CHILDREN OF THE PARTY OF THE PA

GREAT LAKES INITIATIVE CONTRACT PROGRAM

AUGUST 1974

S. Report Date Cheef Green Bay: An Evaluation of Existing and Historical Conditions Supplementary Notes	BIBLIOGRAPHIC DATA	1. Report No. EPA-905/9- 74 -006	2.	3. Recipient's	Accession No.
Lower Green Bay: An Evaluation of Existing and Historical Conditions Author(s) Author(s) Author(s) Performing Organization Name and Address Wisconsin Department of Natural Resources Division of Environmental Standards Box 450 Madison. Wisconsin 53701 L. Sponsoting Organization Name and Address U.S. Environmental Protection Agency Enforcement Division, Region V I. N. Wacker Drive Chicago, Illinois 50606 13. Supplementary Notes EPA Project Officer: Howard Zar 16. Assuratis A Survey is made of current and historical information relating to the quality over t last four decades is documented. A historical shift in fish production from high quality native species to low quality exotic species has occurred. Increasing areas of the Bay as far as 40 kilometers. Nutrient loads have caused the areas where eutrophic conditions exist to increase. These and other factors have led to a dislocation for recreational use. Documentation of the expected reduction in pollutant loads due to present control straegies is also provided. Field studies performed in this program indicate slight improvements in bay water quality over recent years. A water quality model, suitable for expectational use. Documentation of the expected reduction in pollutant loads due to present control straegies is also provided. Field studies performed in this program indicate slight improvements in bay water quality over recent years. A water quality model, suitable for winter conditions, is also being developed which will allow predictions of improvement in bay water quality due to present and future pollution control strategies. The fina report will be available in January, 1975. 175. Key Wods and Document Analysis. Par Descriptors Water Quality, Aquatic Biology, Water Pollution 176. Availability Statement 177. - 1. Report Number. Each individually bound report shall carry a unique alphanumeric designation selected by the performing organization or provided by the sponsoring organization. Use uppercase letters and Arabic numerals only. Examples FASEB-NS-87 and FAA-RD-68-09.
- 2. Leave blank.
- 3. Recipient's Accession Number. Reserved for use by each report recipient.
- 4. Title and Subtitle. Title should indicate clearly and briefly the subject coverage of the report, and be displayed prominently. Set subtitle, if used, in smaller type or otherwise subordinate it to main title. When a report is prepared in more than one volume, repeat the primary title, add volume number and include subtitle for the specific volume.
- 5. Report Date. Each report shall carry a date indicating at least month and year. Indicate the basis on which it was selected (e.g., date of issue, date of approval, date of preparation.
- 6. Performing Organization Code. Leave blank.
- 7. Author(s). Give name(s) in conventional order (e.g., John R. Doe, or J.Robert Doe). List author's affiliation if it differs from the performing organization.
- 8. Performing Organization Report Number. Insert if performing organization wishes to assign this number.
- 9. Performing Organization Name and Address. Give name, street, city, state, and zip code. List no more than two levels of an organizational hierarchy. Display the name of the organization exactly as it should appear in Government indexes such as USGRDR-1.
- 10. Project/Task/Work Unit Number. Use the project, task and work unit numbers under which the report was prepared.
- 11. Contract/Grant Number. Insert contract or grant number under which report was prepared.
- 12. Sponsoring Agency Name and Address. Include zip code.
- 13. Type of Report and Period Covered. Indicate interim, final, etc., and, if applicable, dates covered.
- 14. Sponsoring Agency Code. Leave blank.
- 15. Supplementary Notes. Enter information not included elsewhere but useful, such as: Prepared in cooperation with...

 Translation of ... Presented at conference of ... To be published in ... Supersedes ... Supplements ...
- 16. Abstract. Include a brief (200 words or less) factual summary of the most significant information contained in the report. If the report contains a significant bibliography or literature survey, mention it here.
- 17. Key Words and Document Analysis. (a). Descriptors. Select from the Thesaurus of Engineering and Scientific Terms the proper authorized terms that identify the major concept of the research and are sufficiently specific and precise to be used as index entries for cataloging.
 - (b). Identifiers and Open-Ended Terms. Use identifiers for project names, code names, equipment designators, etc. Use open-ended terms written in descriptor form for those subjects for which no descriptor exists.
 - (c). COSATI Field/Group. Field and Group assignments are to be taken from the 1965 COSATI Subject Category List. Since the majority of documents are multidisciplinary in nature, the primary Field/Group assignment(s) will be the specific discipline, area of human endeavor, or type of physical object. The application(s) will be cross-referenced with secondary Field/Group assignments that will follow the primary posting(s).
- 18. Distribution Statement. Denote releasability to the public or limitation for reasons other than security for example."Release unlimited". Cite any availability to the public, with address and price.
- 19 & 20. Security Classification. Do not submit classified reports to the National Technical
- 21. Number of Pages. Insert the total number of pages, including this one and unnumbered pages, but excluding distribution list, if any.
- 22. Price. Insert the price set by the National Technical Information Service or the Government Printing Office, if known.

LOWER GREEN BAY: AN EVALUATION OF EXISTING AND HISTORICAL CONDITIONS

ENVIRONMENTAL PROTECTION AGENCY Region V

Great Lakes Initiative Contract Program
Report Number: EPA-905/9-74-006

EPA Project Officer: Howard Zar

August, 1974

U.S. Environmental Protection Agency Region 5, Library (PL-12J) 77 West Jackson Boulevard, 12th Floor Chicago, IL 60604-3590 This report has been developed under auspices of the Great Lakes Initiative Contract Program. The purpose of the Program is to obtain additional data regarding the present nature and trends in water quality, aquatic life, and waste loadings in areas of the Great Lakes with the worst water pollution problems. The data thus obtained is being used to assist in the development of waste discharge permits under provisions of the Federal Water Pollution Control Act Amendments of 1972 and in meeting commitments under the Great Lakes Water Quality Agreement between the U.S. and Canada for accelerated effort to abate and control water pollution in the Great Lakes.

This report has been reviewed by the Enforcement Division, Region V, Environmental Protection Agency and approved for publication. Approval does not signify that the contents necessarily reflect the views of the Environmental Protection Agency, nor does mention of trade names or commercial products constitute endorcement or recommendation for use.

ENVIRONMENTAL PROTECTION AGENCY

ABSTRACT

A survey is made of current and historical information relating to the quality of the waters of Green Bay, Lake Michigan. The steady decline in water quality over the last four decades is documented. A historical shift in fish production from high quality native species to low quality exotic species has occurred. Increasing areas of the Bay exhibit low oxygen levels. In winter, under the ice, low oxygen levels now extend into the Bay as far as 40 kilometers. Nutrient loads have caused the areas where eutrophic conditions exist to increase. These and other factors have led to a dislocation of recreational use.

Documentation of the expected reduction in pollutant loads due to present control strategies is also provided. Field studies performed in this program indicate slight improvements in bay water quality over recent years. A water quality model, suitable for winter conditions, is also being developed which will allow predictions of improvement in bay water quality due to present and future pollution control strategies. The final report will be available in January, 1975.

SUMMARY

The change in nutrient loadings to Green Bay over the past thiry or forty years is difficult to document because of the paucity of data. The resulting algae growth has always been a part of the recorded history of Green Bay and may be associated with the origin of its name. In the recent two or three years the total algae growth may not have varied greatly but its extent and local concentration appear to have varied.

The Lower Fox River remains the largest source of nutrients and wastes for Green Bay. During the past twenty years pulp and paper production for mills along this river have approximately doubled. The BOD₅ and suspended solids discharge from these mills are now approximately what they were twenty years ago after an intermediate period of higher loadings. BOD₅ loadings from sewage treatment plants have risen in the past ten years along the Lower Fox River.

Several investigations have indicated that there is a counterclockwise circulation of the surface water in the southern end of Green Bay below the Oconto River and above Long Tail Point. It has been suggested that this current brings cleaner water down the western shore of the Bay while Fox River water follows the east side northward to Sturgeon Bay. It has been postulated that this movement creates two discreet water masses in lower Green Bay, one characteristic of the Fox River water and the other characteristic of the water of Green Bay. The division between these masses is Long Tail Point and the submerged bar extended towards it from the east.

Wind and current patterns play the most important roles in the mixing and transport of water within Green Bay. In the late fall and in the spring, winds from the direction of Lake Michigan bring in large quantities of fresh lake water which are trapped in the Bay. This influx may be less important than that from

the input of lake water, driven by seiche motion, through the passages between the Bay and Lake Michigan. Green Bay becomes thermally stratified weeks before the adjacent deeper water of Lake Michigan. The effects of temperature and wind appear to make Green Bay into an independent lake separate from Lake Michigan.

Investigations of the type of bottom sediment in Green Bay show that an area at the extreme lower end of the Bay contains a high content of sewage sludge, derived from a combination of the inflowing Fox River and the outfall of the Green Bay sewage treatment plant. Brown silt was found to be common northeast of Long Tail Point and along the eastern shore. Brown mud, more cohesive than silt or the semifluid mud of the lower Bay, occured in the deeper water further north in the Bay. Bathymetric data from a 1968 survey was compared with the final work sheets of the U.S. Lake Survey for the Southern Bay (1943) and the Northern Bay (1950). In the region below Sturgeon Bay there were several areas where the bottom depth decreased substantially (two to four feet) over the brica period of seventeen years. The data were interpreted to indicate that Green Bay was filling in at a rate of 10 to 100 times that associated with larger bodies of water.

A historic change in the species composition of the commercial fish catch has occurred in Green Bay as well as in the Great Lakes in general. The early fishery (circa 1900) consisted of lake trout, white fish, lake herring, chubs, walleye and sturgeon. The present major commercial species are carp, smelt, alewife and perch. This represents a shift from high quality native species to low quality exotic species.

Several investigations of the bottom fauna of Green Bay have been carried out in the past 35 years. A recent, extensive investigation concluded with the view that if pollution of the Bay, via the Fox River, continues then a) the dominent species will, to an increasing extent, be associated with gross pollution, b) a larger abiotic area around the river mouth can be expected

since conditions there have become unsuitable for even the pollution tolerant organisms, c) pollution intolerant midge larvae would be expected to decrease in abundance at stations farther north in the lower Bay and d) the pollution tolerant Oligochaete, the only group which increased in absolute and relative abundance in the past twenty years, would become even more important in the benthic community.

Dissloved oxygen concentrations in Green Bay appear to have decreased in the past thirty years. During warm weather, critical dissolved oxygen conditions are common on the Fox River and for a distance of 3-5 km into the Bay. In the colder months (from about mid-November into April), the dissolved oxygen in the river is generally in excess of 5 mg/l. However, during the winter and particularly after prolonged heavy ice cover, low dissolved oxygen concentrations can extend into Green Bay for distances of nearly 50 km. During the period of open water, reaeration causes a recovery of oxygen levels beyond the Long Tail Point area.

The majority of people who have contact with Green Bay do so in a recreational context. These people are often not aware of the many aspects of water quality which are important in the Bay. Water quality and characteristics as perceived by users rather than as monitored by scientists are important in decision making designed to improve the condition of the Bay.

INTRODUCTION

This report consists of a survey of current and historical information about the quality of the waters of Green Bay, Lake Michigan. Some aspects of water quality are easier to define than others. For example, dissolved oxygen concentrations, biochemical oxygen demand, bottom fauna levels and nutrient additions to natural waters with the resultant growth of nuisance organisms are obvious subjects for the definition of the quality of water in Green Bay. These matters will be discussed in detail because they are most susceptible to quantitative measure. In addition, there are aspects of water quality which are less easily defined in a quantitative way. Among these are the mixing, transport, and dispersal of water in Green Bay, the changes in the commercial fishing industry, the constitution of the bottom sediments and public attitudes with respect to Green Bay. These subjects are important in any discussion of the long-term trends in Green Bay. The current and historical information about these subjects will also be reviewed. An attempt will be made to identify the relation between these factors and water quality.

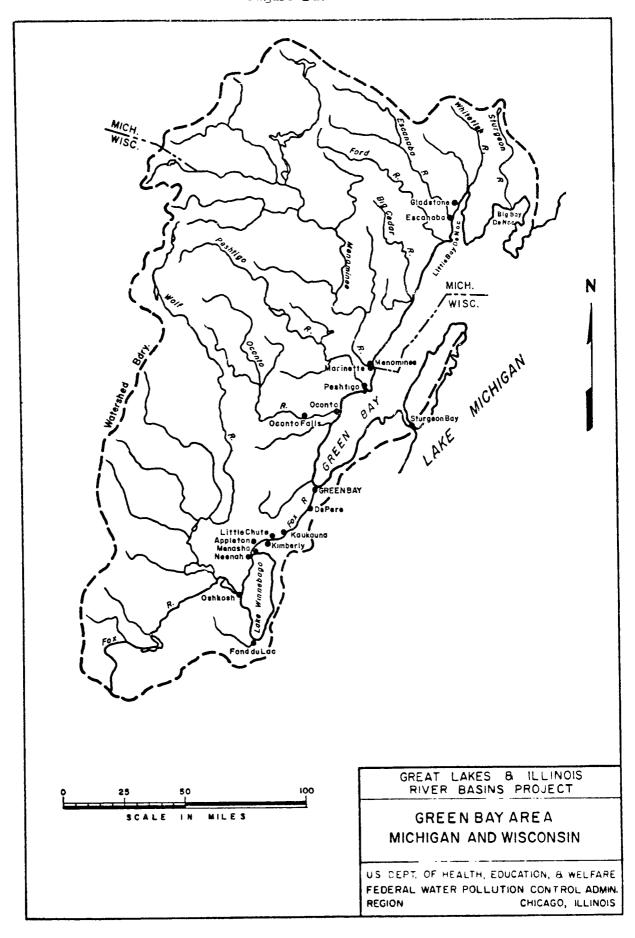

SETTING

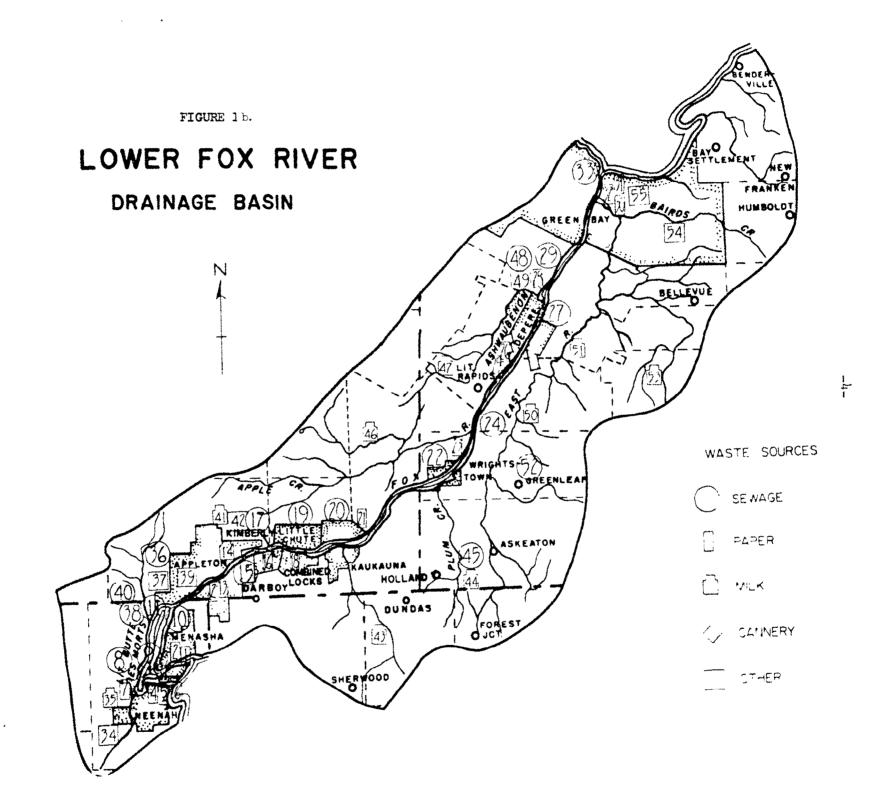

Green Bay is a shallow estuary-like bay in the northwest corner of Lake Michigan. It is approximately 190 km long, with an average width of 37 km and has a mean depth of about 20 meters (U.S. Federal Water Pollution Control Administration, 1966). Only in a few places near the middle part of the Bay do depths exceed 60 meters; for the Bay as a whole, most depths are less than about 40 meters, and the western inshore region is less than about 18 meters deep. The principal axis of the Bay is oriented in a NNE-SSW direction. The Green Bay watershed contains a total drainage area of approximately 40,000 km², or about one-third of the total Lake Michigan basin. Approximately two-thirds of the watershed lies within Wisconsin, the remainder in Michigan (U.S. Federal Water Pollution Control Administration, 1966). The geographical setting of Green Bay is shown in Figure 1 along with the basins of the major tributary rivers.

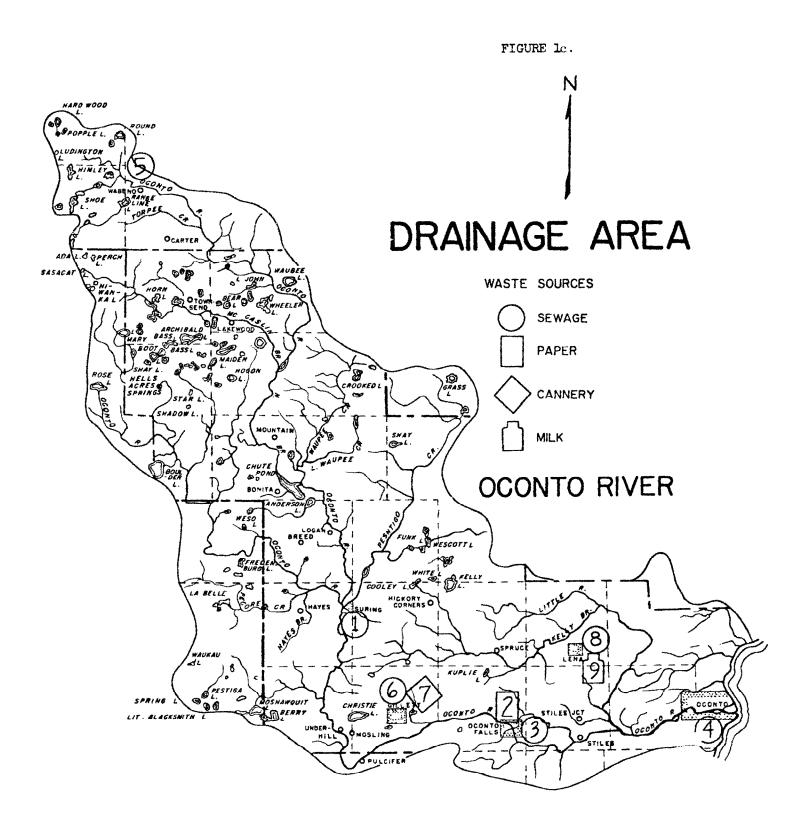

Large concentrations of people and industry are characteristic of the Green Bay watershed, especially along the major tributary, the Lower Fox River. The most significant source of degraded water is the paper and pulp industry which discharges wastes with a population equivalent of 1,300,000 (Wisconsin Department of Natural Resources, 1973). The second major source of degraded water in the watershed is effluent from numerous municipal waste treatment plants. Combined storm and sanitary sewers in the larger communities contribute significantly to the waste problem.

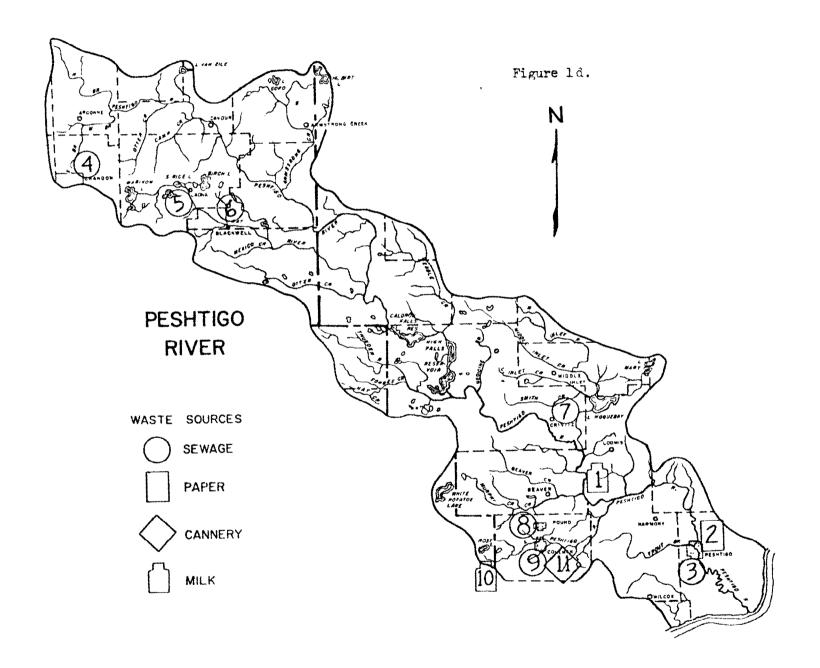

Major rivers of Wisconsin which discharge into Green Bay are the Fox, Oconto, Peshtigo and the Menominee. The lower segment of the Menominee River marks the boundary between Michigan and Wisconsin and about 65 percent of its total drainage basin is located in Michigan. North of the Menominee River, the only significant discharges into the Bay are from the Cedar River and Little Bay de Noc which is the entryway for both the Whitefish and Escanaba Rivers. There are no

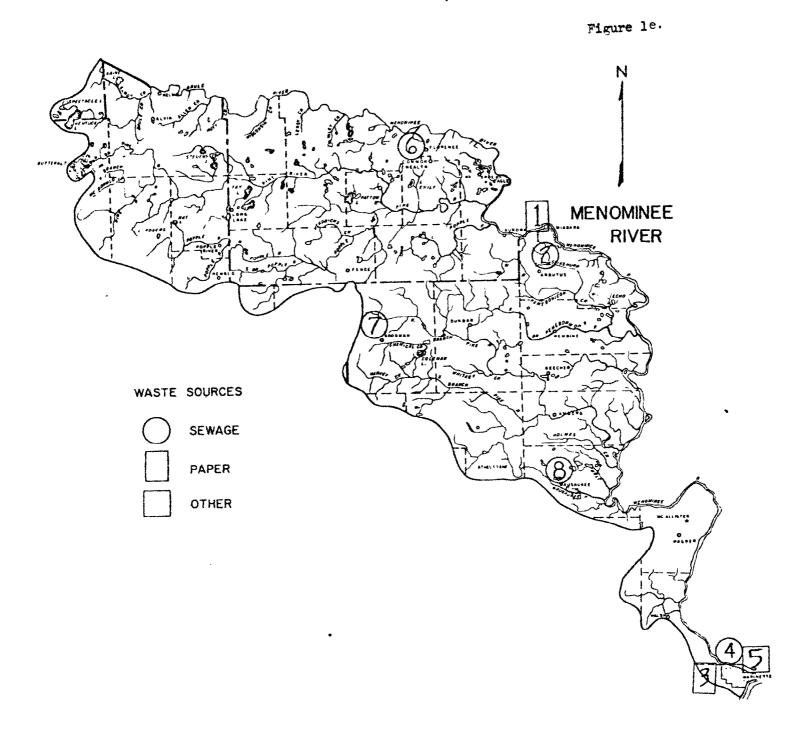

-3-Figure 1a.

significant streams draining into Green Bay east of the Fox River. Smaller streams tributary to the Bay on the west and north of the Fox include Duck Creek, Suamico River and Pensaukee River. All carry silt and some carry industrial debris.

The drainage areas of the major tributaries to Green Bay are shown in Table 1.

TABLE 1. DRAINAGE AREAS--MAJOR TRIBUTARIES OF GREEN BAY.*

Stream	Length	Drainage Area	Mean Discharge
Fox	322 km	16,687 km ²	ll7 m ³ /sec
Menominee	193	10,748	88
Peshtigo	233	2,991	24
Oconto	209	2,416	16
Escanaba	185	2,382	25
Whitefish	_	816	_
Cedar	-	-	2

^{*}U.S. Federal Water Pollution Control Administration, 1966.

Problems of water quality are most severe at the southern tip of Green

Bay adjacent to the mouth of the Fox River. Other regions of degraded water

quality are at the mouths of the Oconto, Peshtigo, Menominee and Escanaba Rivers.

NUTRIENTS AND THEIR EFFECT ON NATURAL WATER SYSTEMS

Organic and inorganic complexes of carbon, nitrogen and phosphorus function as nutrients and/or buffers in natural waters. Complex relationships exist between algal blooms and concentrations of these nutrients. Micronutrients such as iron, cobalt, zinc, molybdenum, silica and others, in addition to sodium, potassium and calcium, also play a role in the growth of algae in natural waters. Buffering capacity is important in controlling the chemical availability of carbon, nitrogen, phosphorus and trace elements. In enriched waters, the buffering capacity could be increased directly by the addition of charged compounds and indirectly by the amino acids, organic acids and CO₂ resulting from increased biological activity. Since the enzymatic reactions which regulate the growth of algae are often pH dependent, biological activity would be favored in situations where precipitous changes in pH are prevented.

The following macroscopic factors must be considered in a complete discussion of nutrients in natural waters:

- 1. the analytical detection of increased amounts of nutrients,
- 2. measureable and often explosive increases in algal populations,
- 3. a decreased transparency in natural waters which affects photosynthesis,
- 4. in thermally stratified deep lakes, gruadually decreasing dissolved oxygen in the bottom waters,
- 5. decreased organism diversity, sometimes proceeded briefly by increasing diversity,
- 6. appearance of new, undesirable species and disappearance of old ones,
- 7. increasing silting and accelerating accumulation of bottom sediments.

A discussion of the algal growth in Green Bay must deal with many, if not all, of these factors. Nutrient availability is but a single, though exceedingly important, factor. The historical performance of numerous lakes verify that the extent of production generally is related to nutrient concentration (Thomas, 1969;

Rodhe, 1969). Simply, nutrient-rich lakes are expected to produce large algal crops. The following table (Table 2) defines the concept of enriched waters in terms of the photosynthetic rates of free-floating algae (Phytoplankton) that occur in response to increasing nutrient concentrations.

TABLE 2. PHOTOSYNTHETIC RATES OF PHYTOPLANKTON IN OLIGOTROPHIC AND EUTROPHIC LAKES, mgC/m² day

	Oligotrophic	Eutrophic Natural	Polluted
Mean rates in growing season	30 - 100	300 - 1, 000	1,500 - 3,000
Annual rates	7 - 25	75 - 250	350 - 700

(Bartsch, 1972)

Increased amounts of nitrogen and phosphorus have been suggested as the primary cause of algal blooms because these nutrients are generally found to be limiting in concentration in natural waters. Of these two, phosphorus is most often found to be the element whose concentration is the limiting factor in algal blooms. Although the importance of carbon in regulating algal growth has long been known, it received little attention until recently (Kerr et al, 1970; Kuentzel, 1969; Lange, 1967). Increased supplies of carbon (as well as nitrogen and phosphorus) are needed to support continued algal growth. The availability of large concentrations of CO_2 generally preclude conditions in which carbon becomes the limiting nutrient in aquatic systems. Only under unusual conditions will carbon be a limiting nutrient. The availability of these growth nutrients depends upon physical parameters such as pH, temperature and light, as well as rates of supply and demand. Specific rates for chemical reactions in the environment are among the least known of these parameters.

Bartsch (1972) has discussed the problem of eutrophication control. The primary question becomes which nutrient or nutrients should be eliminated, to what degree and by what method. The recent "Symposium on Nutrients and

Eutrophication--The Limiting Nutrient Controversy" (American Society of Limnology and Oceanography, 1972) dealt with this problem. It was generally agreed by the participants that the only realistic option for controlling or reversing cultural eutrophication in lakes is to remove phosphorus from the waters which supply these lakes. The theory that carbon should be regarded as the nutrient which is growth limiting under some conditions and should be the focus of control attempts (Lange, 1967; Keuntzel, 1969; Kerr, 1970) was rejected as generally nonapplicable. Vallentyne (1970) has pointed out that carbon is too ubiquitous to be controlled. Efforts by Morton et al (1971) to control algae growth by CO2 control were not successful in waters open to the atmosphere. Nitrogen is only partly controllable because of the many sources (for example, blue-green algae can fix N_2 directly from the air when fixed nitrogen is the limiting nutrient). It was concluded that phosphorus can be controlled by an adjustment of human affairs. The most practical method appears to be removal of phosphorus in municipal waste treatment plants. Current practical methods for this removal also have the added significant advantage of an accompanying reduction in BOD levels.

Carbon

Plants require large amounts of carbon and are incapable of growing on their cellular carbon compounds. Conversely, these plants require small amounts of nitrogen and phosphorus and possess the capability for growth on cellular nitrogen and phosphorus compounds.

In aquatic ecosystems, plants require carbon in the form of ${\rm CO_2}$ and ${\rm HCO_3}^-$ for growth (Allen, 1952; Hoare and Moore, 1965; Pearce and Carr, 1967). Oxidation of organic material and carbon dioxide in the air provide the extensive concentrations of ${\rm CO_2}$ and ${\rm HCO_3}^-$. The primary processes involving carbon which occur in aquatic ecosystems may be summarized as follows:

RESPIRATION: Organic Compounds + O_2 - bacteria \rightarrow CO_2 + H_2O PHOTOSYNTHESIS: CO_2 + H_2 - bacteria \rightarrow Organic Compounds + O_2

Addition of organic carbon should stimulate the growth of the bacteria which are necessary for these conversions. The bacterial organisms utilize several forms of organic carbon for growth (unlike the algae which utilize ${\rm CO_2}$ or ${\rm HCO_3}^-$) and are more efficient than the algae in removing the phosphorus from water (Rigler, 1956). The photosynthetic process generates carbohydrate complexes which are used for growth by algae cells and other aquatic life. Phosphorus is used for the storage of energy in phosphate bonds when adenosine triphosphate (ATP) and other phosphorus-containing residues are formed. The oxidation of carbonaceous material produces ${\rm CO_2}$ which tends to lower the pH of the aquatic system according to the following:

$$co_2 + H_2O \rightleftharpoons H^+ + HCO_3^- \rightleftharpoons H^+ + CO_3^{2-}$$

Under anaerobic conditions which exist at various times in Green Bay and in the Fox River, the carbon in organic material is converted into methane.

Nitrogen

It has been suggested that $\mathrm{NH_h}^+$ may be the form of nitrogen which is absorbed at the molecular level by cells (see Brezonik et al, 1973, for a summary of this point). This is the form of ammonia which is present in highest concentration in acidic or well-buffered, slightly basic systems because of the equilibrium:

$$NH_h^+ \rightleftharpoons NH_3 + H^+$$
 pKa = 9.3

Buffering capacity is important in the control of the chemical availability of carbon, nitrogen, phosphorus and trace elements. The addition of charged ions, amino acids, other organic acids, and other species as the result of increased biological activity contributes to a well-buffered system. Thus, the oxidation of organic matter tends to stabilize the pH of natural waters, a stabilization which further enhances the conditions for algal growth.

Rainfall contributes nitrogen in the form of NO_3^- to natural waters. The decomposition of organic matter under aerobic <u>or</u> anaerobic conditions produces ammonia (NH₃). The direct fixation of N_2 by blue-green algae contributes to the nitrogen budget of natural waters.

Under aerobic conditions, oxidation of ammonia occurs according to the following reactions:

$$2NH_{3} + 3O_{2} \xrightarrow{\text{bacteria}} 2H^{+} + 2NO_{2}^{-} + 2H_{2}O$$

$$2HNO_{2} + O_{2} \xrightarrow{\text{bacteria}} 2H^{+} + 2NO_{3}^{-}$$

$$NH_{3} \xrightarrow{\text{nitrification}} NO_{3}^{-}$$

This nitrification process provides the primary mechanism whereby the ammonia generated by organic decomposition is removed from aquatic systems. Failure to maintain oxygen levels leads to a buildup of ammonia concentrations which eventually become lethal to aquatic organisms. The buildup of ammonia concentrations also impedes the recovery from low oxygen levels.

The reduction and removal of NO_3^- can occur in a <u>denitrification</u> process. The NO_3^- is reduced to N_2 . The consensus now is that denitrification occurs at significant rates when oxygen is absent from the system or at least sufficiently low enough to allow anoxic enzymes to develop (Brezonik <u>et al</u>, 1973). Reduction of NO_3^- to N_2 is accompanied by the oxidation of organic matter to CO_2 . The net process is exothermic. Since the cells have no means for storing the energy released in this process, the use of NO_3^- rather than NH_3 (or NH_4^+) for the assimilation of nitrogen by plants is wasteful of energy.

The natural processes under aerobic conditions (oxidation of organic material) favor the assimilation of nitrogen in the form of NH₄⁺. These processes tend to maintain well-buffered systems or to slightly reduce pH. Excess concentrations of ammonia are removed via nitrification to NO₃⁻. Unfortunately, in lower Green Bay, anoxic conditions may contribute to the buildup of concentrations of ammonia which are lethal to fish.

Phosphorus

Since phosphorus is generally the growth limiting nutrient in many natural water systems, its role is examined in greater detail. Phosphorus exists in natural waters in various forms. Orthophosphate $(P0_{\downarrow}^{3-})$ and phosphite $(P0_{2}^{-})$ appear in agricultural runoff. There are several condensed phosphates, including pyrophosphate $(P_{2}0_{7}^{-1})$, metaphosphate $(P0_{3}^{-})$ and polyphosphate $(P_{3}0_{10}^{5-})$. Polyphosphate, as the sodium salt, is a major component of many modern detergents. The term organically bound phosphate is reserved for all organophosphorus compounds.

The role of phosphorus in metabolism of algae is related to the storage of energy. In the photosynthesis process, light converts inorganic phosphate into residues such as adenosine triphosphate (ATP) in organic molecules. The oxidation of organic material releases considerable amounts of energy. For example, the process glucose + $O_2 \longrightarrow OO_2 + H_2O$ has a \triangle H = 268 $\frac{\text{kcal}}{\text{mole}}$. This energy is stored in cellular molecules as phosphate bonds in subgroups such as ATP. This stored energy may be used as a driving force in many other metabolic reactions.

Phosphorus is generally absorbed by algae as PO_{\downarrow}^{3-} . However, at least some algae have the necessary enzymes to convert more complex phosphate compounds to orthophosphate to facilitate absorption. Much of the phosphorus incorporated into algal cells occurs as polyphosphate. The algae are capable of "luxury uptake" of phosphorus (uptake greater than that required for growth).

It is not known if "luxury uptake" is a universal capability of algae or exists only in a limited number of species. Laboratory observations have shown that some algae are able to continue through several reproductive generations without added phosphorus input (Bartsch, 1972). This has no lasting impact on eutrophication because growth depends upon useable or available phosphorus at the appropriate time in the cells in the water. Live algae will not share their adequate or surplus nutrients with nutrient-limited algae. Once a

nutrient is tied up with living algae, that nutrient is not available for other plants until the original dies (Fitzgerald, 1971). Phosphorus comes off rapidly when algae die. Nitrogen does not come out and the nitrogen is not readily available to other algae without a long period of degradation. The extent to which growth due to phosphorus storage occurs under natural conditions is not well established, but laboratory studies indicated population increases of more than a month with some algae (Levin, 1963). "Luxury uptake" leads eventually to some settling out of phosphorus compounds when algae die. Lund (1950) has suggested that Asterionella, which contains luxury amounts of phosphorus, sinks to the deeper waters where the growth of the organism is regulated by decreased light. During the spring turnover, these cells serve as the inoculum for that season's population. Thus, cells contain luxury amounts of phosphorus at the beginning of the growing season.

Phosphate may be lost at high pH by precipitation with counterions such as Ca²⁺ or Fe²⁺. These precipitated phosphorus compounds are available for algal growth. The release of phosphorus from sediments may be considerable and appears to be more rapid under anaerobic rather than aerobic conditions (Fitzgerald, 1971). This point will be discussed in greater detail in the following section which is concerned with the specifics of phosphorus loadings to Green Bay. The rate of equilibration between soluble and insoluble forms of phosphorus compounds is generally faster than the algae growth rate. Thus the solubility of phosphorus compounds does not appear to be a limiting factor for the growth of algae. As an example of this, laboratory studies have shown that teeth can support algae growth (Fitzgerald, 1971).

Both aquatic plants (algae) and bacteria absorb phosphorus. Rigler (1956) has estimated that about 75 percent of absorbed phosphorus is found in bacteria rather than algae.

Mixed algae populations contain carbon, nitrogen, and phosphorus in a weight ratio approximating 41:7.2:1 (Bartsch, 1972). The essential nutrient present in least supply relative to need will limit growth and thus determine the size of the algal crop. If the environment offers 82 weight units of carbon, 14.4 of nitrogen, but only one of phosphorus, growth will be limited by a deficiency of phosphorus. Adding phosphorus in abundance at this point via sewage or otherwise will destroy its growth regulating function. This is now what is happening at many localities in this country.

A closely related concern is the gradual decrease in the nitrogen/phosphorus ratio as natural waters receive sewage and/or other high phosphorus-bearing pollutants. The added phosphorus reaches an excess and is no longer growth-limiting. On the basis of studies on 40 European lakes, Thomas (1969) concluded that "It is certain that oligotrophic (nutrient-poor) lakes on which man has had little or no influence all have phosphate as the limiting factor."

Vallentyne (1970) has reported that addition of phosphate can increase algae that form the basis of fish food supplies. Increased fish yields of from 50 to 500 percent may follow. The following ratios have been suggested as measures of eutrophication (Bartsch, 1972).

	N/P
Oligotrophic	15 or more Phosphorus limited
Eutrophic	Around 5
Polluted	2-3 No longer P-limited

Bartsch (1972) has reviewed sources of phosphorus throughout the nation.

Among the results are the following:

(a) under optimal operating conditions, the effluent from an activated sludge plant has a typical N/P ratio of 2 to 3. The ratio of N/P for the Green Bay municipal sewage treatment plant effluent was less than 1 for the

period October, 1970 - October, 1971. From January, 1971 to January, 1972, the Fox River provided a N/P ratio of nutrients to Green Bay of approximately 18. The total input of phosphorus in all forms was approximately 6,000 kg during this period (Sager and Wiersma, 1972);

- (b) the phosphorus content of domestic sewage is about 3 to 4 times the level found before the advent of synthetic detergents at about 1945 (Stumm and Morgan, 1962). Sawyer (1952) estimated the 1950 detergent industry contribution at about 1.6 lb. P/person/year. A 1955 estimate was 1.9 lb. P/person/year (Engelbrecht and Morgan, 1959). A task force estimate for 1958 gives 2.1 pounds (anon., 1967). Phosphorus consumption in detergent formulations is second only to consumption in fertilizers;
- (c) while a national average is unavailable, a recent source (Prince and Bruce, 1971) estimates that approximately 50 percent of the municipal phosphate discharge in Canada to Lakes Erie and Ontario is from detergents. In the U.S., the corresponding figure is 70 percent. Based on these values, it is estimated that detergent phosphorus accounts for 40 percent of the total input into the two lakes.

Algae Growth in Green Bay

Chlorophyll <u>a</u> has been used as measure of the extent of algae growth in Green Bay in several recent surveys. Generally, low concentrations of orthophosphate and nitrate are found in the summer and fall, compared to other seasons of the year. This is the period of the year when high densities of phytoplankton are found. Rousar and Beeton (1973) measured chlorophyll <u>a</u> concentrations on July 12, 1971 at 21 stations in lower Green Bay. They found values which ranged from 7.0 to 14.4 ug/1.

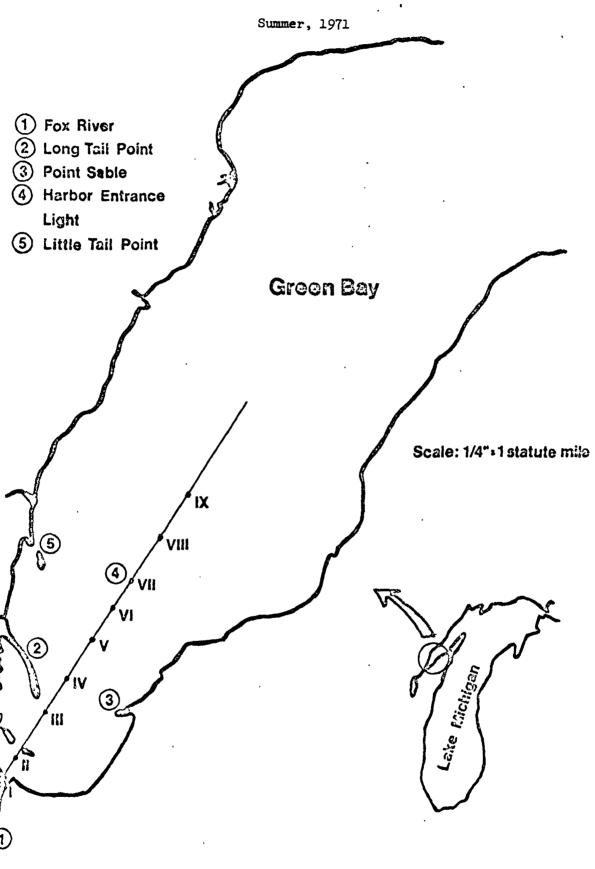

For the period June-August, 1971, Sager (personal communication to Rousar and Beeton) measured chlorophyll <u>a</u> concentrations which ranged from 1.2 to 57.4 ug/l (average 21.9 ug/l). Seven stations were sampled from near the mouth of the Fox River and extending to about 65 km north of the river. The highest values were found near the mouth of the Fox River with steep concentration gradients in the lower Bay. Monthly samples at the confluence of the Fox River with Green Bay from June, 1970 to October, 1971 yielded a range of 0.2 to 80 ug chlorophyll <u>a</u>/liter (average 24). Rousar and Beeton (1973) speculate that the noticeable lower results obtained by Sager may be related to differing sample handling techniques.

Schraufnagel et al (1968) found that algae blooms were generally confined to the inner Bay area in the summer of 1966. Blooms were observed only occasionally between the 10-mile light (16 km) and the 48 km station. Beyond 64 km planktonic algae blooms were not noted. The nutrient data is moderately consistent with planktonic algae observations.

Holland (1969) measured chlorophyll \underline{a} concentration at three stations situated 32 to 48 km from the south end of the Bay from April to November, 1965, and obtained an average of 10.4 ug/l. From the same region, Rousar and Beeton (1973) found an average of 18.6 ug/l in July, 1971.

Sager (1971) studied the nutritional ecology and community structure of the phytoplankton of Green Bay in the summer of 1970 at nine stations which extended 21.5 km into the Bay (see Figure 2). He found the highest concentrations of algae (as measured by both chlorophyll \underline{a} and as dry weight of plankton) in the region 2.5 to 8 km from the mouth of the Fox River. There was a low uptake in phosphorus by phytoplankton in the presence of high soluble phosphate (PO_{μ}³⁻) concentrations. A relationship was suggested to exist between a bloom of the nitrogen-fixing blue-green algae <u>Aphanizomenon</u>

Figure 2.

flos-aquae on August 12 and a surge of phosphate-rich water from the Fox River on July 22. The position where the bloom occurred and the timing of this bloom are consistent with an estimated flushing time of 29 days for this region (Modlin and Beeton, 1970). In general, an inverse relationship was found to exist between luxury uptake of phosphorus and high phosphorus concentration in the water. Measurements suggested the existence of two water masses in the lower bay, one characterized by Fox River parameters and the other representing the bay water.

Vanderhoef et al (1972, 1973) have used acetylene reduction as a measure nitrogen-fixation in relation to nutrient levels in Green Bay. They have measured the concentrations of nutrients as well as algae growth at several stations in lower Green Bay in 1971 and 1972. An individual species approach was used rather than a community approach in an attempt to assess the response of the Bay waters to nutrient loadings. Acetylene reduction activity closely correlated with population increases of blue-green algae, primarily species of Aphanizomenon and Anabaena, and these population increases occurred at sites where the soluble phosphate concentration was high. Their conclusions were many and specific:

(a) High soluble phosphate concentrations preceded <u>all</u> major increases in heterocystis nitrogen-fixing blue-green algae. If high concentrations of soluble phosphate are present and if the concentration of fixed nitrogen is the limiting factor in the growth of species which do not fix nitrogen, then the competitiveness of nitrogen-fixing blue-green algae may be increased. Large increases in fixed nitrogen lagged the large phosphate increases. During blooms of nitrogen-fixing algae, soluble phosphate concentration decreased considerably (concentrations of 30-50 ug P/1 fell to 10 ug P/1 or less). Acetylene reduction was never high where soluble phosphate concentration was less than 12 ug P/1.

- (b) Periodic increases in soluble phosphate concentration promotes the growth of nitrogen-fixing algae. Seasonal mixing mobilizes nutrients. Phosphate concentration is probably the limiting factor in the growth of nitrogen-fixing species of algae in Green Bay.
- (c) Fluctuations in the concentrations of nitrate, nitrite and ammonium ion do not correlate with fluctuations in nitrogen-fixing activity nor with the total amount of algae. Temperature variations do not correlate with nitrogen-fixing activity.
- (d) Iron is present in the waters of Green Bay and plays a role in the nutrient balance. Phosphate removal methods take out both iron and phosphate. Phosphate removal by wastewater treatment is more likely to control algal bloom formation than is phosphate removal from detergents alone.
- (e) The contribution of fixed nitrogen by nitrogen fixation in the inner. 725 km² of the Bay was estimated to be close to 40 percent of the total inorganic nitrogen $(NH_4^+ + NO_3^-)$ contributed by the Fox River during the period between June 14 and August 17, 1972.

These studies by Vanderhoef et al (1972, 1973) suggest that an investigation of species response to nutrient loadings may be a useful approach to the question of algae growth in Green Bay.

NUTRIENT AND WASTE LOADINGS AND THEIR EFFECT

ON THE FOX RIVER AND GREEN BAY

Municipal and Industrial Waste Loadings to the Fox River

The Wisconsin Department of Natural Resources and its predecessor agencies, in cooperation with the pulp and paper industry, have collected information essential for the determination of the effect of liquid wastes on the Fox, Oconto, Peshtigo and Menominee Rivers and Green Bay. Some of this information for industrial and municipal waste dischargers is summarized in Appendices I-V. Appendix I contains past pulp and paper mill production and past and projected waste loadings for the years 1950-1977. For these mills, the present and proposed waste treatment facilities are presented in Appendix II.

The past and projected river loadings by municipal sewage treatment plants (1948-1978) along the Lower Fox, Oconto, Peshtigo and Menominee Rivers are presented in Appendix III. These data are in the form of discharge, BOD, suspended solids and nitrogen loadings to these rivers. Present and proposed waste treatment facilities for the treatment plants along these rivers are listed in Appendix IV.

For the years 1966-1968, a comprehensive point source and stream survey was carried out on the Lower Fox, Oconto, Peshtigo and Menominee Rivers. This information is summarized in Appendix V. Reference to this data shows that for 1967, the total BOD₅ loading to the Lower Fox River from mill, municipal plant and other industrial or manufacturing sources was 315,000 lb/day of which less than 10 percent was from municipal treatment plants. Appendix VI presents the surface water quality data for the years 1950-1973 for the Lower Fox, Oconto, Peshtigo and Menominee Rivers.

Figure 3 summarizes past pulp and paper mill production and past and projected discharge data (BOD and suspended solids) for the years 1950-1977. Projected data comes from the interim effluent guidelines associated with the Wisconsin Pollutant Discharge Elimination System (WPDES). It should be noted that during the late 1950's, the committee on water pollution revised its sample handling and analysis procedures with the result that five-day biochemical oxygen demand (BOD₅) test results reported prior to about 1958 are lower, by as much as 20 percent, than their actual values. All BOD₅ values reported in the appendices are nonadjusted figures. Sewage treatment plant loadings to the Lower Fox River (BOD and discharge rate) are summarized in Figure 4 for 1956, 1966, 1973 and 1977 (projected).

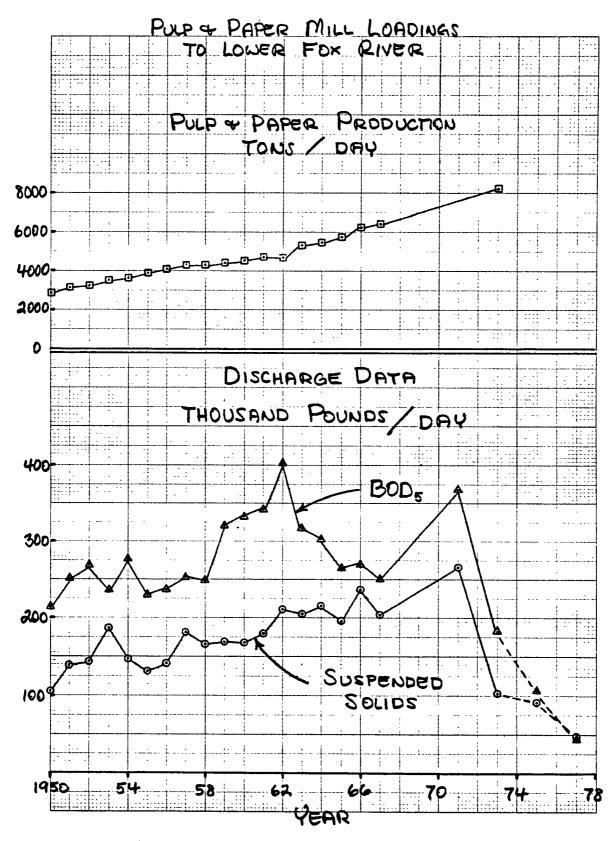

Nutrient loadings to the Lower Fox River by pulp and paper mills and by municipal treatment plants for 1971 are presented in Tables 3 and 4. Table 4 includes data from nine of the eleven municipal treatment plants investigated by Sager and Wiersma (1972), those nine for which additional historical data exists.

Phosphorus Loadings

Available nitrogen and available phosphorus are conceded to be the most important and necessary nutritional components for excessive aquatic growths and eutrophic conditions. Participants in a symposium on nutrients and eutrophication (American Society of Limnology and Oceanography, 1972) concluded that phosphorus most often is the limiting nutrient in algal growth.

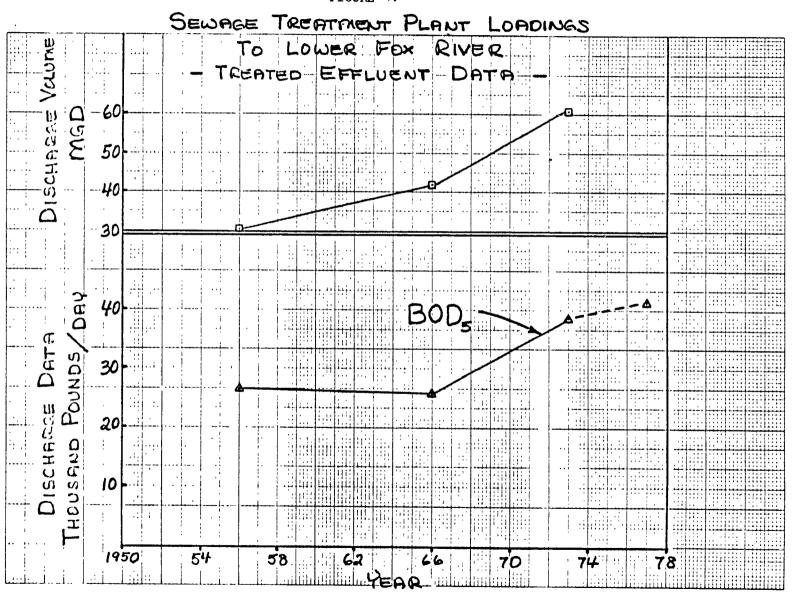

Phosphorus in the form PO_{\downarrow}^{3-} (orthophosphate) appears to be the limiting nutrient for algal emergence in Green Bay. Vanderhoef <u>et al</u> (1972) found that large inputs of soluble phosphate into the Bay preceded active N₂-fixation accompanying blue-green algal blooms. The variations of phosphorus concentrations were closely correlated with fluctuations in the growth of nitrogen-fixing algae.

^{*} Sager, P. E. and J. H. Wiersma, 1972, Nutrient Discharges to Green Bay, Lake Michigan From the Lower Fox River, Proc. 15th Conf. Great Lakes Res.: 132-148. Internat. Assoc. Great Lakes Res.

Phosphorus data was originally reported on a PO4 basis but has been converted to a P basis in this table.

The findings of Vanderhoef et al (1972, 1973) suggest that phosphorus is the limiting nutrient. Mean soluble phosphate concentrations in 1971 ranged from 3 to 55 ug/l, compared to a range of 35 to 81 ug/l in 1972 for comparable sites from the mouth of the Fox River to Sturgeon Bay. The higher concentrations in 1972 were apparently caused by higher spring runoff of phosphate into Lake Winnebago due to heavy rains before complete ground thaw. Algal growth and C_2H_2 -reducing activity were correlated with the higher phosphorus concentrations in 1972. Furthermore, the major bloom in 1972, Aphanizomenon, extended an average of 8 km farther north into the Bay than in the 1971 bloom of Anabaena. The 1971 study concluded that phosphorus was the dominant factor limiting algae growth under the conditions in Green Bay, while the 1972 study concluded that phosphorus or some nutrient input paralleling that of phosphorus was the limiting nutrient for N2-fixing algae in the lower Bay region.

The Fox River is the major source of phosphorus enrichment of Green Bay.

Table 5 (Sridharan and Lee, 1972) shows the input of phosphorus from the five major tributaries. The Fox River is the principal source, contributing approximately 81 percent of the estimated total 4,734,754 lbs. P/year (2,149,578 kg P/year).

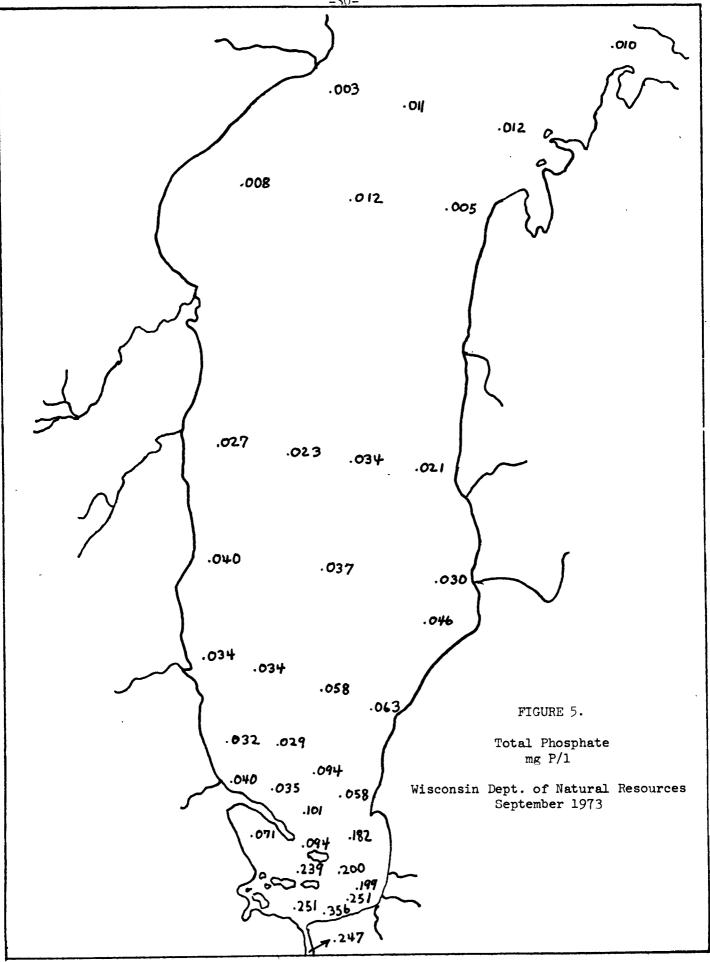

Quarterly sampling and analysis for phosphorus conducted over an eight-year period at the mouth of the Fox River by the Wisconsin Department of Natural Resources showed that the range of total soluble phosphate concentration was 0.14 to 0.40 mg P/1 with an average of 0.23 mg P/1 (Sridharan and Lee, 1972). A study by Allen (1966), involving monthly samplings of lower Green Bay near Little Sturgeon Bay, showed low phosphorus concentrations averaging 0.007 mg P/1 for soluble phosphate and 0.033 mg P/1 for total phosphate for an eight-month period. Figures 5 and 6 (Wisconsin Department of Natural Resources, 1973) show that the concentrations of total phosphate and orthophosphate decrease as the distance

from the mouth of the Fox River increases. These findings are consistent with results of other studies and justify considering the Fox River as the major source of phosphorus input.

Approximately two-thirds of the total phosphorus discharged by the Fox-Wolf River is contributed by municipal and industrial wastes. (For estimated source input, see Table 6). According to Wiersma et al (1973), the Lower Fox River drains only 7 percent of the total drainage basin of the Fox-Wolf River system. The most severe deterioration of water quality occurs in this section. A concentrated municipal-industrial complex makes intensive use of the river for disposal and assimilation of wastes.

Sager and Wiersma (1972) established a biweekly monitoring program for municipal treatments to assess the nutrient input to the Lower Fox River from October, 1970 to September, 1971. Annual loadings of orthophosphate and total phosphorus (both as P) averaged 1,417 lb/day (641 kg/day) and 2,094 lb/day (949 kg/day), respectively. The Green Bay Metropolitan Plant contributes approximately 50 percent of these totals. This amount is very significant for Green Bay since the plant is located 0.5 km from the mouth of the river and essentially discharges its effluent directly to Bay waters.

While nutrient-rich wastes from the sewage treatment and industrial plants on the Lower Fox River are very important, the water quality of the river is already reduced by Lake Winnebago water. This hypereutrophic lake contributes waters with high algae and nutrient concentrations, especially phosphorus, to the Lower Fox River. Sager and Wiersma (1972) considered Lake Winnebago to be a significant influence on the water quality of the river and lower Green Bay. The average annual loadings from Lake Winnebago for total phosphorus as PO₄³⁻ is 6,620 lb/day (3,012 kg/day) and almost equals the total phosphorus for the sewage treatment plants (see Table 7). Seasonal fluctuations of nutrient

Sager and Wiersma (1972)

loadings to Green Bay are closely correlated, not only with changes in Fox River flow, but also with variations in the water quality of Lake Winnebago.

Runoff from rural agricultural land and urban areas are believed to be a substantial source of phosphorus input to Green Bay. A study conducted by the U.S. Department of Health, Education and Welfare (Hall, 1966) found that the amount of phosphate reaching streams from land runoff in the Green Bay area was about 1,167,000 pounds (531,000 kg) of phosphorus per year. Table 5 shows estimated phosphorus input from rural runoff and urban runoff to the Fox-Wolf River system to be 822,000 lbs./year (37,400 kg/year), 33.5 percent and 95,800 lbs./year (43,600 kg/year), 3.5 percent, respectively. In conclusion, phosphorus contributed by surface runoff from nonpoint sources is a significant and measureable source.

Sager and Wiersma (1972) noted that, during the spring (March-May), loadings of nutrients were the highest. The levels were more than could be accounted for by Lake Winnebago and municipal treatment plants. Surface runoff from the drainage basin partially contributed to this excess. Sager (1971) found that extremely high concentrations of soluble phosphate in the inner Bay were correlated with heavy precipitation and a subsequent increase of phosphorus in the river. The heavy precipitation caused runoff which produced loadings to the municipal treatment plants in excess of capacity. In addition, the incomplete separation of storm and sanitary sewers contributes to inefficient phosphorus removal. Only within the past few years have the cities of Green Bay, Neenah and Menasha separated their sewage systems.

Sridharan and Lee (1972) indicate that sediments in the Fox River and Green Bay were potentially a significant source of phosphorus. Sediments contained large amounts of phosphorus and demonstrated releasability to overlying waters under laboratory conditions. Rates of release ranged from 3×10^{-6} to 3.4×10^{-4} mg P/g sed/hr for oxic conditions and a high rate of release

 3.2×10^{-5} to 8×10^{-3} mg P/g sed/hr for anoxic conditions. Sediments contained levels of phosphorus up to 2,000 ppm. Although these findings were under laboratory conditions, the relatively shallow, highly turbulent nature of the lower Bay region should at times approach the well-mixed conditions occurring in the laboratory and produce optimum conditions for release.

The rate of release of phosphorus from sediments was found to be dependent on several factors (Sridharan and Lee, 1972). Proximity of stations to the mouth of the Fox River was associated with both higher release rates and amounts of release. Orthophosphate and total phosphate concentrations in sediments and water of stations 4 and 5a located at or near the mouth of the Fox River showed the highest rates of release (Table 8, Figure 7). Station 11 had the lowest rate of release. The amount of phosphorus released was the highest at station 5a and decreased at stations 5, 9 and 11 with increasing distance from the mouth. Phosphorus release was directly affected by the nature of the sediment. Regions of low percent solids were associated with high orthophosphate release. Station 11 contained more sand size particles (high percent solids) than the other locations in lower Green Bay. Station 11 has a poor release of orthophosphate when compared to station 5a which is high in silt-like particles, low in percent solids. Furthermore, it was found that high iron concentrations were associated with high orthophosphate release. Station 5a was found to have a high iron concentration. Since iron has been associated with anoxic phosphorus release, and higher concentrations of iron were found in the leaching solution of 5a than in 5, then a higher orthophosphate release from station 5a is predictable.

Jayne and Lee (1971) sought to model phosphate transport between the sediment and water. They defined a distinct region extending about 3 km from the mouth of the Fox River that was nearly cut off from the Bay by a peninsula and sandbar. This region served as a source of phosphate for the overlying waters during the summer months. The sediment here accounted for 20 to 30

Stations 5, 5a, 5a Core, 11 and 4 were sampled on October 6 1969 and Station 9 was sampled on October 28, 1968.

Sridharan and Lee (1972)

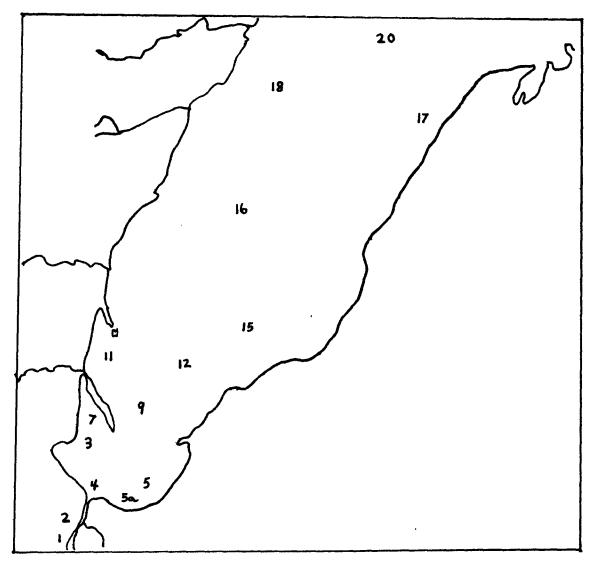

FIGURE 7. Sampling Stations for Green Bay.

Sridharan and Lee, 1972

percent of the phosphorus transported out of this constricted area during summer. Beyond this region, phosphate was absorbed by the sediments during the period May through November, for which data were collected. Jayne and Lee were unable to predict phosphate transport due to insufficient hydrodynamic information.

Sager and Wiersma (1972) found that the sediments along the Lower Fox River could partially account for the seasonal fluctuations in phosphorus loadings to the Bay. Assimilation and sedimentation apparently explained the decrease in concentrations of orthophosphate during summer and fall. During winter and spring, the downstream concentrations showed an increase. This increase was believed to be due to reduced assimilation of orthophosphate caused by colder temperatures and an increase in release of orthophosphate from bottom sediments generated by increased flow rates creating greater disturbances and sediment suspension.

Levels of phosphorus in the Bay can be used to describe the dispersal and distribution of Fox River water and can give insight to eutrophication processes which occur. However, when considering levels in certain areas or trends in levels, precautions must be taken. Beeton (1969) found that published data on increases in nutrients or eutrophication for the past 90 years were generally inadequate for evaluating trends. No trend in phosphorus levels was found due to insufficient and conflicting data. The data was obscured by analytical differences, too few samples combined with unrepresentative coverage, and conflicting results.

Studies which determined phosphorus levels for Green Bay yielded results similar to those of Ahrnsbrak and R. A. Ragotzkie (1970) with regard to the dispersal of Fox River water and mixing of Bay waters. Sager and Wiersma (1972) found that total phosphorus and orthophosphorus concentration gradients

were steeper inside of Long Tail Point than at the outer points (Fig. 8, 9). This agrees with Ahrnsbrak and Ragotzkie (1970) who found the greatest change in percent composition of river and Bay water, a decrease of about 30 percent by volume, in this same area. Total phosphorus gradients reflect dilution and dispersal patterns better than orthophosphorus gradients. Sager and Wiersma felt that this dilution is caused by processes of absorption, sedimentation, biological uptake and release being involved with the dynamics of orthophosphate distribution.

Rousar and Beeton (1973) also found a steep concentration gradient from the mouth of the Fox River to station 10, 16 km out (Fig. 10). This gradient was a result of dilution of polluted Fox River discharge by Bay water. North of station 10, no clear patterns of mixing of Bay and Fox River water were apparent. Values of phosphorus concentrations for all samples ranged from 30.5 to 430 ug P/liter and averaged 87.8. Excluding the three stations closest to the mouth of the Fox River, the average was 47.7 ug P/liter.

Sager (1971), by studying phytoplankton concentrations, was able to define two discrete water masses in lower Green Bay. One mass was characteristic of Fox River parameters and the other was representative of Bay water. The diffuse interface between the two water masses was located approximately 8 km from the mouth of the Fox in the vicinity of Long Tail Point. The extreme lower Bay was dominated by river species which exhibited high biomass and low uptake of luxury phosphorus in the presence of high available phosphorus. The Bay area water consisted of low biomass and high luxury uptake of orthophosphate in the presence of low concentrations of available phosphorus.

In addition to large variations in levels of phosphorus as one proceeds out into the Bay, variations in phosphorus levels have also been detected between the eastern and western half of the lower Bay area. The eastern portion generally

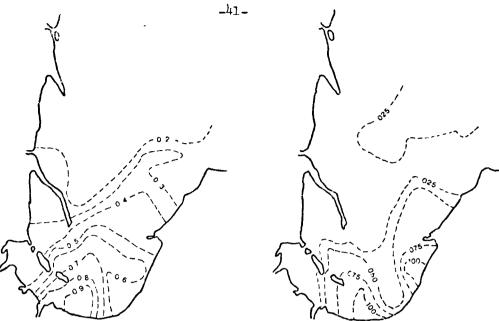

FIG. 8. Total phosphate isopleths (mg/l) in lower Green Bay (20 July 1971).

FIC. 9. Orthophosphate isopleths (mg/l) in lower Green Bay (20 July 1971).

Sager and Wiersma (1972)

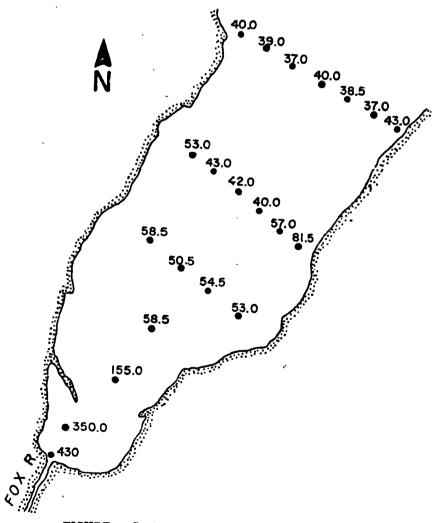

FIGURE 10. Surface concentrations of total phosphorus in µg P/liter from 2 m depth.

Rousar and Beeton (1973)

demonstrates higher concentrations of orthophosphate than the western. The highest concentrations appear in the southeast corner of the Bay (Fig. 9). Sager and Wiersma (1972) suggest that these results reflect the dispersal of Fox River water moving out and along the eastern shore. Lower westerly values may also be attributed to the influence of nutrient assimilation by the predominant marshy character of the shoreline.

The southeast corner contains higher concentrations of orthophosphate than exist at the mouth of the Fox River. This appears to reflect regeneration activity. Sager and Wiersma (1972) could not determine whether this regeneration activity originated from bottom sediments or suspended organic material or both. Total phosphate concentrations were also high in this area, indicating a possible local concentration of organic matter or algae in suspension. Massive algal growths as high as 90 mg chlorophyll a/m^3 (Sager, 1971) and high concentrations of phosphorus with high release capabilities (3.4 x $10^{-4}/g$ sed/hr Sridharan and Lee, 1972) in this area could supply sufficient substrates for the release of orthophosphate from decomposition or other chemical activity.

As mentioned earlier in this report, phosphorus loadings to the Bay are subject to seasonal variations. Knowledge of these fluctuations is essential for the assessment of the importance of the various sources of phosphorus input and for the demonstration of processes of assimilation and release of phosphate in the river system.

Sager and Wiersma (1972) have monitored variations in total phosphate and orthophosphate concentrations for ten stations (Figure 11) from Lake Winnebago to the mouth of the Fox River. Seasonal variations in phosphorus input were related to the quality of Lake Winnebago discharges and to the processes of assimilation, sedimentation and release in the river. The effect

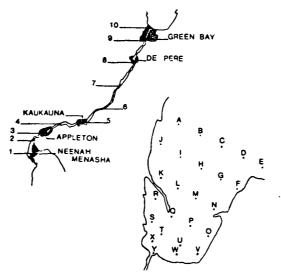

FIG. 11. Sampling stations on the Fox River (1-10) between Like Winnebago and Green Bay and on lower Green Bay (A-Y). The Harbor Entrance Light (station C) is 9.5 mi. (15.3 km) from the mouth of the river.

Sager and Wiersma (1972)

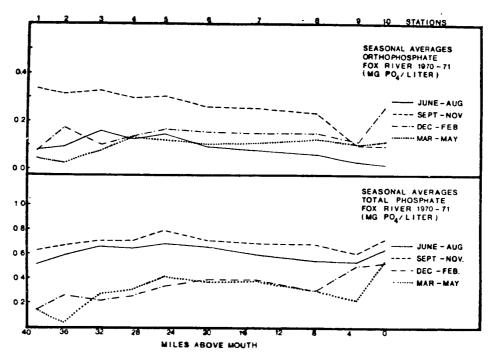

FIG 12. Seasonal averages of orthophosphate and total phosphate concentrations in the Fox River. Averages based on weekly samples, July to September 1910 and biweekly samples thereafter to October 1971.

Sager and Wiersma (1972)

of these variables with respect to phosphorus varied with seasonal conditions. Figure 12 shows seasonal averages of orthophosphate and total phosphate concentrations during the period July, 1970 to October, 1971. The following is a discussion of their findings.

During the fall period, the effect of phosphorus release from Lake Winnebago following the summer growth of algae is evident from the observed high concentrations at station I. Algal abundance during fall is at a substantially lower level than the summer period, approximately 44 mg/m³ to 77 mg/m³ chlorophyll a, respectively. Orthophosphate concentrations decrease as one moves downstream in both summer and fall. This reflects chemical assimilation and sedimentation by the river system. Quiescent waters behind the numerous dams are possible sites for deposition of phosphate associated with algae, organic matter and inorganic matter. Concentrations decrease downstream despite an input of approximately 4,400 lbs./day (2,000 kg/day) of orthophosphate from the eleven sewage treatment plants along the river.

The response of the river during winter and spring to the additional loadings by municipal treatment plants is different from that in summer and fall. During this period, the average concentrations of orthophosphate is lower throughout the river. However, concentrations increase as one moves downstream. The downstream increase can be attributed to colder water temperatures which cause reduced assimilation capabilities by the sediments and an increase in the release or regeneration of phosphorus from bottom sediments, suspended solids, plant materials, etc. This is aided in the spring by runoff from agricultural lands, and higher turbulent flows acting to resuspend the bottom materials. The lower overall concentrations of orthophosphate during winter and spring is apparently due to increased flow rates (greater volume) and decreased phosphorus loadings from Lake Winnebago.

Data for total phosphorus demonstrates the same downstream trend of increasing concentrations for winter and spring. It appears that the same factors (low rates of assimilation, municipal loadings and release from the river, especially with increased flow rates) account for this pattern as they did for the orthophosphate pattern. Summer and fall concentrations of total phosphorus in the river are high and reflect a combination of low flow rates and excessive algal growths of Lake Winnebago and the Fox River.

Summer concentrations of total phosphorus in the Fox River were lower than the fall concentrations despite algae densities which were highest in summer. The high orthophosphate concentrations found in the fall period could be responsible for the higher total phosphorus values. The high orthophosphate concentrations for fall, 61 percent of the total phosphorus, was apparently due to decomposing organic matter.

In summary, Lake Winnebago contributes phosphorus compounds to the lower Fox River in excess of or approximately equal to that contributed by municipal treatment plants. Seasonal variations of phosphorus loadings to Green Bay from the Fox River can be explained in part by seasonal changes in assimilation and release in the river and Lake Winnebago. Spring loadings to the Bay are highest among the seasons and usually represent levels greater than that which can be attributed to Lake Winnebago and municipal treatment plants. Sources of this increase could be surface runoff from the drainage basin and release from the river system.

Nitrogen Loadings

Nitrogen is added to Green Bay in substantial quantities as the result of loadings by the Fox River. Sager and Wiersma (1972) have found the annual average loadings at the mouth of the Fox River to be 17,100 lbs./day (7,800 kg/day) for nitrate-nitrogen (NO_3-N) and 12,400 lbs./day (5,600 kg/day) for ammonia-nitrogen (NH_3-N).

Two major sources of nitrogen to the Fox River are loadings from Lake Winnebago and from municipal treatment plants. Tables 6 and 7 give average loadings from these sources. The average annual loadings from Lake Winnebago are 9,940 lbs./day (4,500 kg/day) and 5,200 lbs./day (2,400 kg/day) for NO₃-N and NH₃-N, respectively. Comparable loadings from municipal treatment plants are 597 lbs./day (273 kg/day) and 4,408 lbs./day (2,000 kg/day), respectively. These values indicate that Lake Winnebago is the most significant source of nitrogen based on a yearly period. However, when considering loading levels for seasonal periods, it is found that municipal treatment plants are the most significant sources in summer and account for almost 75 percent of the loadings to the Bay (Sager and Wiersma, 1972).

Nitrogen loadings from the Fox River are subject to seasonal fluctuations.

Table 9 shows seasonal average loadings to Green Bay from the Fox River at station 10 which is located near the mouth of the river. There is a large difference between the highest loading period, March-May, and the lowest loading period, June-August. These fluctuations are caused by several interacting factors; biological decomposition, concentrations of dissolved oxygen, concentrations of algae, surface runoff in the drainage basin, flow rates and assimilation by the river system. The following is a summary of seasonal variations in concentrations and loadings of nitrogen complexes based on the findings of Sager and Wiersma (1972).

Levels of NH₃-N were closely correlated with dissolved oxygen (DO) levels in the Fox River. Figure 13 presents data for seasonal averages of DO and NH₃-N concentrations in the Fox River. The most significant seasonal change in DO level was in the summer and fall months when average concentrations decreased in the middle section of the Fox River. This seasonal DO sag was caused by high organic loadings in this portion of the Fox River and high decomposition rates characteristic of warm temperatures in summer and fall. Furthermore, the lower flow rates encountered in summer and early fall also contribute to depressed

TABLE 9. Average loadings to Green Bay from the Fox River at Station 10. Values in 1bs./day.

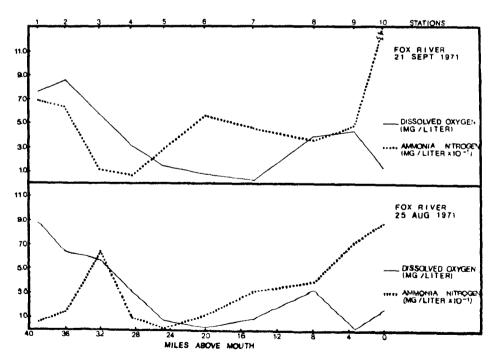

FIG.14. Changes in ammonia-nitrogen concentrations in relation to dissolved oxygen deficits in the Fox River.

Sager and Wiersma (1972)

oxygen levels. Beyond the midsection of the river, DO concentrations begin to recover as a result of decreased BOD loadings. However, at the mouth of the Fox River, increased organic loading from the De Pere-Green Bay area again results in depressed DO content. The low dissolved oxygen values and increased rates of decomposition during the summer and fall are reflected in the gradual increase of NH₃-N concentrations downstream. Summer NH₃-N concentrations were the highest. In contrast, NH₃-N concentrations were lowest in winter and reflected high DO concentrations and low rates of organic decomposition associated with winter conditions.

The midsection and the mouth of the Fox River were highly significant in producing increased levels of NH₃-N. Both areas demonstrated severe oxygen deficits and a release to the Fox River and Bay of NH₃-N as a by-product of organic decomposition. The high value of NH₃-N at the mouth of the Fox River in summer corresponds to decreased loadings of NO₃-N and reflects a possible chemical reduction process in this oxygen deficient area. Figure 1^h represents data from two sampling dates in summer and early fall of 1971 and illustrates the relationship of DO deficiencies and increased concentrations of NH₃-N.

Nitrogen in water discharged from Lake Winnebago is predominately associated with organic matter. Loadings of NO₃-N and NH₃-N were lowest during summer months when algae were utilizing and assimilating these nitrogen complexes. During the summer and fall, chlorophyll <u>a</u> concentrations produced by high densities of phytoplankton ranged from 40 to 180 ug/1. It appears that the decomposition of this algae and organic matter in the fall and winter resulted in increased loadings of NO₃-N and NH₃-N in the Fox River. Nitrate and ammonia forms contribute between 14 percent and 19 percent of the total nitrogen loadings at this time. However, during spring, greater loadings of inorganic nitrogen leave Lake Winnebago, partially due to increased flows (Table 7).

Ammonia-nitrogen loadings to the Bay were lowest in summer, 6,480 lbs./day (2,900 kg/day), and highest in spring, 25,600 lbs./day (11,600 kg/day). These increases during spring were apparently the result of surface runoff in the drainage basin and increased flow rates. Spring loadings are also affected by assimilation processes along the course of the Fox River. It appears that NO₃-N is assimilated in the Fox River between Lake Winnebago and the mouth of the river throughout the year, but only during spring do the NO₃-N loadings increase at the mouth of the Fox River. NH₃-N is assimilated in the river during the summer months.

Nitrogen fixation by organisms can be a significant nonpoint source of nitrogen input to the Green Bay system. Nitrogen fixation resulting from algal blooms contributes substantially to the Bay's combined nitrogen and intensifies eutrophication. Vanderhoef et al (1972, 1973) have investigated this source of nitrogen input by using acetylene reduction as an index of nitrogen fixation. During the peak week of Anabaena bloom (June 12 to June 19, 1972), 9^{l_1} ,000 kg of fixed nitrogen were added to the surface 2 meters of water in the lower l_1 00 km² of the Bay by l_2 -fixing algae. Throughout the summer, the average rate of l_1 02 reduction at the two highest nitrogen fixation sampling sites was greater than 50 moles per liter per hour. In a region constituting a major portion of the lower Bay, it was estimated that 2.9 x l_2 10 kg of l_1 1-N was produced by nitrogen fixation between June l_2 14 and August 17, 1972. For the same period, l_2 1.5 x l_3 10 kg (l_4 1+ NO3-)-N was discharged to the Bay by the Fox River.

A limited amount of historical data exists for nitrogen concentrations in Green Bay. Therefore, it is difficult to assess changes in levels over the years. However, it may be reasonable to obtain information about Green Bay by making correlations with trends found for Lake Michigan.

Beeton (1969) has documented environmental changes for Lake Michigan. Figure 15 shows nitrogen data from the Milwaukee water plant. Organic nitrogen (albuminoid ammonia) has increased and inorganic nitrogen (nitrate) has decreased over a 38-year period. Inorganic nitrogen is apparently converted by plankton to organic nitrogen resulting in the albuminoid ammonia increase. Surveys of several areas of Lake Michigan by the U.S. Public Health Service (1962, 1963) suggest that this conversion continues to be significant in parts of Lake Michigan. Nitrate concentrations were 0.12 ppm in the southern part of Lake Michigan and 0.19 ppm in the central part. The lower nitrate values in the southern portion were attributed to the uptake of inorganic nitrogen by plankton which were more numerous in this region (Risley, Fuller, 1965). Allen (1966) found that nitrates were much lower in the highly productive waters of Green Bay than in Lake Michigan. In fact, nitrate concentrations were so low in September of 1965 that it was not measureable. Allen's data confirms the conclusion that Green Bay, especially the lower Bay, is more advanced in terms of eutrophication than Lake Michigan.

Schraufnagel et al (1968) investigated pollution in the Lower Fox River and Green Bay during 1966 and 1967. Table 10 is a summary of the nutrient data collected. Concentrations are expressed as mg/l. No conclusions can be made for the region inside of the 10-mile (16 km) light since only two nutrient samples were collected and the results are inconsistent. The summer samples collected beyond the light generally revealed less than .3 mg/l total inorganic nitrogen (sum of ammonia, nitrite, and nitrate nitrogen). The data suggests that the concentrations of nitrogen beyond 10 miles (16 km) are marginal for blooms of planktonic algae. Algae blooms were generally confined to the inner Bay area and observed only occasionally between 16 km and 48 km from the mouth. No algal blooms were found beyond 64 km. The nitrogen data are moderately consistent with the algae observations.

Schraufnagel, et al (1968)

Chlorophyll <u>a</u>, ammonia and organic nitrogen concentrations obtained by the Wisconsin Department of Natural Resources in September, 1973 are presented in Figures 16, 17 and 18. In general, areas which demonstrated high chlorophyll <u>a</u> concentrations, indicating high algal concentrations, had the highest values of organic nitrogen and ammonia nitrogen.

MIXING, DISPERSAL AND TRANSPORT OF WATER IN GREEN BAY

The movement of water in Green Bay depends upon several factors. One of these is the oscillation of water in a bay, lake or landlocked sea known as a seiche. Seiches have been noted in Green Bay since the time of the earliest French explorers, although the changes in height are not exceptionally large. Both Father Marquette (Bacqueville de La Potherie, 1722) and Father Andre in 1677 (Martin, 1916) observed water movements in Green Bay which were described as tides.

Indications are that the daily changes in the Green Bay water level that are called seiches are due to atmospheric pressure as well as wind direction and velocity. These variations can extend to the lower portions of tributary streams. Streamflow reversal has been observed on the East River which joins the Fox River about 2.3 km from the Bay. This reversal has been observed as far as 7.4 km along the East River (Schraufnagel et al, 1968).

That rapid changes in water levels can occur was documented during a survey of the Fox and East Rivers in 1956-1957 (Scott et al, 1957). The level of the East River was observed to vary by 1.43 meters over a period of one year. A substantial change took place in a very short time. On November 18-19, 1957, the elevation of the East River changed by 1.33 meters in a period of 17 hours. The usual change in river elevation is approximately 0.3 meter per day but occasional changes of only 0.03 or 0.06 meter occur between reversals. Fluctuations of water level in the Bay may cause a reversal of flow in the Fox River. The effect has been noticed as far as the De Pere dam, a distance of 11 km (Schraufnagel et al, 1968). On one occasion, flow on the Fox River near its mouth was measured at slightly over 280 m³/sec and it was moving upstream.

In the late fall and in the spring, winds from the direction of Lake Michigan bring in large quantities of fresh lake water which are trapped in the Bay. This influx is less important than that from the input of lake water through the many passages between the Bay and the lake. Seiche motion is the cause of this latter input. The associated current reversals occur typically every twelve hours. Surface water leaves the Bay while water at lower depths enters. Although the net flow is outward, this mechanism does provide a source of fresh Lake Michigan water which is then subject to the independent circulation of the Bay (U.S. Federal Water Pollution Control Administration, 1966).

The influence of seiche motion in Green Bay has been investigated by Mortimer (1965), Saylor (1964) and Johnson (1960, 1962, 1963). It is found that the Bay has a restricted exchange of water with the rest of Lake Michigan which minimizes dilution and flushing processes. Eventually all of the water that flows into Green Bay flows out into Lake Michigan, but these flows are probably small in comparison to the water movements associated with the currents and seiches (Schraufnagel et al, 1968).

Wind and current patterns play the most important roles in the mixing and transport of water within Green Bay. The wind patterns in Green Bay for late summer and early fall show that the prevailing winds are from the west through the southwest (U.S. Federal Water Pollution Control Administration, 1966).

For the late fall and winter, the prevailing winds are from the west through the northwest. During May to August, the prevailing winds are from the south through the southwest. Early spring (April) and late fall are the only times when the prevailing winds are from Lake Michigan. The effect of a northeast wind can be enormous. In the spring of 1973, the community of Green Bay was hit with the worst flooding in its history. Ninety km per hour winds brought three meter waves crashing into the city, while 6 meter waves pounded the neighboring shoreline.

Green Bay becomes thermally stratified weeks before the adjacent deeper water of Lake Michigan. The shallow southern end of the Bay is nearly 7°C warmer than the deeper north end in June, and more than 12°C warmer than the deeper lake water. Measurements in June, 1962 and May and June, 1963 show that thermal stratification in Green Bay is separate from stratification in the main portion of the lake (U.S. Federal Water Pollution Control Administration, 1966). The effects of temperature and wind appear to make Green Bay into an independent lake separate from Lake Michigan.

It has been suggested (Ragotskie, Ahrnsbrak and Synowiec, 1969) that bays of the Great Lakes can, in some ways, be considered analagous to coastal estuaries of the oceans. However, the primary physical mechanisms effecting the dispersal and transport of pollutants may be quite different from those acting in a tidal estuary. Seiches provide an analagous but more complex forcing mechanism for horizontal water movement, and density gradients are entirely due to thermal and diffusion effects with no salinity contribution.

Several features of Green Bay make it desirable for the study of water movement in a freshwater bay. First, the long, narrow shape of the basin makes it ideal for diffusion and dispersal studies. The rather limited exchange of Bay waters with those of Lake Michigan make Green Bay an almost separate lake. Secondly, the major portion of pollutants enter at the head of the basin and act as a tracer for the movement of water through the Bay.

Recently there have been studies aimed at a description of the movement of polluted Fox River water in Green Bay. Ahrnsbrak and Ragotskie (1970) have described mixing processes in the Bay. Modlin and Beeton (1970) have described the dispersal of Fox River water in Green Bay. For these studies, the assumption has been made that the Fox River is the only significant source of pollutants which enter the Bay. The data in Table 11 support this assumption.

TABLE 11. Average discharge rates of water, suspended solids, and chlorides for 4 rivers entering the southern lobe of Green Bay.

		Suspended	l Solids	Chlorides		
River, Location	Discharge Rate (m³·day-1)	Concentration (mg·1-1)	Net Transport (kg·day ⁻¹)	Concentration (mg·1-1)	Net Transport (kg·day ⁻¹)	
OCONTO at Oconto	2.35 x 10 ⁶	9.8	2.3 x 10 ⁴	6.7	1.57 x 10 ⁴	
MENOMINEE at Marinette	8.96 x 10 ⁶	5.3	4.75×10^4	1.4	1.25 x 10 ⁴	
PESHTIGO at Peshtigo	2.25 x 10 ⁶	5.6	1.26 x 10 ⁴	0.6	1,35 × 10 ⁴	
FOX at Green Bay	11.3 x 10 ⁶	17.1	19.3 x 10 ⁴	12.3	13,9 x 10 ⁴	

AHRNSBRAK and RAGOTZKIE (1970)

The four significant rivers which enter the southern two-thirds of the Bay are given with their average discharge rates, concentration of chlorides and suspended solids, and the net transport of those pollutants. Based on these flows, it can be seen that as a pollution source, the Fox River is nearly an order of magnitude larger than the other three rivers combined.

Modlin and Beeton (1970) used conductivity measurements as a probe of the lakeward movement of Fox River water in Green Bay. In 1968, they found a counterclockwise circulation of the surface water in the southern end of Green Bay below the Oconto River and above Long Tail Point. As a result, water which they described as river water extended northward for almost 40 km along the east shore. Lake Michigan water appeared to occupy the western two-thirds of this area. The lakeward movement of the Fox River water is generally along the east side where it may constitute as much as 80 percent of the northward current. These observations are consistent with those of Schraufnagel et al (196) who suggest that the river water may frequently become well dispersed across the lower 16-24 km of the Bay. They suggest that a counterclockwise current brings cleaner water down the western shore of the Bay,

sweeps eastward at about the latitude of the Green Bay harbor entrance light and then moves northward in the eastern half of the Bay. The usual pattern of currents found by Schraufnagel et al (1968) is for Fox River water to continue in a northerly direction into the Bay for about 15 km and then veer to the east and follow the east side of the Bay northward to Little Sturgeon Bay. Movement of the water along the west side of the Bay is southward to near Pensaukee and then eastward and northward. The southern part of this counterclockwise current lies in the vicinity of the two outer channel lights.

Schraufnagel et al (1968) suggest that there appear to be pockets in the lower Bay which permit little water movement in and out. On occasions the waters of the Fox River, although somewhat concentrated along the shipping channel, appear to be fairly well dispersed across the lower 16 to 24 km of the Bay. Density measurements indicate that in summer months the warmer river waters overflow the lake waters, but in the winter months, the river waters tend to follow the bottom for some distance before diffusing into the main body of water.

The conditions at the extreme southern end of Green Bay (below Long Tail Point and the sand bar extending towards it from the east) drew special attention from Modlin and Beeton (1970). They found in 1968 that approximately 70 percent of the water in this region was river water. Ahrnsbrak and Ragotskie (1970) concluded from conductivity studies that the water below Long Tail Point consists of 50 to 80 percent by volume of Fox River water. Under southerly winds, a tendency for a tongue of water with a concentration of 30 to 40 percent river water can be identified extending northward along the east side of the Bay approximately 15 to 20 km. However, under the influence of northerly winds, this tongue was not observed. North of Long Tail Point, the concentration of Fox River water decreased rapidly (as shown by conductivity measurements), a value greater than 25 percent seldom being observed beyond 25 km north of the mouth

of the river. Northward concentrations are described as very low and the effect of the Fox River is described as small. From diffusivities derived from their data, Ahrnsbrak and Ragotskie (1970) suggest the existence of a barrier to horizontal mixing in the area of Long Tail Point, while northward the Bay appears to be well mixed and the transit of Fox River water is much more rapid. They postulate that Long Tail Point and the bar extended towards it from the east are effectively the outfall site for the effluent of the Fox River water in Green Bay. Similarly, Sager (1971) describes two discreet water masses in lower Green Bay, one characteristic of the Fox River water and the other representative of the water of Green Bay.

The distribution of suspended solids is also a measure of the flow and dispersal of river water in Green Bay. Recent estimates of suspended solid concentrations at the mouth of the Fox River range from 7 to 20 mg/l (Sager, 1971; Ahrnsbrak and Ragotskie, 1970).

Sager (1971) measured light penetration by means of Secchi disc readings throughout the summer of 1970 at several stations along a line extending 22 km from the Fox River mouth. He found that there was a consistent pattern of increase along the sampling transect, but with the steepest gradient noted in the first 5 to 7 km. The decrease was ascribed to both dilution and sedimentation processes. Low transparency in the inner Bay area was affected by phytoplankton concentrations and suspended solids from the sediments in the extensive regions where the water depths are generally less than 2 to 3 meters. Here the bottom sediments are subject to wind-induced turbulence.

Schraufnagel et al (1968) measured light transparency in Green Bay during the summer of 1966. The Bay was divided in subregions as shown in Figure 19.

The result of their measurements is shown in Table 12.

TABLE 12. LIGHT TRANSPARENCY IN GREEN BAY (SECCHI DISC DEPTHS) SUMMER, 1966.

Zone	Secchi disc Readings	Approximate Distance from Mouth
A	0.450.60 meters	O km
В	,	2
С	0.300.90	2-3
D	0.300.90	3-4
E	0.450.60	3-4
F	0.901.2	
G	0.901.2	
Entrance light	1.51.8	17
Middle Green Bay	1.82.1	
Sturgeon Bay	2.7 3.0	56
Washington Island	4.96.0	112

The investigation in 1938/1939 (Wisconsin Committee on Water Pollution, 1939) did not measure light transparencies. However, measurements were made of the total solids (ppm = mg/1) in each water sample. The total solids content decreased consistently with distance from the Fox River mouth.

Modlin and Beeton (1970) used conductivity measurements to estimate the flushing rate in lower Green Bay. Flushing rate is defined as the length of time it takes one day's accumulation of river water to move through a bay or portion of a bay. The longer the flushing rate, the greater the effect the river water has on an area. The results are shown in Table 13.

TABLE 13. AVERAGE CONDUCTIVITY, PERCENTAGE OF RIVER WATER AND FLUSHING TIMES FOR TWO ZONES IN LOWER GREEN BAY

Zone 1 is the area below Long Tail Point; Zone 2 is the area above Long Tail Point, north to an east-west line at Oconto.a

Date/Zor	ne	Average Conductivity umhos at 25 ⁰ C	Percent River Water	Flushing Time Days
1968/1	(July)	345 277	70 15	29 78
1969/1 2	(August)	340 279	64 16	33 127

aModlin, R. F. and A. M. Beeton. Dispersal of Fox River water in Green Bay, Lake Michigan.

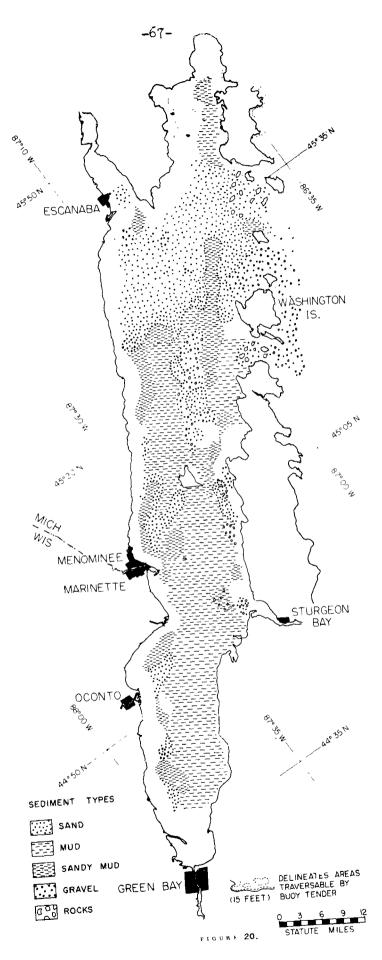

The effect of river discharge rate can be seen in this data. The river discharge rate in August, 1969 averaged 5.9 x 10^6 m³/day. For this flow, the net flushing rate was 160 days. In July, 1968, the discharge was greater by almost 3 x 10^6 m³/day and, consequently, the flushing rate decreased to 107 days. Under normal flow conditions, the residence time of Fox River water in the lower Bay is considerable.

NATURE AND CONSTITUTION OF THE BOTTOM SEDIMENTS

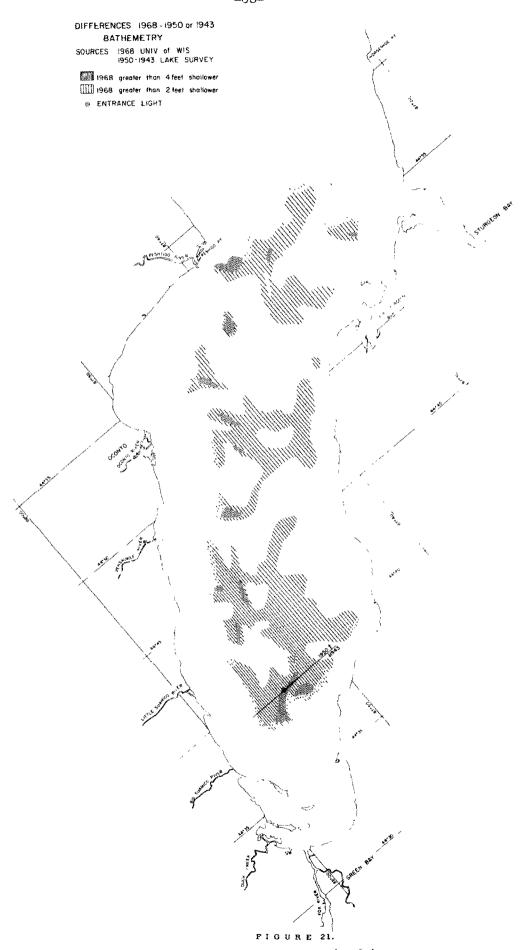

An understanding of the relationship between the bottom sediments and the sources of materials which enter Green Bay requires a knowledge of the type and distribution of these sediments. Qualitative and semiquantitative descriptions of bottom sediments have been a part of the extensive surveys in the Bay. In July, 1968, a comprehensive geological-geophysical survey of the shallow subbottom structure and near surface sediments of Green Bay was carried out by Moore and Meyer (1969). They were able to map the major textural types of deposits which floor Green Bay by means of a variety of techniques—heavy dredging, core sampling and acoustic and seismic profiling.

Figure 20 shows the naturally grouped sediment types. It shows that mud is the prevailing sediment type in the southern part of Green Bay, with sand the second most common type. Sand covers the western near shore areas of southern Green Bay. A strip of sand bottom varying between two and three miles in width apparently extends the full length of the western shore. Sand and sand mixed with mud also occurs at depth in the northern part of Green Bay and there the pattern suggests a trend parallel to the long axis of the Bay.

The bathymetric data from the 1968 survey was compared with the final worksheets of U.S. Lake Survey for the Southern Bay (1943) and the Northern Bay (1950). This comparison was judged by Moore and Meyer (1969) to be the most significant result from the 1968 survey. In the region of the Bay below Sturgeon Bay, there were several areas where the bottom depth decreased substantially over the relatively brief period of seventeen years. In Figure 21 the shaded areas indicate decreases in floor depth of more than 1.2 meter (four feet) or more than 0.6 meter (two feet). Moore and Meyer (1969) call attention to the relationship between the areas of the Bay where these decreases have occurred and the sediment and nutritive sources. An independent check of the validity of these results was also afforded by the overlap of the

Moore and Meyer (1969)

Moore and Meyer (1969)

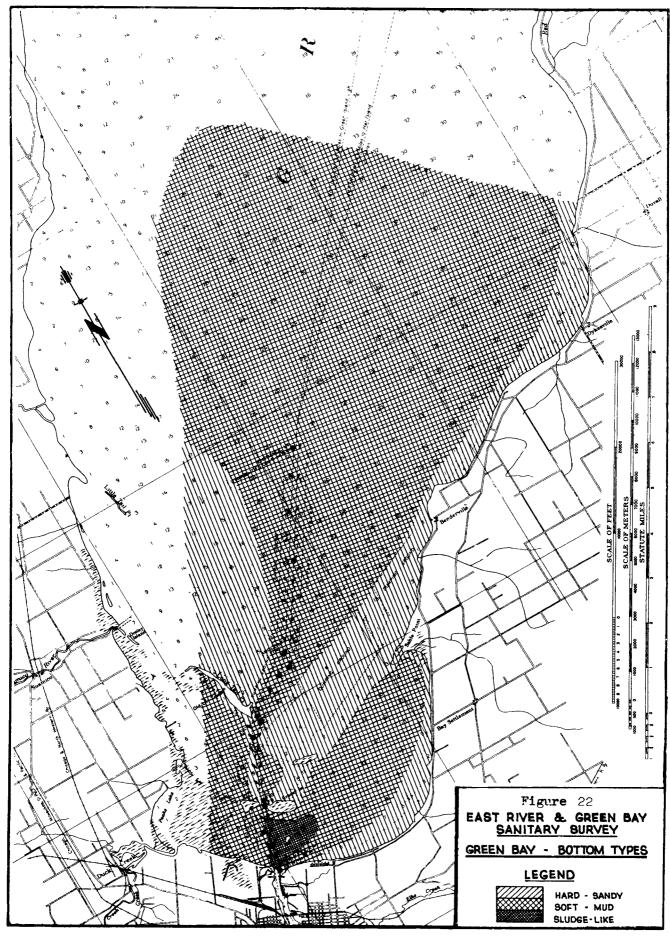

1943 lake survey bathymetric data south of the harbor entrance light and the 1950 data to the north. This comparison shows a decrease in depth of 0.3 to 0.6 meter (1 to 2 feet) in the seven years between those surveys in areas where equal or greater amounts of filling were found since 1950. The lake survey procedures were similar or identical in 1943 and 1950. Moore and Meyer (1969) raise the spector that Green Bay will cease to exist as a body of water because of the "extremely high" sedimentation rates.

The data were interpreted to indicate that Green Bay was filling in at a rate of 10 to 100 times that associated with larger bodies of water.

Distribution of dredged materials do not appear to influence these results. Maintenance dredging of the Green Bay ship harbor is done by the Corps of Engineers. The dredged materials are usually disposed of in deep waters (over 50 feet). A polluted zone is created when any organic matter is deposited in this way. In 1966, the Corps of Engineers constructed a diked area about 3.2 km north of Fox River mouth to be used as a depository of dredgings considered to contain pollutional material (U.S. Federal Water Pollution Control Administration, 1966).

Several investigators have described the bottom sediments in a qualitative way during the course of their studies of Green Bay bottom fauna. A description of the bottom sediments was part of the 1938/1939 survey (Wisconsin State Committee on Water Pollution, 1939). The result was a map of the sediment distribution of the lower Bay (Figure 22).

An area at the extreme lower end of the Bay contained a fairly high content of sewage sludge derived from a combination of the inflowing Fox River and the outfall of the Green Bay sewage treatment plant. Its decomposing condition was evidenced by the appearance and odor and by the fact that there were large numbers of gas bubbles when its supernatant water warmed up in the spring.

Wisconsin State Committee on Water Pollution (1939)

Howmiller and Beeton (1970) have investigated the bottom fauna of Green Bay. In the course of this investigation (which is discussed in detail in a later section) they describe the bottom material within a few kilometers of the Fox River as a semi-fluid black-brown mud which resembles sewage plant sludge. It appeared to be highly organic, smelled of sewage and hydrogen sulfide, and contained many small vegetable fibers. Brown silt was common northeast of Long Tail Point and along the eastern shore where the mixture of lake water and river water moves northward. Brown mud, more cohesive than silt or the semifluid mud of the lower Bay, occurred in the deeper water further north in the Bay.

FISHERY IN GREEN BAY

This section is designed to highlight those aspects of fishing in Green Bay which can be related to water quality in the Bay rather than designed to be an extensive survey.

Lloyd (1966) has sketched the background of Green Bay fishing. Much of the historical information is qualitative and is expressed in superlatives. Natives and travelers did most of their fishing on many of the large tributary streams and took advantage of migratory fish runs. Father Andre, a French priest, wrote in 1674 that it was impossible to conduct church services because of the immense pile of drying fish which created objectionable odors.

The Indians built a fish weir across the Fox River from which they speared northern pike, sturgeon and muskellunge. As communities stabilized, a productive commercial fishery developed. Pike, whitefish, herring and sturgeon were taken in large quantities in the 1850's.

The first annual report of the Wisconsin fish commissioners in 1874 indicated a concern about the decline of fish populations, especially whitefish and trout. In an effort to offset declining numbers of fish, a hatchery was constructed at Pensaukee in 1875 to hatch lake trout and whitefish spawn for stocking Lake Michigan. In 1877, one million whitefish fry were stocked in Green Bay. The first lake trout eggs were stocked in 1880. At this time, regulatory rules were developed to protect declining fish populations.

The present character of the fishing industry varies considerably over the various regions of the Bay.

The northern bays adjacent to Michigan's Upper Peninsula have shallow, warm waters which support walleye populations sufficient for commercial fishing. The northern part of Green Bay has deep and cold water where species

of fish appropriate to this habitat are caught in great numbers. Ports like

Gills Rock in Door County have been centers for fall herring and spring whitefish

fishery. Here the lake trout was the predominant predaceous fish in years past.

Southern Green Bay has a predominance of warmwater species with perch most important. Carp, northern pike, drum, suckers, white bass, bullheads and catfish also occur here. The principal predaceous fish is the northern pike. Perch occur in waters less than 25 meters deep throughout the Bay. New species which have entered recently have wide distribution ranging from the shallows of estuaries to the greatest depths. Both the smelt and alewives are in this category.

The commercial fishing industry in Green Bay constitutes a considerable proportion of the total production in Green Bay. The data (Table 14) show that in recent years, as well as in the past, the commercial fish catch in Green Bay has constituted approximately one-half of the total catch throughout Lake Michigan.

The fish populations of Green Bay have fluctuated violently since the midforties and to a lesser extent in the period 1929 to 1946. These fluctuations
have been interpreted as the expression of year class strength operating within the
influences of a well-developed fishery. However, details of population growth or
decline remain unknown. The species may affect each other as indicated by the
recent near extinction of one species followed by the explosive growth of others.
The comments of Patten (1969) may well apply to Green Bay: "Alter or adjust a
population here and remote, unforeseen consequences may be generated, possibly
dramatically elsewhere. And if long enough time lags or distances separate
primary causes and ultimate effects, an event may never be associated with a
reaction which in fact it initiated." Recently, Walter and Hogman (1971)
have constructed a mathematical model which incorporates statistical feedback

COMMERCIAL FISH PRODUCTION OF GREEN BAY IN RELATION TO LAKE MICHIGAN (IN THOUSANDS OF POUNDS)

From: U. S. Bureau of Commercial Fisheries, Report on Commercial Fisheries Resources of the Lake Michigan Basin, 1965, (for data previous to 1964) and Michigan, Ohio and Wisconsin Landings, Current Fisheries Statistics, (U. S. Department of Commerce) National Marine Fisheries Service, (for reports since 1964).

and considers a large set of system variables which may affect each species' rate of abundant change. The model has the capacity to respond to changes in water quality. However, these changes, which are of considerable importance, do not enter because of lack of a qualitative relationship between water quality and population.

The nature of the commercial fishing industry on Lake Michigan has changed dramatically in the past thirty years. The judgment is inescapable that this change has resulted from the activities of man. It is difficult to assess the effect of water quality on changing fish populations in the presence of so large an influence. Nevertheless, some factors can be identified. Smith (1968) has pointed out that commercial fishing for sturgeon was prohibited in 1929, long before the recent large influences. It was suggested that the environment for sturgeon was no longer suitable, since it was usually more abundant in those areas that had suffered the severest pollution. The decrease in lake herring in Lake Michigan was enormous in the period 1954-1962 when the alewife was becoming abundant in the lake. The lamprey, as well as the alewife, has probably contributed to the decline of the lake herring, but it should be noted that the major lake herring fishery was in Green Bay, where accelerated eutrophication may well have contributed to the collapse of the lake herring population.

floyd (1966) and Beeton (1969) have discussed the habitat in which various species exist. The following is a summary of their work. An emphasis has been placed on the identification of changes in habitat which are related to changes in water quality.

Cold-Water Species

Lake trout has disappeared from the Bay fishery although they are beginning to reappear in small numbers as a result of stocking. The primary factor responsible for their disappearance was the lamprey. However, it has been suggested

(Lloyd, 1966) that the lamprey cannot be regarded as the only cause for decline.

Increased fertilization of the Bay places a higher oxygen demand on the deep,

cold waters which could force the lake trout out of some of its preferred habitat.

Whitefish have also been affected by lamprey depredations and their numbers since the 1940's have been much less than during the prelamprey period. They also are affected by increased enrichment and could have been squeezed out of acceptable habitat.

Chubs, known as deep-water cisco, frequent deep, cold waters. They were never a large component of the Green Bay fishery. Although small in size, and therefore not the chosen prey of the lamprey, the decline closely coincided with the increase in alewives.

Lake herring or shallow-water cisco has been the most important catch in these waters. Exceptionally high populations occurred immediately following lamprey reduction of the predaceous lake trout. As alewife numbers rose, cisco declined. Eutrophication also contributed to a declining habitat, a subtle factor which will never be adequately measured.

Smelt were first detected in Lake Michigan in the 1920's. They reached a peak in the 1940's and 1950's and have declined somewhat since. The ultimate population is not likely to be as high as the early peaks.

Alewives were first detected in 1952 and became a part of commercial catches in 1956. Within ten years they became the dominant species in the fishery industry despite their low commercial value.

Warmwater Species

Warmwater species are found in the shallow waters, southern Green Bay, the estuaries and bays.

Lake sturgeon have become a fish which is only occasionally found in the commercial nets. This long-lived primitive fish lost its spawning grounds among the rocks of the large rivers when they were cut off by dam building and pollution.

Northern pike are a product of shallow water. Most of the commercial catch is made on the west shore of southern Green Bay. There has been a steady erosion of spawning areas as harbors expand and marshes adjoining the Bay are filled or drained.

Walleye is found in abundance in the Northern Bays in Michigan. They move to Oconto on the west and the Strawberry Islands on the east shore.

Perch have been the most important marketed catch. Long-term changes in abundance are not evident. Perch abundance does not appear to be significantly affected by more adverse environmental conditions including low dissolved oxygen concentrations; their spawning grounds are not affected as they will spawn over sandy or rocky bottoms amid vegetation or debris. Their primary food supplies, consisting of either plankton or bottom fauna, may be increased by enrichment.

Carp are found in shallow, warm water of the Bay. They exist in water with low dissolved oxygen; they feed on plankton, bottom fauna or vegetation and spawn in this environment. Thus, enrichment of the Bay favors this fish.

Summary

The fishery in Green Bay has changed radically in recent years due to the activities of man. The result has been a shift of production from <u>primarily</u> high quality native species to low quality exotic fish.

Pollution has caused a deterioration of the cold-water habitat and has rendered previously desirable spawning grounds as useless. Enrichment has accentuated plant growth which favors carp. In addition, fishermen complain of fish with off flavors, probably a direct or indirect result of pollution.

BOTTOM FAUNA

A biological evaluation of natural water includes a consideration of the conditions for phytoplankton, zooplankton, vertebrate (fish) and invertebrate organisms. The invertebrate organisms are particularly useful for investigations of water quality since they are relatively immobile and consequently are directly subjected to any polluted conditions in their habitat. If they are subjected to the influences of a contaminant, then they must respond by a physiological adaptation or they must die.

All gradations and variations of adaptability toward adverse conditions may occur. Some species cannot tolerate any appreciable pollution whereas others are not only tolerant but appear to thrive. Intolerant species may be reduced in numbers or disappear. Tolerant forms respond according to the severity of the pollution. When competition is reduced by the elimination of more competitive intolerant forms, the population of the more tolerant forms may increase.

Pollution normally expresses itself on the bio-habitat and aquatic organisms in one of two ways. It may be toxic to the organisms and, in this situation, the substance will usually affect all organisms uniformly. Here one does not observe a specific group which becomes more or less predominant. The tendency is for the disappearance of all species simultaneously. This situation is most often noted with wastes which contain heavy metals, tars or oils, chlorinated hydrocarbons or other more exotic materials. Alternately, pollution may cause changes in the environment which favor certain species of organisms and is detrimental to others. This is the situation most frequently observed with organic types of pollution, such as paper mill wastes, milk plant wastes, sewage treatment plant wastes, etc.

Aquatic organisms must derive their oxygen from the water and, consequently, when an organic waste decomposes, it competes with the organisms for the oxygen present. Generally, if decomposition is rapid and natural reaeration replaces

lost oxygen, then significant levels of dissolved oxygen will remain in the water. This situation often exists at summer temperatures. However, if decomposition continues for lengthy periods, oxygen levels may be reduced to critical levels for animals that are not adapted for the most efficient use of dissolved oxygen. Some organisms are not only efficient at extracting oxygen from the water but may also derive oxygen from the air and utilize waste organic material for food. Increasing numbers of these kinds of bottom organisms are a useful measure of polluted waters.

Since 1938, there have been several extensive chemical and biological surveys whose aim has been to assess the severity and extent of pollution in Green Bay (Wisconsin State Committee on Water Pollution, 1939; Surber and Cooley, 1952; Balch et al, 1956; U.S. Federal Water Pollution Control Administration, 1966; Schraufnagel et al, 1968; Howmiller and Beeton, 1970, 1971). As a part of each of these surveys, bottom samples were collected for analysis of benthic invertebrate animals. These analyses included classification of types as well as a count of bottom dwelling animals.

Surber and Cooley (1952) compared numbers and types of organisms at nine of their stations in the lower Bay in May, 1952 with data from nine comparably located stations sampled during the period November, 1938 to February, 1939 (Wisconsin State Committee on Water Pollution, 1939). In both studies, the predominant species in lower Green Bay were found to be the pollution tolerant Oligochaete (Tubificidae), commonly known as sludgeworms, and midge larvae (Chironomidae).

A comparison of the numbers of these species for 1938-39 and 1952 appears in Table 15.

TABLE 15

From: Surber and Cooley (1952)

The increase in numbers of these pollution tolerant species led Surber and Cooley to conclude that there was an increase in pollution during the intervening thirteen years. The complete data from the 1938-39 and 1952 surveys appears in Appendix VII.

A survey by Balch et al (1956) was carried out in January, 1955. The samples from Inner Green Bay (that portion south of a generally east-west line from Long Tail Point to Point Sable) indicated a limited population of bottom-dwelling invertebrates. The fauna of Inner Green Bay was composed principally of pollution tolerant midge larvae and sludge worms. Numbers of midge larvae varied from 0 to 172 per m² and were restricted to four species. Numbers of worms varied from 0 to 2,627 per m². Numerous samples contained no living invertebrates.

Samples from Middle Bay (Long Tail Point to Little Tail Point) contained a large population and wide variety of bottom-dwelling species. The species were of the tolerant or very tolerant varieties.

Outer Bay (north to Sturgeon Bay) contained the most varied invertebrate population of the study. The complete data from the 1955 survey appears in Appendix VIII.

The possibility that January samples were not taken at a population peak was specifically dismissed. It was then concluded that there had been a marked reduction in the numbers of these forms compared to numbers obtained in the earlier studies. This judgment has been criticized by Howmiller and Beeton (1970) who have shown that the population of bottom organisms varies widely during a period of several months.

A survey in 1962-63 (U.S. Federal Water Pollution Administration, 1966) included bottom fauna counts. Unfortunately, the time of year when samples were collected was not specified and the results were expressed as total count of bottom fauna with only qualitative reference to type of animal. Total populations in 1962 and 1963 ranged from 5,000 to 15,000 organisms per square

meter near the Fox River mouth, mostly sludgeworms and bloodworms. The numbers fell to about 500 organisms per square meter 16 km out into the Bay. Some pollution sensitive snails were found about 8 km from the mouth of the Fox River. The concentrations of bottom fauna obtained in the 1962-63 study are shown in Figure 23.

At the same time, benthic populations of 2,000 to 5,000 organisms per square meter were found near the mouth of the Oconto River. The population decreased to 500 per square meter 8 km from the mouth of the river. The area was dominated by bloodworms rather than sludgeworms. A few pollution-sensitive scuds existed less than two miles from its mouth.

A population of 800 organisms per square meter, mostly pollution-tolerant sludgeworms and bloodworms, was found near the mouth of the Peshtigo River.

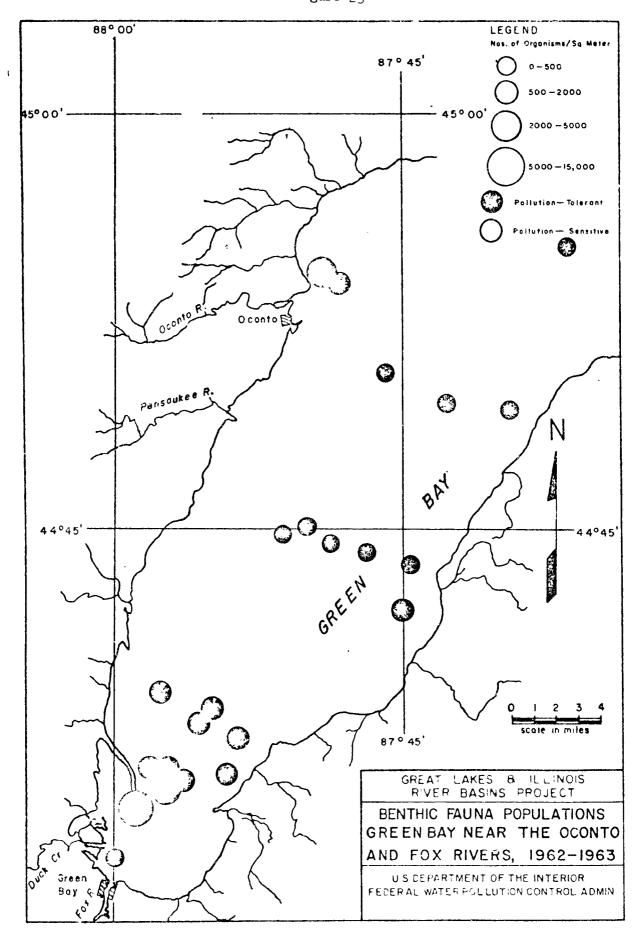

Near the mouth of the Menominee River, the population was 2,500 organisms per square meter. However, about 5 km out from the mouth of the river, a population of 1,300 per square meter of pollution-sensitive scuds was found. The concentrations of bottom fauna in the vicinity of the Menominee and Peshtigo Rivers is shown in Figure 24.

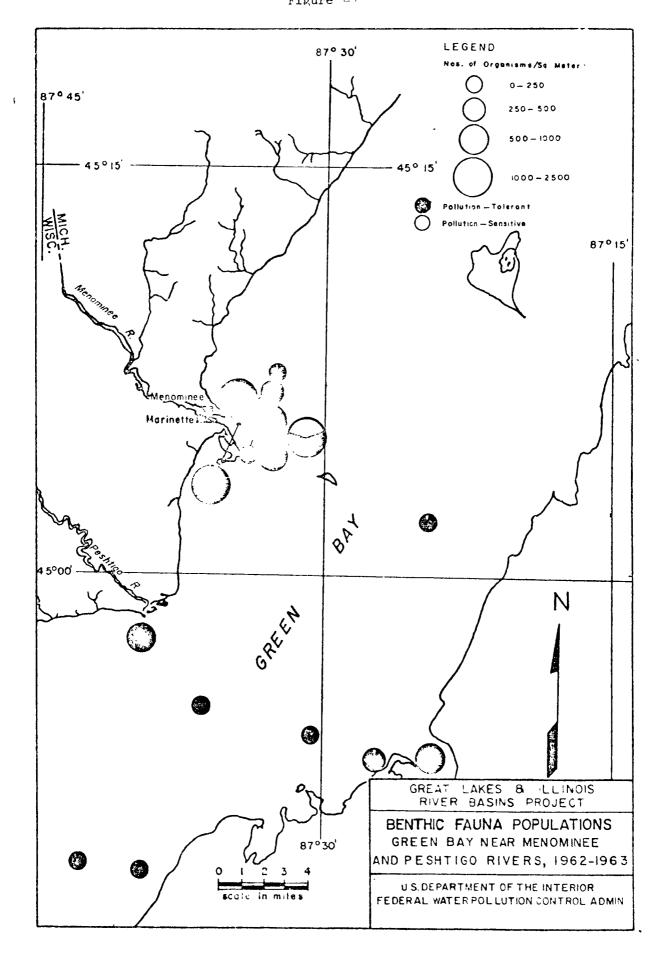

A summary of these data appears in Table 16.

TABLE 16. BENTHIC FAUNA POPULATIONS IN GREEN BAY, 1962-63

Location	Counts	Discussion
Fox River mouth 8 km from mouth 16 km from mouth	5,000-1,500/m ² 500/m ²	mostly sludgeworms or bloodworms some pollution-sensitive scuds mostly sludgeworms or bloodworms
Oconto River mouth 3.2 km from mouth 8 km from mouth	2,000-5,000/m ² 500/m ²	a few pollution-sensitive scuds dominated by bloodworms <u>not</u> sludgeworms
Mouth of Peshtigo River	800/m ²	mostly pollution-tolerant sludgeworms and bloodworms
Menominee River mouth 5 km from mouth	2,500/m ² 1,300/m ²	pollution-sensitive scuds

-83-Figure 23

An extensive water quality investigation of Green Bay was carried out in 1966 and 1967 by the Wisconsin Department of Natural Resources (Schraufnagel et al, 1968). Bottom invertebrate organism populations were obtained during the investigation. The following observations were made:

- 1. Within 1.6 km of the channel in the Inner Bay (south of Long Tail Point) populations were depressed to the extent that no bottom organisms were observed. Between 2.4 and 3.2 km of the channel concentrations of 0 to 270 organisms per m² were noted. At 5 km east of the channel, the population was dominated by midgefly larvae and approximately 190 to 270 bottom macro-invertebrates per square meter were noted. In the intermediate vicinity of Long Tail Point, the bottom populations were dominated by sludgeworms, but the numbers were generally under 1,000 organisms per square meter. In the ship channel, two samples revealed 146 and 314 oligochaete worms per square meter.
- 2. Middle Green Bay (from the entry light north to Sturgeon Bay) had a bottom population dominated by sludgeworms but generally less than 1,600 per square meter. Midgefly larvae (Chironomus) were routinely observed but only about 220 organisms per m².
- 3. Outer Green Bay (Sturgeon Bay to Washington Island) began to reveal significant numbers of pollution intolerant species.

Schraufnagel et al (1968) concluded that only tolerant and very tolerant species dominate the macro-invertebrate population in lower and middle Green Bay. An important qualitative observation was made about nymphs of the pollution-sensitive burrowing mayfly (Hexagenia), commonly known as Green Bay fly, which had been an important part of the benthic community. The adults were once "known to gather under outdoor electric lights in the City of Green Bay, literally by the bushel on many summer evenings" (Wisconsin State Committee on Water Pollution, 1939). The nymphs were found in 31 percent of the samples in 1938-39, but in only one area in 1952. They were absent from samples in 1955 and 1966.

The most extensive survey to date of the Oligochaete fauna of Green Bay has been carried out by Howmiller and Beeton (1970). They sampled 103 stations between the City of Green Bay and Washington Island in 1966-67 and in 1969. Oligochaete worms have been the most abundant macro-invertebrates throughout lower and middle Green Bay in all studies since 1938-39. Howmiller and Beeton (1970) found that these animals comprised 60 percent of all invertebrates sorted from samples taken in the inner Bay and about 50 percent of the macro-invertebrate bottom fauna in the remainder of the Bay. Other invertebrate groups represented in the samples were, in order of abundance: midge larvae, amphipods, isopods, leeches, molluscs and mayfly nymphs.

Large numbers of tubificid Oligochaete worms have long been cited as evidence of pollution. Surber (1957) suggested that an abundance of tubificids in excess of 1,000 per square meter apparently truly represented polluted habitats. Wright (1955) and Carr and Hiltunen (1965) used the following numbers of Oligochaetes to designate pollution areas in western Lake Erie: light pollution, 100-999 per square meter; moderate pollution, 1,000-5,000; heavy pollution, more than 5,000. Howmiller and Beeton (1970) conclude that by these standards, lower Green Bay is heavily polluted. In addition, they find that, according to Wright's standards, the middle Bay was moderately polluted in 1969.

Howmiller and Beeton (1970) have pointed out that little is known of the seasonal dynamics of Oligochaete populations. They showed that the population of the lower Bay decreased sharply at the same stations between October, 1966 and May, 1967. They attributed this decrease to depleted oxygen conditions which occurred over much of this area during the winter months. Howmiller and Beeton (1971) have criticized the conclusions, drawn from the 1955 survey, that there had been a reduction in the number of pollution tolerant benthic animals in the period since the surveys of 1938 and 1952. The survey in January, 1955 may have been taken during a seasonal period of reduced population.

Howmiller and Beeton (1971) have examined earlier data in an attempt to compare current bottom conditions with earlier conditions. They concluded that critical comparison with past studies is difficult because (a) measurements were seldom made at the same stations, (b) the measurements were not made at the same season of the year, and (c) different apparatus and methodology were used. Prior to the mid-sixties, few investigators attempted to identify worms as to species or even genera. In an attempt to eliminate these sources of inaccuracy, the benthos of 27 stations of lower and middle Green Bay were sampled on May 26, 1969. The same stations had been sampled in a similar way on

Table 17 reports the changes which have occurred in the lower and middle portions of Green Bay between 1952 and 1969 (Howmiller and Beeton, 1971).

TABLE 17. PERCENTAGE OF OLIGOCHAETE IN THE BOTTOM FAUNA OF GREEN BAY, 1952 AND 1969

	<u>1952</u>	<u>1969</u>	
Lower Bay (south of entrance light) Middle Bay (entrance light to Sturgeon Bay)	66% 23%	85% 64%	

Goodnight and Whitley (1960) proposed that the relative abundance of Oligochaete worms in the benthos should be used as an index of pollution. A good condition existed if the bottom fauna were less than 60 percent Oligochaete, "doubtful" if 60-80 percent, and high polluted if more than 80 percent Oligochaetes. According to these standards, the Lower Bay has deteriorated from a doubtful condition to a highly polluted state in the intervening seventeen years. The Middle Bay has gone from a "good condition" to a "doubtful" one since 1952.

The aquatic larvae of midges (Chironomidae) were the second most abundant and widespread members of the benthic fauna in both 1952 and 1969. The Chironomidae includes many species which are adapted to a wide range of

environmental conditions. As a group, they display pollution tolerance second only to the Oligochaete. Like many Oligochaete, the pollution tolerant midges have an abundant supply of hemoglobin which makes them very efficient at obtaining oxygen at the low concentrations associated with organic pollution. The midges decreased markedly in the vicinity of the Fox River mouth. Increased numbers were found at stations north of Long Tail Point. This increase was not as great as the increase in Oligochaete with the result that the midges decreased in relative importance from an average of 48 percent in 1952 to 37 percent in 1969 in the middle Bay and from 37 to 26 percent for the entire Bay.

Howmiller and Beeton (1971) have summarized their results for the various species in lower Green Bay for which comparison can be made with the earlier study by Surber and Cooley (1952). Pollution intolerant species are included in these comparisons. These results appear in Figure 25 and are summarized in Table 18.

Howmiller and Beeton (1970, 1971) conclude that if pollution of the Bay, via the Fox River, continues:

- 1. The dominant species will, to an increasing extent, be associated with gross pollution;
- 2. A larger abiotic area around the river mouth can be expected, since conditions have become unsuitable for even the pollution tolerant organisms;
- 3. Midge larvae would be expected to decrease in abundance at stations farther north in the lower Bay;
- 4. The Oligochaete, the only group which increased in absolute and relative abundance between 1952 and 1969, would become even more important in the benthic community. Most others have declined. The zone of maximum abundance will be found farther out into the Bay from the mouth of the Fox River.

^{*} Nematoda were very numerous in many samples but certainly not sampled quantitatively, hence not counted.

[†] Not taken in Ekman grab sample but numbers of animals in parentheses were recorded from Ponar grab sample taken at the same time.

DISSOLVED OXYGEN

Measurements of dissolved oxygen concentrations have been a significant part of Green Bay surveys since 1939 (Wisconsin State Committee on Water Pollution, 1939; Surber and Cooley, 1952; Balch et al, 1956; Schraufnagel et al, 1968; Sager, 1971). The dissolved oxygen content of lower Green Bay depends upon the condition of Fox River water as it reaches the Bay. The temperature, flow rate and dissolved oxygen levels in the Fox River vary considerably with the season of the year. This seasonal fluctuation is the most significant factor which influences the condition of Fox River water as it enters Green Bay. The relative importance of the Fox River in relation to other tributaries of Green Bay has been discussed earlier. (See Table 11).

The discharge of decomposable organic wastes to a confined body of water results in the development of a degree of pollution dependent upon the oxygen requirements of these wastes and the amount of dissolved oxygen availabe in the receiving waters. Where the load of organic wastes exceeds the self-purification capacity of the stream, critical and zero dissolved oxygen concentrations develop at downstream locations.

Biochemical oxygen demand (BOD) measures the amount of oxygen utilized by decomposing organic matter. The relationship between the biochemical oxygen demand and dissolved oxygen is controlled by temperature, time, reaeration rate, and concentration. When the water temperature increases, the dissolved oxygen concentration at saturation decreases and the organic decomposition rate increases. Under these warmwater conditions, the point of low dissolved oxygen will be found near the point of waste discharge. Conversely, with cold temperatures, the zone of low dissolved oxygen is farther downstream from the waste source. Critical oxygen conditions are least likely to occur in open stream waters with the temperature just above

the freezing point because of the higher saturation dissolved oxygen concentrations, low decomposition rates and improved reaeration capacity. With ice cover, much of a stream's reaeration capacity is lost and critical conditions can develop at substantial distances from the waste source.

Dissolved oxygen concentrations were measured extensively during a survey conducted in 1938-39 (Wisconsin State Committee on Water Pollution, 1939). This survey consisted of a series of stations extending northward for 37 km and covered the period from November, 1938 until June, 1939. In November, before ice cover had formed, the dissolved oxygen content was high, varying between 85 and 100 percent of saturation for all samples. The lowest values occurred in waters closest to the mouth of the Fox River. After safe ice had formed, dissolved oxygen samples were obtained within the inner Bay, directly off Point Sable, and at Dyckesville. These samples showed that the waters in the inner Bay were generally at 85 percent saturation, the waters off Point Sable at 30 percent saturation, and the waters at Dyckesville at 90 percent saturation. In February and March, 1939, a series of measurements were made on a weekly basis at more than fifty stations in order to assess the effect of ice cover on dissolved oxygen content and to define the extent and direction of travel of this water low in dissolved oxygen. The results of these measurements were interpreted to indicate that oxygen depletion occurred throughout the period of ice cover. The oxygen depletion was divided into three zones: (1) the zone of deoxygenation, (2) the zone of maximum oxygen depletion, and (3) the zone of recovery. A zone of deoxygenation extended from the mouth of the Fox River to Point Sable; from there a zone of maximum oxygen depletion existed along the east shore for varying distances, increasing in length but not width as the period of ice cover increased. investigators suggested that the zone of maximum oxygen deplotion was occasionally divided into two zones by the introduction of unpolluted water high in oxygen content from the western portion of the Bay. The points where this water was introduced were considered as local zones of recovery where the polluted and unpolluted waters merged. As long as ice cover remained, this zone of recovery receded further and further towards the north.

Data from the late spring months of 1939 indicated that the zone of deoxygenation was located within that portion of the Fox River below the sulfite mills in the City of Green Bay and the zone of maximum oxygen depletion existed within the inner Bay (south of the Long Tail Point--Point Sable line). The zone of recovery caused by reaeration and mixing existed immediately outside the inner Bay. Differences in oxygen demand between summer and winter were ascribed to increased rates of oxygen uptake at the higher temperatures. The workers in 1939 discarded the theory that bottom conditions might be the cause of the areas of low dissolved oxygen content in both winter and summer. They found that the oxygen content in winter at the mouth of the Fox River was always high, a point where bottom conditions were poorest in terms of oxygen demand. Maximum oxygen depletion took place near Point Sable where the water depth was 9.2 meters.

Measurements of biochemical oxygen demand (BOD) accompanied measurements of dissolved oxygen. Under winter conditions, water at the mouth of the Fox River had a high (10-12 ppm) BOD. From this point, the BOD fell rapidly to a low of about 2 ppm near Point Sable and remained constant northward throughout the central and eastern portions of the Bay. In May, 1939, BOD at the mouth of the river was approximately 5 ppm. This value remained the same to a point approximately in the middle of the inner Bay (along the ship channel) and then dropped to 3 ppm within approximately one-half mile of this point and remained fairly constant at this value through the remainder of the

Bay as far north as Dyckesville. These values were more erratic in their distribution than those noted under winter conditions, probably because of mixing from wind action. The BOD and dissolved oxygen measurements for the spring of 1939 are summarized in Appendix IX.

The investigators in 1939 attributed the relationship between dissolved oxygen depletion and biochemical oxygen demand in Green Bay to the waste sulfite liquor in the Fox River water. The differences between winter and summer conditions were ascribed to differences in the rate of the biochemical oxygen demand of the sulfite liquor at high and low temperature.

Dissolved oxygen concentrations in lower Green Bay were measured extensively from the summer of 1955 until March, 1956 (Balch et al, 1956). It was found that from the middle of June until the middle of August, the region south of the Grassy Islands was generally deficient in oxygen (4 to 19 percent saturation. corresponding to dissolved oxygen values of 0.3 to 1.7 ppm). In this same region, the BOD was high (a variation of 15.5 to 24.0 ppm). These results contrasted with the 1938-39 survey which revealed dissolved oxygen values no lower than 2-3 mg/l during all periods when there was no ice cover. No BOD values in 1938-39 reached the levels found in the 1955-56 study.

In the summer of 1955, the region north of the Grassy Islands and south of the Long Tail Point—Point Sable line showed a great deal of variation in dissolved oxygen concentration. On two occasions, samples in this region contained no dissolved oxygen. The BOD here ranged from 11.5 to 26.5 ppm.

Most of the other samples had concentrations corresponding to 50 to 80 percent saturation and had a biochemical oxygen demand of 4 to 9 ppm. The remainder of the measurements throughout Green Bay during the summer of 1955 were described as normal in both dissolved oxygen and in BOD content.

Measurements were made during the period of ice cover in February, 1955 (Balch et al, 1956). Although the data was regarded as inadequate for a comprehensive understanding of the conditions obtained beneath the ice on Green Bay, they were used to give a general indication of winter conditions. A "generally reduced dissolved oxygen content" south of an east-west line from the tip of Long Tail Point to Sable Point. Various analyses for dissolved oxygen within this area ranged from 0.1 ppm to 2.0 ppm. The higher value was noted in the vicinity of the mouth of the Fox River. On the east shore of Green Bay, north of Point Sable to a point approximately midway between Point Sable and Point Comfort, a series of samples taken on February 16, 1955 indicated water that varied from a trace to 6.6 ppm in dissolved oxygen. The higher readings were close to shore. Approximately one mile from shore in water over 20 feet deep, there was no measureable dissolved oxygen.

Samples taken in surveys during late January and early March, 1956, indicated a different condition than that present under the ice in February, 1955. On the east shore of the Bay, dissolved oxygen in the vicinity of Point Sable was about 0.2 ppm on top and 0.0 ppm on the bottom. BOD in this vicinity varied from 7.1 to 11.6 ppm. In the vicinity of Point Comfort, the dissolved oxygen on the bottom ranged from 0.1 to 0.3 ppm, but the surface waters contained as much as 15.0 ppm. Near Dyckesville, there appeared to be some indication of oxygen depleted water as one station contained 0.1 ppm dissolved oxygen on the bottom. On March 6, 1956, the oxygen content of the water in the vicinity of Dyckesville at several stations close to shore was less than 0.5 ppm. In general, reduced oxygen was noted 15 miles farther north in 1956 than in 1955 at the same time of year. The data from the 1955/1956 survey appears in Appendix X.

The survey in 1966-67 by Schraufnagel et al (1968) measured dissolved oxygen extensively under both winter ans summer conditions. Data from February 9-11, 1966 (Table 19) showed that decomposition of discharge wastes

from the Fox River affected dissolved oxygen values for distances of 6 and 8 km from the river mouth. The discharges of the Fox River during the winter months normally revealed variable but nevertheless sufficient oxygen levels to sustain fish life. Observed values in the river were typically between 6 and 12 mg/l at this time. At the same time, samples taken at stations on the west side of the bay at a distance of 29 km from the mouth of the Fox River (designated as Middle Bay) did not show any appreciable dissolved oxygen reduction during this period except in the immediate vicinity of the mouth of the Oconto River (Table 19). Samples on the east side of Middle Green Bay indicated that although ice cover had been of only four weeks' duration, the dissolved oxygen had been substantially reduced near the bottom in the vicinity of Dyckesville (24 km from the mouth of the Fox River), but at Kohl's Landing (40 km) no depletion of dissolved oxygen in the bottom could be observed (Table 19).

On March 10, 1966, just before ice breakup, more samples were taken (Table 20). Dissolved oxygen concentrations at Sable Point remained relatively high during this period. At Dyckesville, the oxygen conditions had deteriorated with a 0.5 mg/l observation at the bottom 0.4 km off shore. In general, ice conditions in the winter of 1966 were similar to those in 1939. Dissolved oxygen levels were found to be similar in the Sable Point area in the two years. However, in the vicinity of Dyckesville, limited sampling suggested that the dissolved oxygen concentrations were lower than in 1939, especially near the bottom. The region of the inner Bay in 1966 had consistently lower concentrations of DO than did this region in 1939. The region north of Long Tail Point is less amenable to comparison because of the paucity of data for the winter of 1966. However, there were stations in 1966 in the region about Long Tail Point which had DO concentrations significantly lower than values found in this region in 1939. The judgment is made here that DO concentrations in the winter of 1966 were generally lower in several regions of Green Bay than they were in 1939.

Extensive measurements were made during the summer of 1966 (see Figure 19). Monitoring stations in Zone A (the mouth of the Fox River, Mason Street Bridge) revealed ample dissolved oxygen during the winter months, but low dissolved oxygen during the summer months. On April 6, the dissolved oxygen was 12.0 mg/l at the surface. By July 5, the concentration had fallen to 2.8 mg/l. On August 12, no dissolved oxygen could be detected in the river. Gas bubbles were observed and hydrogen sulfide odors were pronounced. The low dissolved oxygen values generally prevailed through October 20.

The area between the mouth of the Fox River and Grassy Island (Zone B) was affected by the waste load of the Fox River. On July 5, the dissolved oxygen concentration was still over 4 mg/l. On August 12, the dissolved

oxygen in this region was less than 1 mg/l. This condition persisted through September 7, but by October 20 the dissolved oxygen was over 4 mg/l at Grassy Island.

The zone (Zone C) just east of the ship channel to the east shore and extending approximately 0.8 km from the shore was defined distinctly because of wind blown algae accumulations and wave action along the shore. The effect of zero detectable oxygen in the Fox River discharge during the summer was noted in this region. For a distance of 2.4 km east of the channel, no oxygen was detected. Three point two (3.2) km east of the channel, the dissolved oxygen concentration was 4.1 mg/l and at 4.0 km, the dissolved oxygen concentration was variable but probably in the vicinity of 6 mg/l. On October 20, when the river was still discharging water devoid of dissolved oxygen, the station east of the channel was still less than 1 mg/l, while at 3.2 km, the concentration was approximately 3 mg/l.

^{*}For station location, see Figure 27.

The remaining portion of the Bay below Long Tail Point and east of the ship channel (Zone D) was found to contain a concentration of dissolved oxygen sufficient to sustain fish and fish food organisms. Only one sample in the channel, halfway between Grassy Island and Long Tail Point, revealed less than 2 mg/l dissolved oxygen. The other samples revealed concentrations greater than 4 mg/l throughout the summer months. This represented some depletion due to waste stabilization since without wastes saturated values of 8 to 10 mg/l dissolved oxygen would be expected.

The west side of the Bay below Long Tail Point (Zone E) showed dissolved oxygen values that appeared to be free of the influence of wastes.

The region north of Long Tail Point and extending to Sturgeon Bay (Zones G and F), as well as the region from Sturgeon Bay to Washington Island, showed no effects from the waste discharges of tributary streams during the summer of 1967.

In early February, 1967, the ice cover in lower Green Bay exceeded 0.4 meters (20 inches). On February 8, the dissolved oxygen concentration within three miles of the Fox River mouth was sufficient to sustain fish and fish food organisms. However, at a distance 6.4 km from the mouth of the Fox River and east of the ship channel (Sable Point area), the dissolved oxygen concentration was less than 0.5 mg/l (Table 21).

^{*}For station location, see Figure 28.

Dissolved oxygen concentration near the shore north of Sable Point was essentially zero. Concentration increased along the ship channel where values were probably not influenced by waste stabilization (Table 22).

The area east of the harbor light and extending toward the shore revealed no dissolved oxygen at the bottom and only 2 to 3 mg/l at the surface. Proceeding west, north or east, the dissolved oxygen condition tended to improve, exceeding 5 mg/l at all surface sites. The bottom concentrations were significantly reduced (less than 3 mg/l) out to approximately 26 km. Beyond this distance,

there was no depletion in dissolved oxygen on February 9. Commercial fishermen during this period had been forced to move nets from sites that were recording less than 1 mg/l at the bottom and were having no difficulty in areas recording the higher values.

In order to determine how far the front of low dissolved oxygenated water had proceeded, the region from Dyckesville to Sturgeon Bay was surveyed again in March. By March 9, the commercial fishermen had abandoned the Dyckesville area as a site of net fishing. The dissolved oxygen concentrations were not as low as were observed a month earlier. Stations 2, 3 and 4 (Table 23) which had previously recorded dissolved oxygen values of less than 1 mg/l, revealed values of no less than 2 mg/l. However, stations 10, 12 and 13, which were approximately 29 km from the mouth of the Fox River and which revealed no apparent oxygen depletion in February, had less than 1 mg/l on March 9. Stations 27 and 28 (43 km from the mouth of the Fox River) also had less than 1 mg/1 dissolved oxygen near the bottom. In this region, fishermen were taking dead fish out of one end of their nets while 800 feet away at the other end they were taking live fish. The dissolved oxygen concentrations at these points were 0.1 and 9.9 mg/l, respectively. These observations were suggestive of the magnitude of the oxygen depletion and of the sharp gradients in oxygen concentrations that can be detected miles from the source of wastes.

A final series of dissolved oxygen measurements were made on March 23, 1967 at stations 40-43 km from the mouth of the Fox River. Low concentrations of dissolved oxygen were found in almost all bottom waters between the channel and 0.8 km from the east shore. Surface waters retained an adequate dissolved oxygen concentration to sustain fish life.

A comparison of D.O. concentrations in the winters of 1939 and 1967 in Green Bay shows that concentrations in the inner Bay (south of Long Tail Point) were substantially lower in 1967 than in 1939. The concentrations in the region above Long Tail Point and along the eastern shore were consistently lower in 1967 than in 1939.

- 1. During warm weather, critical dissolved oxygen conditions are common on the Fox River from Appleton through the City of Green Bay and for a distance of 3-5 km into the Bay.
- 2. In the colder months, from about mid-November into April, the dissolved oxygen in the river is generally in excess of 5 mg/l. However, during the winter and particularly after prolonged heavy ice cover, low dissolved oxygen concentrations can extend into Green Bay for a distance of nearly 50 km.
- 3. During the period of open water, reaeration causes a recovery of oxygen levels beyond the Long Tail Point area.

In general, the dissolved oxygen levels in 1966-67 were lower in several regions of the Bay compared to levels for the same region in 1939.

Sager (1971) measured the dissolved oxygen concentrations in lower Green Bay on a weekly basis during the summer of 1970. Nine sampling stations were set up along a line which ran from the Fox River mouth to a point 22 km up the Bay (Figure 2).

It was estimated that about 60 percent of the estimated 500,000 pounds of 5-day, 20° C BOD discharged daily to Green Bay came from the Fox River (U.S. Federal Water Pollution Control Administration, 1966). The high BOD concentrations in the river lead to depressed oxygen levels for a distance of several miles into the Bay (Table 24).

On August 21, the dissolved oxygen level had dropped to 0.2 mg/l at the mouth of the river. In general, low values of dissolved oxygen were found near the river mouth, followed by rapid recovery of oxygen levels at distances removed from the river mouth.

TABLE 24. DISSOLVED OXYGEN CONCENTRATIONS--1970

STATIONS	I	II	III	IV	V	VI	VII	VIII	IX

^{*}See Figure 2 for station locations.

Summary

In summer, high biochemical oxygen demand and rapid assimilation of wastes at warm temperatures leads to a condition of zero or, at best, low dissolved oxygen concentration in the water of the Fox River as it enters Green Bay. The rapid assimilation of these waste continues in the lower Bay keeps oxygen concentrations low despite open waters and natural reaeration. Beyond Long Tail Point, the natural reaeration allows for a rapid recovery of dissolved oxygen concentrations. Recovery is aided in summer by photosynthesis associated with dense algal growth.

In winter, the concentrations of dissolved oxygen in the river remains high (8-10 mg/l) because of reduced assimilation processes at lower temperatures.

Ice and snow cover on the Bay block the physical transfer of oxygen to the Bay.

The result is that the slow assimilation of wastes continues for distances up to 50 km from the mouth of the Fox River. The flow pattern of river water causes these conditions to exist along the east side of the Bay.

PUBLIC ATTITUDES TOWARD GREEN BAY

The majority of people who use or have contact with Green Bay do so in a recreational sense. These people are usually not aware of the many aspects of water quality which are important in Green Bay. Ditton and Goodale (1972) have surveyed the attitudes of those who use Green Bay in an attempt to more precisely define those aspects of water quality which are important to these people. These attitudes should play a significant role in planning the allocation of Green Bay resources.

The recreational use of water has been the most rapidly growing use of water. Recreational requirements of the Great Lakes Basin population may triple from 637 million recreational days in 1970 to 1.9 billion recreational days in 2020 (Great Lakes Basin Commission, 1971).

The commission found that 44 percent of the population preferred water-based activities over any other. While population levels and recreation demands in the Great Lakes Basin are both increasing, the effective supply of Lake Michigan water is being systematically reduced through conflicting water uses. These conflicts have resulted in degraded water quality conditions, closed beaches and reduced shoreland property values.

The multiple use concept of management has recreation as but one water use. Other uses include navigation, waste disposal, power generation, flood control, wildlife conservation, industrial water supply and irrigation. Theoretically, Lake Michigan is supposed to support all these uses. The term multiple use has come to stand for conflicting water uses eventually leading to impairment or displacement of some uses.

The passage of the Federal Water Project Recreation Act (PL 89-72) granted statutory authority for outdoor recreation as an equal among project purposes. The act recognized that the federal government had a responsibility

to meet at least part of the demand for outdoor recreation. In addition to impaired water quality, inappropriate shoreland development, grandfather clauses in zoning ordinances, erosion processes, and lack of public access and/or facilities are shoreland conditions that restrict the optimal recreational use of the Lake Michigan coastal zone.

A decline in water quality in Green Bay has had several effects on marine recreational uses of the Bay and the attitude of people toward the Bay. A large dislocation of recreational use of Green Bay has occurred, particularly in the southern regions and particularly for body contact and partial body contact recreation. This is not a recent phenomenon, but one of gradual erosion over a period in excess of the four decades for which some documentation is available. The economic loss is substantial. Individual loss occurs in time and money for dislocation. There is a community loss of revenue due to suppressed value of adjacent properties. There is a loss of revenue which accrues from diminished recreational uses. There is a loss of weekend and seasonal trade. There is a loss of aesthetics. Smell and dead fish reduce the recreational potential of Green Bay waters for noncontact users.

Different groups are deterred by different conditions as they view them-either the perception or the condition must be changed, depending on how closely
perception matches actual conditions.

The survey by Ditton and Goodale (1972) can be used by economists, planners, state and local officials, educators and numerous other interested parties as a guide to the demand for recreational resources in Green Bay by user group and location and by place of residence and other categories. Water quality and characteristics as perceived by users rather than as monitored by scientists can be used to determine the ramifications of action designed to improve the condition of the Bay.

REVIEW OF HISTORICAL DATA SOURCES

AND GENERAL COMMENTS

Pollution control enforcement became a reality in Wisconsin when the 1927 state legislature created the Committee on Water Pollution, granted authority for the issuance of orders and provided penalties for the violation of orders. The committee was charged with the responsibility of coordinating all state activities concerning water pollution control and one of its first activities, in conjunction with representatives of the pulp and paper industry and the state Board of Health, was to engage in a series of surveys of all pulp and paper mills throughout the state.

These Cooperative Annual Wastewater Surveys provided the means for monitoring the progress of the industry's efforts to improve the quality of its waste discharges in accordance with an agreement reached by pulp and paper mill executives and the participating state agencies in 1926. These early improvements included the reduction of fiber losses by way of savealls and recirculation systems and more efficient use of manufacturing chemicals. Appendix I presents the results of these surveys for mills located along the Lower Fox, Oconto, Peshtigo and Menominee Rivers, for the period of 1950 - 1967 when the mill surveys were discontinued. Data for 1971 and 1973 were obtained from the Wisconsin Pollutant Discharge Elimination System (WPDES) permit files and the Wisconsin Department of Natural Resources' NR 101 monthly industrial reporting files respectively. The limitations for 1975 and 1977 correspond to proposed EPA effluent guidances as established in accordance with the Federal Water Pollution Control Act Amendments of 1972. These guideline figures are subject to revision and represent 30-day maximum allowable averages. Appendix II briefly describes existing and proposed wastewater treatment facilities at the various pulp and paper mills of interest to this study.

At the time of the inception of the Committee on Water Pollution, the lack of adequate treatment of municipal wastes was of great concern, primarily because of the public health hazards involved. As a result, the state was divided into 28 major drainage basins for the purpose of informing local communities about the necessity for treatment of sewage and industrial wastes. By 1940, approximately 90 percent of the sewered population of the state was connected to treatment plants and by 1971, 76 percent of the existing plants provided secondary biological treatment. Drainage basin surveys have been conducted throughout the state at various intervals and have been instrumental in defining all significant point sources of pollution and evaluating river conditions in relation to those sources. Appendix V summarizes the results of the most recent basin survey for the Lower Fox, Oconto, Peshtigo, and Menominee Rivers and identifies the location of each point source in terms of River miles from the mouth of the respective rivers. The basin survey reports are now the responsibility of the Water Quality Evaluation Section, Bureau of Water Quality, Wisconsin Department of Natural Resources (WDNR).

River waste loadings from municipal sewage treatment plants are listed in Appendix III. The tables present both treated and known raw sewage loadings whereas the graphs depict only the treated effluent data. Raw sewage bypass, as listed in the appendix, refers to bypass at the treatment plant as a result of overloaded conditions. This does not include bypassing through overflows in combined sewer systems, designed for the collection of both municipal sewage and storm water runoff. For those years in which bypass data are not listed, bypassing probably occurred but was not monitored.

In addition to the proposed changes and improvements at various sewage treatment plants, as described in appendix IV, and in accordance with the agreements reached by the participating members of the Lake Michigan Enforcement Conference held in 1968, it is the goal of the state of Wisconsin to control pollution from all combined sewerage systems by July, 1977. This action includes the separation

of all existing combined sewers and the prohibition of this type of collection in new developments except where alternate techniques can be employed. Until recently, most of the fourteen communities of interest to this study had utilized combined sewers. As of this writing, only De Pere, Oconto and Marinette have yet to complete their separation programs.

The enforcement conference also provided a recommendation for phosphorus removal from all municipal wastewater discharges. Section NR 102.04 of the Wisconsin Administrative Code, dated September, 1973, incorporates this recommendation by stating:

Communities with a population of 2,500 and over in the lakes Michigan and Superior basins shall achieve an 85% reduction of phosphorus on an annual basis, and there shall be a commensurate removal from industrial wastes containing more than 2 mg/l of total phosphorus and having an annual phosphorus discharge greater than 8,750 pounds.

A proposal is now being considered which would replace "85% reduction" with a limit of 1 mg/l of total phosphorus on a monthly average basis.

Information for the Green Bay Metro treatment plant for the years 1946 - 1962 was obtained from the Annual Report of the Green Bay Metropolitan Sewerage District Commission while the data for 1966, and for the years prior to 1971 for all remaining treatment plants, are found in their respective basin survey reports. BOD₅ and suspended solids data for 1971 - 1973 were obtained from the monthly Sewage Treatment Plant Operator Reports whereas projected waste loadings correspond to proposed EPA guidances and represent maximum allowable 30-day averages.

Sewage treatment plant nutrient data was acquired from several sources including: 1) 1968 data - basin survey reports of 1969 for the Oconto, Peshtigo and Menominee Rivers; 2) 1971 data - report of Sager and Wiersma, 1972; 3) 1972 data - Summary Report on Water Quality and Wastewater Discharges during the summer of 1972, by the Water Quality Evaluation Section, Bureau of Water Quality, WDNR; and 4) 1973 data - Treatment Plant Operator Reports, 24-hour composite

surveys, and individual grab samples. Kjeldahl nitrogen (KJEL-N) refers to the particulate and dissolved organic fractions of nitrogen plus inorganic ammonia nitrogen (NH₃-N). Total -P includes soluble and particulate organic and inorganic phosphorus fractions whereas soluble phosphorus (SOL-P) refers only to the dissolved orthophosphate (PO_{\downarrow}) species as derived by filtration of water samples through 0.45 micron filter paper prior to analysis.

Appendix VI is a summary of surface water quality surveys. The data for 1950 - 1960 are the results of cooperative stream surveys which were carried out in conjunction with the mill surveys. Data for the remaining years, 1961 - 1973, were obtained from four of the 43 monthly monitoring stations located throughout the state, the results of which are compiled by the Surveillance Section, Bureau of Water Quality, WDNR. All river flow data were collected by the U.S. Geological Survey.

The interpretation of the combined effects of municipal and industrial wastes on Green Bay requires at least a reasonable account of actual waste loadings entering the bay from its tributaries. Appendix XI is a summation of 5-day BOD loadings from the Lower Fox, Oconto, Peshtigo and Menominee Rivers for the years 1956 - 1973. The loadings were calculated from the data in Appendix VI according to the following formula:

In all cases the river sampling stations, from which the <u>actual loadings</u> were determined, are upstream from one or more important point source. In order to arrive at the <u>estimate</u> of total loading from each river, the combined downstream point source loadings, for those years in which complete data are available, were added to the actual loadings. This is valid because of the proximity of the point sources to the river sampling stations. The Peshtigo estimate will be

somewhat inflated since the last major point source is about 10 miles upstream from the bay. Data for the years 1956 - 1960 are averages for the summer months only and will reflect a seasonal influence, especially in regards to the levels of dissolved oxygen.

APPENDIX II.

LOWER FOX, OCONTO, PESHTIGO AND MENOMINEE RIVERS - PRESENT AND PROPOSED WASTE TREATMENT FACILITIES, PULP AND PAPER MILLS

APPENDIX

LOWER FOX RIVER

Green Bay Packaging, Inc. - Green Bay

Waste abatement facilities include internal controls and an evaporation and burn system. A reverse osmosis system is planned to be operational in 1975 with the ultimate goal for a complete recycle program.

Charmin Paper Company - Green Bay

Currently has internal treatment through the use of savealls, a clarifier for water treatment and air scrubber solids, and an evaporation and burn system for concentrated pulp mill liquors. Company proposes to divert residual pulp mill wastes to the Green Bay Metro treatment plant by October 1, 1975.

American Can Company - Green Bay

Present facilities include dual primary settling lagoons for paper mill wastes and an evaporation and burn system for concentrated pulp mill wastes. By October 1, 1975, will divert residual pulp mill wastes to the Green Bay Metro treatment plant.

Ft. Howard Paper Company - Green Bay

Secondary biological treatment is now in operation.

Nicolet Paper Company - De Pere

Treatment includes duplicate primary clarification in addition to sludge dewatering.

Thilmany Pulp and Paper Division - Kaukauna Hammermill Paper Company

Presently has primary clarification plus polishing ponds for paper mill wastes and an aeration lagoon plus polishing pond for pulp mill wastes. Investigating alternatives for improved secondary treatment to meet proposed EPA effluent guidances by July 1, 1977. Has also requested an adjudicatory hearing from the Department of Natural Resources for review of the guidance limitations in the issued permit.

Appleton Papers - Combined Locks

Treatment includes duplicant primary clarifiers plus evaporation and burning for concentrated pulp mill wastes. Now investigating secondary biological treatment to meet EPA proposed effluent guidances by January 1, 1977.

Kimberly - Clark - Kimberly

Has duplicate primary clarifiers and sludge dewatering. Currently investigating secondary biological treatment in order to meet proposed EPA effluent guidances by July 1, 1977.

Consolidated Paper Company - Appleton

Evaporation and burn system for concentrated pulp mill wastes. Internal primary clarification is proposed to be operational by September 1, 1975. Remaining wastes are proposed to be directed to the Appleton municipal treatment plant by July 1, 1977.

Riverside Paper Company - Appleton

Concentrated wastes are diverted to the Appleton municipal treatment plant. Dilute saveall wastes are discharged directly to the Fox River.

John Strange Division - Menasha Corp. - Menasha

Concentrated wastes are now sent to the Neenah - Menasha Metro treatment plant. Diluted wastes diverted to the Fox River. Additional treatment alternatives are being investigated to meet proposed EPA effluent guidances by January 1, 1976.

Gilbert Paper Company - Menasha

All process wastes are presently directed to the Neenah - Menasha Metro treatment plant along with water treatment solids.

George A. Whiting Company - Menasha

Presently provides internal saveall treatment. Proposes to install primary treatment by January 1, 1976 in order to meet proposed EPA effluent guidances.

Kimberly - Clark, Lakeview Mill - Menasha

Currently provides primary clarification plus sludge dewatering.

Kimberly - Clark, Badger Globe Mill - Neenah

All process wastes are directed to the Neenah - Menasha Metro treatment plant.

Kimberly - Clark, Neenah Division

All process wastes directed to the Neenah - Menasha Metro treatment plant. Water treatment plant solids proposed to be diverted to municipal system by August 1, 1974.

Bergstrom Paper Company - Neenah

Present treatment for process wastes consists of a primary clarifier plus sludge dewatering facilities. These effluents are proposed to be diverted to the Neenah - Menasha Metro treatment plant by July, 1976. Company has requested an adjudicatory hearing for review of the Department of Natural Resources issued permit which requires connection to the municipal plant.

OCONTO RIVER

Scott Paper Company - Oconto Falls

Present treatment includes primary clarification for paper and dilute pulp wastes and evaporation and burning and a holding lagoon for concentrated pulp mill wastes. Present plans are for modification of the holding lagoon into a joint municipal-industrial aerated lagoon system to serve the mill and the City of Oconto Falls.

PESHTIGO RIVER

Badger Paper Mills - Peshtigo

Currently has duplicate primary settling lagoons for paper mill wastes and has installed a new evaporation and burn system for concentrated pulp mill wastes. Residual pulp mill wastes are proposed to be diverted to a joint municipal and industrial treatment plant now under construction for the mill and the City of Peshtigo.

MENOMINEE RIVER

Scutt Paper Company - Marinette

Existing treatment consists of primary clarification with backup settling lagoon and sludge dewatering. Presently investigating alternatives for improving existing systems to meet proposed EPA effluent guidances by July 1, 1976.

APPENDIX IV.

LOWER FOX, OCONTO, PESHTIGO AND MENOMINEE RIVERS - PRESENT AND PROPOSED WASTE TREATMENT FACILITIES, MUNICIPAL SEWAGE TREATMENT PLANTS

APPENDIX IV

LOWER FOX RIVER

Green Bay Metropolitan Sewerage District

Present facilities include a trickling filter type of sewage treatment with disinfection. Plant expansion is now underway and will consist of activated sludge plus phosphorus removal with a design capacity of 52 MGD.

De Pere, City

Treatment consists of activated sludge with disinfection and phosphorus removal. Plant design is underway and will include expansion of existing activated sludge system plus tertiary filtration.

Wrightstown, Village

Treatment is by way of trickling filter system with disinfection of effluent. No future plans have been submitted.

Kaukauna, City

Kaukauna plant also provides treatment for Village of Combined Locks. Treatment consists of activated sludge with disinfection and phosphorus removal. Plant design is currently underway for a regional system to be designated as "Heart of the Valley" Sewage Treatment Plant. Treatment will consist of activated sludge process plus phosphorus removal. Approximate completion date, 1977-1978.

Little Chute, Village

Currently has activated sludge process with disinfection and phosphorus removal. Plans are to abandon plant and connect to Heart of the Valley plant.

Kimberly, Village

Facilities include activated sludge treatment with disinfection and phosphorus removal. Plans are to abandon current plant and connect to Heart of the Valley plant.

Appleton, City

Treatment consists of activated sludge with disinfection and phosphorus removal. Plant designs are complete and include modification of the activated sludge system.

Menasha, Town - S.D. #4, East Plant

Two parallel treatment plants, both of which are of the activated sludge process with disinfection and phosphorus removal. No future plans submitted.

Menasha, Town - S.D. #4, West Plant

Contact stabilization process with disinfection of effluent. No future plans submitted.

Neenah-Menasha Sewerage Commission

Present facilities provide for activated sludge treatment plus disinfection and phosphorus removal. Plant designs have been completed and include expansion of activated sludge process to handle 40 MGD.

OCONTO RIVER

Ocon City

tment consists of trickling filter plus activated sludge with disinfection and phosphorus removal.

Oconto Falls, City

Currently has trickling filter with disinfection of effluent. Joint treatment facility with Scott Paper Company under consideration. Proposal is for aerated lagoon.

Gillett, City

Activated sludge process with disinfection. No future plans have been submitted.

PESHTIGO RIVER

Peshtigo, City

Treatment is by way of trickling filter and disinfection. Aerated lagoon for joint treatment with Badger Paper is now under construction.

MENOMINEE RIVER

Marinette, City

New activated sludge plant was placed in operation during 1973. Treatment provides disinfection and phosphorus removal. Previously, only primary treatment was provided.
