SELECTED ECONOMIC CONSIDERATIONS

Production Levels

During 1973, VC production was at the 5.3 billion pound level with PVC and its copolymers at the 4.6 billion pound level. PVC has become a very important polymer as evidenced by the broad dependence of nearly every branch of industrial and commercial activity upon products and components fabricated from this plastic. In Table 1, major PVC products manufactured during 1973 are identified.

The U.S. VC/PVC industry has been operating for more than forty years, and over the past five years has shown an average annual growth rate of 14 percent -- a rate of growth that had been expected to taper off only moderately in the next few years.

The size of this industry can be appreciated by considering that the synthesis of the monomer is conducted in fifteen U.S. plants, and forty-three facilities are engaged in polymerization of PVC (including its use as a copolymer) with almost all of these plants currently operating at or near capacity. At least 7,500 plants are engaged in fabricating products from PVC. About 1,500 workers are employed in monomer synthesis and an additional 5,000 in polymerization operations. Estimates have suggested that up to 350,000 workers may be associated with the fabrication plants.

The wholesale value of the annual output of fabricated products based on PVC is at least several billion dollars.

Competitive Substitution

Should requirements for worker safety or environmental controls drive the price of PVC resin upward, it seems likely that some PVC products would be displaced by products using other plastics or other materials. Other products dependent on PVC might disappear altogether from the marketplace. Probably one-fourth to one-third of current PVC products by value are marginally competitive with other plastic products. At significantly higher prices a lesser number probably would find substitutes in other materials at higher costs. Identified in Table 2 are a few of the substitute materials that might be considered. For some uses, there are no apparent substitutes.

Table 1
MAJOR PVC PRODUCTS

Market Category	Products	1973 1000 metric tons
I. Apparel	Baby pants	12
	Footwear	66
	Outerwear	31

International Aspects

U. S. based manufacturers currently produce about one-third of the western world's supply of resins, with the U. S. market also consuming about one-third of the total. In 1973, 3.7 percent of PVC and 7.8 percent of VC manufactured in the United States were exported. Prior to the recent U. S. concern over worker and environmental controls at VC and PVC facilities, there was no reason to anticipate a major change in the U. S. share of production or market during the next few years. Recent increases in demand for PVC resins -- and concurrently for VC -- at attractive prices have been of worldwide dimensions with expansion plans for PVC manufacturing being considered by a number of companies at home and abroad.

There is presently an import duty on PVC resin from countries with status as Most Favored Nations of 1 1/4 cents per pound plus six percent ad valorem and from other nations of four cents per pound plus 30 percent ad valorem. Given the current U. S. market price of 18 to 24 cents per pound for the general purpose uncompounded resin, there has been little incentive to import PVC resin. Also, there currently is little export incentive because of short U. S. supply and unattractive foreign prices. However, higher prices as a result of more stringent worker or environmental controls in PVC resin plants in the United States than abroad might well stimulate significantly increased imports.

Control Technology

While there appear to be a number of general approaches for reducing the discharge of VC into the environment at VC and PVC resin plants and the discharge of PVC at resin plants, in many respects the approaches must be tailored to the individual plants. All VC plants and some PVC resin plants are outdoors while other PVC plants are at least partially enclosed. A variety of production processes are used, and different kinds of technology are employed. However, there are some common measures that would reduce VC emissions.

FOR VC PLANTS:

1. Reducing the escape into the atmosphere of VC when venting the tank car gauge tube, disconnecting the feeding line, and closing the valves during rail tank car loading. Mechanical disconnect devices and double block and bleed piping are available to ease this problem.

2. Improving the quality of pumps to reduce the possibility of leakage due to failure of seals. Pumps are available today which could minimize this problem.

3. Venting unintentional leaks and spills into a system which is flared and, preferably, scrubbed.

FOR PVC RESIN PLANTS:

1. Collection and destruction of purge gases from the reaction kettles prior to opening for cleaning, sampling, or recharging.

2. Centralized collection and filtering of VC vapor discharges from dryers and centrifuges.

With regard to PVC particulate in air and water discharges, improved housekeeping and relatively simple ventilation filtering systems are usually technically feasible and effective.

Laboratory data have shown that VC can be adsorbed on activated carbon. Concentrated VC vapor streams have produced a recovery working capacity on carbon equivalent to about ten percent of the carbon weight. Ambient air contaminated with low levels of VC produces significantly lower adsorbent working capacities. Control of dilute VC is therefore possible but may not be practical using activated carbon. Carbon regeneration using steam or pressure swing appears possible, with recovery of desorbed VC for recycle.

Clearly, these approaches will not eliminate losses but should materially reduce them. In the longer run, the development of continuous flow processes, the use of larger kettles, better housekeeping, and/or reductions in the number of feed lines might result in more dramatic reductions of VC leakage.

THE MATERIALS BALANCE AT VINYL CHLORIDE AND POLYVINYL CHLORIDE FACILITIES

Vinyl Chloride Production Facilities

Detailed, reliable data for estimating material losses at VC facilities with precision are not readily available. Therefore, only generalized estimates have been attempted.

A simplified block diagram for production of VC from ethylene and chlorine is shown in Figure 1. Some VC complexes utilize oxychlorination units; others produce ethyl chloride from the by-product hydrogen chloride (HCl) and ethylene. However, the production of dichloroethane (EDC) allows for many approaches to recycling of light and heavy materials such that the losses of VC are reduced. Even vent streams of inerts can be scrubbed with EDC for maximum removal of VC before venting. Light ends such as methane are usually flared and VC is converted to water and small amounts of HCl.

VC losses have come primarily from vent streams, the storage and transportation loading systems, and seepages from pumps. If vent streams are not scrubbed or flared, the amount of VC reaching the atmosphere increases considerably. This in turn is influenced by the purity of the ethylene and the chlorine being fed into the units. Usually, these inerts come out in the EDC unit but may be carried on depending upon the producer's philosophy regarding the purity of the EDC to be fed to the cracker. Experience has been that the higher the purity of EDC both with regard to light and heavy material, the greater the efficiency of the cracking.

It is frequently difficult to pinpoint the areas and quantities of VC losses. However, some generalizations can be made for, as an example, a plant producing 500 million pounds per year of VC. (The industry is heading toward plants of this size and larger.) Tank car loading losses may be several hundred pounds per day. Vent stream losses could reach another 100 pounds per day while losses of VC entrapped in the water effluent might be a few pounds per day. In addition to these very small operating losses, there are undoubtedly unintentional losses from leaking pumps, flanges, and containment vessels, with total plant losses probably less than 0.1% or less than 500,000 pounds per year.

From an environmental standpoint, the disposal of the heavy chlorinated hydrocarbons may also present a problem. Some are sold to solvent scrap dealers for salvage. In the past much of the material has been dumped at sea or put into landfills or deep wells. More recently, incineration has been used, which is known to produce HCl emissions.

Polyvinyl Chloride Polymerization Facilities

Reasonably reliable data are available for estimating material losses at PVC facilities. However, generalizations applicable to the entire industry must be surrounded with many caveats. It must be emphasized that there are a number of PVC processes, and each plant has its own idiosyncrasies.

VC losses will fluctuate depending on the care exercised in operating the PVC plant, types of products produced, frequency of product change, method of PVC shipment, and emergency situations. Estimates of losses have varied widely in the industry, indicating the complexity of establishing precise losses for a given facility and overall losses on a nationwide basis.

In general, older PVC plants are smaller than those being built today and are equipped with smaller sized reactors. With small reactors, the number of batches required to produce a given amount of PVC is greater, and thus the number of process steps are increased with a greater potential for loss of both VC and PVC. Further, a small plant has the disadvantage of having to make frequent resin changes to meet customer demands. During these changeovers a certain amount of off-grade resin is produced.

In addition, older plants have the added burden of higher maintenance than new plants, but this tends to stabilize after a few years. The handling of VC and the production of the high quality resins which are demanded by the marketplace require a reasonable maintenance program. Maintenance consists primarily of the care of agitator seals, pump seals, and valves and the removal of polymer which slowly builds up in VC lines -- primarily in the recovery system. Although many older facilities have been in operation for years, they are usually not the same as when first installed. Some of the operators have continually updated the plants for many reasons including labor savings systems, new product requirements, replacement of wornout equipment, addition of new product lines, and safety.

When VC was cheap and there was little concern about its toxicity, the emphasis was almost exclusively on productivity. Often this resulted in high losses of VC to the environment as recovery cycles were reduced. Today, the picture is changing. Not only are the producers trying to reduce the direct VC losses, but they are also trying to minimize PVC losses by scheduling longer production runs between product changes. As an example, the newer large plants are set up with multiple production lines. This allows the dedication of one line to a given product which results in very low resin loss due to product change.

The traditional method of stating yield of VC in PVC plants has been based upon pounds of prime resin in the bag as compared to VC invoiced. This often has led to a misunderstanding about VC losses with the interpretation that a 94% yield means 6% VC loss to the environment. In fact some VC may never actually be received because of the inability to measure the weight of tank cars accurately, some of the losses are in the form of PVC scrap, and some losses escape as PVC particles.

A properly run and maintained suspension plant using technology that is ten years old should be capable of obtaining a 95% or higher yield unless some especially esoteric resin is being produced along with large amounts of scrap or off-grade resin. For the older plants, the losses will probably be significantly higher. Other than overall sloppy operation, the recovery system is the single most important part of the plant governing VC losses. If insufficient time is allowed or vacuum is not applied, then the VC content in the PVC/water slurry will be greater than necessary. As a result, VC losses will occur in the centrifuge effluent water, drier/ product collector vent air, the venting of the reactor, and the slurry tank.

The magnitude of VC and PVC losses in a typical PVC plant is described in Figure 2. These losses are expressed as a range of losses depending on the feed rate, reactor size, reactor cleaning procedures, batch sizes, level of technology, and general housekeeping and operating procedures.

The following comments on manufacturing practices may help put these losses into perspective:

1. VC Feed - This is shipped as virtually 100% VC and does not normally contain an inhibitor.

2. VC Unloading - Considering normal losses in disconnecting the piping, sampling, tank gauging, pump and compressor seals to the tank cars, losses to the atmosphere should not be greater than 100 pounds per car.

3. VC Charging - A 0.05% loss between storage and polymerization should cover losses from flanges and seals throughout all VC handling equipment.

4. Polymerization - The loss from build-up of PVC on the walls of the reactor is split between reactor wash-out and the slurry strainer.

5. Reactor Venting - Before the reactor can be cleaned, residual VC is vented. After recovery and emptying the PVC resin, the reactor is full of a mixture of air, moisture, and VC at ambient conditions.

6. Recovery - Processing schemes will vary, but one of the most widely used is the direct recovery of unreacted VC from the reactor. While the reaction can be carried out further, economically it is essentially complete at 90% conversion or even less depending on the type of resin. At this point the residual VC is recovered by means of compressors which evacuate VC from the reactor. The recovered VC is condensed and distilled before recycling to the reactor.

7. Drying - Unreacted VC is collected in the recovery system but there are losses of polymer in the drier due to coalescence of the resin and periodic clean-out. This is almost entirely scrap.

8. Product Collector - Most plants use bag collectors so that the loss of resin is less than one pound per hour, but there are losses due to product changes which raise the total.

9. Screening - Oversize resin is removed from the final product. This material consists of scrap and off-grade resin. With the current PVC shortage much of this off-grade resin is used as prime resin by special customers.

10. Miscellaneous - In addition to the above losses, others occur as scrap or off-grade polymer and as quality control samples.

a. Bad Batches - Most plants experience batches which are off specification. These range from "just slightly off" to solid batches, with losses at 2 to 3 batches per month or about 0.4% or 40 pounds per hour average. Salvage value depends upon the degree of "off-grade" and market conditions.

b. Samples - Probably about 0.05% or 5 pounds per hour and is usually destroyed in testing.

c. Polymer Build-up - VC slowly polymerizes in the pipe lines, particularly the recovery system, and must be removed periodically. No quantitative value is available for this loss.

d. Spillage - Some of the product is shipped in bulk and some is bagged. While some spillage occurs in bulk handling, more occurs in bag filling and in bag breakage.

e. Centrifuge Effluent - Some PVC enters the effluent water.

11. Product Change-Over - As indicated previously there are losses in the drier and collector due to cleaning for changes from one product to another. In addition one must segregate the first product that comes through this system. The amount can vary widely depending upon the number of changes and the sensitivity of the product to contamination from the previous product.

The foregoing analysis, together with estimates provided by industry, suggests that the losses of VC at PVC polymerization facilities currently range from about 3.0 to 6.3% while PVC losses are on the order of 1.3%.

PRODUCTION OF VC FROM ETHYLENE AND CHLORINE

Σ PVC LOSSES = 1.35%
Σ LOSSES = 4.35 - 7.65%

APPENDIX IV

INTERIM METHOD FOR SAMPLING AND ANALYSIS OF VINYL CHLORIDE IN WASTE WATER EFFLUENTS AND AIR EMISSIONS

Scope and Application

The initial basis for this method was developed during the monitoring program carried out by EPA Region IV in March and April. The techniques used by Region IV provided guidance for the monitoring activities of other Regions, and the experiences of all Regions were then incorporated into this refined version of the original Region IV approach.

This method is applicable to VC determinations in water effluents, sludges and scums, and atmospheric emissions. The limit of detection is approximately 0.06 mg/l in water and 0.06 ppm (v/v) in air samples.

Summary of Analytical Procedures

Water composite samples, air continuous composite bag samples, and air and water grab samples are analyzed without cleanup by gas chromatography (GC). Separations are effected by selection of one of two types of columns depending upon the nature of the sample. Detection is by means of the flame ionization detector (FID). Tetrahydrofuran extracts of sludges and scums are used for injection into the GC. Air continuous samples on activated carbon are extracted with carbon disulfide, and the extract is analyzed by direct injection into the GC.

Calibration curves are developed using gravimetrically prepared calibration solutions, or by using known dilutions of VC in carrier gas.

VC confirmation should be made by mass spectrometric analysis of the GC eluent if possible. Independent confirmation may also be made in the event of extraordinarily high VC concentration samples by using long path Fourier transform IR spectrophotometry. This IR technique requires special equipment and about 20 cubic feet of air samples.

Interferences

Certain volatile hydrocarbons such as neopentane, butadiene, and freon 12 have elution characteristics similar to VC. However, on the GC column substrates specified in these procedures, these have not usually presented problems of resolution of the VC peak. When column substrates other than those specified have been used, impurities from solvents and carbon adsorbents have been

found to interfere with the VC elution peak. Under certain conditions a peak is associated with the injection and subsequent withdrawal of the microsyringe into and from the GC septum. These peaks can also give interferences with the VC peak. Withdrawal should be timed to avoid overlap of this peak with the VC peak.

Apparatus and Materials

Gas Chromatograph

Flame Ionization Detector

Recorder - any potentiometric strip chart recorder which is compatible with the detector system. An integrator is also desirable to estimate peak areas.

Column Materials for Waste Water, Sludge, or Scum Samples

Borosilicate glass tube or stainless steel tube - 6' x 2.5 mm ID preferred. When GC configuration requires columns of other dimensions, these should be used.

Solid support - 60 to 80 mesh Gas Chrom Q

Liquid Phase - 4% FFAP on specified solid support (weight percent). Liquid phase on solid support can be purchased directly from commercial distributors.

Column Materials for Air Samples

Borosilicate glass tubing or stainless steel tubing - 8' x 2.5 mm ID preferred. When GC configuration requires columns of other dimensions, these should be used.

Solid support - Carbopak A

Liquid phase - 0.4% Carbowax 1500 on solid support (weight percent). Liquid support on solid phase can be purchased directly from commercial distributors.

Continuous Air Monitoring Materials - Carbon Adsorption Option

Adsorption Tube - pyrex glass, 18" x 3/8" OD

Activated coconut charcoal, 8-16 mesh. Any good commercial grade, e.g. Fischer Scientific Company can be used.

Becton-Dickson 27 gage 3/8" hypodermic needle flow control

Vacuum pump

Air flow meter

Continuous Air Monitoring Materials and Equipment - Bag Sampling Option

Environmental Measurements, Inc., Programmable Bag Sampler

Tedlar bags (or equivalent)

Gas Pressure Regulator (0-5 PSIG)

Microsyringes - 10, 25, 50, and 100 microliter (graduated)

Gas-tight sample syringes - 1 and 50 ml (graduated)

Vacuum Sampling Cans - 370 ml steel Vacu-Samplers, or glass sampling bottles. Cans and bottles should be flushed with clean air or nitrogen and evacuated prior to use. Evacuated containers should be protected from rough handling to prevent implosion or collapse.

Sampling Bags (Tedlar or equivalent) - 12" x 12", 36" x 36", equipped with sampling valves and speta for GC sample withdrawal

Automatic water sampler - compositor (manual sampling is optional) equipped with sample refrigeration capabilities, and a a means to prevent loss of vinyl chloride from open bottles

Glass sampling bottles with teflon lined screw type caps - 50 ml capacity or other sizes depending upon sampler requirements

Septum-sealed vials - 1 to 10 ml capacity

Volumetric Flask, Glass stoppered, 25 ml

Medicine droppers

Dedicated GC/M.S. for confirmatory tests (preferable)

Barometer

Thermometer

Anemometer

Reagents, Solvents, and Standards

Carrier gases - zero nitrogen or helium

FID gases - zero hydrogen, oxygen

Tetrahydrofuran, reagent grade, peroxide-free

Carbon tetrachloride (reagent grade)

Carbon disulfide (reagent grade)

Standards

VC in zero air, 50 ppm (± 2%) v/v

VC, analyzed reagent grade (lecture bottle)

Sampling

A. Water Samples

All waste water discharge points identified in NPDES permits should be sampled for VC. A minimum of three successive 24-hour composite samples of each site should be taken. Compositing interval should be one hour (manual or automatic sampling is optional). Compositing interval of 20 minutes may be used if the automatic sampler has this capability. Samples should be taken at waste treatment units such as clarifiers and scum and sludge separators. Two 8-hour composites should be taken from the effluents from each of these points, and one 8-hour composite should be taken of scum and sludge from each separator unit.

Compositing interval should be one hour. Three grab samples of clean process water (city or private well) should be taken as blanks.

Samples should be taken in 50 ml bottles with gas-tight, teflon-sealed, screw cap closures, or in equivalent containers required by the characteristics of automatic samplers. All water, sludge, and scum samples should be refrigerated during collection and storage. Compositing volumes should be selected to assure head space above the sample is absent or minimized to avoid loss of VC by its partitioning into the gas phase when samples are sealed. Provisions should be made to avoid such losses during continuous monitoring operations.

Estimates of discharge flows should be made using any appropriate measuring device (venturi, weir, magnetic meter, etc.).

Samples should be preserved by refrigeration and protected from sunlight until they are ready for analysis.

B. Air Samples

Sampling sites should be selected which are downwind and in the plume of the atmospheric emissions from the plant. Samples should be collected only in areas where local residents or neighboring industries would be exposed. At a minimum,

sampling should be conducted over a period of five days. Sites should be selected in the following array: one site immediately upwind (A) and one immediately downwind (B) of the plant site; four sites about 0.4 miles from the plant site, one laterally left (C) and one laterally right (D) of the plant site on a line roughly perpendicular to the prevailing wind direction and two (E, F) downwind from the plant site; two sampling sites (G, H) approximately 0.5 miles downwind; single sampling sites, each at distances approximately 0.6 (I), 0.8 (J), 1.0 (K), and 3.0 (L) miles downwind from the plant site. If wind is fish-tailing severely, move sampling sites G and H approximately 0.5 mile upwind of the fish-tailing wind direction from the plant. The sites specified are minimum. Additional sites may be selected contingent on overriding micrometeorological considerations. These should be determined in consultation with the Regional meteorologist. These may be at ground or some elevated level, as determined by the plume survey or as estimated by release of meteorological balloons, anemometer, and wind direction indicators, etc.

SAMPLING SITES

Prevailing Wind Direction

Miles from plant site	Site Symbol	Time	Minimum Sampling Schedule Mon	Wed	Fri
0.0	A				
0.4	C Plant D	0800	A, A, B	A, B, B	A, A, B
0.0	B	1000	C, D, F	C, D	C, D, D
0.4	E F	1200	A, E	A, G, G	A, E
0.5	G H	1400	B, B, F	B, H	B, B, G
0.6	I	1600	C, G	E, K	I, J
0.8	J	1800	D, I	-	L, L
1.0	K	2000	-	H, L, L	-
3.0	L				

(Note: All times are ± 30 minutes for manual grab samples, or ± 2 minutes for automatic, programmable bag samplers).

Grab samples should be taken in 50 ml gas-tight syringes, 50 to 100 ml glass sampling bottles, 370 ml "Vacu-Sampler" metal cans, or 12" x 12" capacity Tedlar-type bags. Both the Vacu-Samplers and the glass sampling bottles should be evacuated prior to use. (Caution: These may implode or collapse when under vacuum. Use due care in their handling). The perfect gas laws should be assumed to estimate gas volumes. Gas-tight syringes are flushed several times with ambient air before a sample is taken. After the sample is taken, the gas-tight syringe is locked and sealed until it is ready for analysis.

The Tedlar-type bag samplers may be filled by pulling the walls of the bag apart manually, or better, by placing the bag in an enclosure and pulling a vacuum on the outside surfaces of the bag. The bag is sealed until it is ready to be analyzed. Tedlar-type bags are preferred for grab sampling.

All samples should be protected from sunlight.

Continuous Sampling - Carbon Adsorption Option:

Continuous samples are taken in pyrex tubes (approximately 3/8" O.D. x 18" long) packed with a good grade of activated coconut shell charcoal. The charcoal is added to the tube in three segments, each 3-inches long, and each separated by a glass wool plug. The two ends of the tube are also plugged with glass wool. Both ends of the pack adsorption tube are plugged with serum caps during transport and for storage purposes.

Flow rate through the tube is controlled by inserting a Becton-Dickson 27 gage, 3/8" hypodermic needle through one of the serum caps into the end glass wool plug. Air is sucked through the tube by connecting it to a conventional vacuum pump. The arrangement is similar to that used in the National Air Surveillance Network. Flow rate should be about 200 ml per minute. For each adsorption tube, the flow rate should be calibrated in the laboratory before the sample is taken and should be verified again in the laboratory after the sample is taken. Clean needles frequently to prevent plugging.

The adsorption efficiency of the carbon in the adsorption tube should be verified in the laboratory by preparing a 5 ppm v/v VC mixture in the 36" x 36" Tedlar-type bag and drawing this through the adsorption tube. Flow rates should be verified before and after the experiment. It is important to note that all collections should be made with the adsorption tubes held in an upright position to minimize channeling. Adsorption tubes should be protected from sunlight either by wrapping with foil or by enclosing them in a box.

Each segment of the adsorption tube is worked up separately by etching the tube in the middle of a 3" section with a file, successively breaking each segment and spilling its contents into measured volumes of carbon disulfide in glass stoppered test tubes. The additions should be effected cautiously and with cooling in an ice bath since the interaction of activated carbon with carbon disulfide is quite exothermic. A 2 microliter aliquot of the supernatant solution should be injected on the carbowax 1500 column for estimation of the adsorped VC. Successive analysis of the three adsorption tube segments will indicate the amount of break-through of VC through the adsorbent.

The same procedure should be used for taking samples in the field.

Continuous Sampling - Programmable Bag Sampler Option: The sampler is programmed to take twenty-four consecutive one-hour composite samples. Each one-hour sample is analyzed separately for VC content. Sampling rate of the individual pumps should be verified before and after use of the sampling device. Record the temperature and atmospheric pressure at which the samples are taken. All gas volumes and concentrations should be corrected to 25°C and one atmosphere (760 mm Hg). At a minimum, continuous samples should be taken at sites A, B, C, and D at ground level, unless otherwise indicated by micrometeorological conditions.

Calibration

A. Gas Analysis - Gas Dilution Option:

Record ambient temperature and atmospheric pressure.

Evaluate the 36" x 36" Tedlar-type bag. Add 1 liter of the standard VC gas mixture (50 ppm, v/v) to the bag. This addition may be made with a flow meter or with a gas-tight syringe. Dilute with nine liters of zero nitrogen or helium carrier gas. This gives a concentration of 5.0 ppm (v/v) of VC. (13 ng/ml at 25°C and one atmosphere.)

Evacuate a 12" x 12" Tedlar-type bag and add 0.5 l of the 5.0 ppm (v/v) concentration mixture. Dilute with 2 liters of zero nitrogen or helium carrier gas. This gives a concentration of 1.0 ppm (v/v) VC, (2.6 ng/ml at 25°C and one atmosphere).

Evaucate a 12" x 12" Tedlar-type bag and add 0.5 l of the 1.0 ppm (v/v) VC calibration mixture. Dilute with 2 liters of zero nitrogen or helium carrier gas. This gives a concentration of 0.2 ppm (v/v) VC (about 0.52 ng/ml at 25°C and one atmosphere).

Evacuate a 12"x 12" Tedlar-type bag and add 0.75 l of the 0.2 ppm (v/v) VC calibration mixture. Dilute with 1.75 liters of zero nitrogen or helium carrier gas. This gives a concentration of 0.06 ppm (v/v) VC (about 0.16 ng/ml at 25°C and one atmosphere). This is about the limit of detection for direct injection into the GC.

With a gas-tight syringe, inject 1 ml aliquots of the 5.0, 1.0, 0.20 and 0.06 ppm (v/v) VC calibration mixtures into a GC equipped with a Carbowax 1500 or Carbopak column and an FID detector. Use zero nitrogen or helium as carrier gas at a flow rate of 60 ml/min. Operate the inlet and the column isothermally at room temperature.

Prepare a calibration curve. Repeat until the calibration curve is reproducible.

B. Gas or Water Analysis - Gravimetric option:

Stock solution of VC.

Pipet 40.0 ml of carbon tetrachloride into a tared 50 ml glass stoppered volumetric flask and accurately weigh to 0.1 mg.

Attach a tygon delivery tube to the VC lecture bottle valve. Attach the end of the delivery tube to a piece of glass tubing which has been constricted at one end, flush out the tube with VC, and slowly bubble VC into the CCl_4 containing volumetric flask until about 5.0 mg of VC has been added. Precautions should be exercised to prevent loss of carbon tetrachloride during this operation. Reweigh the volumetric flask to determine the weight of added VC. Fill the volumetric flask to the 50 ml mark (approximately 100 ppm wt/vol). (These operations should be carried out in a hood).

Transfer 1 ml of the stock solution of VC to a 25 ml volumetric flask and dilute to the 25 ml mark with carbon tetrachloride (approximately 4 ppm w/v).

Transfer 5 ml of the 4 ppm VC solution to a 10 ml volumetric flask and dilute to the 10 ml mark (approximately 2 ppm, w/v). Repeat dilution for a solution approximately 1 ppm, and 0.2 ppm.

Transfer the stock solution to a teflon-lined screw capped bottle. This solution can be kept for extended periods of time Transfer the diluted solutions to serum vials and cap them with teflon-lined serum cap septa.

Inject 1 ml aliquots of the calibration solutions in the GC equipped with Carbowax 1500 on Carbopak A packed columns and an FID detector. Use Zero nitrogen or helium carrier gas at a flow rate of 60 ml/min. Operate the inlet at 150°C and the column at 60°C. After the VC peak has been eluted, program the column temperature to 150° C to elute solvent. Cool column back to 60°C for follow-on concentrations.

Repeat procedure using a GC equipped with a 4% FFAP on Gas Chrom Q packed column and FID detector. Operate under the same conditions. Prepare a calibration curve to be used be used with water samples.

Procedure

Water Sample Analysis

Untreated water samples (1-5 microliter aliquots) are injected directly into the GC.

A 4% FFAP on "Gas Chrom Q" packed column is used. Nitrogen zero gas or helium is used as the carrier gas at a flow rate of 60 ml/min. Inlet temperature is set at 150°C. The column is operated isothermally at 62°C. Detection is by FID.

Report concentration of VC in sample in mg/l.

Sludge and Scum Samples

Extract 5 grams of sludge or scum sample with 100 ml of tetrahydrofuran (THF). Analyze THF extract in the same manner used for water samples. If VC concentrations are too high, make appropriate dilutions of the THF extracts.

Report concentration of VC in sample in mg /g of sample.

Air Sample Analysis

Grab samples.

Use a 0.4% Carbowax 1500 on Carbopak A packed column. Use nitrogen zero gas or helium as the carrier gas with a flow rate of 60 ml/min. Operate the column and inlet at room temperature. Use a flame ionization detector.

Untreated air samples (1 ml) are injected directly into the GC. VC contamination of syringes requires attention.

Report concentration of VC in gas samples in ppm (v/v).

Continuous Samples

Use same procedure as previously discussed for calibration of adsorption tube efficiency.

Quality Control

Duplicate sample analyses are recommended as a quality control check.

SUMMARY OF REGIONAL ACTIVITIES

This Appendix briefly summarizes the results of the preliminary VC monitoring activities conducted by EPA Regional Offices during the Spring of 1974 at the request of the Task Force. More detailed reports are available from the Regional Offices.

The sampling and analyses were carried out in a very short period of time using new methods, based on the Agency's best scientific judgement. They represent, in the Agency's opinion, the best methods then available. In large measure, the sampling and analysis methods were based on previous analytical studies in which similar chemicals were evaluated. However, they had not been thoroughly tested for accuracy and precision under field conditions.

Prior to and during the sampling and measurement only limited quality control and standardization of procedures could be applied in the time available. The methods utilized were interim procedures which have already been subjected to further modification.

The nature of the PVC manufacturing process results in the escape of VC pulses which could lead to widely fluctuating levels of VC in the ambient air. So, too, changes in air movement may influence concentrations at a given station at any one time. Therefore, the VC data reported are preliminary in nature and are subject to change as additional monitoring is performed. Individual measurements probably underestimate the VC levels due to the possibility of VC leakages and other inaccuracies in the monitoring system.

Region I: Leominster, Massachusetts: Borden Chemical Company (PVC); May 9, 10, 13.

1. One hundred and fifty-seven discrete (grab) ambient air samples were collected on plant property and within a 3.0 mile radius of the plant. The VC concentrations ranged from less than the detectable limit of 0.06 ppm to 6.0 ppm. The samples exceeding 1 ppm were obtained on plant property near the fenceline.

2. Twelve 24-hour integrated ambient air samples were collected at the fenceline on plant property. The VC values ranged from less than the detectable limit of 0.06 ppm to 1 ppm.

3. VC concentrations in three 24-hour composite waste water samples taken from the lagoon effluent ranged from 0.15 to 0.29 ppm.

4. VC concentrations in two sludge samples taken from the lagoon near the outlet measured at the 0.05 - 0.06 ppm level on a wet basis.

5. The plant is located in a residential/industrial area on the edge of Leominster with residential developments adjacent to plant property.

6. Shifting meteorological conditions and rain hampered the sampling program.

Region II: Flemington, New Jersey: Tenneco Chemicals, Inc. (PVC); May 29-31.

1. Forty-three discrete ambient air samples were collected on plant property and within a 2.0 mile radius of the plant. The VC concentrations outside the plant property ranged from less than detectable (0.01 ppm) to 0.05 ppm. On plant property a single sample collected on the dryer building roof contained 5.6 ppm. At ground elevation, the VC concentrations on plant property ranged up to 0.30 ppm.

2. Twenty-three integrated ambient air samples were collected for 24-hour periods on plant property and within 2.0 miles of the plant. The VC values ranged from 0.005 to 0.038 ppm on plant property and from less than detectable to 0.031 ppm outside the plant area.

3. Two integrated one-hour ambient air samples collected within 0.1 mile of the plant showed VC at levels of 0.32 ppm and 0.18 ppm.

4. A maximum level of 20 ppm was detected in three 24-hour composite samples taken from the water effluent discharge into the Bushkill Brook, which immediately flows into the Raritan River. This amounts to approximately 400 lbs/day.

5. VC concentrations in sludge samples taken from the lagoon areas on plant property ranged from less than detectable to 1,000 ppm in wet weight concentrations; however, the concentration at the sludge disposal area was 54 ppm.

6. The plant is located in an area in which manufacturing facilities are interspersed with farmland and relatively large acreage residential properties. There are a number of small communities within a few miles of the plant.

Region III: Delaware City, Delaware: Stauffer Chemical Company (PVC) and Diamond Shamrock Chemical Company (PVC); May 20-22. S. Charleston, West Virginia: Union Carbide Corporation (PVC); May 24.

1. The air sampling and analysis activity was organized around a mobile laboratory equipped with a gas chromatograph using a flame ionization detector. VC levels were later confirmed by mass spectrometer.

2. A single discrete ambient air sample at the fenceline of the Diamond Shamrock plant showed 0.2 ppm VC.

3. Four discrete ambient air samples taken near the Stauffer Chemical plant ranged from 0.3 to 0.7 ppm VC. The highest level was recorded 0.5 miles from the plant and the lower levels at 0.25 miles from the plant.

4. The area immediately adjacent to the Delaware City complex is lightly populated residential areas for several miles.

5. Water samples collected at the Union Carbide plant gave VC values of 1.1 and 0.8 ppm for grab samples at several outfalls and 0.35 for a 24-hour composite. Samples obtained from the Kanawha River did not have a detectable level of VC.

6. Sampling was attempted but was not feasible due to limited time and equipment difficulties at the PVC plants of the Firestone Plastics Company in Perryville, Maryland, and Pottstown, Pennsylvania.

Region IV: Louisville, Kentucky: B.F. Goodrich Chemical Company (PVC); March 19-21 and May 8-16.

1. The initial air monitoring program conducted in March was preliminary to the more extensive program in May which showed significantly higher levels.

2. In May there were 39 discrete ambient air samples collected in the area designated industrial (within 0.8 miles from the plant center). The VC concentrations ranged from less than 0.05 to 5.6 ppm, with 10 samples exceeding 1 ppm. In the area designated residential/ industrial, 149 samples were collected within 0.8 miles of the plant with VC concentrations ranging from less than 0.05 to 33 ppm. The average concentrations at the site registering 33 ppm were between 0.5 and 1 ppm, but 18 samples had concentrations greater than 5.0 ppm. Four samples were obtained in strictly residential areas with VC values of 0.05 to 1.6 being observed. The 1.6 value was 0.8 miles from the plant.

3. Five sampling sites were established within 0.6 miles of the plant for integrated air sampling over 24 hours. VC values ranged from less than 0.001 to 0.53 ppm. The highest value was obtained from a sampling site 0.2 miles from the plant center.

4. Wastewater from the clarifier discharge was measured in March at 2 to 3 mg/l in 24-hour composite samples.

5. Dewatered clarifier sludge and clarifier scum contained 193 and 162 ppm of VC, respectively.

Region V: Painesville, Ohio: Uniroyal, Inc. (PVC) and Robintech, Inc. Inc. (PVC); May 9-14.

1. Four of 137 ambient air samples taken at distances up to 3.0 miles from the plant showed levels exceeding 1 ppm of VC with the highest level being 2.26 ppm. Many of the samples were less than 0.1 ppm.

2. Nine 24-hour integrated ambient air samples taken at various distances from the plant showed levels up to 0.2 ppm of VC.

3. VC levels in 11 of 17 water effluent samples were less than 0.2 ppm, with three samples exceeding 1 ppm, including a high of 3.7 ppm.

4. VC levels in nine sludge samples, as the sludge would leave the plant property, ranged from 9 to 3520 ppm.

5. The complex is surrounded by residential areas.

Region VI: Plaquemine, Louisiana: The Goodyear Tire and Rubber Company (PVC) and Dow Chemical Company (VC); April 7-9.

1. There were 31 discrete ambient air samples collected within 3.0 miles of the complex with VC concentrations ranging from less than detectable (.001 ppm) to 7.81 ppm. Most of the readings were less than 1 ppm, with the highest value at the property line.

2. VC concentrations in wastewater effluent measured by 24-hour composites were all below .05 ppm.

3. VC concentrations in residual reactor scrapings at the Goodyear plant ranged from 23 to 31 ppm.

4. The small communities of Morrisonville and Eliza are located less than 1 mile north and northwest respectively of the Goodyear plant. A few homes from Morrisonville extend almost to the north property line of the Goodyear plant.

5. Very limited air sampling was conducted in the Houston area in the vicinity of the plants listed below. However, in view of the inadequacy of this activity, the sampling effort in this area is being continued.

Deer Park, Tex., PVC Plant - Diamond Shamrock Corp., Diamond Shamrock Chemical Co.

Deer Park, Tex., VC Plant - Shell Chemical Co., Industrial Chemicals Division

Houston, Tex., VC Plant - Tenneco, Inc., Tenneco Chemicals, Inc.

Pasadena, Tex., VC Plant - Ethyl Corporation

Region IX: Long Beach, California: B.F. Goodrich Chemical Company (PVC); American Chemical Corporation (VC); American Chemical Corporation (PVC); May 7-10.

1. One hundred and eighty 10-minute integrated ambient air samples were collected within 3.1 miles of the complex. About 11 percent of the

readings exceeded 0.5 ppm, while 5 percent exceeded 1.0 ppm. The maximum value measured was 3.4 ppm in a sample taken 3.1 miles from the plant; however, the average level measured at this point was about 0.5 ppm.

2. Samples of wastewater effluents were composited for 8 to 24 hours and yielded values from 3.5 to 8.9 ppm, with individual samples reading up to 22 ppm.

3. Sludge samples showed values ranging from 290 to 4200 micrograms of VC per gram of dry sludge.

4. The complex is surrounded by residential areas. Within the three mile radius of the plants there are eleven schools.

PERSISTENCE OF VINYL CHLORIDE

The available information on the stability and persistence of VC in the environment is currently very limited. Some literature and laboratory studies have recently been initiated by industry and by EPA. This discussion summarizes the findings of EPA to date and particularly the results of research efforts at EPA research facilities undertaken in response to the needs of the Task Force for at least preliminary data on environmental fate. Results of related experiments reported by industry seem to be consistent with the discussion.

Behavior of Vinyl Chloride in Air

The peak absorption of VC in the ultraviolet region is very far below the solar cutoff of about 2900 A, indicating that VC would not undergo reaction in sunlight in the absence of other reactive chemicals. When irradiated with simulated solar radiation in the presence of nitrogen oxides (nitric oxide and nitrogen dioxide), VC reacts to form a variety of products. The available laboratory results indicate a rate of reaction of about 8 to 10% per hour for VC, recognizing that reaction rates may vary with concentrations. The direct and indirect reaction products identified included ozone, nitrogen dioxide, carbon monoxide, formaldehyde, formic acid, and formyl chloride. High eye irritation levels were found with human exposure panels which is consistent with the products identified.

The low reaction rate of VC, including reactions in the presence of nitrogen oxides, indicates that within a few miles downwind of VC emission sources VC will persist and can be considered a stable pollutant. The usual meteorological dispersion equations for gases could be applied to approximate concentrations. Because of temperature inversions and the absence of sunlight at night during the fall and winter, buildup of VC might be of particular concern during such periods. Clearly at greater distances from emission sources, VC will have greater opportunity to disperse and degrade.

The noxious gases which are products of VC reactions should not be ignored. In air quality regions with large industrial activities involving large volume production of these chemicals, such products may contribute appreciably on particularly sunny days to eye, nose, throat, and lung irritation.

Behavior of Vinyl Chloride in Water

The loss of VC from water at constant temperature and pressure depends on the rate of agitation or aeration. Distilled water in a beaker spiked with 16 ppm VC, when rapidly stirred at 22°C with a magnetic stirrer, lost 96% of VC in two hours, while quiescent water at the same concentration lost only 25% VC. There was no significant difference in the rate of VC losses from distilled water, river water, or effluent from a VC plant stirred at the same rate, indicating negligible adsorption effects with particulate matter. Plots of log water concentration versus time give straight lines, indicating volatility to be the only important loss mechanism.

Hydrolysis over a pH range of 4.3 to 9.4 does not appear to be an important pathway for loss of VC from water. Chemical reaction of VC in the clarifier effluent from a VC plant was followed at 50°C for 57 hours at pH 4.3, 8.0, and 9.4 in sealed septum vials. Concentrations indicated that VC at these three pH values decreased at the same rate. This lack of pH dependence suggests that the loss of VC occurred by volatilization rather than hydrolysis, or at least there is a very slow hydrolysis rate. This experiment should be repeated in leak-proof reaction vials.

Very preliminary experiments do not show photolysis as an important pathway for loss of VC in water. However, there are many uncertainties in the experimental techniques, and additional studies are needed in this area.

Earlier theoretical studies are consistent with these experimental results. One study on the transfer of small non-reactive molecules across the air-water interface (as in stream aeration) used a kinetic approach to predict that VC will be rapidly lost from an aqueous solution, with the rate of loss being a function of water turbulence, mixing efficiency, and molecular diameter. Another study, using a thermodynamic approach, predicted a rapid rate of evaporation of low solubility chlorinated hydrocarbons, including compounds of low vapor pressure.

Despite the foregoing efforts there is a general absence of data concerning VC in aquatic systems. It is conceivable that as the result of poor or erratic mixing in lakes or ponds, together with slow but continuous release of VC from sediments and sludges, VC could persist long enough to accumulate biologically, via direct absorption or via the food chain, or to cause other ecological effects.

Behavior of Vinyl Chloride in Closed Rooms

Tables 1 and 2 present data concerning concentrations of VC in a typical room following release of a pesticidal spray containing VC.

TABLE 1
One Hundred and Twenty Second Release of Insect Spray in 133,000 Liter Room

SAMPLE	TIME	COLUMN I		COLUMN II	
		VC	FREON-12	VC	FREON-12
No. 1	Collected at breathing zone during spray	41.64 ppm	8.15 ppm	41.9 ppm	7.94 ppm
No. 2	15 minutes	16.91	3.13	17.1	3.30
No. 3	30 minutes	1.38	0.27	1.32	0.25
No. 4	60 minutes	0.08	0.018	0.061	0.018
No. 5	120 minutes	0.012	-	0.010	-

TABLE II
Thirty Second Release of Insect Spray in 21,400 Liter Room

SAMPLE	TIME	COLUMN I VC	COLUMN I FREON-12*	COLUMN II VC	COLUMN II FREON-12*
No. 1	Collected one minute after spray	380.1 ppm	84.8 ppm	383.6 ppm	83.2 ppm
No. 2	30 minutes later	52.1	9.9	48.7	10.3
No. 3	60 minutes	24.6	4.8	22.5	4.7
No. 4	150 minutes	10.3	2.1	9.3	2.2
No. 5	Collected in adjacent hall 151 minutes	0.83	0.17	0.17	0.15

*Freon-12 concentrations were determined using hydrocarbon response factors to compare dilution effects; the actual concentration is higher by a factor of 5.3.

HEALTH EFFECTS OF VC

This Appendix presents much of the epidemiological and toxicological data available as of August 1974, on the health effects associated with exposure to VC, together with a few interpretive comments supplementing information presented in the body of the report. However, the Appendix does not present an exhaustive review or evaluation of available information.

Table 1 summarizes the data, collected by CDC/NIOSH, on the confirmed cases of angiosarcoma of the liver in VC/PVC workers in the United States and abroad. A total of 15 occupational cases have been discovered in the United States and confirmed as angiosarcoma of the liver. Of the 15 cases, 2 are still alive and undergoing treatment. Fourteen of the 15 were employed in PVC production plants and the remaining one in a PVC fabrication plant. The average age at death for the U.S. PVC production workers was 48.5 years (with a range from 36 to 61 years) which is about seven years younger than the average age of death from liver cancer in the U.S. male population. Based on the data available for the workers, the latent period for this disease appears to be on the order of twenty years, a period consistent with latencies observed for other occupational, chemically induced cancers.

In the U.S. PVC production worker cases, all of the men were at one time "pot cleaners", required to enter the reactors in order to chip the residue of the chemical reaction from the sides of the "pots." Since the residue often contained pockets of trapped gases that were literally released in the cleaner's face when they were ruptured by his chipping operation, the potential for exposure to high levels of VC while cleaning these tanks was particularly great during the early years of this operation.

Ten cases of worker-related angiosarcoma of the liver have been reported from five foreign countries to date.

Table 2 summarizes the epidemiological data, collected by CDC from the Connecticut Tumor Registry, on five confirmed cases of angiosarcoma of the liver, including one accountant in a PVC fabrication plant and two residents near PVC fabrication plants. The case of occupational exposure occurred in a man who had been employed for 10 years as an accountant in a factory which produces vinyl sheets and processes PVC resins; it is reported that he frequently visited the production area of the plant. Of the two cases who had no occupational exposure to VC or PVC, one was a 73 year-old man who lived his entire life within two miles of a PVC wire insulation plant. The other was an 83 year-old woman, a housewife and retired cook, who had lived for 35 years within one-half mile of the vinyl products plant at which the accountant had been employed.

While these findings establish no causal connection between exposure to PVC and angiosarcoma of the liver, they do raise the possibility of such a relationship. Time will be needed to define the possible risk factors in persons who have worked with PVC since the latency period appears to be so long. Because of the rarity of this tumor, the additional finding in this study of angiosarcoma of the liver in persons who had no occupational exposure to VC, but who may have had community exposure, is also worrisome but again establishes no causal connection. Epidemiologic investigation of additional cases of hepatic angiosarcoma that may be found to have had possible community exposure to VC will be necessary to clarify the significance of these cases.

Tables 3A - 3D present the findings of the MCA-funded mortality study of VC/PVC workers, conducted by Tabershaw/Cooper Associates.

In calculating the risk of death, the usual method is to express the number of deaths which actually occurred as a percentage of the number which would have been expected in a comparable population observed over the same age and time intervals. This statistic is called the Standardized Mortality Ratio (SMR). Using the U. S. male population as the standard population of comparison, the SMRs were calculated for each of the 35 cases of death for which detailed mortaility rates are published on a national basis. In the standard population each SMR would be equal to 100. The statistical significance of the deviation of each SMR in the study population from the expected value of 100 was tested. A single asterisk indicates those SMRs which differed significantly from 100 at the 5 percent level, that is, which had a probability of .05 or less of occurring by chance. A double asterisk indicates those which were significant at the 1 percent level. SMRs based on fewer than 5 observed cases were not tested for significance. The overall mortality of the study population is statistically significantly lower than that of the U. S. male population. There were 352 observed deaths compared with 467 expected, for an SMR of 75.

For each job, an exposure score was estimated by industrial hygiene and safety personnel in each plant. A score of 1 was given for low exposure, 2 for medium, and 3 for high. The number of months each worker spent on a given job was multiplied by the appropriate exposure score. The total for each worker was then divided by the total number of months of exposure to give an Exposure Index (EI) for that worker. Table 3A shows the SMRs for workers with an EI below 1.5 versus those at 1.5 or above. The dividing point of 1.5 represents a level halfway between low and medium exposure. Table 3B shows similar results for workers with less than 5 years exposure versus those with 5 years or more.

In order to examine the possible interaction between duration and level of exposure, the study population was divided into 4 groups on the basis of both EI (low vs. high) and duration of exposure (short vs.

long) using the same dichotomization as Tables 3A and 3B. Table 3C shows the results for short versus long exposure in the low EI group, and Table 3A shows the same comparison in the high EI group. When the study population is divided according to length and duration of exposure (Tables 3A and 3B) and combinations of these measurements (Tables 3C and 3D), three major patterns emerge. For malignant neoplasms as a whole, the SMR increases with increasing exposure, whether measured by level, duration, or both. In the high exposure group with 5 years or more exposure (Table 3D) there are 36 observed cases and 26.11 expected. For cardiovascular - renal diseases as a group, there are also increases in the SMR with increasing exposure, but the number of observed cases remain less than expected, the differences being statistically significant in all groups except the high exposure, long duration group. For all other causes, there are no consistent relationships with exposure.

Within the malignant neoplasms, the largest (although not statistically significant) SMR is in cancers of the buccal cavity and pharynx, with 5 observed, 2.84 expected, and an SMR of 189. However, Tables 3A and 3D show that all these cases have an EI below 1.5, and 4 out of 5 have less than 5 years exposure.

Cancer of the digestive system shows no excess in the study population as a whole. However, in those workers with EIs of 1.5 or higher, there are 12 observed cases where 9.14 are expected (Table 3A). In the subgroup of the above workers with 5 years or more exposure, there are 11 observed cases and 7.47 expected.

Respiratory cancer shows a slight excess in the total group, and a similar pattern for different exposure categories, with 13 observed versus 10.28 expected when the EI is 1.5 or higher, and 12 observed versus 8.50 expected when, in addition, the duration of exposure is 5 years or more.

Malignant neoplasms of other and unspecified sites show an excess in the total group, and an increase with both level and duration of exposure (Tables 3A and 3B). The relationship with exposure is more pronounced, since those with exposures of less than 5 years have fewer cases than expected.

The lymphosarcomas, although occurring at about the expected rate when the whole group is considered, are concentrated almost entirely in the high exposure long duration group. In that category there are 4 cases observed and 1.84 expected.

The Tabershaw/Cooper Study is based on an examination of 328 death certificates. The authors acknowledge three areas where bias might have entered: (a) choice of the U.S. male population as the

standard, (b) absence of 15% of the study population (untraceable), and (c) discovery, as the study ended, of a group of 1500 workers whose exposures occurred up to 35 years ago and who are not included in the study group. Since the latency period fo r angiosarcoma of the liver is averaging 18 years at least, it would appear desirable to examine the data for these 1500 workers.

In addition to the Tabershaw/Cooper study several other epidemiological studies presented during the recent OSHA hearings suggest the possibility of a multiple cancer risk.

Table 4 summarizes many of the published and unpublished toxicological and epidemiological studies of human and animal exposures to VC. A list of the references cited in Table 4 completes this Appendix.

Table 2

CASES OF HEPATIC ANGIOSARCOMA, CONNECTICUT, 1935-1973

Case No.	Age	Sex	NCI Diagnosis	Date of Original Diagnosis	Date of Death	Medical History	Occupation	Place of Residence
1	73	M	Hepatic Angiosarcoma	11-25-67	12-3-67	2 months history of diarrhea, , anorexia, and 20 lb weight loss. Intermittent abdominal pain. Non-tender, firm epigastric mass. Died after 9 days with spontaneous ruptured liver leading to shock. Past history of alcohol intake.	Fireman 1917-42 Aluminum worker 1942-44 Corset cutter 1945-61 Retired 1961-67	Bridgeport - entire life
2	47	M	Alcoholic Cirrhosis Portal Fibrosis	1-15-73	2-15-73	Initial symptoms RUQ abdominal pain with vomiting. Cecal volvulus found, Rx cecopexy, over next 6 weeks pain continued with weakness. RUQ tenderness with 2 FB liver. Diagnosed by needle biopsy on 1-15-73. Deteriorated slowly until death 31 days later.	Accountant - Vinyl Co., 1963-73 Accountant - Plastic Belt Co., 1956-63 Previously accountant-other states	Bridgeport - 1956-73 Previously many locations
3	83	F	Hepatic Angiosarcoma	12-19-73	1-22-74	Admitted 12-2-73 with short history of RUQ abdominal pain radiating to R shoulder. Had RUQ tenderness. Open liver biopsy 12-19-73 showed large tumor. No resection. Deteriorated until death 34 days later.	Housewife Restaurant cook 35 yrs	Stratford 35 years
4	76	F	Hepatic Angiosarcoma	3-12-50	3-19-50	1 month history of anorexia with abdominal pain and back pain. Firm epigastric mass. Died 6 days after admission with carcinomatosis and pulmonary emboli.	Housewife	Windsor Locks
5	50	M	Hepatic Angiosarcoma	-	5-4-73	Admitted for abdominal pain and jaundice 3-27-73. 4 FB liver. Discharged. Readmitted 4-29-73 with abd distension, general edema, icterus, fever, shaking chills. Rapid downhill course with death due to renal and hepatic failure. Past history of alcohol intake.	Fisherman and carpenter before 1959 Plasterer 1959-60. Unemployed 1960-73.	Puerto Rico 1923-59 New York City 1959-73 Bridgeport 1973

HUMAN DATA

Authors	Species	Sex	No.	EXPOSURE Hrs. per Day	Days	Conc. ppm	Total Dose ppm-Days	Observations	Pathology
Von Oettingen (1955)	Human					12,000		Dangerous	
						10,000		Narcosis	
						25,000		Produced symptoms of dizziness, disorientation, headache and burning sensation on soles of feet.	
Gabor Mecca-Radu Manta (1962) Chem. Abstract	Human		82	Workers exposed to DDT, Benzene, Hexachlorocyclohexane, VC, PVC.				Blood: Decrease in catalase Increase in peroxidase, indonhenoloxidase and gluthathione Changes occurred during second year of work.	None reported
Lester Greenberg Adams (1963)	Human	M	3	Twice per day		0	0	1/5 slightly dizzy	
		F	3	for 3 days,		4,000	83.3	0/6 had any effects	None reported
				5 min. sessions		8,000	166.7	1/6 slightly dizzy	
				at 6 hours intervals		12,000	250.0	2/6 definitely dizzy	
						16,000	333.2	5/6 dizzy, nausea, blurred vision and heaving symptoms stopped after exposure	
						20,000	416.7	6/6 intoxicated, one with persistent headaches	
								50% level of no effect is 1.3%	
								No statement about repeated exposures	
Gabor Radu Preda Abrudean Juanof Anca Valczkay (1964) Chem. Abstract	Human		78	PVC Workers				Decrease plasma albumin Increased B and 8 globulin Decrease in B/8 for serum lipoproteins Decrease in serum cholinesterase Decrease in pseudo cholinesterase Normal blood catalase Normal serum pyruvic acid	None reported
Grigorescu Toba (1966) Chem. Abstract	Human			Experimental: PVC Workers Control: Other clinically healthy people				Hypothesis: VC+H_2O>chloral + chloracetic acid (1). Results: (1) was found in 80% of exptl. people, but in none of controls. Most of + findings were in people exposed 2-5 years. In these cases, α-globulin is higher, β-globulin is lower than people with no (1) in urine, capacity to metabolize (1) decreased after 2 years.	None reported

Harris Adams (1967)	Human		2	-	-	-	-		One worker had knee cap and toes involved in the acro-osteolysis. Other worker only hands.
Wilson McCormick Tatum Creech (1967)	Human	M	31	-	-	-	-	No cases of acro-osteolysis diagnosed in 1000 individuals who handled finished resin or used for plastic product production	31/3000 (3%) workmen associated VC polymerization founds to have acro-osteolysis.
								Age range of affected workers 26-47. Incubation period greater than 12 months of polycleaning experience.	22/31 Acro-osteolysis associated with Reynaud's sumptoms.
Bareeta Stewart Mutchler (1969)	Human	M	13	7.5	1	50 250 500	15.6 78.1 156.2	Breath decay curves, 0 to 20 hrs. after exposure were measured. Level in breath at 4 hrs. is ≃ 1%. No adverse effects noted. About the same set of breath decay curves following occupational exposure.	None Reported
Kudryautseva (1970) Abstract	Human	M F	50 43	-	-	-	-	1. Changes in ECG: rhythm, conductance, polarization. 2. Increase in systolic index.	None Reported.
Viola (1970) Unpublished	Human	-	1	8	1095			Acro-osteolysis symptoms, Reynaud's syndrome, aversion to fats, enlarged liver	Aerometry: (VC) on factory filters at air discharge time: 2 000 ppm (VC) at point o. worker entry: 2,000 ppm in plants where acro-osteolysis occurred-150 ppm (max) in plant with no disease (VC) on gangway and other parts of plant: 10 to 15 ppm.
			5	8	1825			Raynaud's syndrome	
			15		-			Enlarged liver, minor liver insufficiency.	
			500*					13/500 had acro-osteolysis. Olefactory threshold is 0.8 to 1%. Acute nervous symptoms become evident when it is easily perceptible.	

*In several other factories

HUMAN DATA

Authors	Species	Sex	No.	Hrs. per Day	Days	Conc. ppm	Total Dose ppm-Days	Observations	Pathology
Dinman Cook Waterhouse Magnuson Ditcheck (1971)	Human		5011	21,510	**Man-years**		Experience	Conditions associated with hand cleaning of polymerizers. There appeared to be correlation between reactor degassing time and acro-osteolysis.	25 cases of acro-osteolysis. 16 other individuals questionable Acro-osteolysis appears to be systemic rather than local disease. Reynaud's phenomenon was statistically related to acro-osteolysis.
Dodson Dinman Whitehouse Nasr Magnuson (1971)	Human	M	4	1-23 Months				All patients had worked as PVC reactor-vessel cleaners. Neg. Ca and P balance in one subject. Plethysmographic abnormalities were present in 3 subjects. Esophageal motility within normal limits. Catacholamine, -Hydroxyindole Acetic Acid excretion normal. All other numerous clinical laboratory investigations negative.	Reynaud's phenomenon anteceded osteolytic lesions in all four subjects. ^{18}F scintiscans correlated with radiographic lesions. No liver enlargement or hypothyroidism. Additional smaller abnormalities found in ulnar styloid, oscalcis and patella.
Kramer Mutchler (1971)	Human	M	98	-Up to 25 years Experience				Performed statistical correlation between several clinical measurements and total dose and time-weighted average VC concentration. 2 liver function indices show a positive correlation with total dose (abnormally high). a) Icterus index b) Bromsulphalein 3 other indices are dose-related but are not outside normal limits: a) systolic and diastolic blood pressure. b) hemoglobin negative correlation. c) beta-protein.	None reported.

HUMAN DATA

Authors	Species	Sex	No.	EXPOSURE Hrs/Day	Days	Conc. ppm.	Total Dose ppm-days	OBSERVATIONS	PATHOLOGY
Meyerson Meier (1972) Abstract	Human	-	1						Acroosteolysis Had unique papular skin lesions which have been described only in PVC workers
Markowitz McDonald Fethiere Kerzner (1972) Abstract	Human	-	-						Describes acroosteolysis symptoms. Incidence is <3% among workers
Lange Juhe Stein Veltman (1973)	Human	-	13					Ages 29-52 Reactor cleaners 2-18 yrs. employment	Latent period: 1½-3½ years in 11 patients; 7 and 11 years in other 2 patients. Acro-osteolysis symptoms. Peripheral vessel stenosis. Thrombopenv (low count) is the first objective symptom described in all patients; lung fibrosis orginating in portal system, large spleen, impaired lung function, 10% mortality. This is the first objective symptom described

Marsteller Lelbach Miller Juhe Lange Pohmer Veltman (1973)	Human	-	120	1½ to 21 years.				20 PVC workers were studied out of 45 with suspected skin problems, 30 to 56 years old.	Liver enlarged in 13/20. Pain in Rt. upper abdomen in 2/20. Hyperlipidemia has been diagnosed in 1967 after 6 years in 1/20. Jaundice history in 1955 before exposure in 1968, liver dysfunction was diagnosed, no alcoholism. Spleenomegaly in 7/20. Total bilirubin was 1 mg/100 (which is upper normal limit) in 3/20. Bromsulphalein test was abnormal in 19/20 (>5% retention after 45 minutes). SGOT was >12 mU/ml in 17/20. SGPT was elevated (15-30) in 14/20. Alkaline phosphatase was >48 uU/ml in 2/20 Hypothrombocytemia (<150x 10^3 /mm^3) was found 19/20(<100X10^3/m^3) ir Acro-ostyeolysis was seen in 4/20. Varicose veins of esophagus in 3/20 Liver histology: Collagen transformation of walls of sinusoids in 5/20. Focal activation of Kupfer cells in 1?/20. Local fatty infiltration in 14/20. Fibrosis of septa and capsule intralobular and portal spaces in 17/20. No additional blood parameters were normal. 9 immunological tests were done [illegible] not repeated.

Table 4

SUMMARY OF TOXICOLOGICAL AND EPIDEMIOLOGICAL STUDIES ON VINYL CHLORIDE

ANIMAL DATA

Authors	ANIMALS Species	Sex	No.	Hrs/day	Days	EXPOSURE Conc. ppm	Total Dose ppm-days	Observations	Pathology
Von Oettingen (1955) (Review Article)	Cats	ND	ND	ND	ND	ND	ND	VC is promptly excreted by lungs; 82% is eliminated after inhalation stops	
	Cats	ND	ND	<4	1	100,000 to 130,000	<1,200	Blood VC concentration reaches 15-17 mg%	
	Cats	ND	ND	<4	1	180,000	<30,000	This concentration causes same intra-auricular pressure reduction as 13,000 ppm dichloroethylene, 30,000 ppm ether	
	Cats	ND	ND	<4	1	200,000	<33,000	Cardiac insufficiency	
	Cats	ND	ND	4	1	250,000 to 300,000	<40,000 to 50,000	Even this does not produce complete cardiac failure	
	Cats	ND	ND	ND	ND	ND	ND	Blood levels are 40 mg% at time of cardiac arrest, 27-30 mg% at time of respiratory arrest	
	Rabbits Dogs	ND	ND	1 min.	1	170,000	118	This is the narcotic concentration	
	Mice	ND	ND	1 min.	1	86,000 to 123,000	60 to 85	This is the narcotic concentration	
	Dogs	ND	ND	<4	1	100,000	<12,000	Cardiac irregularities, ECG abnormalities	
	Dogs	ND	ND	3	7 for several wks	10,000	475	No major change in liver or kidney	
	Dogs	ND	ND	3	7 for several wks	200,000	9,500	Marked salivation, vomiting, respiratory arrest	
	Mice	ND	ND	10 min.	1	245,000 to 295,000	1,700 to 2,040	This is the lethal range for 10 minutes exposure	
	G. Pigs	ND	ND	short time	1	200,000 to 400,000	ND	All killed	

ANIMAL DATA

Authors	ANIMALS Species	Sex	No.	Hrs/day	Days	EXPOSURE Conc. ppm	Total Dose ppm-days	Observations	Pathology
Von Oettingen (1955) Review Article Continued	G. Pigs	ND	ND	0.5-1	1	100,000	2,000 to 4,000	Dangerous to life	
	G. Pigs	ND	ND	0.5-1	1	5,000	100 to 200	Higher concentrations than this cause severe lung edema and hyperemia of liver and kidney	
	G. Pigs	ND	ND	0.5-1		ND		Order of toxicity is: carbon tetrachloride ≃ chloroform < VC ≃ ethyl chloride	
Mastromatteo Fisher Christie Danziger (1969)	Mice	ND	5	0.5	1	100,000	2,080	Sequential effects were: 1. irritation, 2. increased motor activity, 3. twitching, 4. tremor, incoordination, 5. unconscious, 6. deep narcosis. All animals recovered in 5 minutes.	Mice: Light lung engorgment, kidney swelling; Rats and G. Pigs: same lung picture.
Fisher Christie Danziger (1960)	Rats	ND	5	0.5	1				
	G. Pigs	ND	5	0.5	1				
	Number of animals and duration of exposure same as above					200,000	4,160	1/5 mice died after 30 minutes, same symptoms as above but appeared sooner. Guinea pigs unsteady for 20 min. after exposure.	Lung engorgement, no edema in all species. One rat had fatty liver.
	Number of animals and duration of exposure same as above					300,000	6,250	5/5 mice and 5/5 rats died; 1/5 guinea pigs died; 4/5 guinea pigs recovered in 25 minutes.	Liver and kidney was congested, tracheal epithelium damaged
	Number of animals and duration of exposure same as above					400,000	8,330	2/5 guinea pigs died	Same symptoms, more severe
Torkelson (1) Oyen Rowe (1961)	Rats	M	10	7	(5d/wk)	500	14,000	Growth and gross appearance were normal. Liver/body weight ratio and absolute liver weight larger than control in males. Liver/body weight and absolute liver weight not larger than control in females Blood SGOT, SGPT, SUN, alkaline phosphatase were normal.	Central lobular liver degeneration. Kidney tubular damage.
		F	10	7	(4.5Mo)				

Authors		ANIMALS Species	Sex	No.	Hrs/day	Days	EXPOSURE Conc. ppm	Total Dose ppm-days	Observations	Pathology
Torkelson Oyen Rowe (1961) continued			M	5	7	(5d/wk)	0	0	Control animals	
			F	5	7	(4.5mo)				
	(2a)	Rats	M	12	7		200		All groups were normal in appearance, mortality and growth.	Gross pathology was normal.
			F	12	7	138				
		G. Pigs	M	10	7	exposures	200		Hematology (hemoglobin, hematocrit, cells) was normal.	Microscopic pathology was normal in all species except liver of M and F rabbits: Central lobular granular degeneration and necrosis.
			F	8	7	in 204				
		Rabbits	M	3	7	days	200		Liver function tests (SUN, SGOT, SGPT, alkaline phosphatase) were normal.	
			F	3	7	($6\frac{1}{2}$				
		Dogs	M	1	7	months)	200	8,050	All organ/body weight ratio normal except M and F rats, where liver/body weight ratio was increased.	
			F	1	7			to		
		Matched controls, both exposed and nonexposed groups				5d/wk		8,400		
	(2b)	Same protocols					100	4,000 to 4,200	All animals were normal in appearance, mortality and growth. Hematology (hemoglobin, hematocrit, cells) was normal. Liver function tests (SUN, SGOT, SGPT, alkaline phosphatase) were normal. Liver/body weight ratio of M and F rats were larger than controls.	Gross and microscopic appearance of tissues were normal.

(1963)			ND	2	0-2	1	100,000	0-8,330	Corneal reflex disappears, no gross pathology.
			ND	1	5 min.	1	150,000	552	Deep anesthesia.
					42 min.	1		4,380	Respiratory failure of same animal.
			ND	1	2	1	150,000	12,500	Deep anesthesia, complete recovery after exposure. No pathology observed.

ANIMAL DATA

Authors	Species	Sex	No.	EXPOSURE Hrs. per Day	Days	Conc. ppm	Total Dose ppm-Days	Observations	Pathology
Lester (2) Greenberg Adams (1963)	Sherman rats	M	9	8	2 then 13	100,000 80,000	Variable	After animal deaths, replacements were made in chambers. Two males survived all 15 exposures. Remaining animals and replacements survived an average of eight exposures	
Cont'd		F	9	8	Same exposures as above.			One died after two exposures at 100,000 and twelve at 80,000. One died after two exposures at 100,000 and twelve at 80,000. Six/nine survived all fifteen exposures.	
		M	9	8		0		Control animals	
		F	9	8		0		Control animals	
								Growth stopped during exposures and resumed at normal rate after exposures.	Lungs had focal pneumonia which healed after two weeks of recovery from exposure. One-third of animals had parasitic cysts in liver. Liver pathology same as controls, but more variation in amount of fatty infiltration. Spleen had advanced lymphocytic hyperplasia. Kidney pathology same as controls.
								External appearance normal. Liver color, appearance, consistency, degree of congestion was same as controls.	
	(3) Sherman rats	M	15	8	5days/week for 3 months	20,000	434,000		
		F	15	8		20,000	434,000	1/30 died. External appearance of all animals normal. Liver larger, spleen smaller than controls. White blood cells lower, lymphocytes higher, neutrophils lower than controls. Body weight and hemoglobin were same as controls.	All organs had normal gross appearance. Liver parasitic cysts in all animals. Liver fat normal. No abnormal histology. Congestion and swelling greater in liver than controls. Congestion and swelling less in kidney than controls. Congestion and swelling same in spleen as controls.
		M	15	8	Same	0	0	Control animals.	
		F	15	8	Same	0	0	4/30 died.	

ANIMAL DATA

Authors	Species	Sex	No.	EXPOSURE Hrs. per Day	Days	Conc. ppm	Total Dose ppm-Days	Observation	Pathology
Lester Greenberg Adams (1963) Cont'd (4)	Sherman rats	M	5	8	19	50,000	317,000	No mortality. On days 1-4, animals lost weight, showed neuorological symptoms. On days 4-19, weight gain was normal. Serum transaminase, hematocrit, and prothrombin times were normal. White and red cell counts were lower than controls. Hair: all 5 males had thin hair and scaly tails; females and controls were normal. Liver/body weight ratio was higher than controls. Control animals.	Gross organ appearance was same as controls. Liver pathology showed congested cells. Liver parasitic cysts seen in all animals.
		F	5	8	19	50,000	317,000		
		M	5	8	19	0	0	Control animals.	
		F	5	8	19	0	0		

ANIMAL DATA

Authors	Species	Sex	No.	EXPOSURE Hrs. per Day	Days	Conc. ppm	Total Dose ppm-Day	Observations	Pathology
Kuebler (1964) Abstract	Rats	ND	ND	2	100	5,000	41,600	No effect at 5,000 and 150,000 ppm.	No histological damage
	Mice	ND	ND	2	100	15,000	125,000	At 50,000, animals were hyperactive, but	
	G. Pigs	ND	ND	2	100	50,000	416,000	returned to normal after exposure.	
	Mice	ND	ND	0.5 minutes		Distance 20-25cm.	ND	Animals sprayed with a shellac-based hair spray	No change in lung histology
Vazin Plokhova (1968a) Abstract	Rabbits	ND	ND	"chronic"		3,500 3,900	ND	Brain electrical activity changes: Appearance of beta waves (80 Hertz) in anterior and posterior hypothalamus along with circulatory changes.	
Vazin Plokhova (1968b) Abstract	Rabbits	ND	ND	4	167 (5.5 mos.)	3,500 to 3,900	ND	Decreased heart rate, arrhythmia Decreased ECG voltage Decreased duration of systole Reduced blood flow. Increased arterial pressure.	Altered β waves in EEG from posterior hypothalamus. Potentials from anterior and posterior hypothalamus increased by 18-30% and 70-85% respectively.
Vazin Plokhova (1969a) Abstract	Chinchilla rabbits	ND	8	4	150	8 to 12	200 to 300	After 20 days, blood adrenaline rose from 3.5 μqm% to 6.15 μqm%; at 40 and more days, it was 6.6 μqm%. Posterior hypothalamus electrical activity also changed. This is the direct cause of hypertension.	
Vazin Plokhova (1969b) Abstract	Rats	ND	ND		150 (5 months)			Disrupted cardiac work rhythm. Bradycardia and arrhythmia. Reduced relative duration of I-II and T-II intervals. Relative duration of QRS complex did not change. After 15 days recovery: cardiac activity rhythm returned to normal, but the duration of the sound interval remained below initial levels for another 15 days. Therefore, max. permissible VC concentration is significantly less than .03mg/l (12ppm).	

ANIMAL DATA

Authors	Species	Sex	No.	EXPOSURE Hrs. per Day	Days	Conc. ppm.	Total Dose ppm-Days	Observations	Pathology
Clapp Kaye Young (1969) Abstract	Rats	ND	ND	-	1	Sub-Cutaneous	ND	Urine contains allylmercapturic acid and 3-hydroxypropylmercapturic acid. These compounds arise by the reactions of allyl compounds with glutathiones.	
Viola (1970a)	Wister Rats	M M	25 25	4	260 (5days per wk for 12 months)	30,000 0	$1,300 \times 10^3$	Animals slightly sleepy during exposure. Gross behavior deteriorated after 10 months. 13/50 died of cardio-respiratory complications. 2/50 died of bleeding in the peritoneal cavity. No mention of skin tumors.	Most animals had pathological involvement of brain, liver, kidney, thyroid. Severe proliferation of cartilege and bone abnormalities in small metatarsal bones. Severe tissue degeneration in brain and liver and thyroid. Connective tissue invaded small arteries in feet. Enlarged, proliferating Kupfer cells in liver.
Viola (1970b)	Rats Wister 300 gm	-	90	1	1	10,000	417	Distribution of VC in tissue: Red cells had much more VC than serum-high variation VC is in urine, but major quantity is lost via lungs. ½(VC) falls rapidly in first hour in expired air, blood, urine, and brain, liver kidney. After 3 hrs. no VC is measurable.	None observed.
Viola Bigotti Caputo (1971)	Rats Wister	M M	26 25	4 5day/wk 1 5day/wk	260 260	30,000 0	1300×10^3 0		Controls showed no tumors. Almost all exptl. animals developed skin and lung tumors. Very few bone tumors; when seen they were in all 4 extremities. 65%-70% of tumors were skin tumors near parotid and submaxillary glands. Frequencies: SKIN LUNGS BONE 26/26 16/26 16/26 Lung tumors were glandular. New cartilage and subsequent ossification in 4 extremeties. Hard mass first seen after 10 months exposure.

DISPOSAL OF PRODUCTS CONTAINING POLYVINYL CHLORIDE

This discussion on disposal of PVC emphasizes incineration and landfilling, the only presently used large-scale methods for the disposal of solid wastes. There is also a limited discussion of resource recovery possibilities.

Incineration

The two areas of concern related to PVC incineration are incinerator air pollution and incinerator and gas scrubber corrosion.

Hydrogen chloride is the major toxic material released when PVC is burned. It has been shown that virtually all of the chlorine is released from PVC on combustion, resulting in HCl. It is estimated that 0.2 percent of solid waste is PVC, and 16 x 10^6 tons per year of solid waste are incinerated in the United States. Thus, on the order of 32,000 tons of PVC are burned annually, releasing approximately 18,500 tons per year of HCl as air emissions.

Other solid waste sources which can produce HCl are chlorides in food waste, plants, grass clippings, and inorganic salts. The formation of compounds requires volatilization and reaction with incinerator flue gases. Achinger and Baker compiled data indicating an emission factor of six pounds of HCl per ton of solid waste burned. Recent data on HCl emissions obtained by Battelle show a factor of 5.1 pounds per ton. A value of five to six pounds per ton would be a reasonable emission factor to use for HCl emissions from municipal incinerators. Using an emission factor of 5.5 pounds per ton gives 44,000 tons per year of HCl produced by incineration of municipal solid waste. The amount of HCl produced from PVC using the above calculation is 42 percent of the total.

Much more HCl is probably now emitted to the atmosphere from the nation's coal-burning power plants than from our municipal incinerators. However, there still could be a hazard in the immediate vicinity of an incinerator as a direct result of its HCl emissions. Of particular concern is the possible dispersal of the stack gases to cause the ambient concentrations of HCl at ground level to exceed harmful concentrations. However, HCl is not at the present time regulated by EPA.

Other air pollutants could be formed from the additives in PVC during incineration. Several additives are usually incorporated into the polymer to emphasize particular properties not inherent in the base polymer. The types of additives are antioxidants, antistatics, colorants, fillers, plasticizers, and stabilizers. Some of the additive agents used are: antioxidants--phenols, amines, phosphates, and sulfur compounds; antistatics --amine derivatives, quaternary ammonium salts, phosphate esters,

polyethylene glycolesters; colorants--salts or oxides of metals, aluminum, copper and inorganic pigments; fillers--silica, glass, calcium carbonate, metallic oxides, carbon, cellulose fillers, asbestos; plasticizers--phthalates, organic phosphates; stabilizers--lead salts of acids, barium, cadmium, calcium, zinc, alkyl tin compounds.

It is highly unlikely that large quantities of VC will be emitted during incineration of PVC. There is no evidence that PVC will chemically revert to VC. Some small amounts of entrapped monomer might conceivably survive incineration, but these quantities would be very low.

The second area of concern with incineration of PVC is firebox corrosion and corrosion of pollution control equipment. HCl can be a major factor related to corrosion of this equipment during incineration at certain temperatures. In the case of plastics, PVC is the major source of chlorine leading to HCl, but other plastics may also contain some chlorine. Incinerators with heat exchangers will have corrosion problems on the fire side of the exchange equipment when the combustion gases contact the outer metal surface. Other surfaces of concern are in the cooling area and in the gas scrubbers.

Estimates indicate that in incinerators with heat-recovery systems PVC in the refuse will increase tube maintenance costs by 15 to 20 per-percent over that to be expected if PVC-free refuse was used as fuel.

About 95 percent of the incinerators in this country have some type of air pollution control equipment that is exposed to the high chloride environment resulting from refuse combustion. Because of the high chlorine content of the combustion products, the cooling and precipitating water from the scrubbers that contacts the flue gas contains large quantities of chloride and is extremely corrosive to the structure.

In summary, technology exists for controlling the HCl emissions that result from incineration of solid waste; however, the application of this technology will result in increased costs. If technology is not applied, then the contribution of PVC to the nation's air pollution problem will increase because of the projected increases in the usage and disposal. HCl scrubbing technology is available, but its application results in corrosion problems. Depending on construction materials, design, and operation, these problems can be either large or small.

Landfilling

PVC does not decompose significantly within the normal time frame of most other municipal solid wastes. It comprises only about 0.2 percent of the total municipal solid waste being landfilled today, and the effect of PVC on the reuse of the landfill site, at least in the short run, should be negligible.

Since PVC degrades very slowly, in the landfill environment it should not add significantly to the production of leachate or decomposition gases as do other parts of the refuse. The additives of greatest concern are probably the plasticizers. However, if a sanitary landfill is designed and operated with today's technology, disposal of PVC products in a sanitary landfill should pose no special problems to the operation or to the ultimate use of the site.

Resource Recovery

Recycling of solid waste is a growing industry. Technology has been developed to recover some resources from many of the items in the municipal waste stream. However, the technology to separate plastics or PVC from the waste stream has not yet been commercially demonstrated. The solution to the separation of plastic waste from other components of the municipal waste stream is one deterrent to direct recycling and reuse of plastics, including PVC. However, gathering and centralizing the waste products are also major problems.

Some types of scrap PVC from the fabrication process are presently being recycled back into the manufacturing process. This reduces the solid waste from plastic fabrication plants and reduces the need for new raw materials.

There is work underway to develop means for utilizing the benefits of recycling the total municipal waste stream. Examples of these recycling techniques are listed below:

- -- To recover heat given off during the incineration of solid waste containing PVC and other combustible materials as electricity or steam for heating. An example is EPA's research contract with the Combustion Power Company of Menlo Park, California, in which combustion gases are expanded through a turbine to produce power.

- -- To recover the products of a refuse pyrolysis operation either as a pipeline gas or as feed material for a nearby refinery. An example is EPA's research grant with West Virginia University in which refuse pyrolysis is being studied on a bench-scale. A second example is the Bureau of Mine's research effort to convert refuse to pipeline gas. Also, US and Japanese industrial firms are actively exploring this area.

The recent change in the world's supply of crude oil should speed up research and development on new and existing ways to utilize more fully the resource of waste PVC.

ACTIVITIES OF TASK FORCE

The principal activities undertaken or stimulated by the Task Force are set forth below:

MARCH	-	Recognition of problem of pesticidal sprays containing VC-- Responsibility assigned to Office of Pesticide Programs
MARCH	-	Analysis of material losses during PVC polymerization process
MARCH 19-21	-	Pilot monitoring effort at B. F. Goodrich Plant in Louisville
MARCH	-	Preliminary evaluation of health effects data
APRIL 2	-	Meeting with representatives of PVC manufacturers organized by Manufacturing Chemists Association
APRIL 4	-	Meeting with representatives of interested environmental groups
APRIL	-	Development of interim methodology for VC sampling and analysis
APRIL/MAY	-	Visits to VC manufacturing facilities and to PVC polymerization, compounding, and fabrication facilities
APRIL 12	-	First of series of interagency meetings convened by EPA
APRIL/MAY	-	Monitoring at seven complexes involving 10 PVC and 2 VC plants
APRIL/MAY	-	Review of health effects data
APRIL 30	-	Review of Industrial Biotest toxicological experiments
MAY 27-31	-	Preliminary VC water persistence studies
MAY	-	Preliminary VC air persistence studies
MAY/JUNE	-	Recognition of air emissions problem -- Responsibility assigned to Office of Air Quality Planning and Standards
JUNE 3	-	Technical review of monitoring activities
JUNE 11	-	Administrator's meeting with senior executives of 29 companies producing PVC and VC
JULY	-	Development of improved methodology for VC sampling and analysis
