil vehicle relative to the vegetative vehicle, unitless

AC_s = average contaminant soil concentration, pg/g

DF_g = fraction of cattle diet that is pasture grass, unitless

AC_g = average concentration of contaminant on pasture grass, pg/g

DF_f = fraction of cattle diet that is feed, unitless

AC_f = average concentration of contaminant in feed, pg/g

The following is offered as brief guidance to these terms and also the justification for the values selected in the example Scenarios in Chapter 5.

- **Beef/milk bioconcentration factor, BCF:** Fries and Paustenbach (1990) developed the concept of a beef/milk bioconcentration ratio and applied it to 2,3,7,8-TCDD. BCF is defined as the concentration of contaminant in fat of cattle products (i.e., dairy and beef) divided by the concentration in dry matter intake. One key difference in the dietary intake of cattle raised for beef versus cattle raised for dairy is that cattle raised for beef tend to be pastured more than dairy cattle and be more exposed to contaminated soil, whereas lactating cattle are more often fed high quality feed, including grains which are expected to be substantially residue free since they are a protected vegetation. Another key difference is that the dioxins in lactating cows generally will reach a steady state in the fat of the animal (muscle fat and milk fat) much more rapidly than in non-lactating cattle because the excretion of milk will result in a large excretion of dioxins. For non-lactating cattle, excretion only occurs in feces and urine. Based on modeling, McLachlan (1994) speculates that it would take approximately 6 years for dioxins to reach steady state in non-lactating cattle because of the slow excretion rate through feces and urine, and that at steady state, concentrations in the muscle fat of non-lactating cattle would be much higher than in milk. However, dioxin concentrations in beef fat are generally found to be similar to that in milk fat. McLachlan (1994) explains it this way: "...it will take 6 yr to approach this steady state, much longer than the 1.5 yr that beef cattle typically live. During this time, the animal is also growing, continuously diluting its contaminant reservoir. As a result, the contaminant levels in commercial beef fat are generally not much higher than in milk fat." For this reason, the BCFs that are developed below based mostly on milk fat will be applied to both milk and beef fat.

Based on literature studies of cattle consuming feed contaminated with dioxin-like compounds, Fries and Paustenbach (1990) calculated a BCF of between 4 and 6, and assumed a value of 5.0 for 2,3,7,8-TCDD. Being developed directly from data of cattle ingesting contaminated feed, this BCF value of 5.0 already considers the bioavailability of the experimental contaminated feed. It will be assumed that the bioavailability of the cattle vegetation in this assessment equals that of the experimental feed. Therefore, a value of 5.0 can go directly into Equation (4-45) when applied to concentrations in grass and pasture. However,

this value should not be applied to soil, since it has been shown that TCDD on soil is less bioavailable than TCDD on other vehicles. This is why a B_s appears in Equation (4-45) - it adjusts BCF when applied to a soil concentration. The value of B_s is described below. The Fries and Paustenbach (1990) literature review is reproduced in Table 4-5, which additionally shows results generated based on information in McLachlan, et al. (1990) and Fries, et al. (1999).

Although the BCF of 5 determined by Fries and Paustenbach (1990) for 2,3,7,8-TCDD appears high based on the literature for this compound, Fries and Paustenbach (1990) discuss how short duration feeding trials (the 21 days of Jensen and Hummel (1982) and the 28 days of Jensen, et al. (1981)) do not result in steady state bioconcentration ratios. Extrapolating the data to a point where steady state is speculated to be reached, Fries and Paustenbach (1990) developed the arguments for the range of 4 to 6 for 2,3,7,8-TCDD. The second example compound in Chapter 5 was 2,3,4,7,8-PCDF. Fries and Paustenbach (1990) observed that bioconcentration ratios for PCDDs and PCDFs decreased significantly as chlorination increased, although their literature seems to imply that this effect is most pronounced for hepta- and octa- PCDDs and PCDFs. They could not locate data in the literature for penta-PCDDs or PCDFs.

McLachlan, et al. (1990) was the first study where BCFs for cow milk could be generated for furan congeners. They conducted a mass balance of dioxin and furan congeners in a lactating cow. They carefully accounted for 16 of the 17 dioxin and furan congeners of toxicity equivalency to 2,3,7,8-TCDD in the intake of a lactating cow in food, air, and water, and measured amounts in feces, urine, and milk, while attributing the rest of the intake to a compartment they termed, storage/degradation/experimental error. They obtained data well into steady state, and provided information necessary to estimate milk BCFs including: information appropriate to estimate the dry matter intake by the cattle; ng/day congeners in feed, water, and air; L/day milk production (density assumed to be 0.9 g/cm^3); and percent fat in milk. The data for estimating the dry matter intake of the cattle was expressed in two ways. One, the wet weight of feed materials was given, and assuming a dry weight fraction (the actual dry weight fraction was not given), one could estimate a dry matter intake. Two, it was stated that the feces flux of 5 kg/day was 30% of the dry weight intake. Therefore, the dry matter intake is calculated at 16.7 kg/day. However, in a later report on this same data set (McLachlan, 1993), it was stated that the feces flux from this experimental animal of 7 kg/day was 33% of dry matter intake. In a personal communication (letter, M. McLachlan to M. Lorber dated 4/2/95), the author confirmed that the correct total dry matter intake was 21 kg/day, and this value was used in the generation of BCFs shown in Table 4-5.

Fries, et al. (1999) conducted a feeding experiment where four cows were fed PCP-contaminated wood. Specifically, a 3 g/day dose of ground PCP-treated wood as administered to each cow for 58 days. The mixed feed was sampled, and a sample of each cow's milk was obtained on days 28, 42, and 56. Feed amounts were carefully controlled to not only these cows but to other cows at the USDA agricultural research facility. Bulk milk was obtained from cows who were not treated, and the concentrations from these samples served not only as controls for the laboratory, but also were used to calculate a limited set of BCFs for background settings. BCFs were calculated when both feed and milk were higher than background. The results for the cows fed the wood as well as for background cows are shown in Table 4-5. As seen, there is reasonable agreement between the cows fed the contaminated wood and the background cows, with the exception, perhaps, of two of the furan congeners, and there is also good agreement between these BCFs and those developed from the data of McLachlan, et al. (1990). Also, the BCF for 2,3,7,8-TCDD was highest in this experiment at 7.1 as compared to other BCFs calculated for 2,3,7,8-TCDD

The McLachlan data will be used to assign BCFs for the demonstrations in Chapter 5. The BCF value for 2,3,7,8-TCDD value is 5.73 and the BCF for 2,3,4,7,8-PCDF is 4.13, in the demonstration scenarios which include a dioxin, a furan, and a PCB. For the demonstration of the incinerator, the suite of dioxin-like compounds are demonstrated, and the full BCF set developed by McLachlan and coworkers will be used.

A review of the literature for PCBs is given in Table 4-6. McLachlan and coworkers measured a suite of PCBs in his lactating cow mass balance experiments and reported the results in McLachlan (1993). However, unlike the dioxin results which showed a favorable mass balance result (i.e., most of the mass of the dioxin intake by the cow could be accounted for in the feces, urine, and milk - the remainder attributed to storage, metabolism, or experimental error), the PCBs results showed that up to 40% more PCBs were being excreted through urine, feces, and milk, than was taken up by the cattle. McLachlan (1993) discounted the possibility that the cow was losing body fat which could explain the result, and instead speculated that there was secondary contamination of the feed through binder twine that had been treated with recycled oil (i.e., the amount of PCB intake by the cow was underestimated). In any case, this data could not be used to generate BCFs for PCBs.

Although PCBs, dioxins, and furans are related compounds in terms of environmental fate characteristics, a difference in bioaccumulation potential is noted with higher degrees of chlorination, based on the study of Tuinstra, et al. (1981). Their work implies increasing bioaccumulation potential as the degree of chlorination increases. They developed BCF values

(defined in the same manner as in this assessment) for a suite of congeners identified to occur in Aroclor 1260 administered to lactating cows. Therefore, their data allowed for a partial examination on congener bioaccumulation patterns. The results given in Table 4-6 are interpreted from the data supplied in Tuinstra, et al. (1981). Tuinstra determined the identity and percentage of specific congeners which comprise Aroclor 1260. He was able to identify 36 congeners, but could only quantify 27 of them (because of the unavailability of standards for 9 congeners). These 27 comprised 81%, by mass, of the Aroclor 1260. Tuinstra was able to estimate BCF values for most, but not all, of the identified congeners - for 23 of the 27 congeners they identified (which equaled 77% of the congeners, by mass, of Aroclor 1260). As seen in Table 4-6, the average congener-group BCF value increases from about 2 to 4 going from hexa- to nanochloro-PCBs. However, there was a wide range of measured BCF values for specific congeners. In the heptagroup, for example, Tuinstra estimated BCF values between 0.4 and 5.2. Fries, et al. (1973) showed increasing BCF values in milk fat at 20, 40, and 60 days for Aroclor 1254 up to a value of 4.8 at day 60. The body fat BCF value at 60 days, the only time such a measurement was taken, was 3.4. The trend of having a higher BCF value for milk fat as compared to body fat for lactating cows was also noted by Willett, et al. (1987). They fed lactating cattle Aroclor 1254 sorbed to ground corn. In three sequential periods of 60 days, they fed the cattle 10, 100, and then 1000 mg/day of Aroclor 1254. Given their average daily dry matter intake of 19.5 kg during the experiment, the concentration during each of those 3 periods was 0.51, 5.13, and 51.28 mg/kg (ppm). However, milk and body fat concentrations of PCBs were given after 60, 120, and 180 days, so that for estimation of the BCF value, what is needed is average concentration of Aroclor intake after these periods. These averages are 0.51, 2.82, and 18.97 mg/kg. Given the reported concentrations of PCBs in milk and body fat after these experimental periods, BCF values were estimated and given in Table 4-6. Two studies, that of Willett and Liu (1982) and Perry, et al. (1981), contained data from which estimates of BCF could be made, except that these studies did not report daily dry matter intake. An estimate of 19.5 kg/day was assumed for lactating cattle for these studies, which was the experimental dry matter intake noted by Willett, et al. (1987). Willett and Liu (1982) dosed cattle for only 20 days, and arrived at the lowest noted BCF value for Aroclor 1254, 1.2. The trend of increasing BCF value over time of dosing was noted by Fries, et al. (1973). Willett, et al. (1990) conclude that steady state is reached after about 60 days, so that estimates of BCF made from experiments less than 60 days may not reflect steady state conditions. Perry, et al. (1981) had a high BCF value, 4.2, despite the dosing period being only 32 days. This would appear to be the result of having a high concentration in the diet. Similarly high BCF values with corresponding high

concentration in dosed intake were noted in Fries, et al. (1973) and Willett, et al. (1987). It should be noted that the concentrations in body fat in the studies of Willett and Liu (1982) and Perry, et al. (1981) were corrected as recommended by Willett, et al. (1990) in estimating BCF values.

Five trends for PCBs were discussed above: 1) that steady state is reached after approximately 60 days, 2) that higher BCF values appear to result with higher concentrations in feed, 3) that BCF values for milk fat may exceed those of body fat for lactating cows (this also seems true for dioxins/furans; see Table 4-5), 4) that the BCF values tend to increase with increasing chlorination of PCB congener groups, and 5) that this fourth trend is based on a limited set of data and much variability exists within specific congener groups.

Generally there is a sparsity and inconsistency in the data which would allow for definitive estimation of BCF values for the example heptachloro-PCB example compound in Chapter 5, 2,3,3',4,4',5,5'-PCB. Most of the data noted is for Aroclor 1254, and this data implies BCF values between 1.2 and 4.8. Based on the results from Tuinstra, et al. (1981) for the average of eight heptachloro-PCBs, a BCF value of 2.3 will be assigned to 2,3,3',4,4',5,5'-PCB.

It should be noted that all bioconcentration or biotransfer parameters, such as the BCF, are qualified as second order defaults for purposes of general use. Section 6.2. of Chapter 6 discusses the use of parameter values selected for the demonstration scenarios, including a categorization of parameters. Second order defaults are defined there as parameters which are theoretical and not site specific, but whose values are uncertain in the published literature. The parameter values in this category should be considered carefully by users of the methodology.

● **FF:** Fries and Paustenbach (1990) summarize pertinent literature to conclude that cattle raised for beef are not slaughtered without an intervening period of high-level grain feeding. Agricultural statistics (USDA, 1992) show that 32.9 million cattle were slaughtered in 1991. Of this number, 6.1 million were cows and bulls that likely did not go through a feedlot prior to slaughter. Quarterly statistics from 1991 show that at any time, cattle and calves on feed for slaughter range from 10 to 12 million. Fries uses these statistics to conclude that 75 to 80% of the total beef supply is from animals that went through a feedlot finishing process, and that the portion of beef that did not go through a feedlot process are (generally speaking) those 6.1 million cows and bulls (personal communication, G. Fries, USDA Agricultural Research Service, Beltsville, Maryland, 20705). He suggests that a representative feedlot finishing process would include a length of 120 days and diet consisting of 20% corn silage and 80% grain. The grains can be assumed to be residue-free, since grains are protected and, as discussed above, little

within plant translocation of outer contamination can be assumed. Also, the ears of the corn silage are in the same category, leaving only the stalks and leaves of the corn silage impacted by atmospheric transfers of dioxin-like compounds.

A feedlot finishing process is important to consider if assessing beef impacts in a site-specific assessment. However, data could not be found in the literature which measured the impact of this process to beef concentrations. Such impacts could occur as the result of increased weight gain from substantially residue-free feeds. Fries and Paustenbach (1990) and Stevens and Gerbec (1988) modeled the impact of a residue-free grain-only diet for four months prior to slaughter. Based on within-cow dilution and depuration considerations, both efforts estimated that the feedlot process would reduce beef concentrations by about one-half. This translates to an assignment of 0.5 for FF. This was the assumption used in the air-to-beef food chain validation exercise described in Chapter 7.

The demonstration scenarios of Chapter 5 assume that farming families slaughter a portion of their cattle for home consumption, and that they do not put their cattle through any special diet before slaughter. Therefore, an FF = 1 is assumed for the demonstration scenarios in Chapter 5.

With the use of an FF, it is noted that the quantity in the parenthetical of Equation (4-45) above describes the cattle diet prior to slaughter.

- **Soil bioavailability, B_s**: This parameter reduces the bioconcentration ratio, F, considering that soil is a less efficient vehicle of transfer compared to feed. Remember that the values of BCF appropriate for Equation (4-45) already consider bioavailability and were developed from experimental data placing the BCF of 2,3,7,8-TCDD in the 4 to 6 range. Fries and Paustenbach (1990) reviewed several studies on the oral bioavailability of TCDD in soil in the diet of rats, and concluded that soil is a less efficient vehicle of transfer as compared to rat feed. If the same is true for cattle - that soil is less efficient than their feed - than the BCF value must be reduced when applied to soil ingestion. Most studies reviewed by Fries and Paustenbach used corn oil as the positive control, since there is a high absorption of TCDD in rats when corn oil is used as the vehicle, with 70-83% of the administered TCDD dose absorbed. Their literature review on rat data showed that the bioavailability of TCDD in soil was between 0.4 and 0.5 that in corn oil, or 0.3 to 0.4 overall. The literature implied a range of 0.5 to 0.6 of TCDD in standard rat feed is absorbed, and although few studies were available, a similar 50% absorption rate of TCDD in cattle feed was noted. They concluded, therefore, that the rat data was a reasonable surrogate for cattle. The B_s can be thought of as the ratio of BCF values between soil

and feed, or, $(BCF_{soil})/(BCF_{feed})$. If the difference in BCF_{soil} and BCF_{feed} is explained solely by bioavailability differences, then the ratio of overall bioavailability of soil to feed should equal this ratio. As described above for rat data, the overall bioavailability of soil was 0.3-0.4, and the overall bioavailability of feed was 0.5-0.6. The ratio of overall bioavailabilities is, therefore, (0.3-0.4)/(0.5-0.6). If the argument that this ratio equals the ratio of BCFs is valid, than this would lead to a B_s of 0.5 to 0.8. This implies that absorption of TCDD when soil is the vehicle is 50 to 80% of what it would be if feed were the vehicle. These assumptions and implications are made for this assessment, and the soil bioavailability term, B_s, used for all example compounds in Chapter 5 is 0.65.

- **Soil diet fraction, DF_s:** Fries and Paustenbach (1990) report that soil intake by cattle feeding on pasture varies between 2 and 18% of total dry matter intake, depending on whether the grazing area is lush or not. The soil diet fraction would be lower for cattle which are barn-fed with minimal opportunity for contaminated soil intake. Cattle raised for milk are rarely pastured, so one possible assumption for estimating milk fat concentrations would be a DF_s of 0.0. Fries and Paustenbach (1990) assumed between 0 and 2% of the dry matter intake by lactating cattle was soil in various sensitivity tests. Since cattle raised for beef are commonly pastured, a conservative assumption would be a high DF_s of 0.15 (15%), although a more reasonable assumption which would consider grazing in lush conditions and/or a portion of diet in feed or supplemental feed leads to DF_s less than 0.10. Fries and Paustenbach (1990) assumed DF_s of between 0 and 0.08 for beef cattle in various sensitivity tests. The example settings in Chapter 5 assume 0.02 (2%) for lactating cattle, and 0.04 (4%) for beef cattle.

- **Feed and grass diet fractions, DF_f and DF_g:** The sum of the three diet fractions, $DF_s + DF_f + DF_g$ must equal 1.0. Setting DF_s equal to 0.02 (2%) for lactating cattle assumed that they are pastured to some extent or could be taking in residues of soil sticking to home grown feed. Assuming lactating cattle graze a small amount of time, the DF_g for lactating cattle will be 0.08 (8%). This assessment simplifies the definitions of dairy and beef cattle diets by defining non-pasture grass vegetation simply as "feed". Feeds include hay, silage, grain, or other supplements. While dairy cattle are lactating, 90% of their dietary intake is assumed to be in this general category. Beef cattle spend a significant amount of time pasturing. However, their diet is supplemented with hays, silages, and grains, and particularly so in colder climates where they need to be housed during the winter. In this assessment, the simple assumption that

they ingest equal proportions of pasture grass and feeds is made. Therefore, with 4% soil ingestion, DF_f and DF_g are both 48% for beef cattle.

- **Average contaminant soil concentration, AC_s:** The simplest assumption for AC_s would be that it equals the initial level of contamination, C_s. However, this would be too high if the cattle also graze in uncontaminated areas. Where cattle have random access to all portions of a grazing area with contaminated and uncontaminated portions, a ratio of the spatial average of the contaminated area to the total area should be multiplied by C_s to estimate AC_s. If cattle spend more time in certain areas, these areas should be weighted proportionally higher. Different assumptions for determining AC_s might also be in order when using Equation (4-45) to estimate milk fat as compared to beef fat concentrations. Lactating cattle, if pastured, might graze on different areas than beef cattle. After determining a spatial average based on current conditions, a second consideration might be given to temporal changes. If soil levels are expected to change over time (due to changes in source strength or other factors) then the concentrations should be averaged over the exposure duration as well. The example scenarios in Chapter 5 where beef and milk exposures were estimated were termed "farms". The methodologies in this chapter were used to estimate the average soil concentration over the entire farm property. Assuming the cattle are raised on the farm property, than 100% of their intake of soil comes from the farm. This means that the average soil concentration, AC_s in Equation (4-45), is equal to the level of contamination given as the initial level, or determined as average for the farm based on fate and transport algorithms.

- **Average feed and pasture grass concentration, AC_f and AC_g:** The concentration of contaminant in pasture grass or feed is equal to C_{abv} as calculated in Equation (4-36). As described earlier, pasture grass or feed grown on-site can be impacted by air-to-plant vapor phase transfer and particulate deposition. Refinements noted above include the empirical parameter VG_{ag} equals 1.00 when applying the air-to-leaf transfer algorithm to pasture grass and 0.50 when applied to cattle feed. A refinement noted here, and like AC_s above, is that an assumption needs to be made about the fraction of feed or fraction of pasture grass that is impacted by contamination. Part of the feed diet could come from outside sources and not be contaminated, and part of the grazing area could be far from a localized area of soil contamination, making it less impacted by contaminated particulates or vapors. The simplest assumption is that the entire vegetative diet of the cattle includes pasture grass and feed impacted by the contaminated soil, in which case AC_f and AC_g would equal C_{abv}. For the sake of

simplicity and consistency, the assumption made for AC_s was also made for AC_f and AC_g in the example Scenarios in Chapter 5. That is, the grass and feed intakes of beef and dairy cattle originate within the farm property and concentrations in grass and feed are a function of the soil concentrations within the farm property; AC_f and AC_g are equal to C_{abv} as calculated in Equation (4-36). For site-specific situations, AC_f and AC_g should be estimated as C_{abv} reduced according to assumptions on quality of cattle feed, and impacts of air-borne contaminants on grazing land and cattle feed grown at the site where cattle are raised.

There is one final but critical note on solving for beef and milk concentrations given a solution for C_{fat} as in Equation (4-45). Human daily ingestion amounts are typically expressed in whole product rather than the fat portion of product. Whole milk is 4% fat, meaning that the C_{fat} needs to be multiplied by 0.04 to get whole milk concentration. Similarly, beef is generally 18-22% fat, meaning that the C_{fat} needs to be multiplied by 0.18-0.22 to get whole beef concentration. However, the ingestion rates in this assessment for beef and milk were developed on a fat basis, so no adjustment is necessary.

4.3.4.4. *Chicken and Egg Concentrations*

The algorithm to estimate the concentration of contaminant in chicken and/or eggs is the same algorithm as in beef/milk above. The experiments used to develop the chicken and egg bioconcentration factors were conducted by the Hazardous Materials Laboratory at the California EPA (Stephens, et al. 1995), and they will be described below. To review, the equation used to calculate the concentration of dioxin-like compounds in chicken and egg fat is:

$$C_{fat} = (BCF\ DF_s\ B_s\ AC_s) + (BCF\ DF_g\ AC_g) + (BCF\ DF_f\ AC \quad (4\text{-}46)$$

where:

C_{fat} = concentration in chicken fat or egg fat, pg/g

BCF = bioconcentration ratio of contaminant developed for chicken vegetative intake, unitless

DF_s = fraction of chicken diet that is soil, unitless

B_s = bioavailability of contaminant on the soil vehicle relative to the vegetative vehicle, unitless

AC_s = average contaminant soil concentration, pg/g
DF_g = fraction of chicken diet that is incidental vegetation while free ranging, unitless
AC_g = average concentration of contaminant on free range vegetation, pg/g
DF_f = fraction of chicken diet that is feed, unitless
AC_f = average concentration of contaminant in feed, pg/g.

The scenario of principal concern for chicken and egg contamination is the free range chicken scenario. This is the scenario where chickens are allowed to graze during all, or a portion, of their lives. The feed they consume could be spread out on the ground or in troughs. When they are free ranging but not eating their formulated feed from troughs, they still may forage for vegetation or earthworms which would give them considerable exposure to soil and vegetation, not to mention the earthworms which could be a source of dioxin-like compounds (earthworm exposure is not considered in this model). The percentage of all chickens raised for meat or eggs in this manner is a very small percentage of the total; most chickens are raised in commercial settings where their cages are raised and they have little exposure to soil or vegetation. When raised this way, their exposure to dioxins is only through the feed, and measurements of dioxin in chicken feed have shown little or no dioxin residues (Chang, et al, 1989; Stephens, et al, 1995). Chang, et al. (1989) sampled eggs from three sources: from foraging chickens that were raised near a contaminated PCP site in Oroville, CA (see the discussion of BCF below for a discussion of this site), from foraging chickens that were raised 4.5 km away in the neighboring town of Palermo, and from a grocery store, which were considered the control eggs. They found that the eggs from the foraging chickens near the site contained the highest concentrations of dioxin and furan congener groups (individual congeners were not reported in Chang, et al., 1989), with eggs from Palermo containing concentrations of dioxins and furans about 3 to 5 times less, and the commercial eggs being one to two orders of magnitude less than the eggs from near the PCP site.

The demonstration of this pathway in Chapter 5 is a free range scenario. The following is offered as brief guidance to the parameters in Equation (4-46) above and also the justification for the values selected in the example Scenarios in Chapter 5.

- **Chicken/egg bioconcentration factor, BCF:** In 1987, an explosion and resulting fire occurred at the Koppers Wood Preservative Treatment plant in Oroville, CA. Subsequent environmental studies found soil concentrations of the tetra through octa congener groups up to the ppm level adjacent to the fire site, and impacts to foraging chickens were also found, as was

discussed above (Chang, et al, 1989). The concern over this site led Stephens, Petreas, Hayward, and colleagues at the Hazardous Materials Laboratory (HML) of the California Environmental Protection Agency (Cal-EPA) to begin an investigation to test the hypothesis that grazing chickens would bioaccumulate dioxins. The first phase of their study, the laboratory phase, involved dosing chickens with feed mixed with soils of varying known levels of dioxins and furans. The completed results of this study have been published (Stephens, et al. 1995), with earlier publications available on the design and some interim results (Stephens, et al., 1992; Petreas, et al., 1991). Briefly, the study design was as follows. White Leghorn (Babcock D 300) chickens were randomly assigned to three groups with 22 individual chickens per group. The control group was fed a formulated laying-bird diet containing 10% uncontaminated soil - i.e., soil from a rural background setting with low levels of dioxins and furans. The TEQ concentration on this uncontaminated soil was less than 0.5 ppt. The "low" group was fed the same formulated diet to which they mixed soil to obtain a 9 (feed):1 (soil) ratio. The decision to have soil be 10% of the diet was based on discussions they had with agricultural experts on the amount of soil a free range chicken would take in. The soil had a CDD/F concentration of 42 ppt I-TEQ. It was taken from the backyard of a residence near the Koppers site, and had a similar sandy loam texture as the uncontaminated soil. The "high" group was fed the same formulated diet containing 10% of the same backyard soil but this time with several of congeners spiked in the soil to much higher levels. The concentration on this spiked soil rose to 459 ppt I-TEQ. Analysis by Stephens, et al. (1995) suggested that this spiking did not affect the bioavailability of the spiked congeners in the soil. Analysis of the feed before the introduction of any soils showed non-detects (with detection limits near or below 1 ppt, mostly at 0.1 ppt) for all congeners. Once the soils and feed were mixed, the I-TEQ concentrations in the feed/soil mixture for the "control", "low", and "high" groups were 0.6, 3.2, and 35.8 ppt, respectively (counting non-detects at half-detection). Eggs were collected every 5 days during the first month and every 10 days thereafter. Chickens were culled on days 10, 20, 41, 80, 164, 188, 210 and 278. Samples were taken of blood, feces, liver, adipose, and thigh muscle. Stephens, et al. (1995) reported on the analysis of liver, adipose, thigh muscle and egg for the suite of 17 dioxin-like compounds at various time intervals.

They also developed bioconcentration factors for these four tissues and for both feeding regimes, "low" and "high". To calculate the BCF, they averaged the tissue concentrations for days 80 and 164 when the animals had apparently reached a steady state, and for eggs at days 80, 160, and 178. The same will be done for the calculation of BCFs in this assessment. However, the BCFs for this assessment will be different than those published by Stephens, et al. (1995).

Their BCFs were defined as the concentration in the whole tissue on a wet weight basis divided by the concentration in the feed/soil mixture. Furthermore, although the concentration in the soil/feed mixture was determined and reported, Stephens, et al. (1995) surmised that the concentrations in the soil alone were more reliable than the concentrations measured in the feed/soil mixture. Therefore, the concentrations to which the chickens were exposed was calculated as the soil concentration divided by 10. The difference for this assessment is that the BCFs will be defined as the concentration in the tissue on a lipid basis divided by the concentration in soil, rather than the feed/soil mixture. The calculation for BCFs will also involve the use of the soil bioavailability term, B_s, as shown above in Equation (4-46). The procedure to calculate BCFs from the data is now explained.

Assuming that the chickens were not exposed to vegetation and that the feed concentrations were equal to 0.0 in the Cal-EPA experiments, Equation (4-46) reduces to the following:

$$C_{fat} = BCF\ DF_s\ B_s\ AC_s \qquad (4\text{-}47)$$

The congener-specific BCFs were then easily calculated assuming that the DF_s is equal to 0.10 and, the B_s is equal to 0.65, as it was above for the beef/milk bioconcentration algorithm, and directly using the soil concentrations as reported in Stephens, et al. (1995). Table 4-7 shows the final BCFs calculated in this manner from the Cal-EPA data. Stephens, et al. (1995) made the following three pertinent observations regarding this data and the development of the BCFs: 1) the highest concentrations were found in the liver, implying that mechanisms other than lipid solubility operate in that organ, 2) the soil had a high organic matter content, which the authors suggested would result in a lower observed bioavailability of the dioxins in the chickens than could have been observed had the soil organic matter content been lower and perhaps more typical of agricultural soils, and 3) the BCFs were higher in the "high" exposure group as compared to the "low" exposure group.

With regard to the first observation, the higher BCFs for the liver as compared to the other three tissues is apparent from Table 4-7 for both the low and high group. This is not relevant for exposure unless, of course, one were predicting concentrations in chicken livers for human consumption. In that case, one could use the liver-specific BCFs in Table 4-7. With regard to the second observation, this is important in that it provides some justification for the B_s of Equation (4-47) which was assigned a value of 0.65. The BCFs in Table 4-7 should, therefore,

be interpreted as BCFs specific to non-soil chicken intakes which are assumed to include chicken feeds and incidental vegetation in the model used in this assessment. This makes the chicken/egg BCFs analogous to the beef/milk BCFs. With regard to the third observation, Stephens, et al. (1995) tested the observation statistically and found that the BCFs of 3 congeners - 12378-PCDD, 234678-HxCDF, and 1234678-HpCDF - were significantly different at the $p < 0.05$ level and that the BCFs of 2 congeners - 2378-TCDF and 1234789-HpCDF - were significantly different at the $p < 0.025$ level. Even without statistical significance, it does appear that the trend of higher BCFs for the high exposure regime holds up for the other congeners as well.

Other interesting trends to observe in this data qualitatively (without statistical rigor) are related to the bioconcentration differences between adipose, thigh, and egg within the low group alone and/or compared against the high group. One important observation is that, in the low group, the dioxins concentrate more in the adipose lipid as compared to the thigh lipid, but this difference is much smaller in the high group. This might suggest that the dioxins deposit first, or preferentially, in adipose tissue rather than muscle tissue at low doses. Another trend is that, at the low dose, the dioxins concentrate in the lipid of the thigh and the egg about equally, but in the high group, the dioxins concentrate more in the thigh lipid as compared to the egg lipid.

In real world settings, soil concentrations to which chickens are exposed are expected to be more like the “low” exposure as compared the “high” exposure. Because of this, the BCFs for the low exposure group will be used in this assessment. For site-specific assessments where the soils are highly contaminated, and the assessor has justification for assuming that chickens are grazing on the highly contaminated soil, it would be appropriate to use the BCFs for the “high” group. The BCFs developed for the thigh and egg will be used for the calculation of concentrations in chicken meat and eggs, respectively. This is a different strategy than for the calculation of dioxin concentrations in beef or milk. There, a single set of BCFs were used to calculate concentrations in the fat of beef or milk. Here, the data appears robust enough to support separate BCFs. BCFs for two congeners in the low group could not be reliably calculated because one or both of the measurements (i.e., the soil/feed measurement and/or the tissue measurement) were below the quantification limit. These congeners are 2378-TCDD and 234678-HxCDF. For 2378-TCDD, it is noted that for the high exposure group, the 2378-TCDD BCF is about 1.3 times that of the 12378-PCDD BCF for both the thigh and egg. Based on this observation, the BCF for 2378-TCDD for thigh and egg will be 8.8 (i.e., 6.8*1.3) and 7.8 (6.0*1.3), respectively. The BCFs for the three HxCDFs for which a BCF could be estimated appear to be within a factor of 2-3 of each other. Based on this observation, the BCF for 234789-HxCDF for the thigh and egg will be estimated as an average for the three HxCDFs for these

tissues for which the BCF was derived. This calculation results in a 234789-HxCDF BCF of 4.1 for thigh and 6.2 for egg.

The only data that could be found for developing PCB BCFs was from a study by Fries, et al. (1977), and this data was only pertinent for Aroclor mixtures. Fries, et al. (1977) fed caged White Leghorn hens, 41 weeks of age, various PCB Aroclor mixtures at either 2 or 20 ppm in their standard breeder diet. Data was taken at nine weeks, after establishment of steady state, for body fat and egg concentrations of the 6 different Aroclor mixtures. In order to calculate concentrations, Fries et al. (1977) assumed that the eggs weighed 50 grams and that the body fat was 10% of the full weight of body tissue. BCFs for these Aroclors were calculated in this assessment as the ratio of the egg fat concentration to the feed concentration, for egg BCFs, and the body fat concentration to the feed concentration. Fries, et al. (1977) had provided full egg concentrations, and these were converted to egg fat concentrations by assuming that lipid is 10% of the full egg weight. The assumption of Fries, et al. (1977) that the fat content of his tested tissues was 10% will be retained here. The BCFs for the Aroclors are shown in Table 4-8.

A noteworthy trend for this data, as observed by Fries, et al. (1977), is that the PCBs appear to be retained at greater amounts as the degree of chlorination continues but then drops off at the higher chlorinated congeners. This is apparent in Table 4-8, as the BCFs increase through Aroclor 1248, but then drop off for Aroclor 1254 for the low dose and at 1268 for the high dose. The BCFs for the eggs continue to increase suggesting that excretion through eggs continues to be a mechanism for removal through the high chlorinated congeners. It is unclear that the BCFs from this study are pertinent to the modeling of this assessment, not only because they are on Aroclors and not on the dioxin-like PCB congeners, but also because soil concentrations are unlikely to reach the 2-20 ppm level for individual dioxin-like PCBs. Still, it is the only data that could be found. Without rigorous justification, it will be assumed that the BCFs for the low dose of Aroclor 1254, 6.5 for egg fat and 7.4 for body far, are appropriate for the dioxin-like PCB demonstrated in Chapter 5, 2,3,3',4,4',5,5'-PCB.

It should be noted that all bioconcentration or biotransfer parameters, such as the BCF, are qualified as second order defaults for purposes of general use. Section 6.2. of Chapter 6 discusses the use of parameter values selected for the demonstration scenarios, including a categorization of parameters. Second order defaults are defined there as parameters which are theoretical and not site specific, but whose values are uncertain in the published literature. The parameter values in this category should be considered carefully by users of the methodology.

- **Soil bioavailability B_s; Feed, grass, and soil diet fractions, DF_f, DF_g, and DF_s; and average feed, grass, and soil concentrations, AC_f, AC_g, AC_s:** The soil bioavailability is assumed to be 0.65, as it was for the beef/milk algorithm. It is important for users to understand that the BCFs were developed with this assumption. If other users believe it is more appropriate to assume that the BCFs as directly derived from the Stephens, et al. (1995) experiments are equally appropriate for soils, incidental vegetation, and feeds, than the BCFs need to be adjusted downward by multiplying them by 0.65. If doing this, users should then not apply a B_s in the calculation of chicken and egg concentrations for a free range or other scenario which has the chickens exposed to soil. Following on the lead of the Cal-EPA experiments, it will be assumed that soil is 10% of a free range chicken diet, and DF_s will be equal to 0.10. Since the chickens are free ranging, it also seems reasonable that they should exposed to some incidental vegetation. No guidance could be found on the assignment of DF_g, but it does seem reasonable that the chicken would ingest less incidental vegetation than soil, particularly if their exposure to soil occurs when the chickens are feeding and their feed is spread out on a certain patch of ground worn bare to soil. On that basis, DF_g will be assigned a value of 0.05, and DF_f will be 0.85. The soil concentration, AC_s, could be modeled as in the case of erosion from a site of contamination to a site of exposure, or as in the case of stack emission deposition. For the latter case, the soil concentration assumed will be the untilled soil concentration. The soil concentration could also be specified, as in the case of soil contamination which is on-site. The incidental vegetation will be assumed to be leafy, as in grass, and the concentration in the grass will be modeled as grass would be modeled in the context of the source category. Based on the measurements of Chang, et al. (1989) and Stephens, et al, (1995), it will be assumed that the concentration on chicken feed will be zero.

4.3.5. Specific Cases of Soil Contamination

This section provides background information on specific sites of soil contamination which have been studied for the presence and impact of dioxin-like compounds. These include landfills used for disposal of ash from municipal waste combustion facilities, the disposal of sludge from pulp and paper mills, and sites of soil contamination typified by the sites monitored in the National Dioxin Study (in many cases, Superfund sites or sites that were in some stage of being considered for inclusion on the NPL list at the time of the study; EPA, 1987). Discussion of these particular sites does not imply that they represent the bulk of such sites nationally, or that they are discussed here based on any critical environmental or exposure rational. They are discussed because they present unique issues for emissions and fate and transport of dioxin-like

compounds from sites of soil contamination, and because they have been studied. Issues discussed below are pertinent for other types of off-site soil contamination sites.

4.3.5.1. *Landfills Receiving Ash from Municipal Waste Incinerators*

Particular issues regarding landfills receiving ash include: the impact of soil cover on releases, the ash concentrations, the size of such landfills, the quantity of ash generated by incinerators, and the fugitive emissions that result from ash management. Key sources providing information for this section include a methodology document describing approaches to estimating environmental releases and exposures to ash (EPA, 1991), and a contractor report applying these types of methodologies using site-specific data from several ash landfills (MRI, 1990). Each of the identified topics will be discussed in turn.

- **Landfill Cover:** Whether or not ash is covered once it is disposed of at the landfill is critical in determining releases and subsequent exposures. Currently, practices at operating landfills vary from no coverage after disposal on active portions of the landfill to daily coverage of disposed ash. MRI (1990) visited six facilities disposing ash, including ash monofills and municipal solid waste landfills. In one of the facilities, an ash monofill located at the site of the combustor, the disposal area encompassed 15 acres and did not use daily cover until final elevation was reached. At that time, a clean cover of 2 feet of soil would be applied. At a second facility, located at the site of the combustor but landfilling municipal solid waste as well as ash, ash was used for different purposes, including a subbase roadbed material, as soil substitute for earth work, and as a daily cover for MSW receipts. An assumption of bare surfaces (i.e., no vegetation) during the period of landfilling activity, with concentrations of dioxin-like compounds equal to concentrations in the ash would appear to be appropriate assumptions for practices at these two landfills.

Where daily cover is employed, however, appropriate assumptions are not straightforward. Of the remaining four sites studied by MRI, two employed daily covers ("clean cover material" in one case and a "HDPE liner" in the other, sic), and daily coverage practices were not discussed for two sites. Approaches described for airborne emissions and erosion losses would have to be modified when daily cover is applied. First, losses of contaminants via overland soil or wind erosion could not be expected to occur when cover (soil cover or otherwise) is in place, although the active part of the landfill would be subject to erosion during an operating day. Even in that case, however, site-specific practices might include little or no ash disposal during periods of soil-erosion-producing storms. Depending on site-specific practices,

one might estimate annual erosion losses using methodologies described in this assessment, and then empirically reduce erosions losses based on these practices and scientific judgement.

Air emissions from active portions of the landfill, as in wind erosion and volatilization, also are obviously impacted by cover practices. These emissions would occur during the actual disposal. Wind erosion and volatilization fluxes could be estimated as given in earlier sections, and then reduced by two-thirds, which might correspond to an assumption of disposal during 1/3 of a day or a year, etc. When covered by soil or a synthetic cover, wind erosion losses would not occur. However, buried residues may diffuse through layers of clean soil and be released via volatilization.

Estimates of volatilization release via diffusion through clean cover have been made. A rigorous approach for such estimates is detailed in Hwang, et al. (1986). Use of this approach requires a computer to iteratively solve a partial differential equation, expressed in terms of a Fourier series. It can be shown, with these equations, that the vapor emission rate through such a cover will not reach steady state for hundreds of years. Hwang's approach was applied to an earlier assessment for 2,3,7,8-TCDD (EPA, 1988b). Calculations were performed for 2,3,7,8-TCDD contamination with a thickness of contamination of 8 ft, and clean caps ranging from 10 to 25 cm. The results of this exercise suggest that the average emission rate of a 70-year period are 1/4 to 1/5 of what they would be without the cap. Based on this exercise, a simple assumption might be made that a clean cap will reduce the average emission rate calculated without a clean cap by 80%. However, these results are not consistent with those described in Jury, et al. (1990). The analytical solution developed by Jury was demonstrated on 35 organic compounds. One exercise conducted by Jury was to estimate the cover thickness required to restrict volatilization to less than 0.7% of the mass incorporated in soil. For 2,3,7,8-TCDD, the thickness was estimated at 0.7 cm for a sandy soil and 0.2 cm for a clayey soil. This appears to contradict the work of Hwang since it shows an essentially insignificant loss for a cap much less thick than the 10-25 cm cap in the exercises using Hwang's approach. However, Jury's approach allows for assumptions on degradation of the buried compound. For that exercise, Jury assumed that the half-life for 2,3,7,8-TCDD was 1 year. This is a very rapid degradation rate, given information that the dioxin-like compounds resist degradation, particularly when not exposed to sunlight. On the other hand, the Hwang model assumes no degradation loss, and as such, the generalization from his exercise might be an overestimate. Hwang's exercise might also have overestimated since it assumed a rather thick 8-ft layer of subsoil contamination. From these arguments, it would appear that neither exercise appropriately evaluated the difference in volatilization in a no cover versus a cover situation.

The above discussions concerned flux calculations when cover practices are used. One set of adjustments discussed reduced a total potential flux of volatilized or wind eroded losses based on a portion of the time that the ash would be uncovered. A second discussion indicated that some loss via volatilization might be modeled with a clean cap. In any case, it is clear that cover practices will reduce losses. Cover practices must be considered when evaluating the exposure to ash disposed of in landfills.

- **Ash Concentrations:** A key consideration, of course, in modeling transport of dioxin-like compounds from an ash landfill is the concentration on the ash. Ash concentrations of dioxin-like compounds have been found to vary widely, from non-detect (generally less than 0.1 ppb) to the hundreds and thousands of part per billion. Table 4-9 appears in EPA (1991) and summarizes concentrations of dioxin-like compounds and PCBs found in fly, bottom, and combined ash. These data are a summary of 19 references, ranging in publication date from 1974 to 1990. It should be noted that, except for 2,3,7,8-TCDD and 2,3,7,8-TCDF, results listed are for congener groupings defined by degree chlorination.

- **Size of Landfill and Amount of Ash Landfilled:** The size of the landfill and the amount of ash applied daily or over time are both required for estimating exposures nearby. These can both be obtained from site-specific observations. Amounts of daily disposed ash are required to estimate fugitive particulate emissions, as will be discussed shortly. Amounts of daily or ultimate disposal are also tied to landfill size, or the portion of a landfill that is active on a daily basis. One common practice is to fill cells of a landfill one at a time, and once filled, to cover with a 2-ft (or so) layer of clean soil. The appropriate size in this case is the average size of a landfill cell. If daily coverage is applied, than the size for modeling purposes corresponds to the area over which daily coverage occurs. This can also vary depending on the depth of disposal during a day. A six-inch daily coverage, for example, would take twice as much space as a 1-ft depth of daily disposal. If the intent of a day's disposal is to cover over the entire area of an active cell, then depth of coverage need not be considered in determining landfill size.

Determination of landfill size (or the size of the active portion of the landfill) may be required in the absence of site-specific information, such as in the planning stages for a new incinerator. This is where details on landfill management need to be determined. One important detail, as already noted, is the amount of ash generated for daily disposal. Cook (1991) assumes that bottom and fly ash combined comprise about 11% of total receipts on a volume basis. However, a relationship between ash generated and solid waste received by an incinerator on a

mass basis is more useful for estimating daily disposal amounts. In an EPA (1990f) report on ash characterization, ash mass was estimated as an average of 29.5% of municipal solid waste received in five facilities studies, with a narrow range of 25-35%. This mass was estimated on a wet weight basis. Ash is wetted when exiting the incinerator, and water comprises 20-30% of the total weight at that point. If the ash is immediately trucked for landfill disposal, its total weight includes the weight of this quench water. Often ash is stored at the incinerator site in piles prior to disposal, that storage ranging from hours to days. In this circumstance, much of the quench water would have drained off or evaporated, and then the total weight hauled would be closer to a dry weight estimate. In summary, the amount of ash generated to be disposed of a daily basis can be estimated as: the daily receipt of municipal solid waste (tons) * a wet weight ash fraction (0.25-0.35) * a wet to dry weight conversion if appropriate (wet weight * 0.80, e.g.).

- **Fugitive Particulate Emissions:** Fugitive emissions can occur from the time ash exits the incinerator for temporary storage at the facility site (or immediate loading onto trucks for disposal) until ultimate disposal. Approaches to estimate fugitive releases from incinerator ash management are described in EPA (1991), and will be summarized here.

As noted, ash can be wet when exiting the quench tank. If stored at the facility site prior to disposal in a landfill, leaching from piles can occur. Because dioxin-like compounds are strongly hydrophobic, however, the impact of leaching is unlikely to occur much beyond the soil beneath and near the storage piles. If loaded onto trucks when very wet, leaking onto roadways may also occur. If these storage piles are left uncovered, they would of course be subject to erosion losses, which might move residues further from the piles than just leaching of water from the piles.

Of more concern than water-borne losses due to ash management are fugitive emissions of dry ash. Wind erosion, which can occur from open storage piles or uncovered portions of the landfill, is a fugitive emission that has been discussed for soil contamination. Specific practices in the management of ash can also result in fugitive emissions. Such practices include: 1) loading onto and dumping out of trucks, 2) truck transport from the incinerator facility to the landfill site, 3) truck or other traffic over paved or unpaved roadways at the incinerator site, at the landfill site, or other roadways containing contaminated dust, and 4) spreading and compacting of ash at the landfill site. A set of empirical emission factor equations for estimating fugitive particulate emissions, called "AP-42" equations, have been developed by EPA's Office of Air Quality Planning and Standards (EPA, 1985a; EPA, 1988a). Specifics on applying these equations for ash management are described in EPA (1991). An example of their application

using site-specific information for ash management is detailed in MRI (1990). An abbreviated listing of emission factor equations that have been used in these two publications are:

- Vehicular traffic over unpaved roadways. Dust on the surfaces of roads, both unpaved and paved, can become suspended due to vehicular traffic. When these roadways are near ash storage piles or within the landfill, that dust can become contaminated. The emission factor equation for emissions from unpaved roadways is:

$$E_{up} = 1.7\ k_{unp} \left(\frac{scu}{12}\right) \left(\frac{Vs}{48}\right) \left(\frac{W}{2.7}\right)^{0.7} \left(\frac{nw}{4}\right)^{0.5} \left(\frac{365 - NP}{365}\right) \quad (4\text{-}48)$$

where:

E_{up}	=	emission flux for unpaved surfaces, kg/VKt (VKt equals vehicle kilometer traveled)
k_{unp}	=	particle size multiplier specific to the unpaved road emission flux equation, unitless
scu	=	silt content of unpaved roadway, %
Vs	=	vehicle speed, km/hr
W	=	vehicle weight, kg
nw	=	number of wheels per vehicle, unitless
NP	=	number of days with >0.25 mm precipitation per year, unitless

- Emissions off trucks in transit. Although no emission factor equations have specifically been developed for trucks while in transit from the incinerator facility to the landfill, such emissions can occur if the ash is dry, and partially or completely uncovered. The following equation for estimating emissions from open storage piles has been suggested for use in estimating fugitive emissions from trucks in transit (EPA, 1991; the emission factor equation from EPA, 1985a). Note that use of this equation will require specific management assumptions in order to estimate the number of uncovered hectares per day: the number of trucks in use per day, the surface area of trucks, the percent of uncovered area if a tarpaulin is used, the moisture content of ash, and so on.

$$E_t = 1.9 \left(\frac{sca}{1.5}\right) \left(\frac{f}{15}\right) \left(\frac{365 - NP}{365}\right) \quad (4\text{-}49)$$

where:

E_t = particulates emitted from trucks in transit, kg/day/hectare
sca = silt content material of ash, %
NP = number of days with >0.25 mm precipitation per year
f = percentage of time that the unobstructed wind speed exceeds 5.4 m/s.

- Loading and unloading. The unloading operations at the disposal site may result in the release of fugitive dust. The following emission factor equation provides emission factors for kilograms of particulate emitted per megagram (metric ton, or 1000 kg) of soil loaded and unloaded:

$$E_{lu} = 0.0016\ k_{unl} \left(\frac{U_m}{2.2}\right)^{1.3} \left(\frac{MC}{2}\right)^{-1.4} \quad (4\text{-}50)$$

where:

E_{lu} = emission factor for loading and unloading, kg dust/MT ash
k_{unl} = particle size multiplier, unitless
U_m = wind speed, m/s
MC = material moisture content, %.

- Spreading and compacting of ash at the landfill. An emission factor specifically for ash spreading and compacting has not been developed. However, emission factor equations for similar applications have been applied for estimating fugitive emissions due to spreading and compacting. MRI (1990) used an AP-42 emission factor developed for dozer moving of overburden in western surface coal mines. Kellermeyer and Ziemer (1989) assumed that the spreading and compaction of ash was analogous to vehicular transport on unpaved surfaces, and used the emission factor for that process. A third possible assumption is that the processes of spreading and compacting are analogous to agricultural tillage. That emission factor equation for agricultural tillage is:

$$E_{at} = 5.38 \; k_{at} \; scs^{0.6} \qquad (4\text{-}51)$$

where:

E_{at} = emission factor for agricultural tillage, kg/ha
k_{at} = particle size multiplier, unitless
scs = silt content of soil, %.

When applying such equations, there are further key issues to consider. These include:

- Concentrations on fugitive ash emissions: When such an emission occurs from ash surfaces, such as from storage piles, off trucks in transit, in spreading and compacting, and so on, than there is a good argument to assume that such concentrations on such emissions are "enriched" in comparison to an ash average. The argument here is similar to the argument for enrichment assumed for eroded soils: processes resulting in fugitive air emissions favor lighter particles with more surface area and hence more sites for binding. No data could be found to assign a value to an ash enrichment ratio. MRI (1990) did, however, take data on municipal waste combustor facility roadway dust, and based on that data and statistical evaluations, speculated that fly ash constituted the principal source of lead and cadmium found on paved surfaces. Since fly ash is finer than bottom or combined ash, one hypothesis for this finding is that fugitive emissions from ash management at the combustor site transported these finer particles to roadway surfaces. This is not to imply, however, that concentrations in dust suspended from roadways due to traffic should be higher in concentration than concentrations in ash - this enrichment concept only applies to ash surfaces themselves. Rather, the concentration on roadway suspended dust should be lower than on the ash. This is because contaminated dust on roadways mixes with clean dust from other sources. As noted, MRI (1990) did take roadway dust samples, and their data appears to place such a dilution factor (concentration on roadway dust divided by concentration on ash) in the range of 0.1 to 0.3. Specifically, they took particulate samples from landfill haul routes while at the same time taking samples of incinerator ash being delivered for disposal the same day. Each paired sample (roadway particulate and ash), were measured for four metals: As, Cd, Cr, and Pb. Several paired samples were taken on both paved and unpaved haul routes. Ratios were then generated for roadway particulate metal concentrations over ash metal concentrations. Results were: As - paved and unpaved ratios were similar and consistently near 0.1 (roadside particulate concentrations of As were 10% of ash

concentrations of As), Cd - paved and unpaved ratios were similar and ranged between 0.0 and 0.4, Cr - paved ratios ranged from 0.3 to 0.6, while unpaved had a wide range of 0.3 to 2.0, Pb - paved and unpaved ratios were similar between 0.0 and 0.2. For analogous situations - daily deliveries of contaminated ash - one might assume a dilution factor in the 0.1-0.2 range.

- Selection of values for emission factor equations: As noted, all these equations are empirical equations. They were developed from data on sites where such emissions occur, such as strip mining sites. EPA (1988a) describes the range of conditions over which such equations were developed. What is meant by "conditions" are such factors as the range of vehicle weights in the data set, the range in number of wheels on such vehicles, and so on. Application of these equations for situations not included within these ranges should be done cautiously. Very critical also is the selection of the particle size multiplier variable, k. These values range from about 0.10 to no higher than 1.0. Lower k values are used to estimate emissions of the smallest sized particles; generally particles less than 5 μm in diameter. Higher k values are used to estimate emissions of all sized particles less than a higher diameter, usually either 15 or 30 μm. If these equations are used to only estimate particulate inhalation exposures, than the k value corresponding to 10 μm sized particles, or inhalable sized particles, should be used. When used to estimate total emissions, than the highest k value listed should be used. Such estimations are appropriate when also evaluating impacts to off-site soils or vegetation.
- Controls for fugitive emissions: All these equations were developed when no fugitive emission controls were in place. Common controls for roadway dust suppression include wetting or use of a chemical dust suppressant. Ash transported in trucks is commonly wetted and/or a tarpaulin is used to control emissions off trucks. There is no guidance or data on the effectiveness of such controls, but they must be considered. In demonstrating these procedures, EPA (1991) assumed that controls on emissions resulted in 90% reductions in potential emissions. If a control is known to be in place and used on a regular basis, than this percent reduction is probably a reasonable starting assumption.

4.3.5.2. *Land Application of Sludge from Pulp and Paper Mills*

This discussion focuses on an assessment on the land application of sludge from bleached kraft and sulfite pulp and paper mills (EPA, 1990e). Focusing on this source of sludge does not imply that pulp and paper mills produce more sludge than other industries, or that sludge from pulp and paper mills contains more dioxin-like compounds than other sludges. However, it is known that dioxin-like compounds are found in pulp and paper mill sludges. Also, because of the 104-mill study in 1988, much information is available on the content and disposal of this

sludge (further information on the 104-mill study can be found in EPA (1990c,d)). Some of the issues briefly discussed below for pulp and paper mill sludges would also pertain to sludges containing dioxin-like compounds from other sources.

EPA (1990e) described frequency distributions of concentrations of 2,3,7,8-TCDD and 2,3,7,8-TCDF for 79 mills reporting this information and also broke out the data based on disposal option. Although EPA (1990e) used the disposal option breakout of concentrations in their assessment of the impacts of the various options, it is not felt that the disposal option of choice is based on concentration. Over all options, the median (50% percentile as given in EPA (1990e)) and maximum 2,3,7,8-TCDD concentrations found in sludges were 51 and 3800 ng/kg (ppt), respectively. The median and maximum 2,3,7,8-TCDF concentrations found were 158 and 17100 ppt.

Fate and transport for contaminants is sludge is dependent on disposal means. Of the approximate 2.5 million metric tons of pulp and paper mill sludge generated annually (as estimated in the 1988 104-mill study), five principal options for disposal were noted: landfilling (44% of all sludge disposed), surface impoundments (24%), land application (12%), incineration (12%), and distribution and marketing (8%). Impacts by incineration were not discussed in EPA (1990e) and are not discussed in this section. Key issues pertaining to each disposal issue are now discussed.

- **Landfilling:** The issue of coverage as discussed above for ash landfills is relevant for any landfill. However, fugitive particulate emissions during sludge handling and disposal is not an issue as it was for disposal of ash from incinerators due to the differences in moisture content. Sludge is much higher in moisture at the time it is disposed of in comparison to ash - with moisture contents as high as 90%.

- **Surface Impoundments:** It was assumed in EPA (1990e) that sludge disposed of in surface impoundments have a higher moisture content as compared to sludge disposed of in landfills. Surface impoundments were located at the mill site, explaining the assumption for a higher moisture content. A surface impoundment in the EPA (1990e) assessment was defined as a facility in which the sludges are stored or disposed on land without a cover layer of soil. For this type of management, soil cover would not be an issue. Concentrations would be those measured in the sludge. Also, vegetative cover would be expected to be minimal, which would influence parameters associated with soil erosion.

- **Land Application:** Twelve percent of all sludge produced annually was land applied. Four of the 104 mills applied the sludge to forest land, two mills land applied the sludge to agricultural land, and two mills used the sludge for abandoned mine reclamation. The high organic matter content (EPA (1990e) assumed a 25% organic carbon fraction in sludge) and high fraction of clay-sized particles make sludge an attractive soil amender. Sludge is either applied to the land surface with or without incorporation. When not incorporated, sludge can be assumed to replace surface soils and concentrations would be those in the sludge. When incorporated, soil concentrations can be estimated simply as (in mg/kg): (mass of contaminant added, mg)/(mass of sludge added, kg + mass of soil in mixing zone, kg). One key issue when incorporated is the number of years of such treatments. Most of the land application uses of paper and pulp mill sludges reported in EPA (1990e) made applications in only one year. As easily seen in the above suggested equation, higher concentrations result with more years of incorporation. The other key issue with incorporation, of course, is the depth of incorporation. For agricultural applications, the depth of incorporation assumed in EPA (1990e) was 15 cm, similar to the 20 cm incorporation assumed for home vegetable gardening in this assessment. For silvicultural uses, the assumption in EPA (1990e) was 2.5 cm, which corresponds to some but minimal mixing. For abandoned mine reclamation, the assumption was 0 cm incorporation. Routes of exposure might also vary from focuses in this document depending on land application choice. When applied to agricultural land, impacts to food crops would demand particular attention (the procedures in this assessment were demonstrated with home grown vegetables, although of course impacts to food crops are critical when agricultural field soils are impacted by dioxin-like compounds). When applied to forest land, ecological impacts might warrant particular attention, as was discussed and demonstrated in EPA (1990e). A final issue to consider when land applying sludge to land is a rate of dissipation/degradation of dioxin-like compounds. Landfills and surface impoundments have ongoing surface applications and over time, the total depth of applications in the range of meters, so an assumption of a constant source strength over a period of exposure, as was assumed in this assessment for soil contamination sources, is reasonable. However, if only a few centimeters of surface soil are impacted, which might be the case for single applications to land and/or surface applications with no incorporation, an assumption of dissipation may be warranted. EPA (1990e) assumed no degradation of 2,3,7,8-TCDD in their assessment of impacts from land applications.

- **Distribution and Marketing Uses:** The volume of sludge distributed and marketed was approximately 8% of the total amount of sludge generated for the 104-mill study. For this

use, sludge was composted and then sold as a soil amendment in residential, agricultural, and commercial settings. More attention to the dermal contact pathway appears appropriate for this usage. Site-specific factors, and the values for these factors used in EPA (1990e), include: 1) depth of incorporation - 0, 15 and 25 cm in assumptions characterized as high, best, and low estimates, 2) garden size - 0.016 and 0.022 hectares characterized as low/best estimate and high, and referencing a national gardening survey, 3) rate of application - between 5 and 20 dry metric tons per hectare references a USDA publication on use of sewage sludge compost for soil improvement and plant growth, and 4) years of using such compost - 20 without specific reference. The years of application is needed for estimating soil concentrations during and after the period of exposure, using a simple ratio as discussed above in land application.

4.3.5.3. *Sites Studied in the National Dioxin Study*

The National Dioxin Study (EPA, 1987) focused on sites of known or suspected contamination of soil by 2,3,7,8-TCDD. There were 7 "Tiers" of investigation, with roughly decreasing expectations of finding 2,3,7,8-TCDD. Tiers 1 and 2 included 2,4,5-TCP production and associated disposal sites (Tier 1) and sites where 2,4,5-TCP was used as a precursor in the manufacture of pesticidal products and associated disposal sites (Tier 2). These tiers had the highest expectation for finding 2,3,7,8-TCDD. There were originally thought to be 450 sites that would fall in Tiers 1 and 2, but after investigation, only 100 sites were included for study. Some were downgraded into Tier 3. Of the 100 sites studied, 20 were on or were proposed for inclusion in the Superfund National Priorities List. Tiers 3 and 5 were associated with 2,4,5-TCP formulation (Tier 3) and use (Tier 5). Tier 6 were organic chemical or pesticide manufacturing facilities were 2,3,7,8-TCDD was suspected of being present. Tier 4 included combustion sources and are not discussed further in this section. Tier 7, basically an examination of background areas, are also not discussed here.

Issues that are identified as important in fate and transport modeling for this subcategory of off-site sources include concentrations, the possibility of ground water contamination, and site-specific characterization. These are discussed in turn.

- **Concentrations:** Only 11 of the 100 Tier 1 and Tier 2 sites were eventually classified as requiring "no further action" because 2,3,7,8-TCDD soil concentrations were very low, < 1 ppb, or not detected (with detection limits generally at 1.00 ppb). Where it was detected, a general trend was to find very high concentrations where 2,4,5-TCP production wastes were stored or disposed of, with much lower concentrations at soils near these particular

areas. At hot spots, concentrations were as high as 2,000 parts per million, but generally soil concentrations were in the parts per billion. It was this parts per billion generalization that led to the assignment of a 1 ppb soil concentration for the demonstration of the off-site source category in Chapter 5. There were findings in the low ppb range for Tiers 3, 5, and 6, but at much lower frequency and no findings higher than the tens of ppb range. For exposure assessments, the characterization of soil concentrations in a site containing hot spots has to be carefully considered. For site evaluations and proposed options for remediation, an areally weighted average might be considered, although this could dilute loss estimates depending on the area chosen - choosing a large area corresponding to property lines might, for example, lead to an "average" concentration orders of magnitude lower than concentrations found in hot spots. One approach which should be considered is a "hot spot" impact compared to an areally averaged impact. It should also be remembered that removal of highly contaminated soils is a common practice and another option for evaluation would be a concentration assuming hot spots are removed.

- **Potential for Ground Water Contamination:** PCBs have been found in ground water in sites associated with dielectric fluids of transformers. Oils can migrate through soils as a separate immiscible phase and reach ground water, which has been the common explanation for PCB impacts to ground water. Ground water contamination by 2,3,7,8-TCDD has very rarely been found in ground water, although it has been released to the environment in an oil matrix. The Times Beach area of Missouri is the principal example of this release, where waste oils containing 2,3,7,8-TCDD were used for dust control. Ground water sampling did occur in many of the Tier 1 and 2 National Dioxin Study sites, but the results were mostly non-detects. One occurrence at 0.18 ppt was noted for the Hyde Park site of Hooker Chemical in Niagara, NY, and a high of 1.8 ppb was found in an on-site monitoring well at National Industrial Environmental Services in Furley, KS. There were, however, numerous high occurrences in sub-soil samples in hot spot areas, in bottom sediments of evaporation lagoons, and so on, in the hundreds of ppb range.

There have been some limited experimentation showing different patterns of 2,3,7,8-TCDD migration in soils in the presence of solvents or in an oily matrix. Palusky, et al. (1986) studied the mobility of 2,3,7,8-TCDD in soils associated with each of 6 solvents. Migration was found to be higher with aromatic solvents and chloroform in comparison to saturated hydrocarbons and methanol. They speculated that the extent of migration related to the solubility of 2,3,7,8-TCDD in the solvent. Puri, et al. (1989) studied the migration potential of 2,3,7,8-

TCDD in soil, water, and waste oil mixtures. Over time, they observed a reversible sorption pattern of TCDD, and concluded that a carrier medium with a significant amount of waste oil would play a dominant role in the movement of TCDD through soils.

- **Site-specific Characterization:** In the case of landfills or sludge land application sites, the assignment of a soil concentration and an area can be made with some reasonableness. Such is not the case with the industrial contamination sites such as those studied in the National Dioxin Study, as briefly discussed above in the concentration bullet. Most of the sites studied in the National Dioxin Study were in the order of tens of hectares to below ten hectares. On the other hand, the Dow Chemical site in Midland, Michigan is described as a site 607 ha in size (Nestrick, et al, 1986). That area corresponds to the size of the property, and the many soil sampling sites within that area were described as "background". Several of the pesticide formulator sites studied in Tier 3 were 2 hectares or less in size. Many of the them were extensively or partially paved with buildings, which complicate fate and transport modeling. Some of the Tier 5 sites of 2,4,5-TCP use were agricultural fields, which are less complicated to describe. However, two sites were described as 2500 acres in size, which again is very large and makes assignment of an average soil concentration non-trivial. Other use sites were described as railyards and railroad rights of way. While estimates of loss into air could be made in complicated sites such as these, use of soil erosion modeling becomes very complicated if not undoable with paved areas, buildings, drainage ditches, roads, and the like.

4.4. ALGORITHMS FOR THE STACK EMISSION SOURCE CATEGORY

Contaminants emitted from incinerator stacks are transported in air and deposit on the exposure site, water bodies that may be used for drinking or fishing purposes, and on surrounding land. Chapter 3 describes the application of the ISCST3 model to obtain vapor-phase air concentrations and deposition rates of particles at a specified distance from an example stack emission source. These quantities are assumed to be given for purposes of discussion in this section; further discussion of the air transport modeling is given in Chapter 3.

Estimating soil concentrations based on particulate depositions follows a similar approach as estimating exposure site soil concentrations resulting from erosion of contaminated soil from off-site areas of contamination. Section 4.4.1. describes how soil concentrations are estimated given total (wet plus dry) deposition rates. Surface water impacts are assumed to result from direct deposition onto surface water bodies as well as erosion from the impacted effective drainage area. This solution is an extension of the solution given in Section 4.3.1. for the soil

contamination source category, and is given in Section 4.5.2. Following now are bullet summaries for similarities and small refinements to algorithms previously discussed:

- **Air impacts:** The atmospheric transport modeling described in Chapter 3 was comprised of two computer simulations: one which considered that emissions were in a vapor form and were transported as such, and one which considered that emissions were in particle form and likewise were transported as such. The result of the vapor-phase runs was a unitized ambient air concentration at various distances up to 50 km in all directions from the stack. Only the results in the predominant wind direction were used in this demonstration. The result of the particle-phase runs were an ambient reservoir of air-borne contaminants sorbed to particulates (used only for inhalation exposures), and wet and dry deposition unit rates also at various distances up to 50 km. By "unitized", what is meant is that emissions for the vapor or particle runs can be thought of as "1" mass/time (g/sec) emissions. Results for all distances are linear with respect to this emission rate; that is, if the rate of vapor contaminant determined to be emitted is "5", than ambient air concentrations at any location are 5 times what they are when "1" is assumed to be emitted. The same holds true for emissions in the particle phase. Chapter 3 developed a framework for assigning a vapor and a particle fraction for specific dioxin congeners. For example, 2,3,7,8-TCDD was assumed to have a vapor fraction of 0.51 (51% was in vapor form) and a particle fraction of 0.49. The final model results for air concentrations, and dry and wet deposition rates for all congeners, starting from these unit model runs and then incorporating congener-specific emission rates and vapor/particle splits, are given in Tables 3-12 to 3-17. The vapor-phase air concentrations were used to model vapor phase transfers in the vegetative bioconcentration algorithms. They were also used, summed with the simulated reservoir of particle-bound contaminants, to estimate the total reservoir of contaminant available for inhalation exposures.
- **Vegetative impacts:** The rates of wet and dry deposition modeled by ISCST3 were used to determine vegetative impacts. The model for particle deposition impacts to vegetation is described in Section 4.3.4.2 above. Of course, this above section solves for dry deposition as a reservoir times a dry deposition velocity (for dry deposition), and as a reservoir times rainfall and a washout factor (for wet deposition); such a solution is not required for the stack emission source category

since the deposition totals are estimated by the ISCST3 model. Other parameters for the vegetative model - the B_{vpa} (air-to-leaf vapor transfer factor), the R_w (fraction of wet deposition retained on vegetation surfaces), crop yields and interceptions, and the vegetative washout factor, k_w, are used for the stack emission source category.

- **Biota concentrations:** The algorithm estimating concentration in fish tissue based on bottom sediment concentrations is the same as in previous source categories. Modeled rates of contaminant deposition on particles onto the exposure site are used to estimate a "tilled" and an "untilled" soil concentration, as described below in Section 4.4.1. Underground vegetable concentrations are a function of tilled soil concentrations. The soil concentration used for cattle soil ingestion is untilled. Beef and milk concentrations are again a function of vegetative and soil concentrations, diet fractions, and bioconcentration and bioavailability factors as described in Section 4.3.4.3.

4.4.1. Steady-State Soil Concentrations

Chapter 3 describes the use of the ISCST3 Model to estimate the particulate phase deposition rates at the exposure site. This total deposition rate, F, includes both dry and wet deposition, and is used to estimate the soil concentrations. The deposition of contaminated particulates from the air is assumed to be somewhat analogous to the process of eroding contaminated soil from an off-site source depositing on an exposure site. Specifically, the following assumptions are also made: 1) only a thin layer of soil becomes contaminated, 2) this layer is either "untilled" or "tilled", depending on surface activities, and 3) surface residues are assumed to dissipate with a half-life of 25 years corresponding to a first order decay rate of 0.0277 yr^{-1}. Considerations of upgradient erosion and exposure site soil removal are not made. Depositions occur over the exposure site and surrounding land area on an on-going basis. It might be said that upgradient soil concentrations are similar to exposure site concentrations at all times. Like the soil source categories, a tilled mixing depth of 20 cm, and an untilled mixing depth of 2 cm is assumed for this source category. The qualitative mass balance statement (similar to the one made above in Section 4.3.2, with ΔC equaling change in exposure site soil concentrations over time) can now be made as:

(the incremental addition to C resulting from the change in deposition of stack emitted particulates) -

ΔC = (the incremental substraction of C resulting from degradation of residues at the exposure site)

This is mathematically stated as:

$$\frac{dC}{dt} = \frac{F}{M} - kC \quad (4\text{-}52)$$

where:

C = the exposure site soil concentration, mg/kg
F = deposition rate of contaminant on particles, mg/yr
M = mass of soil at exposure site into which contaminant mixes, kg
k = first order dissipation rate constant, 1/yr.

The solution to this equation is:

$$C = \frac{F}{kM} \left(1 - e^{-kt} \right) \quad (4\text{-}53)$$

which computes C as function of time, t. Similar to the assumption made above in Section 4.3.2, the steady state solution for C is simply F/kM. The deposition rates supplied by the ISCST3 model are in units of g/m^2-yr, so a conversion to mg/yr requires a multiplication by the land area of the exposure site and a multiplication of 1000 mg/g. Procedures to estimate M are given above in Section 4.3.2.

4.4.2 Surface Water Impacts

The solution for stack emission impacts to surface water bodies is an extension of the solution for the soil contamination source category described in Section 4.3.1. Stack emissions deposit onto soils within the effective drainage area to result in an average basin-wide soil concentration. Soil erosion then delivers contaminants to surface waters as in Section 4.3.1. Stack emissions also directly deposit onto and impact the surface water body as well. All the assumptions laid out at the beginning of Section 4.3.1 apply here as well. New quantities needed for this solution include: a rate of contaminant deposition onto soils of the effective drainage area used to estimate average soil concentrations (such concentrations are estimated using the

approach given in Section 4.4.1. above), a rate of contaminant deposition onto the water body, and a rate of particulate matter deposition onto the water body.

Equations (4-1) through (4-8) are now displayed again with these additions.

$$C_{swb}\ ER_w + DEP_c = C_{wat}\ V_{wat} + C_{ssed}\ M_{ssed} + C_{sed}\ M_{sed} \quad (4\text{-}54)$$

where:

C_{swb} = concentration on soil entering water body, mg/kg
ER_w = total watershed annual soil erosion, kg/yr
DEP_c = total annual direct deposition of contaminant, mg/yr
C_{wat} = dissolved-phase concentration in water column, mg/L
V_{wat} = water body annual volume, L/yr
C_{ssed} = concentration on suspended sediment, mg/kg
M_{ssed} = mass of suspended sediment introduced per year, kg/yr
C_{sed} = concentration on sediment settling to bottom, mg/kg
M_{sed} = mass of bottom sediment introduced per year, kg/yr

Mass balance and equilibrium equations continue:

$$ER_w + DEP_p = M_{ssed} + M_{sed} \quad (4\text{-}55)$$

$$M_{ssed} = f_s\ ER_w + f_{sd}\ DEP_p \quad (4\text{-}56)$$

$$M_{sed} = (1 - f_s)\ ER_w + (1 - f_{sd})\ DEP_p \quad (4\text{-}57)$$

$$C_{wat} = \frac{C_{ssed}}{KD_{ssed}} \quad (4\text{-}58)$$

$$C_{sed} = C_{ssed} \frac{OC_{sed}}{OC_{ssed}} \quad (4\text{-}59)$$

where:

DEP_p = total annual direct deposition of particulate matter, kg/yr
f_s = fraction of annual erosion remaining as suspended materials, unitless
f_{sd} = fraction of annual deposition remaining as suspended material, unitless
Kd_{ssed} = soil-water partition coefficient for contaminant in suspended sediment, L/kg
OC_{ssed} = fraction organic carbon in suspended sediment, unitless
OC_{sed} = fraction organic carbon in bottom sediment, unitless

Substituting again as in Equation (4-7):

$$C_{swb}\ ER_w + DEP_c = C_{ssed} \left[\frac{V_{wat}}{Kd_{ssed}} + f_s\ ER_w + f_{sd}\ DEP_p + \frac{OC_{sed}}{OC_{ssed}} \right.$$

$$\left. \left[(1 - f_s)\ ER_w + (1 - f_{sd})\ DEP_p \right] \right] \quad (4\text{-}60)$$

As before, the bracketed quantity in the right hand side of Equation (4-60) can be termed ϕ, so that C_{ssed} can be solved as $(C_{swb}\ ER_w + DEP_c)/\phi$. The numerator in this term can be expanded to describe contaminant contributions by the effective drainage area which has received depositions, the first quantity in the numerator, and to describe direct depositions, the second quantity:

$$C_{swb}\ ER_w + DEP_c = C_w\ SL_w\ A_w\ E\ SD_w + RDEP_c\ A_{wat}\ 1000 \quad (4\text{-}61)$$

where:

C_{swb} = concentration on soil entering water body, mg/kg
ER_w = total watershed erosion, kg/yr
DEP_c = annual deposition of contaminant on water body, mg/yr

E	=	enrichment ratio, unitless
C_w	=	average soil concentration of dioxin-like compound in effective area of watershed, mg/kg
SL_w	=	average unit soil loss for land area within watershed, kg/ha-yr
A_w	=	effective drainage area of watershed, ha
SD_w	=	sediment delivery ratio for watershed, unitless
$RDEP_c$	=	rate of contaminant deposition, g/m^2-yr
A_{wat}	=	area of water body, m^2
1000	=	converts g to mg

Again as before, the right hand side of Equation (4-61) can be termed, ρ, and the concentration in suspended sediment, C_{ssed}, is equal to ρ/ϕ. Other water body concentration terms, C_{wat} and C_{sed}, can now be solved using Equations (4-58) and (4-59). Guidance on these terms and assignment of values for the demonstration scenarios in Chapter 5 is now given.

- **C_{swb} and ER_w:** Equation (4-61) shows all the terms necessary to arrive at an estimate of the annual contaminant entry into the water body via erosion, the C_{swb} * ER_w term. Section 4.4.1 describes the algorithm to estimate soil concentrations given a deposition rate of contaminant. One deposition rate will be chosen to represent average deposition rates over the effective drainage area of the watershed (the effective drainage area is termed A_w). This rate will be the rate given in ISCST3 modeling at 5.0 kilometers. Tables 3-15 and 3-16 (Chapter 3) display wet and dry deposition rates for this distance. These rates are added to arrive at total deposition, shown in Table 3-17. Second, a representative mixing depth to characterize average watershed soil concentrations needs to be selected. Previous algorithms used a mixing depth of 20 cm for tillage activities, specifically home gardening, and 2 cm for non-tilled soil concentrations. For the sake of demonstration, it will be assumed that a representative watershed depth will equal 10 cm, which might be interpreted as an average of tilled and untilled lands within the effective drainage area. The values for SL_w (6455 kg/ha-yr), A_w (100,000 ha), ER (3), and SD_w (0.06) were all given and discussed in Section 4.3.1. and will not be repeated here.

- **DEP_c:** The second quantity of Equation (4-61) describes the annual input to the surface water body that comes from direct deposition. This term is $RDEP_c$ * A_{wat} * 1000, where $RDEP_c$ is the rate of contaminant deposition onto the water body (g/m^2-yr) , A_{wat} is the area of the water body (m^2) , and 1000 converts g to mg. The rate of contaminant deposition at 5 km will

also be used to describe direct deposition impact to the surface water body. Depositions nearer to the emission source will be greater and depositions further from the emission source will be less. The area of the water body has not been required for any other reason, and one will now be given. First, the effective drainage area of 100,000 ha is reasonably large and has resulted in a river with an annual flow volume of $4.8*10^{11}$ L/yr ($4.8*10^{8}$ m^3/yr). This volume is also equal to the average cross sectional area of the river (m^2) times stream velocity (m/yr). Assuming a stream velocity of $4.73 * 10^{6}$ m/yr (15 cm/sec; ½ ft/sec), which is reasonable for a river, the cross sectional area is solved as 100 m^2. An average 5 m depth and 20 m width appear reasonable. This width times the stream length would give stream surface area, A_{wat}. Assuming a rectangular shaped watershed, dimensions of 500 ha wide by 2,000 ha long (to arrive at the 100,000 ha effective drainage) seem reasonable. This length of 2,000 ha translates to 200,000 meters, and the full surface area of the stream is $4*10^{6}$ m^2. This will be the value assumed for A_{wat}.

- **DEP_p:** The rate of particulate deposition onto the lake is required to achieve a mass balance of all annual soil erosion + particle deposition contributions to water body solids. The rate of particulate matter emitting from the stack and arriving at downwind locations was not supplied in Chapter 3. Goeden and Smith (1989) modeled the impacts of a resource recovery facility to a local water body. In their analysis, they assumed that the stack emitted 4.63 g/s particulate matter and that the annual deposition of stack-emitted particulate matter to the nearby impacted water body was 0.03 g/m^2-yr. This deposition rate will be adopted for this assessment. Now, with the surface area as solved for above at $2*10^{6}$ m^2, the total particle deposition, $DEP_{p,}$ is 60 kg/yr.

- **f_s and f_{sd}:** These are the fractions of total erosion and depositing particles remaining as suspended materials within a year. As discussed in the solution for the contaminated soil source category in Section 4.3.1, f_s was solved for as: a value for total suspended solid, TSS of 10 mg/L, multiplied by a total flow volume V_{wat} of 4.8×10^{11} L/yr, divided by the total erosion into the water body, $1.29*10^{7}$ kg/yr. This resulted in an f_s of 0.36. Note that this implies a total suspended load of 480,000 kg/yr. It could be assumed that the minuscule 60 kg/yr of particles directly depositing onto the stream remain in suspension during the year, on the basis of being smaller in size than eroded soil. This assumption will, in fact, be made, but it will be supported as follows.

In a quiescent water body, settling occurs through gravity and can be expressed in terms of Stokes Law:

$$V_s = (g / 18\mu) (\rho_s - \rho) d^2 \quad (4\text{-}62)$$

where:

V_s	=	Stokes settling velocity, cm/sec
g	=	acceleration of gravity, 980 cm/sec^2
μ	=	absolute viscosity of water, g/cm-sec (poise)
	=	0.089 g/cm-sec @ 25 C
ρ_s	=	particle density, g/cm^3
ρ	=	density of water, 1 g/cm^3
d	=	particle diameter, cm

For purposes of this discussion, a reasonable assignment of particle density of is 2.5 g/cm^3 for depositing particles or eroding soil. Therefore, making substitutions, the right hand side of Equation (4-62) reduces to 918 d^2.

Now, assumptions for the particle sizes of eroding soil and depositing particles can be made to arrive at a ratio of settling velocities, V_{ssoil}/V_{spart}. The basis for assigning an enrichment ratio for delivery of contaminants via soil erosion was that fine-sized particles were the ones eventually reaching the water body via erosion. Lick (1982) states that a major fraction of the sediments (suspended and bottom) in the Great Lakes are fine grained, silts and clays, and that data from Lake Erie indicates that 90% of the sediments are of this category. Brady (1984) shows USDA's classification of soils according to particle size, and gives a range of 0.0002 to 0.005 cm for silt sized particles and less than 0.0002 for clay size particles. The following assumptions are made to arrive at a representative diameter for particles in eroded soil: eroded soil is comprised of a 50/50 split of these two sized particles, silt-sized particles are, on the average 0.0026 cm in diameter, and clay size particles are 0.0001 cm in diameter. With these assumptions, the average particle size for eroding soil is 0.0014 cm. The settling velocity for a 0.0014 cm particle is 1.8 x 10^{-3} cm/sec. In Section 3.4.3, Chapter 3, the argument was developed that 87.5% of the total emission rate of dioxin-like congeners would be associated with particles less than 2 μm. The basis of this argument was a surface area to volume ratio, with smaller particle sizes having significantly larger ratios. This does not mean that 87.5% of the 1 kg/yr depositing particles are of this size. However, for this discussion, the size of depositing particles will be assumed to be 2 μm (2 x 10^{-4} cm), since these size particles deliver most of the dioxin-like compounds to the water body (and the ultimate purpose of this exercise is to determine a

value for the fraction of depositing particles which remain suspended and impact suspended sediment concentrations). The settling velocity, V_{spart}, is estimated as 3.7×10^{-5} cm/sec.

The ratio V_{ssoil}/V_{spart} is about 50. Said another way and with all the assumptions and simplifications made above, depositing particles will remain in suspension 50 times longer than eroding soil in a quiescent water body.

Given this high a difference in settling velocities, it seems reasonable to assume f_{sb} equals 1.0. The fraction of soil erosion remaining in suspension, f_s, will be estimated given TSS, V_{wat}, etc., as before (see Section 4.3.1), only DEP_p (the total amount of depositing particles, in kg/yr) will comprise a given increment of suspended materials when solving for f_s.

- **V_{wat}, OC_{ssed}, OC_{sed}, and Kd_{ssed}:** These have all been discussed in Section 4.3.1. The values for these parameters in the demonstration scenarios in Chapter 5 are: $V_{wat} = 4.8 \times 10^{11}$ L/yr, $OC_{ssed} = 0.05$, $OC_{sed} = 0.03$, and $Kd_{ssed} = OC_{sed} * Koc$, where Koc is the organic partition coefficient of the contaminant.

4.5. ALGORITHMS FOR THE EFFLUENT DISCHARGE SOURCE CATEGORY

Dioxin-like compounds can be released to waterways via various types of effluent discharges such as discharges from municipal waste water treatment facilities and pulp and paper mills using chlorine bleaching. These emissions have declined substantially in recent years, especially from pulp and paper mills. Since the procedures for considering point source discharges to waterways are somewhat different than those associated with the nonpoint source procedures for soil contamination and stack emissions, they are covered separately in this section. This source category is also different from others in that effluent discharges into surface water bodies are assumed only to impact fish and water.

The approach used in this report is an extension of the "simple dilution" model described in the Superfund Exposure Assessment Manual (EPA, 1988c). Other models are available which offer more spatial and temporal resolution than the model described here. One such model is the EXposure Analysis Modeling System, or EXAMS (Burns, et al., 1982, and Burns and Cline, 1985). The EXAMS and a simple dilution model were both applied in an assessment of effluent discharges from pulp and paper mills (EPA, 1990d). In this assessment, 98 of the 104 pulp and paper mills were modeled with both models using site-specific information (water body flow rates from STORET for all but 6 of the mills, effluent flow rates and contaminant discharges, etc.). Three key quantities - one model result and two model parameters - led to a range of exposure conditions for humans consuming fish impacted by discharges from these pulp and

paper mills: a water column concentration, a bioconcentration factor (BCF) applied to the water column concentration to get fish tissue concentration, and a fish ingestion rate. The simple dilution model was used to estimate total water concentrations - i.e., mg TCDD total/L water. The EXAMS model was used to estimate dissolved phase water column concentration - i.e., mg TCDD dissolved in water column/L water. Then, with each set of water concentrations, two sets of exposure estimates (a low and a high estimate, in one sense) were generated - one with a BCF of 5,000 and a fish ingestion rate of 6.5 g/day, and one with a BCF of 50,000 and a fish ingestion rate of 30 g/day. Note that in deriving the range of results in that exercise, the BCF was applied to both a total and a dissolved phase water concentrations. EPA (1993b) and EPA (1995) discuss several bioconcentration/bioaccumulation empirical parameters for 2,3,7,8-TCDD, and makes the clear distinction for those which are to be applied to a total water concentration versus those applied to a concentration in the dissolved phase. The dilution and EXAMS model study indicated that the simple dilution model generally estimated higher water column contaminant concentrations compared to the EXAMS model, although this trend was not consistent among all water bodies modeled. The results from both models were comparable when the receiving water body had relatively low suspended solids concentration.

One key limitation of the EXAMS and the simple dilution model for use with dioxin-like compounds in aquatic systems is that they do not account for sediment transport processes. The EXAMS model was designed to determine the fate of transport of contaminants in the dissolved phase. Another spatially and temporally resolved model for this source category is the Water Analysis Simulation Package, the most up-to-date version termed WASP4 (Ambrose, et al., 1988). This model does include sediment processes and has been applied in a comprehensive evaluation of 2,3,7,8-TCDD bioaccumulation in Lake Ontario (EPA, 1990b). It requires extensive site-specific parameterization, but should be considered for more detailed site-specific evaluations of strongly hydrophobic and bioaccumulating contaminants such as the dioxin-like compounds.

The dilution model described below will be demonstrated in Chapter 5 with a set of data developed using site-specific data from the 104 pulp and paper mills of the 104-mill study. As will be discussed below, a hypothetical effluent discharge will have characteristics developed as the average of key characteristics from the 104 mill study. These key data include: flow rates of the receiving water bodies, suspended solids concentration in these receiving water bodies, effluent discharge flow rates, suspended solids in the effluent discharges, organic carbon content of solids in the effluent stream, and discharges of 2,3,7,8-TCDD.

4.5.1. The Simple Dilution Model

The principal assumption for the simple dilution model is that contaminants released into a water body uniformly mix and equilibrate with the surrounding water in an area near the effluent discharge point. This area is commonly referred to as a "mixing zone". For application of this model with dioxin-like compounds, what is desired is a concentration on the suspended solids in this mixing zone. Multiplication of the organic carbon normalized concentration on suspended solids and a Biota Suspended Solids Accumulation Factor, or BSSAF, will result in a concentration of contaminant in fish lipids. This is defined similarly to the BSAF used for other source categories of this assessment, except that the organic carbon normalized concentration is that of suspended solids rather than of bottom sediments.

The BSSAF is one of several empirical factors discussed for estimating the impact to fish in water bodies impacted by 2,3,7,8-TCDD (EPA, 1993b). Others include the BSAF, total and dissolved phase bioconcentration factors (BCFs), and total and dissolved phase bioaccumulation factors (BAFs). BAFs and similar to BSAFs and BSSAFs in that all three reflect total exposure of fish to contaminant, including water column, sediment, and food chain exposures. The BCFs reflect water column exposures only. EPA (1993b) states that there is currently no data available on organic carbon normalized concentrations of dioxin-like compounds on suspended solids, hence no basis to compare BSAF and BSSAF. This assessment assumes a similar numerical assignment of BSSAFs and BSAFs.

The total water concentration in a simple dilution model is:

$$C_{tot} = \frac{MASS_c}{Q_e + Q_u} \qquad (4\text{-}63)$$

where:

C_{tot} = total water concentration, mg/L
$MASS_c$ = mass of contaminant in discharge, mg/hr
Q_u = harmonic mean flow at a point just upstream of effluent discharge, L/hr
Q_e = effluent flow, L/hr

Dissolved phase and suspended sediment concentrations are then estimated using an approach developed by Mills, et al. (1985) and others:

$$C_{wat} = \frac{C_{tot}}{1 + (Kd_{mix} \; TSS_{mix} \; 10^{-6})} \quad (4\text{-}64)$$

$$C_{ssed} = Kd_{mix} \; C_{wat} \quad (4\text{-}65)$$

where:

C_{wat}	=	dissolved-phase water concentration of contaminant, mg/L
C_{tot}	=	total water column concentration, sorbed + dissolved, mg/kg (note: mg/kg is essentially equal to mg/L since 1 L ≈ 1 kg)
Kd_{mix}	=	suspended sediment-water partition coefficient for contaminant in mixing zone, L/kg
TSS_{mix}	=	total suspended solids in water column in mixing zone, mg/L
C_{ssed}	=	concentration of dioxin-like compounds on suspended sediments, mg/kg
10^{-6}	=	converts mg/L to kg/L

The total suspended solids concentration in the mixing zone is a function of the suspended solids just upstream of the discharge point and the suspended solids introduced in the effluent stream:

$$TSS_{mix} = \frac{TSS_u \; Q_u + TSS_e \; Q_e}{Q_u + Q_e} \quad (4\text{-}66)$$

where:

TSS_{mix}	=	adjusted total suspended solids concentration, mg/L
TSS_u	=	total suspended solids concentration at a point just upstream of effluent discharge, mg/L
TSS_e	=	total suspended solids concentration in effluent discharge, mg/L
Q_u,Q_e	=	upstream harmonic mean flow and effluent discharge flow rates, L/hr

The suspended solids partition coefficient in the mixing zone is a function of the organic carbon partition coefficient of the contaminant and the organic carbon fraction of suspended solids:

$$Kd_{mix} = Koc\ OC_{mix} \quad (4\text{-}67)$$

where:

Kd_{mix} = suspended sediment-water partition coefficient in the mixing zone, L/kg
Koc = compound specific organic carbon partition coefficient, L/kg
OC_{mix} = organic carbon content of suspended sediments in the mixing zone, unitless

This organic carbon content can be solved as the weighted average concentrations of the organic carbon contents of the suspended solids in the effluent discharge and the suspended solids of the receiving water body:

$$OC_{mix} = \frac{TSS_u\ Q_u\ OC_u + TSS_e\ Q_e\ OC_e}{TSS_u\ Q_u + TSS_e\ Q_e} \quad (4\text{-}68)$$

where:

OC_{mix} = organic carbon content of suspended solids in mixing zone, unitless
TSS_u = total suspended solids concentration at a point just upstream of effluent discharge, mg/L
TSS_e = total suspended solids concentration in effluent discharge, mg/L
Q_u,Q_e = upstream harmonic mean flow and effluent discharge flow rates, L/hr
OC_u, OC_e = organic carbon contents of suspended solids upstream of the discharge point and within effluent discharge stream

Fish lipid concentrations for this solution are then given as:

$$C_{lipid} = BSSAF \frac{C_{ssed}}{OC_{mix}} \quad (4\text{-}69)$$

where:

C_{lipid}	=	fish lipid concentration, mg/kg
BSSAF	=	biota suspended solids accumulation factor, unitless
C_{ssed}	=	concentration of dioxin-like compounds on suspended sediments, mg/kg
OC_{mix}	=	organic carbon content of suspended sediments, unitless

Finally, whole fish concentrations are simply this lipid concentrations times a fraction of fish lipid, or $C_{lipid} * f_{lipid}$.

The harmonic mean flow, Q_e, is distinct from the long term average flow. To understand the difference, the following discussion is offered. Assume, for this discussion, that the effluent flow, Q_e, is much lower than the receiving water body flow, Q_i, and therefore it can be neglected. The daily average total water concentration to which a fish is exposed, C_i, is then a function of the daily mass of chemical released, $MASS_i$, divided by the average flow for that day, Q_i:

$$C_i = \frac{MASS_i}{Q_i} \quad (4\text{-}70)$$

Bioconcentration factors are multiplied by an average concentration, C_{avg}, over n days. Assuming the loading is constant, $MASS_i$ = MASS, then the average concentration is given as:

$$C_{avg} = \frac{1}{n} \Sigma \frac{MASS}{Q_i} \quad (4\text{-}71)$$

This is equivalent to:

$$C_{avg} = \frac{MASS}{Q_H} \quad (4\text{-}72)$$

where Q_H is the harmonic mean flow defined by:

$$\frac{1}{Q_H} = \frac{1}{n} \Sigma \frac{1}{Q_i} \quad (4\text{-}73)$$

This is different from the arithmetic average flow, Q_{avg} (i.e., mean flow):

$$Q_{avg} = \frac{1}{n} \Sigma Q_i \quad (4\text{-}74)$$

To see how these numbers would differ, consider 10 daily average flows of 1, 1, 1, 1, 2, 2, 3, 4, 7, 10. The Q_H is calculated as 1.72, whereas the Q_{avg} is calculated as 3.20. The difference is further illustrated by considering the effect on the calculation of the concentration to which one would apply the bioconcentration factor. If the daily load were 10.0, then the sequence of water concentrations would be 10, 10, 10, 10, 5, 5, 3.3, 2, 1.4, and 1. The average concentration is 5.77, and this is the appropriate concentration to use with a bioconcentration factor. If the daily load of ten were divided by the Q_H of 1.72, one would arrive at this correct concentration, but if the daily load were divided by the average flow of 3.2, the incorrectly calculated average concentration would be 3.1.

The key model parameter for the effluent discharge model is the BSSAF. A value of 0.09 for 2,3,7,8-TCDD was assumed for BSAF based on data from Lake Ontario. One important difference between the Lake Ontario ecosystem and the effluent discharge source category is that the impact to Lake Ontario is thought to be principally historical (EPA, 1990b), while for the effluent source category, the impact is, by definition, ongoing. This difference may translate to differences in assignment of BSSAF as compared to BSAF. Consider two aquatic settings where bottom sediments are found to have equal concentrations of dioxin-like compounds - one in

which contamination is ongoing and one in which contamination is primarily in the past. For the aquatic setting where contamination occurred in the past, water column and suspended sediment concentrations would be lower as compared to the aquatic setting where contamination is ongoing, because water column impacts are only a function of depuration of bottom sediments for the historically impacted water body. It is certainly arguable that exposure of aquatic organisms is greater in the ecosystem where impacts are ongoing, as compared to a system where impacts are historical, when bottom sediment concentrations are equal in the two systems. Now recall the assumption made for the soil contamination and stack emission source categories (in both cases the water body impact is ongoing) concerning the relationship between suspended and bottom sediments - that the organic carbon normalized concentrations are equal. If this is a valid assumption for a system with ongoing impacts, and if in fact fish are relatively more exposed when impacts are ongoing rather than historical, then this argues that a BSSAF for an ongoing contamination setting should be greater in numerical value than a BSAF for a setting where contamination was historical.

However, no data could be found to support such a hypothesis, and there would be no numerical basis for an assumed difference between BSAF and BSSAF. For this reason, the values assumed for BSSAF and BSAF are equal for this assessment. It should be noted that all bioconcentration or biotransfer parameters, such as the BSSAF, are qualified as second order defaults for purposes of general use. Section 6.2. of Chapter 6 discusses the use of parameter values selected for the demonstration scenarios, including a categorization of parameters. Second order defaults are defined there as parameters which are theoretical and not site specific, but whose values are uncertain in the published literature. The parameter values in this category should be considered carefully by users of the methodology.

The effluent discharge solution algorithm was evaluated using data and information from the 104 pulp and paper mill study (EPA, 1990c), which measured discharges of 2,3,7,8-TCDD from 104 mills in 1988, and from the National Study of Chemical Residues in Fish (NSCRF; EPA, 1992a), which measured fish tissue concentrations of 2,3,7,8-TCDD at points downstream from several of these mils. A third modeling study (EPA, 1990d) collected critical data for this modeling evaluation, such as harmonic mean flows downstream of the mills. Finally, the National Council for Air and Stream Improvement (NCASI) provided details on their assessment of this data, which was used here. Importantly, this information included linking specific fish samples to specific mills. A full description of this modeling evaluation is in Chapter 7, Section 7.2.3.6.

There was a dichotomy of model performance as a function of the size of the receiving water body. For most of the mills, the receiving water bodies had harmonic mean flows around 10^8 L/hr, with a range of 10^7 to 10^9 L/hr. A small number of mills, however, discharged into more substantial receiving water bodies which had an average flow of 5×10^{10} L/hr. Comparing model predictions of fish tissue concentrations for mills discharging into the smaller water bodies, it was found that the model tended to underpredict fish tissue concentrations - the average predicted whole fish concentration was near 7 ppt, whereas the average observed whole fish concentration was near 15 ppt. The same was not true for the large receiving water bodies. In that case, the average whole fish tissue concentration observed was an order of magnitude or more higher than predicted whole fish concentration. No precise explanation could be given for this result. The most likely explanation is that, for these large water bodies, there were other sources of dioxin releases. This comparative exercise did assume inherently that the effluent discharge was the sole source of fish tissue concentrations of 2,3,7,8-TCDD.

It was noted that, for the smaller receiving water bodies, an increase in the assumed BSSAF of 0.09 (which was the value of BSAF assumed otherwise in this assessment) to 0.20 resulted in an average model prediction of fish tissue concentration of near 15 ppt, essentially the same as the observed fish concentration. This could be some empirical evidence for the argument developed above - that the BSSAF for a system with ongoing impacts should be greater in numerical value than a BSAF developed from data on an ecosystem where impacts were primarily historical.

In any case, parameters for the demonstration scenario in Chapter 5 for this source category were derived from 104-mill data. Data from only 77 of the mills was used for the following parameter developments. Mills not included are: 1) the ten mills discharging into the largest water bodies, 2) 9 mills for which EPA (1990d) was unable to derive harmonic mean flows from STORET data, and 3) 8 mills for which data on total suspended solids content in the effluent stream was unavailable from EPA (1990c; actually 11 mills did not suspended solids data, but three were in other categories deleted).

Values of model parameters for the demonstration are now summarized:

- **TSS_u, TSS_e:** The average upstream total suspended solids term from the 77 mills, TSS_u, was 9.5 mg/L. The average suspended solids concentration within the effluent streams from the 77 mills was 70 mg/L.

- **OC_u, OC_e:** No information was available on the organic carbon content of the suspended solids upstream of the effluent discharge point. A value of 0.05 was assigned, which was the value assigned for other source categories. No data as well could be found for the

organic carbon content of the effluent solids. However, such solids are essentially biosolids from biological treatments of mill sludges. The organic carbon content of such solids is expected to be much higher than 0.05. The value recommended for OC_e was 0.36 (Steven Hinton, PhD., P.E., National Council of the Paper Industry for Air and Stream Improvement, Inc.; Department of Civil Engineering, Tufts University, Medford, MA 02155). This was based on an average proportion of carbon in algal biomass of 0.36 given in Morel (1983).

- **Q_u, Q_e:** Flow values for the receiving water and effluent stream were summarized in EPA (1990d). The average effluent flow rate, Q_e, for the 77 mills was $4.10 * 10^6$ L/hr, and the average harmonic mean flow for the receiving water body, Q_u, was $4.65 * 10^8$ L/hr.

- **Koc, BSSAF, f_{lipid}:** Values of Koc and f_{lipid} are the same ones which have been used for the other source categories. As discussed in the introduction to this section, the Biota Suspended Solids Accumulation Factor, BSSAF, will be assumed to be the same as the Biota Sediment Accumulation, BSAF. This value is 0.09 for 2,3,7,8-TCDD.

- **$MASS_c$:** The mass of 2,3,7,8-TCDD exiting from the 77 mills averaged 0.197 mg/hr. However, this data was pertinent for 1988. Since then, pulp and paper mills have reduced the discharge of dioxin-like compounds in their effluents by altering the pulp bleaching processes. Gillespie (1992) reports that data on effluent quality from all 104 mills demonstrate reductions in discharges of 2,3,7,8-TCDD of 84%. On this basis, the value of $MASS_c$ for all three example compounds will be 0.0315 mg/hr (16% of 0.197 mg/hr).

Using these parameters in the simple dilution model for 2,3,7,8-TCDD results in the following:

1) If the mass loadings of 2,3,7,8-TCDD are assumed to be fully sorbed to solids in the effluent discharge, and not to exist in the soluble phase in the discharge, than the concentration of 2,3,7,8-TCDD on discharging effluent solids is $1.1*10^{-4}$ mg/kg, or 110 ppt.

2) The total suspended solids concentration in the mixing zone, TSS_{mix}, equals 10.0 mg/L. The organic carbon content of suspended solids in the mixing zone, OC_{mix}, is estimated as 0.069. It is seen how the effluent discharge influences these two key quantities: the unadjusted TSS_u was given as 9.5 mg/L, and the unadjusted OC_u was 0.05.

3) The overall suspended solids concentration of 2,3,7,8-TCDD in the mixing zone after mixing and equilibrating with surrounding water, C_{ssed}, was 4.5 ppt. This compares to the concentration that might be on the effluent solids of 110 ppt, indicating more than an order of magnitude reduction in concentration by mixing with solids of the receiving water body, and partitioning into the water column.

US EPA, 1995	Lake Trout	Lake Ontario	NA			EPA (1995) claims that the Lake Ontario data from EPA (1990b) was reanalyzed for the suite of dioxin-like congeners. It is not clear why the 2378-TCDD for lake trout was 0.059 in this study but listed as 0.07 for lake trout in EPA (1990b). It is also not clear how many samples of fish and sediment were reanalyzed for the data on the right. Also listed to the left are the "bioequivalency factors", or BEFs, as listed in EPA (1995) and as developed from this data set. See text for more detail.
2378-TCDD				0.059	1.00	
12378-PCDD				0.054	0.92	
123478-HxCDD				0.018	0.31

Table 4-2. Available Biota to Sediment Accumulation Factors, BSAF, for PCBs.

Reference/Congener	Fish Species	Water Body	BSAF	Comments
EPA (1990b) PCB	trout, salmon, perch, bass	Lake Ontario	1.40, 0.77, 0.52, 0.86, 3.35, 1.42	These BSAF were compiled in EPA (1990b) from several data sources, years of study, and fish species. The summary provided was not specific in terms of BSAFs associated with specific fish species. It is assumed that "PCBs" described in EPA (1990b) meant "total PCBs". There was one BSAF of 0.58 derived in EPA (1990b) for Aroclor 1254
EPA (1995) Total PCBs PCB 105 PCB 118 PCB 156 PCB 180	Trout	Lake Ontario	 1.85 2.70 4.09 3.97 3.78	EPA (1995) used the data of Oliver and Niimi (1988) to derive the BSAFs listed for total PCBs and the PCB congeners. EPA (1995) also lists BSAFs for numerous other non-dioxin-like PCB congeners.
EPA (1995) PCB 77 PCB 105 PCB 118 PCB 126 PCB 167 PCB 180 PCB 189	Trout	Lake Ontario	 0.29 4.49 1.72 3.21 0.69 3.26 0.71	EPA (1995) derived these BSAFs based on their reanalysis of sediment and trout data from the original Lake Ontario study (1990b). EPA (1995) also lists BSAFs for numerous other non-dioxin-like PCB congeners.

Table 4-2. (cont'd)

Reference/Congener	Fish Species	Water Body	BSAF	Comments
EPA (1995) PCB 77 PCB 105 PCB 118 PCB 167 PCB 180 PCB 189	Brown Trout	Green Bay, WI	 4.12 5.35 4.96 16.0 10.96 3.45	EPA (1995) derived these BSAFs from data on lake trout from the Green Bay. The study from which these data came from was described as EPA's Green Bay/Fox River Mass Balance Study which involved extensive sampling of water, sediment and fish in 1989. No further citation was provided in EPA (1995) for this study.
Parkerton, et al (1993) trichloro-PCB tetrachloro-PCB pentachloro-PCB hexachloro-PCB heptachloro-PCB octachloro-PCB	lake trout, whitefish	Siskiwit Lake	 0.45-2.6 0.71-1.3 3.4-9.4 2.9-20.8 12.5 2.2-12.7	Compiled by Parkerton, et al. (1993) from data in Swackhammer, et al. (1988) and Swackhammer and Hites (1988); Parkerton presents data for individual congeners - summary at left aggregates by chlorination and includes both fish species; only one data point presented by heptachloro-PCB.
Parkerton, et al (1993) Total PCBs	Three species of marine fish	Rio de La Plata, Argentina	 4.40	Determined by Parkerton, et al (1993) from Columbo, et al (1990) on total PCBs. Columbo reference has data on PCBs 5-8, 14, 19, 28-31, 52, 101, 110, 138, 153, 180.

Table 4-2. (cont'd)

Reference/Congener	Fish Species	Water Body	BSAF	Comments
Parkerton, et al (1993)	flounder, lobster, crab	New Bedford Harbor		Compiled by Parkerton, et al. (1993) from data in BOS (1990); summary at left is the range of values for PCB congener groups, and averaged across the noted species.
dichloro-PCB			0.11-0.59	
trichloro-PCB			0.26-0.65	
tetrachloro-PCB			0.65-1.02	
pentachloro-PCB			1.05-2.08	
hexachloro-PCB			1.29-4.00	
heptachloro-PCB			0.84-2.74	
octachloro-PCB			0.23-1.17	
nonachloro-PCB			0.02-0.38	

Table 4-3. Data and parameters used to determine the part of the plant concentration which was due to the deposition of particle bound dioxins (see below table for definition of columns).

Column Definition:
#1 - Congener Group
#2 - Vapor/Particle Fractions. Ratios in parenthesis were the fractions measured in the 2-stage air sampling equipment. See text for more detail.
#3 - Total air concentration, pg/m^3
#4 - Particle bound air concentration, pg/m^3
#5 - Plant concentration calculated to be due to particle deposition, ng/kg fresh
#6 - Total plant concentration, ng/kg fresh
#7 - Plant concentration calculated to be due to vapor transfer, estimated as Column 6 - Column 5, ng/kg fresh
#8 - Percent of plant concentration due to vapor transfers.

Table 4-4. Development of the B_{vpa} using data of Welsch-Pausch, et al (1995) compared against the B_{vpa} as developed in EPA (1994) (see below table for column definitions).

[1] McLachlan, et al. (1990) was not a dosed feeding study; the single cow studied was given normal rationing. The first sample was taken Feb 16, 1989, two months after the last calving on Dec. 22, to maximize the possibility that steady state had been reached. The 92 days listed was from Dec. 22 until the last sample on Mar. 24.
[2]Fries, et al. (1999) were derived from a study where ground up PCP-treated wood was added to the cows' feed. Results are presented only for congeners where concentrations were above background for both milk and feed. Comparison with BCFs derived for other cows which were fed a normal diet (without PCP-treated wood) setting were comparable to the feeding experiment; these background BCFs are shown in parenthesis

5. DEMONSTRATION OF METHODOLOGY

5.1. INTRODUCTION

This document has provided methodologies and background information for conducting site-specific exposure assessments for dioxin-like compounds. Chapter 2 summarized an overall exposure assessment framework, Chapter 3 described mechanisms of formation of dioxin-like compounds in stack emissions and the fate and transport modeling of releases from the stack to a site of exposure, and Chapter 4 provided methodologies to estimate exposure media concentrations for three sources of contamination, which were termed source categories.

The purpose of this chapter is to put all this information together and demonstrate the methodologies that have been developed. For this demonstration, exposure scenarios are developed which are associated with the three source categories. These categories were defined in Chapter 4, and are:

- **Soil Contamination**: The source of contamination is soil. The contaminated soil could occur at the site of exposure, such as in worker exposure scenarios at Superfund sites or contaminated soil at a residence, or the contaminated soil could occur distant from the site of exposure, such as a residence near a Superfund site.
- **Stack emissions:** Exposed individuals reside in the vicinity of the site where stack emissions occur and are exposed to resulting air-borne contaminants, and soil and vegetation on their property is impacted by deposition of contaminated particulates.
- **Effluent discharge:** A discharge of dioxin-like compounds in effluents impacts surface water and fish. Exposure occurs through consumption of the impacted fish and water.

An additional and important scenario is developed which merges the fate and transport algorithms of the soil contamination and emission source categories. This scenario is called, "background conditions". Further details on the structure and fate algorithms of the background conditions scenario are provided in Sections 5.3 through 5.5 below.

The demonstration in this chapter is structured around what are termed exposure scenarios. As defined in Chapter 2, an exposure scenario includes a description of the physical setting of the source of contamination and the site of exposure, behavior of exposed individuals, and exposure pathways. Chapter 2 also described the objective of exposure assessors to

determine "central" and "high end" exposure scenarios. This objective was an important one for this demonstration, and the strategy to design such scenarios is detailed in Section 5.2 below.

For the soil contamination and the effluent discharge source categories, three dioxin-like compounds are demonstrated for each exposure scenario, including 2,3,7,8-TCDD, 2,3,4,7,8-PCDF, and 2,3,3',4,4',5,5'-HPCB. For the stack emission source and the background conditions demonstrations, a different approach is taken with regard to compounds demonstrated. The 17 dioxin and furan compounds of non-zero toxicity are demonstrated; no dioxin-like PCBs are demonstrated. Exposure media concentration results are developed for all 17 congeners. As well, a "toxic equivalent" exposure media concentration, or TEQ concentration, is calculated as the sum of the individual congener concentrations multiplied the congener's Toxicity Equivalency Factor, or TEF. As described in Chapter 1, TEQ concentrations are determined using the WHO 1998 scheme, and the TEQs of this chapter are therefore further identified as WHO_{98}-TEQ_{DF}. Final exposure estimates (Lifetime Average Daily Doses, or LADDs) are developed based on the WHO_{98}-TEQ_{DF} exposure media concentrations for these demonstrations.

Section 5.2 describes the strategy for development of the demonstration exposure scenarios. Section 5.3 gives a complete summary of the demonstration scenarios. Section 5.4 provides some detail on the example compounds demonstrated. Section 5.5 describes the source strength terms for the scenarios. Section 5.6 summarizes the results for all scenarios, which are exposure media concentrations for all exposure pathways, and exposure estimates which are Lifetime Average Daily Doses (LADDs) for all pathways. Also, several observations and additional analyses are provided in Section 5.6.

5.2. STRATEGIES FOR DEVISING EXPOSURE SCENARIOS

Chapter 2 of this document described procedures to assess individual exposures to known sources of contamination. Central and high end exposure patterns, and exposure parameters consistent with these definitions were proposed in that chapter. The demonstration in this chapter attempts to merge procedures for estimating individual exposures to known sources of contamination and current thoughts on devising central and high end exposure scenarios.

An exposure assessor's first task in determining patterns of exposure is to fully characterize the exposed population in relation to the source of contamination. If the extent of contamination can be characterized, then the exposed population would be limited to those within the geographically bounded area. An example of this situation might be an area impacted by stack emissions. Chapter 3 demonstrated the use of ISCST3 atmospheric dispersion model to predict ambient air concentrations and depositions rates for all points surrounding the stack.

Results listed in Tables 3-16 through 3-19 were only for the prevailing wind direction. As can be seen on these tables, the points of maximum impact were within 1 km of the stack. By overlaying the concentration isopleths onto a population density map, the exposed population can be identified. If the extent of contamination is not as clearly defined, such as extent of impact of nonpoint source pollution (impacts from use of agricultural pesticides, e.g.) or the compound is found ubiquitously without a clearly defined source, then the emphasis shifts from geographical bounding to understanding ambient concentrations, exposure pathways and patterns of behavior in general populations. The background conditions scenarios do, in fact, focus on the development of realistic ambient concentrations for its source strength terms.

After identifying the exposed population, the next task is to develop an understanding of the continuum of exposures. The exposures faced by the 10 percent of the population most exposed has been defined as high end exposures. Those faced by the middle of the continuum are called central exposures. Another important estimate of exposure level is a bounding exposure, which is defined as a level above that of the most exposed individual in a population. Arriving at such an understanding can be more of an art than a science. One consideration is the proximity of individuals within an exposed population to the source of contamination. For the incinerator example discussed above, one might begin an analysis by assuming that bounding or high end exposures occur within a kilometer from the stack, in the prevailing wind direction. Another important consideration is the relative contribution of different exposure pathways to an individual's total exposure. While individuals residing at this distance from the incinerator might experience the highest inhalation exposures, they may not experience other exposure pathways associated with contaminated soil on their property - such as consumption of home grown vegetables, dermal contact, or soil ingestion. Families with home gardens and individuals who regularly work in those gardens may reside over a kilometer from the incinerator and possibly be more exposed because of their behavior patterns. Screening tools, such as the algorithms of this assessment which are amenable to spreadsheet analysis (except for the ISCST3 modeling), can be used in an iterative mode to evaluate the interplay of such complex factors. When applied to a real world situation, information should be sought as to the makeup and behavior patterns of an exposed population.

The third principle task for evaluating impacts on an exposed population is to understand the relationship between impacts attributed to the source in question and the background exposures faced by the identified population. Assessors should attempt to answer the following question for dioxin-like compounds: What exposures to dioxin-like compounds would the identified populations have if the source in question were not in existence? The exposures faced

by the identified in the absence of the source in question can be termed "background" or "cumulative" exposures; cumulative in two senses: that the exposures faced by the identified population result from the cumulative impacts of all sources in their environment and from all pathways. Chapter 2 describes approaches to determining background exposures to dioxin-like compounds, and this chapter demonstrates one way to evaluate background/cumulative exposures for a specific site.

The demonstration in this chapter attempts to be consistent with the goal of quantifying central and high end exposures, and properly considering background exposures. However, it is not exhaustive in its analysis, nor should it be construed as a case study with widely applicable results. All the scenario definitions, parameter values, and so on, were construed to be plausible and reasonable, and to demonstrate the application of a site-specific methodology, not to set any regulatory precedent.

Following are bullet summaries of key features of the structure and intent of the demonstrations.

- **Exposed populations:** Exposed individuals are assumed to reside in a rural setting. Exposures occur in the home environment, in contrast to the work environment or other environments away from home (parks, etc.). The presumption is made that the sources of contamination of this assessment can occur in rural settings in the United States. It is further assumed that the behavior patterns associated with the exposure pathways can exist in rural settings. Several of these behaviors characterized as high end relate to individuals on farms as compared to behaviors characterized as central for individuals not on farms. The exposed population for this demonstration, therefore, consists of rural individuals in farming and non-farming residences.
- **Plausibility of source strength terms:** The objective to determine plausible levels of source strength contamination was an important one for this demonstration. Sources demonstrated include small areas of soils with concentrations that have been found in industrial sites, stack emissions with emission rates typical of facilities containing state-of-the-art emission controls, and effluent discharges where characteristics of the effluent stream including rate of contaminant discharges were developed from recent data from pulp and paper

mills. Also, the background conditions scenarios include watershed soils and air concentrations which have been measured in an actual rural background setting. Section 5.5 describes the source terms in detail.

- **Proximity to sources of contamination:** The background scenarios use soil and air concentrations which have been measured in an actual background setting. Therefore, proximity to the source of contamination is not an issue. The effluent discharge source category is unique from the others in that soils or air are not impacted by the source. Only the surface water body into which the effluent is discharged is impacted. The only exposure pathways considered for this source category are drinking water and fish ingestion. Like the demonstration of background conditions, proximity is not an issue for this source category because the simple dilution model does not model fish and water concentrations as a function of distance from the source. It is felt that the water movement of a river or stream receiving the effluent discharge allows for sufficient mixing such that the simplistic dilution approach is reasonable for the dioxin-like compounds. As well, fish are not stationary so that a relationship between distance to source and where the fish are caught would be hard to develop or defend. Individuals in the effluent discharge demonstration simply exhibit behaviors associated with an impacted water body - they fish and they consume the water. Proximity to a stack emitting dioxin-like compounds was identified as an important determinant for identifying the continuum of exposures. Assuming there is a uniform distribution of exposure-related behaviors among exposed populations, i.e., their behavior patterns are not a function of where they live in relation to the stack, the most exposed individuals will be those exhibiting high end exposure behavior nearest the stack. This was the assumption made for purposes of this demonstration. A set of high end exposure behaviors and pathways were demonstrated for individuals residing 500 meters east of the stack, and a set of central exposure pathways were demonstrated for individuals residing 5000 meters east of the stack. The highest ambient air concentrations, and dry and wet deposition rates were simulated to occur at 200 to 1000 meters downwind, justifying 500 meters as an appropriate point for assuming high end impacts. Tables 3-16 through 3-19 listing concentrations and depositions rates as a function show that air concentrations and dry depositions rates at 5000 meters are only about half of what they are at 500 meters, although wet deposition rates are about 20 times

higher at 500 meters as compared to 5000 meters. Without rigorous justification, the model output (concentrations and deposition rates) at 500 and 5000 meters was felt to appropriately characterize high end and central exposures. The site of contamination in the demonstration of the soil contamination source category is 10 acres in size and has concentrations that have been found in industrial sites. A working hypothesis is made that the population most exposed are those residing very near the site. Their soil is assumed to become contaminated over time due to the process of erosion; these processes normally do not carry contaminants long distances across land, particularly land developed with residences or where erosion is interrupted with ditches or surface water bodies. People from the surrounding community can be impacted by visiting or trespassing on the contaminated land, volatilized residues may reach their home environments, they may obtain water and fish from impacted water bodies, and so on. It seems reasonable to assume that those residing near these sites comprise the principally exposed individuals, or equivalently, the individuals experiencing the high end or bounding exposures associated with these areas of soil contamination. The soil contamination source category will be demonstrated with a single, high end scenario. The exposure site is assumed to be located 150 meters downgradient from the site of soil contamination.

- **Central and high end exposure patterns:** Chapter 2 described the exposure pathways that are considered in this methodology, and justified assignment of key exposure parameters (contact rates and contact fractions, exposure durations, and so on) as central or high end estimates. The bullet above discussing exposed populations indicated that several of the behavior assumptions were specific to individuals on farms, and that these behavior patterns were evaluated as "high end". "Central" behavior patterns were those for individuals residing in a non-farm residence. High end behaviors assumed to be different for individuals on farms versus central behaviors for individuals not on farms include, for example, residing on larger tracts of land (10 acres assumed for farmers; 1 acre assumed for non-farmers) and ingestion of home produced and impacted beef. Other patterns of behavior modeled as central and high end are not specifically associated with farming and not farming, but are assumed to be plausible for individuals in rural settings. These include home gardening for fruit and vegetables, inhalation exposures, children that ingest soil, and the use of impacted surface water bodies

for drinking and fish to be ingested. Finally, a set of additional exposure pathways are modeled which are outside the scenarios altogether. These include the pathways of milk ingestion, chicken, and egg ingestion. Like the beef ingestion pathways, these pathways involve home production of the food products. Since an objective of the scenario development was to be realistic, it was felt that a scenario involving home production of the four animal food products: beef, milk, chicken, and eggs (not to mention fruits and vegetables), was highly unlikely. However, a scenario involving production of at least one animal terrestrial food product is more realistic.

- **Consideration of background exposures**: Background scenarios are devised which include the same exposure pathways and exposure parameters as the source-specific scenarios. The difference is that the exposure media concentrations are "background" or "cumulative" as contrasted to concentrations that result only from the source being modeled. Specifically, the background scenarios use, as input, "background" air and soil concentrations, and model all subsequent terrestrial and aquatic impacts. By structuring the background scenarios in this way, the key question, "What would be the exposure of individuals if the source in question did not exist?" is most specifically answered. Chapter 2 described a second approach to the issue of background exposures, and that was the comparison of source/scenario specific exposures to a generic background exposure. Volume II of this assessment has estimated that a general background exposure to WHO_{98}-TEQ_{DFP} is about 60 pg/day. One could, therefore, compare any source-specific estimates to this overall background estimate. Further detail on the specifics of the background scenarios is given below.
- **Realism of modeled concentrations:** The air and soil concentrations of the background scenarios are, by definition, realistic since they were derived from actual measured concentrations from a background site. For all other exposure media of the background scenarios, and in all other scenarios, the exposure media concentrations were modeled. The realism of modeled exposure media concentrations is dependent on the appropriateness of the models used for such estimations and the assignment of parameter values for those models. One way to arrive at a judgement as to the realism of estimated concentrations is to compare predictions with observations. To the extent possible (i.e., given the availability of appropriate data), model predictions of exposure media concentrations are

compared with occurrence data in Chapter 7, which describes several model validation exercises. As is shown, predictions fell within the realm of observed data. Chapter 4 describes the justification of all model parameter values. Many of the parameters are specific to the contaminants. Some contaminant properties were estimated as empirical functions of contaminant-specific parameters: the root concentration factor, RCF, was estimated as a function of the octanol water partition coefficient, Kow, for example. Other parameters were measured values, such as the vapor pressure or some of the bioconcentration factors. For non-contaminant parameters such as soil and sediment properties, patterns of cattle ingestion of soil (and other bioaccumulation/biotransfer parameters), and many others, selected values were carefully described and crafted to be plausible.

5.3. EXAMPLE EXPOSURE SCENARIOS

As noted above, all exposures occur in a rural setting. Exposure pathways were those which could be associated with places of residence in contrast to the work place or other places of exposure. The example scenarios are structured so that some (but not all) of the behaviors associated with high end exposures are included in the "high end" scenarios and all the central behaviors are in the scenarios characterized as "central". To summarize, the components which distinguished the high end exposure scenarios in contrast to the central scenarios include:

- Individuals in the central scenarios lived in their homes and were exposed to the source of contamination for only 9 years, in contrast to individuals in the high end scenarios, who were exposed for 30 years (except for the exposure pathway of soil ingestion, where the individuals are assumed to be children ages 2-6, and in both the central and high end scenarios, the exposure duration is 5 years).
- Individuals in the central scenarios lived on properties 1 acre in size, whereas individuals in the high end scenarios lived on properties 10 acres in size.
- Individuals in the high end scenario associated with the stack emission source category lived 500 meters from the incinerator, whereas individuals in central scenario lived 5000 meters from the incinerator.
- Individuals in high end scenarios obtained a portion of their beef from home-raised cattle stocks - such individuals are obviously farmers. Consumption of terrestrial animal food products were not assessed for non-farming rural individuals, representing the central scenarios.

- On the other hand, farming individuals in the high end scenarios were not assumed to recreationally fish. A fish pathway was included only in the central scenarios.
- Ninety percent of the inhaled air and ingested water by the high end individuals were assumed to be contaminated, whereas only 70% of these exposures were with impacted media for the central individuals. This is based on time at home versus time away from home assumptions for central versus high end individuals. Also, individuals in high end scenarios were assumed to consume 2.0 L/day of water and breathe 20 m^3/day of air as compared to 1.4 L/day and 13 m^3/day for individuals in central scenarios.
- Both the central and high end scenarios included a fruit/vegetable ingestion pathway. Although patterns of home production and consumption of fruits and vegetables differ within a population, average behaviors for individuals who home produce fruit and vegetables was assumed for both the central and high end scenarios in this assessment.
- The rates of ingestion of soil by children were higher for the high end individuals than the central individuals.

These are the distinguishing features for the central and high end exposure scenarios. For the sake of convenience mainly, all the scenarios defined below as high end are called "farms", and all central scenarios are called "residences". In addition to the scenarios, high end behaviors including fish, milk, chicken and egg consumption are separately modeled for the background conditions farm setting, the stack emission high end farm setting, and the soil contamination farm setting.

Again, the reason for separating these four pathways from the scenarios is that it is important for assessors to develop scenarios which combine a series of behaviors which are plausible to occur simultaneously in a real world setting. If such a strategy is followed, than the assessor is able to sum the exposures over all pathways to arrive at a total scenario exposure. It does not seem reasonably common in the real world that a single farm would include home production of several terrestrial animal food products (along with recreational fishing), which is why such a scenario is not developed in this assessment. In an exhaustive site-specific analysis, one might begin by evaluating all possible pathways, further evaluating pathways of most exposure, and then determining what pathways occur simultaneously for identified individuals in the exposed population. Only then can be the assessor begin to define a continuum of exposures.

The following bullets describe six exposure scenarios that are demonstrated. The numbering scheme and titles will be referenced for the remainder of this chapter:

Exposure Scenarios 1 and 2: Background conditions, Residence and Farm

Surface soils within the watershed are initialized to soil concentrations of the 17 dioxin-like congeners (no dioxin-like PCBs) which have been found in an actual rural setting. Also, air concentrations of the 17 congeners are initialized to air concentrations which have been found in this same rural setting. More details on this setting are provided in Section 5.5 below. Scenario 1 is the central residential scenario, and Scenario 2 is the high end farming scenario. Bottom sediment in a nearby river becomes impacted by long term erosion and atmospheric deposition. Water and fish in that stream are subsequently impacted. The exposure pathways for Scenario 1 are: water ingestion, air inhalation, fish ingestion, fruit/vegetable ingestion, soil dermal contact, and soil ingestion. The exposure pathways for Scenario 2 are: water ingestion, air inhalation, beef ingestion, fruit/vegetable ingestion, soil dermal contact, and soil ingestion. It is noted that for a background condition, it could be argued that all exposure is to background concentrations in exposure media. In other words, all contact fractions would be 1.00. However, if an assessor wished to compare the incremental impacts from a specific source of dioxin release with impacts an individual would receive by contact with the same exposure media which has only background concentrations of dioxins, than the assessor would assume all the same exposure behaviors (rates of contact, contact fractions). This demonstration takes this approach. When evaluating non-cancer risks using a margin-of-exposure approach, which is also demonstrated in this chapter, it is most appropriate, however, to compare incremental impacts with all background impacts, not only the same source-specific incremental impacts. This is discussed in more detail in Section 5.7, which demonstrates cancer and non-cancer risk assessments.

Exposure Scenario 3: Soil Contamination, Farm

A 40,000 m^2 rural farm is located 150 m (500 ft roughly) from a 40,000 m^2 area of bare soil contamination; an area that might be typical of contaminated industrial property. The surface soil at this property is contaminated with three example dioxin-like compounds to the same concentration of 1 part per billion (ppb). These compounds are: 2,3,7,8-TCDD, 2,3,4,7,8-PCDF, and 2,3,3',4,4',5,5'-HPCB. The 1 ppb soil concentration is reasonable for industrial sites of contamination of dioxin-like compounds, and generally about three orders of magnitude higher than the concentrations of these congeners in background settings. As in the above and all scenarios, bottom sediment in a nearby river is impacted, which impacts the water and fish. The

exposure pathways include: water ingestion, air inhalation, beef ingestion, fruit/vegetable ingestion, soil dermal contact, and soil ingestion.

Exposure Scenarios 4 and 5: Stack Emissions, Residence and Farm

A 4,000 m^2 rural residence (Scenario 4) is located 5000 meters from an incinerator, and a 40,000 m^2 (Scenario 5) rural farm is located 500 meters downwind from an incinerator. Emission data of the suite of 17 dioxin-like dioxin and furan congeners (no dioxin-like PCBs) is available from stack testing of an actual incinerator. This allows for estimation of impacts from each congener individually, and estimation of WHO_{98}-TEQ_{DF} impacts. The modeling of the transport of these contaminants from the stack to the site of exposure and other points in the watershed used the ISCST3 model. Details on the stack emission source for this demonstration and the ISCST3 model application are found in Chapter 3. A nearby impacted river provides drinking water and fish for recreational fishing. The exposure pathways for Scenario 4 are: water ingestion, air inhalation, fish ingestion, fruit/vegetable ingestion, soil dermal contact, and soil ingestion. The exposure pathways for Scenario 5 are: water ingestion, air inhalation, beef ingestion, fruit/vegetable ingestion, soil dermal contact, and soil ingestion.

Exposure Scenario 6: Effluent Discharge into a River

As has been discussed, this source category is different from others in that the air, soil, and vegetation at a site are not impacted. Rather, only surface water impacts are considered. Therefore, central and high end behaviors associated with places of residence are less pertinent for this source category. Exposure parameters associated with central behaviors for the water and fish ingestion pathways were chosen to demonstrate this source category. The source strength was developed from data on pulp and paper mill discharges of 2,3,7,8-TCDD; more detail on this source strength term development is provided in Section 5.5 below. The discharges of the other two example compounds are assumed to be the same for purposes of demonstration. Obviously, however, there is less of a tie to real data for the discharge rate for these other two example compounds. Also noteworthy for this source category as compared to the others is the size of the surface water body into which discharges occur. The other source categories all were demonstrated on water bodies with annual flow rates of $4.8 * 10^{11}$ L/yr. The river size into which the example effluent was discharged was developed from data from the 104 pulp and paper mill study (as discussed in Section 5.5 below). This river size was $4 * 10^{12}$ L/yr, one order of magnitude larger than the river of the other scenarios.

Food pathway analyses outside of the scenario framework: The food consumption pathways of fish, milk, chicken, and eggs are demonstrated using source strength characteristics of the three high end scenarios above: Scenarios 2 (background conditions), 3 (soil contamination), and 5 (stack emission). These food pathways were not modeled in the scenarios themselves. In these analyses, exposure media concentrations are calculated for each source and the pathway exposure estimates are provided. The purpose of these external pathway analyses was to provide further demonstration and to compare impacts from the various food pathways where methodologies have been provided in this assessment.

5.4. EXAMPLE COMPOUNDS

Three compounds were demonstrated for the soil contamination source and for the effluent discharge source category. For purposes of illustration, one compound was arbitrarily selected from each of the major classes of dioxin-like compounds. They are: 2,3,7,8-tetrachlorodibenzo-p-dioxin, 2,3,4,7,8-pentachlorodibenzofuran, and 2,3,3',4,4',5,5'-heptachloro-PCB. For the remainder of this chapter, these compounds will be abbreviated as 2,3,7,8-TCDD, 2,3,4,7,8-PCDF, and 2,3,3',4,4',5,5'-HPCB.

These compounds demonstrate a range of expected results because of the variability of their key fate and transport parameters. The log octanol water partition coefficients (log Kow) for 2,3,7,8-TCDD, 2,3,4,7,8-PCDF, and 2,3,3',4,4',5,5'-HPCB were 6.80, 6.50, and 7.71, respectively. Whereas the span of reported log Kow ranged from less than 6.00 to greater than 8.00, only a few reported values were at these extremes. Increasing log Kow translates to the following trends: tighter sorption to soils and sediments and less releases into air and water, less accumulation in plants and in cattle products (beef, milk), and more accumulation in fish. The Henry's Constants for the three compounds span the range of reported values, with the value of the PCB compound the highest of all reported at $6.6 * 10^{-5}$ atm-m^3/mole. There were few values less than the $4.98 * 10^{-6}$ atm-m^3/mole reported for 2,3,4,7,8-PCDF. Higher Henry's Constants translate to greater amounts of volatilization flux. The fate parameters for these three compounds and the 15 other dioxin and furan congeners are provided in Table 5-1.

For the background conditions and the stack emission demonstrations, Scenarios 1, 2, 4, and 5, a different approach was taken. All 17 of the dioxin-like dioxin and furan congeners were modeled. The ISCST3 modeling exercise described in Chapter 3 allowed for the generation of deposition amounts (wet and dry) and ambient air concentrations of all 17 congeners at sites of exposure for the demonstration of the stack emission source. For the background conditions demonstration, air concentrations were taken from an actual rural site (see Section 5.5). The dry

depositions of particle-bound congeners were estimated as the particle-bound air concentration times a deposition velocity. Based on the measurements of Koester and Hites (1992), this deposition velocity was assumed to be 0.2 cm/sec. Also based on Koester and Hites (1992), who measured wet and dry deposition and showed these two quantities to be roughly equal for settings in Indiana, wet deposition was set equal to dry deposition.

The individual deposition rates and air concentrations for the 17 congeners in Scenarios 1, 2, 4, and 5 were used to model the exposure media concentrations for each congener individually with unique fate and bioaccumulation parameters. The exposure media concentrations include: air, soil, fruit/vegetables, water, fish, and the terrestrial animal food products including beef, milk, chicken, and eggs. A final WHO_{98}-TEQ_{DF} exposure media concentration was estimated using the 1998 WHO TEFs (Van der Berg, 1998):

$$C_{TEQ} = \Sigma\ TEF_i\ C_i \qquad (5\text{-}1)$$

where:

C_{TEQ}	=	Toxic Equivalent concentration
TEF_i	=	Toxicity Equivalency Factor for congener i
C_i	=	concentration of congener i

The final results which are displayed for these scenarios are the WHO_{98}-TEQ_{DF} results only.

5.5. SOURCE TERMS

This section describes the source terms for the example scenarios. The source terms for the demonstration of background conditions, Scenarios 1 and 2, include both the initial air concentrations and the initial soil concentrations. The source terms for the soil contamination source demonstration, Scenario 3, include the area of contamination and soil concentrations. The source terms for the stack emission scenarios, 4 and 5, are the emission rates of contaminants from the stacks. These are described in Chapter 3. What will be detailed here, instead, are the deposition rates, air concentrations, and predicted soil concentrations at the site of exposure. In this way, scenarios 4 and 5 can be compared to the background scenarios, 1 and 2. The source term for the effluent discharge example scenario is the rate of discharge of dioxin-like compounds. This is briefly discussed in this section, with reference to a more detailed discussion in Chapter 7. Following now are discussions on these terms for all scenarios.

Scenarios 1 and 2

The 1994, the Ohio EPA (OEPA) conducted air monitoring in the city of Columbus in order to evaluate the impact of the Columbus Municipal Solid Waste Incinerator (MSWI). This incinerator operated between June, 1983 and December, 1994. Air samples were taken in March and April, 1994, at 6 sites in the city in Columbus and in a background site 28 miles southwest of Columbus. This background site is in the upwind direction from the facility. The air concentrations were higher in the urban air of Columbus as compared to the air concentrations in the background site: the average I-TEQ (I is short for "international"; see Chapter 1 for a discussion of the WHO TEFs versus the I TEFs) air concentration from 10 samples (6 sites, 2 sample dates, but only 5 sites sampled each sample date) in Columbus was 0.092 pg I-TEQ/m^3 as compared to 0.023 pg I-TEQ/m^3 from 2 samples (1 site, 2 sample dates) at the background site. The Ohio EPA visited these same sites in April, 1995, to measure air concentrations once the incinerator was no longer operating. The average air concentration from the 6 urban sites (all 6 sites sampled in 1995) was 0.046 pg I-TEQ/m^3 as compared to the background site of 0.018 pg/m^3. Further details on the 1994 sampling can be found in OEPA (1994) and details on the 1995 sampling can be found in OEPA (1995), and an overall summary of all sampling, including soil sampling, can be found in Lorber, et al. (1998). For the demonstration of background conditions, concentrations of the 17 dioxin-like congeners from the three sample dates at the rural site will be averaged to give the air concentration source terms.

The I-TEQ results discussed above were calculated assuming non-detects were equal to ½ the detection limit. Typically, non-detects are either assumed to be 0.0 or ½ detection limit. For TEQ concentrations, assumptions on the treatment of the detection limit can be an important issue if concentrations are consistently less than the detection limit and/or quantified concentrations are near the detection limit. For many samples of the OEPA sampling at Columbus, it turned out that I-TEQ concentrations did not differ significantly assuming non-detects equal 0.0 or non-detects equal ½ detection limit. For example, for the 10 Columbus samples in Mar/Apr of 1994, the average I-TEQ concentration would be 0.088 pg/m^3 at ND equal to 0.0 instead of 0.092 pg/m^3 at ½ detection limit. Likewise, for most of the congeners, the assumption on handling of non-detects is not critical as most of the samples were positively quantified, and/or the concentrations were sufficiently high such that assumptions on the values used for non-detects was not critical.

This was not the case, however, for 2,3,7,8-TCDD, the most toxic of congeners. For six sites and three sampling dates in the city of Columbus, or 16 data points (5 sites sampled for 2 dates, 6 sites sampled for one date), 6 were positive ranging from 0.0027 to 0.0262 pg/m^3. With

non-detect equal to 0.0, the average of these 16 data points was 0.0048 pg/m^3; with non-detect equal to ½ detection limit, the average concentration was 0.0065 pg/m^3. Although seemingly small, this kind of difference can be important in the calculation of TEQ media concentrations. There were no positive occurrences of 2,3,7,8-TCDD in the three dates of sampling in the rural site.

The detection limit for 2,3,7,8-TCDD varied by sampling, but was always in the narrow range of 0.0043 to 0.0074 pg/m^3 at the rural site. At ½ the detection limit for the three rural samples, the 2,3,7,8-TCDD average concentration would be 0.0029 pg/m^3, but the range of possible concentrations would be 0.00 (ND=0) to 0.0058 pg/m^3 (ND=½ DL).

An examination of the available quantified concentrations at the rural site and in Columbus suggests that assuming ½ detection limit for 2,3,7,8-TCDD would overestimate the air concentration of this congener in the rural site. Concentrations were more available for the penta dioxin congener, 1,2,3,7,8-PCDD, which are now examined to lend some insight about the difference in concentrations between Columbus and the rural site for the lower chlorinated congeners. To estimate the "true" 2,3,7,8-TCDD concentration, it will be assumed that the difference in the urban 1,2,3,7,8-PCDD concentration and the rural 1,2,3,7,8-PCDD concentration is assumed to be similar to the difference in the urban and rural 2,3,7,8-TCDD concentration. Of 16 samples of 1,2,3,7,8-PCDD in Columbus, 10 were quantified. The average concentrations at non-detect equal 0.0 and non-detect equal ½ detection limit for these 10 samples were 0.0151 and 0.0159 pg/m^3, respectively. One of 3 rural samples was quantified, leading to averages of 0.0037 and 0.0045 pg/m^3 at non-detect equal 0.0 and non-detect equal ½ detection limit. This would suggest that the rural concentration of 1,2,3,7,8-PCDD is about 1/4 that of the urban concentration (i.e., 0.0037/0.0151 = 0.245, and 0.0045/0.0159 = 0.28).

For 2,3,7,8-TCDD, where the urban concentration ranges from 0.0048 to 0.0065 pg/m^3, the "true" rural concentration is speculated to range from 0.0012 (0.0048/4) to 0.0016 (0.0065/4) pg/m^3, somewhat smaller than the 0.0029 pg/m^3 by the traditional non-detect equal to ½ detection limit method. For this example, the rural concentration of 2,3,7,8-TCDD will be assigned a value of 0.0014 pg/m^3, the midpoint of the hypothesized range.

All other air concentrations were calculated as the average of the three air samples, assuming ½ the detection limit for non-detects. The WHO_{98}-TEQ_{DF} air concentration for this profile was 0.021 pg/m^3.

In 1995, a soil sampling program was undertaken to evaluate the soils in the vicinity of the Columbus MSWI. This program was sponsored by the EPA with participation of the Agency for Toxic Substances Disease Registry (ATSDR), Ohio EPA and the Ohio Department of

Agriculture, and other state and local agencies. The purpose of the study was to determine whether the soils in the vicinity and also distant from the incinerator were impacted by the operation of the incinerator. Twenty-five samples were available for analysis, including 22 in the city of Columbus, and 3 in the same rural site 28 miles upwind of Columbus where air concentrations were taken. A full discussion of the soil sampling program can be found in EPA (1996), and an overview can be found in Lorber, et al. (1998).

This background scenario will, however, take advantage of the samples which were taken in the background setting. The soil concentration at the background site will be calculated as the average of the three background samples. The final WHO_{98}-TEQ_{DF} soil concentration for the background scenarios was 1.3 ppt. This soil sampling program took soil samples to a depth of 7.5 cm. Therefore, the concentrations as analyzed will be used to represent the "untilled" soil concentration. They will also be used to represent watershed soils for calculation of water body impacts. The question exists as to whether they should also be used to represent the tilled concentrations for the high end farming scenarios and for calculation of below ground vegetable concentrations. Brzuzy and Hites (1995) reported on the concentrations of dioxin in soil profiles from undisturbed background locations. Measuring the concentration in 2 cm increments, they generally found uniform concentrations to a depth of about 5 cm, with dropoffs thereafter. For two sandy soils, they found increasing concentrations which peaked at approximately 30 and 40 cm. Based on this information, the soil concentrations from the rural site used here will be divided by 2 to estimate tilled soil concentrations. A division by 3 to estimate the average concentration over the approximate 20 cm depth of the tilled soil depth for other scenarios in this assessment (stack emissions, soil contamination) would assume no dioxins exist below 7.5 cm in background soils. This was not found in the Brzuzy and Hites (1995) data. That is why the tilled concentration is calculated as the 7.5 cm concentration divided by 2.0 rather than 3.0. Recall that tilled soil concentrations are used to estimate concentrations in below ground vegetables, as well as in the dermal contact pathways, which assume gardening or farming as the cause for soil contact.

In summary, the background scenarios 1 and 2 use air concentrations averaged from three points in time and soil concentrations corresponding to the air samples from an actual rural setting.

It has been stated earlier in this chapter that the fate algorithms for this demonstration of background conditions would merge the fate and transport algorithms for the contaminated soil source with the stack emission source. In particular, the following will be done. First, deposition to soils will not be evaluated; soil concentrations will be supplied as source terms and are not

assumed to change over the course of the time period of the demonstration, as in the soil contamination source category. In the same vein, air concentrations are not assumed to be impacted by soil emissions; the air concentrations will be assumed to be constant and supplied as source terms as in the stack emission source category. Above ground vegetative impacts will be evaluated given the estimated depositions of particle-bound dioxins and the transfer of vapor phase dioxins from the air profile. Below ground vegetative impacts will be based on soil-to-plant transfer algorithms assuming the tilled concentration supplied as a source term. Surface water impacts (water and fish) are a function of direct depositions of particle bound contaminants onto the water body and erosion from watershed soils. The soil concentration used for calculation of water body impacts will be the untilled soil concentration. Terrestrial animal food products are calculated as a function of above ground terrestrial vegetation (impacted only by air to plant transfers) and the initialized untilled soil concentrations.

Table 5-2 summarizes the source terms used for Scenarios 1 and 2, which include the deposition rates, the air concentrations, and the soil concentrations.

Scenario 3

This scenario was designed to be plausible for properties located near inactive industrial sites with contaminated soil. The selection of 1 µg/kg (ppb; or 1000 ppt) for the three compounds was based on 2,3,7,8-TCDD findings associated with the Dow Chemical site in Midland, MI (EPA, 1985; Nestrick, et al. 1986) as well as the 100 industrial sites evaluated in the National Dioxin Study (which included the Dow Chemical site; EPA, 1987). In that study, most of the sites studied had soil concentrations in the parts per billion range. The other key source information is the size of the contaminated area. This scenario will assume a contaminated site 40 hectares, or 40,000 m^2.

Scenarios 4 and 5

Chapter 3 described the application of the ISCST3 atmospheric dispersion model to estimate air-borne concentrations and deposition rates of the contaminants in the vicinity of the hypothetical incinerator, given contaminant emission rates in units of g/sec. As discussed in Chapter 3, the emission factors (mass compound emitted per mass feed material combusted) and resulting emission rates and concentrations (rate = mass compound emitted per time period and concentration = mass compound emitted per unit volume of air emitted) for all the congeners was typical of incinerators with a high level of air pollution control, e.g., scrubbers with fabric filters. The I-TEQ emission factor for the hypothetical incinerator, 4.5 ng I-TEQ/kg material combusted,

was within a range of 0.3 ng I-TEQ/kg municipal solid waste incinerated, to 200 ng I-TEQ/kg hospital waste incinerated. This range was developed from representative test data for source-specific incinerators with a similar high level of pollution control technology. Two hundred metric tons per day of material was assumed to be incinerated at the hypothetical incinerator in order to arrive at emissions in appropriate units of g/sec. The TEQ emission rate was $1.5*10^{-9}$ g/sec. Wet and dry particle-bound deposition rates, in units of pg/m^2 -yr, were determined for all dioxins and furans, at various distances from the stack and in the prevailing wind direction. The exposure sites of Scenarios 4 and 5 are located downwind at 500 and 5000 meters, respectively, from the emission source. Other deposition rates needed for the stack emission source category were those used to estimate average watershed soil concentrations and direct deposition onto the impacted water body. For both the central and high end scenarios, rates of deposition at 5000 meters were used for these purposes. Since the watershed is 100,000 ha, which would be 10,000,000, meters long if it was square, assuming rates of deposition at 5000 meters might translate to an assumption that the stack was located relatively near the impacted water body.

Key source terms for Scenarios 4 and 5 are shown in Table 5-3. To facilitate comparison with the background scenarios, #1 and #2, these terms include the depositions, air concentrations, and soil concentrations.

Scenario 6

All key parameters used in Scenario 6 demonstrating the effluent discharge source category were developed using data associated with the 104 pulp and paper mill study (EPA, 1990). Derivation of the physical parameters including the flow rate of the receiving water body, flow rate of the effluent stream, suspended solids concentrations of the receiving water body and the effluent stream, and so on, are described in Section 4.5 of Chapter 4. An exercise evaluating the simple dilution model for predicting impacts to suspended solids in water body and subsequently to fish tissue concentrations resulting from discharges from these mills is described in Chapter 7. The bottom line conclusion from that exercise was that the simple dilution model appears to work satisfactorily for a screening model: predicted whole fish tissue concentrations for the majority of mills averaged about half as much as measured fish tissue concentrations. This could be due to an underestimate of the uncertain bioconcentration factor, BSAF, or it could be due to other factors. For the minority of mills, those with the highest volumes of receiving water, the model did not work as well. Predicted fish tissue concentrations were around an order of magnitude lower than measured concentrations. The precise reason for this discrepancy is not known, but the most likely explanation that larger water bodies have more uses and more sources

of dioxin-like input - assuming that the fish tissue concentrations result singly from the mill discharge and a few proximate mills may be inappropriate.

Parameters for Scenario 6 were derived from the mills for which the model best performed. The average discharge rate from these mills was 0.197 mg 2,3,7,8-TCDD/hr. However, this data was valid for the time of sampling, which was 1988. Since then, pulp and paper mills have reduced the discharge of dioxin-like compounds in their effluents by altering the pulp bleaching processes. Gillespie (1992) reports that data on effluent quality from all 104 mills demonstrate reductions in discharges of 2,3,7,8-TCDD of 84% overall. On this basis, the discharge rate assumed for 2,3,7,8-TCDD was 0.0315 mg/hr (16% of 0.197 mg/hr). This same rate was assumed for the other two example compounds, although the claim is not being made that they are emitted by pulp and paper mills.

It is important to note that these discharge assignments are not intended to reflect current discharges of dioxin-like compounds from pulp and paper mills, even for 2,3,7,8-TCDD. Data from the 104-mill study did allow for development of a "composite" effluent discharger in certainly a plausible setting (receiving water body and discharge flow rates, suspended solids, etc.) for pulp and paper mills. Assigning what might be evaluated as a reasonable discharge rate of 2,3,7,8-TCDD from pulp and paper mills for current conditions allows for the example scenario to placed in some context, which was a primary objective of crafting all example scenarios. Individual sources must be evaluated on an individual basis.

In summary, the key source term for the demonstration of the effluent source category include a discharge rate of 0.0315 mg/hr for all three compounds demonstrated, and the discharge of this rate into a water body of size $4.65*10^9$ L/yr.

5.6. RESULTS

The results of this exercise include the exposure media concentrations for all exposure pathways and scenarios, and the LADD exposure estimates. These two categories of results are summarized in Tables 5-4 through 5-10. Following now are several observations from this exercise. As a reminder for the background conditions scenarios, #1 and #2, and stack emission demonstration scenarios, #4 and #5, individual dioxin and furan congeners with non-zero toxic equivalency factors (TEFs) were modeled with unique fate and transport parameters until estimates of exposure media concentration were made. At that point, the WHO_{98}-TEQ_{DF} exposure media concentrations were estimated. For the sake of brevity, the WHO_{98}-TEQ_{DF} results are emphasized in this chapter.

It is important to understand that all observations made below are not general comments. Different results would arise from different source strength characteristics, proximity considerations, model parameter values, different models altogether, and so on. Chapters 6, 7, and 8 on User Considerations, Model Validation and Model Comparisons, and Uncertainty describes many areas of this assessment which should be considered when evaluating the methodology or viewing the results.

5.6.1. Observations Concerning Exposure Media Concentrations

Exposure media results are given in Tables 5-4 through 5-6.

- ***Soil Concentrations***:

1. The lowest exposure site soil concentrations resulted from deposition of particles 5000 m away from the example stack emission source. This was the location of the exposure site in the central stack emission demonstration scenario, Scenario 5. The highest exposure site soil concentrations were predicted for the demonstration of the soil contamination scenario. About 6 orders of magnitude separate the exposure site soil concentrations of 2,3,7,8-TCDD predicted for the central stack emission demonstration scenario, Scenario 4, and the soil contamination scenario, Scenario 5.

2. Concentrations for the stack emission central and high end scenario were about 3 and 2orders of magnitude lower than the central and high end scenarios demonstrating background conditions, respectively. This suggests that the example stack emission source, which was a single emission source with a high level of pollution control, would contribute little to overall background levels in soil.

3. The order of magnitude difference in distance from the stack between the central (5000 meters away) and high end (500 meters) scenarios is matched by the same order of magnitude difference in soil concentrations.

4. For both the background scenarios, 1 and 2, and the stack emission scenarios, 4 and 5, WHO_{98}-TEQ_{DF} soil concentrations were over an order of magnitude higher than 2,3,7,8-TCDD concentrations. The difference in 2,3,7,8-TCDD and WHO_{98}-TEQ_{DF} impacts to all media mirrors the difference in stack emissions of 2,3,7,8-TCDD and stack emissions of WHO_{98}-TEQ_{DF}. This

trend in differences between 2,3,7,8-TCDD and TEQ impacts occurs in all exposure media estimations for both the background scenarios and the stack emission scenarios.

5. For the demonstration of the soil contamination source, exposure site soil concentrations resulting from erosion were the same for all three compounds. This is because the same initial soil concentration was assumed at the site of contamination, and the erosion algorithm contains only one chemical specific parameter. This is the rate of dissipation for eroding contaminants. It was assigned a value of 0.0277 yr^{-1} (25-year half life) for all three example compounds. The stack emission source also has only one contaminant-specific parameter in the algorithm, the soil dissipation rate, and it was also assigned a value of 0.0277 yr^{-1} for all congeners.

- ***Vapor and Particle-Phase Air Concentrations***:

1. The partitioning of air-borne dioxins is modeled differently for the stack emission and the soil contamination sources. For the stack emission source, dioxins are assumed to be in equilibrium between the particle and the vapor phase from stack to receptor. The equilibrium partitioning model is explained in detail in Chapter 3. The application of this model in the demonstration scenario resulted in the 2,3,7,8-TCDD to be approximately 51% in the vapor phase and 49% in the particle phase. For the WHO_{98}-TEQ_{DF} air concentration, the partitioning, as seen in Table 5-4, is about 88% in the particle phase and 12% in the vapor phase for the background scenario, and about 71% particle/29% vapor for the stack emission source category. However, the modeling of dioxins above a site of soil contamination does not result in partitioning that approaches these equilibrium calculations. The volatilization, wind erosion, and dispersion algorithms are described in Chapter 4. As seen in Table 5-5, the vapor phase dominates the total air concentration and is about 95% of the total concentration. Residues which volatilize from the soil are assumed to remain in the vapor phase. However, it is possible that dioxin-like compounds released into the air this way would not remain in vapor phase, but would partly sorb to air-borne particles. An alternate approach to the one take for this assessment would be to sum the total concentrations of dioxins modeled to be emitted from soil, and to repartition them according to the equilibrium calculations. This is not done in this assessment.

2. The background WHO_{98}-TEQ_{DF} air concentration was 0.021 pg/m^3. In contrast, the WHO_{98}-TEQ_{DF} air concentration for the stack emission source was 2 orders of magnitude lower at 500

meters from the stack, at 0.00024 pg/m^3, and was over 2 orders of magnitude lower at 5000 meters from the stack, at 0.000085 pg/m^3.

3. The air concentration of 2,3,7,8-TCDD is highest in the soil contamination source category at 0.0042 pg/m^3. The background air concentration of this congener, used in Scenarios 1 and 2, is actually not that much lower at 0.0014 pg/m^3. There is the same 2 and 3 order of magnitude difference in the stack emission air concentrations of this congener compared to background that is seen in the comparison of other media concentrations - at 5000 m, the 2,3,7,8-TCDD concentration is $4.8*10^{-6}$ pg/m^3, and at 500 m, it is $1.4*10^{-5}$ pg/m^3.

4. The vapor phase air concentration over a site of soil contamination is a function of contaminant-specific parameters including the partition coefficient, Koc, and the Henry's Constant, H. As seen in Table 5-5, the vapor phase concentrations of the three demonstration congeners are different: 0.004 pg/m^3 for 2,3,7,8-TCDD, 0.007 pg/m^3 for 2,3,4,7,8-PCDF, and 0.002 pg/m^3 for 2,3,3',4,4',5,5'-HPCB. The particle phase concentrations were not different, however, since the wind erosion algorithm was not a function of contaminant specific properties.

- ***Water Impacts Including Water, Sediment, and Fish***:

1. There was a 2 order of magnitude difference in all water impacts between the background scenario and the stack emission scenario. This is easily seen in Table 5-4.

2. For the stack emission source category, surface water impacts were not a function of the location of the exposure site, unlike other media concentrations associated with the exposure site including air, soil, and home grown foods. Therefore, the media concentrations will be the same for the central and high end scenarios.

3. The surface water impacts are comparable for the contaminated soil demonstration, Scenario 3, the effluent discharge scenario, Scenario 6, and the background scenarios (#1 and #2). Examining the 2,3,7,8-TCDD fish lipid concentrations, they are: 6.4 ppt for the effluent discharge scenario, 4.3 ppt for the soil contamination scenario, and 3.0 ppt for the background scenarios. The surface water impacts are much lower for the stack emission scenarios, #4 and #5 - the fish lipid concentration is 0.0003 ppt for the stack emission scenarios. This observation is

particularly noteworthy in that the assumed effluent discharge rate is 84% lower than originally measured in the 104-mill study in 1989.

4. The PCB concentrations were between 1 and 2 orders of magnitude higher than the dioxin and furan because the key bioaccumulation variables estimating fish tissue concentrations, the Biota Sediment Accumulation Factor, BSAF, and the Biota Suspended Solids Accumulation Factor, BSSAF (used only for the effluent discharge source category), is 2.0 for the example PCB while it is 0.09 for the example dioxin and and 0.14 for the example furan.

5. Concentrations of WHO_{98}-TEQ_{DF} in water in the background and stack emission scenarios were all less than 0.01 pg/L (ppq), and for the individual congeners in the soil contamination and effluent discharge scenarios was less than 0.1 pg/L. These very low concentrations are the result of high lipophilicity of the dioxins, furans, and PCBs. The water ingestion pathway had the lowest exposure estimates of all pathways.

- ***Terrestrial Vegetation Concentrations***:

1. At first glance, there appears to be roughly a 2-3 order of magnitude difference in above ground vegetables/fruits and above ground leafy vegetation. In fact, this is due to two modeling differences: 1) the fruit/vegetable concentrations are presented in fresh weight. The dry weight to fresh weight conversion factor is 0.15, or equivalently, a dry weight concentration is about 6.7 times higher than fresh weight concentration, and 2) fruit/vegetables are bulky above ground vegetation. Literature data and experimental studies supported the hypothesis that dioxins impacted mainly the outer portions of bulky above ground vegetation and did not translocate to inner plant parts. The vapor phase air-to-plant algorithm, meanwhile, was calibrated to predict leafy vegetation, whole plant, concentrations. Therefore, to reduce predicted leafy whole plant concentrations to more appropriate dilute whole plant concentrations for bulky vegetation, an empirical parameter, VG_{ag}, was introduced. It was assigned a value of 0.01 for bulky above ground fruits/vegetables and 1.00 for leafy vegetation. With these two modeling differences, leafy vegetation dry weight concentrations are 666 times greater than bulky vegetable/fruit fresh weight concentrations. Other differences in concentrations are explained by differences in the particle phase impact algorithms of the two types of vegetation.

2. A more significant difference is found in the algorithms predicting below and above ground vegetation concentrations for the different source categories. Below ground vegetables are higher in concentration as compared to above ground vegetables, as seen in Tables 5-4, for the background and stack emission demonstrations, and in Table 5-5, for the soil contamination source category. However, the degree of difference is significantly more for the soil contamination source category as compared to the stack emission category or background demonstration scenarios. For these latter two cases, below ground vegetables are only between 1 and 2 times higher than above ground vegetables, but for the soil contamination source category demonstration, below ground vegetables are over 3 orders of magnitude higher than above ground vegetables.

The explanation for this trend is found in the air-to-soil model validation exercise which is described in Chapter 7. In that exercise, the background air profile used in the demonstrations in this chapter was modeled to deposit onto soil and mix in a 7.5-cm reservoir. The predicted soil concentrations were shown to match the measured soil concentrations, also used in the demonstrations in this chapter, reasonably well. Therefore, it would appear that the overall model seems to mimic air to soil relationships when air is the principal source of the dioxins in soil. Except for cases of specific soil contamination, this will often be the case, and certainly is expected to be case for background settings where there are no major sources for soil contamination. However, when the soil concentrations were assumed to be the source for air concentrations, and the soil contamination algorithms were used to predict air concentrations above the background soil, it was found that the predicted air concentrations were much lower than the measured air concentrations. Two possible explanations were offered for this trend: 1) the models predicting volatilization and dispersion were underpredicting air concentrations, and/or 2) measured air concentrations in the specific background setting used in the demonstration, and for background settings in general, are not only due to soil emissions, but also from the long range transport of residues from distant sources. In fact, it may be the case that distant sources of dioxin emissions to the air, such as stack emissions, followed by long range transport, explain significantly more of the background air concentrations found than local soil emissions from soils with background concentrations. If so, than a model prediction of background air concentration based on background soil emission will be significantly lower than background air concentrations.

For the purpose of this explanation, one can develop a ratio of air to soil concentration to more fully understand this difference. For the background scenario, and taking air and untilled soil concentrations from Table 5-4, an air to soil WHO_{98}-TEQ_{DF} concentration ratio is, 0.14 for

the background scenario (total air concentration divided by untilled soil concentration, Table 5-4), 0.008 for the high end stack emission scenario, and 0.02 for the central stack emission scenario. The same ratio for the soil contamination scenario is on the order of $1*10^{-5}$. Therefore, the relative strength of air dioxins to soil dioxins is about three to four orders of magnitude higher when air is the source, as in the background scenarios, than when soil is the source, as in the soil contamination scenario.

Since above ground vegetables are a function of air concentrations, it then stands to reason that the discrepancy between below and above ground vegetables will be much higher when soil is the source of contamination as compared to when air is the source of contamination.

3. For the soil contamination demonstration, the tilled and untilled soil concentrations were the same for the three contaminants demonstrated. As noted in the observations for soil concentrations, this is because the parameters predicting exposure site soil concentrations from a distant site of soil contamination are the same for the three contaminants. However, there are differences in the predicted above and below ground vegetation for the three contaminants. Transfers from soil to plant are driven by chemical parameters, particularly the octanol water partition coefficient, Kow. 2,3,3',4,4',5,5'-HPCB and 2,3,7,8-TCDD had similar Kow, with 2,3,4,7,8-PCDF at a lower Kow. Higher Kow translates to tighter sorption to soil, and less transfer to plant, either through root uptake or air-to-leaf transfer. This trend translated to the lower fruit/vegetable concentrations for 2,3,3',4,4',5,5'-HPCB and 2,3,7,8-TCDD as compared to 2,3,4,7,8-PCDF.

- ***Terrestrial Animal Product Lipid Concentrations***:

1. Within each demonstration scenario, there appears to be a reasonably narrow range of predicted lipid concentrations among beef, milk, chicken, and egg fat. The difference is about a factor of 3 to 4. The lowest concentrations are noted for the stack emission demonstration scenarios, in the 10^{-3} to 10^{-2} pg WHO_{98}-TEQ_{DF}/g (ppt) range. The background concentrations were next highest, about two orders of magnitude higher in the 10^{-1} to 10^{0} ppt range, and the soil contamination demonstration was the highest at about two orders of magnitude higher still, at 10^{2} to 10^{3} pg 2,3,7,8-TCDD/g lipid.

2. The differences within a scenario can be explained by a combination of three factors: the apportioning of dry matter intake by the animal between soil and terrestrial vegetation, the

differences in the bioconcentration factors between beef/milk, chicken, and eggs, and the relationships between soil and vegetation as described above. For example, milk fat concentrations were lower than beef fat concentrations in all cases, but within about a factor of two. This was due to assumptions concerning apportioning of total dry matter intake between contaminated soil, contaminated pasture grass, and home-grown contaminated feeds. Beef cattle were assumed to take in twice as much soil as lactating cattle, 4% of their dry matter intake versus 2%, and much more leafy vegetation than lactating cattle, 48% pasture grass versus 8% pasture grass. Another interesting trend is that the chicken and egg fat concentrations are much higher than the beef/milk fat concentrations for the contaminated soil demonstration scenario, but the chicken and egg fat concentrations are lower or comparable for the background and stack emission scenarios. This is due to two factors: the free range chickens had 10% of their diet in soil as compared to 4 and 2% for beef and dairy cattle - this obviously will be important in a contaminated soil scenario, and the above ground vegetation were substantially less impacted, relatively speaking, in the soil contamination scenario as compared to the background or stack emission scenarios, as explained above in the vegetation observations. This would tend to minimize the importance of the vegetation in the diet of beef or dairy cattle in the soil contamination scenario.

3. In the observations concerning surface water impacts, it was noted that the fish lipid concentration of the PCB congener was much higher than the dioxin or furan congener. This was because the BSAF/BSSAF of the PCB congener was much higher at 2.10 as compared to the BSAF/BSSAF of the dioxin and furan congeners, 0.09 and 0.14, respectively. However, the literature suggests that the terrestrial animal bioconcentration factors are more similar for the three congeners. Hence, and as seen in Table 5-5, the beef, milk, chicken, and egg fat concentrations are comparable among the three congeners.

4. Table 5-6 shows the individual congener concentrations in beef for the high end background and stack emission scenarios. Recall that the TEQ beef concentration was about two orders of magnitude higher for the background as compared to the stack emission scenario. For all congeners except the tetra congeners, the difference is this same two order of magnitude difference, and up to 3 orders of magnitude difference for the higher chlorinated congeners. For the tetra congeners, 2,3,7,8-TCDD and 2,3,7,8-TCDF, the difference is an order of magnitude and less. This suggests that the congener profile in the hypothetical incinerator is distinctly

different than the background profile: the incinerator emissions would appear to have a greater proportion of emissions in the tetra congeners as compared to background air or soil.

5.6.2. Observations Concerning LADD Exposure Estimates

Much of the differences between exposure pathways and scenarios is due to differences in exposure media estimation. Therefore, much of the above discussion is also appropriate for analysis of Lifetime Average Daily Dose, LADD, estimates. What will be noted below are unique observations. LADD results are given in Tables 5-7 through 5-11.

1. Like in exposure media estimation, LADDs for the stack emission scenarios, 4 and 5, were the lowest at 10^{-11} to 10^{-7} ng WHO_{98}-TEQ_{DF}/kg-day, followed by the background scenarios, 1 and 2, at 10^{-8} to 10^{-5} ng/kg-day, the effluent discharge scenario which had a fish ingestion LADD in the 10^{-5} range, and finally the soil contamination scenario with the highest LADDs ranging from 10^{-8} to 10^{-3} ng/kg-day for all three compounds demonstrated - the dioxin, furan and PCB.

2. Tables 5-7 and 5-8 also show the percent of total scenario exposure which is accounted for by each pathway. The total scenario LADD was calculated simply as the sum of the pathway LADDs in the scenario, without accounting for any differences in body absorption. It should be remembered, however, that the amount of dioxin absorbed by the soil dermal contact pathway is estimated at 3%. This was accounted for in the calculation of LADD, so that the LADD for the soil dermal contact pathway was "absorbed" dose, while for all other pathways, the LADD was the "administered" or "potential" dose. As discussed in Chapter 2, the absorption for these other pathways was in the neighborhood of 80%, except for soil ingestion, where the absorption is on the order of 30%. Because of this 3% absorption accounted for in the dermal contact pathway, the LADD for this pathway is almost always the lowest of all pathways. From Tables 5-7 and 5-8, it is seen from the individual percentages that the food pathways dominate the scenarios, with fish ingestion dominating the central scenarios and beef ingestion dominating the high end scenarios. Furthermore, the beef ingestion pathway LADD was over an order of magnitude higher than the fish ingestion pathway LADD. This was more due to differences in the exposure parameters including the ingestion and contact rates, and the differences in the lipid content of the full product, rather than lipid concentrations themselves since the fish lipid concentrations tended to be higher than the beef lipid concentrations for a given source. For example, in the background scenario, the fish lipid concentration was modeled as 6.33 ppt WHO_{98}-TEQ_{DF}, while the beef lipid concentration was about one-fourth of that at 1.58 ppt WHO_{98}-TEQ_{DF}.

3. Differences between analogous "central" and "high end" exposure pathway estimates for the background demonstration scenarios, 1 and 2, were near or less than an order of magnitude (inhalation exposure for the central background scenario and the inhalation exposure for high end on-site scenario are analogous exposures). This is because the exposure parameters used to distinguish typical and high end exposures, the contact rates, contact fractions, and exposure durations, themselves did not differ significantly, and these were the only distinguishing features for analogous pathways in the background demonstrations. For the total exposure, however, there was a difference of a factor of 20 between high end and central exposure in the background demonstration scenarios. This is because the high end scenario included consumption of beef, which was the highest exposure pathway and exceeded the fish pathway of the central scenario by over an order of magnitude.

4. In the stack emission scenarios, placing exposed individuals either 500 or 5000 meters away from the incinerator did significantly impact the results. The order of magnitude difference in distance added about an order of magnitude difference in exposure media concentrations and hence LADD estimates. Therefore, the full difference in analogous pathways between the central and high end was closer to 2 orders of magnitude for the stack emission demonstration scenarios.

5. Tables 5-9 and 5-10 show results for the food ingestion pathways that were not included in the scenarios. One observation here is that the terrestrial animal product pathways, including milk, chicken, and egg ingestion pathways, are all less than the beef ingestion pathway, by up to an order of magnitude, despite the fact that the terrestrial food product lipid concentrations were fairly near each other. For example, the chicken fat concentration in the background scenario was 0.61 ppt WHO_{98}-TEQ_{DF}, compared to the beef fat concentration for that scenario of 1.58 ppt. The chicken ingestion pathway LADD was over an order of magnitude less than the beef ingestion pathway, however. This was due to the differences in the four other exposure related parameters which differ for chicken and beef: 1) beef was assumed to be 19% fat while chicken was assumed to be 13% fat, 2) the whole product ingestion rate of beef was 2.45 g/kg-day while the whole product ingestion rate of chicken was 0.97 g/kg-day, 3) according to the analysis of the National Food Consumption Survey described in Chapter 2, the beef ingestion pathway had a higher contact rate of 0.478 compared to the chicken contact rate of 0.151, and 4) the chicken and beef pathways had an additional food preparation factor which considers discarded portions

(bones, etc.) and cooking loss. This factor did not differ greatly for the two food products, 0.55 for beef and 0.49 for chicken.

6. Table 5-11 relates all the pathways considered in this demonstration for the background, the stack emission, and the soil contamination demonstrations. This table includes the food ingestion pathways that were not in the demonstration scenarios. It was constructed by assigning a value of 1.00 to the beef ingestion pathway, and then determining the ratio of the other pathways to the beef pathway. This table again shows the domination of beef and milk exposures, at least given the exposure parameters, lipid contents, and so on, assigned to the demonstration scenarios. The fish pathway was very important in the background scenario as compared to the other two scenarios. The main reason for this was how the models predicted bottom sediments. For the background scenario, the predicted sediment concentration was nearly three times higher at 3.4 ppt WHO_{98}-TEQ_{DF} than the soil to which the cattle were exposed, 1.3 ppt. In contrast, the sediment concentration was nearly an order of magnitude lower at 0.0024 ppt WHO_{98}-TEQ_{DF} than the soil concentration to which cattle were exposed in the high end stack emission scenario, at 0.035 ppt WHO_{98}-TEQ_{DF}. Even more dramatic, there was a two order of magnitude difference in the sediment and soil concentration for the soil contamination site scenario - 1.4 vs. 357 ppt 2,3,7,8-TCDD. Table 5-11 also shows that a childhood pattern of soil ingestion can be an important pathway, ranking along with chicken and egg exposures in the background and stack emission demonstrations. The chicken and egg pathways were considerably more important in the soil contamination scenario as compared to the other two pathways. This is due to the trend of predicting much higher chicken and egg concentrations in the soil contamination scenario as compared to the background and stack emission scenarios; this was discussed earlier in the observations for the exposure media concentrations. Vegetable ingestion was also more important in the soil contamination scenario, which was driven by high below ground vegetable concentration. Vegetable ingestion and inhalation were comparable to the chicken, egg, and soil ingestion pathways in the background and stack emission scenarios. Fruit ingestion, dermal exposure, and water ingestion are all relatively minor compared to the animal ingestion pathways and were less than 1% of the exposures estimated for beef ingestion.

7. Fish was the principal impacted media for the effluent discharge source category, with fish ingestion 19 times higher than water ingestion, the only two pathways considered for the effluent discharge category. Fish was an important route of exposure in the central scenarios for the

background and stack emission scenarios, 1 and 3, explaining over half of all exposures estimated for those scenarios.

5.7. HEALTH RISK DEMONSTRATIONS

Chapter 2 described the procedures to generate estimates of excess cancer risks and the ratio IOB to evaluate potential non-cancer impacts. This section will demonstrate these health risk assessment procedures, using the background and the high end stack emission scenarios.

Recall that excess cancer risk is estimated as the product of the LADD and cancer potency factor, q_1^*. For 2,3,7,8-TCDD, the q_1^* is 1.0 kg-day/ng, and this value is also used for TEQ LADDs. Table 5-12 shows the cancer risk estimates for the background and the stack emission high end scenarios, where LADDs are for WHO_{98}-TEQ_{DF} exposures.

As seen in Table 5-12, there is a 2 order of magnitude difference between the total cancer risk of both scenarios, the same 2 order of magnitude difference in the total LADDs as noted earlier. The cancer risk associated with the high end scenario for the incinerator was $9*10^{-7}$, while the background high end cancer risk was $9*10^{-5}$.

The cancer risk for the background scenario corresponds to a lifetime average daily dose, LADD, of 6 pg WHO_{98}-TEQ_{DF}/day. This is about a factor of seven lower than the background dose of 43 pg WHO_{98}-TEQ_{DF}/day generated in Volume II, Chapter 4 of the Exposure Reassessment Document. The reasons for this difference are: 1) the Volume II background exposure estimate was an average daily dose, ADD, not an LADD calculated in the demonstration scenarios here. The LADD estimated in this chapter assumes 30 years of exposure. The ADD during the exposure period would be just over twice, or 70/30, the LADD; 2) the Volume II background exposure considered additional pathways including fish, dairy ingestion (milk and otherwise), eggs, pork, and poultry. If one adds the additional pathways for the background high scenario - milk, chicken, egg, and fish shown in Table 5-9 - the LADD (and ADD) roughly doubles; 3) the exposure factors are different, with the most important difference being that in the exposure scenarios considered in this chapter, contact fractions of less than 1.0 were assumed - less than 0.5 for the terrestrial animal pathways, in fact.

Some of these differences also are relevant for the procedures demonstrated here to characterize non-cancer risk. Specifically, the procedures described in Chapter 2 require the assignment of a “background body burden” in the calculation of an Increment Over Background, IOB, ratio. The IOB is defined as the ratio of the incremental of body burden due to the source being evaluated (IBB) and the background body burden (BB_{bk}) times 100%. As described in Chapter 2, the BB_{bk} can be a generic U.S. background body burden, or a site-specific background.

The generic adult background body burden is currently evaluated as 5 ng WHO_{98}-TEQ_{DF}/kg. However, this quantity represents the full range of the current adult population; an assessor could consider the background body burden for younger adults rather than the full range of adult ages (younger adults would have a lower background body burden), whether to consider specific populations such as women of child-bearing age (which again might imply a lower concentration as compared to a full population average), and so on. As well, one could develop a body burden that is specific to the site being evaluate. This could be a non-trivial exercise and could involve estimating quantities that have not been considered when evaluating only an increment of exposure due to a specific source. Chapter 2 went into some of the issues to consider when developing a site-specific estimate of background exposure dose/intake or background body burden.

If an assessor could determine an appropriate background exposure dose for a specific site being evaluated, he could then use the simple first order pharmacokinetic model to convert this site-specific dose to a site-specific BB_{bk}. To do so, an assessor needs to estimate the total exposure of an individual (or individuals) to dioxins as though the nearby source being evaluated was not in existence. In a farm family scenario, the family would still be consuming home produced foods, but these foods would only be impacted by background dioxins in the environment, and no longer by the source being evaluated. But they would also be consuming store-bought or restaurant-bought foods. The "total" exposure would include all pathways considered in the scenarios of this chapter, but other pathways as well.

For the purposes of this demonstration, it will be assumed that the farming family in the background scenario consumes foods at similar rates whether or not they are consuming home-produced or store-bought food products, and that their exposure is characterized by all the pathways in the formal scenarios of Table 5-7, as well as the additional scenarios shown in Table 5-9. To estimate their average background daily dose over a lifetime, the exposure duration will increase from 30 to 70 years, and the contact fractions will all rise to 1.00. The resulting daily exposure is 1.16 pg WHO_{98}-TEQ_{DF}/kg-day. This 1.16 pg WHO_{98}-TEQ_{DF}/kg-day will be used here as the "site-specific background dose" against which one can develop IOBs for the incinerator source.

For generation of the increment of body burden due to the incremental exposure, one needs to estimate the ADD during the period of exposure. The total LADD for the stack emission high end scenario, as displayed in Table 5-7, is $1.01 * 10^{-3}$ pg WHO_{98}-TEQ_{DF} /kg-day. The ADD can be simply calculated as this LADD times 70/30, or $2.36 * 10^{-3}$ pg WHO_{98}-TEQ_{DF}/kg-day. It is now possible to calculate the site-specific background body burden, BB_{bk},

and the increment of body burden due to the site-specific source, IBB, using this generalized equation:

$$BB_i = \frac{DD\ AF}{k\ CF_1}(1 - e^{-kt}) \quad (5\text{-}2)$$

where:

BB_i = body burden of interest, either BB_{bk} or IBB, pg/g (ppt) whole weight basis

DD = dose quantity for calculating the BB, either the site-specific lifetime average daily dose, LADD, or the daily dose during the period of exposure to the specific source, ADD, pg/kg-day (whole body weight basis)

AF = absorption fraction

k = first-order rate of decline of dioxin residues from the body, day^{-1}, calculated as $(\ln 2/t_{1/2})$, where $t_{1/2}$ is the half-life, days

CF = conversion factor, 1000 g/kg

t = time of exposure, either lifetime for BB_{bk} or the exposure duration for ADD, days

Using assumptions used in the Risk Characterization as first approximations for pharmacokinetic modeling of TEQs, AF will be assumed to be 0.8, $t_{1/2}$ will be 7.1 years so that k is calculated as 0.000267 day^{-1}. The appropriate values for t include the exposure duration corresponding to the ADD described above for the high end scenario, which is 30 years (10950 days), and the 70 year (25550 days) lifetime assumed for calculation of BB_{bk}. Finally, the DDs equal the 1.16 and 0.00236 pg WHO_{98}-TEQ_{DF}/kg-day, as discussed above.

Substituting these values yields body burdens of 0.007 pg WHO_{98}-TEQ_{DF}/g for IBB and 3.5 pg WHO_{98}-TEQ_{DF}/g for BB_{bk}. The IOB is then easily solved for as, 0.2 % ([0.007/3.5]*100). This increment of body burden increase is very low and can probably be characterized as insignificant. It is also interesting to note that the BB_{bk} at 3.5 ppt TEQ is lower than the general US population background body burden of 5.0 ppt TEQ. As discussed in Volume II of these Exposure Documents, and as alluded to in discussions above, the general US population background body burden is influenced by higher concentrations in older individuals who experienced higher doses in the past. The "steady state" body burden at the current general US background exposure dose of 1.0 pg WHO_{98}-TEQ_{DFP}/kg-day is also lower than 5.0 ppt, at 3.0 ppt. The assessor can choose either the general US background exposure, this steady state exposure at

current US background doses, a site-specific background exposure, or even another background quantity in developing the IBB term for non-cancer risk assessing at specific sites.

It is once again emphasized that the scenarios and all exposure parameters, and the fate modeling with their parameters, used in this demonstration chapter, are not being offered as default values or recommendations for all uses. Chapter 6 contains additional information pertaining to these models, including sensitivity analysis exercises and discussions of model parameters. Chapter 7 provides a critical evaluation of the fate models selected in this methodology, including model comparisons and model validation exercise. Chapter 8 on Uncertainty critically evaluates the fate and exposure modeling approaches and parameters used in this assessment. Information in these three Chapters should be reviewed when evaluating the validity of the approaches demonstrated in this Chapter.

Table 5-1. (con't.)

Definitions for Table 5-1:

TEF:	Toxicity Equivalency Factor	Log Kow:	log octanol water partition coefficient
H:	Henry's Constant, atm-m^3/mole	Koc:	Organic carbon partition coefficient, L/kg
$p°_L$:	liquid sub-cooled vapor pressure, 20°C, atm	B_{vpa}:	Air-to-leaf biotransfer factor, (pg PCDD/g leaf dry)/(pg PCDD/g air)
V/P:	Vapor phase/particle phase percentages	BSAF/BSSAF:	Biota-to-(suspended) sediment accumulation factor, unitless
RCF:	Root concentration factor, unitless	BCF/CCF/ECF:	Beef/milk, chicken, egg fat bioconcentration factor, unitless

Table 5-4. WHO_{98}-TEQ_{DF} environmental and exposure media concentrations for the background conditions scenarios, #1 and #2, and the stack emissions demonstration scenarios, #4 and #5.

Description	Background, Scenarios 1 and 2	Emission, Central Scenario 4	Emission, High End Scenario 5
Air, vapor phase, pg/m^3	$2.59*10^{-3}$	$2.45*10^{-5}$	$6.94*10^{-5}$
Air, particle phase, pg/m^3	$1.87*10^{-2}$	$6.04*10^{-5}$	$1.74*10^{-4}$
Soil, untilled, pg/g	1.29	$4.46*10^{-3}$	$3.51*10^{-2}$
Soil, tilled, pg/g	0.65	$4.46*10^{-4}$	$3.51*10^{-3}$
Soil, watershed, pg/g	1.29	$8.91*10^{-4}$	$8.91*10^{-4}$
Surface water, pg/L	$2.63*10^{-3}$	$3.80*10^{-5}$	$3.80*10^{-5}$
Sediment, pg/g	3.37	$2.39*10^{-3}$	$2.39*10^{-3}$
fish lipid, pg/g*	6.33	$5.64*10^{-3}$	$5.64*10^{-3}$
leafy vegetation, pg/g dry	0.45	$1.86*10^{-3}$	$6.39*10^{-3}$
above ground fruit/veg, pg/g fresh	$5.74*10^{-3}$	$1.20*10^{-5}$	$6.37*10^{-5}$
below ground vegetables, pg/g fresh	$1.94*10^{-2}$	$1.63*10^{-5}$	$1.29*10^{-4}$
beef fat, pg/g*	1.58	$4.35*10^{-3}$	$1.65*10^{-2}$
milk fat, pg/g*	1.10	$3.05*10^{-3}$	$1.11*10^{-3}$
chicken fat, pg/g*	0.61	$2.02*10^{-3}$	$1.38*10^{-2}$
egg fat, pg/g*	0.71	$2.25*10^{-3}$	$1.55*10^{-2}$

* These food concentrations were not uniformly required for all scenarios. For example, the central scenarios did include a fish ingestion pathway, but the high scenarios did not. Similarly, chicken, milk, and egg pathways are demonstrated outside the context of a scenario. These concentrations are presented here for completeness.

Table 5-5. Environmental and exposure media concentrations for 2,3,7,8-TCDD ("dioxin"), 2,3,4,7,8-PCDF ("furan") and 2,3,3',4,4',5,5'-HPCB (PCB) for the soil contamination demonstration, scenario #3, and the effluent discharge demonstration, scenario #6 (NA = not applicable).

Description	Scenario 3 - Soil Contamination			Scenario 6 - Effluent Discharge		
	dioxin	furan	PCB	dioxin	furan	PCB
Air, vapor phase, pg/m^3	0.004	0.007	0.002	NA	NA	NA
Air, particle phase, pg/m^3	0.0002	0.0002	0.0002	NA	NA	NA

Soil Ingestion	$8.86*10^{-8}$	9
Soil dermal contact	$2.55*10^{-10}$	<1
Inhalation	$2.68*10^{-8}$	2
Water ingestion	$4.19*10^{-10}$	<1
Beef ingestion	$8.65*10^{-7}$	86
Vegetable ingestion	$1.83*10^{-8}$	3
Fruit ingestion	$4.05*10^{-9}$	<1
Total	$1.00*10^{-6}$	100

Table 5-8. Lifetime average daily doses, LADD, for 2,3,7,8-TCDD ("dioxin"), 2,3,4,7,8-PCDF ("furan") and 2,3,3',4,4',5,5'-HPCB (PCB) for the soil contamination demonstration, scenario #3, and the effluent discharge demonstration, scenario #6.

Scenario/Pathway	Dioxin, ng/kg-day	Furan, ng/kg-day	PCB, ng/kg-day	Percent of total scenario exposure*
Scenario 3 - Soil Contamination				
Soil Ingestion	$8.99*10^{-4}$	$8.99*10^{-4}$	$8.99*10^{-4}$	23
Soil dermal contact	$4.20*10^{-6}$	$4.20*10^{-6}$	$4.20*10^{-6}$	<1
Inhalation	$4.75*10^{-7}$	$8.12*10^{-7}$	$2.40*10^{-7}$	<1
Water ingestion	$1.33*10^{-7}$	$1.00*10^{-6}$	$1.81*10^{-8}$	<1
Beef ingestion	$2.85*10^{-3}$	$2.10*10^{-3}$	$1.14*10^{-3}$	73
Vegetable ingestion	$1.71*10^{-4}$	$2.05*10^{-3}$	$1.08*10^{-4}$	4
Fruit ingestion	$3.75*10^{-8}$	$7.25*10^{-8}$	$4.04*10^{-8}$	<1
Total	$4.06*10^{-3}$	$5.19*10^{-3}$	$2.29*10^{-3}$	100
Scenario 6 - Effluent Discharge				
Water ingestion	$3.22*10^{-8}$	$5.15*10^{-8}$	$5.29*10^{-9}$	<1
Fish ingestion	$6.60*10^{-6}$	$8.26*10^{-6}$	$2.01*10^{-4}$	100
Total	$6.63*10^{-6}$	$8.31*10^{-6}$	$5.01*10^{-5}$	100

* Results in this column are for dioxin

Table 5-9. Lifetime Average Daily Doses, LADD, of Toxic Equivalents (WHO_{98}-TEQ_{DF}) for exposure pathways evaluated outside of the scenarios for background conditions and stack emissions.

Setting/Exposure Pathway	WHO_{98}-TEQ_{DF} LADD, ng/kg-day
Background Conditions, high end setting	
Milk ingestion	$4.09*10^{-5}$
Chicken ingestion	$2.64*10^{-6}$
Egg ingestion	$3.79*10^{-6}$
Fish ingestion, high ingestion rate	$6.78*10^{-5}$
Stack emissions, high end setting	
Milk ingestion	$4.12*10^{-7}$
Chicken ingestion	$5.92*10^{-8}$
Egg ingestion	$8.31*10^{-8}$
Fish ingestion, high ingestion rate	$6.05*10^{-8}$

Table 5-10. Lifetime Average Daily Doses, LADD, of 2,3,7,8-TCDD ("dioxin"), 2,3,4,7,8-PCDF ("furan") and 2,3,3',4,4',5,5'-HPCB ("PCB") for exposure pathways evaluated outside of the scenarios for the soil contamination and the effluent discharge settings.

Setting/Pathway	Dioxin, ng/kg-day	Furan, ng/kg-day	PCB, ng/kg-day
Soil Contamination			
Milk ingestion	$1.19*10^{-3}$	$8.89*10^{-4}$	$4.77*10^{-4}$
Chicken ingestion	$8.79*10^{-4}$	$7.48*10^{-4}$	$7.39*10^{-4}$
Egg ingestion	$1.09*10^{-3}$	$1.09*10^{-3}$	$9.09*10^{-4}$
Fish ingestion, high ingestion rate	$4.62*10^{-5}$	$2.74*10^{-5}$	$1.17*10^{-3}$
Scenario 6 - Effluent Discharge			
Fish ingestion, high ingestion rate	$2.06*10^{-5}$	$3.44*10^{-5}$	$6.28*10^{-4}$

Table 5-11. Relative magnitude of all exposure pathways evaluated for the background setting and the stack emission, high exposure scenario setting (see table bottom for notes).

Exposure Pathway	Background conditions	Stack emissions	Soil Contamination
Beef Ingestion	1.00	1.00	1.00
Milk Ingestion	0.49	0.48	0.42
Fish Ingestion	0.82	0.07	0.02
Egg Ingestion	0.05	0.10	0.38
Soil Ingestion	0.04	0.10	0.31
Chicken Ingestion	0.03	0.07	0.31
Inhalation	0.02	0.03	<0.01
Vegetable Ingestion	0.02	0.02	0.06
Soil Dermal - high end	<0.01	<0.01	<0.01
Fruit Ingestion	<0.01	<0.01	<0.01
Water ingestion	<0.01	<0.01	<0.01

Notes:
1. 1.00 is the highest pathway, and the values less than 1.00 describe the relation of that pathway to the highest pathway.
2. This table is for the high exposure farm setting only. For the stack emission scenario, the farm was located 500 meters from the stack. Also, the fish ingestion pathway was for the high ingestion rate, 25 g/day, and the soil pathways - dermal and soil ingestion - were for the high contact assumptions only.
3. For the background and stack emission scenarios, results are for TEQs; for the soil contamination scenario, results are for 2,3,7,8-TCDD.

Table 5-12. Cancer risk estimates for the background and stack emission high end scenarios.

Setting/Exposure Pathway	Cancer Risk
Background Conditions, high end setting	
Soil Ingestion	$1.22*10^{-6}$
Soil Dermal Contact	$5.27*10^{-8}$
Inhalation	$2.34*10^{-6}$
Water Ingestion	$2.90*10^{-7}$
Beef Ingestion	$8.30*10^{-5}$
Vegetable Ingestion	$2.36*10^{-6}$
Fruit Ingestion	$3.65*10^{-7}$
Total	$8.96*10^{-5}$
Stack emissions, high end setting	
Soil Ingestion	$3.32*10^{-8}$
Soil Dermal Contact	$3.19*10^{-10}$
Inhalation	$2.68*10^{-8}$
Water Ingestion	$4.19*10^{-10}$
Beef Ingestion	$8.65*10^{-7}$
Vegetable Ingestion	$1.83*10^{-8}$
Fruit Ingestion	$4.05*10^{-9}$
Total	$9.48*10^{-7}$

6. USER CONSIDERATIONS

6.1. INTRODUCTION

The methodology in this document has been earlier described as screening level in terms of theoretical sophistication, but site specific in its application. Chapter 2 described concepts of exposure and assigned values to exposure parameters which define, for purposes of demonstration, a central and a high end exposure pattern. Chapters 3 and 4 described algorithms for the fate, transport, and transfer of dioxin-like compounds, and also assigned parameter values for purposes of demonstration. The methodology was demonstrated in Chapter 5, using exposure and fate and transport parameters which had been laid out in earlier chapters. Those who wish to use the methodology for further analysis of incremental exposures to sources of dioxin-like compounds are now in a position to use the same algorithms, perhaps many of the same parameter values. The purpose of this chapter is to provide guidance on some key issues for potential users.

Section 6.2 discusses the use of the parameter values selected for the demonstration scenarios in Chapter 5 for other applications. Section 6.3 is a sensitivity analysis exercise on the parameters required for algorithms estimating exposure media concentrations. Section 6.4 addresses the issue of mass balance with regard to the source strength terms of the four source categories.

6.2. CATEGORIZATION OF METHODOLOGY PARAMETERS

Table 6-1 lists all the parameters, including names, definitions, and units, that are required for the methodologies of this assessment except the exposure parameters. Exposure parameters are given in Table 2-1 of Chapter 2. Table 6-1 also gives four additional pieces of information for each parameter listed. Three are numerical values which were used in the sensitivity analysis exercises that are described in Section 6.3. below. The parameter values labeled "selected" were the ones used in the demonstration of the methodologies in Chapter 5. Section 6.3. below justifies the high and low values of parameters selected for sensitivity analysis. Other users of this methodology may wish to view these high and low values as reasonable high and low possible values for their applications; note however that the chemical specific parameters are those only for 2,3,7,8-TCDD. The fourth piece of information is a qualitative judgement on the part of the authors of this document as to the appropriateness of using the "selected" parameter values for other assessments. This judgement is categorized in three ways:

1) **First Order Defaults, or FOD:** As defaults, these parameters are independent of site specific characteristics and can be used for any assessment. Also, as first order defaults, it is felt that the values selected for the demonstration scenarios carry a sufficient weight of evidence from current literature such that these values are recommended for other assessments. Several of the chemical specific parameters, such as the Henry's Constant, H, and the organic carbon partition coefficient, Koc, fall into this category. The qualifier above, "current literature", indicates that new information could lead to changes in these values.

2) **Second Order Defaults, or SOD:** Like the above category, these parameters are judged to be independent of site specific characteristics. However, unlike the above category, the current scientific weight of evidence is judged insufficient to describe values selected for demonstration purposes as first order defaults. SOD parameters of principal note are the bioconcentration parameters specific to the chemicals, such the Biota Sediment Accumulation Factor, or BSAF. This parameter translates the ratio of a bottom sediment concentration to a fish tissue concentration. The science is evolving for this parameter, including thought on the extent to which BSAFs generated for one species at one site can be generalized to other sites and/or species, the differences in BSAF between column and bottom feeders, the differences between past and ongoing contamination, and so on. Users should carefully review the justification for the SOD values selected for the demonstration scenarios before using the same values.

3) **Site Specific, or SS:** These parameters should or can be assigned values based on site-specific information. The information provided on their assignment for the demonstration scenarios, and for selection of high and low values for sensitivity analysis testing, is useful for determining alternate values for a specific site. A key class of SS parameters included in Table 6-1 above are the source strength terms - the soil concentrations, effluent discharge rates, and stack emission rates. There are likely to be site-specific applications of this methodology for which detailed information is unavailable. Often the midrange values selected for the demonstration scenarios are suitable for site specific applications when data is unavailable. An example of this category of parameters would be the soil characteristics, such as the porosity, bulk density, and so on.

The exposure parameters have not been categorized as have the contaminant fate and transport/transfer parameters. Assignment of these values are critical as LADD estimates are linearly related to parameter assignments - doubling exposure duration assumptions double LADDs, and so on. All exposure parameters were developed based on information and recommendations in EPA's *Exposure Factors Handbook* (EPA,1989;1997) and *Dermal Exposure Assessment: Principals and Applications* (EPA, 1992). Some of the exposure parameters of

Table 2-1, Chapter 2, are appropriately described as FOD. These include: lifetime, body weights, water ingestion rates, inhalation rates, and an exposure duration for a childhood pattern of soil ingestion. All of the other exposure parameters are better described as either SOD or SS. Attaining site-specific information is recommended for them. However, this is often difficult for site specific assessments and impractical if the procedures in this assessment are used in general assessments. In the absence of site specific information, the following parameters can be considered SOD: adult exposure durations of 9 years for central scenarios (whether they be modeled after "residential" settings or not) and 30 years for high end scenarios (whether "farming" be the model for high end exposures or not), childhood soil ingestion rates, the fruit/vegetable food ingestion rates, the fraction of fruit/vegetable consumption that comes from a home garden, the food preparation factors that were developed for home produced meats, and the fractions of time spent at home (which are applied to inhalation and water ingestion pathways). The remaining exposure parameters pertain to the exposure pathways evaluated as most critical to dioxin exposures. For this reason, users should either pursue site specific information or carefully justify parameter selections in the absence of site specific information. These include the rate of beef, milk, and fish ingestion and the fraction of these food products which are produced at home and hence impacted by the source. Fish ingestion rates for the demonstration of methodologies in this assessment were 8 g/day as the central assumption and 25 g/day for the high end assumption. These were the mean values for the central and upper end ingestion rates from several fish consumption studies characterized as “recreational” fishing studies in EPA (1997). These rates are both more than a national average estimate of fish consumption that was published in an water quality criteria document for 2,3,7,8-TCDD, 6.5 g/day (EPA, 1984). The setting for the demonstration scenarios was a rural setting which contained farm and non-farm residences, and which contained a major water body for recreational fishing purposes. The other parameters are the ingestion rates and contact fractions for beef, milk, chicken, and egg ingestion. The ingestion rates for these food products were developed in EPA (1997) from the 1987-88 National Food Consumption Survey (NFCS) conducted by USDA, and specifically, they were from the “household” portion of the NFCS. This portion of the survey included questions on consumption of home produced foods, which was why it was felt to be appropriate for the demonstration scenarios of this assessment. The contact fractions assigned for the high end scenarios were also developed from information in the household survey of the NFCS.

In addition to the above qualifications, the parameters of this methodology have been categorized in terms of their role in the methodology. The following is a brief description of three principal categories.

Category 1. Human behavior exposure parameters

These are the contact rates, contact fractions, exposure durations, lifetime and body weights used in the following equation for lifetime average daily dose:

$$\text{Lifetime Average Daily Dose (LADD)} = \frac{(\text{exposure media concentration} \times \text{contact rate} \times \text{contact fraction} \times \text{exposure duration})}{(\text{body weight} \times \text{lifetime})} \quad (6\text{-}1)$$

Category 2. Fate, transport, and transfer parameters

These parameters are all the parameters required to estimate exposure media concentrations, except those specifically associated with a contaminant - chemical-specific parameters are included in Category 3 below. All fate, transport, and transfer parameters are listed, defined, and further subcategorized in Table 6-1. Not included in the discussions in Section 6.3 are perhaps the most important terms in this category, and these are critical source strength terms: the concentrations of dioxin-like compounds for the soil contamination scenario, and the release quantities of dioxin-like compounds into the air for the stack emission source category and into the surface water for the effluent discharge source category. A general comment that can be made for fate and transport parameters is that values for the demonstration scenarios were selected to be midrange and plausible, and that this document provides information on selecting alternate values for site-specific applications. Most of the parameters in this category fall under the SS qualification. Subcategories within the fate and transport category include:

- Contaminated and exposure site characteristics: These are areas, soil properties, and depths of tillage (which are depths to which residues transported by erosion or deposition are mixed in conditions of tillage such as agriculture or gardening, and no tillage). Like the soil concentration term, the area of contamination is a site-specific parameter. Soil properties were assigned to be midrange and typical of agricultural soils. Depths of mixing for tilled and untilled circumstances are not known with certainty, and these two parameters were characterized as SOD.

- Soil and sediment delivery parameters: These include parameters associated the erosion of contaminated soil from a site of contamination to a nearby site of exposure and/or to a

nearby surface water body. All but one of the parameters in this subcategory are physical, site-specific parameters which should be evaluated for site specific applications. The one parameter not of this description is the enrichment ratio, which describes the enrichment of eroded soil with dioxin-like compounds, and was assigned a rating of SOD. Geometric parameters include watershed drainage area, water body volumes, and distances. Physical parameters include soil loss estimates, organic carbon contents, water body suspended solids, and background watershed contaminant concentrations.

- Volatilization and dust suspension parameters: These parameters are associated with suspension, dispersion, and transport of contaminants from contaminated soils. One parameter included in this category is the exposure duration, which appears to be misplaced. In fact, the exposure duration is used to determine the average vapor phase air concentration - this is further discussed in Section 6.3 below. Parameters in this category are site-specific and should be evaluated for specific methodology applications.

- Bioconcentration and biotransfer parameters: These include parameters describing the biota and the media surrounding the biota which influence the transfer of dioxin-like compounds from the media to the biota. Some of these parameters are site-specific, although obtaining values may be difficult. Included here are annual rainfall, fish lipid contents, a fresh to dry vegetable weight conversion factor, and yields and intercept fractions for vegetation categories. Others are theoretical; values for these were determined from the literature and can be used for other assessments if better information is unavailable. Included here are atmospheric deposition velocities of particles, washout of wind-suspended particles from the atmospheric, the retention of wet particle depositions on vegetation, empirical correction factors for vapor-phase air-to-plant transfers and soil-to- plant transfers, and the bioavailability of soil as compared to vegetation as a vehicle of transfer of dioxin-like compounds to terrestrial animals. These were given a rating of SOD. A third group describes exposure of the terrestrial animals to dioxin-like compounds through their diet. These include fractions of animal diet which are soil, pasture grass, and feed, and the extent to which these three are impacted by the source of contaminant. Sensitivity analysis below was conducted on beef parameters only, not on the dairy cow, chicken, or egg parameters. It is expected that, in general, the trends should be the same for all the terrestrial animals. The analysis below shows how beef concentrations are impacted by changes in assumptions of how cattle are exposed to dioxin-like compounds through their diet. Since terrestrial animal exposures are most critical for human exposure, the animal exposure assumptions made for demonstrating the methodologies of this assessment should be carefully considered before using them for other assessments.

- Effluent discharge source category: These are three physical parameters that can be determined on a site-specific basis, and include flow rates of the effluent and receiving water body, organic carbon contents of suspended solids in the effluent and the receiving water body, and suspended solids content of the effluent and the receiving water body.

- Stack emission source category: In fact, most of the parameters required to evaluate the impact of stack emissions to a nearby site of exposure have been included in other categories. Sensitivity analysis only focuses on parameters and issues unique to this category. One set of input values are contaminant wet and dry deposition rates. Three depositions are required: one for the site of exposure, one to represent depositions on watershed soils which drain into the water body, and one to represent direct deposition onto the water body. These were all generated using the ISCST3 model, as described in Chapter 3. Two other key inputs generated by the ISCST3 model are the ambient air vapor phase and particle phase concentrations of contaminant at the site of exposure. All such quantities are a function of that model's algorithms and parameter input requirements, particularly the release rate from the stack. Information on the ISCST3 model and its application is given in Chapter 3 and not discussed further in this chapter. Users can determine air concentrations and contaminant deposition rates in other ways, and use those in the methodologies to determine impacts and exposures. The no-till depth of mixing at the site of exposure, d_{not}, is required for the contaminated soil source algorithm as well. It's selected value for the stack emission source category was 2 cm, similar to the 2 cm used in the soil contamination source demonstration. The only other unique parameters not included in other subcategories are the average watershed mixing depth (used for determining watershed soil concentrations, which are then used to determine impacts to water bodies) and the fraction of particles depositing on water bodies which remain in suspension. These are both theoretical values and can be used in other assessments lacking better information.

Category 3. Chemical properties of dioxin-like compounds

The thirteen chemical-specific parameters required for the algorithms of this assessment fall under two categories, FOD and SOD. As such, they are all independent of the specifics of the site. The parameters deemed FOD are chemical fate and transport parameters, some of which are common and often determined in laboratory conditions. These include the Henry's Constant, the organic carbon partition coefficient, and the molecular diffusivity in air. The selected values for these parameters are, in the authors' opinion, the best values derivable from current data. A second set of chemical specific parameters are associated with bioconcentration/biotransfer algorithms. Some of them are determined from field data (data on dioxin-like compounds or

other compounds), and others are determined by experimentation and with that experimentation, development of empirical relationships between a critical transfer factor and the chemical's octanol water partition coefficient. The authors cannot be definitive in a judgement that values given to these parameters be considered default, hence the SOD rating. For these compounds, field/experimental data is conflicting or there simply is a lack of appropriate data. Parameters included in this category are a soil to below ground vegetation transfer factor, two air-to-plant factors: the air-to-leaf vapor phase transfer coefficient and the plant washoff rate constant, two water body to fish parameters: the biota to sediment accumulation factor and the related biota to suspended solids accumulation factor, and the bioconcentration factors for beef, milk, chicken, and eggs. The sorbed fraction was given a "SOD/SS" rating because its assignment is a function of chemical properties as well as an assumption regarding particle density in the airshed. This assessment assumed, "background plus local sources" as the appropriate descriptor for particle density in the airshed. This particle density selection is the site-specific aspect to this parameter assignment. Therefore, for other applications where this airshed particle density is appropriate, users may consider the values for the particle density to be, SOD.

6.3. SENSITIVITY ANALYSIS

Sensitivity analysis was undertaken in order to evaluate the impact of model results with changes in model parameters. The following sections describe the limitations, methodology and parameter selections, and results.

6.3.1. Limitations of the Sensitivity Analysis Exercises

The exercises were not comprehensive and/or definitive. Following are some key limiters:

- **The ISCST3 model was not evaluated in this section.** Chapter 3 describes the ISCST3 model. No sensitivity analysis runs were performed on ISCST3 model output for this chapter. This section does evaluate the impact of different deposition rates and modeled ambient air concentrations on exposure sites soils, surface water, and biota. Chapter 7 describes a model validation exercise on the ISCST3 model, and this exercise includes an evaluation of the impacts of selecting different meteorological data and different source strength terms (i.e., different stack emission rates of dioxins).

- **Sensitivity to changes in exposure parameters was not evaluated.** The basic equation for evaluating lifetime average daily dose was given above as Equation (6-1).

Chapter 2 described all terms in this equation except the exposure media concentration, which was the focus of Chapter 4. Because LADD estimates are a linear function of all exposure parameters, sensitivity analysis was not performed on LADD exposure estimates. The focus of this section instead is on the fate, transport, and bioconcentration/biotransfer algorithms used to estimate the exposure media concentration term in Equation (6-1).

- **The analysis was not exhaustive in its coverage.** Principal algorithms in the fate, transport, and transfer of dioxin-like compounds were evaluated, and all parameters required for algorithms were tested at least once. However, not all possible tests were conducted. Before noting those, following is a list of algorithms which were tested:

  - Volatilization/suspension and transport/dispersion of vapor/particle phase airborne residues from a site of contamination to a site of exposure (using algorithms for the soil contamination source category);

  - Transport via erosion of contaminants at a site of soil contamination to a nearby site of exposure to impact exposure site soils (soil contamination source category);

  - Transport via erosion of contaminants at a site of soil contamination to a nearby surface water body, to impact bottom sediments, water, and fish (soil contamination source category);

  - Transfers of contaminants from soils to below ground vegetables and from air to above ground vegetation (soil contamination source category);

  - Transfers of contaminants from soils to vegetation to beef (soil contamination source category) and from air to vegetation to beef (stack emission source category);

  - Direct discharges of dioxin-like compounds into surface water bodies, and the effect of surface water and effluent parameters on fish and water concentration estimation (effluent discharge source category); and

  - Particle depositions and ambient air concentrations, which result from stack emissions, onto exposure site soils, watershed soils, surface water bodies, and biota (stack emission source category);

The exercise was purposefully limited since several possible exercises would have been duplicative. For example, impacts to terrestrial animal products was limited to an evaluation of the algorithm estimating beef concentrations. Similar trends are expected for the milk, chicken, and egg bioconcentration algorithms. For all the animal pathways, including fish ingestion, the impact to changes in the lipid, or fat, contents was not evaluated in this exercise. All the bioconcentration algorithms estimate the concentration of the dioxin-like compound in fat tissue. The fraction of fat parameters are all required simply to translate a fat concentration to a whole product concentration for purposes of exposure estimation. Therefore, changes to the assumption

of fat contents will translate to a linear change in the estimation of the whole animal product concentration.

A related limitation has to do with the cascading effect of certain parameters. For example, a key contaminant parameter is the organic partition coefficient, Koc, which impacts (among other concentrations) vapor phase air concentrations. Air concentrations are used to estimate above ground vegetation concentrations, including those of grass and cattle feed. Beef concentrations are a function of concentrations in grass and cattle feed. The impact of Koc is evaluated in the context of the soil contamination source category. What is not done in the sensitivity analysis below for this important model parameter (and others as well) is to evaluate the impact of changes in Koc to beef concentrations. What is done, however, is as follows. The sensitivity of air concentration predictions to changes in the partition coefficient are evaluated. Then, the sensitivity to grass and cattle feed concentrations to plus and minus one order of magnitude differences in estimated vapor phase air concentrations are evaluated. In this way, any possible parameter change(s) which influences air concentrations within a plus/minus order of magnitude range is evaluated for grass and feed concentrations. Finally, beef concentration estimations are evaluated within a similar plus/minus order of magnitude change for grass and feed concentrations. With some examination, therefore, the effect of cascading impacts can be determined.

The impact of changing soil concentrations (in the soil contamination source category) to estimates of exposure media concentrations (air, water, biota) is linear and direct in all cases - i.e, increasing soil concentrations by a factor of five increases all impacted exposure media by the same factor of five. For this reason, soil concentrations are not displayed in the sensitivity graphs displayed in the next section, with one exception. This was in the estimation of beef concentrations from soil contamination. Beef concentrations are a function of concentrations in the dry matter diet of the cattle, including soil, grass, and cattle feed. Therefore, if soil concentrations were to change and concentrations on the other intakes were to not change, than beef concentrations would not be a linear and direct function of soil concentrations. However, and in the context of this sensitivity analysis, when changing only soil concentrations, vegetative concentrations are linearly and directly impacted by the same order of magnitude change. Therefore, beef and milk concentrations turn out to be linearly related to soil concentrations.

A final limitation to note is that this exercise does not evaluate the multiple effects of changing more than one independent parameter simultaneously. Other numerical methods, particularly Monte Carlo, can be used to evaluate the impact of simultaneous changes to model

parameters. Applications of this technique to dioxin exposure assessments are discussed in Chapter 8 of this volume.

There are instances where parameters were evaluated as dependent and changes were made simultaneously. One example is in three parameters which are related to the size of a watershed (also termed the "effective drainage area" since such an area might be smaller than a surrounding river system watershed), and which are important in determining the impact of a bounded area of soil contamination to a nearby surface water body. These three include the watershed size, the watershed sediment delivery ratio (which decreases as watershed size increases), and the surface water body volume (which increases as watershed size increases, assuming sources of water - surface runoff, interflow, and groundwater recharge - remain the same on a per unit area basis). To test the impact of watershed size to surface water and sediment concentrations, all three parameters were changed simultaneously in modeling a small and a large watershed. One set of parameters which might not be independent, but which were treated as such in the sensitivity testing, are the chemical specific parameters. For example, a higher organic carbon partition coefficient might be associated with a lower Henry's Constant - tighter binding to soils means less of a tendency to volatilize. Empirical relationships between such chemical specific parameters have not been established, and since there is uncertainty in precise values selected for the dioxin-like compounds, chemical specific parameters were treated as independent parameters.

- **Only a high and a low value for model parameters were tested; no discussions of likelihood for parameter values or distributions of parameter values are included.** Certainly the identification of all model parameters and the justification for assignment of high and low values will be helpful to others using the methodology. Assignment of parameter values for purposes of demonstrating the methodologies in Chapter 5 should be carefully considered when users apply this methodology for specific purposes or specific sites.

6.3.2. Methodology Description and Parameter Assignments

Only two of the six example scenarios of Chapter 5 served as "baselines" in the sensitivity analysis exercises. The single scenario for the soil contamination source category, Scenario 3 in Chapter 5, served as the basis for testing on these algorithms: 1) transport of vapor and particulate phase airborne contaminants from a site of contamination to a nearby site of exposure, 2) transport of soils via erosion to nearby sites of exposure and to surface water bodies to impact bottom sediments, fish, and water, 3) impacts of soil concentrations and other parameters to below ground vegetation, and air concentrations and other parameters to above

ground vegetation, and 4) impacts of soil, grass, and feed concentrations, and other parameters, to beef concentrations. The source strength for this scenario, in summary, was a 40,000 m^2 (4 ha, 10 ac) area of soil concentrations of 1 μg/kg (ppb) within a watershed of size 4,000 ha (40,000,000 m^2; 10,000 ac; 15.5 mi^2) with soils otherwise at 0.0 ppb. Most of the sensitivity analyses focused on predictions that were to occur at the exposure site, which was a farm located 150 meters away. The high end example scenario for the stack emission source category, example scenario #5, served as the basis for the testing the impact of particle depositions and ambient air concentrations on soils and biota. The ambient air concentrations and deposition rates at the site of exposure 500 meters from the stack served as the baseline source strength terms. The single scenario for the effluent discharge source category, example scenario #6, was used to evaluate the impact of parameters required for that source category on fish and water concentrations. The source strength in that case was a discharge of 0.0315 mg/hr into a surface water body with a harmonic mean flow rate of $4.7x10^8$ L/hr. Assignment of that baseline discharge was based on data from the 104 pulp and paper mill study, and then considering reductions is discharges which have occurred in these pulp and paper mills since the 104 mill study in 1988.

The baseline chemical for all these sensitivity runs was 2,3,7,8-TCDD; i.e., all the chemical specific parameters were those assigned to this example compound. The high and low values for parameter testings were determined starting with the 2,3,7,8-TCDD assignments. Care was not taken to encompass a range of possible values for all dioxin-like compounds. However, the ranges that were tested are mostly inclusive of the dioxin-like compounds. What will be noted and discussed below is that mostly the model response to chemical-specific parameters is linear or nearly linear, so that model responses to values outside the ranges tested can be evaluated easily.

All the initial parameter values required for all four source categories, and the values selected for high and low sensitivity analysis were listed above in Table 6-1. Following are brief discussions on the selection of these high and low values. Longer discussions on all parameter values can be found in Chapter 4, which included justifications for all parameter values selected for the demonstration of the methodologies in Chapter 5. Often, ranges of possible values were discussed in Chapter 4; those ranges were the basis of high and low parameter values selected below. Discussions in Chapter 4 are not repeated here, but are referenced below. The summaries below are organized in the same order as the parameter listings in Table 6-1.

● Contaminated and exposure site characteristics: These are the area and distance parameters, and the soil characteristic parameters of the site of contamination and the site of exposure. The "site of contamination" refers to the bounded area of high soil concentration for the soil contamination source category. The "site of exposure" for these sensitivity runs is the small farm which was the basis for the definition of the "high end" example scenarios demonstrated in Chapter 5. The area of the site of exposure, **AES**, and site of contamination, **ASC**, are both 40,000 m^2 in the demonstration scenarios, which is equal to 4 ha or 10 ac. Low and high values tested were 4,000 m^2 (0.4 ha, 1 ac) and 400,000 m^2 (40 ha, 100 ac). The soil description parameters include soil porosity, **ESLP**, particle bulk density, **Psoil**, soil bulk density, **Bsoil**, and the organic carbon fraction, **OCsl**. The assignment of high/low values to these parameters were developed from Brady (1984) and cover a reasonable range of agricultural field soils. The no-till and tillage depths, $\mathbf{d_{not}}$ **and** $\mathbf{d_t}$, refer to the depth to which eroded soil or depositing particulates mix at the site of exposure. The no-till depth was set at 2 cm and was varied between 1 and 10 cm, and the tilled depth was varied between 10 and 30 cm. The no-till concentrations were used to estimate soil concentrations for soil related exposures: soil ingestion and soil dermal contact, and also for the beef and milk bioconcentration algorithm. The tilled concentrations were used only to estimate the concentration in below ground vegetation.

● Soil and Sediment Delivery Parameters: Contaminated soil erodes from a site of contamination, a 4 ha site in the demonstration scenarios, to a nearby site of exposure and also to a nearby river. The distance to the site of exposure from a site of contamination, $\mathbf{DL_e}$, was set at 150 meters for the example scenarios, and varied between 50 and 1000 meters in this exercise. The same initial distance of 150 meters was the distance to the nearby river, $\mathbf{DL_w}$, and it was also varied between 50 and 1000 meters. The unit amount of soil eroding off the site of contamination, $\mathbf{SL_s}$, was initialized at 21520 kg/ha-yr, equal to 9.6 Eng. ton/ac-yr (abbreviated t/ac-yr hereafter). Assumptions inherent in this estimate include: midcontinent range of annual rainfall erosivity (which is also the middle of the range of rainfall intensities of the US), midrange agricultural soil erosivity, a gentle 2% slope, no man-made erosion protection (ditches, etc.), and bare soil conditions. A doubling of this amount to 42,000 kg/ha-yr (19 t/ac-yr) was used as a high erosion estimate off the site of contamination. This could reflect any number of different assumptions, such as more erosive soil, more erosive rainfall, steeper slopes, and so on. A low estimate of one-tenth the default value, at 2100 kg/ha-yr (1 t/ac-yr), could reflect all the same assumptions except a dense cover of grass or weeds, which changes the bare soil

assumption leading to a "C" (cropping management factor) of 1.0 to a C of 0.1. The erosion amount of 2152 kg/ha-yr was the initial amount assumed for a second unit erosion term needed in this assessment, a unit erosion typical of land area between the contaminated and the exposure site, $\mathbf{SL_{ec}}$. The critical assumption in this initialization was that all conditions for this land area were similar to the contaminated site, except that the ground was densely covered with grass or weeds. The value of SL_{ec} was reduced to 0 kg/ha-yr for the low value, which is unrealistically low but might give a sense of how the algorithm would perform if mixing with soil between the contaminated and exposure site were not considered. The high value was 21,000 kg/ha-yr, which is similar to the initial assumption for the contaminated site, could reflect similar erosion conditions between the contaminated site and the exposure site. The third unit soil loss parameter required is one which reflects average erosion conditions within the watershed draining into the water body, $\mathbf{SL_w}$. This was initialized at 6455 kg/ha-yr (2.88 t/ac-yr) which reflects similar erosion conditions as the contaminated site (soil erosivity, rainfall intensity, average slopes, lack of support practices) except some erosion protection due to vegetation - C equal to 0.3 instead of 1.0. It was reduced to 2100 kg/ha-yr, which might translate to C equal to 0.1, and increased to 21,000, which was equal to the initial higher erosion from the contaminated site. The range of the enrichment ratio, ER, was noted at between 1 and 5 for its application in agricultural runoff field data and model simulations, and was given an initial value of 3 in this application. High and low values tested were 5 and 1. An average watershed concentration of contaminant was set at 0 for the soil contamination demonstration scenarios, where the soil concentration of 2,3,7,8-TCDD (and the other example compounds) was set at 1 ppb. This was selected so that the impact to surface water bodies could be demonstrated as an incremental impact. A concentration of 2,3,7,8-TCDD of 1 ppt was chosen to represent "background" conditions. This value is near the 0.3 ppt that was measured in the background setting near Columbus, Ohio, and used in the demonstration of the background scenarios. The value was used to evaluate the impact of a bounded site at 1 ppb when a background concentration of 1 ppt is also assumed to exist. Four parameters reflect watershed size. These include the effective drainage area, $\mathbf{A_w}$, the watershed sediment delivery ratio, $\mathbf{SD_w}$, the volume of the receiving water body, $\mathbf{VOL_w}$, and the surface area of the water body, $\mathbf{AREA_w}$. These are related and should therefore be changed in tandem. The initial watershed size of 100,000 ha (385 mi^2) was reduced to 10,000 ha (39 m^2) and increased to 1,000,000 ha (3850 mi^2). Since the water body volume was estimated using a in/yr runoff times an area, it was concurrently reduced 1 order of magnitude for the small watershed test and increased one order of magnitude for the large watershed. The surface area of the water body was also increased or reduced by an order of

magnitude with the concurrent change in water body volume. The values of SD_w were estimated using Figure 4-4 (Chapter 4), which shows watershed delivery ratios as a function of watershed area. The remaining three parameters further described the water body, and were the total suspended solids, **TSS**, and the organic carbon contents of suspended and bottom sediments, $\mathbf{OC_{ssed}}$ and $\mathbf{OC_{sed}}$. The initial value of TSS of 10 mg/L is typical of a moving water body (stream, river) supportive of fish and other aquatic life. It was reduced to 2 mg/L, which is typical of a stationary water body (pond, lake, reservoir) and increased to 50 mg/L, which begins to be high for a water body expected to be supportive of fish. The organic carbon contents were initialized at 0.05 for OC_{ssed} and 0.03 for OC_{sed}. The premise was that they were related - that sediments in suspension were lighter and likely to be higher in organic carbon content than bottom sediments. They were also changed in tandem to 0.02 (OC_{ssed}) and 0.01 (OC_{sed}) for a low organic carbon sensitivity test and 0.10 and 0.05 for a high organic carbon test.

● Volatilization and Dust Suspension Parameters: Distances and areas are pertinent to estimating vapor-phase and particulate-phase air concentrations, and these have been discussed above in the first two categories. One parameter included for sensitivity testing in this category is the exposure duration, **ED.** It is included in these exercises because the estimation of average volatilization flux over a period of time is a function of that period of time. The derivation of the flux model assumed contamination originates at the soil surface at time zero, and over time, originates from deeper within the soil profile. Therefore, the flux decreases over time (because residues have to migrate from deeper in the profile), and the average flux over a period of time will decrease as that period of time increases. This is further discussed in Chapter 4, Section 4.3.3., and in the original citation for the volatilization flux algorithm, Hwang, et al. (1986). The exposure duration assumed in the high end scenarios was 30 years, this was changed to 1 and 70 years in sensitivity tests. A range of average windspeeds, $\mathbf{U_m}$, around the U.S. was noted at 2.8 and 6.3 m/sec, and these two values were used around the selected value of 4.0 m/sec. The frequency with which wind blows from a site of contamination to a site of exposure, **FREQ**, was set at 0.15, which is appropriate if one assumes that wind blows in all directions roughly equally. It was changed to 0.05 and 0.50, which might translate to an assumption of a prevailing wind direction, either away from or towards a site of exposure. The remaining parameters, fraction of vegetative cover, **V**, threshold wind speed, $\mathbf{U_t}$, and model specific function, **F(x)**, all refer to the wind erosion algorithm which suspends contaminated particulates into the air. Sensitivity tests were applied to this trio for the on-site and the off-site source categories. V for the off-site scenario was initialized at zero, implying bare ground cover; it was increased to 0.9 reflecting

dense ground cover in the single sensitivity test here. It was set at 0.5 for the on-site small farm demonstration scenario, reflecting some bare ground conditions (in the agricultural fields, e.g.) as well as some dense vegetation (in other grassed areas of the farm property). It was decreased to 0 and increased to 0.9. The parameters U_t and F(x) reflect intrinsic erodibility of the soil and were varied together. Values were selected to reflect a high and low wind erodibility soil, following guidance in EPA (1985), the primary reference for the wind erosion algorithm.

● Bioconcentration and Biotransfer Parameters: Several parameters are required for the vegetation concentration algorithm, most of which were associated with the algorithm for dry plus wet deposition of particulates in the soil contamination source category. One parameter not associated with fate and transport was the dry to fresh weight conversion factor, **FDW**. The algorithm calculates vegetative matter concentrations on a dry weight basis, which is appropriate for the role of vegetation in the beef/milk bioconcentration algorithm. However, ingestion rates of fruits and vegetables are on a fresh weight basis, so dry weight concentrations have to be converted to a fresh weight basis. The initial value of 0.15 assumes that fruits and vegetables are 85% liquid. The high and low values tested for this parameter were 0.30 (70% liquid) and 0.05 (95% liquid). Four parameters are described as empirical correction factors for the air-to-leaf algorithm adopted for vapor phase transfers to vegetation (three of the parameters), and for the soil-water-to-root algorithm adopted for below ground vegetation. There is one each for the four principal vegetation considered: below ground vegetables/fruits - $\mathbf{VG_{bg}}$, above ground vegetables/fruits - $\mathbf{VG_{vg}}$, grass - $\mathbf{VG_{gr}}$, and feed - $\mathbf{VG_{ctfd/chfd}}$ (cattle and chicken feed, respectively). The concept for assignment of values to these parameters was the same, and briefly is as follows. The principal biotransfer factors, vapor phase air-to-leaf and soil-water-to-root, were developed for relatively thin vegetation, grass leaves for air-to-leaf transfers and barley roots for soil-water-to-root transfers. Concurrently, there is evidence that the strongly hydrophobic/lipophilic dioxin-like compounds are found only in outer portions of vegetation and not inner portions of bulky vegetation; there is very little translocation of dioxin-like compounds into and within vegetation. Therefore, the full vegetation concentrations of bulky vegetation are expected to be much lower than the concentrations that would be found in their thin outer layers. For above ground bulky fruits/vegetables, two considerations were included in the final assignment of 0.01 to VG_{vg}: 1) a surface area to volume ratio based on this tendency not to translocate into innner portions of the vegetation, and 2) additional reductions in whole fruit/vegetable concentrations that would occur due to washing or peeling. For bulky below ground vegetation, a final value of 0.25 was selected based on: 1) again, this tendency not to translocate into inner portions of below ground

vegetation, and 2) experimental evidence on carrots and potatoes that did indicate more within plant translocations than have been measured for above ground vegetation. The above ground VG_{ag} was reduced to 0.001 and increased to 0.10 in sensitivity testing, and the below ground VG_{bg} was reduced to 0.01 and increased to 1.00. The VG_{gr} was set at 1.00 since the air-to-leaf vapor transfer factors were developed from data on grass, so no correction is warranted. Although there is no justification to change VG_{gr}, a lower value of 0.50 was chosen simply for illustration. The VG_{ctfd} was set at 0.50, recognizing that some cattle feed is unprotected and thin vegetation such as the leaves in silage, while others are protected grains such as corn grain. That value was changed to 0.25 and 0.75 in sensitivity testing. There is one required parameter for the dry deposition algorithm, and this is the particle deposition velocity by gravity settling, V_p, in m/yr. The initial value of 3.2×10^5 m/yr, from a velocity assumption of 1 cm/sec, was given by Seinfeld (1986) as the gravitational settling velocity for 10 μm particles. This is the appropriate size to consider since the wind erosion algorithm was developed only for inhalable size particulates, those less than 10 μm (EPA, 1985). This was reduced to 0.5 cm/sec and 2 cm/sec (transformed to m/yr) for sensitivity testing. Three of the vegetation bioconcentration parameters are associated with the particulate wet deposition algorithm. These are the atmospheric washout ratio, $\mathbf{W_p}$, the retention of particles on vegetation, $\mathbf{R_w}$, and the annual rainfall amount, **R**. The definition, derivation, and ranges for these values are described in Chapter 4, Section 4.3.4.2, and are not repeated here (the ranges are given in Table 6.1). The remaining bioconcentration parameters are the yield and crop intercept values for the three above ground vegetation: vegetables/fruits ($\mathbf{Y_{veg}}$, $\mathbf{INT_{veg}}$), grass ($\mathbf{Y_{gr}}$, $\mathbf{INT_{gr}}$), and cattle feed ($\mathbf{Y_{ctfd}}$, $\mathbf{INT_{ctfd}}$). Again, discussions of chosen, and high and low, values for these quantities are given in Chapter 4, Section 4, and displayed in Table 6.1. It is noted that these two terms are correlated - high yields are correlated with high interception amounts. In sensitivity testing, therefore, these parameters were changed in tandem.

The remaining bioconcentration/biotransfer parameters are for the terrestrial animal bioconcentration algorithms, for beef, milk, chicken, and eggs. For the sake of brevity, only the beef bioconcentration algorithm will be evaluated. The trends found in the testing of this algorithm are expected to be duplicated for the other terrestrial animal products. One of the parameters relates the bioavailability of soil relative to the bioavailability of vegetation, where bioavailability refers to the efficiency of transfer of a contaminant attached to a vehicle. Fries and Paustenbach (1990) developed the bioconcentration factor, BCF, from studies where cattle were given contaminated feed. The studies of McLachlan, et al. (1990), from which BCFs for dioxin congeners were derived and used for this assessment, also used standard cattle feeds. This
