4A-1. AMBIENT OZONE MONITORING AND AIR QUALITY DATA

This section provides a brief overview of ambient O₃ monitoring in the U.S. (Section 4A-1.1), the ambient O₃ concentration data extracted for use in the risk and exposure assessments (Section 4A-1.2), and the data handling procedures used for determining compliance with the existing and potential alternative standards as well as some other relevant air quality metrics (Section 4A-1.3).

4A-1.1 Overview of Ambient Ozone Monitoring

The Clean Air Act establishes air quality monitoring requirements to provide information on ambient concentrations for six criteria pollutants, including O₃, and makes provisions for the collection of other ambient air quality measurements, such as O₃ precursors. The federal regulations for ambient air quality monitoring, including establishment and periodic assessment of local monitoring networks, approved monitoring methods, operating schedules, and protocols for data reporting, quality assurance, and certification, are in Part 58 of the Code of Federal Regulations.

There were over 1,300 ambient O₃ monitoring sites actively operating in the U.S. in 2010. These monitoring sites are operated by over 100 federal, state, local, and tribal agencies, and can be grouped into one of the following networks:

- 1) State and Local Air Monitoring Stations (SLAMS): Monitoring sites operated by state, local, and tribal governments for the purposes of determining compliance with the National Ambient Air Quality Standards (NAAQS), and providing ambient air quality information to help state and local public health agencies evaluate and implement air quality control programs. There were over 1,100 SLAMS O₃ monitoring sites operating in 2010, making up over 80% of the U.S. ambient O₃ monitoring network. There are two important subcategories of SLAMS monitors:
 - a. National Multi-pollutant Monitoring Network (NCore): Approximately 80 monitoring sites (60 urban and 20 rural) operated by state and local agencies. These sites monitor six criteria pollutants (CO, NO₂, O₃, SO₂, PM₁₀, and PM_{2.5}) and other important parameters for the purposes of assessing multi-pollutant impacts on public health, and supporting air quality forecasting.
 - b. Photochemical Assessment Monitoring Stations (PAMS): Approximately 80 monitoring sites operated by state and local agencies with EPA funding. These sites monitor O₃ and its precursors, including NO, NO₂, total NO_x, total reactive nitrogen (NO_y), and over 60 volatile organic compounds (VOCs) for the purposes of understanding O₃ chemistry and transport, aiding photochemical modeling, and

evaluating O₃ precursor emissions control strategies in areas designated nonattainment for the O₃ NAAQS. Some PAMS monitoring sites are co-located with NCore monitoring sites.

- 2) Clean Air Status and Trends Network (CASTNET): Approximately 80 O₃ monitoring sites operated year-round by EPA and the National Park Service (NPS) for the purpose of determining O₃ levels in national parks and other rural areas.
- 3) Special Purpose Monitoring Stations (SPMS): These monitoring sites are used to support various air quality monitoring objectives, such as specific public health and welfare impacts studies, model evaluation, or monitoring network assessments. These monitoring sites are often operated on a temporary basis (up to 24 months), and are generally not used to determine compliance with the NAAQS. Some of these monitoring sites may be operated by local industry or other private interest groups.

SLAMS monitoring sites are required to monitor for O₃ only during the required O₃ monitoring season, which is defined for each state in Table D-3 of 40 CFR Part 58. Many states also operate their O₃ monitors outside of the required O₃ monitoring season. States that are required to operate some or all of their O₃ monitors on a year-round basis include Arizona, California, Hawaii, Louisiana, New Mexico, and Texas. EPA regional offices may approve waivers effectively shortening the length of the required O₃ monitoring season for some individual monitoring sites (e.g. rural monitoring sites which may be inaccessible during the winter months). CASTNET and NCore monitoring sites are typically operated on a year-round basis.

The Federal Reference Method (FRM) for O₃ measurement is the Chemiluminescence Method (CLM). The first ultraviolet (UV) absorption photometric analyzers were approved as Federal Equivalent Methods (FEMs) in 1977 and gained rapid acceptance for NAAQS compliance purposes due to ease of operation, relatively low cost, and reliability. All SLAMS and CASTNET O₃ monitoring sites in the U.S. have been operating UV analyzers since 2005.

Figure 4A-1 shows the locations of the ambient O₃ monitoring sites used in the risk and exposure assessments. Gray dots represent SLAMS monitoring sites, green dots represent CASTNET sites, blue dots represent NCore and/or PAMS monitoring sites, and black dots represent SPMS and other monitoring sites for which data were available.

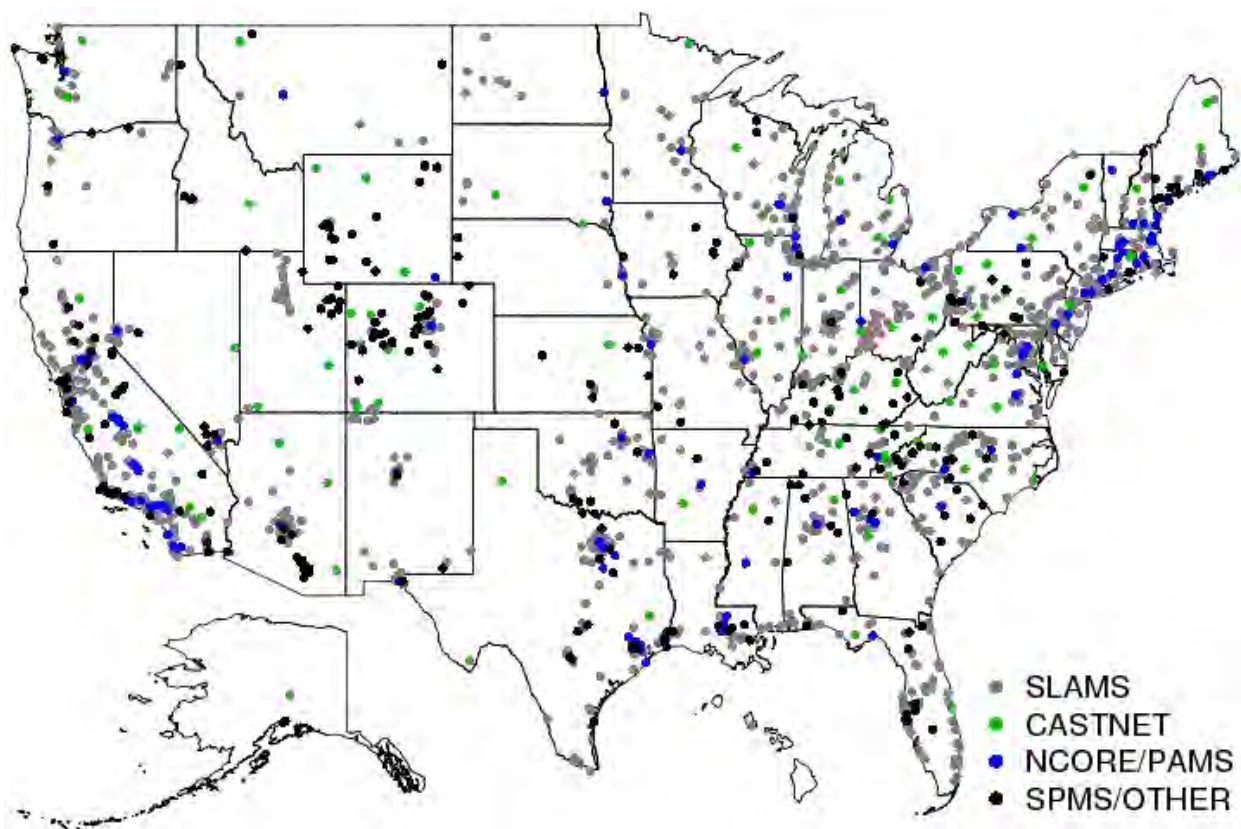

Figure 4A-1. Map of U.S. ambient O₃ monitoring sites in operation during the 2006-2010 period.

4A-1.2 Ambient Ozone Concentration Data

EPA's Air Quality System (AQS) database is a national repository for many types of air quality and related monitoring data. AQS contains monitoring data for the six criteria pollutants dating back to the 1970's, as well as more recent additions such as PM_{2.5} speciation, air toxics, and meteorology data. As of 2010, over 100 federal, state, local, and tribal agencies submitted hourly O₃ concentration data collected from over 1,300 ambient monitoring sites to AQS.

Air quality monitoring data from 1,468 ambient O₃ monitoring sites in the U.S. were extracted for use in the risk and exposure assessments. The initial dataset consisted of hourly O₃ concentrations in ppb collected from these monitors between 1/1/2006 and 12/31/2010. Data for nearly 1,400 of these monitors were extracted from the AQS database in October 2012, and the remaining data were extracted from the CASTNET database at the same time. CASTNET monitors operated by the National Park Service were included in the data extracted from AQS, but the CASTNET monitors operated by EPA did not begin reporting data to AQS until 2011. Data collected from these EPA operated CASTNET monitors prior to 2011 did not meet EPA's quality assurance requirements, but the data were subject to quality assurance criteria, and it is

generally agreed that data collected from CASTNET monitors prior to 2011 is of comparable quality to the regulatory data stored in AQS.

There were a number of subtle, yet noteworthy differences between the air quality data used in the 1st draft REA and the air quality data used in this draft.

1. In the 1st draft REA, multiple AQS data extractions were used for the air quality inputs to various parts of the risk and exposure assessments. In this draft, all air quality inputs were derived from the data extraction described above.
2. In the 1st draft REA, data collected from EPA operated CASTNET sites and other non-regulatory monitoring sites were not included in the air quality inputs to the risk and exposure assessments. In this draft, these monitors were included, but were not used to make determinations of meeting the existing standard or the potential alternative standards.
3. In the 1st draft REA, data collected with O₃ analyzers not using federal reference or equivalent methods were not included in the air quality inputs to the risk and exposure assessments. In this draft, these monitors were included, but were not used to make determinations of meeting the existing standard or the potential alternative standards.
4. In the 1st draft REA, reported hourly O₃ concentrations lower than the minimum detection limit (MDL, 5 ppb for most O₃ analyzers) were replaced with a value of ½ MDL. This is called the “standard sample value” for criteria pollutant data extracted from AQS. In this draft, the actual reported sample values were used, effectively allowing concentrations down to 0 ppb.
5. In the 1st draft REA, hourly O₃ concentrations flagged by the monitoring agencies and concurred by EPA as having been affected by exceptional events were removed from the air quality inputs to the risk and exposure assessments. In this draft, these data were included, but were not used to make determinations of meeting the existing standard or the potential alternative standards, which is consistent with EPA’s exceptional events policy.
6. In this draft, missing data gaps of 1 or 2 hours in length were filled in using linear interpolation. These short gaps often occur at regular intervals in the ambient data due to an EPA requirement for monitoring agencies to perform routine quality control checks on their O₃ monitors. Quality control checks are typically performed between midnight and 6:00 AM when O₃ concentrations are low. Missing data gaps of 3 hours or more in length were not replaced, and interpolated values were not used to make determinations of meeting the existing standard or the potential alternative standards.
7. In this draft, hourly O₃ concentrations from 7 monitoring sites where multiple O₃ analyzers were operated simultaneously in the same physical location were combined to

create a single hourly site record using the highest reported hourly concentration in each hour.

8. In some instances, EPA regional offices may approve the data combinations for pairs of nearby O₃ monitoring sites affected by short distance site relocations for the purpose of making NAAQS determinations. In this draft, hourly O₃ concentrations from 12 such pairs of monitoring sites were combined to create a single hourly site record for each pair.

4A-1.3 Data Handling

To determine whether or not the NAAQS have been met at an ambient air quality monitoring site, a statistic commonly referred to as a “design value” must be calculated based on 3 consecutive years of data collected from that site. The form of the existing O₃ NAAQS design value statistic is the 3-year average of the annual 4th highest daily maximum 8-hour O₃ concentration in ppb, with all decimal digits truncated. The existing O₃ NAAQS are met at an ambient monitoring site when the design value is less than or equal to 75 ppb. The data handling protocols for calculating design values for the existing O₃ NAAQS are in 40 CFR Part 50, Appendix P. In counties or other geographic areas with multiple monitors, the area-wide design value is defined as the design value at the highest individual monitoring site, and the area is said to have met the NAAQS if all monitors in the area are meeting the NAAQS. The initial hourly O₃ concentration dataset was split into two design value periods, 2006-2008 and 2008-2010, and subsequent analyses were conducted independently for these two periods. The following daily summary statistics were calculated from the hourly O₃ concentrations:

1. Daily Maximum 8-hour Average (MDA8) Concentration: There are 24 consecutive 8-hour periods in each day (midnight – 8:00 AM, 1:00 AM – 9:00 AM, ..., 11:00 PM – 7:00 AM). Rolling 8-hour averages were calculated for each period with 6, 7, or 8 hours of data available, using 6, 7, or 8 as the divisor, respectively, and 8-hour periods with fewer than 6 hours of data available were not used. The 8-hour average values were stored in the 1st, or start, hour of the 8-hour period. The MDA8 value is the highest of the 8-hour average values for each day, and the MDA8 values for two consecutive days may have some hours in common. MDA8 values were considered to be valid if there were sufficient data available to calculate at least 18 of 24 possible 8-hour averages, or, if used for design value calculations, if the MDA8 value is greater than the level of the standard. This is the daily metric used in design values and the Smith et al. (2009) short-term mortality study.
2. Daily 10:00 AM – 6:00 PM Mean Concentration: This is the rolling 8-hour average value as defined above for the 8-hour period starting at 10:00 AM. This is the daily metric used in the Zanobetti and Schwartz, 2008 short-term mortality study.

3. Daily Maximum 1-hour Concentration: This is the highest hourly O₃ concentration reported during a given day. Daily Maximum 1-hour values were considered to be valid if there were at least 18 hourly O₃ concentrations reported in a given day. This is the daily metric used in the Jerrett et al. (2009) long-term mortality study.
4. Daily 24-hour Average Concentration: This is the simple arithmetic average of the hourly O₃ concentrations reported during a given day. Daily 24-hour average values were considered to be valid if there were at least 18 hourly O₃ concentrations reported in a given day. This is the daily metric used in the Bell et al. (2004) short-term mortality study.

The daily summary statistics described above were then used to calculate the following annual summary statistics:

1. Annual 4th Highest MDA8 Concentration: This is the 4th highest valid MDA8 value measured at a given monitoring site in a given year. The 4th highest MDA8 values were considered to be valid if there were valid MDA8 values available for at least 75% of the days in the required O₃ monitoring season, or, if used for design value calculations, if the 4th highest MDA8 value was greater than the level of the standard. Data collected outside of the required O₃ monitoring season were used in determining the 4th highest MDA8 value, but were not used in determining validity.
2. May – September Average MDA8: This is the average of all available valid MDA8 values at a given monitoring site during the May – September period (153 days). The May – September average MDA8 values were considered to be valid if valid MDA8 values were available for at least 114 days (75%) in May – September of a given year. Three-year averages of these values were calculated for the 2006-2008 period and used to create the May – September average MDA8 national fused air quality surface described in Appendix 4C. This surface was then used in the national-scale risk assessment based on Smith et al. (2009) described in the Health Risk and Exposure Assessment (HREA) Chapter 8.
3. June – August Average Daily 10:00 AM – 6:00 PM Mean: This is the average of all available daily 10:00 AM – 6:00 PM mean values at a given monitoring site during the June – August period (92 days). The June – August average daily mean values were considered to be valid if daily 10:00 AM – 6:00 PM mean values were available for at least 70 days (75%) in June – August of a given year. Three-year averages of these values were calculated for the 2006-2008 period and used to create the June – August average daily 10:00 AM – 6:00 PM mean national fused air quality surface described in

Appendix 4C. This surface was then used in the national-scale risk assessment based on Zanobetti and Schwartz (2008) described in HREA Chapter 8.

4. April – September Average Daily Maximum 1-hour Concentration: This is the average of all available valid daily maximum 1-hour values at a given monitoring site during the April – September period. The April – September average daily maximum 1-hour values were considered to be valid if valid daily maximum 1-hour values were available for at least 137 days (75%) in April – September of a given year. Three-year averages of these values were calculated for the 2006-2008 period and used to create the April - September average daily maximum 1-hour national fused air quality surface described in Appendix 4C. This surface was then used in the national-scale risk assessment based on Jerrett et al. (2009) described in HREA Chapter 8.

The design value statistic for the existing O₃ standard is the 3-year average of the annual 4th highest MDA8 values described above. Design values greater than the level of the existing standard (76 ppb or higher) are automatically valid. Design values less than or equal to the level of the existing standard must be based on 3 valid 4th highest MDA8 values, with the additional requirement that the 3-year average of the annual data completeness statistics (percent of valid MDA8 values within the required O₃ monitoring season) must be at least 90%. These same criteria were chosen to determine design values for the potential alternative standards. The implications of this choice are that in some cases, a monitoring site may have different design values based on the level of the standard. This may occur for one of two reasons:

1. A monitoring site with insufficient data to determine a design value at higher standard level may have sufficient data to show a violation at a lower standard level. For example, if a monitoring site has a 3-year average annual 4th highest MDA8 value of 72 ppb, but does not meet the data completeness criteria described above, then the site has a design value of 72 ppb for the potential alternative standards of 70 ppb, 65 ppb, and 60 ppb, but does not have a design value for the existing standard of 75 ppb.
2. EPA's current practice is to use only "valid" MDA8 values when determining the annual 4th highest MDA8 value. A valid MDA8 value is either based on at least 18 of 24 possible 8-hour average values, or it is greater than the level of the standard. This can cause the design value to change based on the level of the standard, due to whether certain days are considered valid or not. For example, suppose the five highest MDA8 values at a particular monitoring site for a given year are 78 ppb, 76 ppb, 75 ppb, 74 ppb, and 70 ppb, but the 4th highest value is based on only 12 valid 8-hour averages. Then for the existing standard, the 4th highest MDA8 value is 70 ppb, but for the 70 ppb alternative standard, the 4th highest MDA8 value is 74 ppb.

Figure 4A-2 and Figure 4A-3 show the design values for the existing O₃ NAAQS for all regulatory monitoring sites in the U.S. for the 2006-2008 and 2008-2010 periods, respectively. In general, O₃ design values were lower in 2008-2010 than in 2006-2008, especially in the Eastern U.S. There were 518 O₃ monitors in the U.S. with design values above the existing standard in 2006-2008, compared to only 179 in 2008-2010.

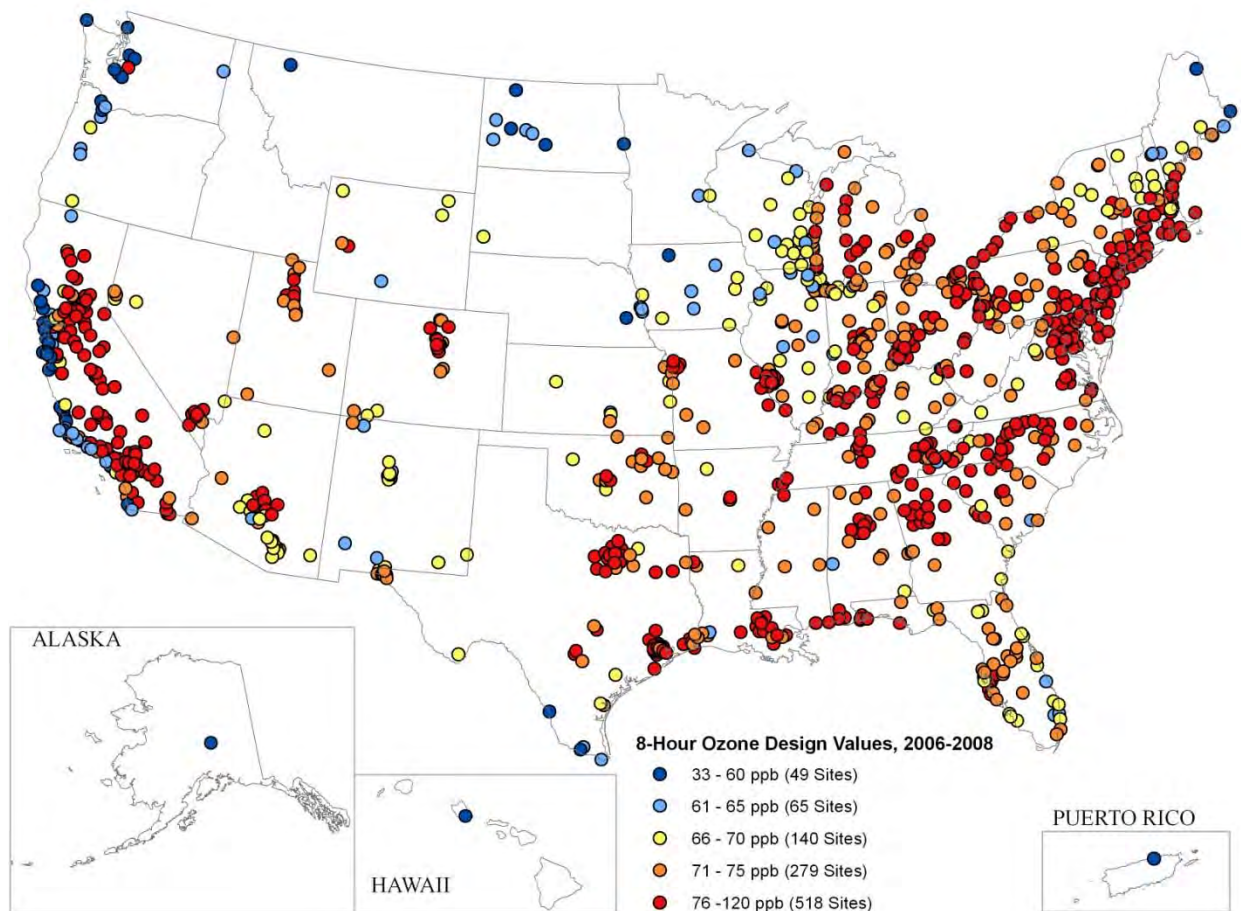

Figure 4A-2. Map of monitored 8-hour O₃ design values for the 2006-2008 period.

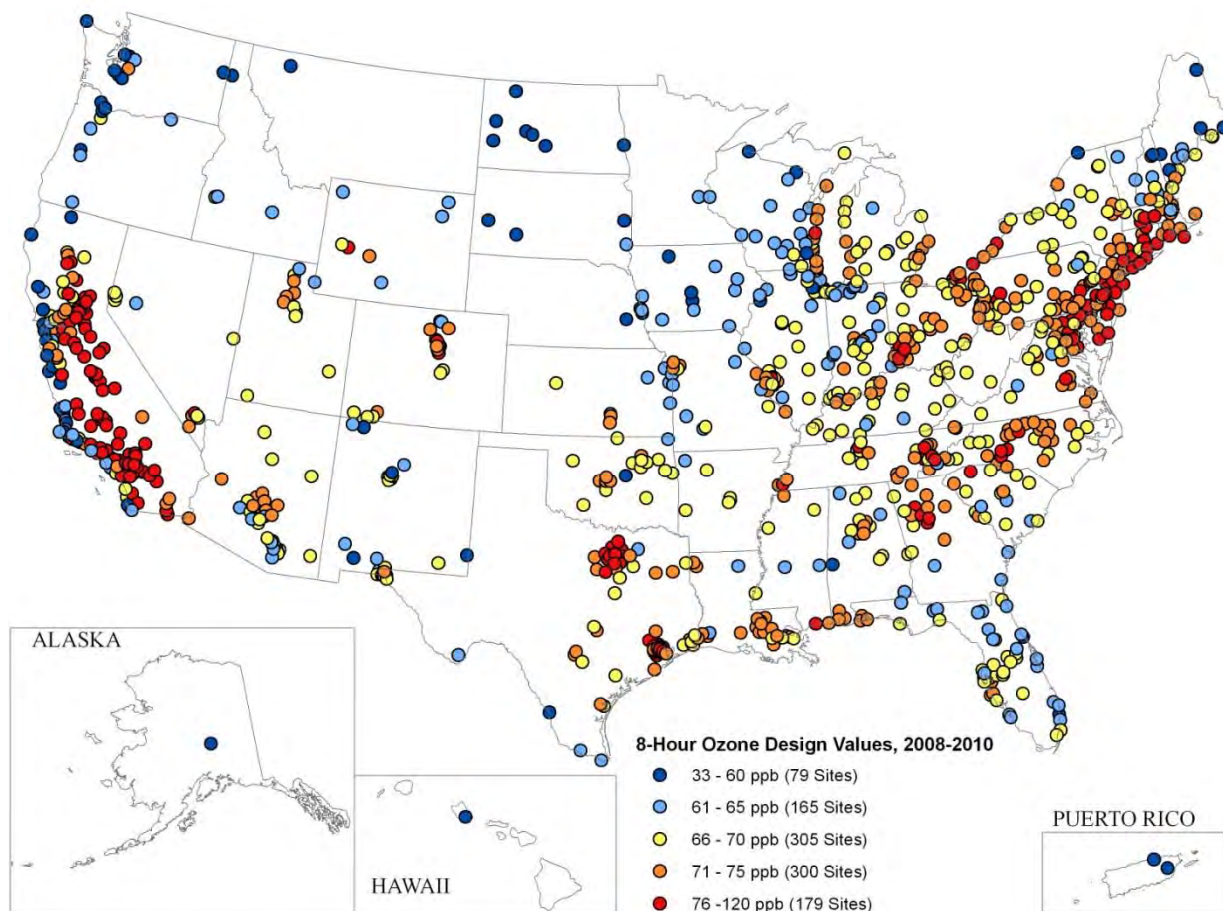

Figure 4A-3. Map of monitored 8-hour O₃ design values for the 2008-2010 period.

4A-2. AIR QUALITY INPUTS FOR THE EXPOSURE AND CLINICAL-BASED RISK ASSESSMENTS

This section describes the 15 urban case study areas used in the exposure and clinical risk assessments described in the HREA Chapters 5 and 6 (Section 4A-2.1), the hourly O₃ concentration spatial fields used as inputs to the Air Pollutants Exposure Model (APEX; Section 4A-2.2), and some methods evaluations supporting the change from nearest neighbor to the Voronoi Neighbor Averaging (VNA) technique for generating the spatial fields (Section 4A-2.3).

4A-2.1 Urban Case Study Areas

The 15 urban case study areas in the exposure (HREA Chapter 5) and clinical risk (HREA Chapter 6) assessments covered a large spatial extent, with boundaries generally similar to those covered by the respective Combined Statistical Areas (CSA) defined by the U.S. Census Bureau. Table 4A-1 gives some basic information about the 15 urban case study areas in the

exposure and clinical risk assessments, including the number of counties, number of ambient O₃ monitoring sites, the required O₃ monitoring season, and the 2006-2008 and 2008-2010 design values. All 15 urban case study areas had 8-hour O₃ design values above the existing standard in 2006-2008, while 13 areas had 8-hour O₃ design values above the existing standard in 2008-2010. Chicago (74 ppb) and Detroit (75 ppb) had design values meeting the existing standard during the 2008-2010 period. The design values in the 15 urban areas decreased by an average of 6 ppb between 2006-2008 and 2008-2010, ranging from no change in Sacramento to a decrease of 15 ppb in Atlanta.

Table 4A-1. Information on the 15 Urban Case Study Areas in the Exposure and Clinical Risk Assessments.

Area Name	# of Counties	# of O ₃ Monitors	Population (2010)	Required O ₃ Monitoring Season	2006-2008 DV (ppb)	2008-2010 DV (ppb)
Atlanta	33	13	5,618,431	March - October	95	80
Baltimore	7	7	2,710,489	April - October	91	89
Boston	10	14	5,723,468	April - September	83	77
Chicago	16	26	9,686,021	April - October	78	74
Cleveland	8	13	2,881,937	April - October	82	77
Dallas	11	20	6,366,542	January - December	89	86
Denver	13	26	3,390,504	March - September	86	77
Detroit	9	12	5,218,852	April - September	81	75
Houston	10	22	5,946,800	January - December	91	85
Los Angeles	5	54	17,877,006	January - December	119	112
New York	27	31	21,056,173	April - October	90	84
Philadelphia	15	19	7,070,622	April - October	92	83
Sacramento	7	26	2,755,972	January - December	102	102
St. Louis	17	17	2,837,592	April - October	85	77
Washington	26	22	5,838,518	April - October	87	81

4A-2.2 Air Quality Inputs to the Air Pollutants Exposure (APEX) Model

The Air Pollutants Exposure Model (APEX) described in HREA Chapter 5 requires spatial fields of air quality concentrations with no missing values as inputs. In the 1st draft REA, the spatial fields were generated using hourly O₃ concentrations from the nearest available monitoring site for each census tract in four of the 15 urban case study areas (Atlanta, Denver, Los Angeles, and New York). Here, the spatial fields were generated with hourly O₃ concentrations interpolated using the Voronoi Neighbor Averaging (VNA; Gold, 1997; Chen et al., 2004) technique described below for each census tract in the 15 urban case study areas. The following paragraphs provide a numerical example of VNA used to estimate an O₃ concentration value for census tract “E” in Figure 4A-4 below.

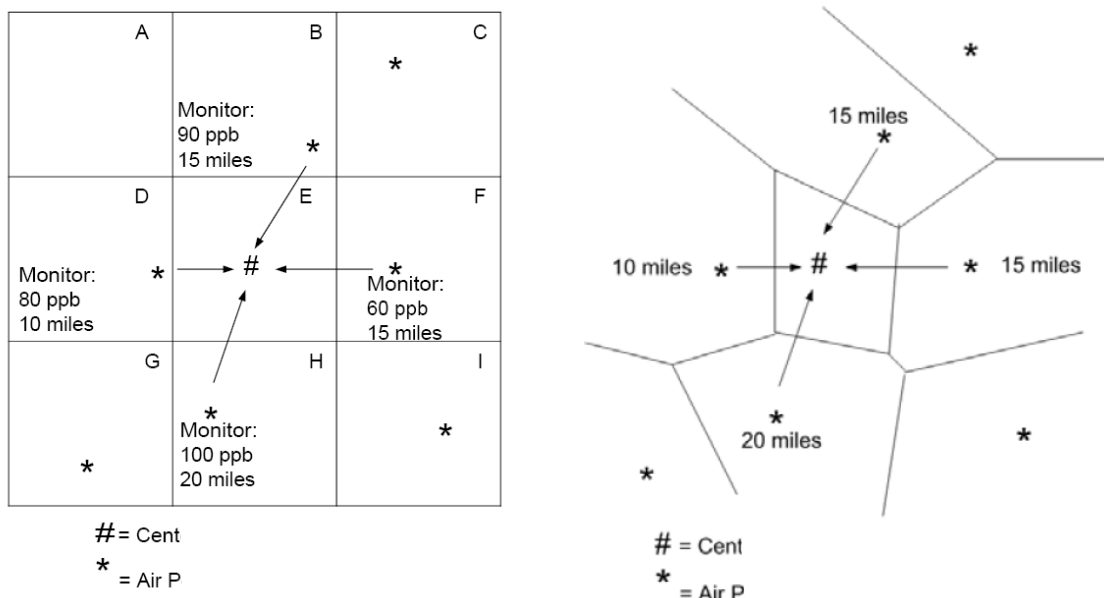

Figure 4A-4. Numerical example of the Voronoi Neighbor Averaging (VNA) technique.

The first step in the VNA technique is to identify the set of nearest monitors for each census tract. The left-hand panel of Figure 4A-4 presents a numerical example with nine census tracts (squares) and seven monitoring sites (stars), with the focus on identifying the set of nearest neighboring sites to census tract “E” in the center of the panel. The Delaunay triangulation algorithm identifies the set of nearest neighboring monitors by drawing a set of polygons called the “Voronoi diagram” around the census tract “E” centroid and each of the monitoring sites. Voronoi diagrams have the special property that each edge of each of the polygons are the same distance from the two closest points, as shown in the right-hand panel of Figure 4A-4.

The VNA technique then chooses the monitoring sites whose polygons share a boundary with the census tract “E” centroid. These monitors are the “Voronoi neighbors”, which are used to estimate the concentration value for census tract “E”. The VNA estimate of the concentration value in census tract “E” is the inverse distance squared weighted average of the four monitored concentrations. The further the monitor is from the center of census tract “E”, the smaller the weight. For example, the weight for the monitor in census tract “D” 10 miles from the census tract “E” centroid is calculated as follows:

$$\frac{1/10^2}{1/10^2 + 1/15^2 + 1/15^2 + 1/20^2} = 0.4675 \quad \text{Equation (4A-1)}$$

The weights for the other monitors are calculated in a similar fashion. The final VNA estimate for census tract “E” is calculated as follows:

$$VNA(E) = 0.4675 * 80 + 0.2078 * 90 + 0.2078 * 60 + 0.1169 * 100 = 80.3 \text{ ppb}$$

Equation (4A-2)

The observed hourly O₃ concentrations in the 15 urban case study areas were used to calculate VNA estimates for approximately 24,935 census tracts * 43,824 hours ≈ 1.1 billion values. The actual number of values was lower than this, because values were not calculated for hours outside the required monitoring season. However, the same VNA procedure was also used to create hourly spatial surfaces based on air quality adjusted to meet the existing standard of 75 ppb, and air quality adjusted to meet the potential alternative standards of 70 ppb, 65 ppb, 60 ppb, and 55 ppb, which effectively increased the total number of VNA estimates by roughly a factor of 5. The computations were executed using the R statistical computing program (R, 2012), with the Delaunay triangulation algorithm implemented in the “deldir” package (Turner, 2012).

Figure 4A-5 through Figure 4A-19 show maps of the 2006-2008 and 2008-2010 design values and May–September “seasonal” average MDA8 values in the 15 urban case study areas based on the VNA spatial fields. The top panels in each figure show the design values, while the bottom panels show the seasonal average values. The left-hand panels in each figure show the 2006-2008 values, while the right-hand panels show the 2008-2010 values. The colored circles in each panel represent census tract centroids, and the colored squares represent monitoring sites. In each panel, counties colored pink indicate the study area boundaries used in the Zanobetti and Schwartz (2008) and/or Smith et al. (2009b) epidemiology studies¹, where applicable. Counties colored gray indicate additional counties within the CBSA boundaries, and counties colored peach indicate any additional counties included in the exposure and lung function risk assessments. Note that the maps show some monitors outside of the study area boundaries. This is because the VNA surfaces were generated using data from monitors within a 50 km radius of the study area boundaries, in addition to the monitors inside the study areas.

¹ The Zanobetti and Schwartz (2008) and Smith et al. (2009) study area boundaries were identical for 6 of the 12 urban case study areas, and had at least one county in common for all 12 urban case study areas. The counties colored pink in Figures 4A-5 through 4A-19 refer to counties included in either of those two studies.

4A-2.3 Evaluation of Air Quality Spatial Field Techniques

As mentioned previously, in the 1st draft REA the air quality spatial fields used as inputs to APEX were based on hourly O₃ concentrations from the nearest monitoring site, while in this

draft the spatial fields were based on the VNA technique described in the previous section. This section presents an evaluation comparing the relative accuracy of the nearest neighbor (NN) and VNA techniques for generating spatial fields of hourly O₃ concentrations.

The evaluations were conducted over 4km gridded domains in Atlanta, Detroit, and Philadelphia using monitored hourly O₃ concentrations from 2005. Due to potential discrepancies in the availability of data, only data collected within the required O₃ monitoring seasons for each area (March – October for Atlanta; April – September for Detroit; April – October for Philadelphia) were considered. Figure 4A-20 below shows maps of the monitored values (AQS, left), NN values (center), and VNA values (right) in Atlanta (top) and Philadelphia (bottom) for a single selected hour in each area. These maps show an extreme example of the differences in the NN and VNA spatial fields. The NN fields (center column) have very sharp breaks between air quality monitors, while the VNA fields (right column) tend to produce much smoother surfaces. The NN fields also have a tendency to spread concentrations out over a large area if the monitoring network is sparse. For example, the highest concentration at the monitor in southern Atlanta is spread out over a large area in the NN fields, but this effect is somewhat mitigated in the VNA fields.

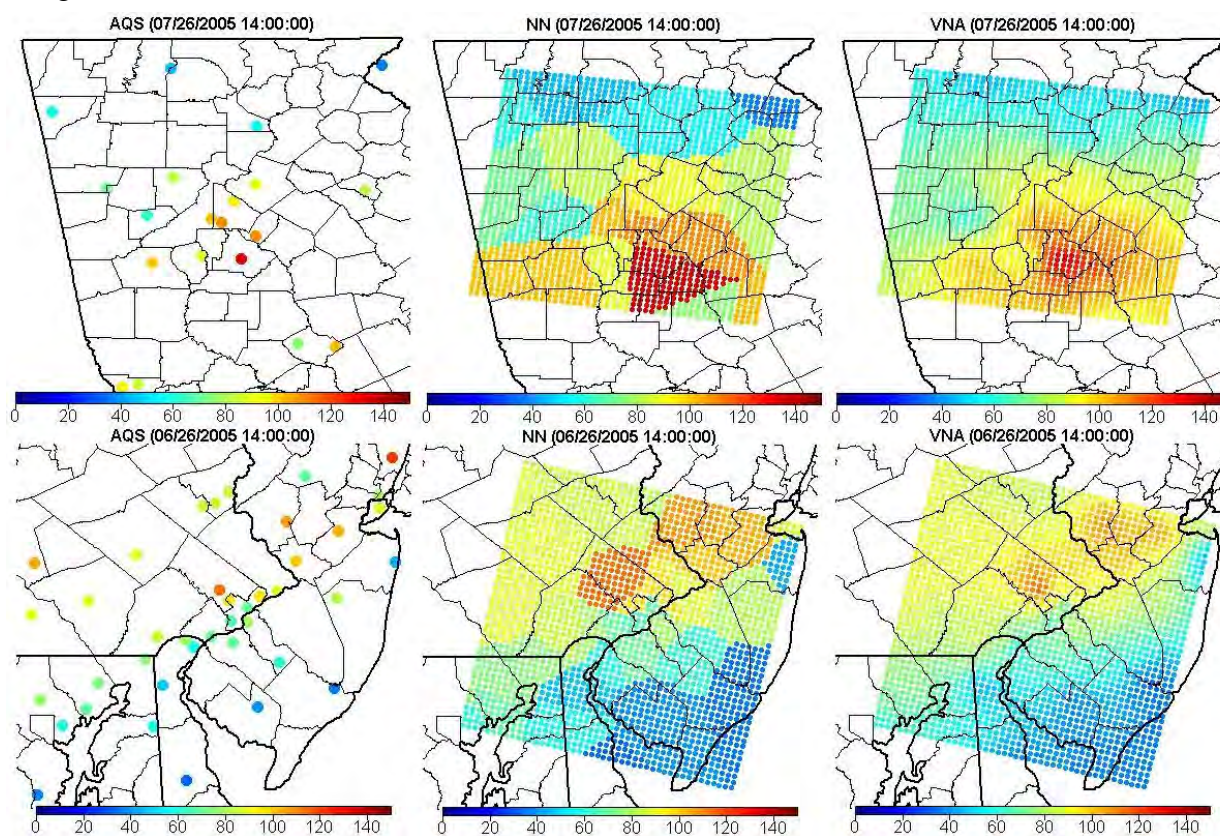

Figure 4A-20. Maps of monitored values (left), nearest neighbor spatial fields (center), and VNA spatial fields (right) for selected hours in Atlanta (top), and Philadelphia (bottom).

A cross-validation analysis was performed to evaluate the relative accuracy of the estimates from these two methods. For each hour in the required O₃ season, the concentrations from each monitor in the 4 km gridded domain were withheld (one at a time) from the input dataset, and the concentrations from the remaining monitors were used to estimate the concentration at the monitoring site that was withheld using NN and VNA. Additional monitoring sites within a 50 km radius of the 4 km gridded domain were used in the estimates, but were not included in the set of monitors that were withheld from the analysis. The estimated values were then compared to the respective monitored concentrations that were withheld, and the relative accuracy of NN and VNA were assessed using three summary statistics: the coefficient of variation (R^2), the mean bias, and the root mean squared error (RMSE).

Figure 4A-21 (Atlanta), Figure 4A-22 (Detroit), and Figure 4A-23 (Philadelphia) show density scatter plots and performance statistics for the NN and VNA spatial fields based on the cross-validation analysis described above for the three urban areas. Each figure shows the monitored hourly O₃ concentrations in ppb (AQS; x-axis) from the monitors which were withheld from the analysis, versus the respective values estimated using the NN (left panel) and VNA (right panel) techniques. In each panel, the plot region was split into 2 ppb x 2 ppb squares, with the colors indicating the number of points falling into each square. The diagonal line in each panel is a one-to-one reference line, and performance statistics for each method are included in the upper left-hand corner. High R^2 values, low mean bias values, and low RMSE values are indicative of good performance.

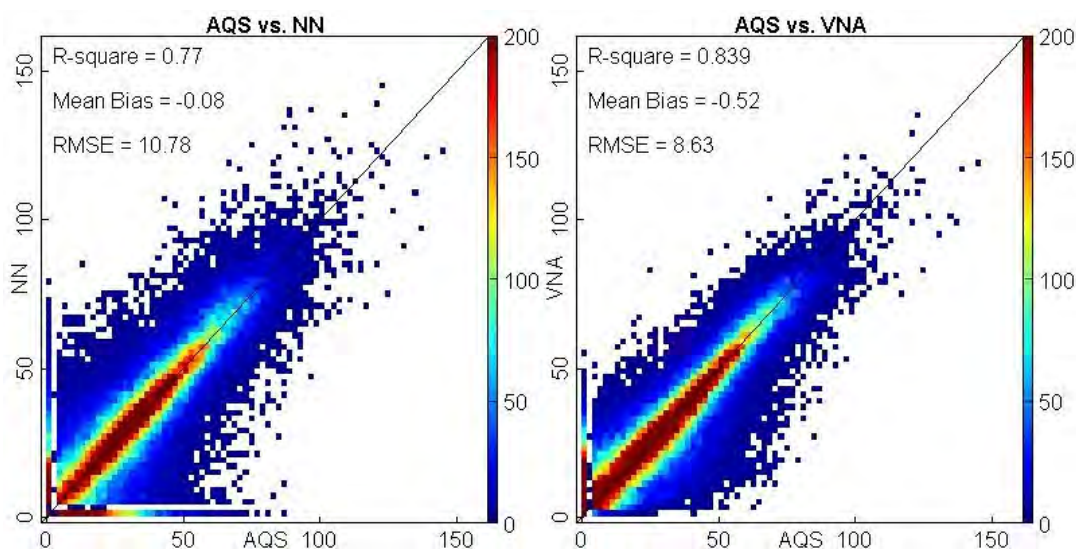

Figure 4A-21. Density scatter plots and performance statistics for the cross-validation analysis of nearest neighbor (NN; left) and Voronoi Neighbor Averaging (VNA; right) spatial field techniques applied to monitored hourly O₃ concentrations in Atlanta, 2005.

Figure 4A-22. Density scatter plots and performance statistics for the cross-validation analysis of nearest neighbor (NN; left) and Voronoi Neighbor Averaging (VNA; right) spatial field techniques applied to monitored hourly O₃ concentrations in Detroit, 2005.

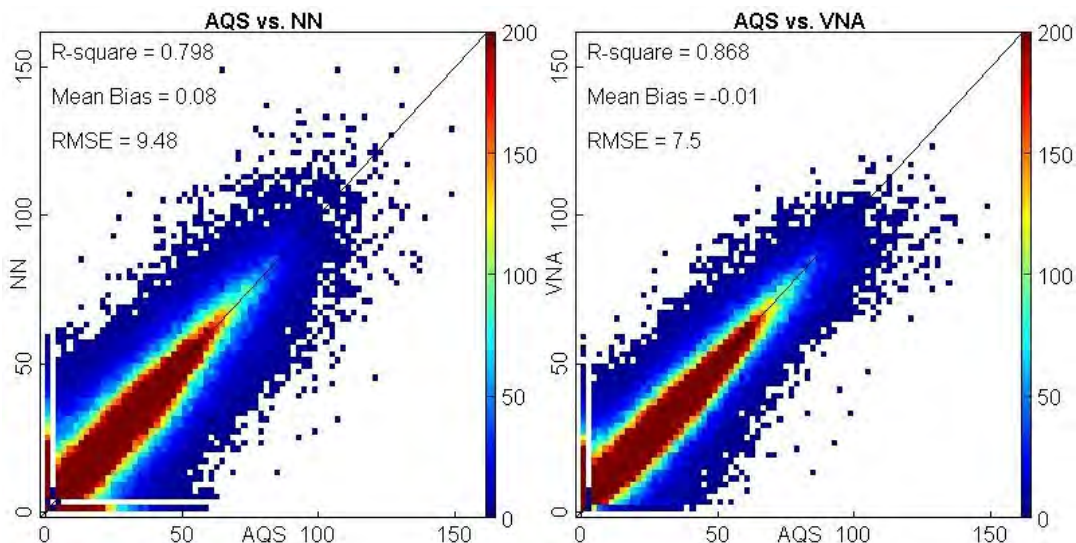

Figure 4A-23. Density scatter plots and performance statistics for the cross-validation analysis of nearest neighbor (NN; left) and Voronoi Neighbor Averaging (VNA; right) spatial field techniques applied to monitored hourly O₃ concentrations in Philadelphia, 2005.

Both techniques had relatively low mean bias statistics in all three urban areas (< 1 ppb in all cases). However, the VNA estimates had higher R^2 statistics and lower RMSE statistics than the NN estimates in all three urban areas, both of which indicate that the VNA technique consistently produces more accurate estimates than NN. This is also reflected by the fact that there is generally less scatter in the density plots based on the VNA estimates than those based

on the NN estimates. From a physical perspective, the VNA technique is also more appealing since it does not produce sharp breakpoints in the estimated values between adjacent monitors when the reported concentrations are different.

4A-3. AIR QUALITY INPUTS FOR THE EPIDEMIOLOGY-BASED RISK ASSESSMENT

This section describes the 12 urban case study areas for the epidemiology-based risk assessment described in HREA Chapter 7 (Section 7.4A-3.1), and the spatially averaged “composite monitor” values used as inputs to the Benefits Mapping and Analysis Program (BenMAP; Section 4A-3.2).

4A-3.1 Urban Case Study Areas

Three distinct sets of boundaries were considered for the 12 urban case study areas in the epidemiology-based risk assessment:

1. Core Based Statistical Areas² (“CBSA” boundaries)
2. Area boundaries defined in the Zanobetti and Schwartz (2008) study (“Z & S” boundaries)
3. Area boundaries defined in Smith et al. (2009) study (“Smith” boundaries)

In the 1st draft REA, the short-term mortality risk estimates were based on the concentration response functions estimated in the Zanobetti and Schwartz (2008) study using the Z & S boundaries. Here, the primary set of short-term and long-term mortality risk estimates described in HREA Chapter 7 are based on the concentration response functions estimated in the Smith et al, 2009 study using the CBSA boundaries. The other two sets of boundaries are used in sensitivity analyses. The first sensitivity analysis uses the Z & S boundaries to assess the impact of changing from the quadratic rollback method used to adjust air quality in the 1st draft REA to the HDDM adjustment method described in HREA Chapter 4 and Appendix 4D. The second sensitivity analysis uses the Smith boundaries to assess the impact of pairing air quality information based on the CBSA boundaries with the concentration-response functions which were derived from air quality information based on the Smith boundaries.

Table 4A-2 gives some basic information about the 12 urban case study areas in the epidemiology-based risk assessment for each set of boundaries. In general, the Z & S and Smith areas were generally smaller and more focused on the urban population centers than the CBSAs.

² Core Based Statistical Areas (CBSAs) are used by the Office of Management and Budget (OMB) to group U.S. counties into urbanized areas. These groupings are updated by OMB every 5 years. The CBSAs used in the epidemiology based risk assessment are based on the OMB delineations from 2008. For more information see: <http://www.whitehouse.gov/sites/default/files/omb/assets/bulletins/b10-02.pdf>

The Z & S and Smith areas were identical in 6 of the 12 urban case study areas, and had at least one county in common for all 12 study areas. The CBSAs were typically smaller than the respective study areas described in Section 4A-2.1 for the exposure and clinical risk assessments, with the exceptions of Baltimore, Dallas, and Houston, where the areas were identical. The final two columns of Table 4A-2 show the annual 4th highest MDA8 values in ppb based on monitors within the three sets of boundaries for 2007 and 2009, the two years upon which the risk estimates in HREA Chapter 7 are focused.

Table 4A-2. Information on the 12 Urban Case Study Areas in the Epidemiology Based Risk Assessment.

Area Name	Boundary Definition	# of Counties	# of O ₃ Monitors	Population (2010)	2007 4 th high (ppb)	2009 4 th high (ppb)
Atlanta	CBSA	28	13	5,268,860	102	77
	Z & S	4	5	3,105,873	98	77
	Smith	2	3	1,612,474	98	77
Baltimore	CBSA	7	7	2,710,489	92	83
	Z & S	2	3	1,425,990	83	71
	Smith	1	1	620,961	73	66
Boston	CBSA	7	11	4,552,402	89	75
	Z & S	3	5	2,895,958	88	75
	Smith	1	2	722,023	72	75
Cleveland	CBSA	5	10	2,077,240	83	72
	Z & S	1	4	1,280,122	83	71
	Smith	1	4	1,280,122	83	71
Denver	CBSA	10	16	2,543,482	97	79
	Z & S	1	3	600,158	76	63
	Smith	3	6	1,613,764	76	72
Detroit	CBSA	6	8	4,296,250	93	73
	Z & S	1	4	1,820,584	92	73
	Smith	1	4	1,820,584	92	73
Houston	CBSA	10	22	5,946,800	90	91
	Z & S	1	17	4,092,459	90	86
	Smith	1	17	4,092,459	90	86
Los Angeles	CBSA	2	21	12,828,837	105	108
	Z & S	1	17	9,818,605	105	108
	Smith	1	17	9,818,605	105	108
New York	CBSA	23	22	18,897,109	94	81
	Z & S	5	6	8,175,133	83	78
	Smith	6	7	9,124,246	94	78
Philadelphia	CBSA	11	15	5,965,343	102	74
	Z & S	1	4	1,526,006	95	72
	Smith	1	4	1,526,006	95	72
Sacramento	CBSA	4	17	2,149,127	93	96
	Z & S	1	8	1,418,788	90	96
	Smith	1	8	1,418,788	90	96
St. Louis	CBSA	16	17	2,812,896	94	74
	Z & S	2	5	1,318,248	94	70
	Smith	1	2	319,294	91	65

Since O₃ is not emitted directly but formed indirectly through photochemical reactions, precursor emissions may continue to react and form O₃ downwind of emissions sources, and thus the highest O₃ concentrations are often measured downwind of the highest concentration of precursor emissions in the urban population center. This phenomenon is reflected in Table 4A-2, where the highest monitored value in the CBSA occurs outside of the Smith boundaries in 9 of 12 areas in 2007, and in 7 of 12 areas in 2009. In addition, there were some instances where the highest monitored O₃ concentrations occurred outside of the CBSAs, but within the respective study areas used in the exposure and clinical risk assessments, which were designed to always include the monitor associated with the highest area-wide design value. For example, in Los Angeles, the CBSA includes Los Angeles County, CA and Orange County, CA, but the highest O₃ concentrations are typically measured further downwind in Riverside County, CA and San Bernardino County, CA.

4A-3.2 Air Quality Inputs to the Benefits Mapping and Analysis Program (BenMAP)

The air quality monitoring data used as inputs to the Benefits Mapping and Analysis Program (BenMAP) were daily time-series of spatially averaged “composite monitor” values for the 12 urban case study areas based on monitored air quality data. These composite monitor values were calculated by taking hour-by-hour spatial averages of the hourly O₃ concentrations for all monitors within a given study area, then calculating the four daily metrics described in Section 4A-1.3:

1. Daily Maximum 8-hour Average (MDA8) Concentration
2. Daily 10:00 AM – 6:00 PM Mean Concentration
3. Daily Maximum 1-hour Concentration
4. Daily 24-hour Average Concentration

These four daily metrics were calculated based on each of the three sets of urban case study area boundaries listed in the previous section, for a total of 12 daily metric/area boundary combinations. Although these 12 values were provided based on available monitoring data for each day in the 2006-2010 period, only a subset of these data were used for the air quality inputs to BenMAP. Since the BenMAP software is designed to run for only one year at a time, we chose to focus on air quality data from 2007 and 2009. In most cases, the 2007 data was meant to represent a year with high O₃ levels, while 2009 was meant to represent a year with low O₃ levels. In some areas, the data were also subset to a particular “O₃ season”, either to match the period used in the respective epidemiology study, or to avoid the potential disparity in data availability which could arise if the air quality data included months outside of the required O₃ monitoring season. Appendix 4D contains “box and whisker” plots showing the distribution of

composite monitor values in each area for current air quality, air quality adjusted to meet the existing O₃ standard, and air quality adjusted to meet the potential alternative standards of 70 ppb, 65 ppb, and 60 ppb. These plots are stratified to show the effects of varying spatial extents (CBSAs vs. Z & S areas), O₃ season lengths (June – August vs. April – October), and years (2007 vs. 2009).

Table 4A-3 gives a list of the air quality inputs to the various BenMAP outputs discussed in HREA Chapter 7, including the health endpoints modeled, the epidemiology studies from which the concentration-response functions were derived, which urban case study areas were modeled, which air quality metrics were used, which O₃ season was modeled, and which set of boundaries were used in calculating the composite monitor values. Rows shaded pink represent air quality inputs used in primary risk estimates, while rows shaded blue represent air quality inputs for risk estimates included as sensitivity analyses.

Table 4A-3. Summary of the air quality inputs to BenMAP.

Health Endpoint	Epidemiology Study	Urban Case Study Area(s)	Air Quality Metric	O ₃ Season	Study Area Boundaries
Emergency Room Visits, Respiratory	Darrow et al. (2011)	Atlanta, GA	MDA8	March - October	CBSA
Asthma Exacerbation, Wheeze	Gent et al. (2003)	Boston, MA	1-Hour Max	April - September	CBSA
Asthma Exacerbation, Wheeze	Gent et al. (2004)	Boston, MA	MDA8	April - September	CBSA
Emergency Room Visits, Asthma	Ito et al. (2007)	New York, NY	MDA8	April - September	CBSA
Mortality, Long-Term (Total and Respiratory)	Jerrett et al. (2009)	all 12 areas	Seasonal Average ³	April - September	CBSA
Hospital Admissions, All Respiratory	Katsouyanni et al. (2009)	Detroit, MI	1-Hour Max	June - August	CBSA
Hospital Admissions, All Respiratory	Lin et al. (2000)	Los Angeles, CA	24-Hour Average	June - August	CBSA
Hospital Admissions, Chronic Lung Disease	Lin et al. (2008)	New York, NY	1-Hour Max	April - October	CBSA
Hospital Admissions, Chronic Lung Disease	Medina-Ramon et al. (2006)	all 12 areas	MDA8	May - September	CBSA
Hospital Admissions, Asthma	Silverman and Ito (2010)	New York, NY	MDA8	April - August	CBSA
Mortality, Non-Accidental	Smith et al. (2009)	all 12 areas	MDA8	Required O ₃ season	CBSA
Mortality, Non-Accidental	Smith et al. (2009)	all 12 areas	MDA8	April - October	CBSA
Mortality, Non-Accidental	Smith et al. (2009)	all 12 areas	MDA8	June - August	CBSA
Mortality, Non-Accidental	Smith et al. (2009)	all 12 areas	MDA8	Required O ₃ season	Smith
Emergency Room Visits, Respiratory	Strickland et al. (2010)	Atlanta, GA	MDA8	May - October	CBSA
Emergency Room Visits, Respiratory	Tolbert et al. (2007)	Atlanta, GA	MDA8	March - October	CBSA
Mortality, All Cause	Zanobetti and Schwartz (2008)	all 12 areas	10AM-6PM Mean	June - August	CBSA
Mortality, All Cause	Zanobetti and Schwartz (2008)	all 12 areas	10AM-6PM Mean	June - August	Z & S

³ For the Jerrett et al. (2009) long-term mortality study, the air quality inputs were based on an annual metric instead of a daily metric. The annual metric was the April – September average of the daily maximum 1-hour concentrations.

4B-1. MODEL SET-UP AND SIMULATION

The air quality modeling underlying the HDDM adjustment methodology described in the Health Risk and Exposure Assessment (HREA) Chapter 4 and Appendix 4D was performed using CMAQv4.7.1 with HDDM for ozone (O_3) (www.cmaq-model.org). A modified version of CMAQ-HDDM-3D was used that tracked species concentrations through all modeled processes, but tracked O_3 sensitivities through the chemistry, transport, and dry deposition subroutines only and did not account for the effects of aerosol and cloud processing due to the uncertainties in these model processes with respect to O_3 sensitivity as well as to conserve computational costs. CMAQ was run using the carbon bond 2005 (CB05) gas-phase chemical mechanism (Gery et al., 1989; Yarwood et al., 2005) and the AERO5 aerosol module which includes ISORROPIA for gas-particle partitioning of inorganic species (Nenes et al., 1998) and secondary organic aerosol treatment as described in Carlton et al. (2010).

4B-1.1 Model Domain

For this analysis, all CMAQ/HDDM runs were performed for a domain that covers the 48 contiguous states included portions of southern Canada and Northern Mexico with a 12 x 12 km resolution (Figure 4B-1). The CMAQ simulations were performed with 24 vertical layers with a top at about 17,600 meters, or 50 millibars (mb). Table 4B-1 and Table 4B-2 provides some basic geographic information regarding the CMAQ domain and vertical layer structure, respectively. Results from the lowest layer of the model were used for analyses to support the O_3 HREA.

Figure 4B-1. Map of the CMAQ modeling domain.

Table 4B-1. Geographic elements of domain used in the CMAQ/HDDM modeling.

Element	CMAQ Modeling Configuration: National Grid
Map Projection	Lambert Conformal Projection
Grid Resolution	12 km
True Latitudes	33 deg N and 45 deg N
Dimensions	396 x 246 x 24
Vertical extent	24 Layers: Surface to 50 millibar level (Table 4B-2)

4B-1.2 Model Time Period

The CMAQ/HDDM modeling was performed for January and April-October of 2007. The simulations included 10 day “ramp-up” periods from December 22-31, 2006 and from March 22-31 2007 to minimize the effects of initial conditions. The ramp-up days were not considered in the analysis for the HDDM results.

4B-1.3 Model Inputs: Meteorology

CMAQ model simulations require inputs of meteorological fields, emissions, and initial and boundary conditions. The gridded meteorological data for the entire year of 2007 at the 12 km continental United States scale domain was derived from version 3.1 of the Weather Research and Forecasting Model (WRF), Advanced Research WRF (ARW) core (Skamarock et al., 2008). The WRF Model is a next-generation mesoscale numerical weather prediction system developed for both operational forecasting and atmospheric research applications (<http://wrf-model.org>). The 2007 WRF simulation included the physics options of the Pleim-Xiu land surface model (LSM), Asymmetric Convective Model version 2 planetary boundary layer (PBL) scheme, Morrison double moment microphysics, Kain-Fritsch cumulus parameterization scheme and the RRTMG long-wave radiation (LWR) scheme (Gilliam and Pleim, 2010).

The WRF meteorological outputs were processed to create model-ready inputs for CMAQ using the Meteorology-Chemistry Interface Processor (MCIP) package (Otte et al., 2010), version 3.6, to derive the specific inputs to CMAQ: horizontal wind components (i.e., speed and direction), temperature, moisture, vertical diffusion rates, and rainfall rates for each grid cell in each vertical layer. The WRF simulation used the same CMAQ map projection, a lambert conformal projection centered at (-97, 40) with true latitudes at 33 and 45 degrees north. The 12 km WRF domain consisted of 459 by 299 grid cells. The WRF simulation utilized 34 vertical layers with a surface layer of approximately 38 meters. Table 4B-2 shows the vertical layer structure used in WRF and the layer collapsing approach to generate the CMAQ meteorological inputs. CMAQ resolved the vertical atmosphere with 24 layers, preserving greater resolution in the PBL.

In terms of the 2007 WRF meteorological model performance evaluation, an approach which included a combination of qualitative and quantitative analyses was used to assess the adequacy of the WRF simulated fields (U.S. EPA, 2011). The qualitative aspects involved comparisons of the model-estimated synoptic patterns against observed patterns from historical weather chart archives. Additionally, the evaluations compared spatial patterns of monthly average rainfall and monthly maximum planetary boundary layer (PBL) heights. The statistical portion of the evaluation examined the model bias and error for temperature, water vapor mixing ratio, solar radiation, and wind fields. These statistical values were calculated on a monthly basis.

Table 4B-2. Vertical layer structure for 2007 WRF and CMAQ simulations.

Layer Top Height (m)	Pressure (mb)	WRF	Depth (m)	CMAQ	Depth (m)
17,145	50	34	2,655	24	4,552

4B-1.4 Model Inputs: Emissions

The emissions data used are based on the 2007 Version 5 emissions modeling platform developed for the Particulate Matter (PM) NAAQS rule (U.S. EPA 2012a, U.S. EPA 2012b). Some small updates to the 2007v5 platform are enumerated below. First we give a general summary of the emissions processing performed for the PM NAAQS 2007 modeling emissions inputs (more details are available in U.S. EPA 2012a, 2012b, and in the PM NAAQS section of <http://www.epa.gov/ttn/chief/emch/index.html>). The 2008 National Emissions Inventory,

Version 2 (<http://www.epa.gov/ttn/chief/net/2008inventory.html>) was the starting point for these emissions, with updates to specific source categories made where necessary to better represent the year 2007. Emissions were processed to photochemical model inputs with the SMOKE modeling system version 3.1 (Houyoux et al., 2000). For this analysis, emissions from wildfires and prescribed burns are estimated based on a multi-year average of data from 2003 through 2010. Electric generating utilities (EGUs) emissions for 2007 are temporalized based on average temporal profiles from 3 years of data. In addition, U.S. emissions are included from other point sources, area sources, agricultural sources (ammonia only), anthropogenic fugitive dust sources, nonroad mobile sources, onroad mobile sources, and biogenic sources. Onroad mobile sources were created using EPA's MOVES 2010b model (www.epa.gov/otaq/models/moves), except that California emissions were adjusted to match the county total emissions obtained directly from the California Air Resources Board. Biogenic emissions were estimated using the Biogenic Emissions Inventory System version 3.14 (BEISv3.14) (Pierce et al., 1998). Other North American emissions are based on a 2006 Canadian inventory and 2008 Mexican inventory. Emissions totals within the 12 km Eastern domain are summarized in Table 4B-3 for CO, NH₃, NO_x, PM₁₀, PM_{2.5}, SO₂, and VOC.

There are a few differences between the emissions data used for this analysis and the data documented in the PM NAAQS 2007v5 platform technical support document (TSD). First, the years used to compute the average fires were 2003-2010, versus 2003-2009 for the PM NAAQS. Second, point source emissions for South Dakota were updated with more recent data. Finally, a correction was made the spatial surrogates used for oil and gas emissions in the Western Regional Air Partnership states and updated spatial surrogates for gas stations and dry cleaners were used.

Table 4B-3. Summary of emissions totals by sector for the 12km Eastern U.S. domain.

Sector Name	Sector description	Emissions (1000 tons/year)						
		CO	NH ₃	NO _x	PM ₁₀	PM _{2.5}	SO ₂	VOC
afdust	Anthropogenic fugitive dust				5,854	825		
ag	Agricultural sources		3,595					
c1c2rail	Locomotive and marine mobile sources (except C3 marine)	219	0.6	1,338	44	41	49	60
avefire	Average year fire emissions	15,598	256	216	1,589	1,347	118	2,797
nonpt	Area sources	4,335	155	1,229	768	676	402	6,671
nonroad	Off road equipment	17,834	1.9	1,878	188	178	101	2,781
onroad	Onroad mobile vehicles	36,757	145	7,561	363	277	40	3,186
othar	Canada and Mexico area sources	4,225	671	918	1,510	451	154	1,815
othon	Canada and Mexico onroad mobile sources	5,173	25	631	23	18	11	405
othpt	Canada and Mexico point sources	1,331	21	1,280	241	159	2,504	626
ptipm	Point sources: electric generation units	704	25	3,357	437	330	9,136	43
ptnonipm	Point sources other than electric generating units	2,934	68	2,077	583	409	1,589	1,074
c3marine US	C3 marine vessels within 4 miles of the U.S. coast	13		138	12	11	105	5.1
c3marine non US	C3 marine vessels more than 4 miles off the U.S. coast	86		1,047	87	80	646	38
beis	Biogenic emissions	8,211		1,931				48,616
total US anthro	Total U.S. anthropogenic emissions used in HDDM (NO _x and VOC only)			17,578				13,819
total	Domain-wide total	97,420	4,964	23,602	11,699	4,802	14,854	68,117

4B-1.5 Model Inputs: Boundary and Initial conditions

The lateral boundary concentrations for the 12km US2 domain are provided by a three-dimensional global atmospheric chemistry model, the GEOS-CHEM (Yantosca, 2004) model (standard version 8-03-02 with version 8-02-03 chemistry). The global GEOS-CHEM model simulates atmospheric chemical and physical processes driven by assimilated meteorological observations from the NASA's Goddard Earth Observing System (GEOS-5). This model was

run for 2007 with a grid resolution of 2.0 degree x 2.5 degree (latitude-longitude) and 46 vertical layers up to 0.01 hPa. The predictions were processed using the GEOS-2-CMAQ tool (Akhtar et al., 2012, Henderson et al., 2013) and used to provide one-way dynamic boundary conditions at one-hour intervals. The O₃ from these GEOS-Chem runs was evaluated by comparing to satellite vertical profiles and ground-based measurements and found acceptable model performance (Akhtar et al., 2012; Henderson et al., 2013).

Initial conditions were extracted from a slightly older model simulation using GEOS-CHEM (Yantosca, 2004) version 8-02-03. The model simulation from which the initial conditions were extracted was also run with a grid resolution of 2.0 of 2.0 degree x 2.5 degree (latitude-longitude) and 47 vertical layers. A GEOS-Chem evaluation was conducted for the purpose of validating the 2007 GEOS-Chem simulation outputs for their use as inputs to the CMAQ modeling system. This evaluation included reproducing GEOS-Chem evaluation plots reported in the literature for previous versions of the model (Lam, 2010).

4B-2. EVALUATION OF MODELED OZONE CONCENTRATIONS

CMAQ is a peer-reviewed, community air quality model that simulates the formation and fate of photochemical oxidants, aerosol concentrations, acid deposition, and air toxics, over multiple scales for given input sets of meteorological conditions and emissions. In order to assure that CMAQ is an appropriate tool to estimate the AQ changes expected to result from a given set of emissions reductions, the model is typically evaluated for each new application. This evaluation consists of assessments of the model itself and an assessment of this particular application of the model.

An independent panel consisting of academic and government experts assessed the science within the CMAQ model version 4.7.1 in September 2011 (http://www.epa.gov/AMD/Reviews/2011_CMAQ_Review_FinalReport.pdf). Among the conclusions of this peer-review report was the finding that the CMAQ science and evaluation efforts was of “very high quality” and have provided a “foundation for the more reliable use of the CMAQ modeling system”.

As CMAQ model version 4.7.1 was being developed, a series of incremental diagnostic tests were performed to assess how model performance varied across a variety of model improvements. This analysis is summarized in Foley et al. (2010) as well as Godowitch et al., (2011). While time and resource intensive, this systematic incremental testing shows “the effect of each scientific improvement on the simulated fields.” This evaluation allowed for a clear comparison with previous model versions and provided assurance that CMAQ v4.7.1 yielded equivalent or improved performance relative to previous CMAQ versions.

Numerous dynamic evaluations of CMAQ's ability to simulate the change in air quality resulting from emissions reductions have been conducted and summarized in the peer-reviewed literature. For instance, Napelenok et al. (2011) concluded that the CMAQ model "is able to reproduce the observed change in daily maximum 8-hour O₃ levels" at the majority of locations when emissions uncertainty is considered. Other dynamic evaluations (Zhou et al., 2013, Godowitch et al., 2010, Gilliland et al., 2008, Godowitch et al., 2007) have suggested that CMAQ may be a conservative estimate of the air quality improvements resulting from emissions reductions.

This TSD summarizes the ability of the model to reproduce 2007 conditions simulated using specific emissions, meteorological, initial conditions and boundary conditions inputs described above. This operational evaluation shows that the CMAQ model predictions for 2007 are equivalent or better than typical regional modeling simulations as summarized in Simon et al. (2012).

In the following sections we present general model performance statistics and plots for five regions of the U.S. We compare model predictions of maximum daily 8-hr average (MDA8) O₃ concentrations to measurements reported in EPA's Air Quality System (AQS) which is a repository of air pollution measurements made by EPA, state, local, and tribal agencies. For the 2007 model performance evaluation, we ran CMAQ for 2007 using the same emissions as those used for the 2007 HDDM runs, except that we included actual wild fires instead of average fires and we used CEM data to for hourly EGU emissions (U.S. EPA, 2012b) instead of the multi-year average temporal method used for the HDDM runs.

The model statistics presented here include mean bias, mean error, normalized mean bias, and normalized mean error as calculated in Simon et al. (2012). Our analysis focuses on regional model evaluation statistics from five U.S. regions as well as evaluations of the 15 urban areas included in the Risk and Exposure Assessment. The five regions are defined as follows: Northeast (Connecticut, Delaware, District of Columbia, Maine, Maryland, Massachusetts, New Hampshire, New Jersey, New York, Pennsylvania, Rhode Island, Vermont), Southeast (Alabama, Florida, Georgia, Kentucky, Mississippi, North Carolina, South Carolina, Tennessee, Virginia, West Virginia), Midwest (Illinois, Indiana, Michigan, Ohio, Wisconsin), Central (Arkansas, Iowa, Kansas, Louisiana, Minnesota, Missouri, Nebraska, Oklahoma, Texas), and West (Arizona, California, Colorado, Idaho, Nevada, New Mexico, Oregon, Utah, Wyoming). Statistics for model performance in these regions and urban areas are shown by season in Table 4B-4 through Table 4B-23 for observed days with MDA8 O₃ values ≥ 60 ppb, observed days with MDA8 O₃ < 60 ppb, and for all observed days. Plots are provided to show regional maps of Normalized Mean Bias by season and time series of modeled and measured O₃ concentrations in each urban area. Time series are provided for MDA8 O₃ from April-October 2007 and for

hourly O₃ from one month from each season in 2007 (January, April, July, October) where monitoring data is available. Note that time series show average concentrations across all monitors within each urban area and the number of monitors included in this average sometimes changes by season since different monitors within each area take measurements over different periods of the year.

4B-2.1 Operational Evaluation in the Northeast U.S.

Table 4B-4 shows that in the Northeastern U.S., model mean bias was generally less than 6 ppb and normalized mean bias was less than 15% in most cases. High O₃ days and summertime days were more likely to be under-estimated by the model while low O₃ days and wintertime days were more likely to be over-estimated by the model. Performance was best in the spring and fall and had the largest errors in the winter. Five of the 15 urban areas evaluated were in the Northeast: Boston, New York, Philadelphia, Baltimore, and Washington D.C.

Model performance at Boston area monitoring sites (Table 4B-5) was similar to that at other Northeastern U.S. sites. The time series plots show that the model has skill at reproducing measured day-to-day variability in MDA8 O₃ concentrations (Figure 4B-6). Hourly daytime and nighttime O₃ concentrations are also well modeled in all seasons with exception of a few 2-3 day periods in July in which the model over-estimates daytime and nighttime O₃ with some over-estimates of daytime peaks in October (Figure 4B-7 through Figure 4B-10).¹

Bulk performance statistics for MDA8 model estimates in New York (Table 4B-6) also look equivalent to both the Boston statistics and those of the Northeast as a whole. Again, the 7-month time series of MDA8 O₃ at NY area sites shows that the model captures synoptic variations in O₃ concentrations (Figure 4B-11). Hourly New York area O₃ in January is generally well captured by the model, although CMAQ does somewhat under-estimate the daytime peaks (Figure 4B-12). The April time series (Figure 4B-13) shows that the model captures the range of measured daytime and nighttime O₃ values but has a 3-day period of over-estimates in early April and a week-long period of under-estimates later in the month. July and October O₃ is well captured by the model on both low and high O₃ days and at night (Figure 4B-14 and Figure 4B-15).

Bulk model performance statistics for Philadelphia (Table 4B-7) are equivalent to those for the Northeast as a whole. The time series plots show that variations of MDA8 are well captured in Philadelphia (Figure 4B-16) and that the model does a reasonable job of estimating day to night O₃ changes in all seasons but has some under-estimates of daytime O₃ in January (Figure 4B-17) and some over-estimates of daytime and nighttime O₃ in October (Figure 4B-20).

¹ Note that the Y-axis scale for the various time series are not consistent

Baltimore MDA8 O₃ performance (Table 4B-8) is generally similar to O₃ performance in the rest of the Northeast except for summertime values which are somewhat more overestimated in Baltimore (8 ppb MB in Baltimore versus 4 ppb MB in the Northeast). Still, these bias and error statistics are well within the range of state-of-the-science model performance described by Simon et al. (2012). As shown by the time series in Figure 4B-21, most model overestimates in this area occur from late July to late August. Outside of that time period, the MDA8 variations from April-October are well captured by the model. The hourly time series plots for Baltimore generally show reasonable agreement between the observed and modeled values although the period of over-estimated daytime O₃ concentrations in July is apparent in Figure 4B-24.

Bulk statistics for Washington D.C. sites (Table 4B-9) are similar to statistics for the rest of the Northeast region. The period of overestimated MDA8 values in late July through August which was seen in nearby Baltimore is less pronounced in Washington D.C. (Figure 4B-26). Hourly time series generally show reasonable performance with some overestimates of nighttime O₃ in October (Figure 4B-30).

4B-2.2 Operational Evaluation in the Southeast U.S.

Model performance in the Southeastern U.S. was in the range of reported performance for state of the science models (Simon et al., 2012). Mean bias for MDA8 O₃ was less than 5 ppb at most sites in the winter and spring and less than 10 ppb at most sites in the summer and fall seasons. Normalized mean bias was generally less than 10% at most sites in the winter and spring and less than 25% at most sites in the summer and fall. Also, there were very few days above 60 ppb in the winter season (4 days at two sites and 0,1, or 2 days at all other sites), but the model generally had trouble capturing O₃ on those days and had mean biases in the range of -5 to -15 ppb on those days. The higher biases in the summer and fall are most pronounced along the Gulf coast and at sites in Florida. Atlanta was the only one of the 15 urban study areas from the HREA which was located in the Southeast region.

There were no O₃ measurements in the Atlanta area during the winter season. Mean bias and normalized mean bias at Atlanta sites for the spring, summer, and fall months were typical of performance throughout the Southeast region. The April to June MDA8 O₃ time series (Figure 4B-35) shows that the model does a good job of capturing the variability between high and low O₃ days. The hourly time series plots for April (Figure 4B-36), July (Figure 4B-37), and October (Figure 4B-38) show reasonable model performance during daytime hours but some persistent overestimates of nighttime O₃, especially in April and July.

4B-2.3 Operational Evaluation in the Midwest

The model performed well compared to observed O₃ concentrations in the Midwest. Mean bias for MDA8 O₃ was around 5 ppb or less at most sites in the winter, spring, and fall and less than 7 ppb at most sites in the summer. Normalized mean bias for MDA8 O₃ was less than 15% at most sites except in the winter when it was somewhat higher (less than 20% at most sites) due to lower observed O₃ concentrations. The model was more likely to be biased high on low O₃ days and biased low on higher O₃ days. No distinct spatial trends are apparent from the maps of normalized mean bias (Figure 4B-39 through Figure 4B-42). Three urban areas in the Midwest were examined more closely for this evaluation: Chicago, Cleveland, and Detroit.

Chicago performance statistics for MDA8 O₃ were similar to those of the rest of the region. The time series of MDA8 O₃ from Apr-Oct 2007 (Figure 4B-43) as well as the hourly time series for January, April, July, and October (Figure 4B-44 through Figure 4B-47) all show that the model does a good job of capturing synoptic variations in O₃ observed in Chicago and reasonably captures both day and nighttime measured concentrations.

No measurements were made during the winter season in Cleveland. MB for MDA8 O₃ on high days (≥ 60 ppb) was similar to MB in the rest of the region, but MB on low O₃ days was somewhat higher than was typically seen in the Midwest (4 ppb vs. 1 ppb in the spring, 11 ppb vs. 6 ppb in the summer, and 4 ppb vs. 3 ppb in the fall). The time series plots for Cleveland sites show good correlation with observed O₃, although a period of moderate model overestimates in daytime O₃ is depicted in July (Figure 4B-48 and Figure 4B-50). Nighttime O₃ concentrations are often overestimated by the model except in the time series shown for April, July, and October the latter portion of October, 2007.

Detroit area sites did not report any O₃ measurements during the winter of 2007. Detroit performance statistics for MDA8 O₃ were similar to those from the rest of the Midwest; however under-estimates on high O₃ days were more pronounced in Detroit than in the rest of the region. The time series shows that the model accurately estimates both day and nighttime hourly O₃ in Detroit in April and July and generally captures the variations in MDA8 O₃ across the April-October time period.

Table 4B-12. Summary of CMAQ model performance at AQS monitoring sites in the Midwest.

Season	MDA8	No. of Days	MB (ppb)	NMB (%)	ME (ppb)	NME (%)

4B-2.4 Operational Evaluation in the Central U.S.

Mean bias for MDA8 O₃ concentrations were in the range of 4 ppb or less at Central U.S. monitoring sites during the winter and spring and less than 13 ppb and 6 ppb in the summer and fall respectively. Normalized mean bias was less than 15% at most sites in winter, spring, and fall and less than 35% at most sites in the summer. Summertime model overestimates were primarily located along the Gulf coast of Texas and Louisiana, mostly occurring on days with MDA8 O₃ concentrations less than 60 ppb. This is similar to summertime overestimates reported for the Southern U.S. which also were more pronounced along the Gulf Coast. Houston, Dallas, and Saint Louis were the three cities from the 15 urban study areas which were located in the Central U.S. region.

Saint Louis mean bias for MDA8 was moderately better than mean bias in the rest of the region for winter and spring periods and substantially better than the mean bias in the rest of the Central region in the summer and fall. The time series plots show that the model does a good job of replicating the observed variations in O₃ (both MDA8 and hourly). Nighttime O₃ is generally well simulated with the exception of a few several day periods in July when nighttime concentrations were overestimated by the model.

Dallas performance statistics for MDA8 O₃ were very similar to those presented for the Central region as a whole with the exception of comparisons made for the fall season which showed that Dallas performed substantially better than average for the region. The time series plot of MDA8 O₃ modeled and measured values (Figure 4B-64) demonstrate consistent high bias on very low O₃ days in May through early September but not in April or October. Hourly O₃ is fairly well replicated in January (Figure 4B-65), April (Figure 4B-66), and October (Figure 4B-68) but is overestimated during July both on low O₃ days and at night (Figure 4B-67).

As mentioned above, the largest summertime overestimates in MDA8 O₃ in the Central U.S. occur along the Texas Gulf coast. This is demonstrated by the Houston model performance statistics. Houston model performance is relatively good and is equivalent to that in the rest of the Central U.S. during the winter, spring, and fall seasons and on high days during the summer. However summertime MDA8 O₃ is overestimated by 15 ppb and 48% on summer days with observed levels less than 60 ppb in the Houston area. This summertime overestimate of low O₃ days is demonstrated in the time series plots in Figure 4B-69 and Figure 4B-72.

4B-2.5 Operational Evaluation in the Western U.S.

Again model statistics for MDA8 O₃ in the Western U.S. are in the range of what has been reported for state of the science model performance in the literature (Simon et al., 2012). Mean bias at most sites was less than 6 ppb in the winter, spring, and fall and less than 10 ppb in the summer. Normalized mean bias at most monitoring locations was less than 10% in the winter and spring, less than 20% in the summer and less than 15% in the fall. Only 3 sites in the West recorded O₃ concentrations equal to or above 60 ppb in winter (a Riverside California site reported 13 days and the other two sites in Sacramento, CA and Sublette county WY reported only 2 and 3 days above 60 ppb). These high wintertime observations were substantially underestimated by the model with an average MB of -34.5 ppb but likely for different reasons. The high days in Riverside California are probably due to traditionally understood O₃ formation that occurs on warm sunny days. The high O₃ concentrations in Wyoming are an example of wintertime O₃ formation that occurs during cold pool meteorology events which have substantial snow cover and extreme temperature inversions and are still an active area of research. Some spatial trends in normalized mean bias are apparent in the winter (Figure 4B-74) and in the summer (Figure 4B-76). Wintertime O₃ is more likely to be overestimated on the West Coast and more likely to be underestimated in the Intermountain West. Summertime model overestimates are greatest along the Southern Coast of California in locations that generally have low observed O₃ concentrations. Three urban study areas from the HREA are located in the Western U.S. and are evaluated in this section: Denver, Sacramento, and Los Angeles.

Denver area model performance was generally comparable to model performance in the rest of the Western U.S. although summertime overestimates of MDA8 were greater in Denver. These summertime overestimates can be seen on many days in Figure 4B-78 and Figure 4B-80.

Figure 4B-79 shows that the model generally captures measured hourly O₃ concentrations in the Denver area on mid to high O₃ days but often overestimates very low O₃ days in the spring. Fall hourly O₃ estimates from the model are reasonably well captured in Figure 4B-81.

Sacramento area model performance for MDA8 O₃ values was reasonably good in all seasons except for the 2 days with high observed O₃ in the winter. The model underestimated those high wintertime concentrations by 32 ppb. Other than those days, model bias was generally less than 10% in the Sacramento area. The time series figures of MDA8 and hourly O₃ concentrations show that the model does well at capturing the day to day and day to night O₃ variations in all seasons.

Los Angeles generally had reasonable model performance with low normalized mean bias number (0-8%) with two exceptions. The 13 high wintertime O₃ days measured in central Riverside County were not captured by the model which had a mean bias for those days at that site of -36 ppb and -45%. Also, the model tended to overestimate O₃ on summertime days with observed concentrations below 60 ppb (15 ppb mean bias). These low summer O₃ concentrations generally occurred along the coast (Figure 4B-92). A map of summertime normalized mean bias (Figure 4B-93) shows that the low O₃ sites are the locations with the largest model bias. Monitors away from the coast generally had fairly low bias (0-20%) with the exception of two sites in western Riverside County. The summer O₃ overestimates shown in the MDA8 time series (Figure 4B-87) are therefore due to performance at those coastal sites. The hourly time series for January (Figure 4B-88), April (Figure 4B-89), and October (Figure 4B-90) generally show good hourly O₃ performance during the day but model overestimates at night.

Table 4B-20. Summary of CMAQ model performance at AQS monitoring sites in the western U.S.

4C-1. OVERVIEW

The need for greater spatial and temporal coverage of air quality concentration estimates has grown in recent years as epidemiology and exposure studies that link air quality to health effects have become more robust and as regulatory needs have increased. These health studies have historically relied upon direct measurements of air quality concentrations, but prohibitive logistics and costs limit the spatial coverage and temporal resolution of available ambient monitoring networks. Numerical methods of interpolation, which predict unknown values from data observed at known locations, have historically been used by researchers to extend the spatial coverage of these monitoring networks with a high degree of confidence to inform exposure studies. However, simple kriging approaches such as Voronoi Neighbor Averaging (VNA) do not take advantage of the greater availability of model predictions of air quality concentrations that can enhance the predictive capabilities of numerical methods. Such “data fusion” methods employ both ambient air quality monitoring data and air quality modeling simulation data as inputs, and therefore take advantage of the measurement data’s accuracy at specific locations and the air quality model’s spatial coverage to generate more robust spatial predictions. For regulatory purposes, the enhanced Voronoi Neighbor Averaging (eVNA) has been the preferred method used by EPA to make spatial predictions of ozone (O₃) as part of conducting health benefit assessments (U.S. EPA, 2010). Given the interest and value of these methods, research and development efforts have focused on improving their predictive capabilities. This includes the Office of Research and Development’s development of the Downscaler (DS) model that can potentially provide predictions that are improved over those of eVNA (Berrocal et al., 2011).

This Appendix describes the methods, evaluation, and results of four different techniques for predicting air quality concentrations. These four techniques are:

- 1) VNA (interpolating the monitoring data),
- 2) CMAQ (using the absolute modeled air quality concentrations),
- 3) eVNA, and
- 4) Downscaler

EPA used the method with the best performance based on the evaluation to generate national air quality spatial fields of seasonally averaged O₃ concentrations as inputs to the national mortality risk burden assessment in Chapter 8 of the O₃ Health Risk and Exposure Assessment (HREA).

Air quality spatial fields are also used in two other applications for the risk and exposure assessments. In Appendix 4A of the HREA, we describe the methodology used to create urban-scale spatial fields of hourly O₃ concentrations for use in the exposure modeling. In Appendix 4A to the Welfare Risk and Exposure Assessment (WREA), we evaluate these same four spatial

field techniques for use in creating national-scale air quality spatial fields for the W126 exposure metric.

4C-2. AIR QUALITY SPATIAL FIELD TECHNIQUES

This section briefly describes the methodology of each of the four techniques considered for generating air quality spatial fields as inputs to the national risk mortality burden analyses described in the HREA Chapter 8.

4C-2.1 Voronoi Neighbor Averaging (VNA)

The Voronoi Neighbor Averaging (VNA; Gold, 1997; Chen et al., 2004) interpolation technique uses inverse distance squared weighted averages of the ambient concentrations from a set of nearest neighboring monitors to estimate the concentration at a specified location (in this case CMAQ grid cell centers). VNA identifies the nearest neighboring monitors for the center of each grid cell using a Delaunay triangulation algorithm, then takes the inverse distance squared weighted average of the hourly O₃ concentrations from each neighboring monitor to estimate an hourly O₃ concentration value for the center of the grid cell. The following paragraphs provide a numerical example of the VNA technique applied to a model grid domain.

The first step in VNA is to identify the set of nearest monitors for each grid cell in the domain. The left-hand panel of Figure 4C-1 below presents a numerical example with nine model grid cells and seven monitoring sites, with the focus on identifying the set of nearest neighboring sites to the center of grid cell “E”, the center cell. The Delaunay triangulation algorithm identifies the set of nearest neighboring monitors by drawing a set of polygons called the “Voronoi diagram” around the center of grid cell “E” and each of the monitoring sites. Voronoi diagrams have the special property that the each edge of the polygons are the same distance from the two closest points, as shown in the right-hand panel below.

Figure 4C-1. Numerical example of the Voronoi Neighbor Averaging (VNA) technique applied to a model grid domain.

VNA then chooses the monitoring sites that share a boundary with the center of grid cell "E". These are the nearest neighboring sites, which are used to estimate the concentration value for grid cell "E". The VNA estimate of the concentration value in grid cell "E" is the inverse distance squared weighted average of the four monitored concentrations. The further the monitor is from grid cell "E", the smaller the weight.

For example, the weight for the monitor in grid cell "D" 10 miles from the center of grid cell "E" is calculated as follows:

$$\frac{1/10^2}{1/10^2 + 1/15^2 + 1/15^2 + 1/20^2} = 0.4675 \quad \text{Equation (4C-1)}$$

The weights for the other monitors are calculated in a similar fashion. The final VNA estimate for grid cell "E" is calculated as follows:

$$VNA(E) = 0.4675 * 80 + 0.2078 * 90 + 0.2078 * 60 + 0.1169 * 100 = 80.3 \text{ ppb} \quad \text{Equation (4C-2)}$$

4C-2.2 Community Multi-scale Air Quality (CMAQ) Model

For more than a decade, the EPA's Community Multi-scale Air Quality (CMAQ; Foley et al., 2010) model has been a valuable computational tool used by EPA and states to inform air quality management programs. The CMAQ system simultaneously models multiple air

pollutants, including O₃, particulate matter, and a variety of air toxics to help regulators determine the best air quality management scenarios for their communities, states, and countries. CMAQ is also used by states to assess implementation actions needed to attain National Ambient Air Quality Standards.

The CMAQ system includes emissions, meteorology, and photochemical modeling components. Research continues in all of these areas to reduce biases and uncertainties in model simulations. CMAQ is a multi-scale system that has been applied over continental, national, regional, and urban modeling domains with progressively finer resolution in a series of nested grids. The CMAQ modeling community includes researchers, regulators, and forecasters in academia, government, and the private sector with thousands of users worldwide.

Modeled air quality concentrations from CMAQ simulations have a twofold purpose in the generation and analysis of air quality spatial fields. First, the modeled concentrations are “fused” with the ambient measurement data using the eVNA and DS techniques. Second, the original modeled concentrations are evaluated against the resulting concentration estimates from the other spatial field techniques, to ensure that those techniques successfully reduce biases in the modeled air quality fields.

4C-2.3 Enhanced Voronoi Neighbor Averaging (eVNA)

Enhanced Voronoi Neighbor Averaging (eVNA; Timin et al., 2010) is a direct extension of VNA used to combine monitored and modeled air quality concentration data. Continuing from the previous numerical example for VNA, suppose the model grid cells containing monitors are associated with modeled concentrations as shown in Figure 4C-2 below. The modeled concentrations are used to weight the VNA estimates relative to the modeled concentration gradient:

$$eVNA(E) = \sum_{i=1}^{n_i} Weight_i * Monitor_i * \frac{Model_E}{Model_i} \quad \text{Equation (4C-3)}$$

where $Monitor_i$ represents the monitored concentration for a nearest neighboring monitor,

$Weight_i$ represents the inverse distance squared weight for $Monitor_i$,

$Model_E$ represents the modeled concentration for grid cell “E”, and

$Model_i$ represents the modeled concentration in the grid cell containing $Monitor_i$.

	A	Model: 100 ppb Monitor: 90 ppb 15 miles	B		C
			*		
Model: 95 ppb	D	Model: 85 ppb	E	Model: 80 ppb	F
Monitor: 80 ppb 10 miles	*	#	*	Monitor: 60 ppb 15 miles	*
	G	Model: 120 ppb Monitor: 100 ppb 20 miles	H		I
*					*

= Center Grid-Cell "E"

* = Air Pollution Monitor

Figure 4C-2. Numerical example of the Enhanced Voronoi Neighbor Averaging (eVNA) technique applied to a model grid domain

Based on the values shown in Figure 4C-2, the eVNA estimate for grid cell "E" is calculated as follows:

$$eVNA(E) = \left(0.4675 * 80 * \frac{85}{95}\right) + \left(0.2078 * 90 * \frac{85}{100}\right) + \left(0.2078 * 60 * \frac{85}{80}\right) + \left(0.1169 * 100 * \frac{85}{120}\right) = 70.9 \text{ ppb}$$

Equation (4C-4)

In this example, eVNA adjusts the modeled concentration in grid cell "E" downward to reflect the tendency for the model to over-predict the monitored concentrations. In general, the eVNA method attempts to use the monitored concentrations to adjust for model biases, while preserving local gradients in the modeled concentration fields. The computations for VNA and eVNA were executed using the R statistical computing program (R, 2012), with the Delaunay triangulation algorithm implemented in the "deldir" package (Turner, 2012).

4C-2.4 Downscaler (DS)

The Downscaler (DS) model is EPA's most recently developed "data fusion" method for spatially predicting air pollution concentrations. Downscaler essentially operates by calibrating CMAQ data to the observational data, and then uses the resulting relationship to predict "observed" concentrations at new spatial points in the domain. Although similar in principle to a linear regression, spatial modeling aspects have been incorporated for improving the model fit,

and a Bayesian¹ approach to fitting is used to generate an uncertainty value associated with each concentration prediction. The uncertainties that DS produces are a major distinguishing feature from earlier fusion methods previously used by EPA such as the "Hierarchical Bayesian" (HB) model (McMillan et al., 2009). The term "downscaler" refers to the fact that DS takes grid-averaged predictions from an air quality model such as CMAQ for input and produces point-based estimates, thus "scaling down" the area of data representation. Although this allows air pollution concentration estimates to be made at point locations where no observations exist, caution is needed when interpreting any within-grid cell spatial gradients generated by DS since they may not exist in the input datasets. The theory, development, and initial evaluation of DS can be found in the earlier papers of Berrocal, Gelfand, and Holland (2009, 2010, and 2011).

Downscaler develops a relationship between observed and modeled concentrations, and then uses that relationship to spatially predict what measurements would be at new locations in the spatial domain based on the input data. This process is separately applied for each time step (daily in this work) of data, and for each of the pollutants under study (O₃ and fine particulate matter, PM_{2.5}). In its most general form, the model can be expressed in an equation similar to that of linear regression:

$$Y(s, t) = \sim\beta_0(s, t) + \beta_1(t) * \sim x(s, t) + \varepsilon(s, t) \quad \text{Equation (4C-5)}$$

where $Y(s, t)$ is the observed concentration at point s and time t ,

$\sim x(s, t)$ is the CMAQ concentration at point s and time t , (This value is a weighted average of both the grid cell containing the monitor and neighboring grid cells.)

$\sim\beta_0(s, t)$ is the intercept, composed of global and local components,

$\beta_1(t)$ is the global slope, (Local components of the slope are contained in the $\sim x(s, t)$ term),

$\varepsilon(s, t)$ is the model residual error.

Downscaler has additional properties that differentiate it from linear regression:

1) Rather than just finding a single optimal solution to Equation (4C-5), DS uses a Bayesian approach so that uncertainties can be generated along with each concentration prediction. This involves drawing random samples of model parameters from built-in "prior" distributions and assessing their fit on the data on the order of thousands of times. After each iteration, properties of the prior distributions are adjusted to try to improve the fit of the next iteration. The resulting collection of $\sim\beta_0$ and β_1 values at each space-time point are the

¹ Bayesian statistical modeling refers to methods that are based on Bayes' theorem, and model the world in terms of probabilities based on previously acquired knowledge.

"posterior" distributions, and the means and standard distributions of these are used to predict concentrations and associated uncertainties at new spatial points.

2) The model is "hierarchical" in structure, meaning that the top level parameters in Equation (4C-5) (i.e., $\sim\beta_0(s,t)$, $\beta_1(t)$, $\sim x(s,t)$) are actually defined in terms of further parameters and sub-parameters in the DS code. For example, the overall slope and intercept is defined to be the sum of a global (one value for the entire spatial domain) and local (values specific to each spatial point) component. This gives more flexibility in fitting a model to the data to optimize the fit (i.e. minimize $\varepsilon(s,t)$).

EPA has recently used DS in other applications, such as providing spatial predictions of national daily 8-hour O₃ and PM_{2.5} concentrations at a census tract resolution to the Centers for Disease Control (CDC) for the Public Health Air Surveillance Evaluation (PHASE) project as part of their Environmental Public Health Tracking (EPHT) program.

4C-3. EVALUATION OF AIR QUALITY SPATIAL FIELD TECHNIQUES

This section describes the data, methods, and results of an evaluation that was performed in order to assess the relative accuracy of the predictions generated by the four air quality spatial field techniques described in the previous section.

4C-3.1 Data

The evaluation was designed to assess the relative ability of each spatial field technique to reproduce monitored concentrations for two annual air quality metrics: 1) the 4th highest daily maximum 8-hour O₃ concentration (henceforth referred to as the "4th max"), and 2) the May – September mean of the daily maximum 8-hour O₃ concentrations (henceforth referred to as the "seasonal mean"). For the ambient monitoring data, these two metrics were calculated for all monitors in the contiguous U.S. with complete data for 2007 based on the initial dataset and the data completeness criteria described in HREA Appendix 4A. For the air quality modeling data, the two metrics were calculated from hourly O₃ concentrations based on a CMAQ simulation with a 12 km gridded domain covering the contiguous U.S., and 2007 emissions and meteorology inputs (EPA, 2012b).

4C-3.2 Methods

Cross-validation is a method commonly used to evaluate the ability of statistical models to make accurate predictions. In a cross-validation analysis, the data are split into two subsets, the "calibration" subset, and the "validation" subset. The calibration subset is used to "fit" the model, usually by estimating parameters which establish a relationship between the variable of interest and one or more dependent variables. The resulting model fit is then applied to the

dependent variable(s) in the validation subset, and the predictive ability of the model is assessed by how accurately it is able to reproduce the variable of interest in the validation subset.

The evaluation used a systematic “4-fold” cross-validation scheme based on the CMAQ modeling domain (e.g., 12 km x 12 km grid covering the continental U.S.). The CMAQ modeling domain was divided into four groups, or “folds”, so that each 2x2 block of 12 km grid cells had one member in each fold. Figure 4C-3 shows an example of the resulting four folds with O₃ monitor locations for the area surrounding southern Lake Michigan. Four cross-validations were performed using VNA, eVNA, and DS, for both the 4th max and seasonal mean metrics. The calibration subset in the first cross-validation consisted of the monitors in folds 2, 3, and 4 as shown in Figure 4C-3 (blue dots), while the validation subset consisted of the monitors in fold 1 (red dots). The remaining cross-validations were performed in a similar manner, with three of the four folds used as the calibration subset and the final fold used as the validation subset. Thus, this method resulted in four cross-validation partitions, each with approximately 75% of the monitoring data used in the calibration subset, and the remaining 25% used in the validation subset. Each monitor was included in the validation subset exactly once, resulting in a validation dataset of observed 4th max and seasonal mean values paired with VNA, eVNA, and DS predictions of those values at monitor locations. The CMAQ predictions were simply the modeled 4th max and seasonal mean values for the 12 km grid cells containing O₃ monitors.

Figure 4C-3. Example of the “4-fold” cross-validation scheme used in the evaluation of the air quality spatial field techniques for the southern Lake Michigan area.

4C-3.3 Results

The cross-validation predictions based on the four air quality spatial field techniques were compared with the observed 4th max and seasonal mean values based on the ambient data. The comparison focused on three performance metrics: 1) the root mean squared error (RMSE), 2) the coefficient of variation (R^2), and 3) the mean bias (MB). The results of these comparisons are shown in Figure 4C-4 (4th max) and Figure 4C-5 (seasonal mean), and Table 4C-1 contains a summary of the three performance metrics for each technique.

The cross-validation results clearly showed that VNA, eVNA, and DS more accurately predict monitored 4th max and seasonal mean concentrations than the CMAQ model. The scatter plots and the mean bias statistics indicated that both eVNA and DS were effective at reducing the amount of bias present in the modeled concentrations. The differences between VNA, eVNA, and DS were much smaller, but the performance statistics consistently indicated that overall DS was able to most accurately reproduce the observed values. DS had the highest R^2 values, and the lowest RMSE and MB values of the four techniques for both air quality metrics. In contrast

to eVNA, DS seemed to be an improvement over VNA, which did not make use of the modeled concentration data. Based on these results, DS was deemed the most appropriate technique for generating spatial fields of seasonal mean O₃ concentrations for the national risk mortality burden analyses.

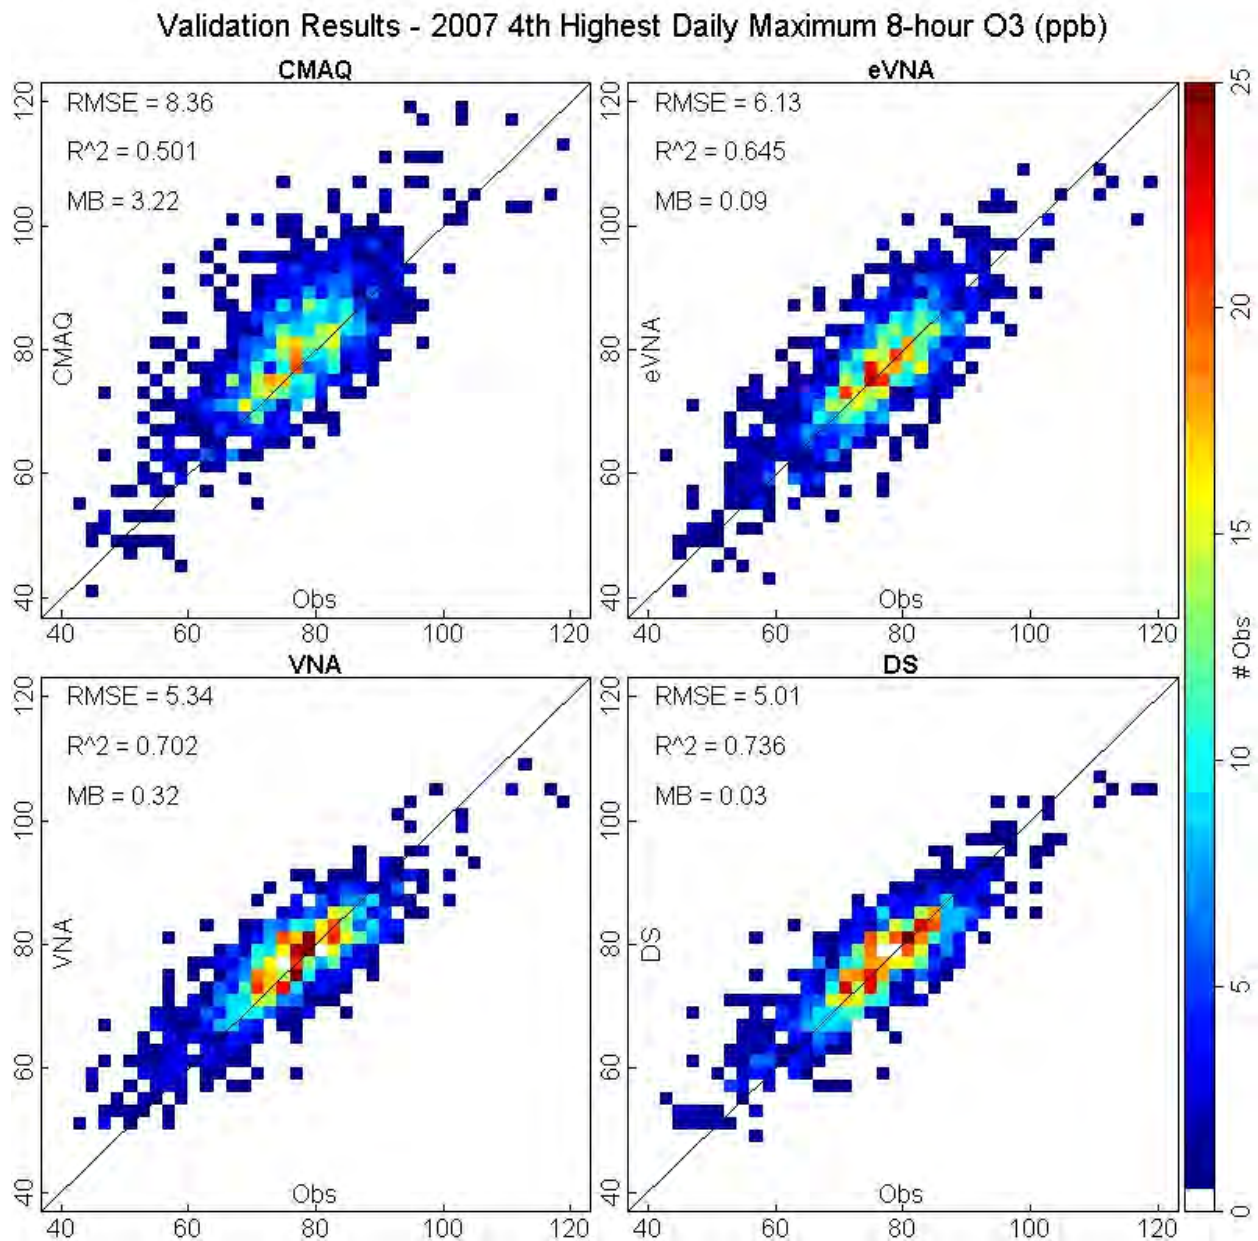

Figure 4C-4. Cross-validation results for the 2007 annual 4th highest daily maximum O₃ concentrations.

Validation Results - 2007 May - September Average Daily Maximum 8-hour O₃ (ppb)

Figure 4C-5. Cross-validation results for the 2007 May-September mean of the daily maximum 8-hour O₃ concentrations.

Table 4C-1. Summary of the cross-validation performance metrics for the four air quality spatial field techniques.

Performance Metric	O ₃ Metric	VNA	CMAQ	eVNA	DS
RMSE	4 th max	5.34	8.36	6.13	5.01
RMSE	seasonal mean	3.56	6.83	3.85	3.39
R ²	4 th max	0.702	0.501	0.645	0.736
R ²	seasonal mean	0.808	0.634	0.779	0.826
MB	4 th max	0.32	3.22	0.09	0.03
MB	seasonal mean	0.08	4.71	0.06	-0.02

4C-4. AIR QUALITY INPUTS TO THE NATIONAL-SCALE MORTALITY RISK BURDENT ASSESSMENT

Three air quality spatial fields were created using DS as inputs to the national mortality risk burden analyses. These fields were based on three seasonal mean O₃ metrics:

- 1) May-September average daily maximum 8-hour O₃ concentration (consistent with the metric used by Smith et al., 2009);
- 2) June-August average daily 10am-6pm mean O₃ concentration (consistent with the metric used by Zanobetti and Schwartz, 2008); and
- 3) April-September average daily maximum 1-hour O₃ concentration (consistent with the metric used by Jerrett et al., 2009).

For the ambient monitoring data, the 2006-2008 average of these annual metrics were calculated for all monitors in the contiguous U.S. with complete data for 2006-2008 based on the initial dataset and the data completeness criteria described in HREA Appendix 4A. For the air quality modeling data, these metrics were calculated from hourly O₃ concentrations based on a CMAQ simulation with a 12 km gridded domain covering the contiguous U.S., and 2007 emissions and meteorology inputs. This simulation differed from the one used for the evaluations in that the wildfire and power plant emissions inputs were based on multi-year averages instead of year-specific estimates. Appendix 4B contains a complete description of this CMAQ simulation and provides relevant model evaluation results.

Figure 4C-6, Figure 4C-7, and Figure 4C-8 show maps of the DS air quality spatial fields for the May-September average daily maximum 8-hour O₃ concentrations, the June-August average daily 10am-6pm mean O₃ concentrations, and the April-September average daily maximum 1-hour O₃ concentrations, respectively. The overall spatial pattern seen in these three fields is very similar, with the highest concentration values for each metric occurring in Southern California.

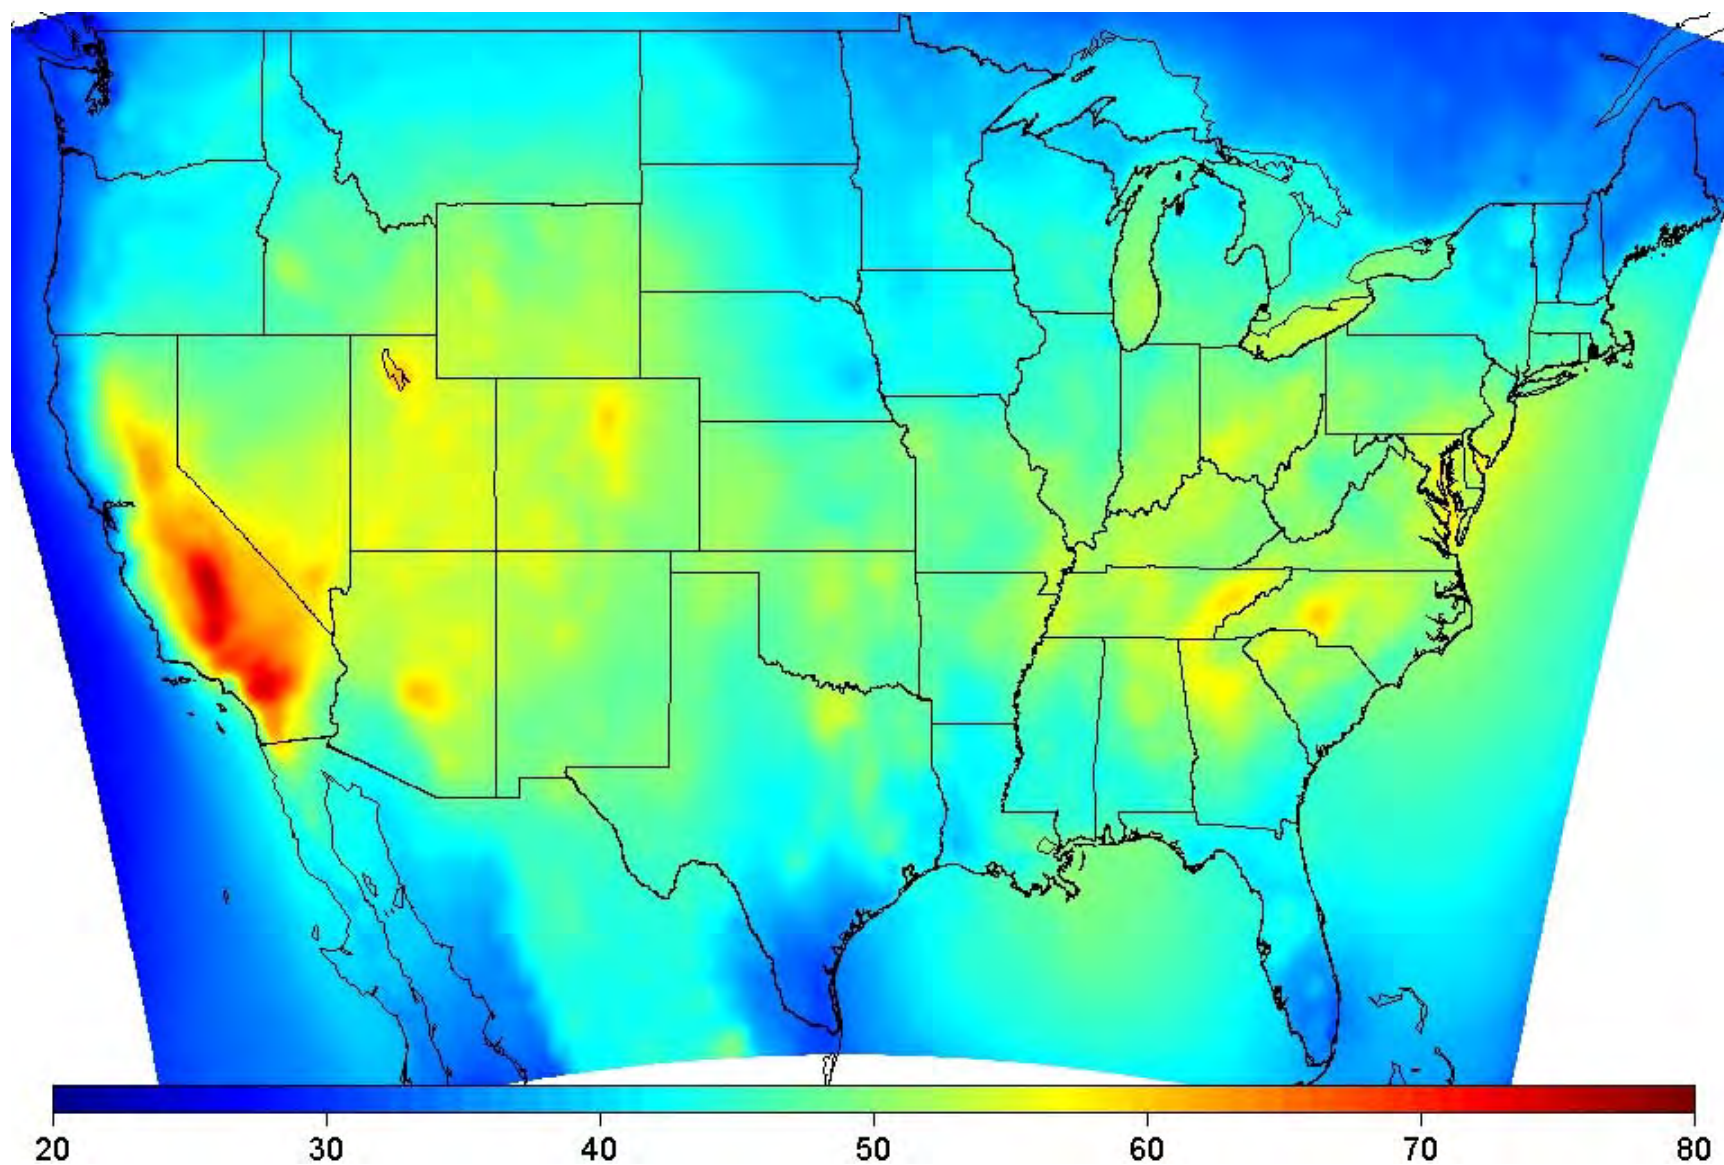

Figure 4C-6. May-September average daily maximum 8-hour O₃ concentrations in ppb, based on a Downscaler fusion of 2006-2008 average monitored values with a 2007 CMAQ model simulation.

Figure 4C-7. June-August average daily 10am-6pm mean O₃ concentrations in ppb, based on a Downscaler fusion of 2006-2008 average monitored values with a 2007 CMAQ model simulation.

Figure 4C-8. April-September average daily maximum 1-hour O₃ concentrations in ppb, based on a Downscaler fusion of 2006-2008 average monitored values with a 2007 CMAQ model simulation.

Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-55

Figure 4D-27. Hourly O₃ distributions at Washington, D.C. area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-56

Figure 4D-28. Monthly O₃ distributions at Atlanta area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-57

Figure 4D-29. Monthly O₃ distributions at Baltimore area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-58

Figure 4D-30. Monthly O₃ distributions at Boston area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-59

Figure 4D-31. Monthly O₃ distributions at Chicago area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative

(65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-60

Figure 4D-32. Monthly O₃ distributions at Cleveland area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-61

Figure 4D-33. Monthly O₃ distributions at Dallas area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-62

Figure 4D-34. Monthly O₃ distributions at Denver area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-63

Figure 4D-35. Monthly O₃ distributions at Detroit area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-64

Figure 4D-36. Monthly O₃ distributions at Houston area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative

(65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-65

Figure 4D-37. Monthly O₃ distributions at Los Angeles area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-66

Figure 4D-38. Monthly O₃ distributions at New York area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-67

Figure 4D-39. Monthly O₃ distributions at Philadelphia area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values. 4D-68

Figure 4D-40. Monthly O₃ distributions at Sacramento area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile

	range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.	4D-69
Figure 4D-41.	Monthly O ₃ distributions at St. Louis area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O ₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O ₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O ₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.	4D-70
Figure 4D-42.	Monthly O ₃ distributions at Washington, D.C. area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O ₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O ₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O ₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.	4D-71
Figure 4D-43.	Mean standard error in maximum daily 8-hr O ₃ concentrations at each monitoring location in Atlanta for the 75 ppb adjustment scenario (top row) and the 60 ppb adjustment scenario (bottom row) for the 2006-2008 time period (left column) and the 2008-2010 time period (right column).	4D-76
Figure 4D-44.	Mean standard error in maximum daily 8-hr O ₃ concentrations at each monitoring location in Baltimore for the 75 ppb adjustment scenario (top row) and the 60 ppb adjustment scenario (bottom row) for the 2006-2008 time period (left column) and the 2008-2010 time period (right column).	4D-77
Figure 4D-45.	Mean standard error in maximum daily 8-hr O ₃ concentrations at each monitoring location in Boston for the 75 ppb adjustment scenario (top row) and the 60 ppb adjustment scenario (bottom row) for the 2006-2008 time period (left column) and the 2008-2010 time period (right column).	4D-78
Figure 4D-46.	Mean standard error in maximum daily 8-hr O ₃ concentrations at each monitoring location in Chicago for the 75 ppb adjustment scenario (top row) and the 60 ppb adjustment scenario (bottom row) for the 2006-2008 time period (left column) and the 2008-2010 time period (right column).	4D-79
Figure 4D-47.	Mean standard error in maximum daily 8-hr O ₃ concentrations at each monitoring location in Cleveland for the 75 ppb adjustment scenario (top row) and the 60 ppb adjustment scenario (bottom row) for the 2006-2008 time period (left column) and the 2008-2010 time period (right column).	4D-80

4D-1. MOTIVATION FOR AN NEW TECHNIQUE TO SIMULATE OZONE CONCENTRATIONS UNDER ALTERNATIVE STANDARDS

As part of the reviews of the National Ambient Air Quality Standards (NAAQS) for ozone (O_3), EPA estimates health risks after O_3 has been adjusted to just meet the existing standard and potential alternative standards. The first draft documents for this review rely upon the quadratic rollback method used in previous reviews to adjust or “roll back” hourly O_3 concentrations in urban areas. Although the quadratic rollback method simulates historical patterns of air quality changes more closely than some alternative methods (e.g. simply shaving peak concentrations off at the NAAQS level), its implementation requires some assumptions that may not always hold true. Specifically, the quadratic rollback method assumes that all monitors in an urban area will have the same response to emissions changes not allowing for temporally varying response depending on time of day. In addition, it assumes that O_3 concentrations never increase in response to emissions reductions. However, during NO_x -saturated (i.e. VOC limited) conditions, NO_x reductions can result in O_3 increases (Seinfeld and Pandis, 1998). Finally, since the quadratic rollback method is purely a mathematical technique and does not account for physical and chemical atmospheric processes or the sources of emissions precursors that lead to O_3 formation, a backstop or “floor” must be used to ensure that predicted O_3 is not reduced below “background” concentrations¹.

EPA has received comments during past O_3 NAAQS reviews and during the January 9-10, 2012 and Sep 11-13, 2013 Clean Air Scientific Advisory Committee (CASAC) meetings for this O_3 NAAQS review which encourage the use of alternate methods to quadratic rollback. In addition, the National Research Council of the National Academies (NRC, 2008) recommended that EPA explore how emissions reductions might affect temporal and spatial variations in O_3 concentrations, and that EPA include information on how NO_x versus VOC control strategies might affect risk and exposure to O_3 .

Photochemical modeling can simulate the O_3 response to emission reductions while avoiding the limitations presented by the quadratic rollback method. While there are uncertainties inherent in any modeling exercise due to uncertainties in inputs and model parameters, photochemical modeling provides a more representative characterization of the spatial and temporal responses of O_3 to emissions reductions. In this document we present a

¹ Background O_3 has been characterized in previous reviews of the O_3 NAAQS as “policy relevant background” or PRB, defined as O_3 concentrations that would exist in the absence of North American anthropogenic emissions. In the current review, we have refined the concept of background O_3 to recognize that there are several possible definitions of background O_3 , reflecting both the geographic source of emissions, e.g. U.S., North American, Global non-U.S., and whether emissions are anthropogenic or natural in origin. In the cases described in this document, “background” refers to O_3 that would exist in absence of U.S. anthropogenic emissions.

model-based O₃ adjustment methodology that allows for adjustments to O₃ concentrations. This new approach is firmly rooted in the latest atmospheric modeling science and was peer reviewed in Simon et al. (2012). This analysis uses EPA's Community Multi-scale Air Quality (CMAQ) photochemical model (www.cmaq-model.org) instrumented with the Higher order Direct Decoupled Method (HDDM) - a tool that generates modeled sensitivities of O₃ to emissions changes - to estimate the distribution of O₃ concentrations associated with achievement of the existing O₃ standard and alternative standards for multiple urban areas. The HDDM sensitivities are applied to ambient measurements of O₃ to estimate how O₃ concentrations would respond to changes in U.S. anthropogenic emissions. We use this methodology to estimate O₃ concentrations meeting the existing and potential alternative standards in the health risk and exposure assessment (HREA) and the policy assessment (PA). The photochemical modeling incorporates emissions from non-anthropogenic sources and anthropogenic emissions from sources in the U.S and in portions of Canada and Mexico. Pollution from sources in other locations within and outside of North America is included as transport into the boundary of the modeling domain. Because the application of the model-based approach focuses on reductions in U.S. anthropogenic emissions while holding constant those emissions that influence U.S. background, all changes in O₃ will be relative to U.S. background. This does not mean that background O₃ concentrations will be constant between recent ambient O₃ conditions and after just meeting the existing or alternative standard levels, because of nonlinearities in the formation of O₃.

4D-2. HIGHER-ORDER DECOUPLED DIRECT METHOD (HDDM)

4D-2.1 Capabilities

Chemical transport models, such as CMAQ, simulate the effects of physical and chemical processes in the atmosphere to predict 3-D gridded pollutant concentrations (Foley et al., 2010, Appel et al., 2008, Appel et al., 2007, Byun and Schere, 2006). These models account for the impacts of emissions, transport, chemistry, and deposition on spatially and temporally varying pollutant concentrations. Required model inputs include time-varying emissions and meteorology fields, time varying concentrations of pollutants at the boundaries of the model domain (i.e. boundary conditions), and a characterization of the 3-D field of chemical concentrations to initialize the model (i.e. initial conditions).

Beyond modeling the concentrations of ambient O₃, chemical transport models can be used to estimate the response of ambient O₃ concentrations to changes in emissions. One technique to simulate the response of O₃ to emissions changes, the brute force method, requires the modeler to explicitly model this response by directly altering the emissions inputs in the model simulation. This technique provides an estimate of the O₃ concentration at the altered

emission level, but often does not provide accurate information regarding the response of O₃ to other levels of emissions since the chemistry for O₃ formation is nonlinear. Therefore, when using only brute force techniques a new model simulation would need to be performed for every emissions scenario under consideration.

Other analytical techniques have been developed to estimate the O₃ response to emissions changes without performing multiple simulations. One such method is termed the Decoupled Direct Method (DDM) (Dunker, 1984). DDM, solves for sensitivity coefficients which are defined as the partial derivative of the atmospheric diffusion equations that underly the model calculations, Equations (4D-1) and (4D-2).

$$s_{ij}(t) = \frac{\partial C_i(t)}{\partial p_j} \quad \text{Equation (4D-1)}$$

$$S_{ij}(t) = \tilde{p}_j \frac{\partial C_i(t)}{\partial p_j} = \tilde{p}_j \frac{\partial C_i(t)}{\partial (\epsilon_j \tilde{p}_j)} = \frac{\partial C_i(t)}{\partial \epsilon_j} \quad \text{Equation (4D-2)}$$

Here, $S_{ij}(t)$, the sensitivity, gives the change in model concentration, C_i , (for instance O₃ concentration) with an incremental change in any input parameter, p_j (in this case emissions). Equation (4D-2) allows us to normalize the sensitivity coefficient, $S_{ij}(t)$, so that it shows response in relative terms for the input rather than in absolute units. Therefore, $\tilde{p}_j(x,t)$ is the normalized input and ϵ_j is a scaling variable (Yang et al., 1997). In general terms, the sensitivity coefficient tells us how a model output (O₃ concentration) will change if a model input (emissions of NO_x or VOC) is varied. This first order sensitivity coefficient, $S_{ij}(t)$ is quite suitable for small changes, but gives a linear response which is unlikely to represent the results of large changes in very nonlinear chemical environments. Second (and third) order derivatives can be calculated to give higher order sensitivity coefficients (Hakami et al., 2003). Higher order sensitivity coefficients give the curvature and inflection points for the response curve and can capture the nonlinearities in the response of O₃ to emissions changes. Using Higher order DDM (HDDM) allows for the sensitivities to be more appropriately applied over larger emissions changes. Hakami et al. (2003) report that for an application in California, HDDM gave reasonable approximations of O₃ changes compared to brute force results for emission changes up to 50% using the first three terms of the Taylor series expansion, Equation (4D-3).

$$C(+\Delta\epsilon) = C(0) + \Delta\epsilon S(0) + \frac{\Delta\epsilon^2}{2} S^2(0) + \dots + \frac{\Delta\epsilon^n}{n!} S^n(0) + R_{n+1}$$

Equation (4D-3)

Here $\Delta\epsilon$ represents the relative change in emissions (for instance $\Delta\epsilon = -0.2$ would be equivalent to reducing emissions by 20%), $S^n(0)$ is the n^{th} order sensitivity coefficient, $C(0)$ is the concentration under baseline conditions (no change in emissions) and R_{n+1} is a remainder term.

A variant of DDM called DDM-3D has been implemented into several chemical transport models, including CMAQ, for both O_3 and particulate matter (PM) predictions (Dunker, 1984; Yang et al., 1997; Hakami et al., 2003; Cohan et al., 2005; Napelenok et al., 2006; Koo et al., 2010; Zhang et al., 2012). These implementations allow the modeler to define the parameters for which first and higher order sensitivities will be calculated. For instance, the sensitivity can be calculated for emissions from a specific source type, for emissions in a specific geographic region, and for emissions of a single O_3 precursor or for multiple O_3 precursors. In addition, sensitivities can be calculated to boundary conditions, initial conditions, and various other model inputs. Sensitivities to different sets of parameters can be calculated in a single model simulation but computation time increases as the number of sensitivities increases. Outputs from an HDDM simulation consist of time varying 3-D fields of first and second order sensitivities.

For the purposes of the O_3 NAAQS analysis, HDDM provides an improved approach compared to existing quadratic rollback techniques for several reasons. First, it captures non-linearity of O_3 response to emissions changes, representing both increases and decreases in O_3 concentrations resulting from emissions reductions. Second, HDDM characterizes different O_3 response at different locations (downtown urban versus downwind suburban) and at different times of day allowing us to incorporate temporal and spatial variations in response into the O_3 adjustment methodology. Finally, HDDM eliminates the need to use “background” O_3 as a floor for rollback since predicted sensitivities are based on model formulations that explicitly account for background sources.

4D-2.2 Limitations

In addition to the many potential benefits of using HDDM to understand and characterize O_3 response to emissions changes, there are several limitations. First, HDDM encompasses all of the uncertainties of the base photochemical model formulation and inputs. So uncertainties in how the physical and chemical processes are treated in the model and in the model inputs propagate to the HDDM results. Also, HDDM can capture response to larger emissions changes than DDM but it is still most accurate for small changes. The larger the relative change in emissions, the less likely that the HDDM sensitivities will properly capture the change in O_3 that

would be predicted by a brute force model simulation. Several studies have reported reasonable performance of HDDM for O₃ up to 50% emission changes (Hakami et al., 2003; Cohan et al., 2005; Hakami et al., 2004), but the magnitude of change over which HDDM will give accurate estimates will depend on the specific modeling episode, size of the model domain, emissions and meteorological inputs, and the size of the emissions source to which the sensitivity is being calculated. In this work, we applied sensitivities derived from model simulations done under varying NO_x levels (see Section 4D-4D-3.2.1) and found that using this technique we were able to replicate brute force estimates using HDDM sensitivities for up to 90% NO_x reductions with a mean bias of less than 3 ppb and a mean error of less than 4 ppb.

4D-3. APPLYING HDDM/CMAQ TO ADJUST OZONE TO JUST MEET EXISTING AND ALTERNATIVE STANDARDS: METHODOLOGY

4D-3.1 Conceptual Framework

This section outlines the methodology from Simon et al. (2012) in which we apply CMAQ/HDDM to estimate hourly O₃ concentrations that might result from meeting the existing and potential alternative standards. As part of the methodology, photochemical modeling results are not used in an absolute sense, but instead are applied to modulate ambient measurements, thus tying estimated O₃ distributions to measured values. The basic steps are outlined below and in Figure 4D-1. Details are given in section 4D-4D-3.2. The inputs, set-up, and evaluation of the modeling system are described in Appendix 4B.

- **Step 1:** Run CMAQ simulation with HDDM to determine hourly O₃ sensitivities to NO_x emissions and VOC emissions for the grid cells containing monitoring sites in an urban area.
- **Step 2:** For each monitoring site, season, and hour of the day use linear regression to relate first order sensitivities of NO_x and VOC (S_{NO_x} and S_{VOC}) to modeled O₃ and second order sensitivities to NO_x and VOC ($S^2_{NO_x}$ and S^2_{VOC}) to the first order sensitivities.
- **Step 3:** For each measured hourly O₃ value, calculate the first and second order sensitivities based on monitoring site-, season-, and hour-specific functions calculated in Step 2.
- **Step 4:** Adjust measured hourly 2006-2010 O₃ concentrations for incrementally increasing levels of emissions reductions using assigned sensitivities and then recalculate 2006-2008 and 2008-2010 design values until all monitors in an urban area just meet the existing and potential alternative levels of the standard.

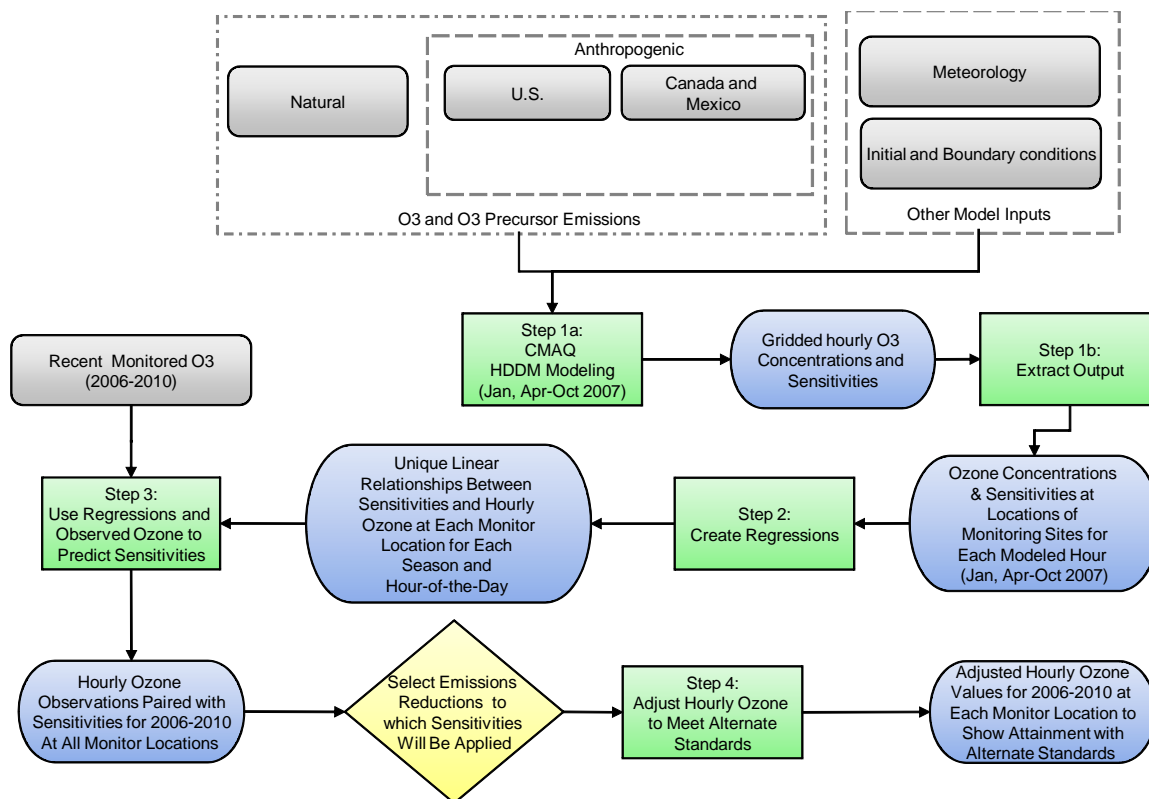

Figure 4D-1. Flow diagram demonstrating DDM model-based O₃ adjustment approach.

4D-3.2 Application to Measured O₃ Concentrations in 15 Urban Areas

In this analysis, we apply the model-based adjustment approach described above for just meeting the existing standard and three potential alternative standards. The analysis covers the 15 urban study areas listed in HREA Chapter 4 using photochemical modeling for January, and April-October of 2007 and ambient data for the years 2006-2010. When running CMAQ with HDDM, additional information is required to designate model inputs for calculating sensitivities. In this analysis, HDDM was set up to calculate the sensitivity of O₃ concentrations to U.S. anthropogenic NO_x and VOC emissions.² US anthropogenic emissions were defined as all emissions in the following sectors: commercial marine and rail, onroad mobile, offroad mobile, Electric Generating Unit (power plant) point sources, non-EGU point, and non-point area. These sectors accounted for 17.6 million of the total domain-wide 23.6 million tons per year of NO_x emissions and 13.8 million of the total domain-wide 68.1 million tons per year of VOC emissions. Sensitivities were not determined for biogenic, fire, Canadian, or Mexican emissions. In addition, sensitivities were not calculated for any emissions originating from outside the domain (i.e. entering through the use of boundary concentrations).

² Sensitivities only tracked U.S. emissions in the contiguous 48 states.

4D-3.2.1 Multi-step Application of HDDM Sensitivities

As discussed in Section 4D-4D-2.2 of this appendix, HDDM has been reported to reasonably replicate brute force emissions reductions up to a 50% change in emissions. For this analysis, it was desirable to have confidence that the HDDM sensitivities could replicate the entire range of emissions reductions. Evaluations of the HDDM estimates compared to brute force emissions reduction model runs confirm that the HDDM estimates of O₃ response to NO_x reductions are fairly comparable for a 50% change. However, HDDM and brute force estimates begin to diverge in comparisons under larger emissions changes (90%). Consequently four additional CMAQ/HDDM runs were performed under different levels of NO_x and VOC emissions reductions in order to characterize O₃ sensitivities to NO_x reductions over a larger range of emissions changes. One CMAQ/HDDM simulation was performed with U.S. anthropogenic NO_x cut by 50%. A second additional simulation was performed with a 90% NO_x reduction. Another set of CMAQ/HDDM simulations were performed for simultaneous NO_x and VOC cuts (50% NO_x and 50% VOC; 90% NO_x and 90% VOC). Emissions of other species were not modified from the base case in these four simulations. These additional HDDM simulations give O₃ sensitivities to NO_x and VOC under conditions with lower NO_x (or NO_x and VOC) emissions in the U.S. These sensitivities are used in a multistep adjustment approach.

Figure 4D-2 gives a conceptual picture of the multistep adjustment procedure using first-order sensitivities. Sensitivities from the base run are used to adjust O₃ concentrations for NO_x emissions reductions up to X%. Additional emission reductions beyond X% use sensitivities from the 50% NO_x cut run until reductions exceed (X+Y)%. Finally, sensitivities from the 90% NO_x cut run are applied for any emission reductions beyond (X+Y)%. In order to more closely approximate the non-linear O₃ response to any level of emissions reductions, 2nd order terms are added to the multistep approximation method in Equations (4D-4) to (4D-7). P represents the percentage NO_x cut for which the ΔO_3 values are being calculated, S and S² are the first and second order O₃ sensitivities to U.S. NO_x emissions, and X and Y are described above. Alternately, Equation (4D-8) can be used with Equations (4D-5) to (4D-7) if simultaneous NO_x and VOC_c cuts are being simulated. Note that the 50% and 90% cut sensitivities used in Equation (4D-8) come from model runs which cut both VOC and NO_x by these percentages in contrast to the NO_x cut only sensitivities that are used in Equation 4D-4. Consequently, Equation (4D-8) works only for equal percentage cuts in both NO_x and VOC emissions. In equations (4D-5) to (4D-8), we cap ΔO_3 , so that O₃ never drops below zero due to emissions changes.

$$\Delta O_3 = -a \times S_{NOx_{base}} + \frac{a^2}{2} \times S_{NOx_{base}}^2 - b \times S_{NOx_{50}\%cut} + \frac{b^2}{2} \times S_{NOx_{50}\%cut}^2 - c \times S_{NOx_{90}\%cut} + \frac{c^2}{2} \times S_{NOx_{90}\%cut}^2$$

Equation (4D-4)

$$a = \begin{cases} \frac{P}{100} & \text{for } P \leq X \\ \frac{X}{100} & \text{for } P > X \end{cases}$$

Equation (4D-5)

$$b = \begin{cases} 0 & \text{for } P \leq X \\ \frac{2 \times (P - X)}{100} & \text{for } X < P \leq (X + Y) \\ \frac{2 \times Y}{100} & \text{for } P > (X + Y) \end{cases}$$

Equation (4D-6)

$$c = \begin{cases} 0 & \text{for } P \leq (X + Y) \\ \frac{10 \times (P - (X + Y))}{100} & \text{for } 100 \geq P > (X + Y) \end{cases}$$

Equation (4D-7)

$$\begin{aligned} \Delta O_3 = & -a \times S_{NOx_{base}} + \frac{a^2}{2} \times S_{NOx_{base}}^2 - a \times S_{VOC_{base}} + \frac{a^2}{2} \times S_{VOC_{base}}^2 + a^2 \times S_{NOx,VOC_{base}}^2 \\ & - b \times S_{NOx_{50}\%cut} + \frac{b^2}{2} \times S_{NOx_{50}\%cut}^2 - b \times S_{VOC_{50}\%cut} + \frac{b^2}{2} \times S_{VOC_{50}\%cut}^2 + b^2 \times S_{NOx,VOC_{50}\%cut}^2 \\ & - c \times S_{NOx_{50}\%cut} + \frac{c^2}{2} \times S_{NOx_{50}\%cut}^2 - c \times S_{VOC_{50}\%cut} + \frac{c^2}{2} \times S_{VOC_{50}\%cut}^2 + c^2 \times S_{NOx,VOC_{50}\%cut}^2 \end{aligned}$$

Equation (4D-8)

Figure 4D-2. Conceptual picture of 3-step application of HDDM sensitivities.

The ideal value for equation transition points, X and Y, are determined by minimizing the least square mean error between the adjusted concentrations using the multistep approach and modeled concentrations from brute force NO_x cut runs. We first determined the value of X which gave the lowest error compared to brute forces estimates at 50% NO_x cuts. Then holding X constant, we determined the value of Y which gave the lowest error compared to brute force estimates at 90% NO_x cuts. This process was performed independently for each of the 15 urban areas in this analysis.

Error in HDDM estimates of hourly O₃ is defined here as the difference between HDDM estimates and brute force O₃. Based on Equations (4D-4) to (4D-7), this can be calculated from Equations (4D-9) and (4D-10) for 50% NO_x cuts:

$$\varepsilon = \Delta Ozone_{HDDM,50} - \Delta Ozone_{BF,50}$$

Equation (4D-9)

$$\varepsilon = \frac{-X}{100} \times S_{NOx_base} + \frac{X^2}{2 \times 100^2} \times S_{NOx_base}^2 - \frac{2(50-X)}{100} \times S_{NOx_{50}\%cut} + \frac{(2 \times (50-X))^2}{2 \times 100^2} \times S_{NOx_{50}\%cut}^2 - \Delta Ozone_{BF,50}$$

Equation (4D-10)

Equation (4D-10) can be rearranged to appear in the form: $AX^2 + BX + C$:

$$\varepsilon = \left(\frac{S_{NOx_base}^2}{2 \times 100^2} + \frac{4 \times S_{NOx_{50}\%cut}^2}{2 \times 100^2} \right) X^2 + \left(\frac{-S_{NOx_base}}{100} + \frac{2 \times S_{NOx_{50}\%cut}}{100} - \frac{400 \times S_{NOx_{50}\%cut}^2}{2 \times 100^2} \right) X + \left(-S_{NOx_{50}\%cut} + \frac{S_{NOx_{50}\%cut}^2}{2} - \Delta Ozone_{BF,50} \right)$$

Equation (4D-11)

$$A = \left(\frac{S_{NOx_base}^2}{2 \times 100^2} + \frac{4 \times S_{NOx_{50}\%cut}^2}{2 \times 100^2} \right)$$

Equation (4D-12)

$$B = \left(\frac{-S_{NOx_base}}{100} + \frac{2 \times S_{NOx_{50}\%cut}}{100} - \frac{400 \times S_{NOx_{50}\%cut}^2}{2 \times 100^2} \right)$$

Equation (4D-13)

$$C = \left(-S_{NOx_{50}\%cut} + \frac{S_{NOx_{50}\%cut}^2}{2} - \Delta Ozone_{BF,50} \right)$$

Equation (4D-14)

Next, the error is squared, summed over all points (error can be calculated for each hourly O₃ value at each monitoring location), and the derivative is set to 0 to determine X which gives the least squares error (Equations (4D-15), (4D-16), and (4D-17)).

$$\varepsilon^2 = A^2 X^4 + 2ABX^3 + (2AC + B^2)X^2 + 2BCX + C^2$$

Equation (4D-15)

$$\sum \varepsilon^2 = (\sum A^2)X^4 + (\sum 2AB)X^3 + (\sum 2AC + B^2)X^2 + (\sum 2BC)X + \sum C^2$$

Equation (4D-16)

$$(\sum \varepsilon^2)' = (4 \sum A^2)X^3 + (3 \sum 2AB)X^2 + (2 \sum 2AC + B^2)X + (\sum 2BC) = 0$$

Equation (4D-17)

The value of X that gives the least squares error will occur at one of the 3 roots of the trinomial in Equation (4D-17) or at 0 or 50. All real roots, 0, and 50 were input into Equation (4D-16) and X was set to the value which resulted in the lowest error in each city. An analogous procedure was followed to determine Y using the 90% NO_x cut brute force simulation and Equations (4D-18) through (4D-24).

$$\begin{aligned}\varepsilon = & \frac{-X}{100} \times S_{NOx_{base}} + \frac{X^2}{2 \times 100^2} \times S_{NOx_{base}}^2 - \frac{2Y}{100} \times S_{NOx_{90\%cut}} \\ & + \frac{2^2 Y^2}{2 \times 100^2} \times S_{NOx_{90\%cut}}^2 - \frac{10(90 - (X + Y))}{100} \times S_{NOx_{90\%cut}} \\ & + \frac{(10^2(90 - (X + Y)))^2}{2 \times 100^2} \times S_{NOx_{90\%cut}}^2 - \Delta Ozone_{BF,90}\end{aligned}$$

Equation (4D-18)

$$\varepsilon^2 = A^2 Y^4 + 2ABY^3 + (2AC + B^2)Y^2 + 2BCY + C^2$$

Equation (4D-19)

$$A = \left(\frac{4 \times S_{NOx_{90\%cut}}^2}{2 \times 100^2} + \frac{100 \times S_{NOx_{90\%cut}}^2}{2 \times 100^2} \right)$$

Equation (4D-20)

$$B = \left(\frac{-2 \times S_{NOx_{90\%cut}}}{100} + \frac{10 \times S_{NOx_{90\%cut}}}{100} - \frac{200 \times (90 - X) S_{NOx_{90\%cut}}^2}{2 \times 100^2} \right)$$

Equation (4D-21)

$$C = \left(\frac{-X}{100} S_{NOx_{base}} + \frac{X^2}{2 \times 100^2} S_{NOx_{base}}^2 - \frac{10 \times (90 - X)}{100} S_{NOx_{90\%cut}} + \frac{100 \times (90 - X)^2}{2 \times 100^2} S_{NOx_{90\%cut}}^2 - \Delta Ozone_{BF,90} \right)$$

Equation (4D-22)

$$\sum \varepsilon^2 = (\sum A^2)Y^4 + (\sum 2AB)Y^3 + (\sum 2AC + B^2)Y^2 + (\sum 2BC)Y + \sum C^2$$

Equation (4D-23)

$$(\sum \varepsilon^2)' = (4 \sum A^2)Y^3 + (3 \sum 2AB)Y^2 + (2 \sum 2AC + B^2)Y + (\sum 2BC) = 0$$

Equation (4D-24)

This methodology can also be adjusted to calculate least squares error cut points for the combined NO_x and VOC emissions reduction case. X and Y cut points which have the least square error in each urban area are shown in Table 4D-1. This 3-step adjustment methodology was shown to be a robust method for minimizing error in the HDDM applications for larger percentage changes in emissions by Simon et al. (2012). Figure 4D-3 through Figure 4D-6 are density scatter plots that compare hourly O₃ estimates from brute force with hourly O₃ estimates from the 3-step HDDM adjustments at all monitor locations in each of the 15 urban areas evaluated in this study. The colors in these plots depict the percentage of points falling at any one location. Mean error for the 50% and 90% 3-step HDDM adjustment NO_x cut cases compared to brute force results are less than 1 ppb and 4 ppb respectively in all 15 case study areas.

Table 4D-1. X and Y cut points used in Equations (4D-4) and (4D-8). Note: the NO_x/VOC sensitivity case was only performed in two cities.

Urban Area	NO _x cuts only		NO _x and VOC combined cuts	
	X	Y	X	Y
Atlanta	40	46		
Baltimore	40	46		
Boston	39	45		
Chicago	38	45	40	46

4D-3.2.2 Relationships between HDDM Sensitivities and Modeled O₃ Concentrations

First and second order hourly O₃ sensitivities to VOC and NO_x were extracted from the HDDM simulation for model grid cells that contained the O₃ monitors in the 15 urban areas. Extracted data included modeled sensitivities at monitor locations for all modeled hours in 2007. These sensitivities cannot be applied directly to observed values for two reasons: 1) high

modeled O₃ days/hours do not always occur concurrently with high observed O₃ days/hours and 2) the modeling time period includes 8 months in 2007 but the time period we are analyzing in this HREA includes five full years of ambient data, 2006-2010. As to the first point, photochemical models are generally used in a relative sense for purposes of projecting design values to assess just meeting the NAAQS standard. In this manner, model predictions are “anchored” to measured ambient values. In general, the average response on high modeled days is used for this purpose. This allows for more confidence in calculated results when “less than ideal model performance [occurs] on individual days” (U.S. EPA, 2007). Similarly, for this analysis we believe it is appropriate to account for the fact the model does not always perfectly agree with measurements and that sensitivities from a low O₃ modeled day would not be appropriate to apply to a high O₃ measured day (and vice-versa) even if they occur on the same calendar day. For the second point, due to current resource and time constraints we were only able to model 8 months in 2007. However, the O₃ exposure analysis evaluates the effects of O₃ decreases for two 3-year periods in 2006-2008 and 2008-2010 most of which is outside the modeled time period. For both of these reasons, a method was developed to generalize the modeled site-, season-, and hour-specific sensitivities so that they could be applied to ambient data during 2006-2010.³

Simon et al. (2012) describe how first order sensitivities are generally well correlated with hourly modeled O₃ concentrations and second order sensitivities are well correlated to first order sensitivities. Based on their analysis, we create a separate linear regression for S_{NO_x} and S_{VOC} as functions of hourly O₃ (i.e. $S_{NO_x} = m \times O_3 + b$) for every site, season⁴, and hour-of-the day examined in this analysis. For instance, for summer 8-am hours at Detroit Site 260990009, S_{NO_x} and O₃ values from all 8 am hours in June-August 2007 are used to fit this relationship. Since only 8 months were modeled (Jan, April-October) regressions for summer season relationships include more data points (92) than those for winter (31), spring (61), and fall (61). Similarly, S²_{NO_x} and S²_{VOC} were calculated as a function of S_{NO_x} and S_{VOC} respectively and S²_{NO_x,VOC} was calculated as a linear combination of both S_{NO_x} and S_{VOC}. Figure 4D-7, Figure 4D-8, and Figure 4D-9 show examples of these regressions for first order NO_x sensitivities for a NO_x-limited site (summertime, downwind of Atlanta), a NO_x-saturated site (autumn, Queens NY), and a transitional site which switches between chemical regimes (spring, Long Island NY). Example

³ The 8 months modeled covered a variety of conditions such that we can use the results from this modeled time period in conjunction with the ambient data from the longer 5-year period for estimating response and applying adjustments

⁴ Here seasons are defined as follows:

For ambient data, Winter = December, January, February; Spring = March, April, May;

Summer = June, July, August; Fall = September, October, November.

For modeled data, Winter = January; Spring = April, May; Summer = June, July, August;

Fall = September, October

relationships are shown for four different times of day with different O₃ response behavior: nighttime (1:00 LST), mid-afternoon (15:00 LST), morning rush-hour (8:00 LST), and evening rush-hour (18:00 LST). The Atlanta area NO_x-limited site (Figure 4D-7) generally showed positive sensitivities which would lead to decreasing O₃ with decreasing emissions. However some limited O₃ increases with NO_x reductions from NO_x (negative sensitivities) occurred at this site during nighttime and rush-hour times. The Queens site had negative sensitivities at these four hours on almost all days indicating strongly NO_x saturated conditions. The slopes from the regressions at the Queens site were negative indicating larger O₃ increases are high concentrations. Finally, the Long Island site had both positive and negative sensitivities but the slope was positive resulting in O₃ increases for low basecase concentrations but O₃ decreases at higher basecase concentrations. Correlations were strongest at the NO_x limited site and during rush-hour and nighttime periods for the other sites. Figure 4D-10, Figure 4D-11, and Figure 4D-12 show these regressions from the same sites and time-periods for second order sensitivities.

Comparisons between brute force and HDDM O₃ estimates shown in Figure 4D-5 and Figure 4D-6, demonstrate that for the vast majority of data points, HDDM replicates brute force with minimal errors. However, these figures show a small number of instances in which HDDM predicts very high hourly O₃ (> 100 ppb) while the brute force emissions simulations show much lower O₃ (< 40 ppb). In such cases, base modeled O₃ is low due to NO_x titration and increases occur with reductions of NO_x. The HDDM sensitivities for these few points appear to be too high to be applied over large emissions changes because of strongly nonlinear chemistry. While the brute force simulations predict modest increases in O₃ at these hours, the HDDM method predicts very large increase in O₃ at these hours. To avoid outlier sensitivities from biasing this analysis, we set a floor value for negative S_{NO_x} values (O₃ increases) in each regression so that S_{NO_x} never drops below the 5th percentile modeled S_{NO_x} (for each site, hour, season grouping) when negative S_{NO_x} values are simulated (see dotted blue lines in Figure 4D-7, Figure 4D-8, and Figure 4D-9). In addition, S_{NO_x} is prevented from dropping below 0 when all modeled S_{NO_x} values were positive (i.e. no modeled increases in O₃). These floor values have the most influence when regressions with highly NO_x-saturated conditions, such as those shown for Queens NY, are applied to ambient O₃ values that are higher than the modeled range. For instance in Figure 4D-9, if there were any measured autumn 18:00 O₃ concentrations above 30 ppb at that site in 2006-2010, the floor would prevent the extrapolation of O₃ increases from the modeled time period to conditions that do not apply. This floor is necessary for O₃ increases which, if extrapolated, could unrealistically increase O₃ without a bound. In contrast, the O₃ decreases can never exceed the total measured O₃ so positive NO_x sensitivities have a built-in upper bound.

For the 50% and 90% emissions cut CMAQ/HDDM simulation, regressions were performed for first order NO_x and VOC sensitivities with modeled O_3 from the base HDDM simulation. The regression technique was performed for the first and second order NO_x and VOC sensitivities from the base run and the 50% emissions cut and 90% emissions cut simulations. The sensitivities from the emissions cut runs were fitted to hourly O_3 concentrations in the base simulation. Simon et al. (2012) found that correlation coefficients using for sensitivities from NO_x cut simulations to base case O_3 concentrations were similar to those with O_3 concentrations from the NO_x cut runs.

Figure 4D-7. Relationship between S_{NO_x} and hourly O_3 at a NO_x -limited site downwind of Atlanta (summer). Relationships are shown for one nighttime hour, one morning rush-hour hour, one daytime hour, and one evening rush-hour hour. The solid blue line show the linear regression for these points and the dotted blue line shows the floor value used for S_{NO_x} based on the 5th percentile modeled value.

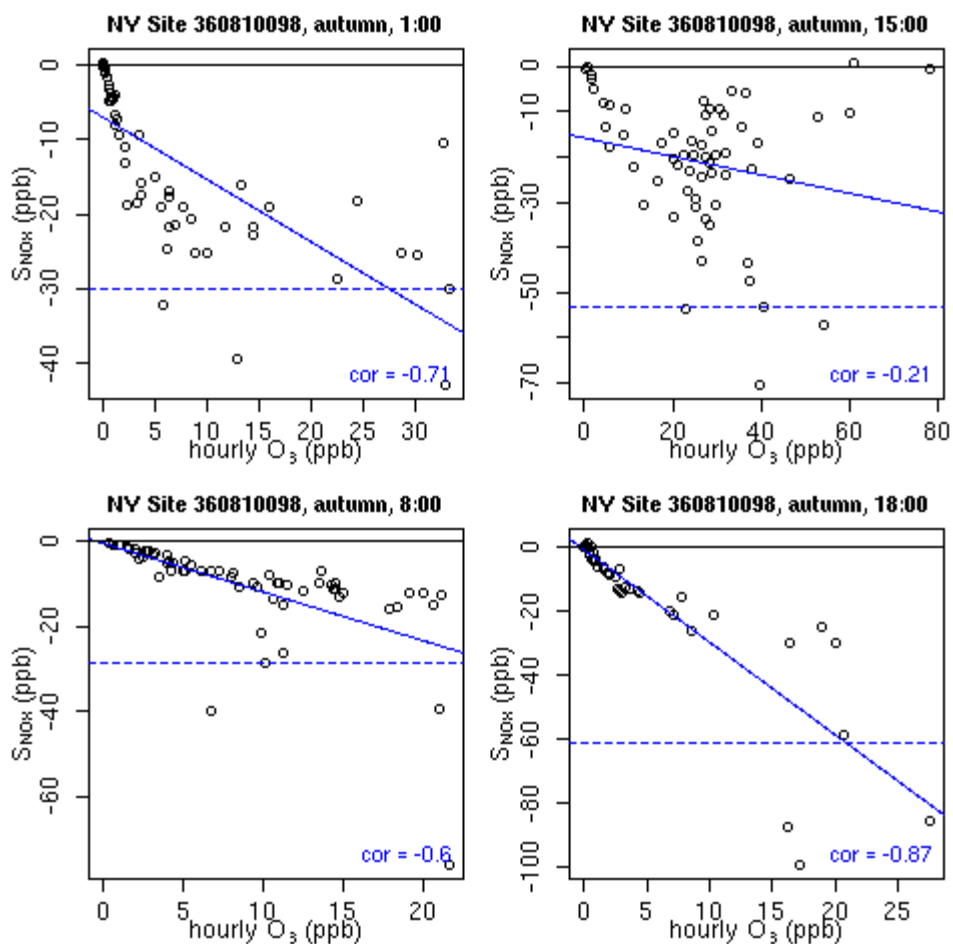

Figure 4D-8. Relationship between S_{NOx} and hourly O_3 at a NO_x -saturated site in Queens County, NY (autumn). Relationships are shown for one nighttime hour, one morning rush-hour hour, one daytime hour, and one evening rush-hour hour. The solid blue line show the linear regression for these points and the dotted blue line shows the floor value used for S_{NOx} based on the 5th percentile modeled value.

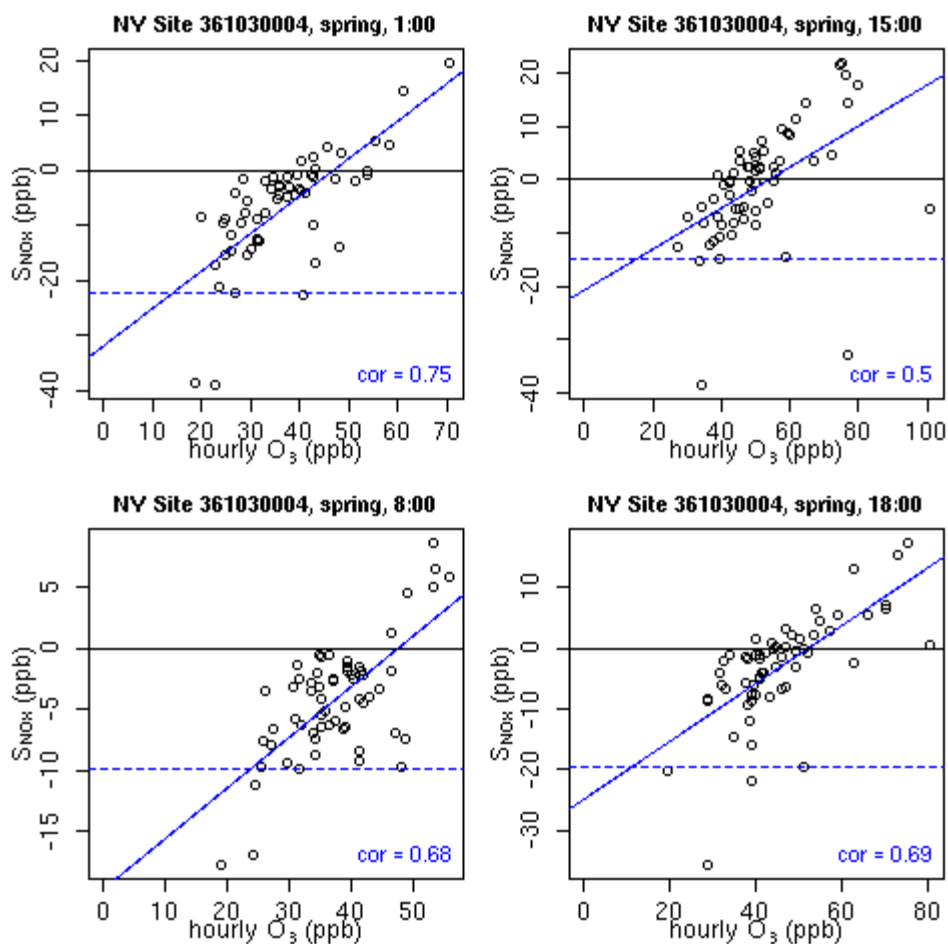

Figure 4D-9. Relationship between S_{NOx} and hourly O_3 at a NO_x -saturated site in Suffolk County, NY on Long Island (spring). Relationships are shown for one nighttime hour, one morning rush-hour hour, one daytime hour, and one evening rush-hour hour. The solid blue line show the linear regression for these points and the dotted blue line shows the floor value used for S_{NOx} based on the 5th percentile modeled value.

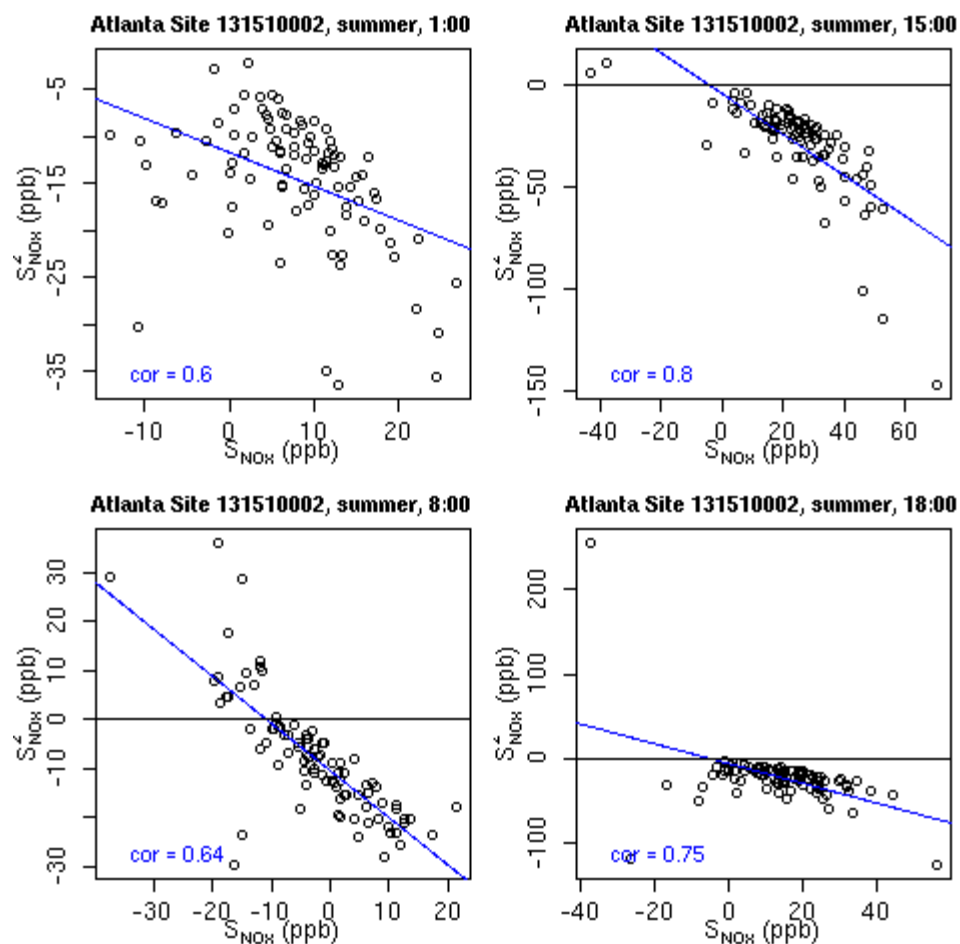

Figure 4D-10. Relationship between S^2_{NOx} and S_{NOx} at a NO_x -limited site downwind of Atlanta (summer). Relationships are shown for one nighttime hour, one morning rush-hour hour, one daytime hour, and one evening rush-hour hour. The solid blue line shows the linear regression for these points.

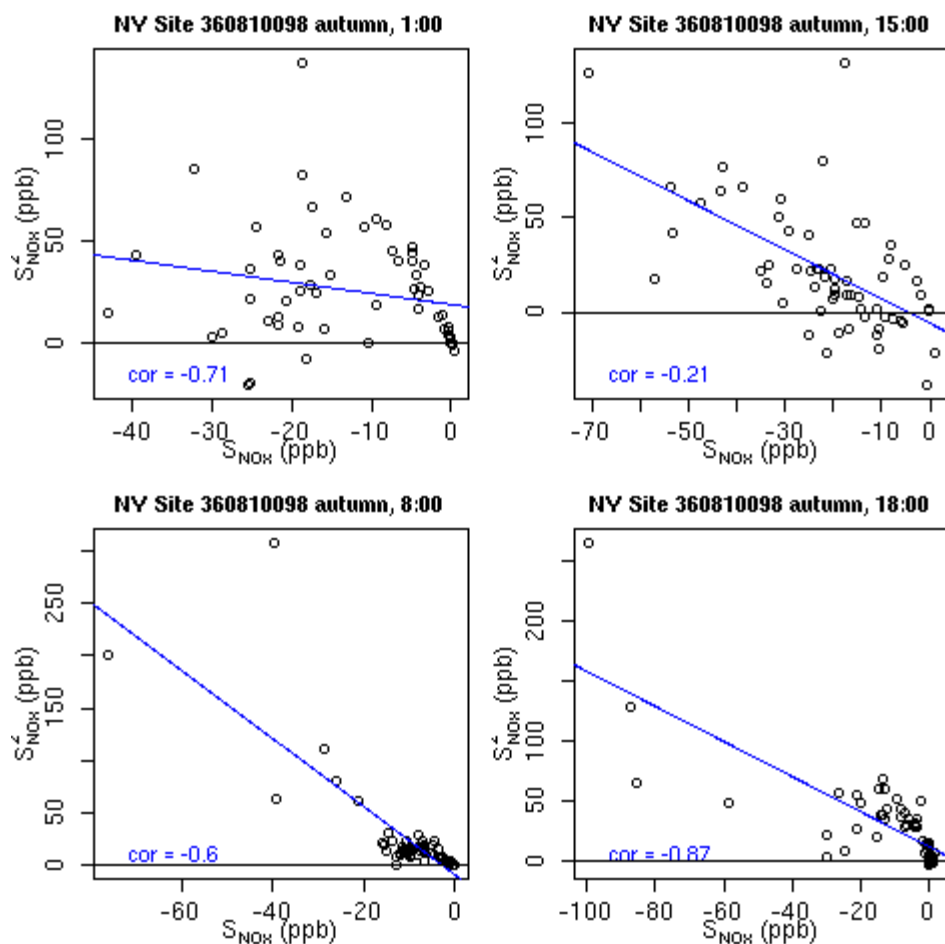

Figure 4D-11. Relationship between S^2_{NOx} and S_{NOx} at a NO_x -saturated site in Queens County, NY (autumn). Relationships are shown for one nighttime hour, one morning rush-hour hour, one daytime hour, and one evening rush-hour hour. The solid blue line shows the linear regression for these points.

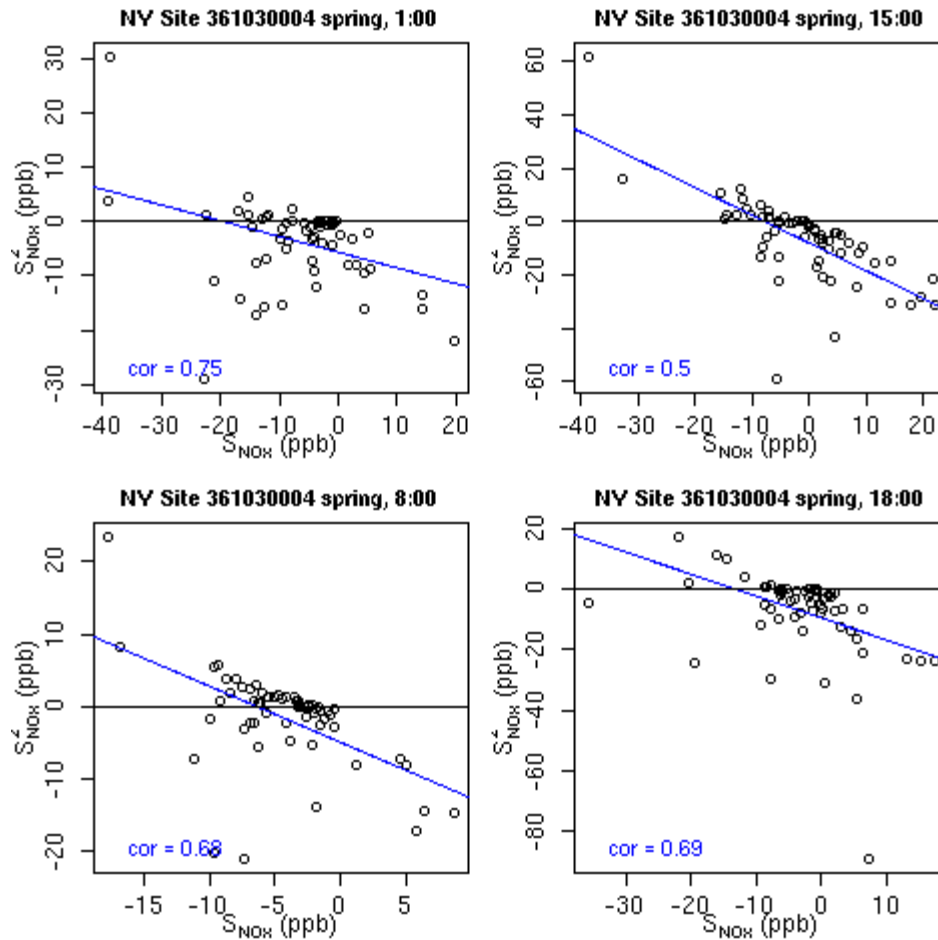

Figure 4D-12. Relationship between S^2_{NOx} and S_{NOx} at a NO_x -saturated site in Suffolk County, NY on Long Island (spring). Relationships are shown for one nighttime hour, one morning rush-hour hour, one daytime hour, and one evening rush-hour hour. The solid blue line shows the linear regression for these points.

4D-3.2.3 Application of Sensitivity Regressions to Ambient Data

To apply the HDDM adjustments to observed data, sensitivities must be determined for each hour from 2006-2010 at each site based on the linear relationship from the modeled data and the observed O_3 concentration. The linear regression model also allows us to quantify the standard error of each predicted sensitivity value at each hour and site.

Observed hourly O_3 from 2006-2010 at each monitor location was adjusted by applying incrementally increasing emissions reductions using Equations (4D-4) to (4D-8) and recalculating MDA8 values for incrementally increasing emissions reductions until an emissions level is reached for which all monitors in an urban area achieved design values at the standard level being evaluated (75, 70, 65, or 60 ppb). Therefore all monitors within an urban area were treated

as responding to the same percentage reduction in NO_x or NO_x/VOC emissions. The final emissions reductions that were applied in each urban study area are given in Table 4D-2.

The standard error associated with each predicted sensitivity from the linear model can be propagated through Equations (4D-4) and (4D-8) to quantify the standard error in the final predicted O₃ concentration. This gives a measure of uncertainty in the predicted mean sensitivity at any given O₃ concentration and allows us to quantify how much our predicted O₃ could change given that uncertainty. Further details on the standard error and uncertainty from the linear fits used in each of the urban study areas are provided in section 4D-4.44D-4.4.

4D-3.2.4 Alternate Methodologies

The methodology used for most of the 15 urban areas is described above. In most cases the O₃ response was calculated using Equation (4D-4) which represents a NO_x-only control strategy. In addition, sensitivities applied to observed data were based on the predicted sensitivity for that hourly O₃ from the site, season, and hour-specific regression. However, two alternate scenarios were used for a few cities as described below.

A combined NO_x/VOC control strategy was applied to two cities for which controlling monitors were sensitive to changes in VOC emissions: Chicago and Denver. These were the only urban study areas in which the addition of VOC reductions allowed adjusted air quality to just meet the targeted standard levels with smaller reductions in NO_x emissions than would be required if VOC emissions were held constant. In these cases, Equation (4D-8) was applied in place of Equation (4D-4) and the X,Y cut points described in Table 4D-1 were derived for the NO_x/VOC control case based on brute force runs that reduced the two O₃ precursors by equal percentages.

In two cities, New York and Los Angeles, results were affected by aberrant behavior at a few monitors which occurred during rush-hour and nighttime hours. At a few highly urbanized monitors during some seasons, the O₃ increases during highly titrated rush-hour and nighttime hours appear to be overestimated, leading to predictions that when NO_x was reduced O₃ would peak during rush-hour periods on the very highest O₃ days (compare outlier dots for 65 ppb standard at 9:00-17:00 to outlier dots for 65 ppb standard at 18:00-8:00 in Figure 4D-23). Even at these monitors, the majority of days did not have this problem as shown by the more normal diurnal pattern for the boxes (interquartile range) and whiskers (1.5 × interquartile range) in Figure 4D-23. As mentioned above, for each predicted hourly O₃ concentration we calculated a standard error based on the uncertainty in the fitted regressions representing the variability in modeled sensitivities which is not explained by hourly O₃ levels alone for each site, season, and hour. So, in addition to the predicted O₃, we can create alternate hourly O₃ datasets based on the standard error in these values. To address the aberrant behavior on the very highest O₃ days in

the adjustment scenarios in New York and Los Angeles, we took the 95th percentile confidence interval for each hourly O₃ prediction and used the lower bound value to determine the NO_x reductions required to meet the existing and potential alternative standards and to calculate the hourly O₃ that would occur under that reduced emission scenario. During most hours and at most monitors, the 95th percentile range was small (less than +/- 2.7 ppb) so the use of the lower-bound of the 95th percentile range made little difference in predicted O₃ concentrations (Table 4D-18 and Table 4D-19). However, using the lower bound of the 95th percent confidence interval allowed us to dampen the effect of over predicted O₃ increases during rush-hour times. Since the O₃ concentrations for each standard level were created using consistent methodology, these O₃ datasets can be used to compare between standards in these cities. In addition, at a single standard level (for instance 75 ppb) these O₃ values can be compared against those obtained using the base methodology in order to quantify uncertainty due to variability in modeled sensitivities. However, O₃ values for one standard obtained using the 95th percentile confidence interval lower bound are not contrasted against O₃ concentrations for a potential alternative standard which were obtained using the base methodology since these datasets are not directly comparable.

4D-4. APPLYING HDDM/CMAQ TO ADJUST OZONE TO JUST MEET EXISTING AND ALTERNATIVE STANDARDS: RESULTS

4D-4.1 Emission Reductions Applied to Meet Alternative Standards

Table 4D-2 reports the percentage reduction in domain-wide emissions that were used to reach the existing and potential alternative standard levels in each urban area. Percentages in Chicago and Denver represent reductions in anthropogenic NO_x and VOC. Percentages in all other cities represent reductions only in anthropogenic NO_x emissions. Percentages in New York and in Los Angeles were calculated based on air quality estimates at the lower end of the 95th percentile confidence interval as discussed above in section 4D-3.2.4. Please note that these reductions and broad nationwide emission cuts are not intended to represent recommended control scenarios since they would not be the most efficient method for achieving the standard in many localized areas.

Table 4D-2. Percent emissions reductions used for each urban area to obtain each standard.

Urban Area	Years	Standard Level*			
		75 ppb	70 ppb	65 ppb	60 ppb
Atlanta	2006-2008	50%	58%	64%	71%
	2008-2010	23%	43%	54%	62%
Baltimore	2006-2008	46%	54%	61%	69%
	2008-2010	44%	52%	60%	67%
Boston	2006-2008	40%	49%	61%	70%
	2008-2010	13%	40%	53%	65%
Chicago	2006-2008	19%	52%	66%	80%
	2008-2010	N/A	27%	55%	70%

	2008-2010	64%	71%	77%	84%
Saint Louis	2006-2008	45%	56%	66%	75%
	2008-2010	10%	34%	50%	63%
Washington D.C.	2006-2008	53%	60%	67%	74%
	2008-2010	31%	50%	60%	71%

* N/A values for the 75 ppb standard level mean that a particular urban area did not have any design values above 75 for that 3-year period so no controls were needed. N/A values for the 60 ppb standard level mean that this adjustment methodology was not able to bring design values down to 60 for that particular city and 3-year period.

⁵ An error was discovered in the Sacramento adjustment to 60 ppb for the 2006-2008 design value period in which 84% NO_x cuts were applied instead of 85% NO_x cuts. The 84% NO_x cuts thus simulate meeting a standard of 61 ppb for Sacramento for those years. Results for the 85% NO_x cut case are not expected to be substantially different from the 84% NO_x cut case that was analyzed.

4D-4.2 Design Values

Table 4D-3 through Table 4D-17 report the design values for sites in each of the urban areas for recent years (2006-2008 and 2008-2010) and for adjusted O₃ levels representing just meeting standards of 75, 70, 65, and 60 ppb. In each table, the highest design value for each scenario is displayed in bold text. These tables demonstrate that in some urban areas high O₃ values at monitors in different locations have different magnitudes of response to reductions in NO_x (and VOC) emissions. Atlanta monitor 132470001, a downwind monitor, had the highest design value for 2006-2008. With the NO_x reduction scenarios to meet various standard levels, the two downtown monitors (131210055 and 130890002) switch to being the highest monitors in the area. These downtown locations which have large amounts of spatially concentrated NO_x emissions are expected to be more VOC limited and therefore less responsive to NO_x emission reductions than surrounding rural and suburban areas. This phenomenon occurs to varying degrees in each of the 15 urban areas included in this analysis. For instance, the difference in response between monitors on high days is very pronounced in Cleveland and in New York. In Cleveland, a downwind monitor located east of the city along Lake Erie was the high monitor for both 2006-2008 and 2008-2010 (39071001). That monitor responded more dramatically to NO_x cuts than another monitor (390850003) which was closer to the city. As a result of adjusting air quality to just meet a 60 ppb standard level at monitor 390850003, the design value at monitor 39071001 was lowered to 45 ppb for the 2006-2008 data and 44 ppb for the 2008-2010 data. Similarly in the New York area, the highest measured O₃ values occurred at downwind sites in Connecticut and on Long Island. Two highly urbanized sites (360050110 in the Bronx and 360610135 in Manhattan) have lower observed design values but become the controlling monitors in the adjustment scenarios for 75, 70, and 65 ppb. In contrast, several cities do not show this change in location of the highest monitor after adjustments to just meet potential alternative standard levels. For example, the highest monitor for the 2008-2010 design value period in the Dallas area (484393009, located on the North side of Fort Worth) remained the highest monitor through all adjustment scenarios for that time period. Similarly, the controlling monitor in Sacramento (060670012, a downwind suburban site) remained the highest or second highest site for all adjustment scenarios. However, in Sacramento, another downwind monitor (060610006) which did not have as high of an observed design value, responded less to emissions changes and essentially “caught up” to the controlling monitor in the 65 and 60 ppb scenarios.

It is important to note that a model-based adjustment technique is uniquely capable of capturing this type of spatial heterogeneity in response to emissions reductions. The quadratic rollback technique used in the first draft HREA forces O₃ at all monitoring sites in an urban area to respond identically.

Table 4D-3. Design values for the Atlanta area regulatory monitors from observed data and for adjustments to meet the existing and potential alternative standards in 2006-2008 and 2008-2010.

Monitor	2006-2008					2008-2010				
	obs	75 ppb	70 ppb	65 ppb	60 ppb	obs	75 ppb	70 ppb	65 ppb	60 ppb
132470001	95	72	66	61	55	78	71	64	59	55
132230003	80	62	58	55	51	70	64	59	55	52

4D-4.3 Distribution of Hourly O₃ Concentrations

Figure 4D-13 through Figure 4D-27 display diurnal boxplots of hourly O₃ concentrations at monitor locations in each urban area for observed air quality, air quality adjusted to meet the existing standard, and an example of air quality adjusted to meet a potential alternative standard (65 ppb), for 2006-2008 and 2008-2010. Note that these plots include data from multiple monitoring sites within each urban area so they generally encompass the overall distribution of O₃ at both the urban core sites and the downwind suburban sites. The hourly plots show similar patterns in most cities for which O₃ concentrations during daytime hours decrease from observed air quality (black) to air quality adjusted to meet the existing standard (red), and decrease further when adjusted to meet a potential alternative standard of 65 ppb (blue). These daytime decreases are generally seen most on high O₃ days represented by outlier dots. In some cities the mid-range O₃ days, represented by the 25th – 75th percentile boxes, remained fairly constant (Boston) and in other cities, mid-range O₃ days decreased (Atlanta). Although daytime O₃ decreases, concentrations during morning rush-hour generally increase. These increases are associated with VOC-limited and NO_x titration conditions near NO_x sources during rush-hour periods. Reducing NO_x under those conditions results in less O₃ titration and thus increases O₃ concentrations. Nighttime increases in O₃ are often seen to a lesser extent than morning rush-hour increases. These phenomena generally lead to a flattening of the diurnal O₃ pattern with smaller differences between daytime and nighttime concentrations as NO_x emissions are reduced. Cases that required more substantial NO_x cuts to reach 75 and 65 ppb standards generally have more pronounced patterns of decreases in daytime O₃ and increases in nighttime O₃ leading to a flatter diurnal O₃ pattern (e.g. Los Angeles in Figure 4D-22). Two cities, Houston and New York, do not follow this general pattern. In Houston (Figure 4D-21), mid-range O₃ values increase during daytime hours as the highest O₃ concentrations decrease. This pattern is consistent with NO_x-limited conditions on high O₃ days but VOC-limited conditions on mid-range O₃ days or potentially NO_x-limited conditions at high O₃ sites and VOC limited conditions at mid-range O₃ sites. Therefore NO_x reductions, which are applied on all days, increase O₃ on mid-range O₃

days. Note that mid-range O₃ days in Houston start out quite low (20-30 ppb) and increase modestly. The changes in O₃ from observed air quality to the existing standard in New York look similar to the trends shown for other cities, but the diurnal O₃ pattern for the 65 ppb potential alternative standard has some unrealistic features which were previously discussed in section 4D-4D-3.2.4 of this appendix. The steep NO_x cuts (~90%) applied to meet a 65 ppb standard in New York result in a very flat diurnal pattern for mid-range values (see boxes from Figure 4D-23) but the outliers represented by dots in Figure 4D-23 show an inverse diurnal pattern with lower O₃ concentrations during the day and higher values at night. This is a result of the modeled sensitivities showing that nighttime O₃ does not respond to NO_x emissions changes on high O₃ nights while daytime O₃ does respond to NO_x emission changes during those same days. Thus the daytime values drop substantially while the nighttime values show no change. These results are not seen when the sensitivities are applied for the more modest cuts (50-65%) to reach 75 ppb. The diurnal pattern in New York for the 65 ppb case for the highest days is clearly unrealistic as there is no chemical process expected to result in daytime values lower than values at night, rather it appears to be an artifact of applying this model-based methodology to extremely large emissions reductions in a location where relationships derived under 3 discrete conditions (base, 50% NO_x cut, 90% NO_x cut) cannot fully characterize sensitivities over the entire range of possible reductions. As discussed previously in section 4D-4D-3.2.4, the use of the lower bound from the 95th percentile confidence interval can mitigate some of this behavior, but in the case of New York some unrealistic outliers still remain. It should be noted, however that this unrealistic diurnal pattern is only seen in the outlier points, and is not seen the box and whiskers which represent 1.5 times the interquartile range (most of the data).

Figure 4D-28 through Figure 4D-42 display the same information as Figure 4D-13 through Figure 4D-27 but for monthly rather than hourly distributions. Note that missing months in these plots indicate that there was no monitor data available for those months and years. Similar to the diurnal plots, the seasonal distributions become flatter when meeting 75 and 65 ppb standard levels especially for the highest O₃ days. This is due to more O₃ decreases during summer months and more O₃ increases in winter months. The O₃ increases in the winter are consistent with the understanding that solar insolation rates are lower in the winter reducing total photochemical activity and shifting the net effect of NO_x emissions on O₃ which can both create O₃ through photochemical pathways and destroy O₃ through titration. In addition, the decreases on the highest O₃ days and increases on the lowest O₃ days show a visible compression of the O₃ distribution in these plots similar to what was seen in the diurnal plots. The changes for mid-range O₃ days also show a pattern of shifting higher mid-range O₃ earlier in the year. While in most cities, the highest interquartile O₃ concentrations in the recent conditions occur in the

summer months (June-August), in many areas the highest interquartile O₃ concentrations shift to spring months (April-May) for the adjustment scenarios of meeting 75 and 65 ppb standard levels. This pattern can be seen most dramatically in Atlanta, Baltimore, Boston, Denver, Los Angeles, New York, Philadelphia, Sacramento, and Washington D.C. This pattern is consistent with higher contribution from non-U.S. anthropogenic sources at lower standard levels than under recent observed conditions. Many of these non-U.S. anthropogenic sources such as stratospheric intrusions and international transport have been shown to peak during spring months as discussed in the Integrated Science Assessment (EPA, 2013).

Figure 4D-13. Hourly O₃ distributions at Atlanta area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values.

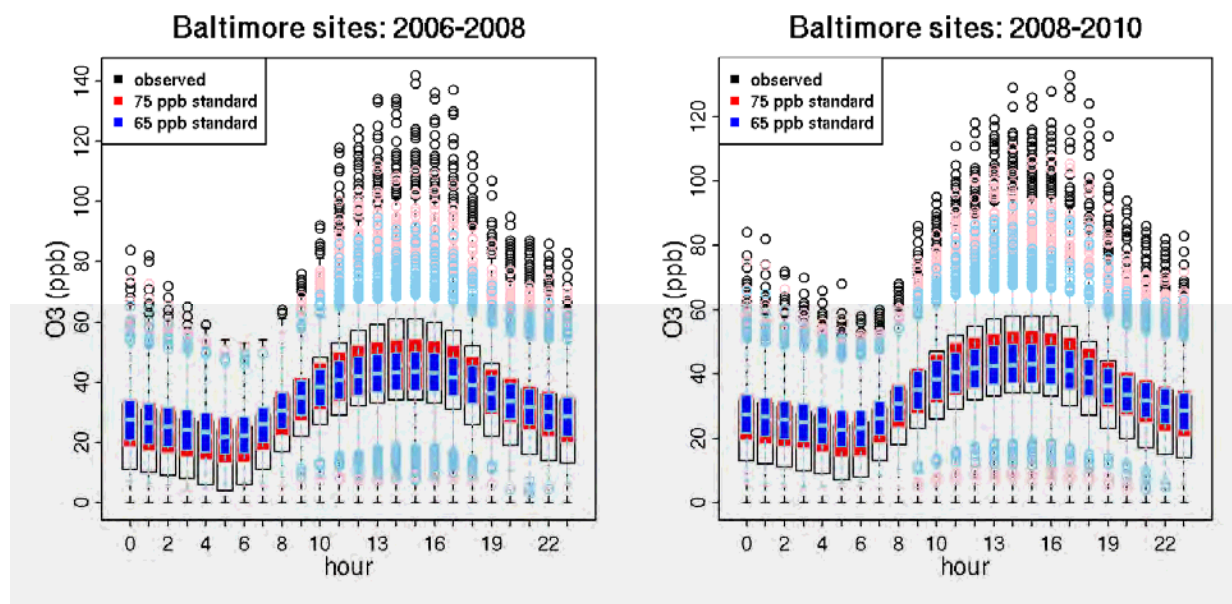

Figure 4D-14. Hourly O₃ distributions at Baltimore area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

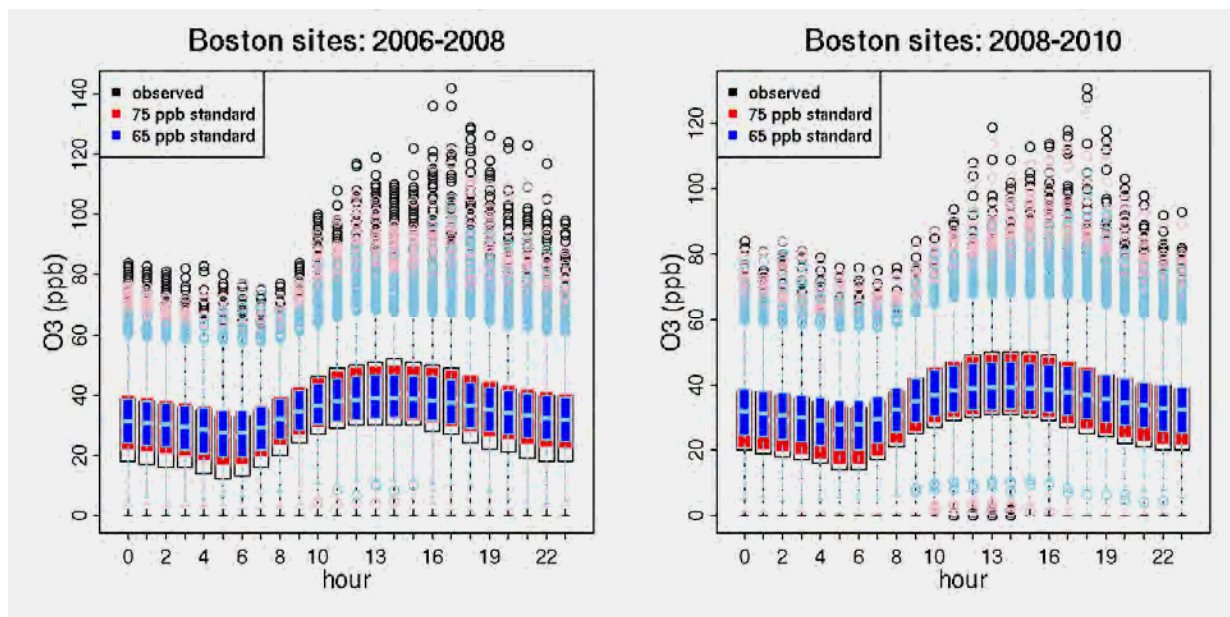

Figure 4D-15. Hourly O₃ distributions at Boston area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

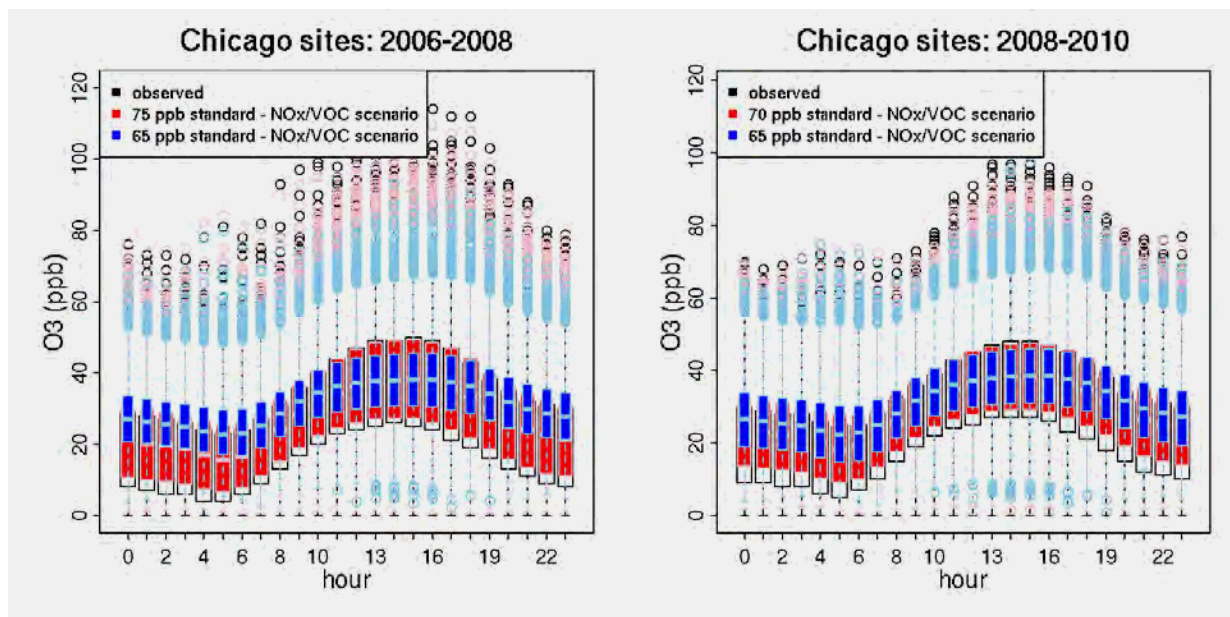

Figure 4D-16. Hourly O₃ distributions at Chicago area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

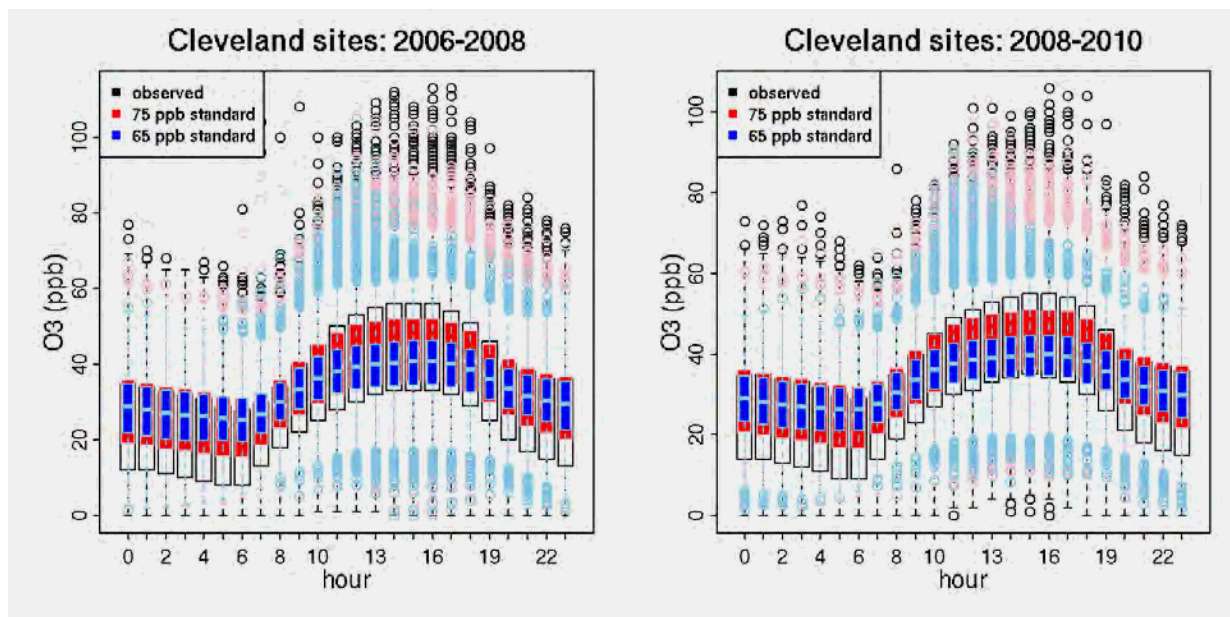

Figure 4D-17. Hourly O₃ distributions at Cleveland area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

Figure 4D-18. Hourly O₃ distributions at Dallas area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

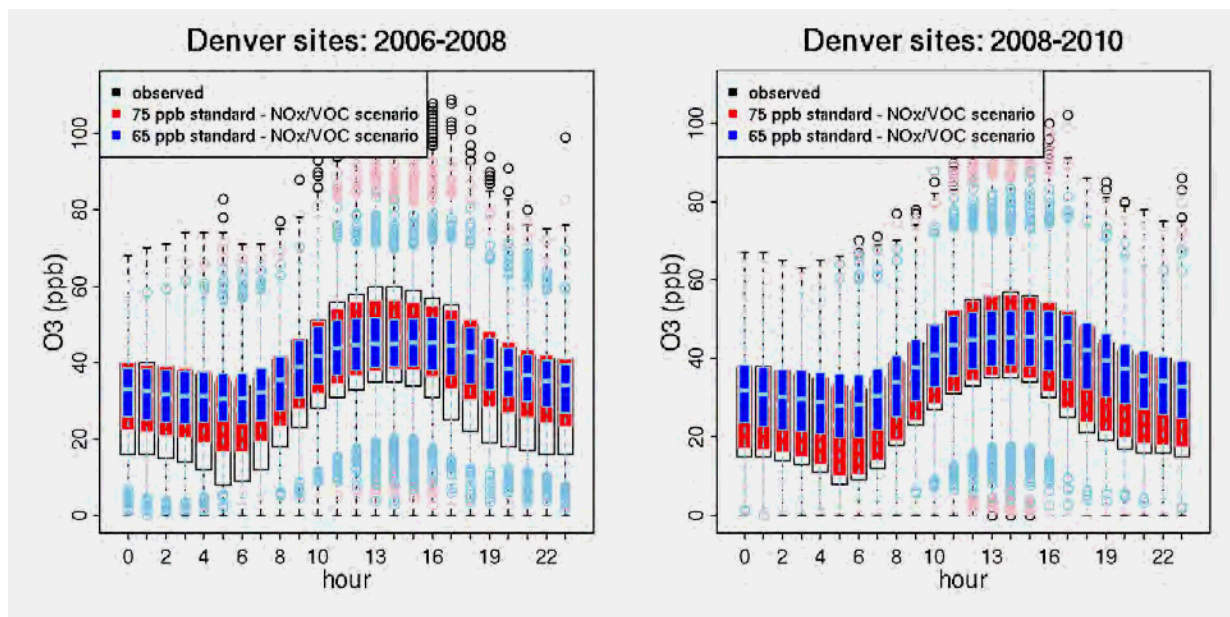

Figure 4D-19. Hourly O₃ distributions at Denver area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

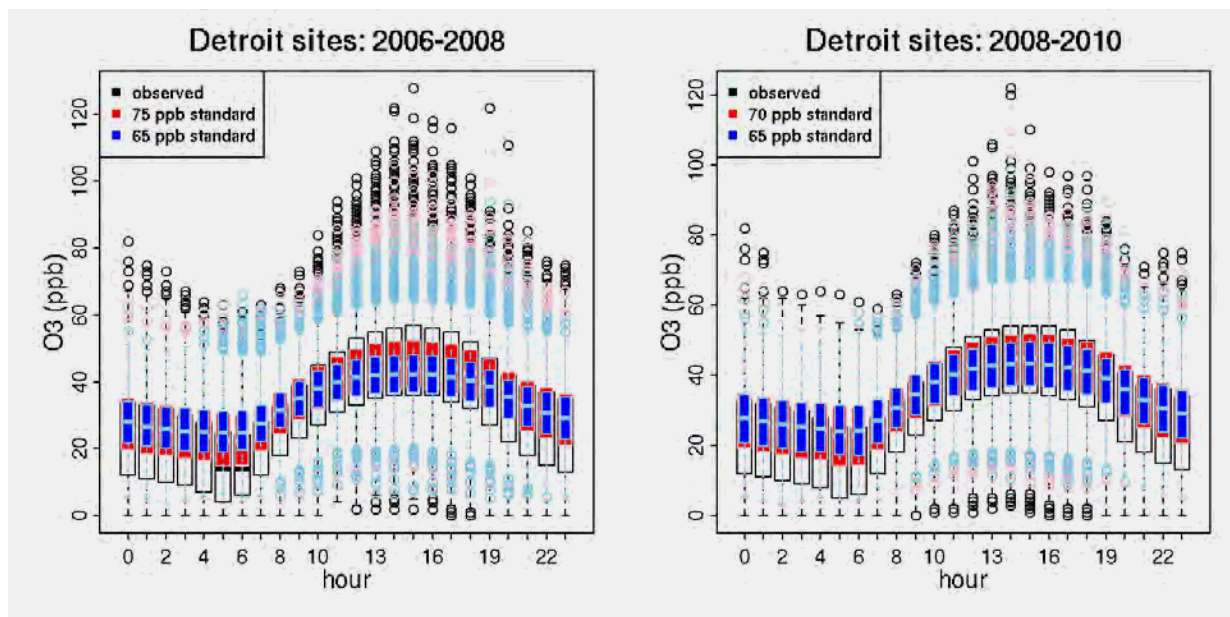

Figure 4D-20. Hourly O₃ distributions at Detroit area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

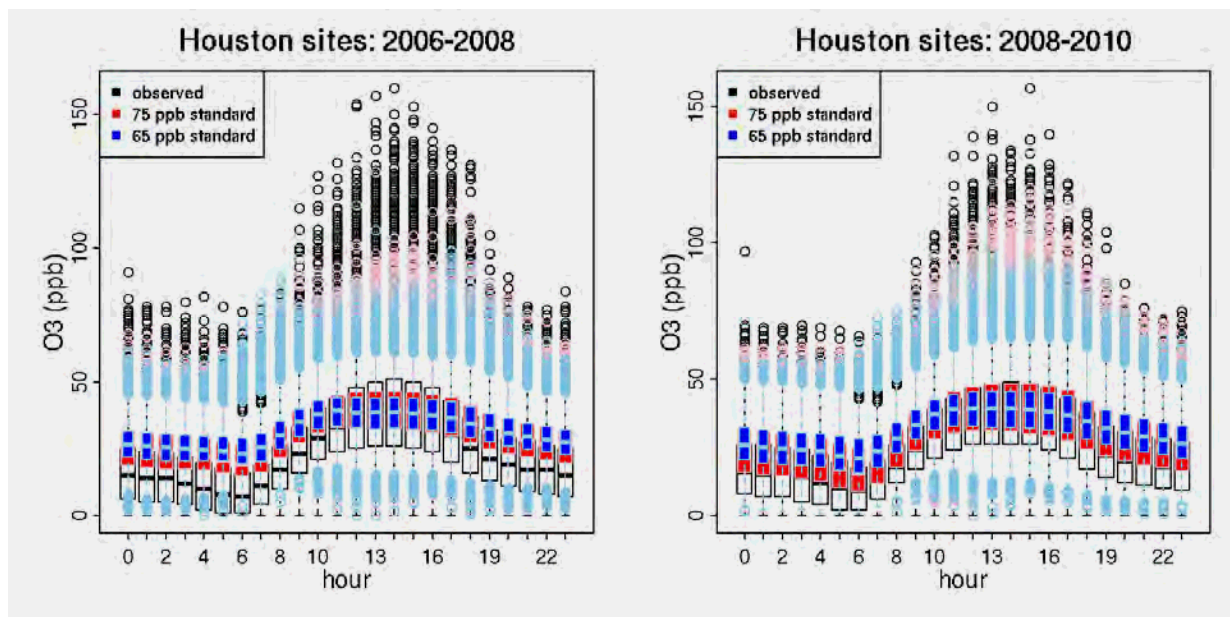

Figure 4D-21. Hourly O₃ distributions at Houston area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

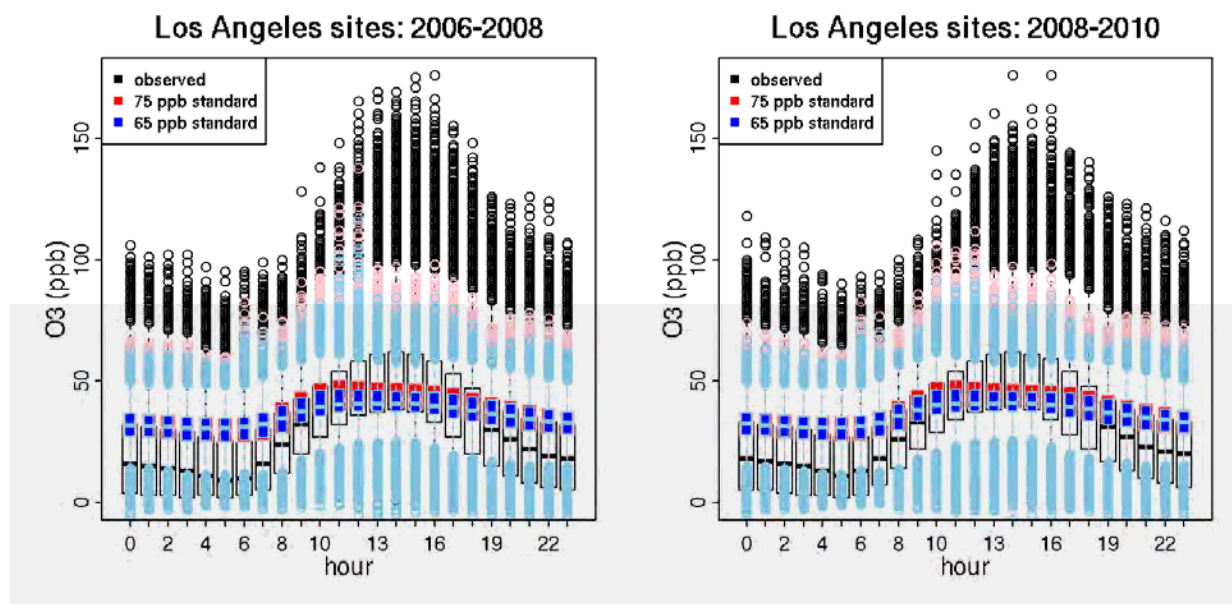

Figure 4D-22. Hourly O₃ distributions at Los Angeles area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

Figure 4D-23. Hourly O₃ distributions at New York area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values.

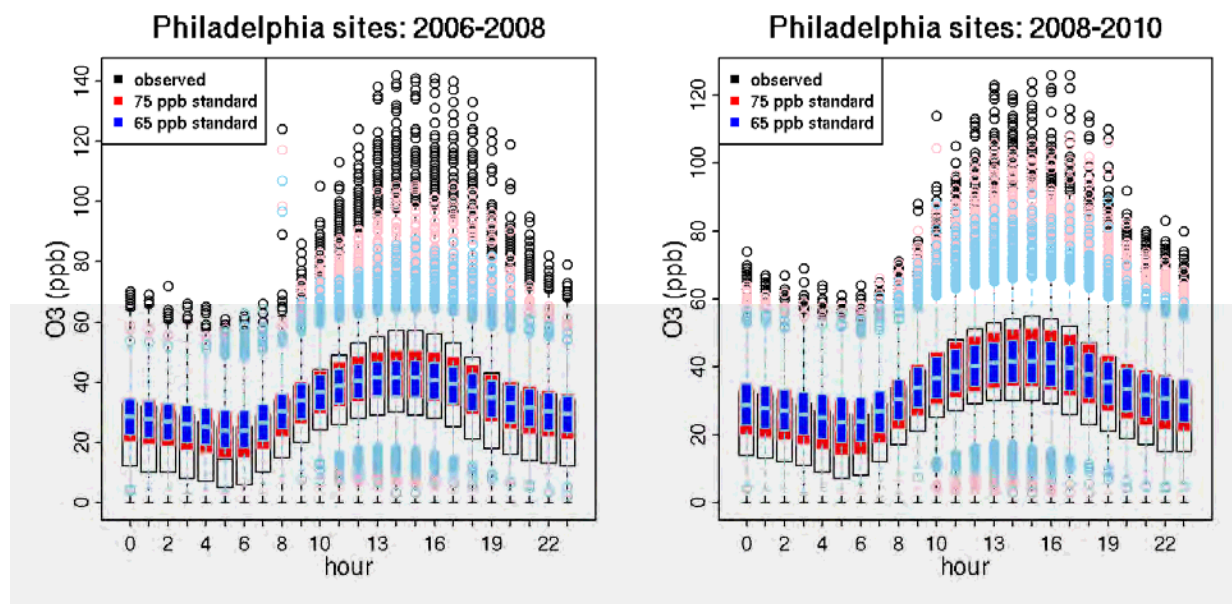

Figure 4D-24. Hourly O₃ distributions at Philadelphia area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

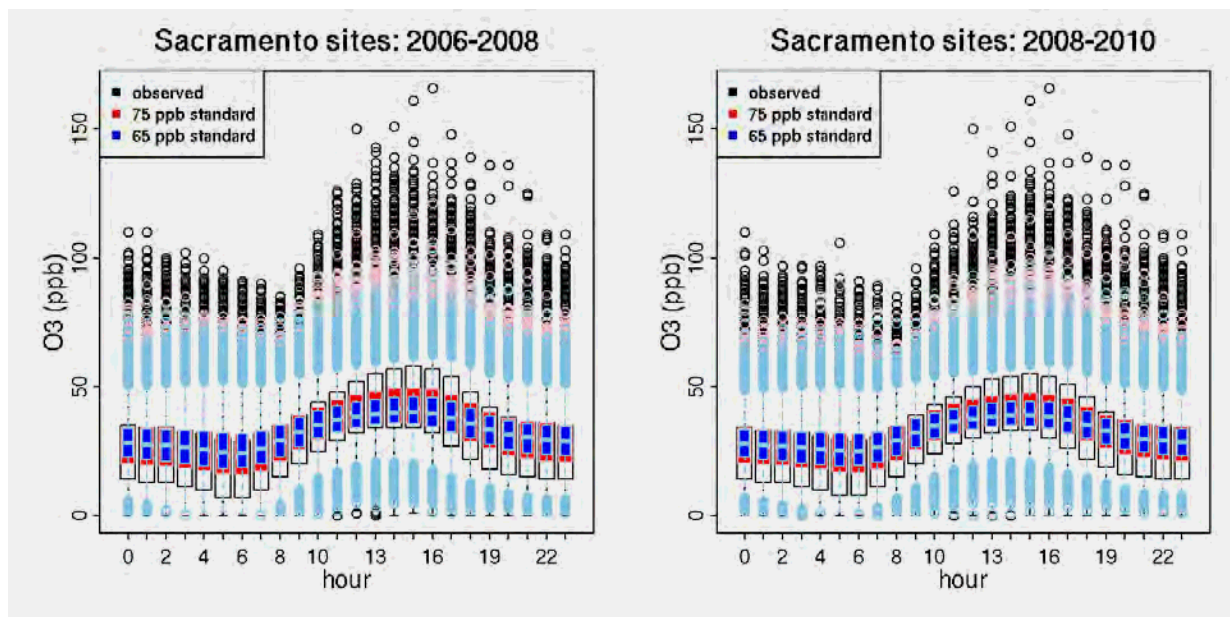

Figure 4D-25. Hourly O₃ distributions at Sacramento area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

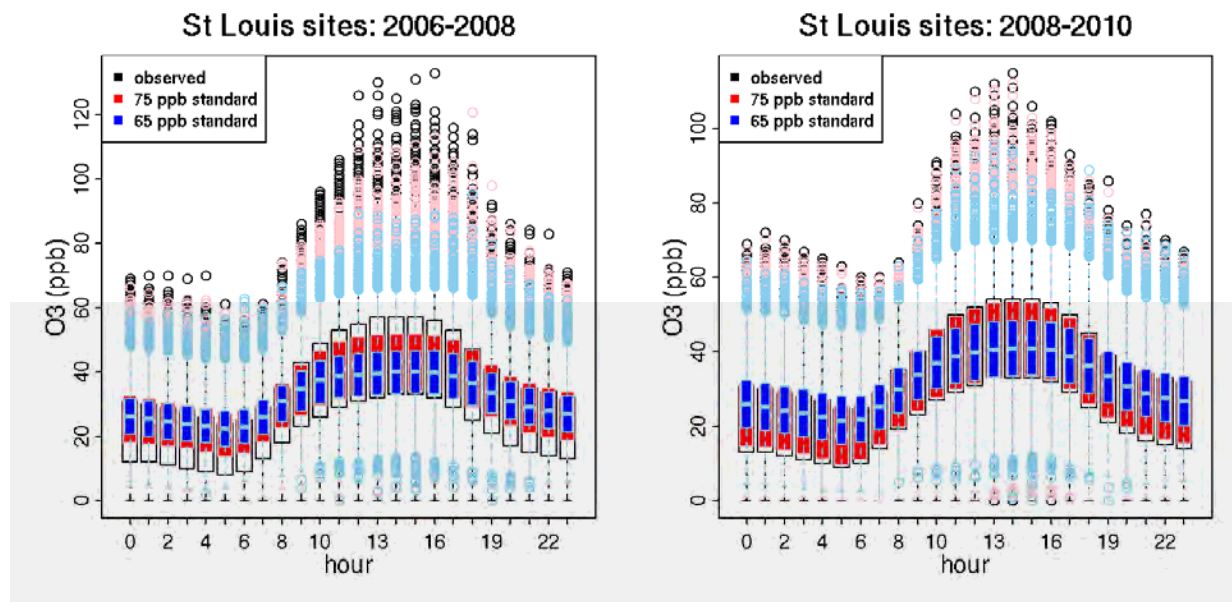

Figure 4D-26. Hourly O₃ distributions at St. Louis area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

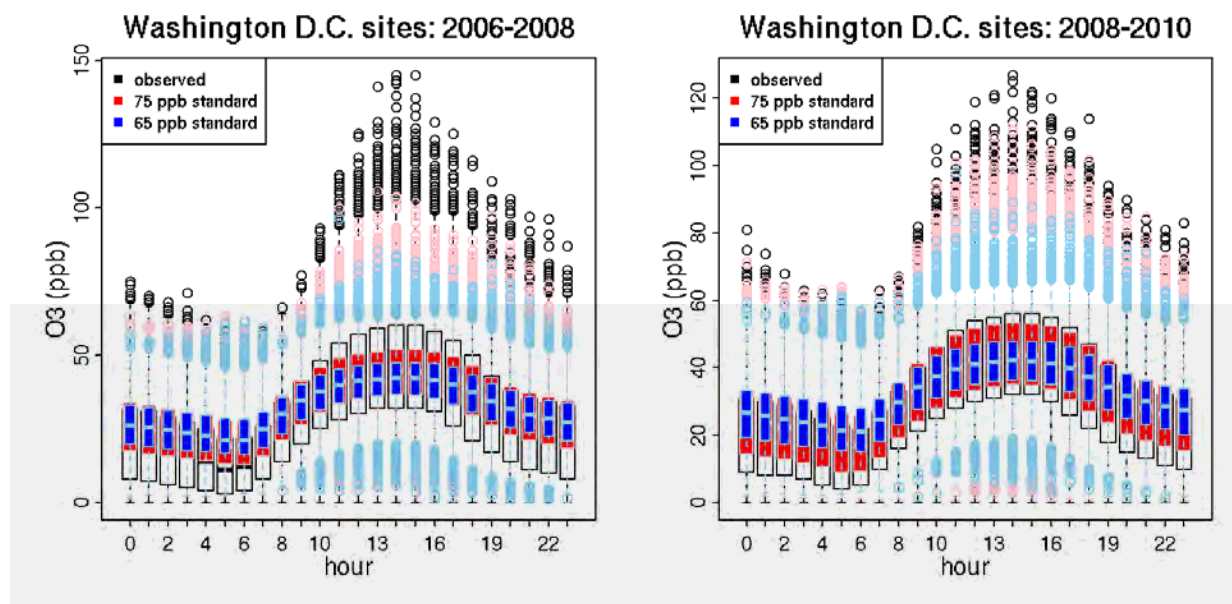

Figure 4D-27. Hourly O₃ distributions at Washington, D.C. area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

Figure 4D-28. Monthly O₃ distributions at Atlanta area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

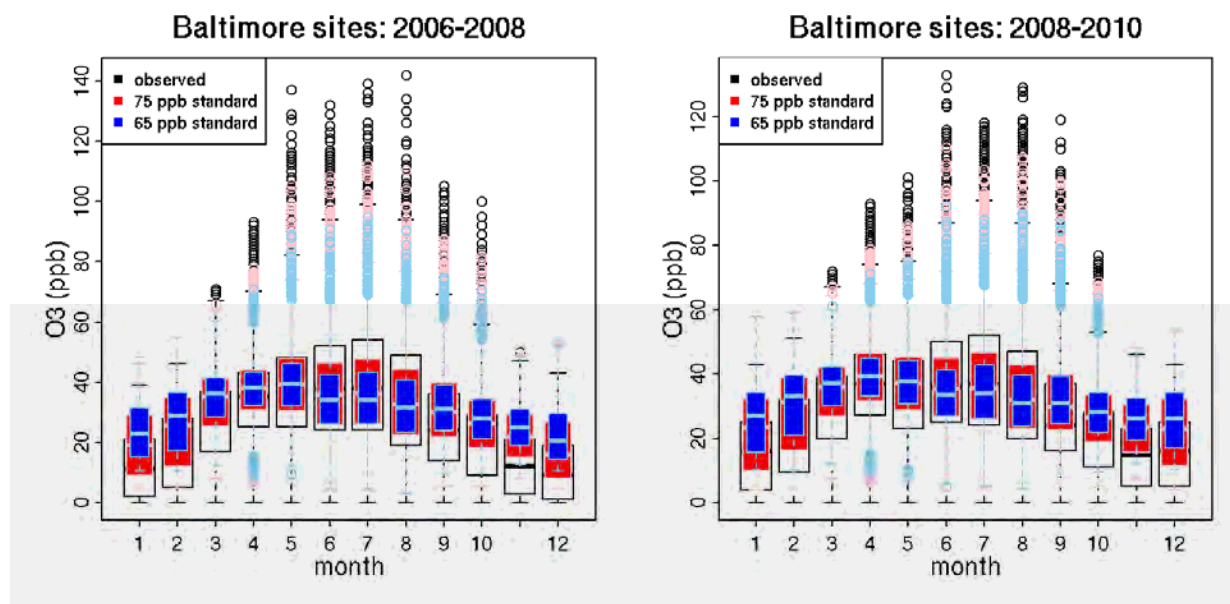

Figure 4D-29. Monthly O₃ distributions at Baltimore area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

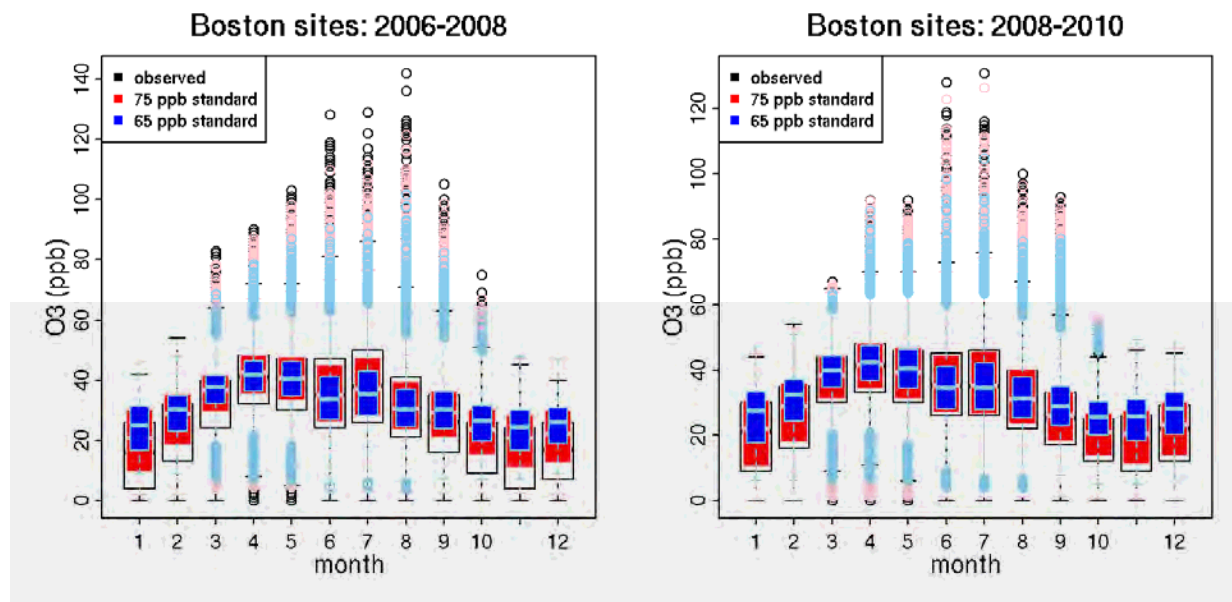

Figure 4D-30. Monthly O₃ distributions at Boston area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

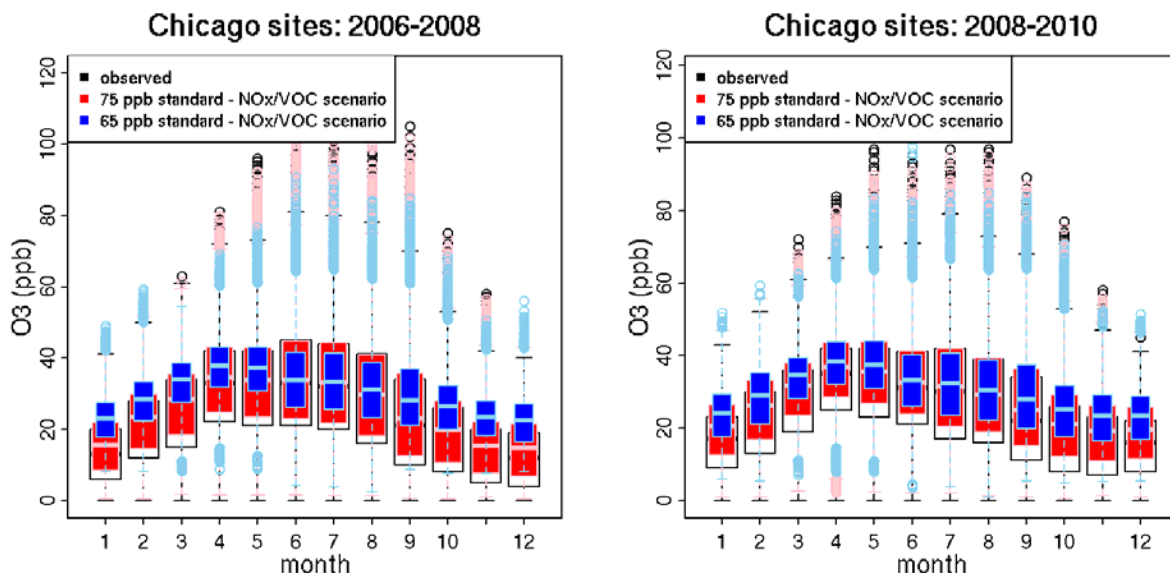

Figure 4D-31. Monthly O₃ distributions at Chicago area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values.

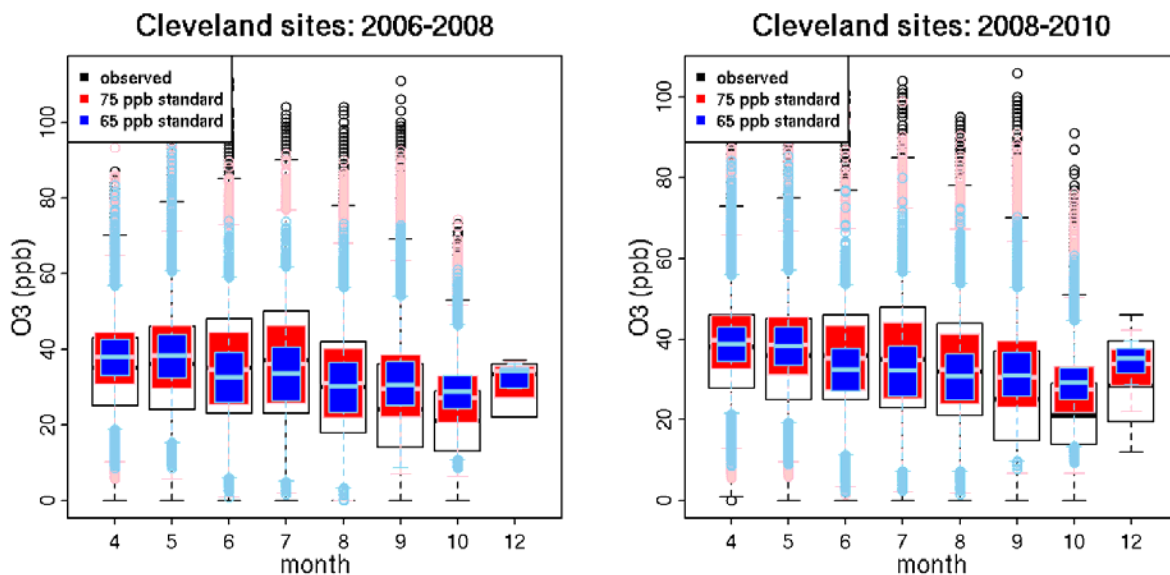

Figure 4D-32. Monthly O₃ distributions at Cleveland area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

Figure 4D-33. Monthly O₃ distributions at Dallas area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

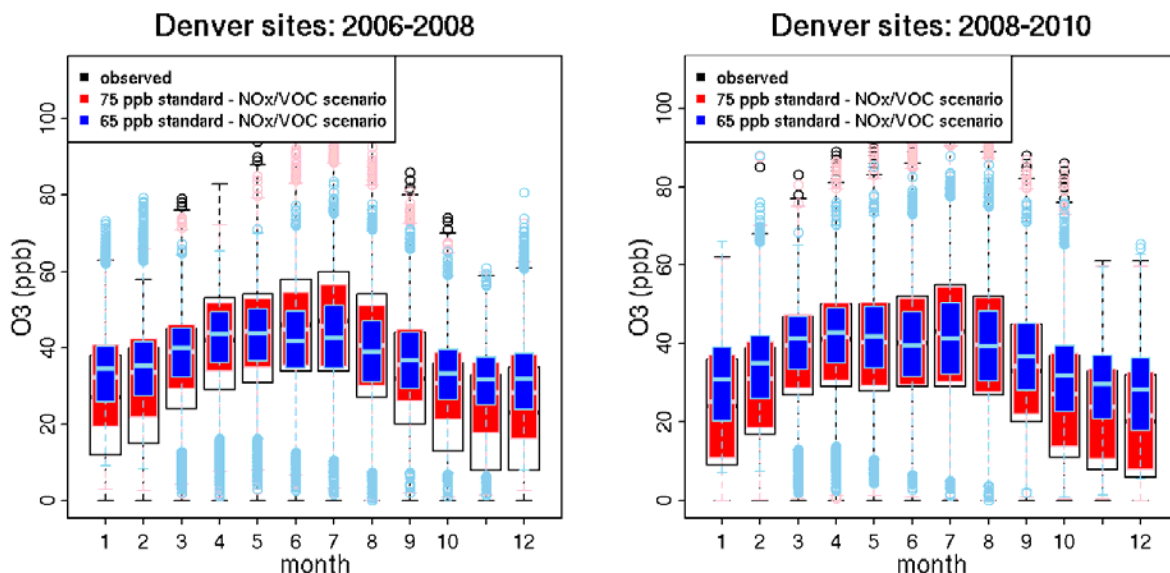

Figure 4D-34. Monthly O₃ distributions at Denver area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

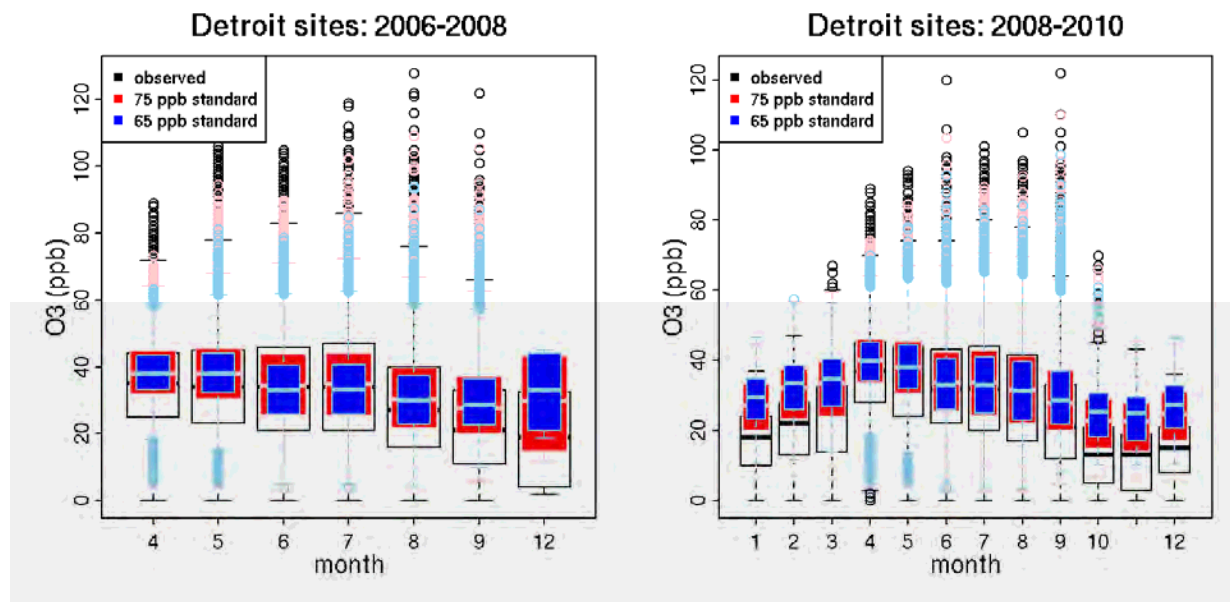

Figure 4D-35. Monthly O₃ distributions at Detroit area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

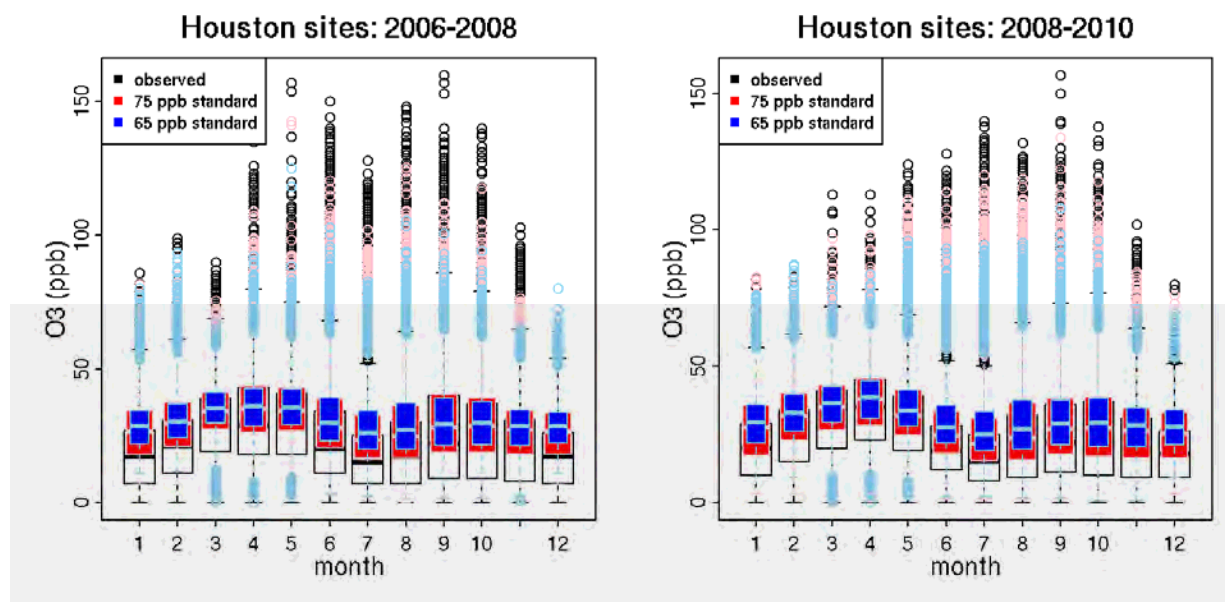

Figure 4D-36. Monthly O₃ distributions at Houston area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

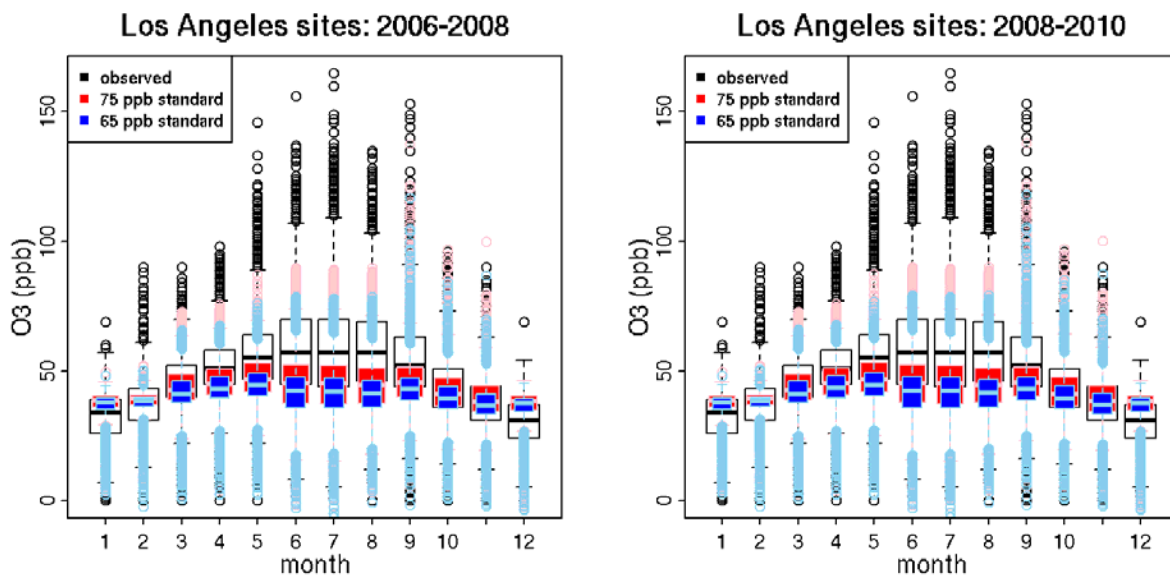

Figure 4D-37. Monthly O₃ distributions at Los Angeles area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

Figure 4D-38. Monthly O₃ distributions at New York area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

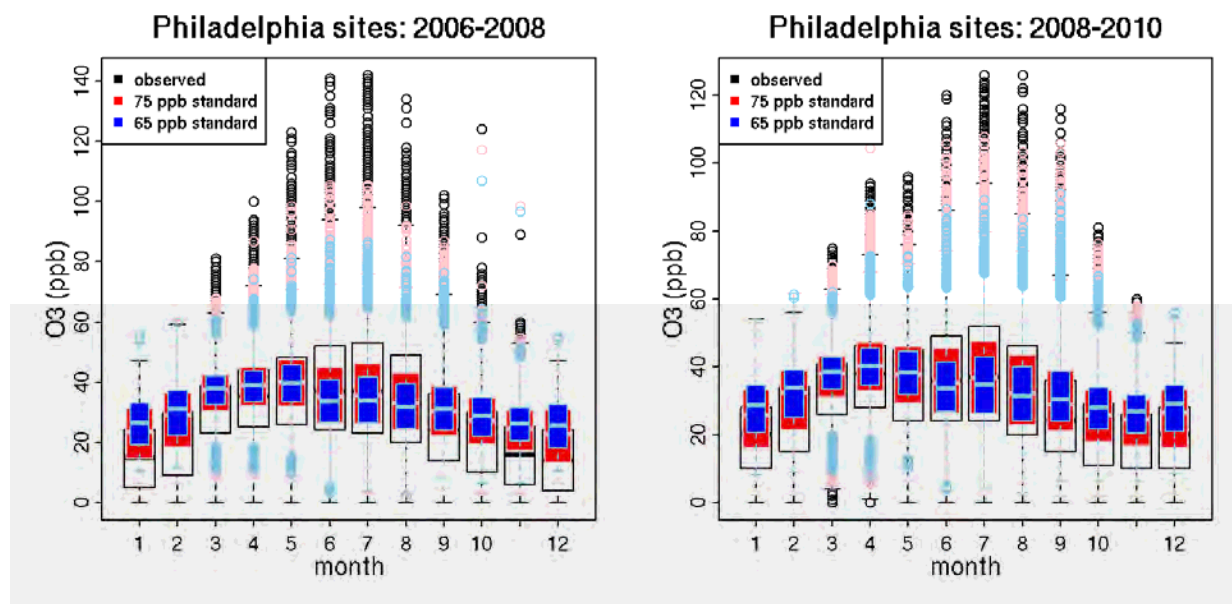

Figure 4D-39. Monthly O₃ distributions at Philadelphia area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

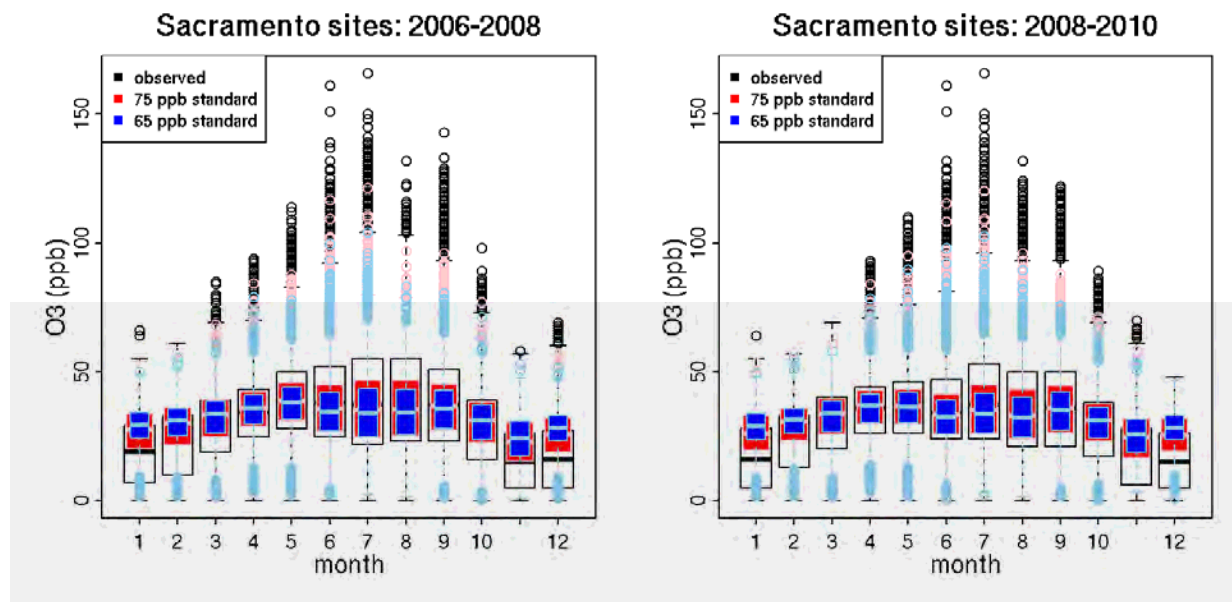

Figure 4D-40. Monthly O₃ distributions at Sacramento area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values.

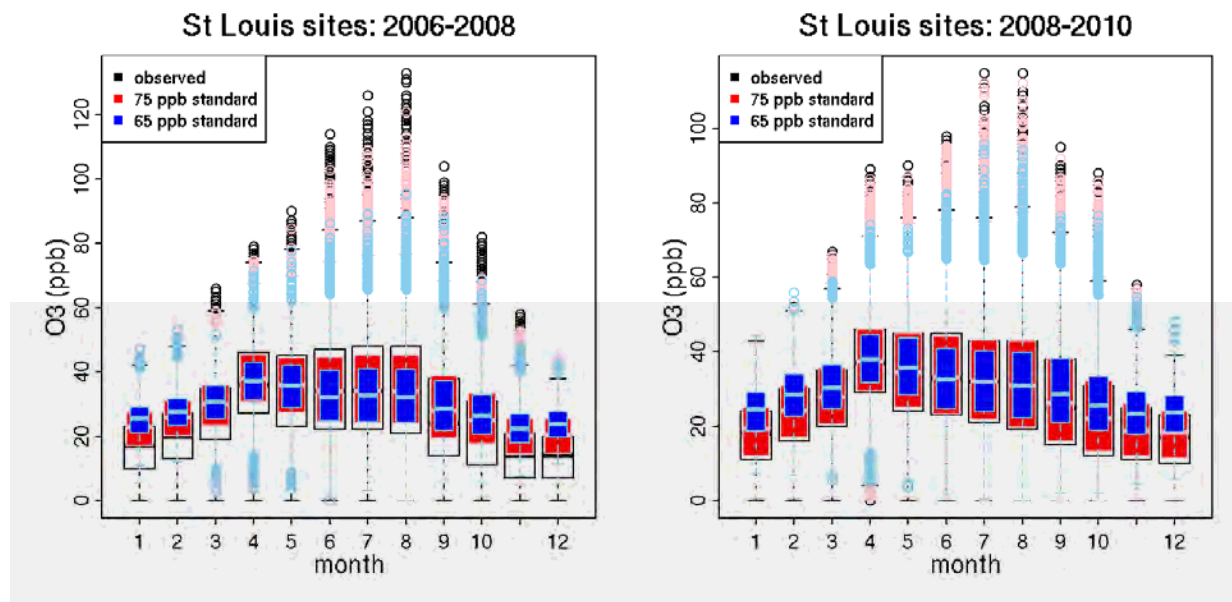

Figure 4D-41. Monthly O₃ distributions at St. Louis area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to $1.5 \times$ the interquartile range and dots depict outlier values.

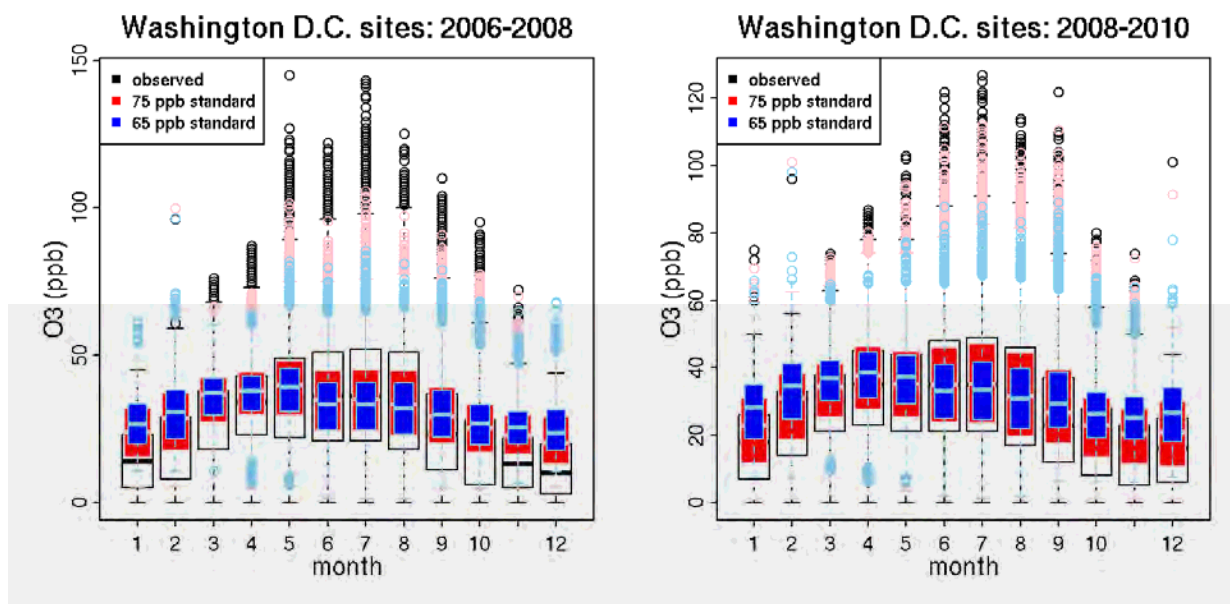

Figure 4D-42. Monthly O₃ distributions at Washington, D.C. area regulatory monitoring sites for observed air quality, and air quality adjusted to meet the existing (75 ppb) and alternative (65 ppb) standards for 2006-2008 (left) and 2008-2010 (right). White boxes (black whiskers/dots) show the observed distribution of hourly O₃ concentrations, red boxes (pink whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 75 ppb adjustment scenarios and blue boxes (light blue whiskers/dots) show the predicted distribution of hourly O₃ concentrations for the 65 ppb adjustment scenario. Boxes show the interquartile range, whiskers extend to 1.5 × the interquartile range and dots depict outlier values.

4D-4.4 Standard Errors for Predicted Hourly and Daily 8-hr Maximum O₃ Concentrations

Standard error values, s^2 , for the predicted sensitivity are calculated using Equations (4D-25) and (4D-26) as described by Wilks (2006):

$$MSE = \frac{\sum (Y_i - \hat{Y}_i)^2}{n - 2}$$

Equation (4D-25)

$$s^2\{\hat{Y}_h\} = MSE \left[\frac{1}{n} + \frac{(X_h - \bar{X})^2}{\sum (X_i - \bar{X})^2} \right]$$

Equation (4D-26)

In Equation (4D-25) mean standard error (MSE) is calculated as the sum of squared residual values from the linear model divided by $n-2$ to account for two degrees of freedom in the fit

(slope and intersect). In Equation (4D-26), the first term characterizes the uncertainty in estimating the true mean given a fixed sample size of n and the second term characterizes the uncertainty in the slope. Taken together, the standard error for each predicted sensitivity coefficient is impacted by the goodness of fit for the linear model (MSE), the sample size (n), and the distance of the x value from the bulk of the data. These standard error values represent the uncertainty in the predicted central tendency from the linear model.

The standard errors were propagated through Equations (4D-4) to (4D-8) to derive a standard error in hourly O_3 concentrations. These hourly O_3 standard errors are thus impacted both by the standard error in the sensitivity and by the amount of emissions reduction applied (i.e. standard error increases with larger emissions changes and thus at lower O_3 standard levels). These hourly O_3 standard errors represent uncertainty in predicted O_3 concentrations due to uncertainty in predicting the central tendency with the linear regression. Standard error values for predicted hourly O_3 were generally small relative to total predicted hourly O_3 concentrations. This indicates that even when regression fits had somewhat lower correlation coefficients, the resulting uncertainty from the use of the regression line does not substantially affect predicted O_3 concentrations.

Table 4D-18 and Table 4D-19 show the mean and 95th percentile standard error for all hourly O₃ values (2006-2010) in each urban area for the existing standard of 75 ppb and the potential alternative standards of 70 ppb, 65 ppb, and 60 ppb.

To further put this uncertainty into a context relevant to the form of the O₃ standard and the metric used in health analyses, we propagated standard errors for hourly O₃ to uncertainties in 8-hr daily maximum O₃ concentrations using Equation (4D-27):

$$\widehat{SE}(\bar{Y}) = \sqrt{\frac{\sum_{i=1}^8 (\widehat{SE}(Y_i))^2}{64}} = \sqrt{\frac{\sum_{i=1}^8 (\widehat{SE}(Y_i))^2}{8}}$$

Equation (4D-27)

Boxplots showing the range of 8-hr daily maximum O₃ standard errors calculated for each cases study area are shown in the chapter 4 of the HREA. Maps of mean standard error in 8-hr daily maximum O₃ concentration at each monitoring location are shown in Figure 4D-43 through Figure 4D-57. These figures generally show that 8-hr daily maximum O₃ mean standard error is small (less than 0.4 ppb) with slightly higher values up to 1.3 ppb in the most NO_x limited areas at the lower standard levels.

Table 4D-18. Mean standard error (ppb) in adjusted hourly O₃ concentration in each urban area for each standard.

Urban Area	Years	Standard Level

4D-4.5 Air Quality Inputs for the Epidemiology-Based Risk Assessment

The air quality inputs to the epidemiology-based risk assessment discussed in HREA Chapter 7 were spatially averaged “composite monitor⁶” values for 12 of the 15 urban study areas. The procedure for calculating these values is described in Appendix 4A. Figure 4D-58 through Figure 4D-69 show boxplots of the composite monitor daily maximum 8-hour values for observed air quality, air quality adjusted to meet the existing standard, and the potential alternative standards of 70 ppb, 65 ppb, and 60 ppb in the 12 urban areas in the epidemiology-

⁶ Composite monitor values are calculated as the average of all monitors within each CBSA. See Appendix 4A for more details.

based risk assessment. There are eight panels in each figure. The panels are designed to show contrasts based on three factors:

1. Spatial extent of the urban study area: the top row of panels in each figure are based on the smaller areas from the Zanobetti and Schwartz (2008) study (Z & S), , while the bottom row of panels are based on the larger Core Based Statistical Areas (CBSAs).
Length of the O₃ season: the 1st and 3rd columns of panels in each figure are based on a shorter June – August O₃ season, which was used in Z & S, while the 2nd and 4th columns of panels are based on a longer April – October O₃ season. The Smith et al. (2009) study was based on the required O₃ monitoring season, which varied by area but often encompassed the April-October period.
2. Year: the two left-hand columns of panels in each figure are based on 2007, while the two right-hand columns of panels in each figure are based on 2009. The epidemiology-based risk assessment focused on these two years: 2007, to represent a year with higher O₃ concentrations, and 2009, to represent a year with lower O₃ concentrations.

There are a few properties common to nearly all of the figures. First, the highest composite monitor values represented by the top whiskers decrease when air quality is adjusted to meet the existing standard, and continue to decrease as air quality is further adjusted to meet lower alternative standard levels. By contrast, the lowest composite monitor values represented by the bottom whiskers increase when air quality is adjusted to meet the existing standard, and continue to increase as air quality is further adjusted to meet lower alternative standard levels. The behavior of the 25th percentile, median, mean, and 75th percentile values making up the boxes varies by urban area and across the three contrasting factors.

The spatial extent contrasts show that the base composite monitor values based on the smaller Z & S study areas tend to be slightly lower than the base composite monitor values based on the CBSAs. This is because the highest O₃ concentrations are often located downwind of the urban area's population center, and the smaller Z & S areas often do not capture the highest observed concentrations. Two notable exceptions to this tendency are Atlanta and Sacramento, where the highest monitored concentrations are located near the population center. The spatial extent contrasts also show that when air quality is adjusted, the highest composite monitor values tend to decrease more quickly for the CBSAs than for the Z & S areas, and conversely the lowest composite monitor values tend to increase more slowly for the CBSAs than for the Z & S areas. This is consistent with observed air quality patterns, which show that as NO_x emissions decrease, O₃ concentrations decrease more quickly downwind of the urban population center, and may increase near the population center due to less titration. This phenomenon also affects the center of the distribution, where we see that the 25th percentile, median, mean, and 75th percentile of the composite monitor values decrease more quickly for the CBSAs than for the Z & S areas. In

cases where we see increases in these values, the values tend to increase more quickly for the Z & S areas than for the CBSAs.

The seasonal contrasts show that the composite monitor values based on observed air quality tend to be lower in the spring and fall months than in the summer months. The highest composite monitor values tend to occur in the June-August period, so the upper tail of the distribution often does not change, but the center and lower tail values are usually lower for the April-October period. One notable exception is Houston, where the highest O₃ concentrations are often observed in the spring and fall months. When O₃ concentrations are adjusted to meet the existing standard, there are many cases where net decreases in the 25th percentile, median, and mean composite monitor values for the June-August period turn into net increases in these values for the April-October period. When air quality is further adjusted to meet the potential alternative standards, initial increases in these values for the April-October period often persist, and in a few cases the increases grow larger as the level of the standard decreases. By contrast, initial increases in the 25th percentile, median, and mean composite monitor values are often reversed when air quality is further adjusted to meet the potential alternative standards.

Finally, the year contrasts are meant to show the effects of changes in emissions and meteorology on the composite monitor values. Precursor emissions were generally higher in 2007 than in 2009, and meteorological conditions were generally more favorable to O₃ formation in 2007 than in 2009. Thus, the composite monitor values based on observed air quality are generally higher in 2007 than in 2009, with the exception of Houston, where the climate regime was the reverse of most of the rest of the U.S. during those two years. When air quality are adjusted to meet the existing and potential alternative standards, the decreases in the 2007 composite monitor values tend to be larger than in 2009, and there tend to be fewer increases. However, it is worth noting that since the emissions and meteorological inputs used in the CMAQ/HDDM modeling for the air quality adjustments were based on 2007 data, we tend to have more confidence in the adjusted values for 2007 than for 2009.

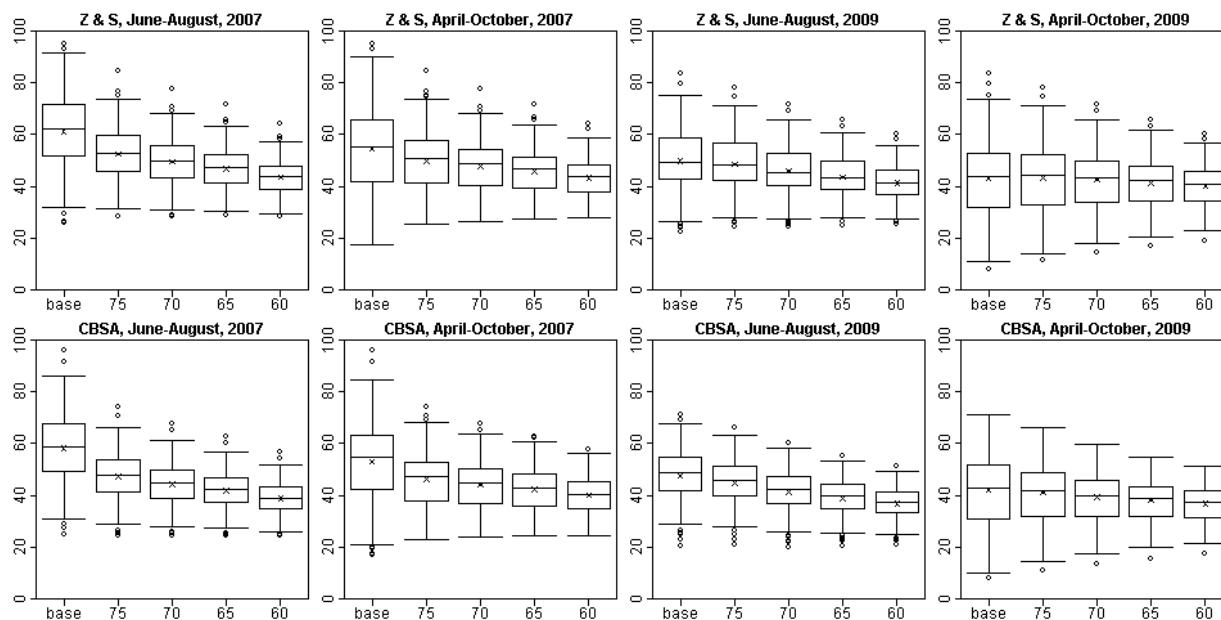

Figure 4D-58. Composite monitor daily maximum 8-hour O₃ values for Atlanta based on observed and adjusted air quality. Boxes represent the median and quartiles, x's represent mean values, whiskers extend up to 1.5x the inter-quartile range from the boxes, and circles represent outliers.

4D-4.6 Air Quality Inputs for the Exposure and Clinical Risk Assessment

The air quality inputs for the exposure and clinical-based risk assessments discussed in HREA Chapters 5 and 6 include spatial surfaces of hourly O₃ concentrations estimated for each census tract in the 15 urban study areas using Voronoi Neighbor Averaging (VNA). The VNA technique and its application to ambient concentrations is described in Appendix 4A. In this section, we present three types of figures that summarize the data from the hourly VNA surfaces (1) observed air quality, (2) air quality adjusted to meet the existing standard,⁷ and (3) air quality adjusted to meet the potential alternative standard of 65 ppb.

Figure 4D-70 through Figure 4D-84 show density scatter plots of the change in daily maximum 8-hour average (MDA8) O₃ concentrations versus the observed concentration based on the hourly VNA estimates in each area. In each of these figures, the left-hand panels show the observed MDA8 values (x-axis) versus the change in those values that occur when air quality is adjusted to meet the existing standard (y-axis). The right-hand panels show the MDA8 values for air quality adjusted to meet the existing standard⁷ (x-axis) versus the additional change in those values that occur when air quality is further adjusted to meet the alternative standard of 65 ppb (y-axis). The top panels show values based on 2006-2008, while the bottom panels show values based on 2008-2010. Within each panel, the x and y values are rounded to the nearest integer and colored to show the relative frequency of each 1 ppb x 1 ppb square within the plot region. Values falling outside of the plot region were set to the nearest value within the plot region, and frequencies above the range in the color bar were set to the highest value within the color bar.

Figure 4D-85 through Figure 4D-114 show maps of the changes in design values (3-year average of the annual 4th highest MDA8 values) and May – September average MDA8 values based on the ambient data and the hourly VNA surfaces. There are two figures for each of the 15 urban study areas, one based on 2006-2008 and one based on 2008-2010 air quality. In each figure, the panels on the left show the changes in these values that occur when air quality is adjusted to meet the existing standard,⁷ and the panels on the right show the additional changes in these values that occur when air quality is further adjusted to meet the alternative standard of 65 ppb. The top panels show the changes in the design values, while the bottom panels show the changes in the May – September average MDA8 values. Within each panel, squares show values based on observed data at ambient O₃ monitoring sites while circles show values based on VNA estimates at census tract centroids. Regions shaded pink indicate counties in either the Z & S or Smith study areas (for the 12 urban study areas in the epidemiology-based risk assessment). The Z & S and Smith study areas had a few counties in common in all 12 areas, and were identical in

⁷ Chicago and Detroit were already meeting the existing standard in 2008-2010. The 2008-2010 figures for those areas are based on air quality adjusted to meet the 70 ppb alternative standard instead of the existing standard.

6 of the areas. Regions shaded gray indicate additional counties in the CBSA, and regions shaded peach indicate any additional counties in the study areas for the exposure and clinical-based risk assessment. The maps also show monitors that are located outside of the exposure study areas. These monitors were adjusted along with the other monitors and used in the VNA estimates, but were not used when determining the emissions reductions necessary to meet standard levels.

Figure 4D-115 through Figure 4D-129 show changes in design values (3-year average of the annual 4th highest MDA8 values) and May – September average MDA8 values in the 15 urban study areas versus population and population density. The population counts and population density information for each census tract were obtained from the U.S. Census Bureau based on the 2010 U.S. Census. Within each figure, the top panels show histograms of the total population stratified by the change in design value or seasonal average, while the bottom panels show scatter plots of population density (x-axis) versus change in design value or seasonal average (y-axis). The left-hand panels are based on 2006-2008, while the right-hand panels are based on 2008-2010. The first and third rows of panels show changes in design values, while the second and fourth rows of panels show changes in May-September average values. Finally, the first and third columns show the changes that occur when air quality is adjusted to meet the existing standard,⁷ while the second and fourth columns show the additional changes that occur when air quality is further adjusted to meet the alternative standard of 65 ppb. Within each panel, values associated with census tracts falling within the epidemiology study areas as defined previously are colored pink, values associated with additional census tracts falling within the CBSA are colored gray, and values associated with any additional census tracts falling within the exposure study areas are colored peach. Population density is shown on a logarithmic scale, with values falling outside of the plot region set to the nearest values within the plot region.

In general, the density scatter plots show that the HDDM adjustment procedure predicts increases in MDA8 O₃ at low ambient concentrations, and decreases in MDA8 O₃ at high concentrations. The vast majority of the increases in MDA8 O₃ occur at ambient concentrations below 50 ppb. The relationship between the starting concentrations and the changes in these values based on the HDDM adjustments is fairly linear with strong negative correlation in all 15 urban areas. In some areas, such as Baltimore and Philadelphia, there is a bimodal pattern near the center of the distribution that could indicate a differing behavior in the urban population center versus the surrounding suburban areas.

The maps reveal several trends in the spatial pattern of changes in O₃ in the urban study areas. The design values decreased almost universally when air quality was adjusted to meet the existing standard with a few exceptions,⁸ and continued to decrease when air quality was further

⁸ All design values from the VNA surfaces decreased when adjusted from recent conditions to the 75 ppb level except for the following: small areas in Boston where design values increased by up to 1 ppb (2008-2010),

adjusted to meet the 65 ppb alternative standard. The design values also tended to decrease more quickly in suburban and rural areas than in the urban population centers. The May-September “seasonal” average MDA8 values also followed this trend to some extent. However, the decreases in the seasonal average values were nearly universal in the suburban and rural areas, while the behavior in the urban population centers varied amongst the cities. The seasonal average values in the urban population centers followed one of three distinct patterns:

1. The seasonal average values decreased when air quality was adjusted to meet the existing standard, and continued to decrease when air quality was further adjusted to meet the 65 ppb alternative standard. (Atlanta, Sacramento, Washington D.C.)
2. The seasonal average values increased or remained constant when air quality was adjusted to meet the existing standard, then decreased when air quality was adjusted to meet the 65 ppb alternative standard. (Baltimore, Cleveland, Dallas, Detroit, Los Angeles, New York, Philadelphia, St. Louis)
3. The seasonal average values increased when air quality was adjusted to meet the existing standard, and continued to increase or remained constant when air quality was further adjusted to meet the 65 ppb alternative standard. (Boston, Chicago, Houston, Denver)

The population plots show a clear and consistent trend regarding the population living in areas associated with various changes in design values and seasonal average concentrations. In almost every figure, there is a positive correlation between population density and change in design value or seasonal average concentration. This suggests that in almost every scenario, when NO_x emissions were reduced, the suburban areas surrounding the urban population center experience more O₃ reductions than in the urban population center. For the 12 urban areas examined in the epidemiology-based risk assessment, the majority of the areas associated with increases in the seasonal average concentration occurred within the epidemiology study area, which tended to be focused on the urban population center.

These figures show that using the HDDM adjustment methodology, peak O₃ concentrations are reduced in urban areas with large domain-wide reductions in U.S. anthropogenic NO_x emissions. In most cases, seasonal average O₃ concentrations also decreased with large domain-wide reductions in U.S. anthropogenic NO_x emissions. However, there were a few cases, such as Chicago and Houston, where current NO_x emissions were high enough to cause titration in the urban population centers so that seasonal average O₃ concentrations were below regional background levels.

Chicago where design values increased by up to 2 ppb (2006-2008) and 4 ppb (2008-2010) and New York where design values increased by up to 3 ppb (2008-2010). All areas where design values increases started with very low design values based on recent air quality conditions.

The figure consists of four maps of the Western United States, arranged in a 2x2 grid. The maps show the change in ozone levels (ppb) for different scenarios and periods. The top row shows the 'Annual 4th Highest MDA8' (Maximum Daily Average 8-hour) and the bottom row shows the 'May - September Average MDA8'. The left column shows the 'Change from Observed to 75 ppb' and the right column shows the 'Change from 75 ppb to 65 ppb'. The color scale at the bottom indicates the 'Change in O3 (ppb)' from -20 (blue) to 10 (red). The maps show that the change from observed to 75 ppb is generally negative (blue/green), while the change from 75 ppb to 65 ppb is generally positive (yellow/red).

4D-117

The figure consists of four maps of the Central United States, arranged in a 2x2 grid. The maps show the change in ozone concentration (ppb) for different scenarios and periods. The top row displays the 'Annual 4th Highest MDA8' (Maximum Daily Average 8-hour), and the bottom row displays the 'May - September Average MDA8'. The left column shows the 'Change from Observed to 75 ppb', and the right column shows the 'Change from 75 ppb to 65 ppb'. A color scale at the bottom indicates the change in O3 (ppb), ranging from -20 (dark blue) to 10 (dark red), with intermediate values at -15, -10, -5, 0, and 5. The maps show that the change from observed to 75 ppb is generally positive (yellow to red) in the central and southern regions, while the change from 75 ppb to 65 ppb is generally negative (blue to cyan) in the same regions. The May - September average shows more localized changes compared to the annual 4th highest MDA8.

4D-118

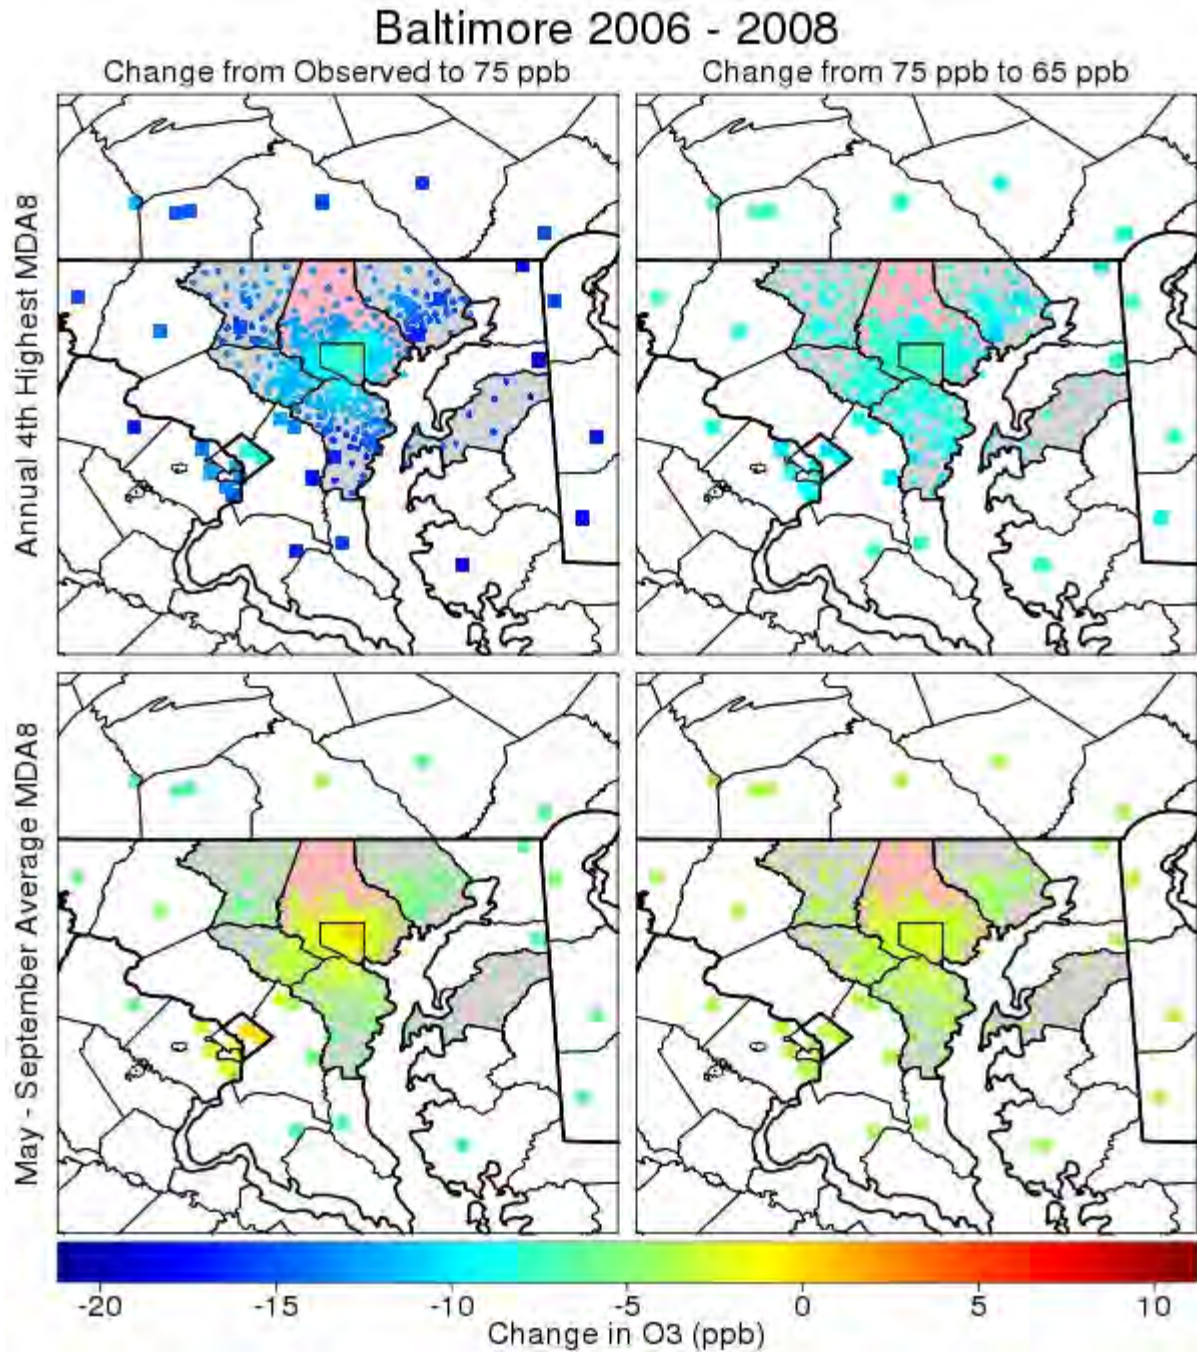

Figure 4D-87. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Baltimore, 2006-2008. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

Figure 10 consists of four maps of the Pacific Northwest region, showing changes in ozone (O₃) in ppb. The maps are arranged in a 2x2 grid. The top row shows 'Annual 4th Highest MDA8' and the bottom row shows 'May - September Average MDA8'. The left column shows 'Change from Observed to 75 ppb' and the right column shows 'Change from 75 ppb to 65 ppb'. A color scale at the bottom ranges from -20 (dark blue) to 10 (dark red). The maps show that the change from observed to 75 ppb is generally negative (blue/green), while the change from 75 ppb to 65 ppb is generally positive (yellow/red).

4D-120

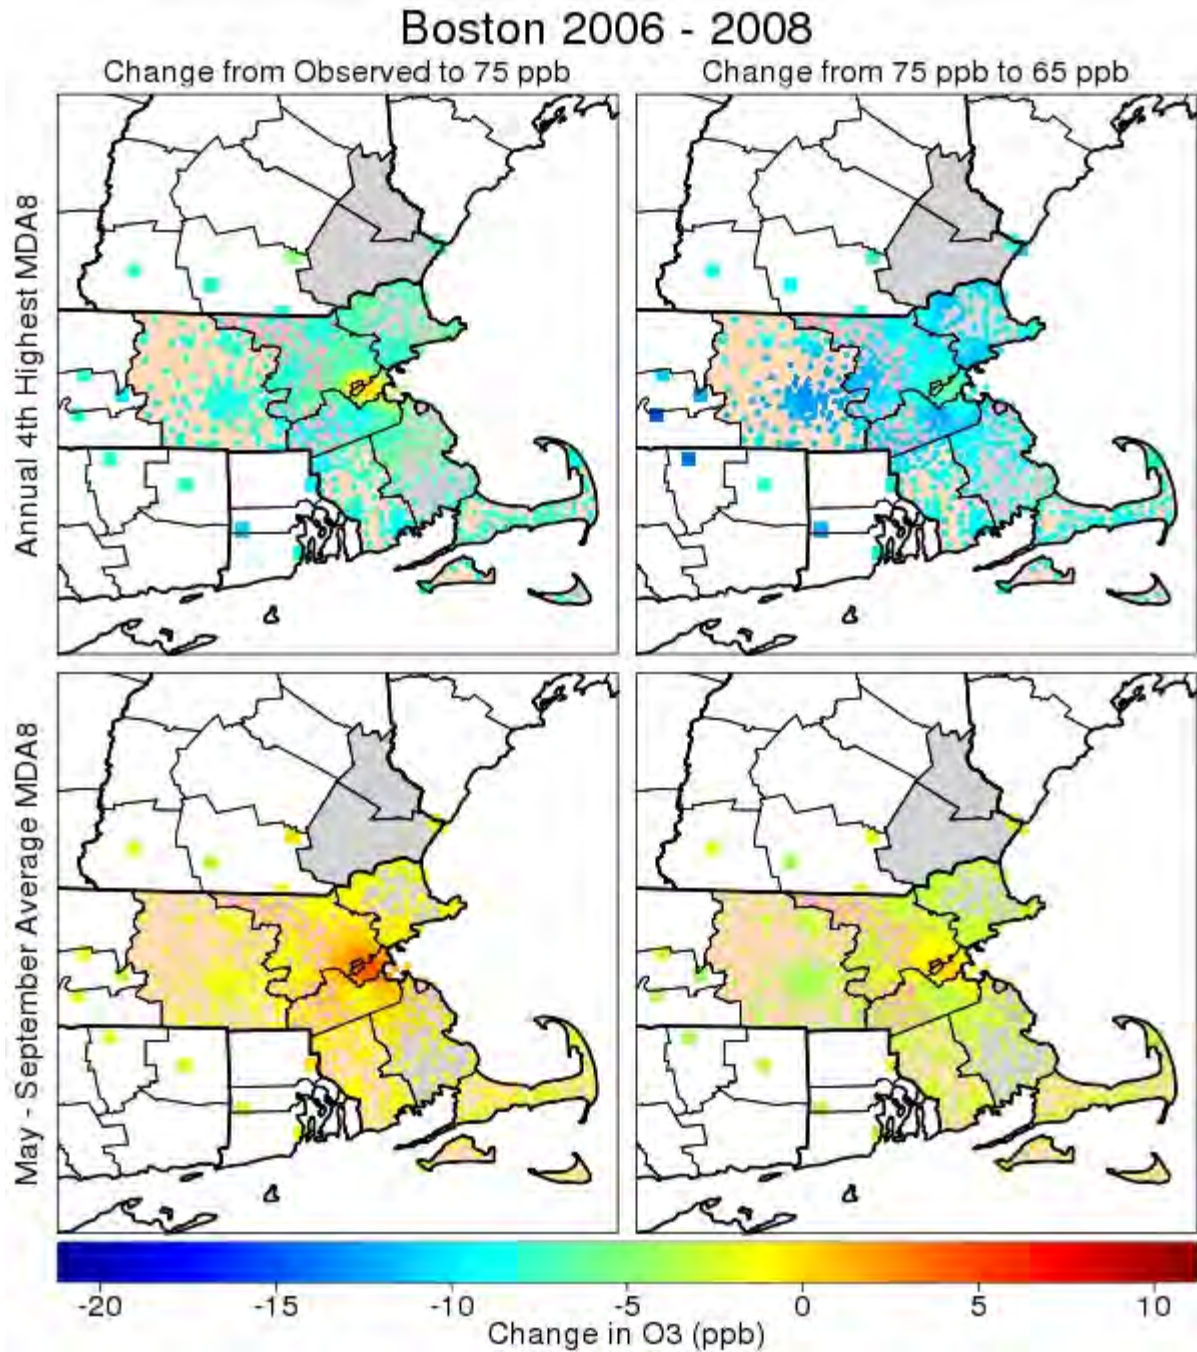

Figure 4D-89. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Boston, 2006-2008. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

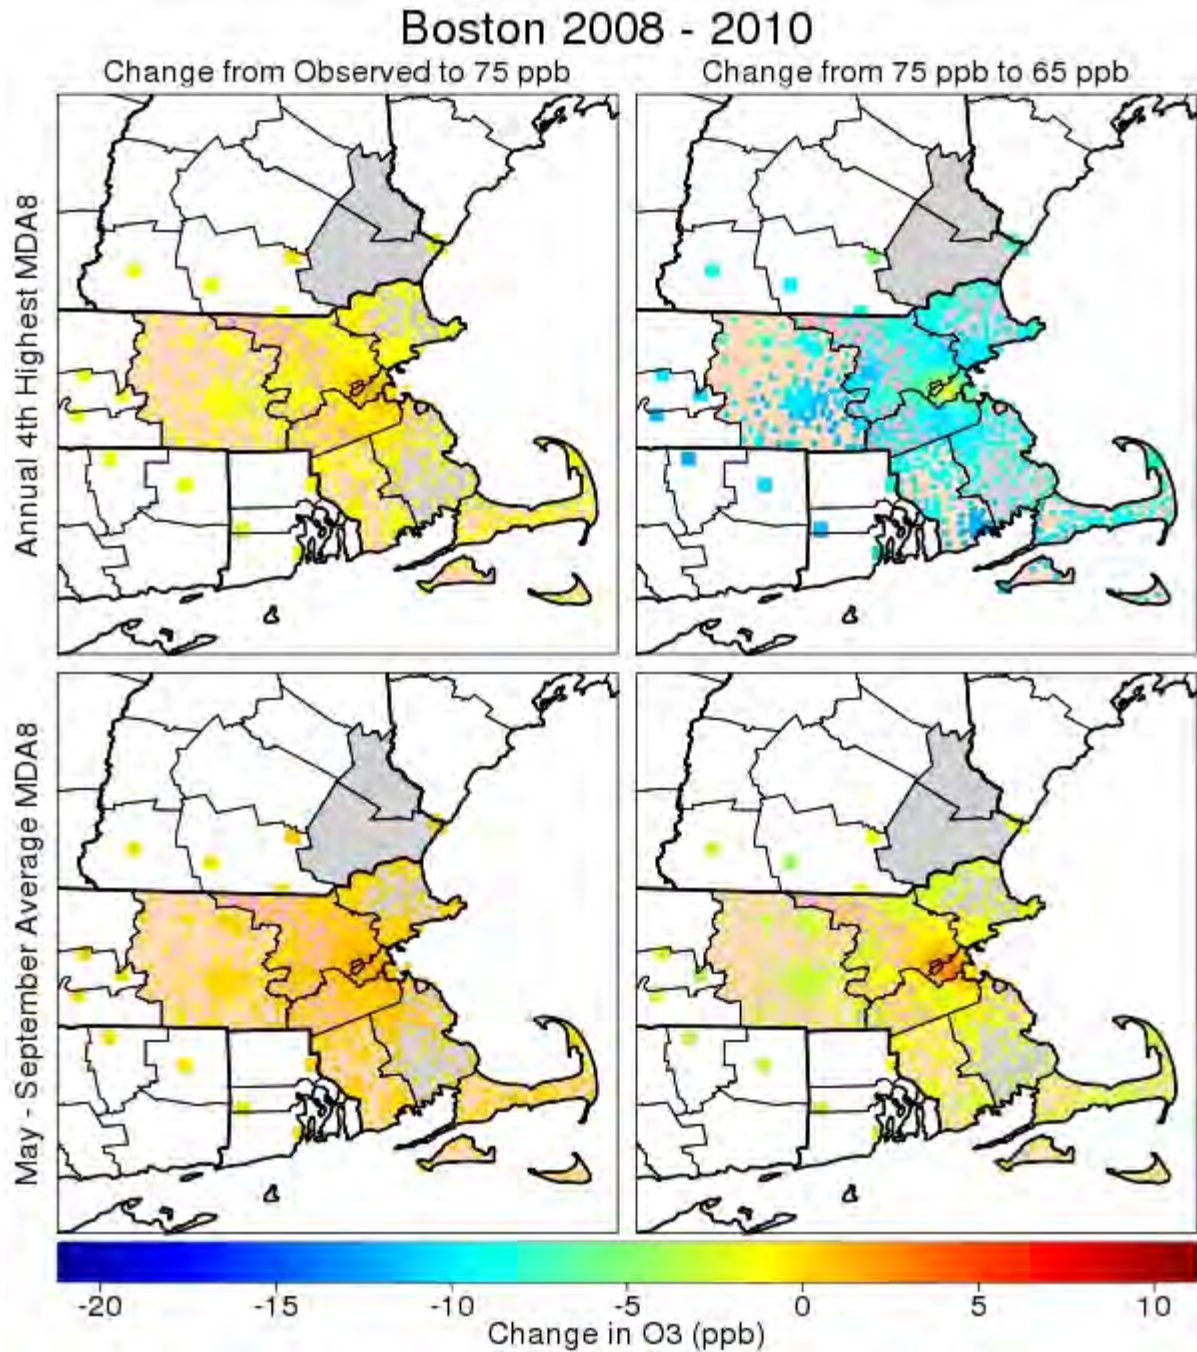

Figure 4D-90. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Boston, 2008-2010. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

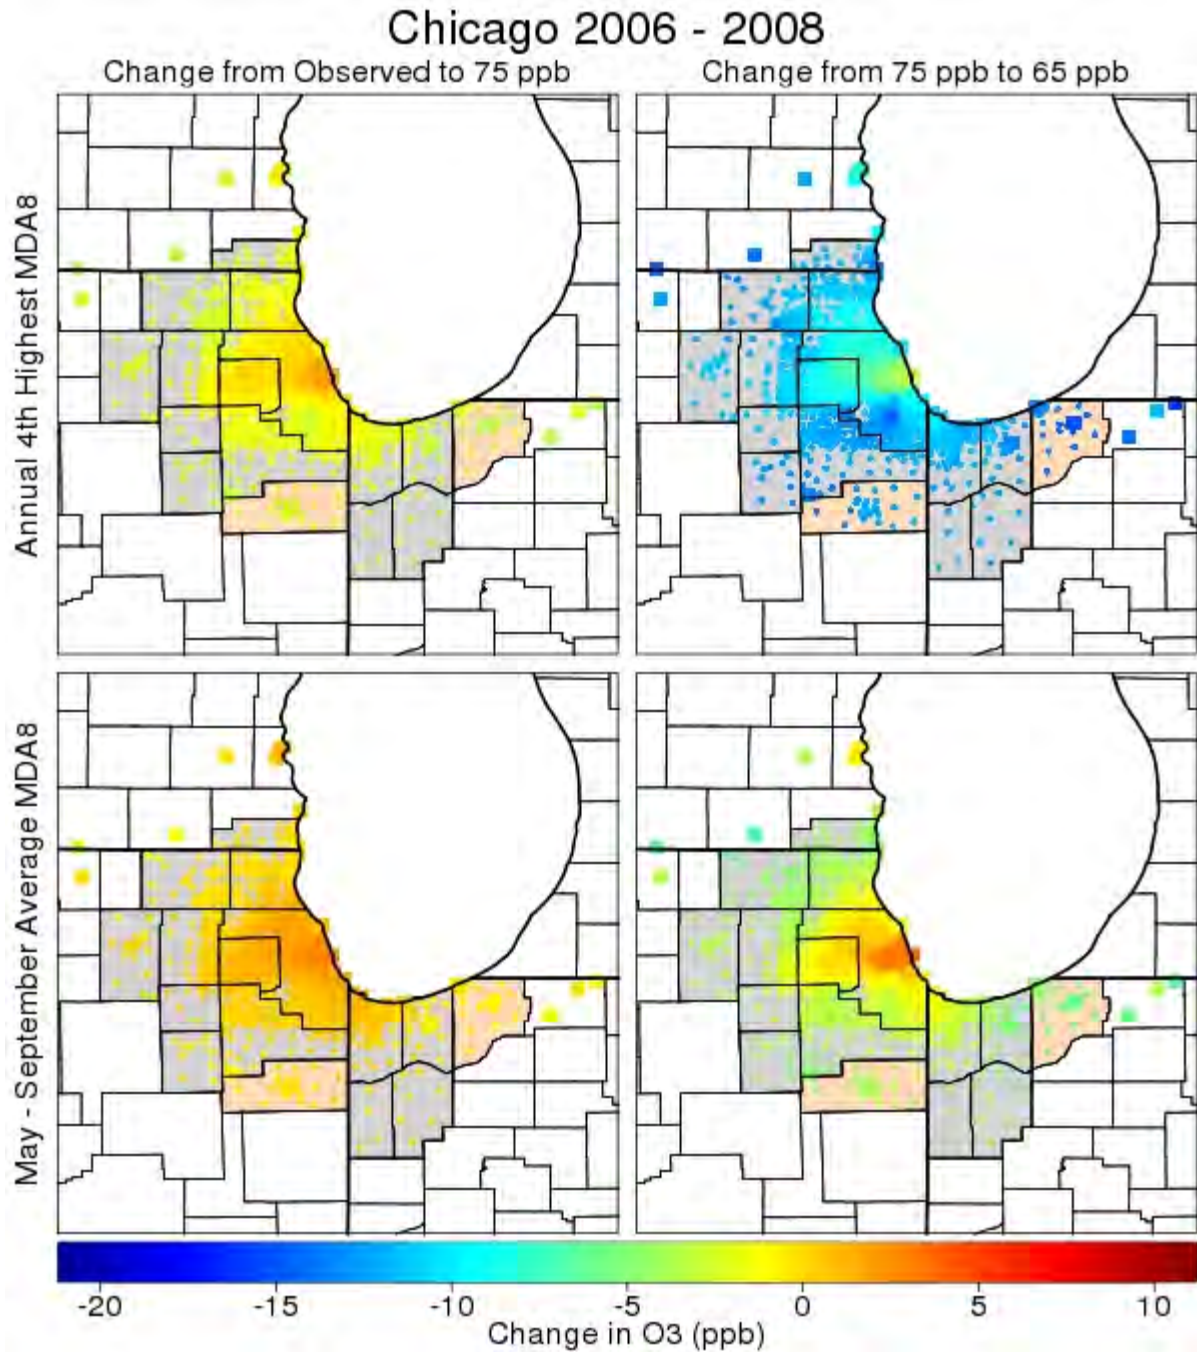

Figure 4D-91. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Chicago, 2006-2008. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

Figure 10 consists of four maps of the Great Lakes region, arranged in a 2x2 grid. The top row is labeled 'Annual 4th Highest MDA8' and the bottom row is labeled 'May - September Average MDA8'. The left column is labeled 'Change from Observed to 70 ppb' and the right column is labeled 'Change from 70 ppb to 65 ppb'. A color scale at the bottom indicates 'Change in O3 (ppb)' from -20 (blue) to 10 (red). The maps show that the change from observed to 70 ppb is generally positive (yellow to red), while the change from 70 ppb to 65 ppb is generally negative (green to blue).

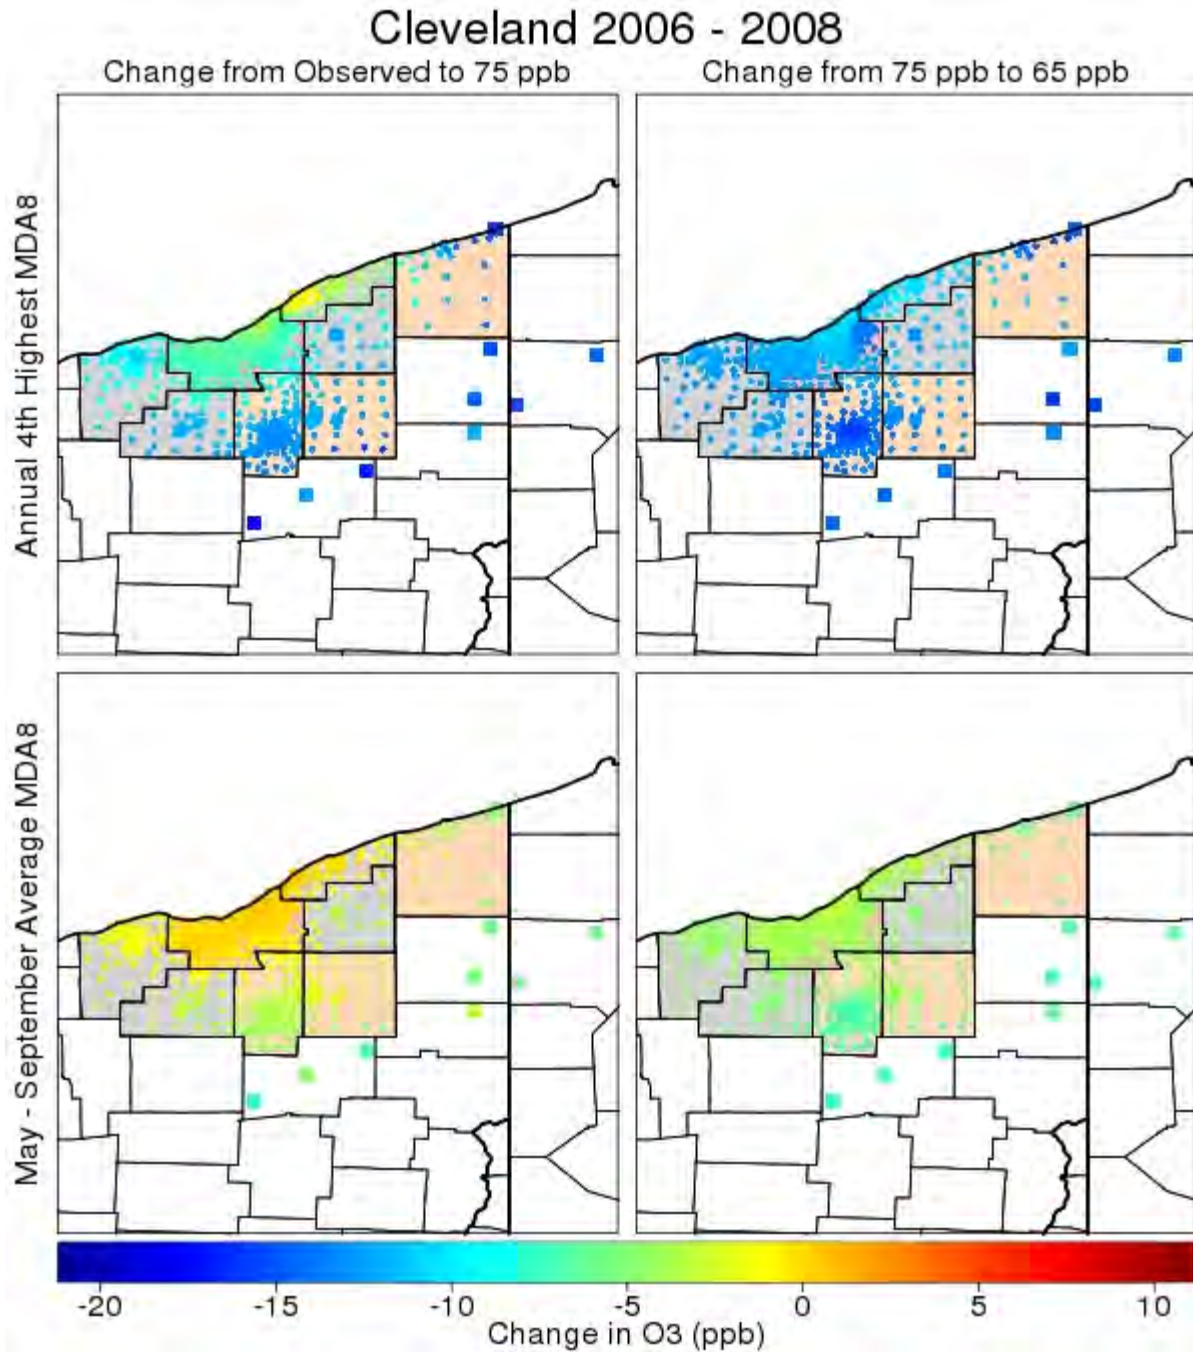

Figure 4D-93. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Cleveland, 2006-2008. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

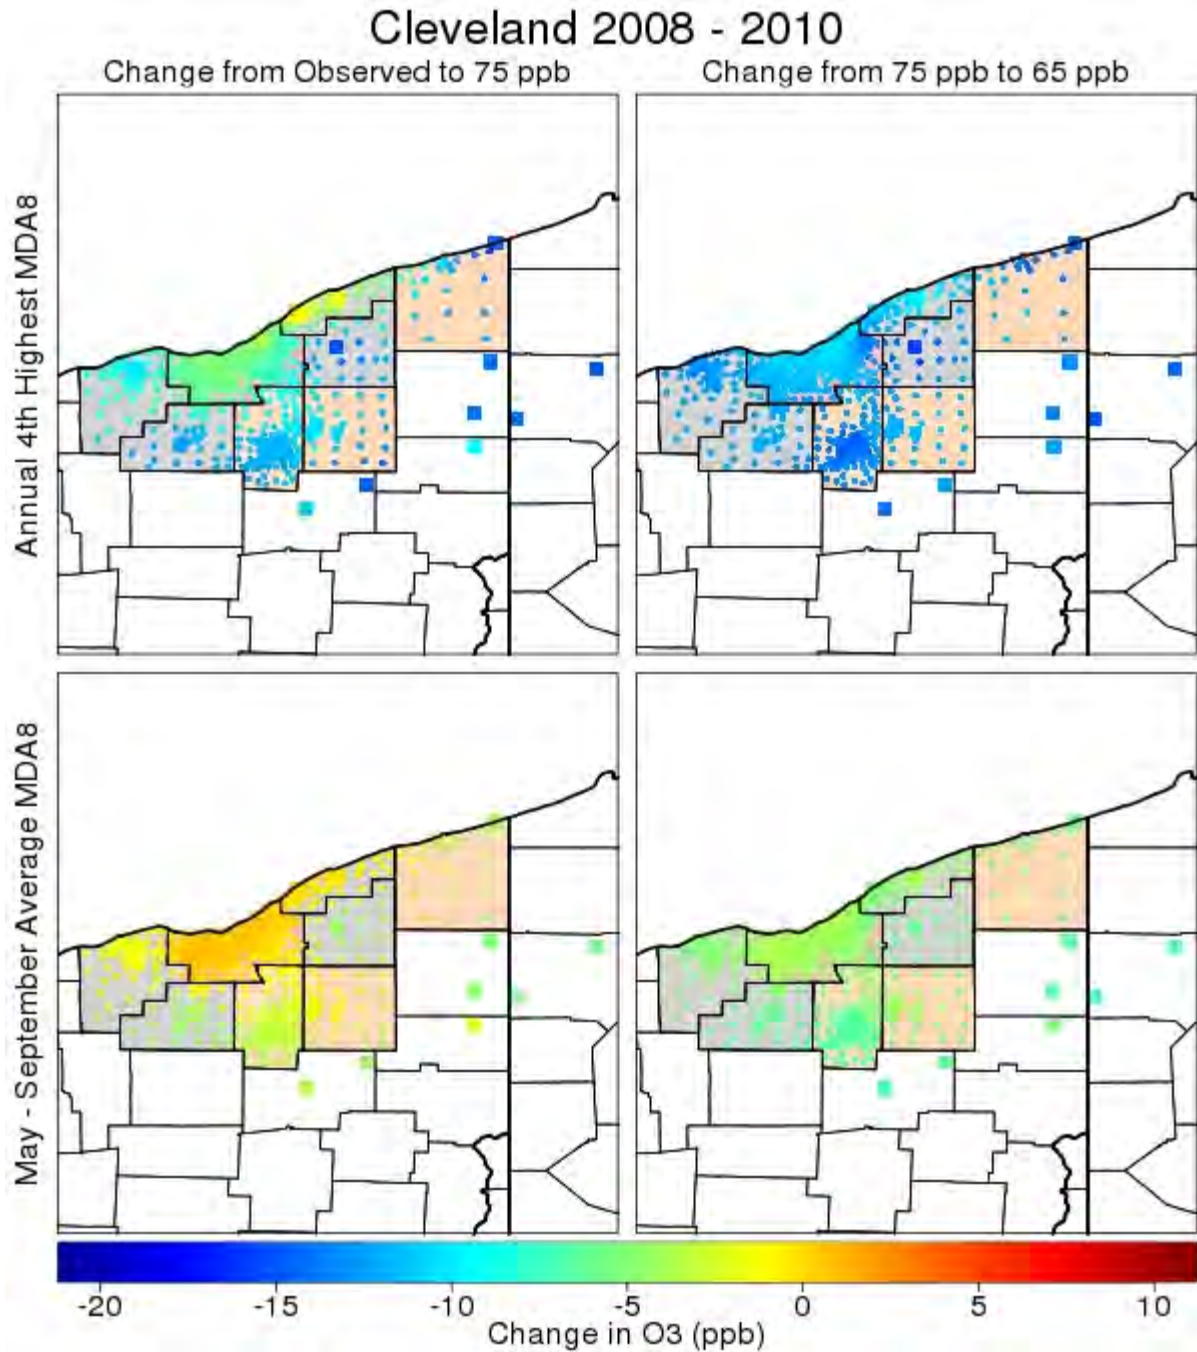

Figure 4D-94. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Cleveland, 2008-2010. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

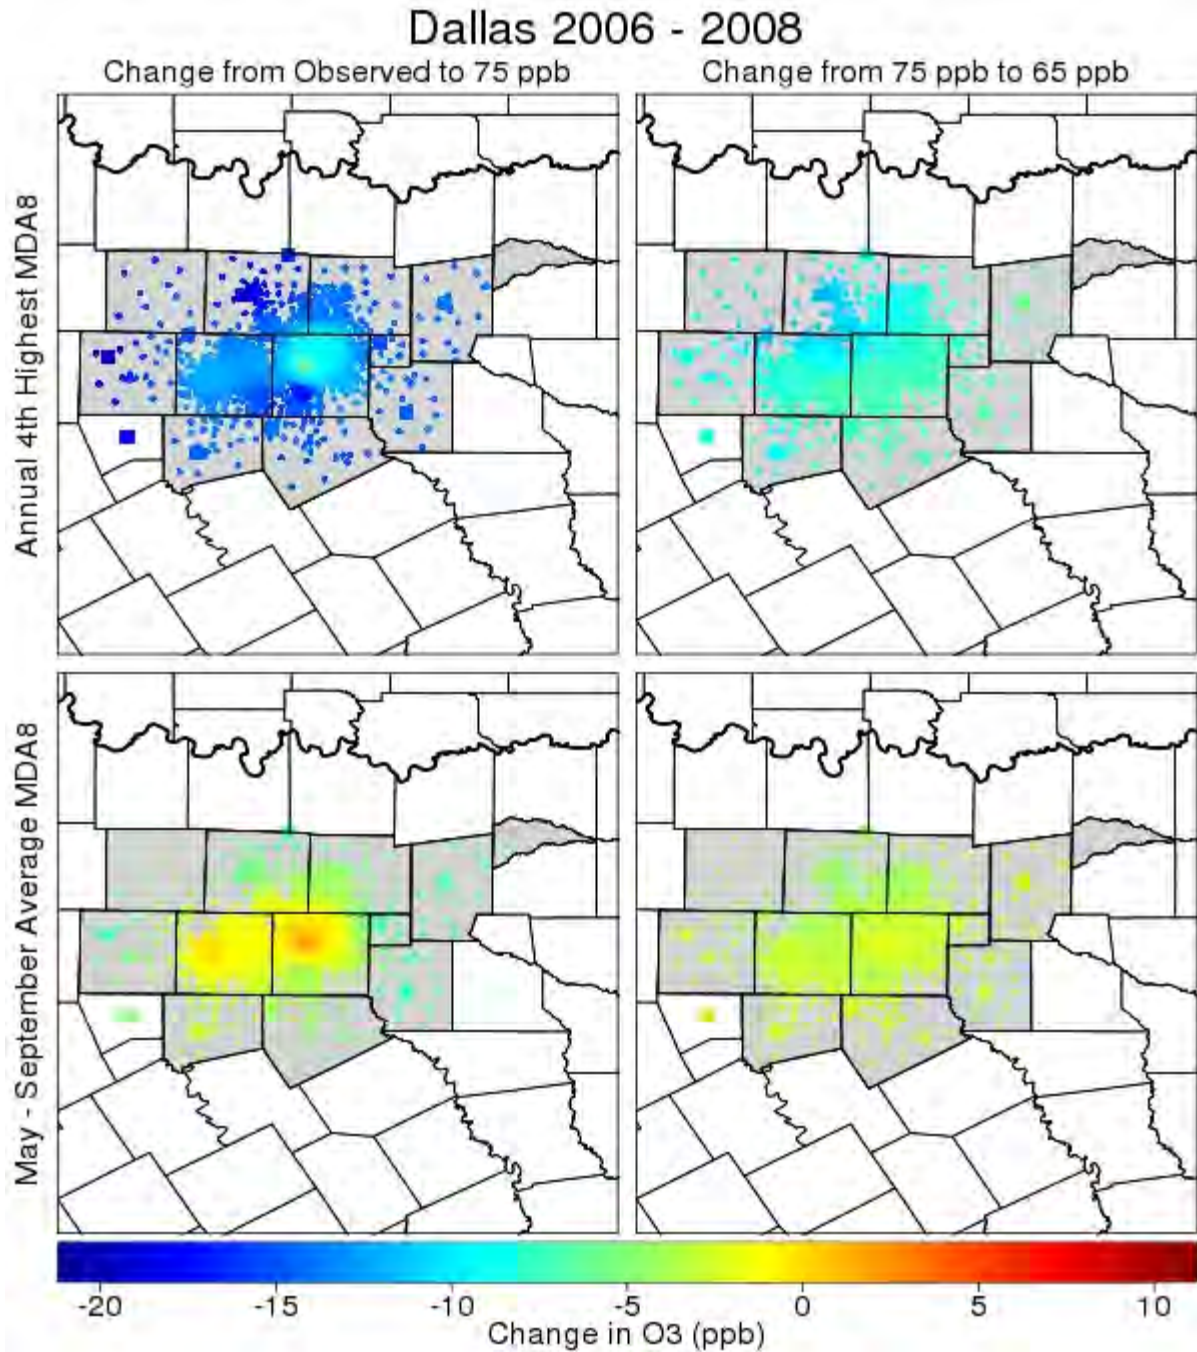

Figure 4D-95. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Dallas, 2006-2008. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

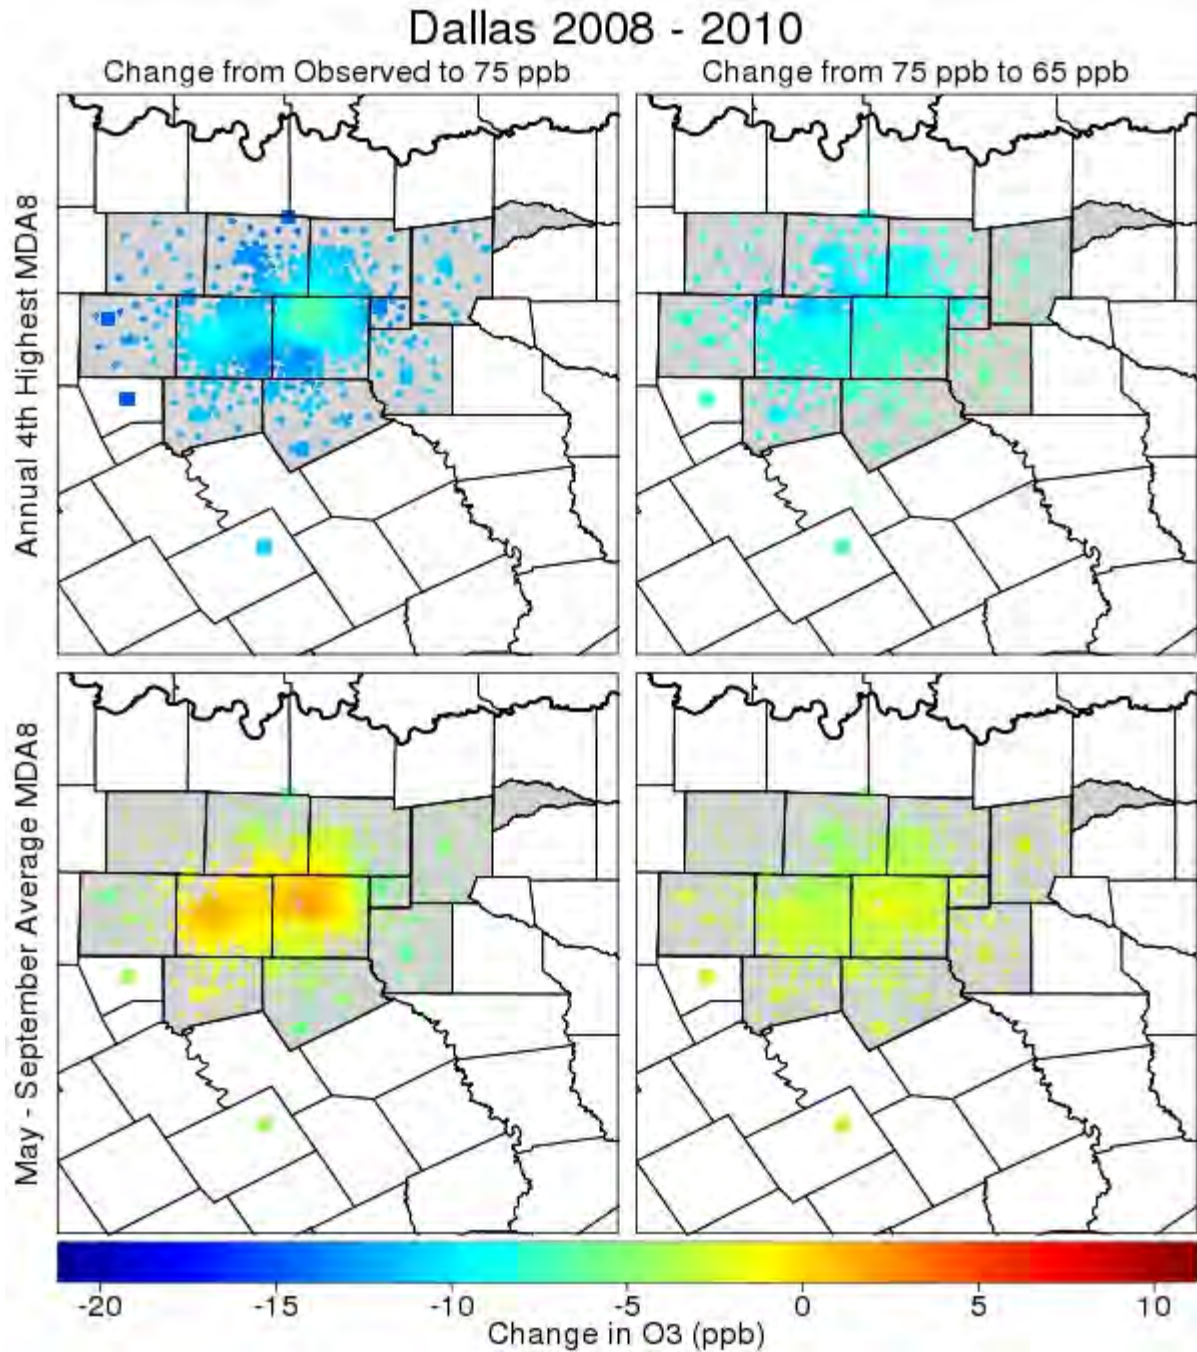

Figure 4D-96. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Dallas, 2008-2010. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

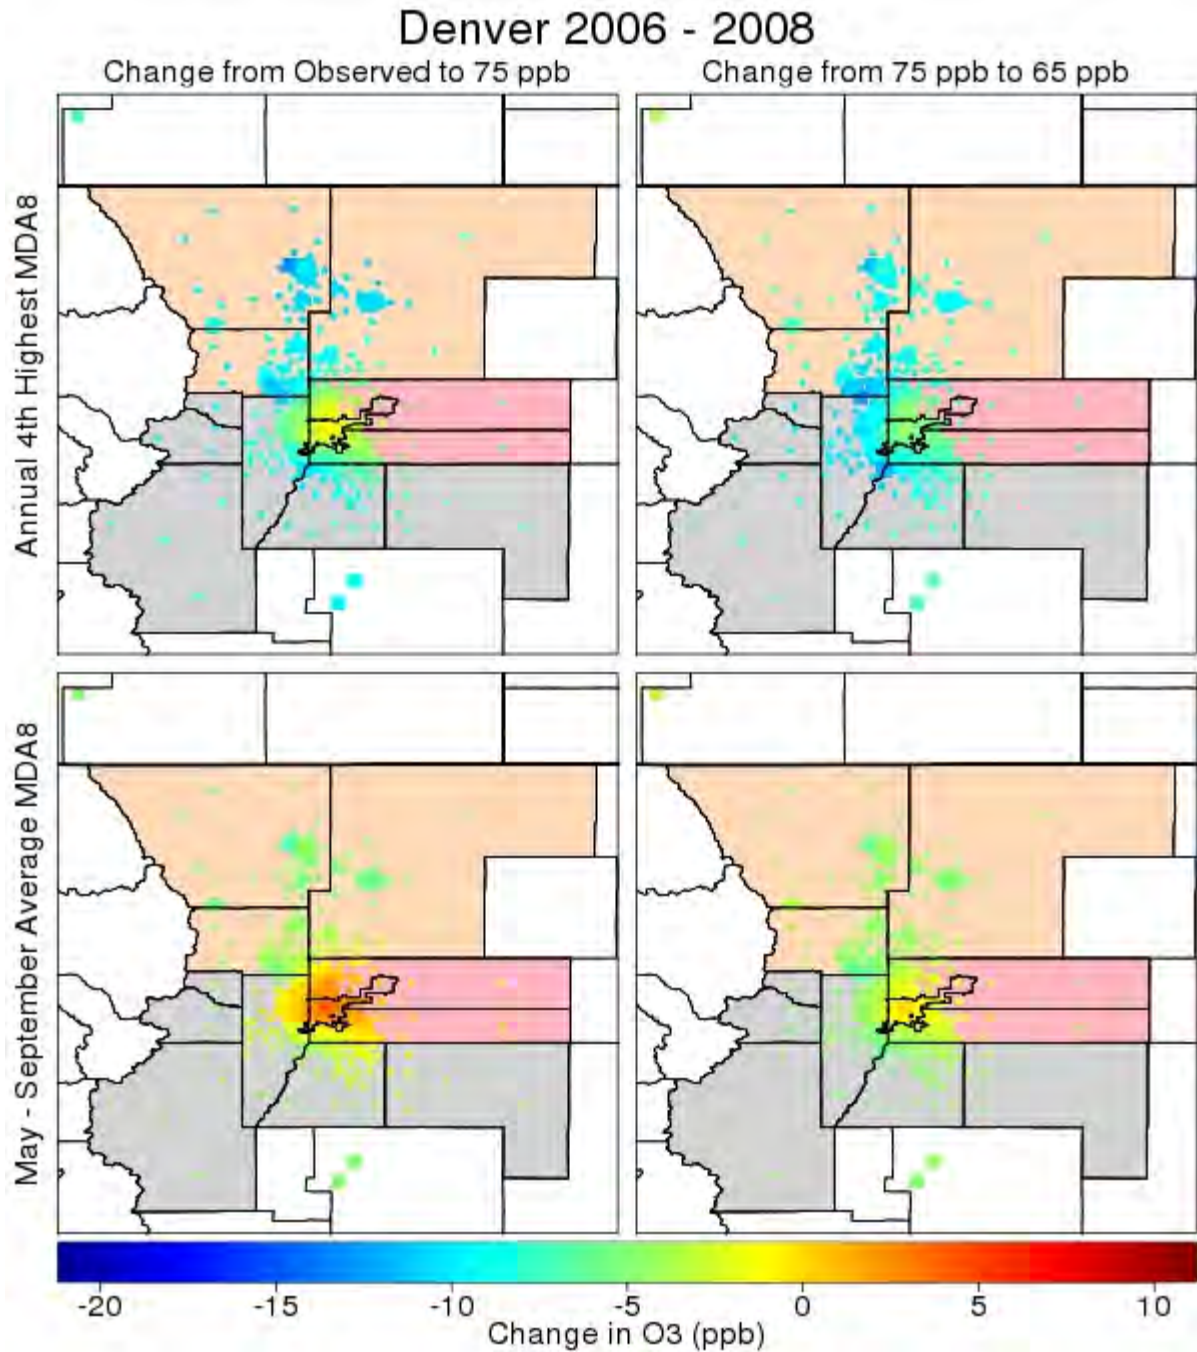

Figure 4D-97. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Denver, 2006-2008. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

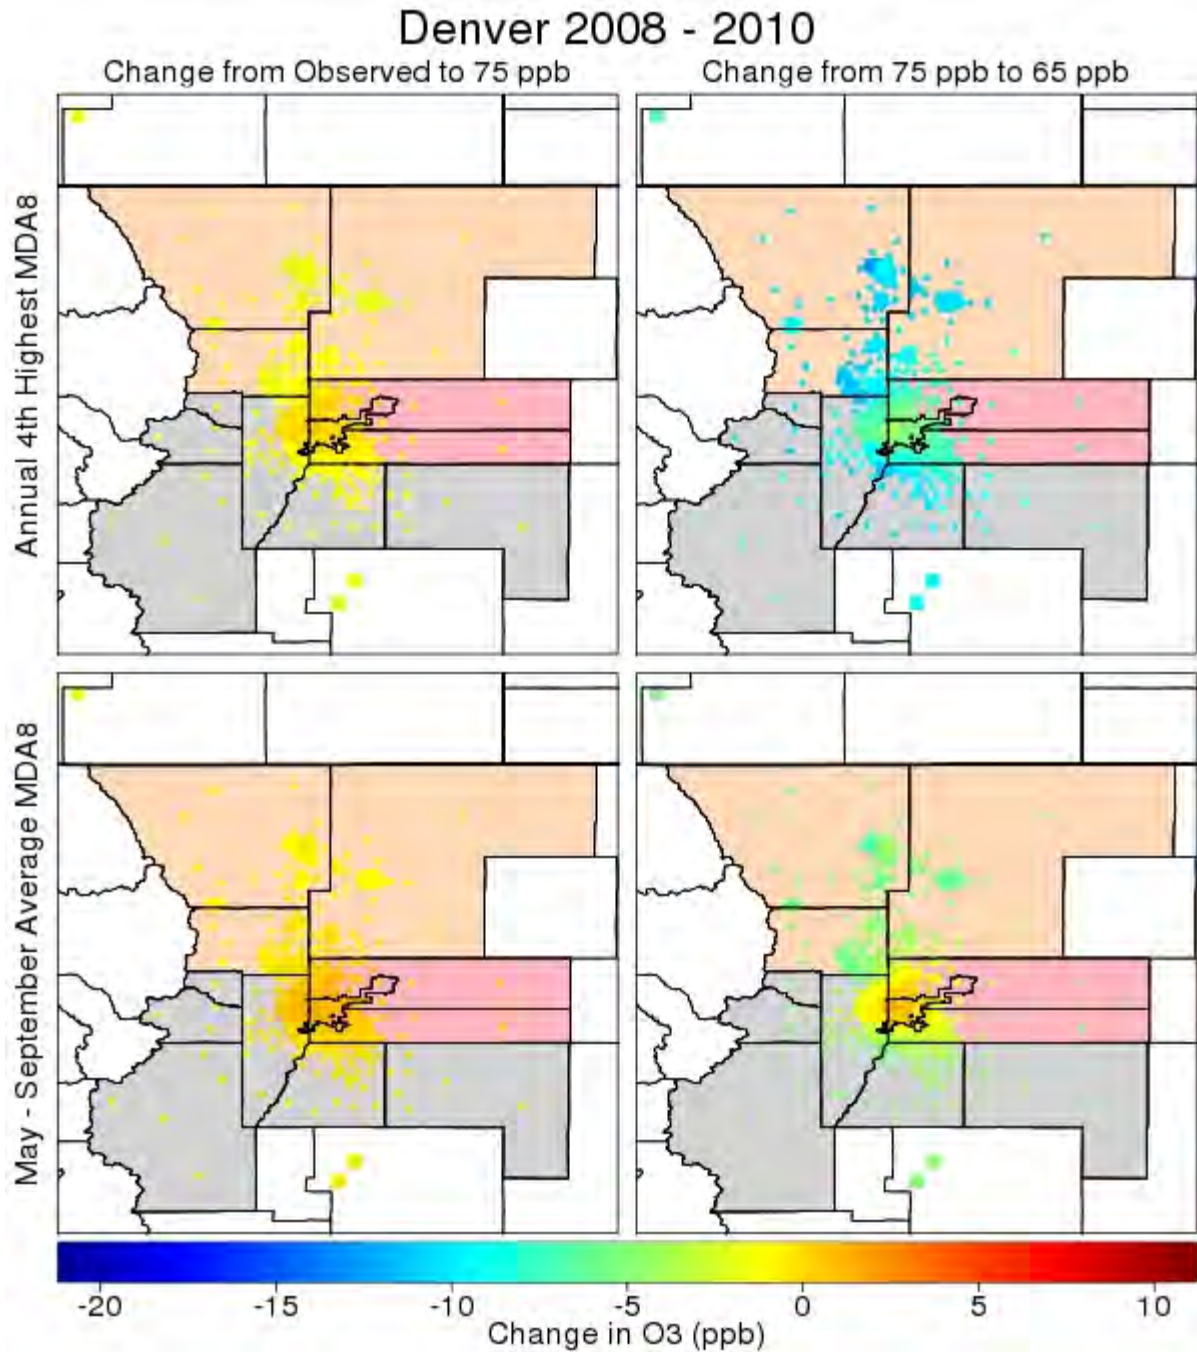

Figure 4D-98. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Denver, 2008-2010. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

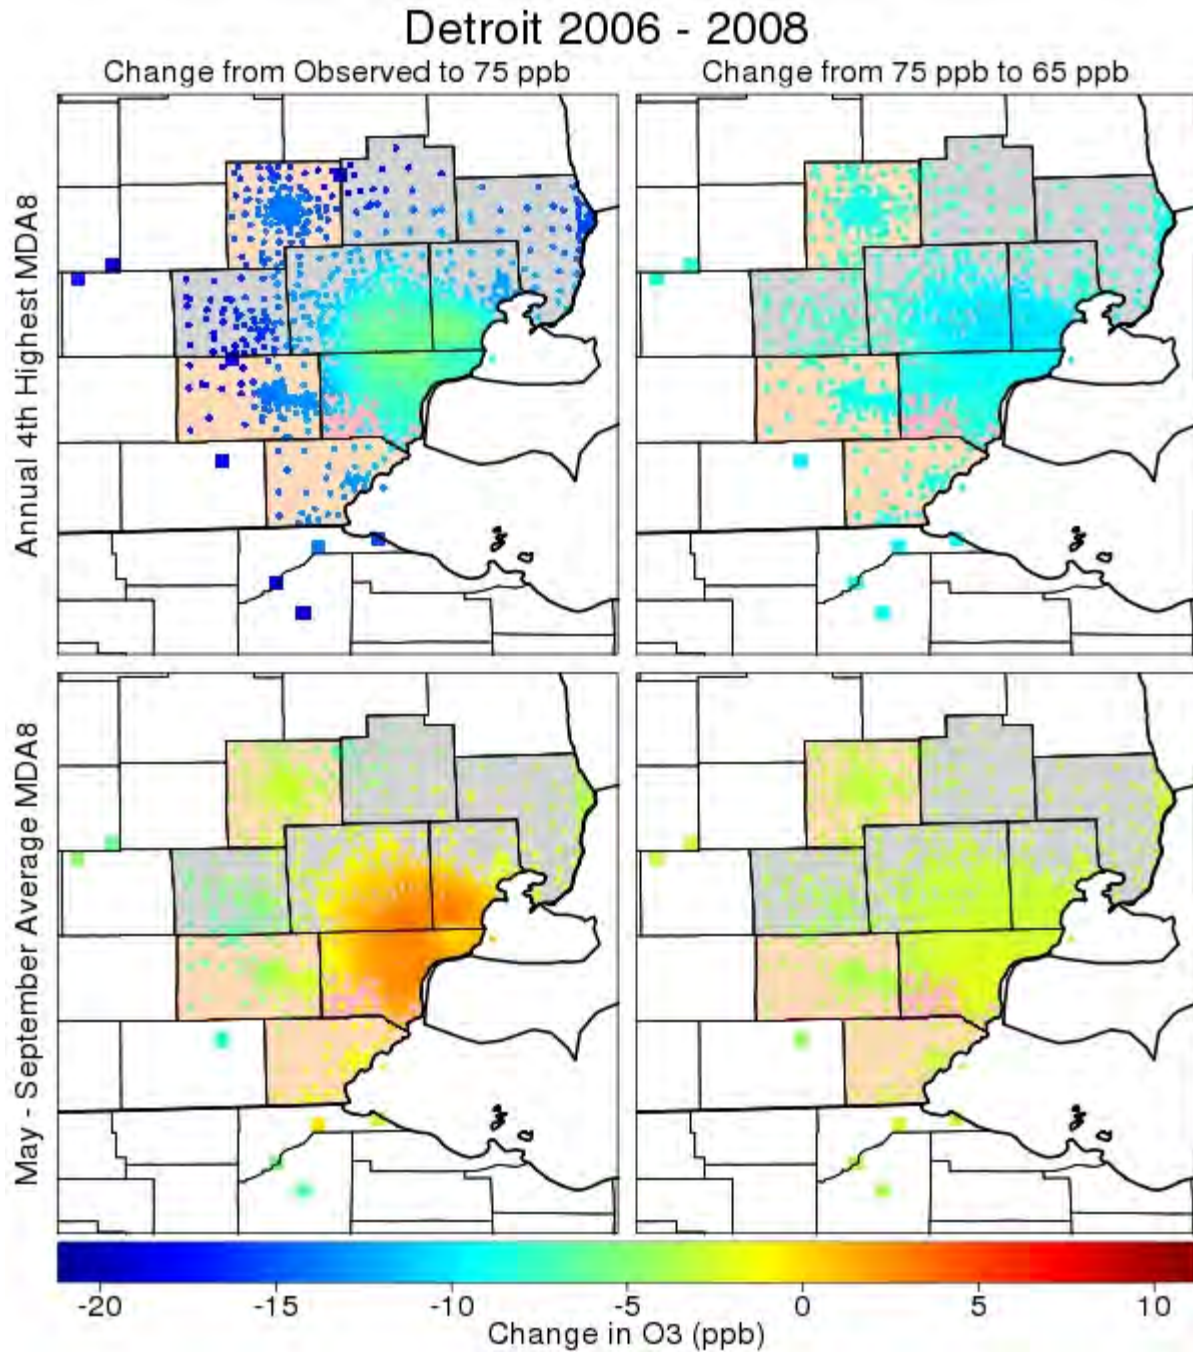

Figure 4D-99. Changes in annual 4th highest MDA8 and May-September average MDA8 values based on HDDM adjustments for Detroit, 2006-2008. The points are colored according to the change in ppb, and values falling outside the range in the color bar were set to the nearest value within the color bar.

The figure consists of four maps of the Pacific Northwest region, arranged in a 2x2 grid. The top row displays the 'Annual 4th Highest MDA8' (Maximum Daily Average 8-hour) ozone concentration, while the bottom row displays the 'May - September Average MDA8'. The left column shows the 'Change from Observed to 70 ppb', and the right column shows the 'Change from 70 ppb to 65 ppb'. A color scale at the bottom indicates the 'Change in O3 (ppb)' from -20 (blue) to 10 (red). The maps show that the change from observed to 70 ppb is generally negative (blue/green), while the change from 70 ppb to 65 ppb is generally positive (yellow/red).

4D-4.7 Comparing Air Quality Adjustments Based on NO_x Reductions Only to Air Quality Adjustments Based on NO_x and VOC Reductions

As mentioned in section 4D-4D-3, HDDM-adjustment scenarios could be carried out either by applying across-the-board reductions in U.S. anthropogenic NO_x emissions or by applying across-the-board reduction in U.S. anthropogenic NO_x and VOC emissions (with equal percentage reductions for the two precursors). The core analysis applied the NO_x-only reductions to all urban study areas except Chicago and Denver for which combined NO_x and VOC reductions were applied. However, in order to address the question of how the choice of NO_x-only emissions reductions affects estimated air quality distributions for adjustments to the existing and alternative standard levels we performed sensitivity analyses for seven cities: Denver, Detroit, Houston, Los Angeles, New York, Philadelphia, and Sacramento. For these seven cities, we performed both NO_x-only and N/VOC emissions reductions scenarios for all standard levels and compared the resulting air quality results. Although in six of these cities the additional VOC reductions did not result in needing lower percentage NO_x reductions, we recognize that some VOC reductions are likely to occur in future years due to on-the-books mobile source rules. However, the large VOC cuts applied here are larger than expected reductions from these rules. Several caveats need to be noted for this analysis. First, this is meant as a sensitivity test only and not as a potential realistic alternative control scenario. Second, because the methodology described in Section 4D-3 restricts the calculations to equal percentage cuts in NO_x and VOC, this sensitivity does not necessarily identify the optimal combination of NO_x and VOC reduction levels. Table 4D-20 shows the percentage reductions that were applied in each scenario for each of the seven cities.

Table 4D-20. Comparison of NO_x-only and NO_x/VOC emission reductions applied in sensitivity analyses for nine urban areas.

City	Years	NO _x -only				NO _x /VOC			
		75 ppb	70 ppb	65 ppb	60 ppb	75 ppb	70 ppb	65 ppb	60 ppb
Chicago	2006-2008	41%	54%	65%	75%	19%	52%	66%	80%

	2008-2010	64%	71%	77%	84%	65%	74%	81%	88%

Figure 4D-130 through Figure 4D-136 show boxplots of composite monitor daily maximum 8-hr O₃ values for recent conditions (base) and each of the eight adjustment scenarios (NO_x-only and NO_x/VOC for 75, 70, 65, and 60 ppb standard levels) in the seven cities evaluated. A range of results can be seen in different urban areas. Denver, Houston, Los Angeles, and New York showed the largest difference between O₃ concentrations in NO_x-only versus NO_x/VOC scenarios while Detroit, Philadelphia and Sacramento had relatively less difference in the O₃ distributions estimated in two types of scenarios. In all cities, the NO_x-only and NO_x/VOC scenarios had very similar O₃ concentrations at the upper end of the distribution (top whiskers and outlier dots in the boxplots). This is not surprising since the adjustment scenarios were implemented to obtain identical 4th high O₃ concentrations. Mid-range O₃ concentrations (25th-75th percentiles) were generally lower in the NO_x/VOC adjustment scenarios than the NO_x-only adjustment scenarios for the same standard level with the exception of New York.

The reduction of mid-range O₃ concentrations in the NO_x/VOC scenarios compared to the NO_x-only scenarios tended to be larger in 2007 than in 2009 and tended to be larger at lower alternate standard levels. In most urban study areas the reduction in mid-level O₃ in the NO_x/VOC scenario compared to the NO_x-only scenario was modest but in Los Angeles it was significant. The change in mid-range O₃ concentrations between the two sets of scenarios was so dramatic in Los Angeles that in many cases the 75th percentile concentration in the NO_x/VOC scenario was lower than the 25th percentile concentration in the comparable NO_x-only scenario. The most dramatic differences between the NO_x-only and the NO_x/VOC scenarios occurred at the low end of the O₃ distribution. In all urban study areas, there were smaller increases in O₃ at low O₃ concentrations in the NO_x/VOC scenario when compared to the NO_x-only scenario for the same standard level. This is especially evident for extreme low concentrations (bottom whiskers for blue NO_x-only scenarios are much higher than bottom whiskers for red NO_x/VOC scenarios in the boxplots) but can also be seen in the 25th percentile O₃ values which are represented by the bottom of the boxes. The reductions were most apparent for Denver, Houston, Los Angeles, New York, and Philadelphia but were more modest in Detroit and Sacramento.

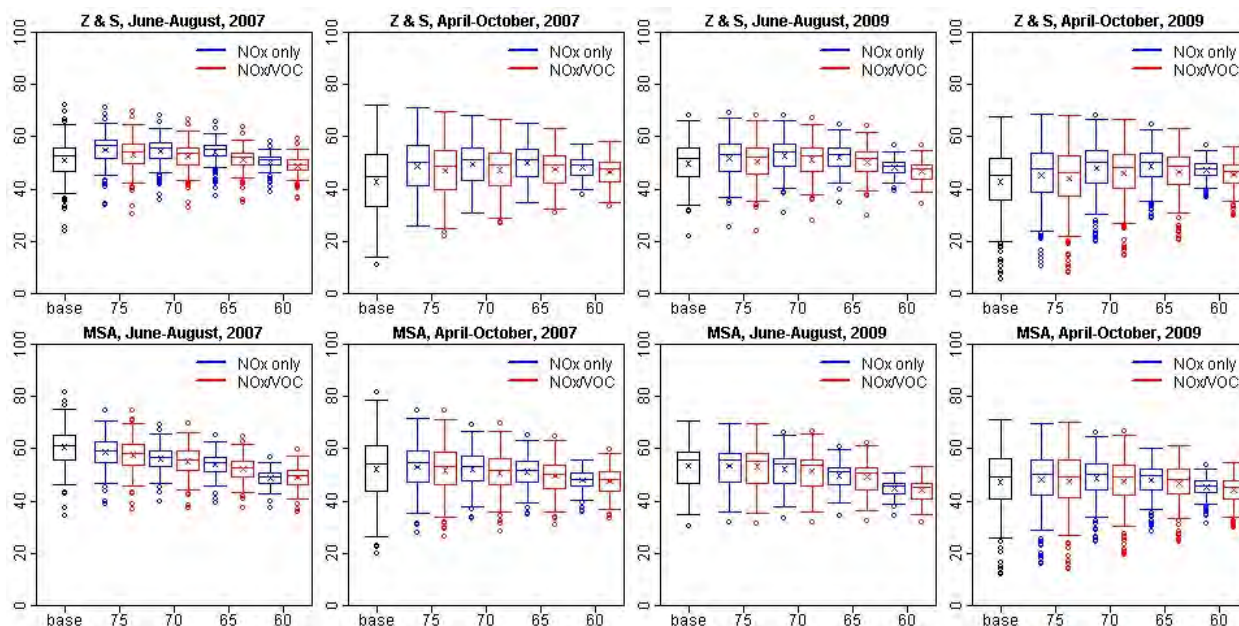

Figure 4D-130. Composite monitor daily maximum 8-hour O₃ values for Denver based on observed and adjusted air quality for the NO_x-only and NO_x/VOC scenarios. Boxes represent the median and quartiles, x's represent mean values, whiskers extend up to 1.5x the inter-quartile range from the boxes, and circles represent outliers.

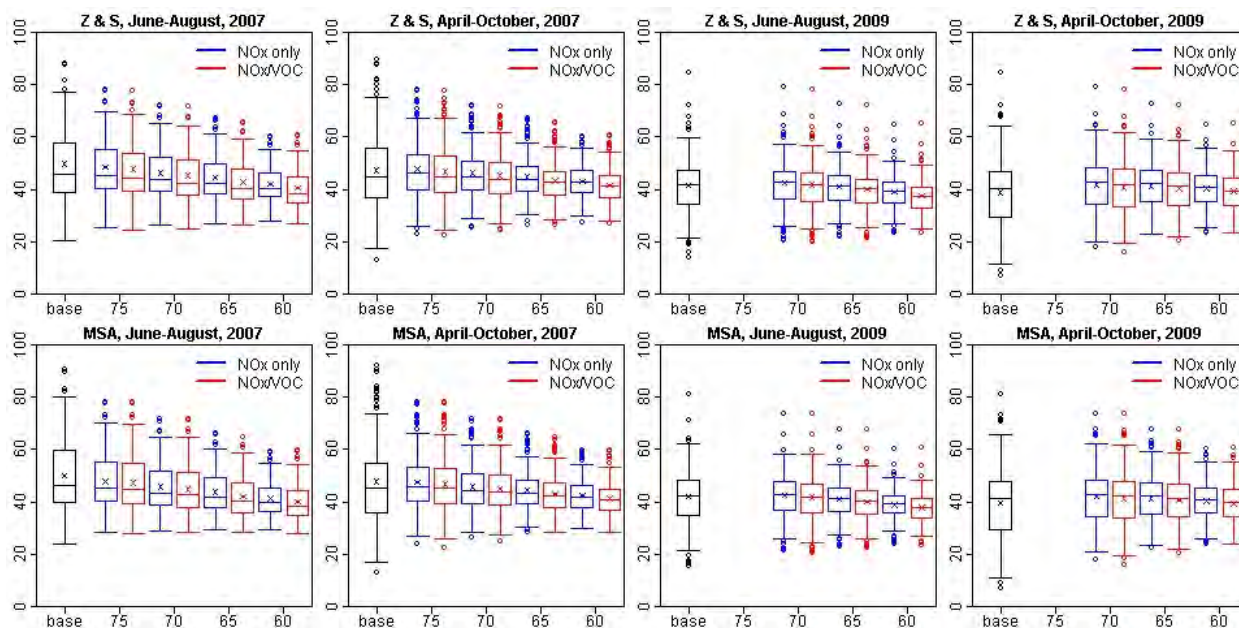

Figure 4D-131. Composite monitor daily maximum 8-hour O₃ values for Detroit based on observed and adjusted air quality for the NO_x-only and NO_x/VOC scenarios. Boxes represent the median and quartiles, x's represent mean values, whiskers extend up to 1.5x the inter-quartile range from the boxes, and circles represent outliers.

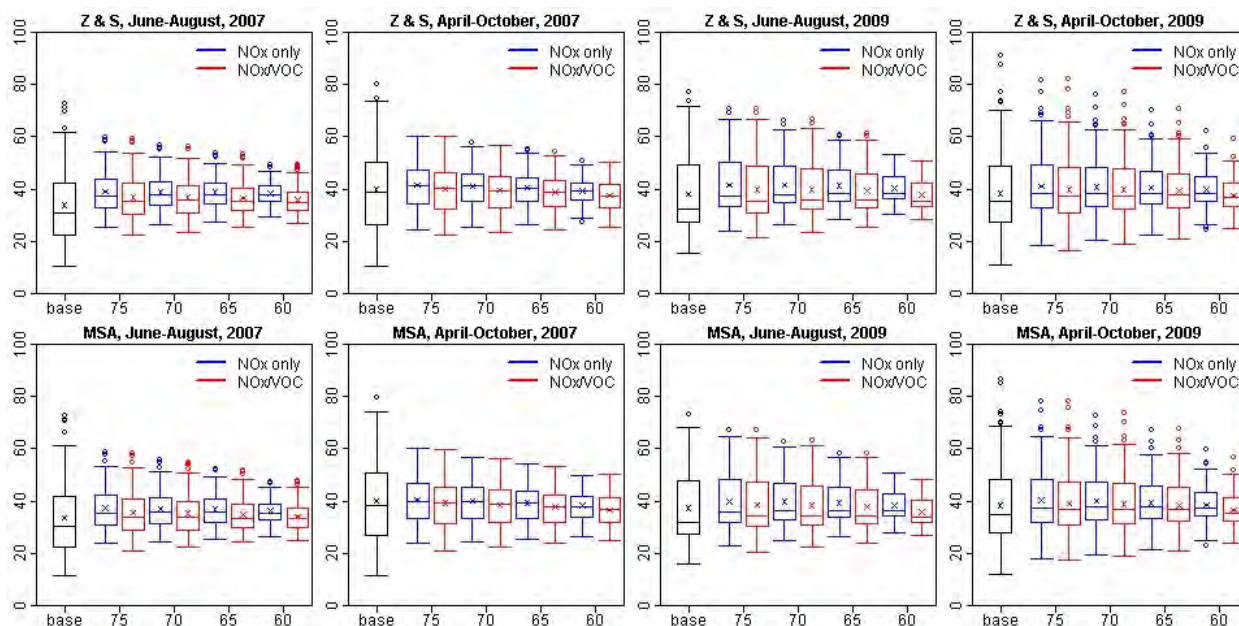

Figure 4D-132. Composite monitor daily maximum 8-hour O₃ values for Houston based on observed and adjusted air quality for the NO_x-only and NO_x/VOC scenarios. Boxes represent the median and quartiles, x's represent mean values, whiskers extend up to 1.5x the inter-quartile range from the boxes, and circles represent outliers.

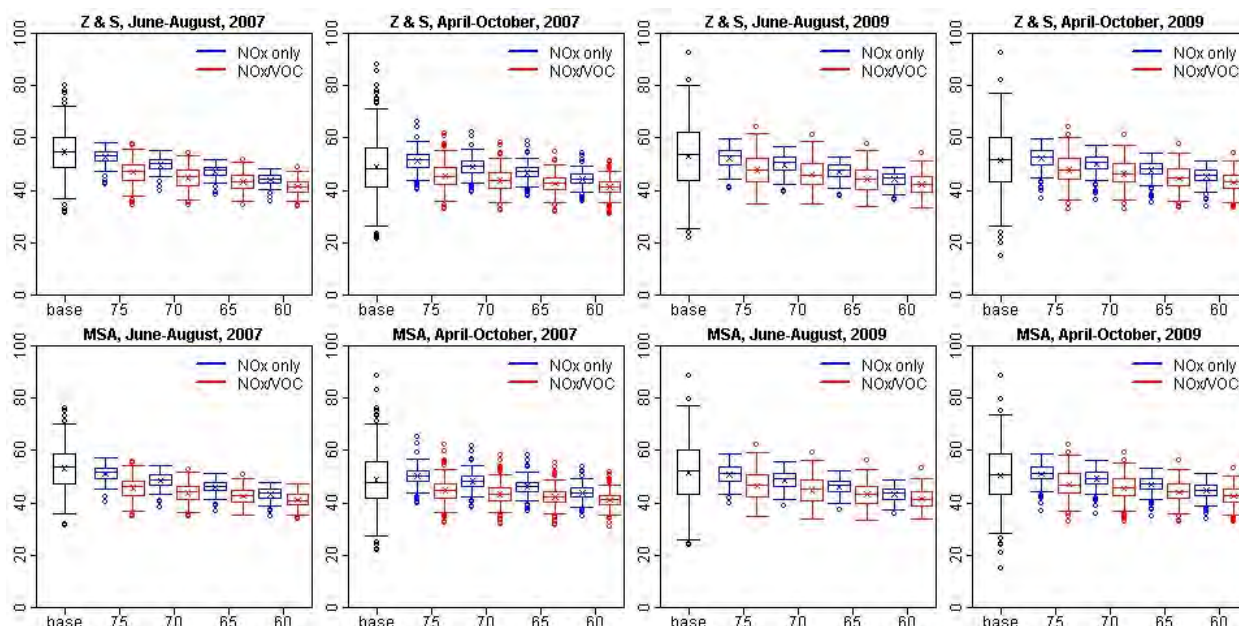

Figure 4D-133. Composite monitor daily maximum 8-hour O₃ values for Los Angeles based on observed and adjusted air quality for the NO_x-only and NO_x/VOC scenarios. Boxes represent the median and quartiles, x's represent mean values, whiskers extend up to 1.5x the inter-quartile range from the boxes, and circles represent outliers.

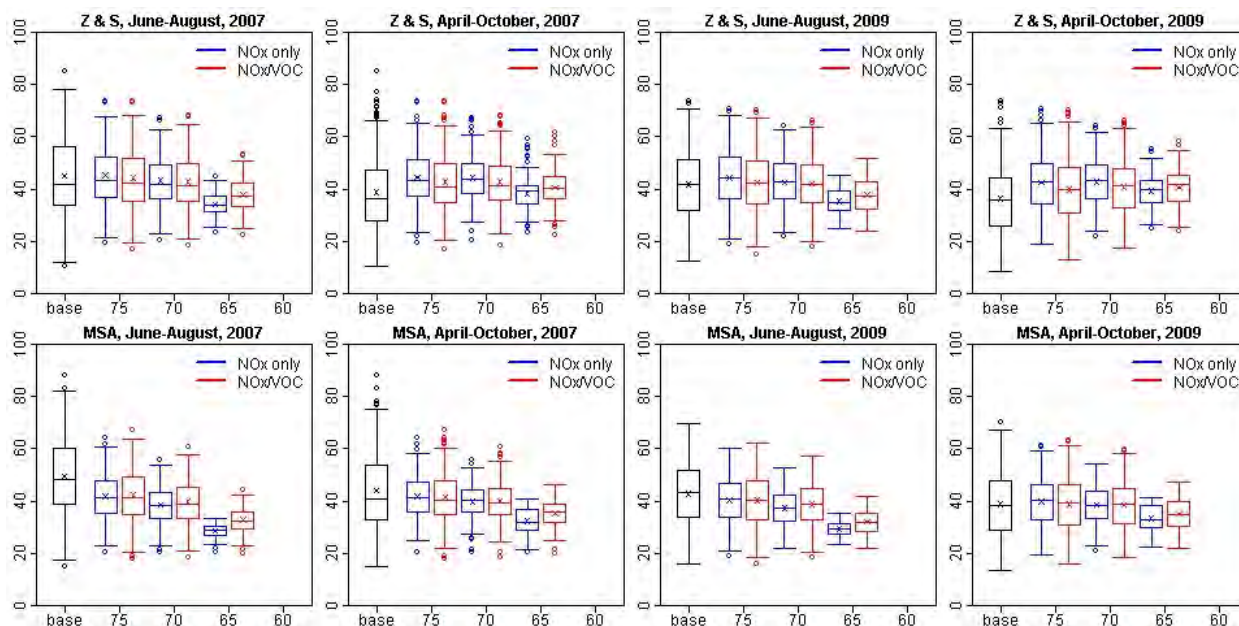

Figure 4D-134. Composite monitor daily maximum 8-hour O₃ values for New York based on observed and adjusted air quality for the NO_x-only and NO_x/VOC scenarios. Boxes represent the median and quartiles, x's represent mean values, whiskers extend up to 1.5x the inter-quartile range from the boxes, and circles represent outliers.

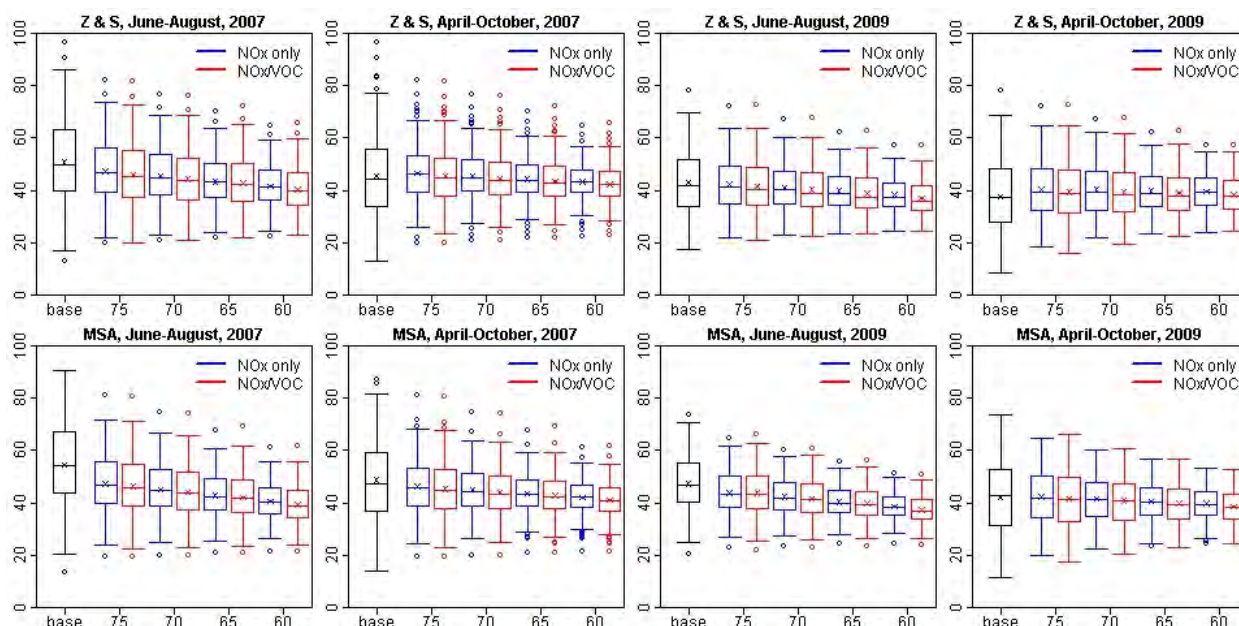

Figure 4D-135. Composite monitor daily maximum 8-hour O₃ values for Philadelphia based on observed and adjusted air quality for the NO_x-only and NO_x/VOC scenarios. Boxes represent the median and quartiles, x's represent mean values, whiskers extend up to 1.5x the inter-quartile range from the boxes, and circles represent outliers.

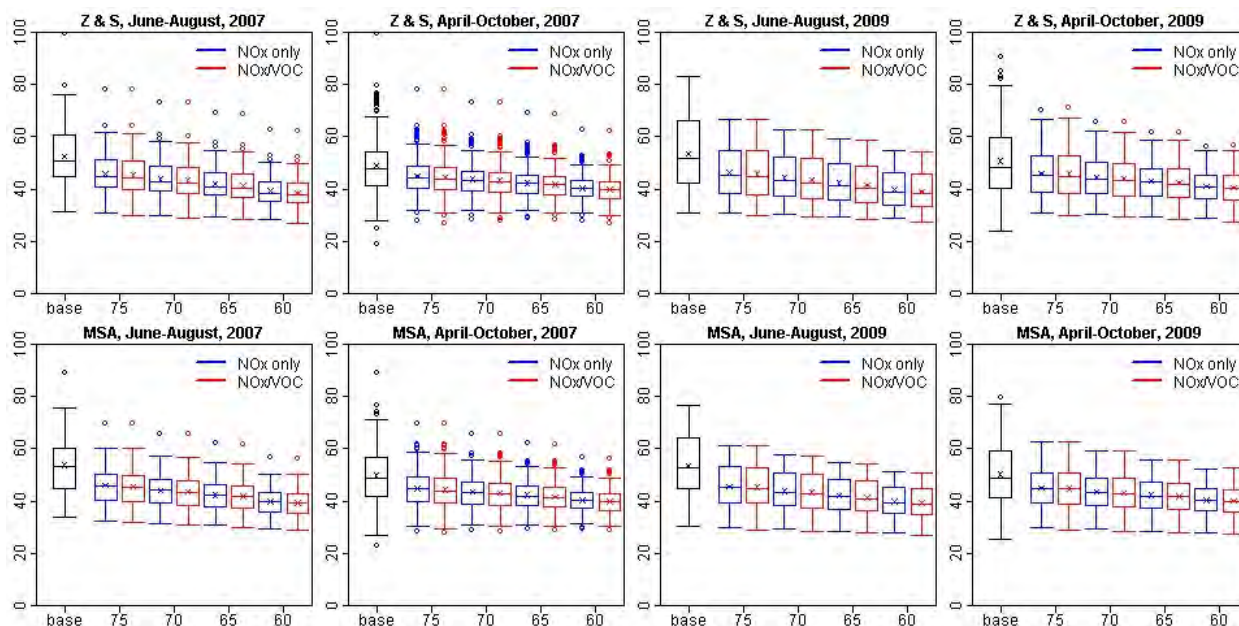

Figure 4D-136. Composite monitor daily maximum 8-hour O₃ values for Sacramento based on observed and adjusted air quality for the NO_x-only and NO_x/VOC scenarios. Boxes represent the median and quartiles, x's represent mean values, whiskers extend up to 1.5x the inter-quartile range from the boxes, and circles represent outliers.

Figure 4D-137 through Figure 4D-143 show maps of the 2006-2008 observed and adjusted April-October seasonal mean of the daily maximum 8-hr O₃ value at monitor locations in each of the urban study areas. Adjusted values are shown for the 75 ppb and 65 ppb NO_x-only and NO_x/VOC adjustment scenarios. As described earlier in this appendix and in HREA Chapter 4, these figures show that for observed 2006-2008 O₃ values, the seasonal mean of the daily maximum 8-hr O₃ concentration was suppressed in the highly urbanized areas compared to surrounding locations. In these figures, it is clear that O₃ concentrations are lower in the center city areas for all cities except Sacramento. The NO_x-only adjustment scenarios resulted in three types of behavior as demonstrated by the top panels on these maps. First, in Denver, Houston, Los Angeles, and New York the NO_x-only adjustment cases resulted in increasing seasonal mean concentrations in center city locations where O₃ was suppressed in observations and decreasing seasonal mean concentrations in outlying areas where O₃ was higher in the observations. This trend is so dramatic in Los Angeles and New York that the spatial gradient becomes inverted in the adjustment cases compared to the observed values (i.e. highest concentrations in urban core areas and lower concentrations in surrounding areas). The second type of response occurred in Detroit where there was little change at the monitor in the center of Wayne County but seasonal mean O₃ at the outlying monitors decreased in the NO_x-only adjustment cases. Finally, in Sacramento and Philadelphia, the NO_x-only adjustment cases cause relatively small decreases in

seasonal mean O₃ throughout the area. When comparing the NO_x-only to the NO_x/VOC adjustment scenarios three types of patterns emerge. In Denver and Los Angeles, the NO_x/VOC adjustment scenarios lead to lower seasonal mean O₃ concentrations than the equivalent NO_x-only adjustment scenarios in the urban core areas but looked similar to the NO_x-only adjustment scenario in the outlying areas. In Houston, Detroit, Philadelphia, and Sacramento, seasonal mean O₃ concentrations in equivalent NO_x-only and NO_x/VOC adjustment scenarios were very similar at monitors throughout the areas although the NO_x/VOC adjustment scenarios lead to slightly lower concentrations. Finally, in New York the 75 ppb adjustment scenarios were similar for the NO_x/VOC and NO_x-only cases but for the 65 ppb adjustment scenarios the NO_x/VOC case actually lead to higher seasonal mean O₃ concentration in the urban core area than the NO_x-only case.

An evaluation of the composite monitor and spatial plot maps leads to several general conclusions for this sensitivity analysis. First, the NO_x/VOC reduction scenarios tended to mitigate increases that occurred in the NO_x-only scenario at the lower end of the O₃ distribution. Second the effect on the NO_x/VOC scenario versus the NO_x-only scenario was less dramatic for mid-range O₃ concentrations and varied from city to city. The NO_x/VOC scenarios lead to lower mid-range O₃ concentrations than the NO_x-only scenarios except in the case of New York. Third, the high end O₃ concentrations at various standard levels were similar in the NO_x-only and the NO_x/VOC scenarios. Finally, the VOC reductions tended to have more impact in urban core areas and relatively little impact in outlying areas. The effects of these air quality sensitivity analyses on risk are evaluated and discussed in HREA Chapter 7.

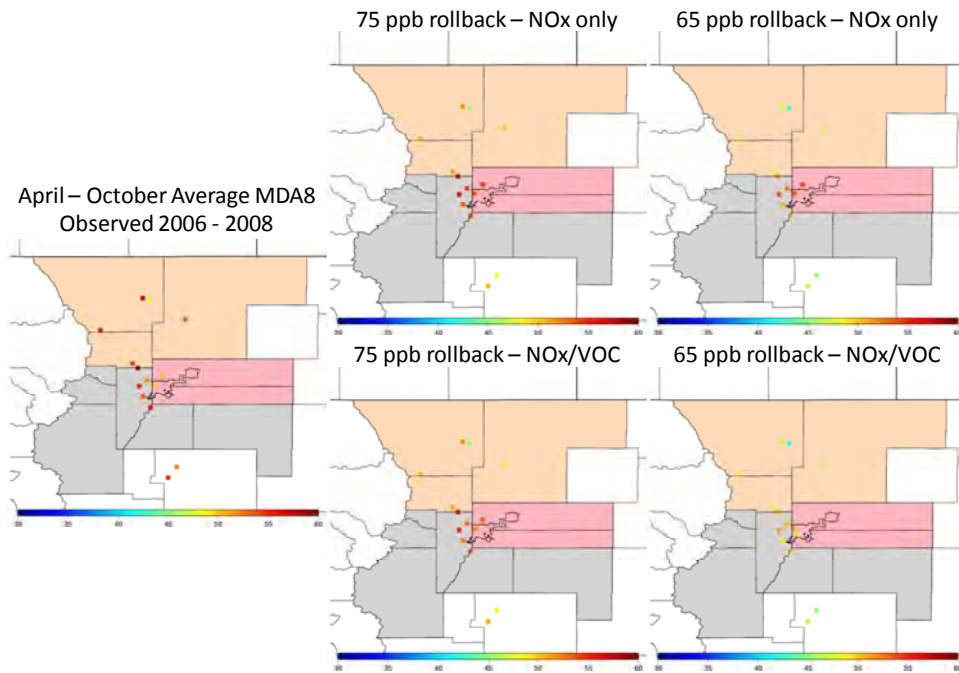

Figure 4D-137. April-October seasonal average of daily maximum 8-hour O₃ values at Denver area monitor locations for observed 2006-2008 conditions (left panel), 75 ppb adjustment scenarios (middle panels), and 65 ppb adjustment scenarios (right panels). NO_x-only adjustments are shown in top panels, NO_x/VOC adjustments are shown in bottom panels.

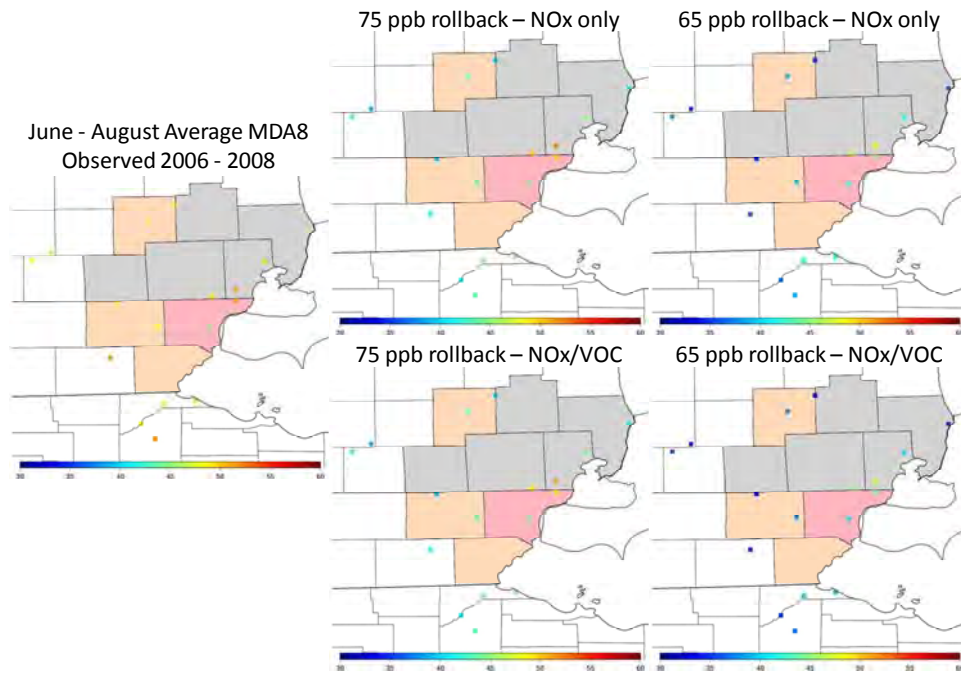

Figure 4D-138. April-October seasonal average of daily maximum 8-hour O₃ values at Detroit area monitor locations for observed 2006-2008 conditions (left panel), 75 ppb adjustment scenarios (middle panels), and 65 ppb adjustment scenarios (right panels). NO_x-only adjustments are shown in top panels, NO_x/VOC adjustments are shown in bottom panels.

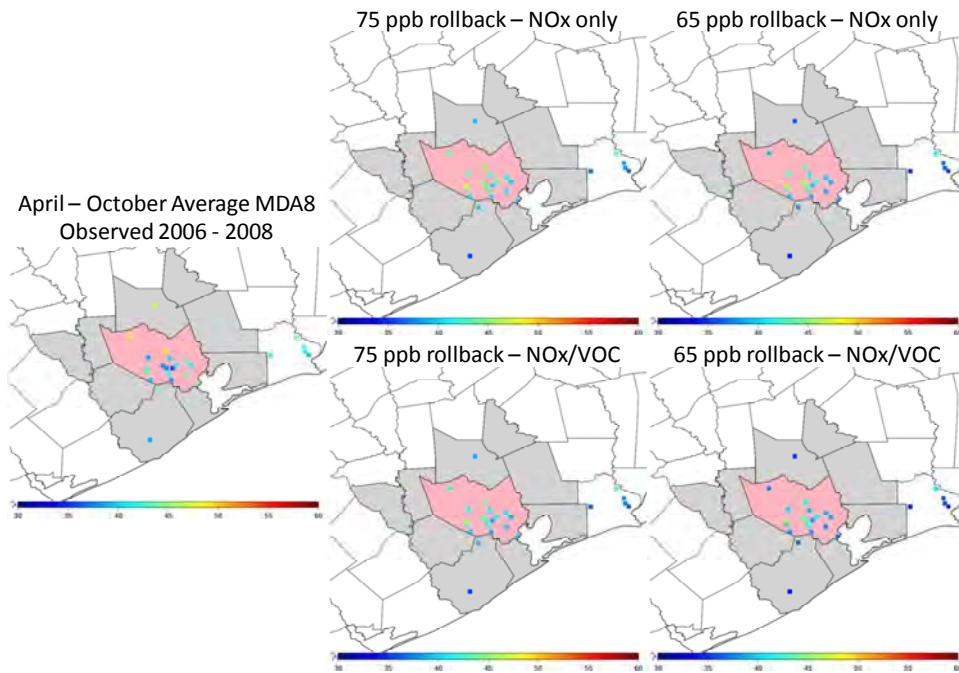

Figure 4D-139. April-October seasonal average of daily maximum 8-hour O₃ values at Houston area monitor locations for observed 2006-2008 conditions (left panel), 75 ppb adjustment scenarios (middle panels), and 65 ppb adjustment scenarios (right panels). NO_x-only adjustments are shown in top panels, NO_x/VOC adjustments are shown in bottom panels.

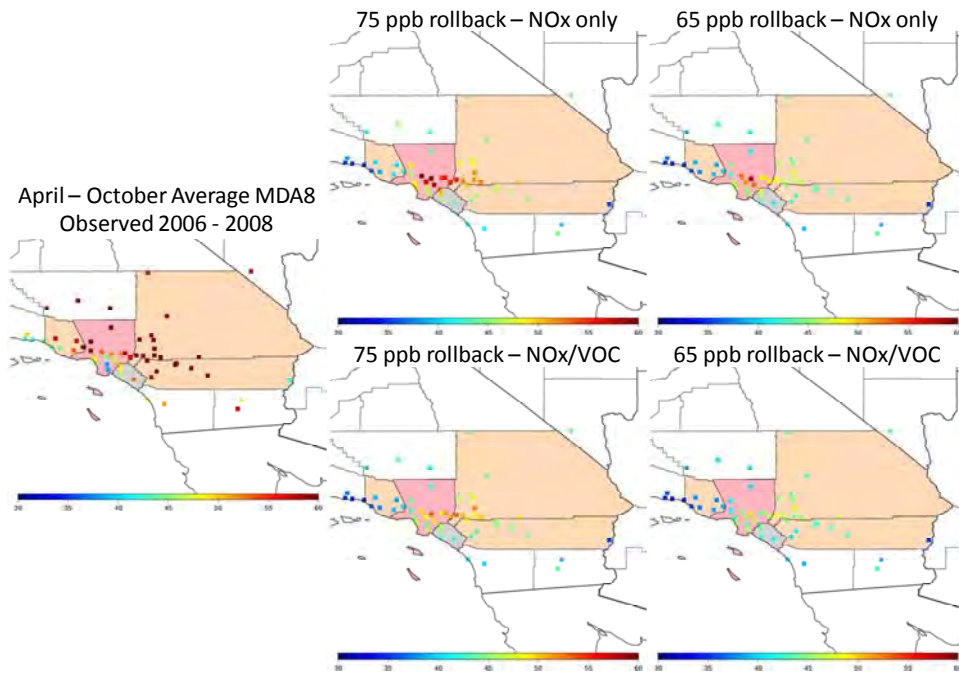

Figure 4D-140. April-October seasonal average of daily maximum 8-hour O₃ values at Los Angeles area monitor locations for observed 2006-2008 conditions (left panel), 75 ppb adjustment scenarios (middle panels), and 65 ppb adjustment scenarios (right panels). NO_x-only adjustments are shown in top panels, NO_x/VOC adjustments are shown in bottom panels.

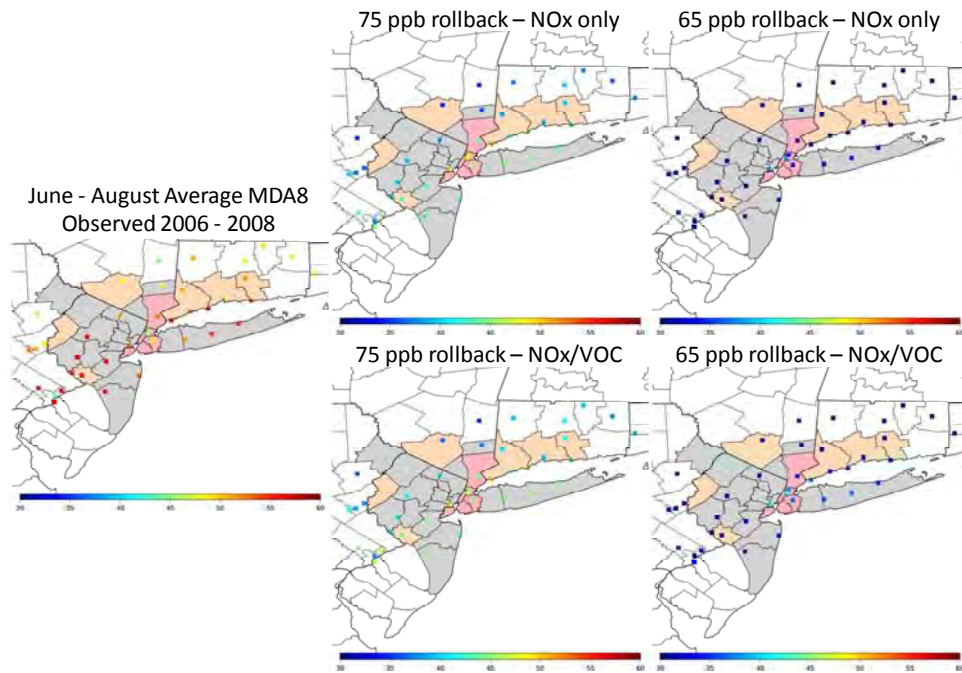

Figure 4D-141. April-October seasonal average of daily maximum 8-hour O₃ values at New York area monitor locations for observed 2006-2008 conditions (left panel), 75 ppb adjustment scenarios (middle panels), and 65 ppb adjustment scenarios (right panels). NO_x-only adjustments are shown in top panels, NO_x/VOC adjustments are shown in bottom panels.

Figure 4D-142. APPENDIX 4E

Evaluation of Seattle Air Quality

List of Figures

Figure 4E-1.	All-site maximum hourly O ₃ (ppb) in Seattle by year and month. This figure combines all hourly O ₃ data from 11 sites in the Seattle area and plots the highest-site value at each hour for Mar-Sep. Boxes represent the median and quartiles, whiskers extend up to 1.5x the inter-quartile range from the boxes, and circles represent outliers.	4E-1
Figure 4E-2.	Map of Seattle area monitoring sites used to create the ozone surfaces for the exposure assessment. Dark brown site is the most urban location (in a residential area of downtown Seattle), orange sites are suburban, sites in the far northern and southern portions of the area are plotted in blue and green respectively, dark green site is a high elevation site.	4E-2
Figure 4E-3.	Map with aerial photography overlay showing where monitors are located with respect to highly urbanized (gray) areas versus suburban and rural areas (green). Downtown Seattle site is circled in orange.	4E-3
Figure 4E-4.	Example of a day with large spatial ozone gradients in the Seattle area. Maximum 8-hr daily maximum ozone value for July 11, 2007.	4E-4
Figure 4E-5.	Example of a day with large spatial ozone gradients in the Seattle area. Maximum 8-hr daily maximum ozone value for July 26, 2007.	4E-5
Figure 4E-6.	Example of a day with large spatial ozone gradients in the Seattle area. Maximum 8-hr daily maximum ozone value for August 29, 2007.	4E-5
Figure 4E-7.	Example of a day with large spatial ozone gradients in the Seattle area. Maximum 8-hr daily maximum ozone value for September 11, 2007.	4E-6
Figure 4E-8.	Cumulative distribution of population living within set distances of an ozone monitor in each urban study area.	4E-7

Investigation of the monitoring network and ambient data trends in Seattle raised serious concerns about the appropriateness of using 2006 data for the purpose of an exposure analysis. Seattle experienced some high ozone events in 2006 that were substantially higher than any measured ozone that occurred in the modeled time period (Jan, April-October 2007) (Figure 4E-1). The model generally predicted ozone disbenefits to NO_x reductions in Seattle on the low ozone days that were predominant in 2007. Because these conditions are not likely to occur on high ozone days, we had serious concerns about extrapolating 2007 sensitivities to 2006 high ozone days.

Figure 4E-1. All-site maximum hourly O₃ (ppb) in Seattle by year and month. This figure combines all hourly O₃ data from 11 sites in the Seattle area and plots the highest-site value at each hour for Mar-Sep. Boxes represent the median and quartiles, whiskers extend up to 1.5x the inter-quartile range from the boxes, and circles represent outliers.

Further concerns come from the lack of measured urban ozone concentrations in all years, but especially in 2006. The Seattle monitoring network is mainly focused on downwind and background areas. There is a single urban monitor in a residential area of downtown Seattle (Figure 4E-2 and Figure 4E-3). The urban monitor was not in operation from January-September of 2006, so no urban measurements were made during most of the 2006 ozone season. Performing a census-tract level exposure analysis for the Seattle and Tacoma urban areas would not be appropriate based solely on ozone values in outlying rural and suburban areas.

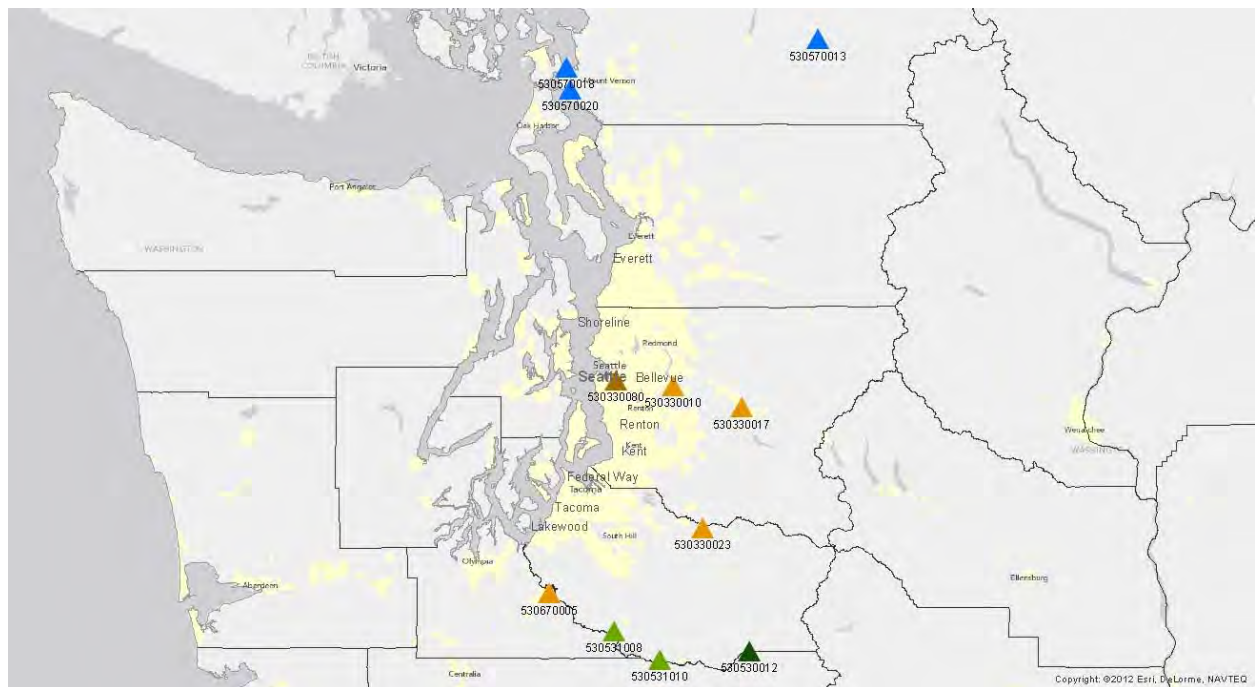

Figure 4E-2. Map of Seattle area monitoring sites used to create the ozone surfaces for the exposure assessment. Dark brown site is the most urban location (in a residential area of downtown Seattle), orange sites are suburban, sites in the far northern and southern portions of the area are plotted in blue and green respectively, dark green site is a high elevation site.

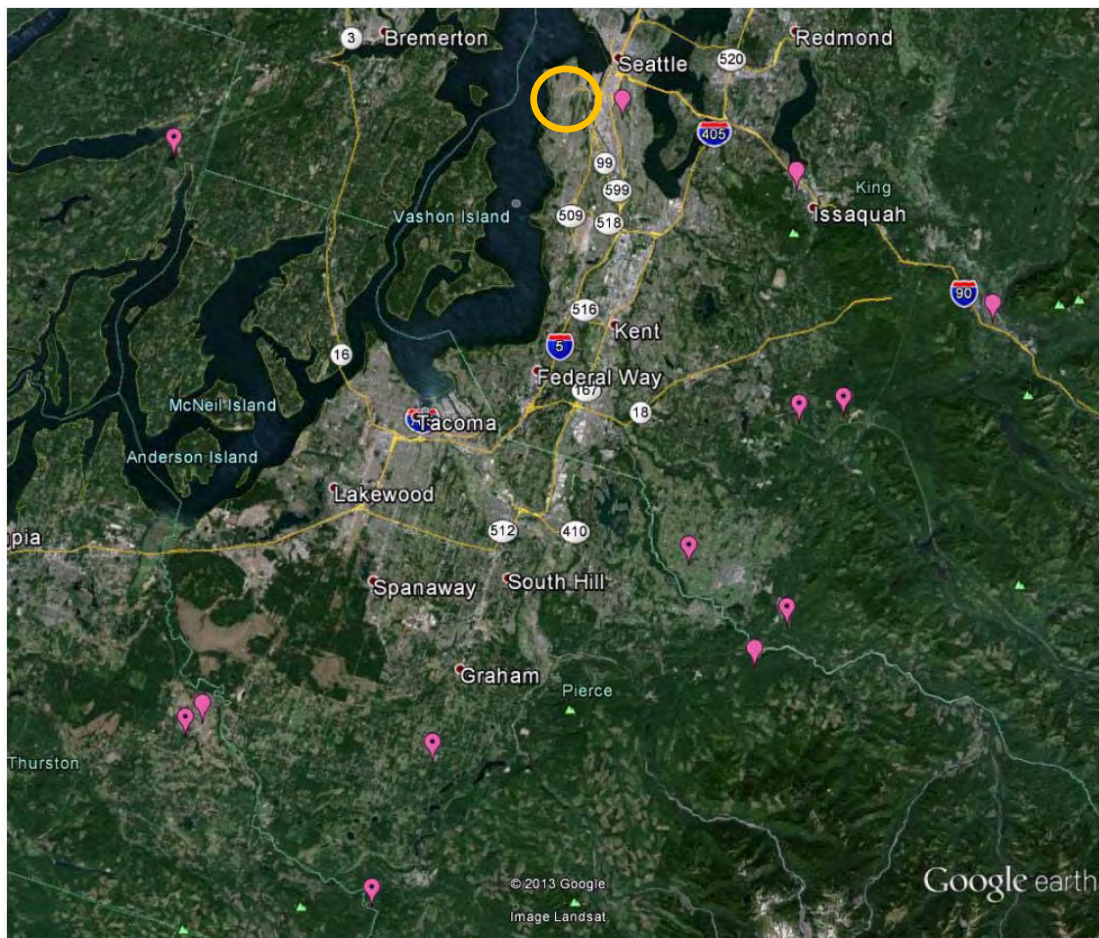

Figure 4E-3. Map with aerial photography overlay showing where monitors are located with respect to highly urbanized (gray) areas versus suburban and rural areas (green). Downtown Seattle site is circled in orange.

Additional concerns were raised about the potential insufficient density of the Seattle ozone monitoring network and subsequently its adequacy for use in a census-tract level exposure analysis beyond the concerns above for 2006. The Seattle area ozone monitoring network was designed primarily to address NAAQS compliance. For this purpose it is appropriate to focus on downwind suburban areas where ozone concentrations are expected to be highest. Modeling suggests that there are often large spatial gradients of ozone within the Seattle/Tacoma area. Figure 4E-4 through Figure 4E-7 show 8-hr daily maximum ozone concentration fields for the Seattle area from the 2007 CMAQ modeling described in Appendix 4A. Spatial fields for exposure modeling are created using interpolation of monitor data and do not capture any modeled spatial gradients. Therefore it is expected that at many times, interpolation of the single Seattle urban monitor with downwind suburban monitors will not adequately represent the ozone values in highly populated urban areas such as Tacoma. In addition, unlike most other urban areas, the Seattle monitoring network for the 2006-2010 time period did not include any upwind monitors (on the West side of Puget Sound).

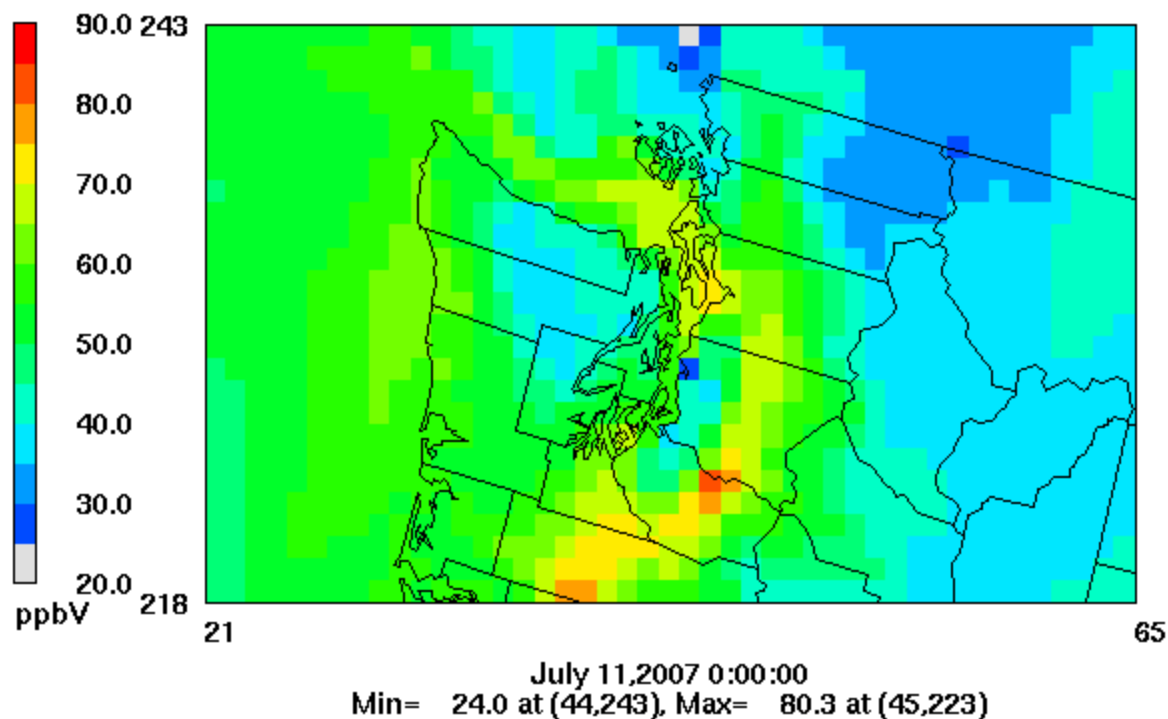

Figure 4E-4. Example of a day with large spatial ozone gradients in the Seattle area. Maximum 8-hr daily maximum ozone value for July 11, 2007.

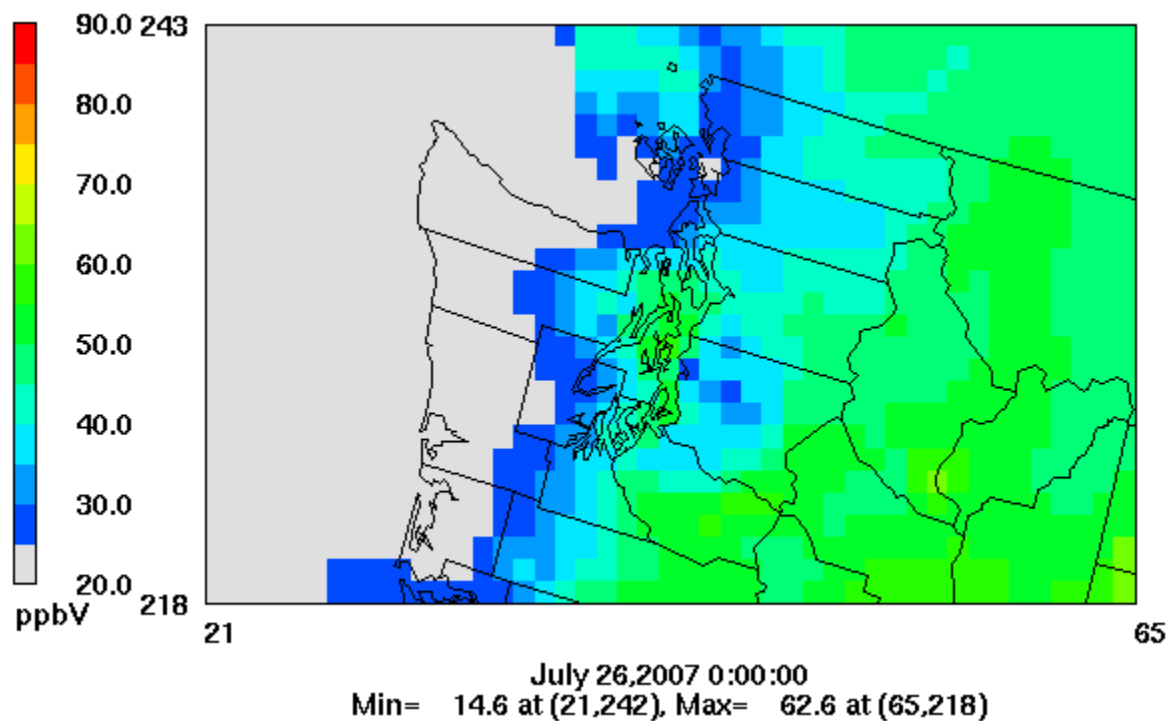

Figure 4E-5. Example of a day with large spatial ozone gradients in the Seattle area. Maximum 8-hr daily maximum ozone value for July 26, 2007.

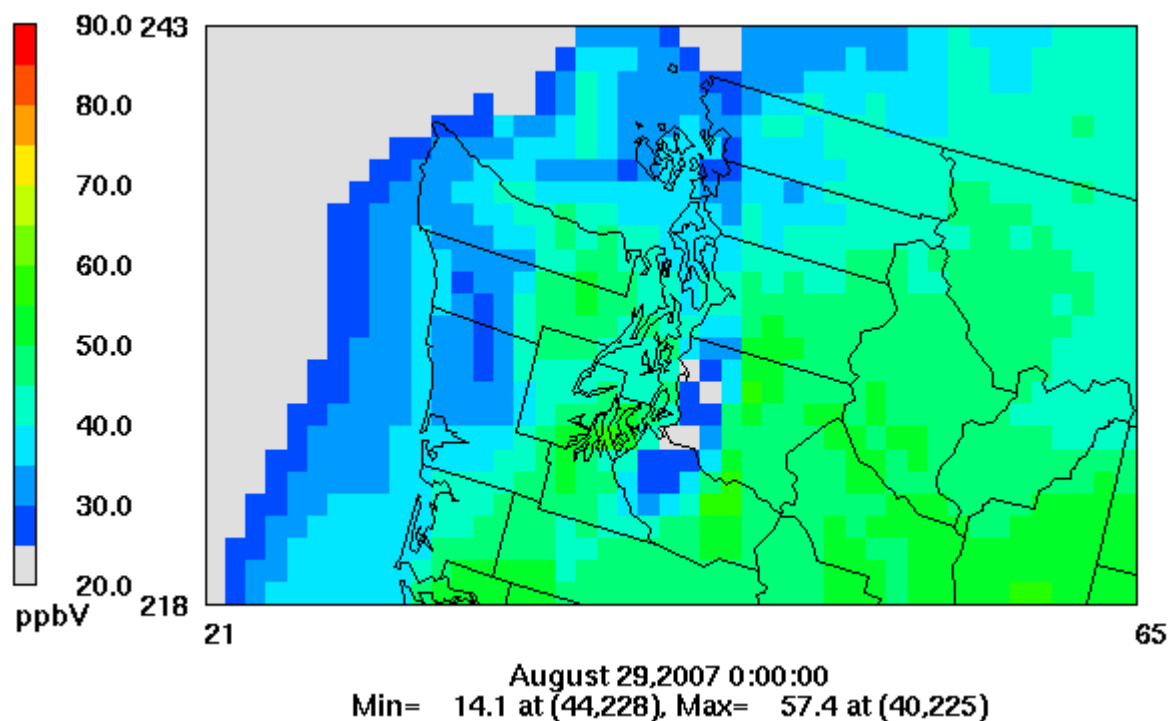

Figure 4E-6. Example of a day with large spatial ozone gradients in the Seattle area. Maximum 8-hr daily maximum ozone value for August 29, 2007.

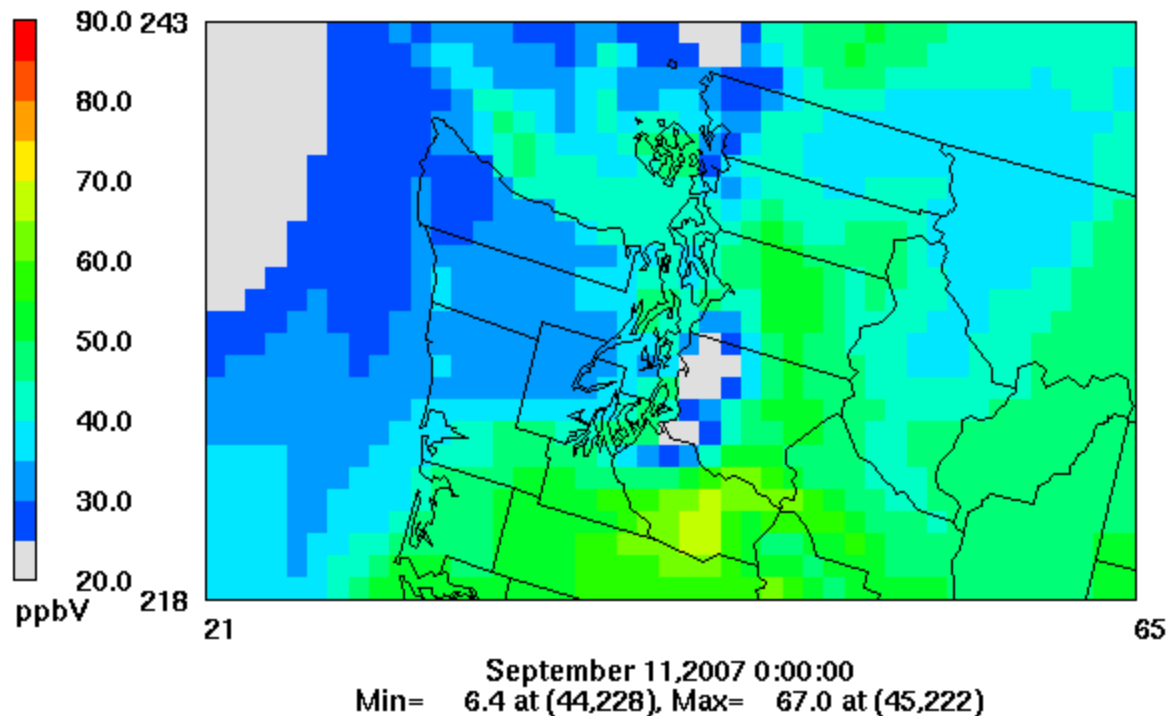

Figure 4E-7. Example of a day with large spatial ozone gradients in the Seattle area. Maximum 8-hr daily maximum ozone value for September 11, 2007.

To further analyze the appropriateness of the Seattle monitoring network for the purpose of performing an exposure assessment, the representativeness of the ozone monitoring network to total population in Seattle was compared to all other urban study areas (Figure 4E-8). This analysis showed that the Seattle monitoring network was much less representative of ozone concentrations where people live than the ozone networks in the other 15 urban study areas. For instance, while more than 75 % of the area-wide population lived within 20 km of an ozone monitor in each of the other 15 urban areas, in Seattle only about 55% of the population lives within 20 km of an ozone monitor. Furthermore, in 13 urban study areas, more than 50% of the population lives within 10 km of an ozone monitor, in 2 urban study areas more than 50% of the population lives within 13 km of an ozone monitor, yet in Seattle, more than 50% of the population lives within 18 km of an ozone monitor. Based on both the sharp spatial gradients predicted by the model and the much sparser monitor coverage in highly populated areas in Seattle compared to other urban study areas, it was determined that the monitoring network in Seattle likely does not capture ozone values representing levels to which large portions of the population are exposed and therefore it would not be appropriate to rely upon the currently available Seattle ozone monitors for the purpose of the exposure analysis which requires accurate fine scale estimates of ozone concentrations where people are exposed.

Figure 4E-8. Cumulative distribution of population living within set distances of an ozone monitor in each urban study area.
