The APTD series of reports is issued by the National Air Pollution Control Administration to report technical data of interest to a limited readership. Copies of APTD reports may be obtained upon request, as supplies permit, from the Office of Technical Information and Publications, National Air Pollution Control Administration, U. S. Department of Health, Education, and Welfare, 1030 Wade Avenue., Raleigh, N. C. 27605

National Air Pollution Control Administration Publication No. APTD 69-14

PREFACE

The Continuous Air Monitoring Projects (CAMP) are the first large-scale effort to obtain comparable, continuous, and concurrent data on gaseous pollutant levels in the atmosphere above major American cities. A fundamental reason for the establishment of the program was the need for such data to augment research on the nature of air pollution and on its impact on man and his environment. The Public Health Service encourages interested research personnel to follow the many avenues of investigation opened by this information.

The CAMP master data files are maintained on magnetic tapes for electronic computer analysis. Copies of these tapes may be obtained by interested persons. Since data from the National Air Surveillance Networks, as well as large quantities of mortality, morbidity, meteorological, and socioeconomic data, are also available on magnetic tapes from various sources, the possibilities for computer analysis are almost limitless. Correspondence concerning the availability or use of CAMP data should be directed to the Chief, Division of Air Quality and Emission Data, National Air Pollution Control Administration, Consumer Protection and Environmental Health Service, DHEW, 801 North Randolph Street, Arlington, Virginia 22203.

This publication presents the results of CAMP operation in Philadelphia during 1962, 1963, 1964, and 1965. Part 1 presents background information about the Philadelphia area to assist the reader in interpreting the data. Part 2 contains a brief summary of the data and the analyses currently available, with interpretation and discussion. Part 3 contains the data summary tables of hourly, daily, and monthly mean concentrations, facilitating the use of this volume as a reference.

Similar publications summarizing operations in Cincinnati, Ohio, and Washington, D. C., have been completed, and volumes for other cities are forthcoming. Additional reports containing subsequent data and specialized reports describing in detail specific analyses will be published. Studies of sample averaging times, of pollutant exposures, and of the ratios of peak to average concentrations are in progress.

ACKNOWLEDGMENT

The National Air Pollution Control Administration acknowledges with appreciation the many contributions of cooperating local agencies to the operation of the Continuous Air Monitoring Projects. In the publication of this volume particular appreciation is expressed to the Air Pollution Control Section of the Division of Environmental Health, Philadelphia Department of Public Health.

ABSTRACT

This report presents the results of the Continuous Air Monitoring Projects (CAMP) in Philadelphia, Pennsylvania, operated by the Public Health Service during 1962, 1963, 1964, and 1965. Data on the atmospheric levels of carbon monoxide, nitric oxide, nitrogen dioxide, sulfur dioxide, total hydrocarbons, and total oxidants are analyzed and discussed. To facilitate the use of this volume as a reference, the data are tabulated as hourly, daily, and monthly mean concentrations Background information about Philadelphia and a description of the instrumentation used are included.

CONTINUOUS AIR MONITORING PROJECTS

INTRODUCTION

Despite the estimate that as many as 6,000 urban areas in the United States are affected to some degree by air pollution, air quality measurements have been made in no more than a tenth of these communities.[1] Generally, these measurements are limited to particulate pollutants. Data from dustfall collectors and high-volume filter samplers are most frequently available, and measurements of soiling (COH or RUDS units)* are sometimes available.

In recent years the technical ability and legal authority to control the emission of particulate pollutants to the atmosphere have increased significantly, and a number of urban areas have made gratifying progress in reducing such pollution. During this period, however, public awareness of and official concern for the less obvious but more complex problems of gaseous pollution have grown. Communities that never have been notably concerned with particulate pollution are noticing increased evidence of photochemical smog in periodic episodes of decreased visibility, eye irritation, and plant damage.

Data on atmospheric concentrations of gases are even more limited than the sparse data on particulates. The National Air Sampling Network of the Public Health Service has measured sulfur dioxide and nitrogen dioxide in about 50 cities by means of 24-hour integrated samples, taken biweekly. Because of costs, routine use of more frequent gas sampling has been limited to the larger urban areas. The Public Health Service has measured intensively gaseous pollutants in some of the smaller urban areas during cooperative air pollution surveys,[2,3,4] but these programs were conducted for relatively short periods. Daily, 24-hour sampling programs are rare and have usually been restricted to collection of integrated samples of at least 2 hours duration, despite the knowledge that atmospheric concentrations of gaseous pollutants can change significantly within a few minutes.

Knowledge of the nature of atmospheric pollution by gaseous contaminants is restricted both by the scarcity of data and by differences among the several methods of sampling and analysis being used to determine the concentration of any single pollutant. These restrictions have hindered comparison and joint interpretation of the

*COH (Coefficient of Haze) units are based on the transmission of light through a soiled filter; RUDS (Reflectance Units of Dirt Shade) are based on the reflection of light by a soiled filter.

results of numerous studies. Furthermore, the lack of concurrent data on two or more gaseous pollutants handicaps studies of the more complex effects and interrelationships.

The need for continuous, concurrent data obtained on several gases by comparable methods in various communities was recognized some years ago. It was apparent that the requisite sampling program would be far more difficult than any previously attempted. Completely satisfactory instrumentation was lacking. The subject itself - rapid and concurrent variations of the various atmospheric pollutant levels - was little understood. The question of which pollutants could and should be measured was largely unanswered. Furthermore, few groups interested in air pollution could obtain the money or the manpower for such an undertaking.

In 1960, Congress provided impetus and financial support for a program capable of solving some of the problems concerning gaseous pollutants and their sampling. Public Law 86-493 directed the Public Health Service to accelerate research into the effects on human health of air pollutants from motor vehicles. Since such pollutants are largely gases, the Continuous Air Monitoring Projects were established to measure the concentrations of various gases in the ambient atmosphere. The necessary instrumentation was developed by the Public Health Service through a contract with a commercial firm, and the operation of the program was assigned to the Air Quality Section of the Laboratory of Engineering and Physical Sciences, Division of Air Pollution. The first station was opened in Cincinnati in October 1961, and by early 1962 six stations were operating. During 1962 and 1963, these six stations were located in Cincinnati, Chicago, Philadelphia, New Orleans, San Francisco, and Washington, D. C. The instruments at the New Orleans station have subsequently been moved to St. Louis, and those at San Francisco to Denver. Each station is equipped to monitor and record, automatically, 24 hours a day, the ambient concentrations of six common gaseous pollutants: carbon monoxide, nitric oxide, nitrogen dioxide, sulfur dioxide, total hydrocarbons, and total oxidants. The stations are operated in cooperation with local air pollution control agencies. Data similar to those obtained in the CAMP operations have also been obtained in Detroit, New York, and Los Angeles at stations provided and operated by local groups.

Additional continuous air monitoring facilities are being included in some state and municipal programs initiated or enlarged with the assistance of Federal grants. These funds for control program grants provided under the Clean Air Act of 1963, totaled $5,000,000 in fiscal year 1966, $7,318,000 in fiscal year 1967, and $18,647,000 in fiscal year 1968.

Insofar as practicable, CAMP station locations are comparable; each station is located in or near the principal business district of the city and away from

significant point sources. Since a CAMP station constitutes only one sampling site in a given community, the measured levels are specific only for the immediate vicinity of the station; still, the data are useful in studies of the broad patterns of temporal variations and pollutant interrelationships affecting the entire urban area. Available information indicates that data from the present stations are representative of at least the central business districts of the cities.

OBJECTIVES

CAMP has two related objectives: (1) to increase knowledge of the nature of air pollution by providing information heretofore unavailable, i.e., comparable, continuous, concurrent data on significant gaseous pollutants from a number of urban areas; and (2) by providing such information, to stimulate necessary investigation and control of pollution. In fulfillment of these objectives, CAMP data have been made available through abbreviated interim summaries since the inception of the program. Sufficient information has now been accumulated to warrant the presentation and the initial interpretations given in this series of reports. The increased availability of this information, through these publications and in subsequent more detailed publications, should encourage its application to many problem areas.

Information provided by CAMP makes possible the intracommunity study of the concurrent variations of several gaseous pollutants and their effects. Analysis of CAMP data has already revealed significant photochemical reactions in communities outside of California, and further investigation of this phenomenon is anticipated. The data are being used in conjunction with meteorological data in mathematical diffusion models, in studies of the effect of large, single sources of pollution on ambient concentrations, and in differentiation of temporal and geographic pollutant patterns.

An understanding of the impact of air pollution on man and his environment requires knowledge of the diurnal and seasonal variability of pollutant levels. In the field, CAMP data can be used in epidemiological studies of health effects. In the laboratory, the data are used in the selection of realistic pollutant concentrations and combinations for exposures of animals and plants. Pollution effects and behavior can also be examined in terms of various time-concentration arrays. In addition, CAMP data provide information necessary for the evaluation of proposed air quality criteria and of the impact of implementing such criteria through air conservation programs.

Techniques for assaying air quality must be developed and improved. Information on relationships of peak to average concentrations over various periods of time may provide guidance for optimum use of continuous and integrating instruments. Similarly, studies of pollutant interrelationships may indicate that one pollutant,

or a combination of a few pollutants, can provide a good index to the behavior of others. Either of these factors could affect both the type and the cost of air quality measurements.

PART 1. PHILADELPHIA, PENNSYLVANIA

This discussion of the nature of the Philadelphia area is included so that features unique to this area can be considered in interpretations of the data in Part 2.

TOPOGRAPHY AND LAND USE

The city of Philadelphia is located in southeastern Pennsylvania at the confluence of the Schuylkill and Delaware Rivers. The city, co-extensive with Philadelphia County, occupies 127 square miles and ranges in elevation from essentially sea level at the Delaware River front to a maximum of 430 feet in the northwestern corner of the city. The terrain rises more or less gradually to the north and northeast and to the west across the Schuylkill River to elevations of around 200 feet in largely residential suburban areas. The northwest section, also residential, includes both the maximum elevation of 430 feet and the deep valleys of the Schuylkill River and of Wissahickon Creek, which flows southward to the Schuylkill River. The land across the Delaware River in New Jersey, south and east of Philadelphia, is low and quite flat.

Heavy industry, concentrated along the Delaware and the lower Schuylkill Rivers, borders the low, flat peninsula on which the downtown area is situated. Industrial plants located along both sides of the Delaware River from Trenton, New Jersey, to Wilmington, Delaware, constitute in this 55-mile corridor passing through Philadelphia one of the nation's ten largest concentrations of industrial activity.

Philadelphia is the nucleus of the fourth largest Standard Metropolitan Statistical Area (SMSA) in the U.S. This area includes Bucks, Chester, Delaware, and Montgomery Counties in Pennsylvania and Burlington, Camden, and Gloucester Counties in New Jersey. At the time of the 1960 census, 4,342,879 persons lived in this 3549-square-mile area. The city of Philadelphia occupies 3-1/2 percent of this area and contains 47 percent of the population in the SMSA. Table 1-1 gives statistics for the City of Philadelphia and for the SMSA and the Urbanized Area* of which Philadelphia is the center and comparative statistics for a number of other

*Urbanized Area includes adjacent incorporated areas of at least 2500 persons and adjacent unincorporated census tracts having a population density of 1000 or more persons per square mile.

PRINCIPAL SOURCES OF AIR POLLUTION

The major pollutant sources of the Philadelphia area can be grouped into eight categories: (1) electric power generation plants, (2) other large fuel-burning industries, (3) petroleum refineries and petrochemical industries, (4) other chemical industries, (5) metals refineries, (6) refuse burning, (7) automobiles, and (8) space heating.

The Philadelphia Electric Company operates eight electric generating plants in the greater Philadelphia area. Coal is the major fuel, supplying 90 percent or more of the energy at all except the Barbados plant (45 percent gas) and the Schuylkill plant (100 percent oil)*. The sulfur content of the coal and oil is

*Base year: 1963.

from 2 to 3 percent. Three plants (Delaware, Schuylkill, and Southwark) are relatively close to the downtown area. The principal pollutants emitted from these electric generating plants are oxides of sulfur, oxide of nitrogen, and particulate matter. High-efficiency collectors on the coal-fired plants within the city limits catch most of the particulates, yet at each plant the remaining fraction emitted amounts to several tons of fly ash daily.

Petroleum refineries, oil storage tank farms, and petrochemical industries are distributed along the Delaware River from Petty Island, north of Camden, southward to below Chester and are concentrated near the confluence of the Schuylkill and Delaware Rivers (see Figure 1-1). Six major petroleum processors in the greater Philadelphia area collectively employ over 11,000 persons and account for approximately 8 percent of the nation's petroleum refining. The principal emissions from petroleum processing are hydrocarbons and oxides of sulfur. Smaller amounts of carbon monoxide, nitrogen oxides, aldehydes, organic acids, ammonia, and particulate matter are emitted.

Diverse chemical industries and allied industries, other than petrochemical, account for a large portion of manufacturing in the greater Philadelphia area and along the Delaware River above and below the city. The more than 40,000 persons

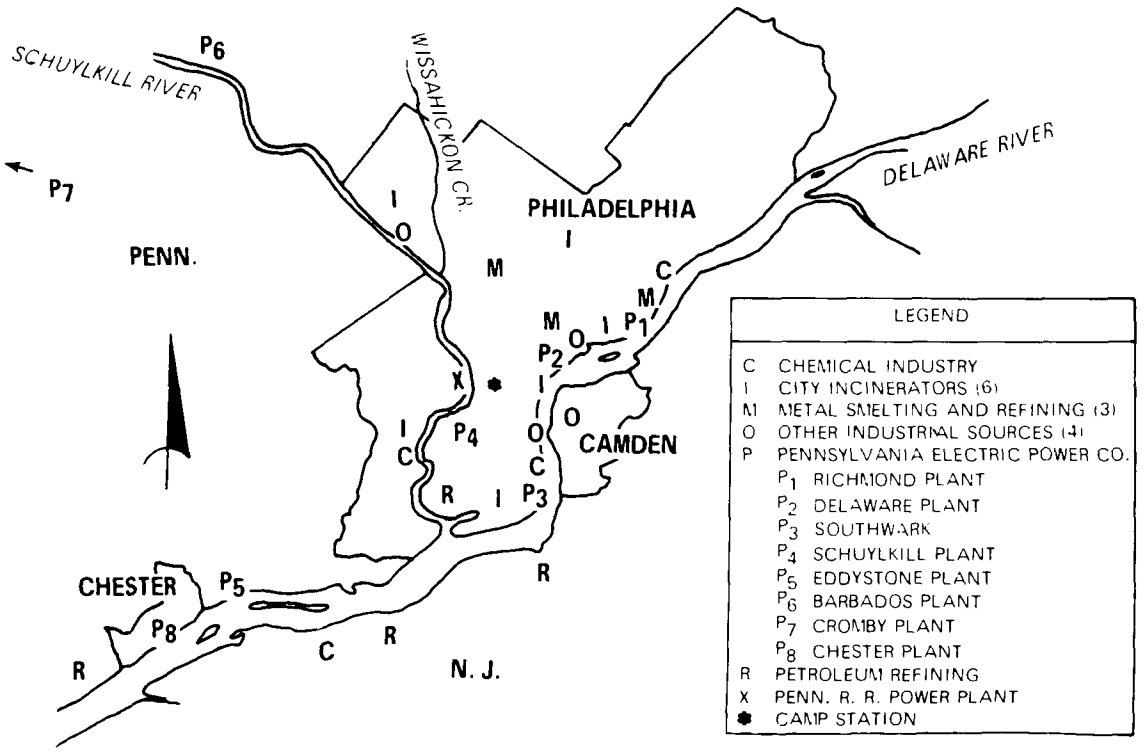

Figure 1-1. Principal sources of air pollution in the greater Philadelphia area.

employed in these industries represent almost 7 percent of the total employment in the eight-county area (Table 1-2). Emissions are primarily dust and vapors, which are occasionally odorous.

The metal industries, concentrated around two areas north of the downtown area, include grey iron foundries, secondary copper and lead smelting, and alloy production. Emissions include metal fumes, sulfur dioxide, dusts, and odors varying with the process involved. In the remaining major category of industrial sources are plants, such as sugar refining, container manufacturing, and metal fabricating, whose emissions are primarily associated with fuel burning rather than with process losses. Many of these are located along or near the Delaware River.

Burnable refuse and garbage are disposed of in six city incinerators, the locations of which are indicated in Figure 1-1. Together these incinerators handle approximately 3000 tons of material per day.

The sources southwest of the central business district are important because about 37 percent of all winds and about 44 percent of winds below 7 mph blow from this southwest quadrant.

METEOROLOGY

Pollutant concentrations in the atmosphere depend not only on the amount of pollution emitted, but also on the extent to which the pollutants are diluted or dispersed in the atmosphere. This in turn depends on the climate and meteorology of the area.

The climate of the Philadelphia area is influenced by the proximity of the Delaware Bay and the Atlantic Ocean. Periods of extended cold weather are relatively rare, and no reading of zero degrees Fahrenheit or below has occurred since January 1936. Periods of unusually high or low temperatures seldom last more than 3 or 4 days. During the summer months, increased humidity caused by prevalent maritime air adds to the discomfort suffered by the population. Extensive fog occurs about ten times a year, usually during the fall and winter. Local fog near the river and over low elevations occurs about 30 times a year. The prevailing wind is from the southwest during the summer and from the northwest during the winter.

The extent of horizontal dilution and dispersion of air pollutants is determined primarily by surface wind speed. Average wind speeds and prevailing directions by month and by season for the 3-year period 1962 through 1964 are presented in Table 1-3. For comparison, corresponding monthly averages for the 23 years preceding 1964 are included. As determined by average wind speeds, the gross capacity for horizontal dispersion in Philadelphia is relatively better in winter and spring than in summer and fall. A detailed analysis by Francis K. Davis

[a]From 'Local Climatological Data,' 1963 summary for Philadelphia, U.S. Weather Bureau.

of weather records for Philadelphia indicates that poorest diffusion conditions occur in late summer and early fall and are usually associated with southwesterly winds of less than 8 mph.[8] These winds cross much of the concentrated industrial area before reaching densely populated residential areas north of the central business district.

No data suitable for evaluation of monthly or seasonal variations in vertical mixing are available. However, because of their fundamental influence on pollutant concentrations, the meteorological conditions governing vertical mixing characteristics must be considered.

The extent of vertical dispersion of pollutants is determined by the stability of the atmosphere, i.e. the degree of turbulent mixing in the air mass. This in turn depends on the temperature gradient in the lowest layer of the atmosphere. If the temperature decreases with altitude at a rate greater than 5.4°C per 1000 feet (the dry adiabatic lapse rate), the atmosphere is unstable and turbulent mixing occurs. If the temperature decreases less than 5.4°C per 1000 feet or increases with height, the atmosphere is stable; and with the exchange of air between the surface and the upper levels suppressed, vertical mixing is inhibited.

The atmosphere is usually unstable during daylight hours. When low-lying air is warmed by the earth's surface it rises and allows cooler upper air to sink in its place. The convection currents produced distribute gaseous pollutants throughout the mixing layer, and the effective depth of this mixing layer determines the degree of vertical dilution. The depth of this layer, determined by the vertical temperature profile, generally is greatest in the afternoon. In Philadelphia, the maximum mixing depth is estimated to range from 4000 feet in summer to about 1270 feet in winter.

During the night, when the earth's surface cools, the decrease in air temperature with altitude usually is less than during the day; thus, vertical mixing is reduced correspondingly. After sunset, heat frequently radiates from the surface of the earth so rapidly that the temperature gradient swings to the stable side of the adiabatic lapse rate and may even become "inverted," i.e. the lower air may become cooler than the upper air. Such a "radiation inversion" is very stable and essentially prevents any vertical dispersion until the inversion is dissipated by the warming of the earth's surface the next morning.

Vertical dilution may also be inhibited when a high pressure system stagnates over the area. These systems affect the eastern United States most frequently in the autumn. In a stagnating high pressure system, the upper air generally is subsiding to lower altitudes. Warmed as it descends, this air forms a layer over the cooler surface air. The "subsidence inversion" thus produced, in contrast to the

nocturnal radiation inversion, may not entirely dissipate during daylight hours and, on occasion, may persist for several days. During periods of such atmospheric stagnation, pollutant concentrations often reach record levels. The U.S. Weather Bureau issues forecasts of meteorological conditions conducive to formation of stagnating high pressure systems likely to persist long enough to cause accumulations of atmospheric pollutants.[9] The Philadelphia area was included in forecasts of eight such conditions for periods totaling 19 days during the 4-year period 1962 through 1965 (Table 1-4). These conditions often last 2 to 3 days.

Table 1-4. AIR POLLUTION POTENTIAL ADVISORIES THAT INCLUDED PHILADELPHIA AREA, 1962-1965

Figure 1-2 shows the cumulative patterns of occurrence of these stagnations over the eastern U.S. since the beginning of the forecast service in October of 1960. Periods during which pollutant concentrations reached particularly high levels are discussed under "Incidents of High Pollution."

AIR POLLUTION CONTROL ACTIVITIES

The 1948 Donora episode was the stimulus for initation of a program of air pollution control in Philadelphia. The Philadelphia Home Rule Charter, adopted in 1952, gave to the city increased opportunity and responsibility for control, and by 1954, concern among civic, industrial, and business groups led to a new Air Pollution Control Ordinance. The city's Department of Public Health was given broad responsibilities to investigate complaints, to abate nuisances and hazards, and to examine plans and specifications for new or remodeled equipment considered to be potential pollution sources. The ordinance was followed by a series of specific regulations for control of a number of air pollution problems.

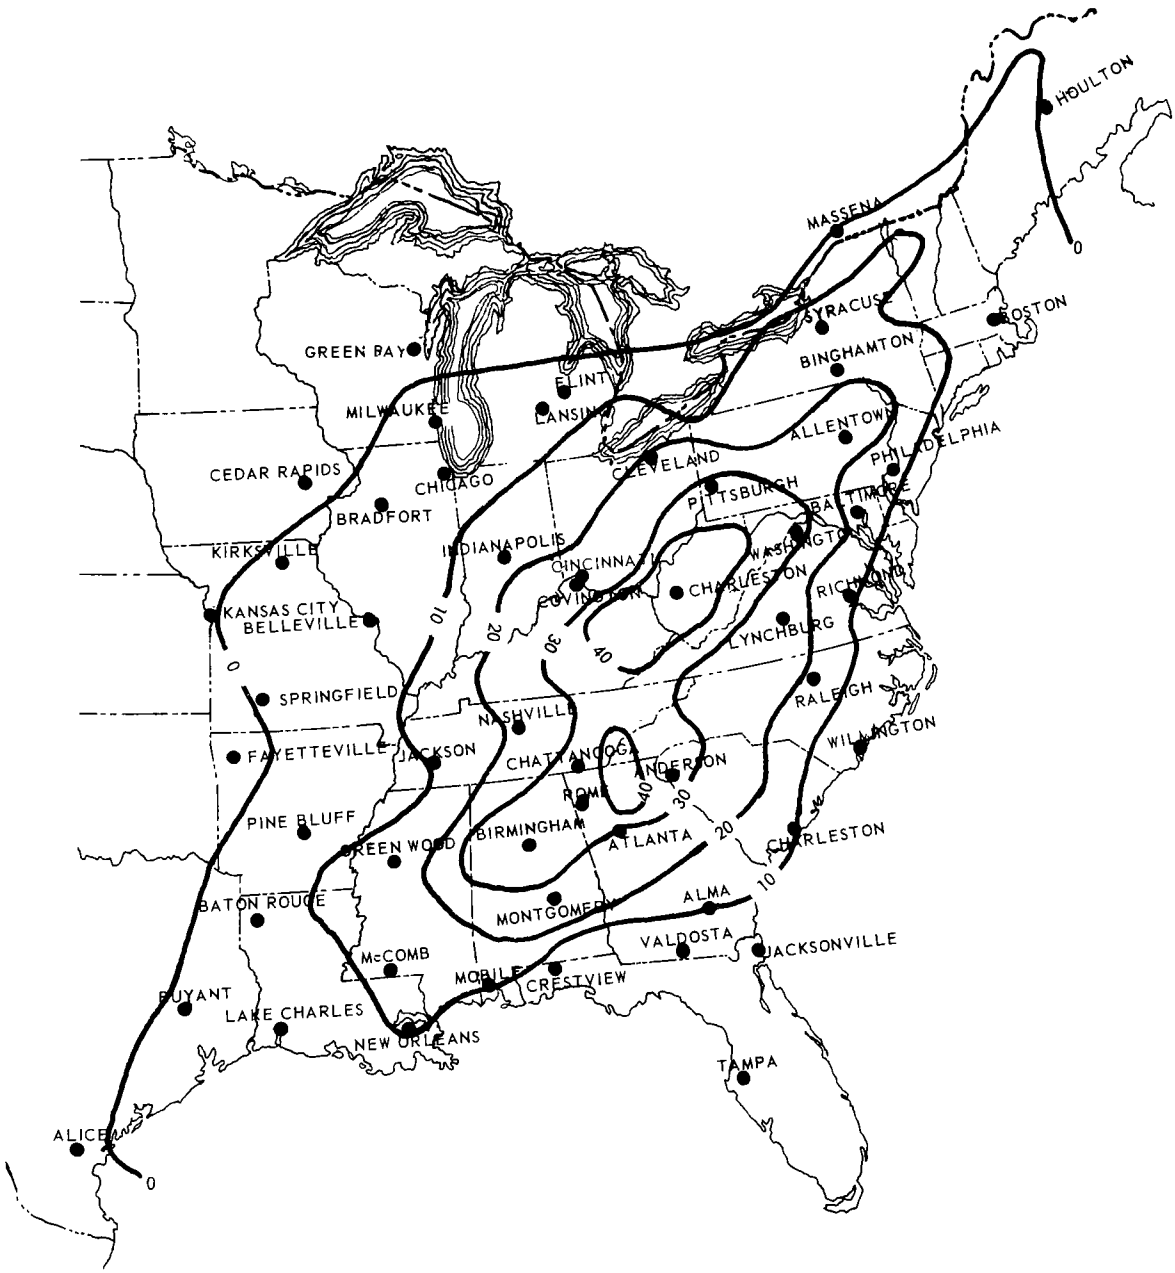

Figure 1-2. Days of stagnation included in air pollution potential forecasts October 1960 – December 1964, Eastern United States.

The air pollution control function of the Philadelphia Department of Public Health has responsibility in three areas: (1) routine inspections and investigations of complaints and violations; (2) engineering evaluations and consultations on equipment installations, permit applications, and industrial process emissions; and (3) laboratory functions including air and source sampling, and requisite chemical analyses. Routinely published summaries of air pollution control activities include information on measurement, investigation, and control of air pollution in Philadelphia.

Figure 1-3 shows the location of 13 sampling sites in periodic use since 1960. Figures 1-4 through 1-6 show the general distributions of suspended particulates, settled dust, and sulfation, respectively, based on measurements and knowledge of sources. Annual average concentrations of these measurements are shown in Figure 1-7.[10]

CAMP STATION SITE

The building housing the Philadelphia CAMP instruments (Figure 1-8) is located on the grounds of the Franklin Institute, at 2031 Race Street, approximately eight blocks northwest of the center of the city (Figure 1-9). Two major traffic arteries pass within 500 feet to the north and east of the station: Benjamin Franklin Parkway, which carries an average of 32,000 vehicles per day, and Vine Street, which is below grade at this point and which carries an average of 52,000 vehicles per day. The neighborhood adjacent to the Franklin Institute is composed of private row houses, apartment buildings, and some small office buildings.

PART 2. RESULTS AND ANALYSES

POLLUTANT LEVELS

The basic CAMP data on gaseous pollutants are neither precisely instantaneous atmospheric concentrations nor 5-minute average levels. The measurements represent instantaneous values of the instrument responses recorded at 5-minute intervals. Each of these instantaneous values, however, reflects some degree of sample integration inherent in the operating characteristics of the instrument systems.

During the period 1962 through 1965, more than 1-1/2 million valid 5-minute measurements of the concentrations of six gaseous pollutants were taken at the Philadelphia CAMP station. In addition, 2-hour soiling index values were collected from 1963 through 1965. Measured concentrations of the gaseous pollutants ranged from maximum values of 5 to 65 times the 4-year average levels to minimum values below the sensitivity of the instruments. Table 2-1 shows the maximum average concentrations for different intervals and the mean for the 4-year period. Data on some pollutants for some months in 1962 are missing because not all instruments

Carbon monoxide, ppm infared analysis	67	54	25	7.53
Total oxidant, ppm 1962-63[a]	0.13	0.11	0.05	0.008
KI analysis 1964-65[b]	0.35	0.33	0.09	0.026
Soiling index, Coh/1000 ft 1963-65		8.1 (2-hr)	5.25	1.29

[a]Oxidant data for this period are not corrected for a negative interference caused by sulfur dioxide. (See Appendix A).

[b]Sulfur dioxide interference has been eliminated from oxidant measurements in 1964 and 1965 data.

were put into operation at the same time. No data were collected in most of May and June and, in come cases, part of July of 1965 because the station was being moved about 40 feet to make room for construction work.

The arithmetic mean of all hourly average SO_2 concentrations measured during 1962 through 1965 was 0.080 ppm. Of the 25,841 valid hourly averages in this 4-year period, 2 percent were 0.40 ppm or more, 1 percent were 0.47 ppm or more, and 0.1 percent, or 26 hourly averages, were 0.69 ppm or more. The highest hourly average, 1.03 ppm, occurred during a 48-hour period of restricted ventilation that had been predicted by the U.S. Weather Bureau's Air Pollution Potential Forecast for October 2 through 4, 1962.

In "Air Quality Criteria for Sulfur Oxides,"[11] the following values are given as those at and above which adverse effects on health may occur:

Averaging interval	SO_2 concentration, ppm	
	Maximum	1 percentile
24 hours	0.05-0.08	0.04-0.06
1 hour	0.12-0.20	0.05-0.11
5 minutes	0.12-0.50	0.05-0.14

With these values, an annual average of about 0.015 ppm can be expected. The report acknowledges that special circumstances may produce higher extreme values without noticeably raising the annual average. However, at the Philadelphia station where the maximum values for the several averaging times are at least five times the listed levels, the annual average of 0.080 ppm is correspondingly greater than the listed annual average of 0.015.

Nitric oxide concentrations during the 4-year period averaged 0.045 ppm. Of the 25,974 valid hourly averages of nitric oxide measurements, 2 percent were 0.23 ppm or more, 1 percent were 0.33 ppm or more, and 0.1 percent, or 26 hourly averages, were 0.75 ppm or more. The highest hourly average concentration of nitric oxide, 1.57 ppm, occurred on the evening of November 30, 1962, the second day of a 5-day Air Pollution Potential Forecast period.[12]

The arithmetic mean of all hourly average NO_2 concentrations for 1962 through 1965 was 0.038 ppm. Of the 27,074 valid hourly averages in this 4-year period, 2 percent were 0.09 ppm or more, 1 percent were 0.11 ppm or more, and approximately 0.1 percent, or 28 hourly averages, were 0.19 ppm or more. The highest hourly average nitrogen dioxide level, 0.32 ppm, occurred on February 6, 1963. The variation in the nitrogen dioxide values is strikingly smaller than that in the nitric oxide values.

The mean of the hourly average concentrations of total hydrocarbons for the period January 1963 through December 1965 was 2.3 ppm. In these 36 months of

19,955 valid hourly averages, 2 percent were 5 ppm or more, 1 percent were 6 ppm or more, and approximately 0.1 percent, or 31 hourly averages, were 9 ppm or more. The highest hourly average concentration was 13 ppm.

Carbon monoxide data are limited for 1962 and 1963; less than 2000 valid hourly averages were recorded, primarily in December, 1962, and in a few scattered months in 1963. Data for 1964 and 1965 are fairly complete. The average of the 13,132 valid hourly averages recorded in the latter 2 years is 7.5 ppm. Two percent of the valid hourly averages were 19 ppm or more, 1 percent were 22 ppm or more, and the highest hourly average was 54 ppm.

The data for total oxidant fall into two categories. Measurements taken in 1962 and 1963 were affected to a certain extent whenever SO_2 was present, since SO_2 causes a negative instrument interference. When this interference resulted in an apparent zero oxidant level, measurements could not be corrected. Since January 1964, a chemical prefilter has been used to remove the interfering SO_2 from the sampled air (see Appendix A). Although summaries of the total oxidant data for 1962 and 1963 are included in Part 3, since they may serve as indicators of relative seasonal levels and diurnal variations, the 1964 and 1965 data provide a better picture of actual oxidant concentrations. Of the 12,469 valid hourly average concentrations in 1964 and 1965, 2 percent were 0.11 ppm or more, 1 percent were 0.14 ppm or more, and the highest hourly average was 0.21 ppm. The average of the oxidant concentration measurements for 1964 and 1965 is 0.26 ppm.

Since oxidant concentration is strongly dependent upon sunlight, it may be useful to consider daytime and nighttime averages separately. The daytime (0600 to 1800 hours) average oxidant concentration for 1964 and 1965 was 0.034 ppm; the nighttime (1800 to 0600 hours) average was 0.021 ppm. This dependence of oxidant concentrations on sunlight is discussed in more detail later.

Table 2-2 shows the number and percent of valid data days in 1964 and in 1965 during which at least one hourly average oxidant concentration equalled or exceeded 0.15, 0.10, and 0.05 ppm, respectively.

Table 2-2. NUMBER OF DAYS HAVING MAXIMUM HOURLY OXIDANT EQUAL TO OR GREATER THAN INDICATED CONCENTRATION, 1964 and 1965

	Concentration						Days of valid data
	0.15 ppm		0.10 ppm		0.05 ppm		
	Number of days	Percent of valid days	Number of days	Percent of valid days	Number of days	Percent of valid days	
1964	9	3	37	13	124	43	289
1965	4	2	23	9	110	42	261

Because of the relocation of the station, as previously mentioned, no measurements were taken during most of May, June, and, in the case of some pollutants, July, 1965. The apparent drop in incidence of high oxidant concentrations in 1965 is probably due to this interruption during the season when oxidant concentrations are high, rather than to a real decline in incidence.

Tables 2-3 through 2-8 are frequency distributions of 5-minute concentrations of sulfur dioxide, nitric oxide, nitrogen dioxide, total hydrocarbon, total oxidant, and carbon monoxide.

In Figure 2-1, distributions of pollutant concentrations in Philadelphia are compared with those at other CAMP stations. The interpretation of frequency distributions such as those used in Figure 2-1 is explained in Appendix A. Distributions are graphed for 1962 through 1965, except in the oxidant graph which incorporates only 1964 and 1965 data. Levels of sulfur dioxide and of carbon monoxide at the Philadelphia station were second only to those at Chicago. Concentrations of NO and of total hydrocarbons are intermediate with respect to those at other CAMP locations. NO_2 concentrations are above the median. The oxidant curves for all sites except San Francisco are closely grouped, but Philadelphia's is one of the highest.

VARIATIONS IN POLLUTANT LEVELS

The mean concentrations of the pollutants, listed in Table 2-1, give only a partial picture of air quality in Philadelphia. Variations in concentrations with time are equally important. Two underlying cycles in pollutant concentrations, the long-term seasonal cycle and the daily or diurnal cycle, are products of the combination of changes in rates of pollutant emission with changes in rates of dilution, dispersion, and assimilation. The long-term seasonal cycle is apparent in the graphs of the monthly means for 1962 through 1964 (Figure 2-2). The monthly means are shown as percentages of the 4-year mean to emphasize the patterns of variation. The actual concentrations of the pollutants are discussed in detail later.

Nitric oxide and oxidant show the most prominent seasonal cycles. Nitric oxide reaches its highest levels during the winter and diminishes through the summer. In contrast, the concentrations of total oxidant reach a maximum in the summer when solar energy flux is greatest. The average oxidant concentration for the 1962 through 1963 period is lower than for 1964 and 1965 as a consequence of the previously mentioned negative interference from SO_2. Consideration of the monthly oxidant means as percents of the average concentrations permits comparison of the patterns of seasonal variation for all four years. The seasonal variations in NO_2, CO, and hydrocarbon concentrations are less pronounced than others. The NO_2 concentration tends to be somewhat smoothed by compensating atmospheric reactions,

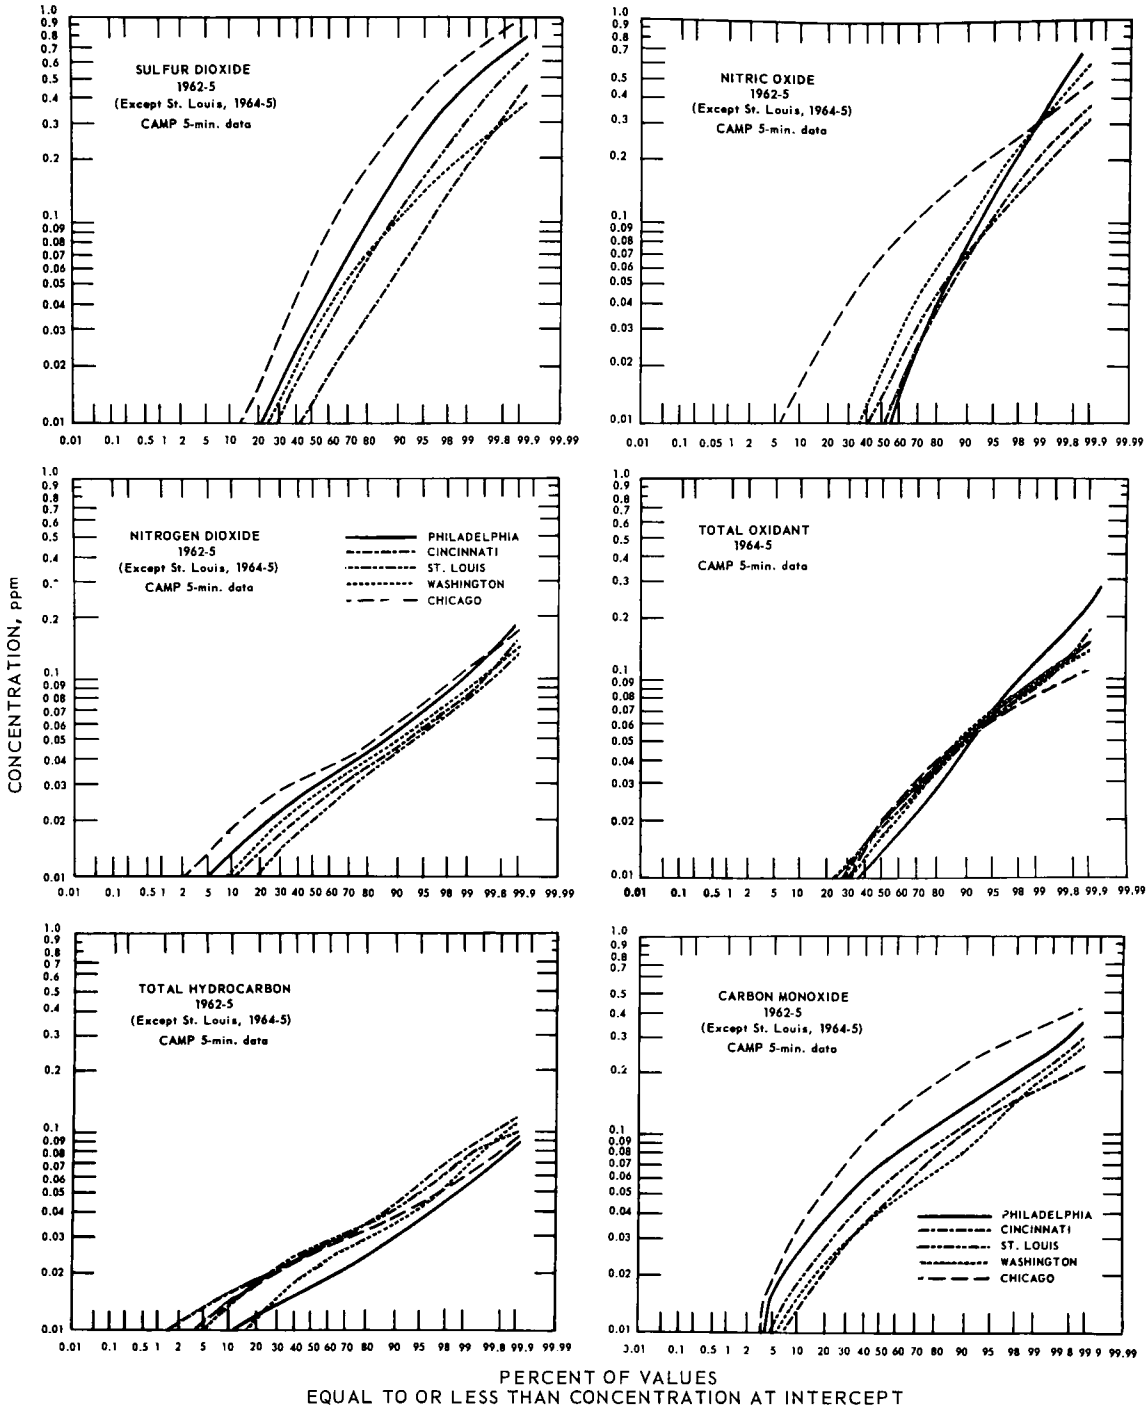

Figure 2-1. Pollutant levels in six CAMP cities, 1962-1965.

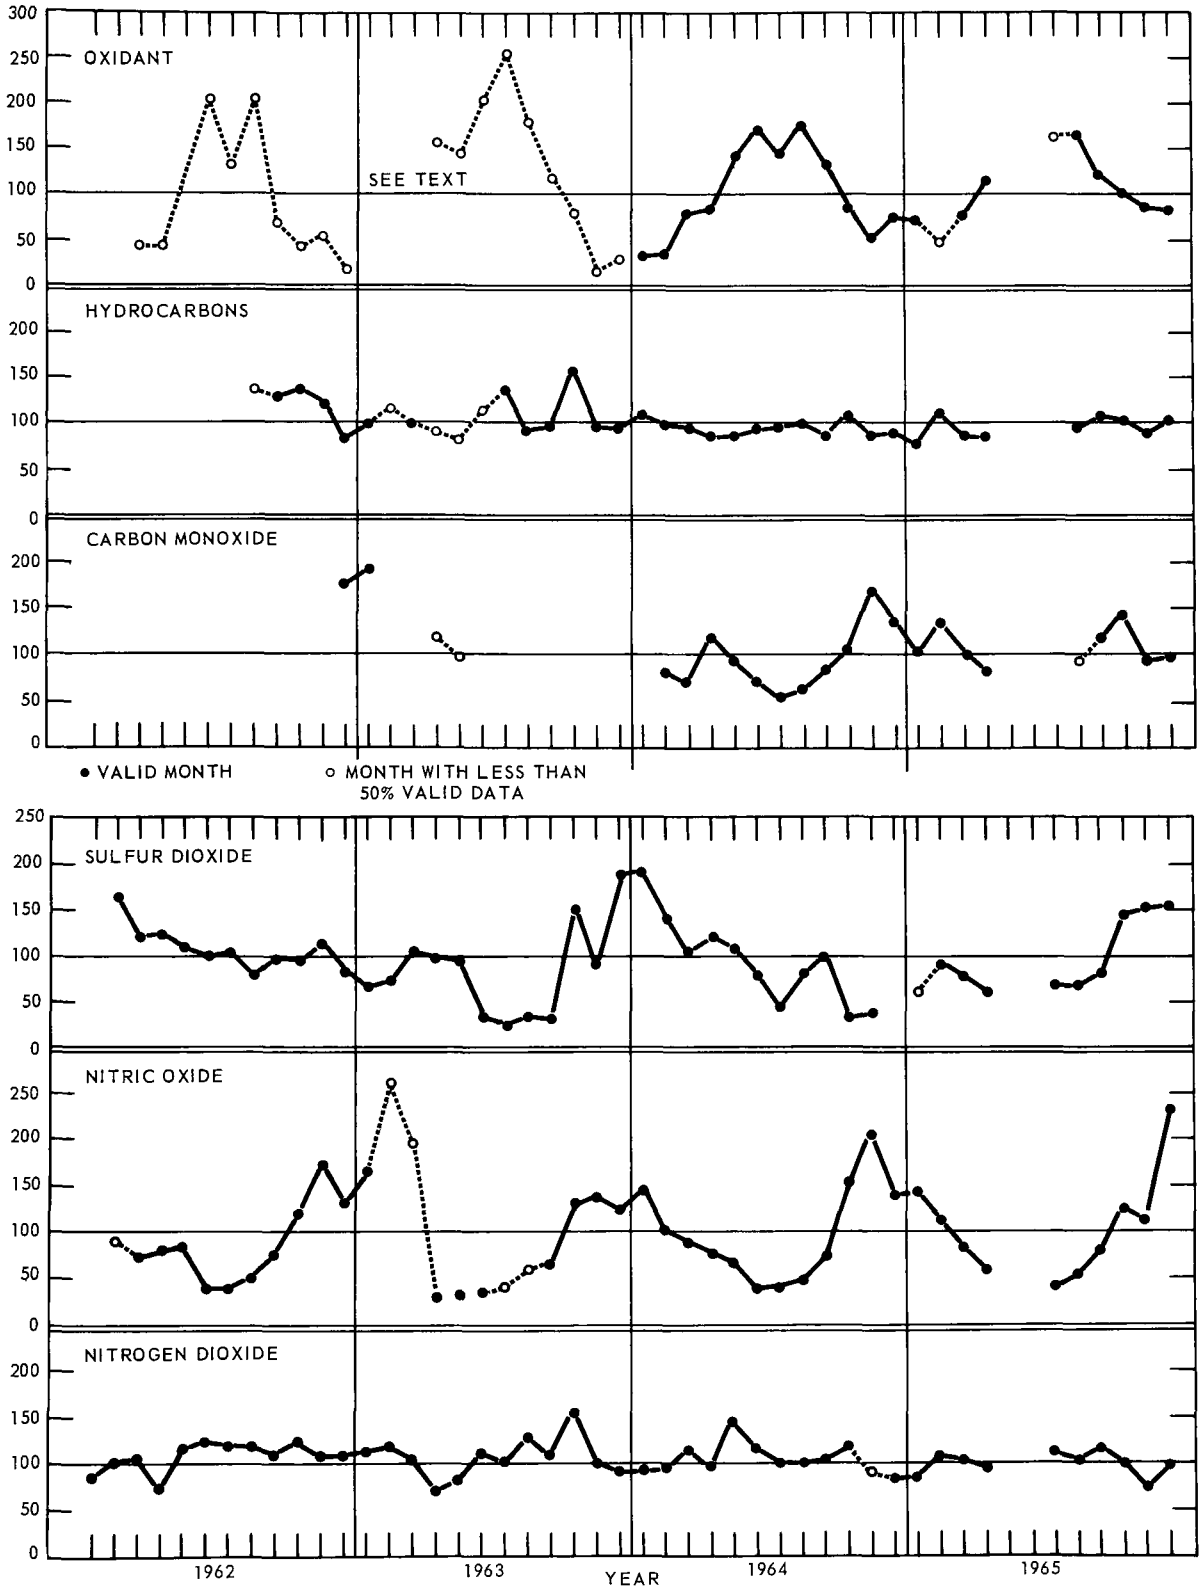

Figure 2-2. Seasonal variation of gaseous pollutant levels.

discussed later. Major portions of CO and of hydrocarbons are produced by automobiles at fairly constant rates throughout the year. Data on CO, though sparse, suggest a pattern of higher winter levels that may be attributable to space heating. The lack of a recurrent seasonal pattern for SO_2 has not yet been satisfactorily explained, though it may result from suspected variations in the typical wind patterns from the direction of strong, nearby point sources.

The daily cycle also results from the combined effects of changes in source strength and in dilution capacity of the atmosphere and is affected, in some cases, by photochemical reactions. Obviously, the seasonal and daily cycles are not independent. Both daily activities and daily weather patterns change with the seasons. Therefore, the diurnal variations in the atmospheric concentrations of gaseous pollutants are averaged by seasons (Figure 2-3). For comparison of the patterns of variation, the hourly average concentrations are plotted as a percent of the 4-year mean except in the graphs for total oxidant and for carbon monoxide, which are based upon data for 1964 and 1965.

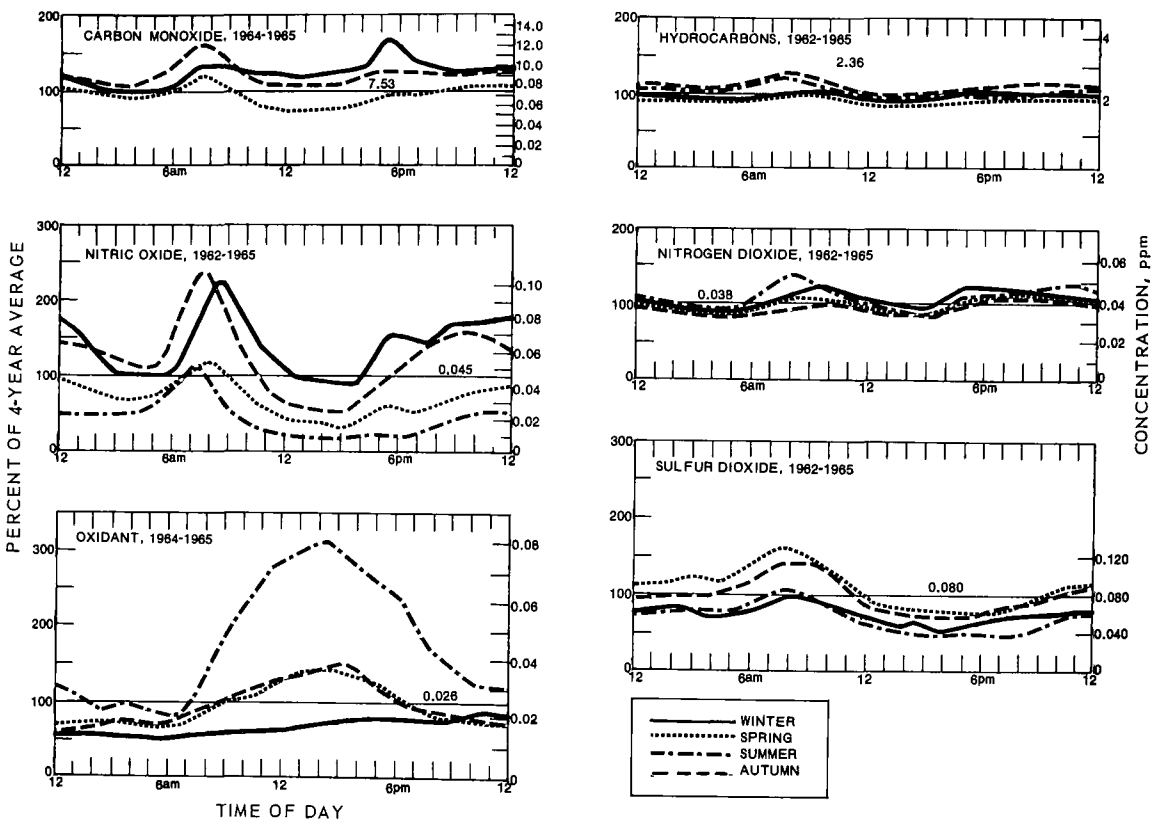

Figure 2-3. Diurnal patterns of pollutant concentrations, by season.

All of the pollutants except total oxidant exhibit approximately the same general pattern - a maximum in the morning and a minimum in the afternoon. The morning peak is due primarily to increased emissions associated with the beginning of the day's activities, e.g., industrial and commercial processes and space heating, and to increased motor vehicle exhaust during the morning traffic peak. However, another important factor contributing to the morning peak is the prevalence, prior to sunrise, of minimum dilution capacity of the atmosphere.

The morning peaks in the patterns for NO, for hydrocarbons, and for CO appear approximately an hour earlier in the summer than in the winter, because while CAMP data are based on standard time throughout the year, activities in Philadelphia are based on daylight savings time in the summer months. Because the spring and fall seasons contain both standard and daylight savings time periods, the morning peaks during these seasons tend to be broader.

Following the morning peak, as increasing mixing height and rising wind speed improve the atmosphere's capacity to disperse and dilute pollutants, the concentrations of most of the pollutants usually decline fairly steadily to a minimum sometime in mid-afternoon. In contrast, the concentration of total oxidants begins to increase quite rapidly just after sunrise, reaching a maximum around noon or shortly thereafter and then declining to base-line levels by sunset. Since the substances comprising the total oxidants result primarily from photochemical reactions, the rate of production is dependent upon the intensity of solar radiation, which increases during mid-morning. For the concentrations of total oxidants to increase from one hour to the next, the rate of photochemical reaction must surpass the dilution capacity, which also increases during mid-morning. Also, on the calm, sunny days characteristic of atmospheric stagnations, since dilution and dispersion parameters do not develop fully, oxidant concentrations can increase far above normal daily averages.

EFFECT OF ATMOSPHERIC DILUTION CAPACITY

Because the influence of atmospheric dilution capacity on both long-term seasonal variations and short-term daily fluctuations is relatively important and affects all the emitted pollutants in essentially the same manner, it is discussed here separately prior to the more detailed discussions of the individual pollutants.

The best dilution conditions generally exist in the afternoon when the depth of the unstable mixing layer is greatest and wind speeds are highest. Figure 2-4 shows the diurnal variation in one parameter of the dilution capacity, horizontal wind speed. In all seasons, average wind speeds are highest after midday. Consequently, afternoon levels of all the pollutants except total oxidant are usually at a minimum.

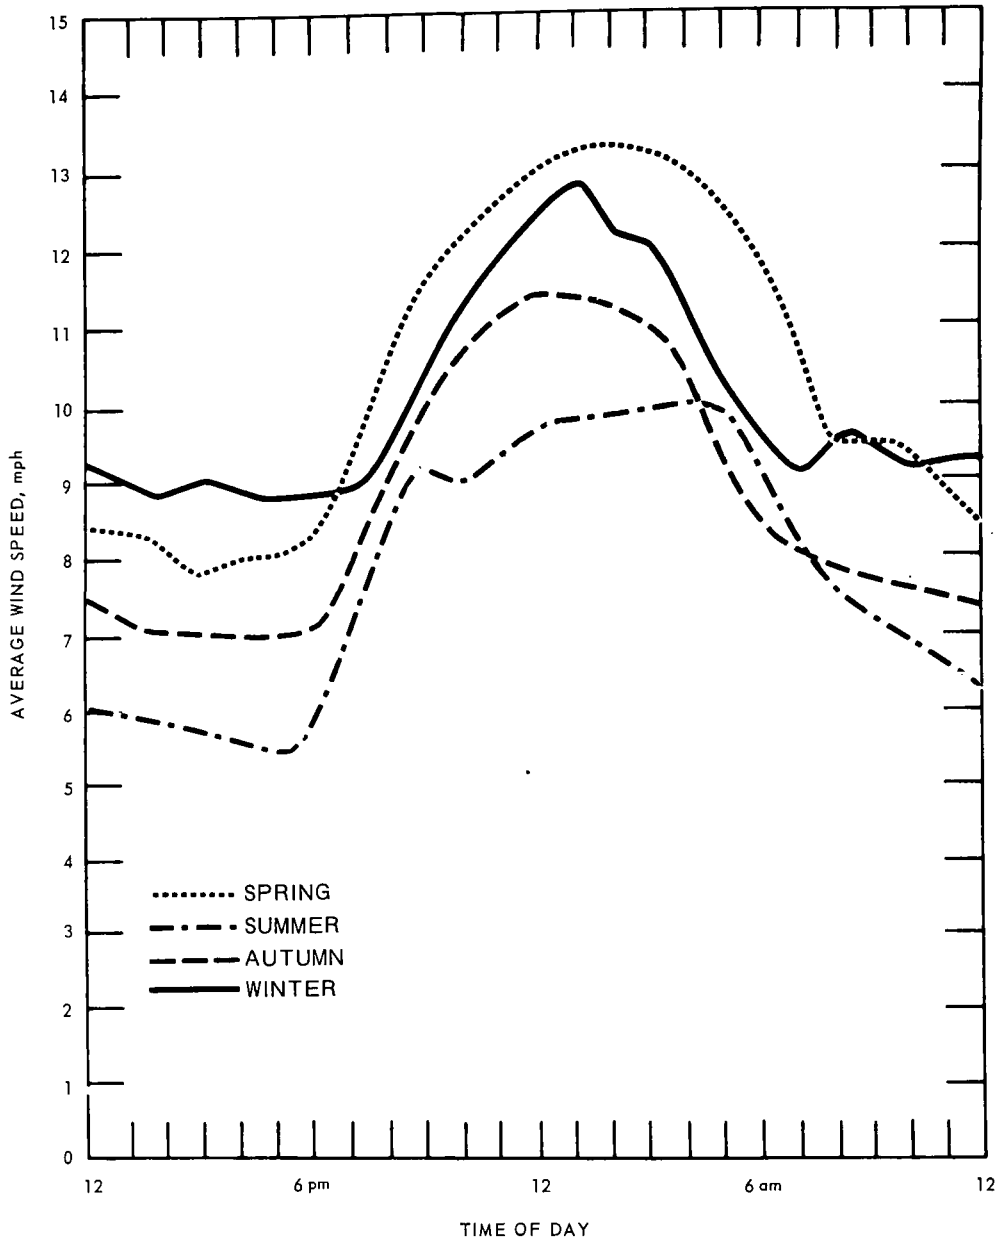

Figure 2-4. Diurnal variation in horizontal air movement, Philadelphia 1962-1964.

In the evening, when the atmosphere becomes stable and wind speeds diminish, pollutant emissions are dispersed less rapidly and atmospheric concentrations increase. Reduced dilution conditions usually continue through the night, and the minor decrease in pollutant concentrations during the early morning hours prior to sunrise is due primarily to a diminished rate of emissions. Peak levels occur in the morning, generally between 7 and 9 a.m., when emissions, rapidly increasing

with the start of the day's activities, temporarily exceed the increasing dilution capacity.

Occasionally, a high-pressure weather system becoming almost motionless over a relatively large area of the eastern United States tends to change the usual daily cycle of natural ventilation. As a result of this condition, which significantly restricts the ability of the atmosphere to disperse and dilute pollution, concentrations may continue to build up beyond the time of the normal morning peak. The distinction between the typical nighttime inversion and the occasional "stagnation" inversion is explained in Part 1 under "Meteorology." The effect of inhibited dilution on pollutant concentrations during stagnations is discussed later under "Incidents of High Pollution."

DISCUSSION OF RESULTS

All pollutants emitted into the atmosphere at a given time are dispersed or confined similarly according to the prevailing weather conditions. Significant differences between the seasonal or diurnal patterns of different pollutants result not from the influence of meteorological factors, but, for the most part, from differences in emission patterns. These patterns, along with sources of individual pollutants and variability of pollutants, are discussed here.

Sulfur Dioxide

Since the monthly average SO_2 concentrations for the 4-year period 1962 through 1965 (Figure 2-2) do not indicate a consistent annual pattern, the seasonal diurnal patterns for each year are plotted separately in Figure 2-5. The daily variations in SO_2 concentrations during three of the spring seasons are quite consistent; however, the variations during spring 1965 depart from the pattern. The summer patterns for 1962, 1964, and 1965 show the characteristic morning peak around 8:00 a.m., but the pattern for 1963 is comparatively flat throughout the day. As Figure 2-2 shows, the monthly averages for June, July, and August, 1963, are among the lowest of the 4-year period. The fall seasons of 1962, 1963, and 1965 have definite morning peaks; but in the fall of 1964 the morning peak is not pronounced, and the monthly averages are again among the lowest for the 4-year period. Because the winter season bridges the calendar year, including December of one year and January and February of the following year, only three winter seasons are represented. The diurnal pattern for the winter of 1963-1964 shows a much more pronounced morning peak than the other two winters, and the monthly averages (Figure 2-2) reflect this difference. The monthly averages in December 1963 and in January 1964 are the highest of the 4-year period.

The major emissions of sulfur dioxide come from point sources, either from the combustion of sulfur-bearing fossil fuels for space heating, process heating, and

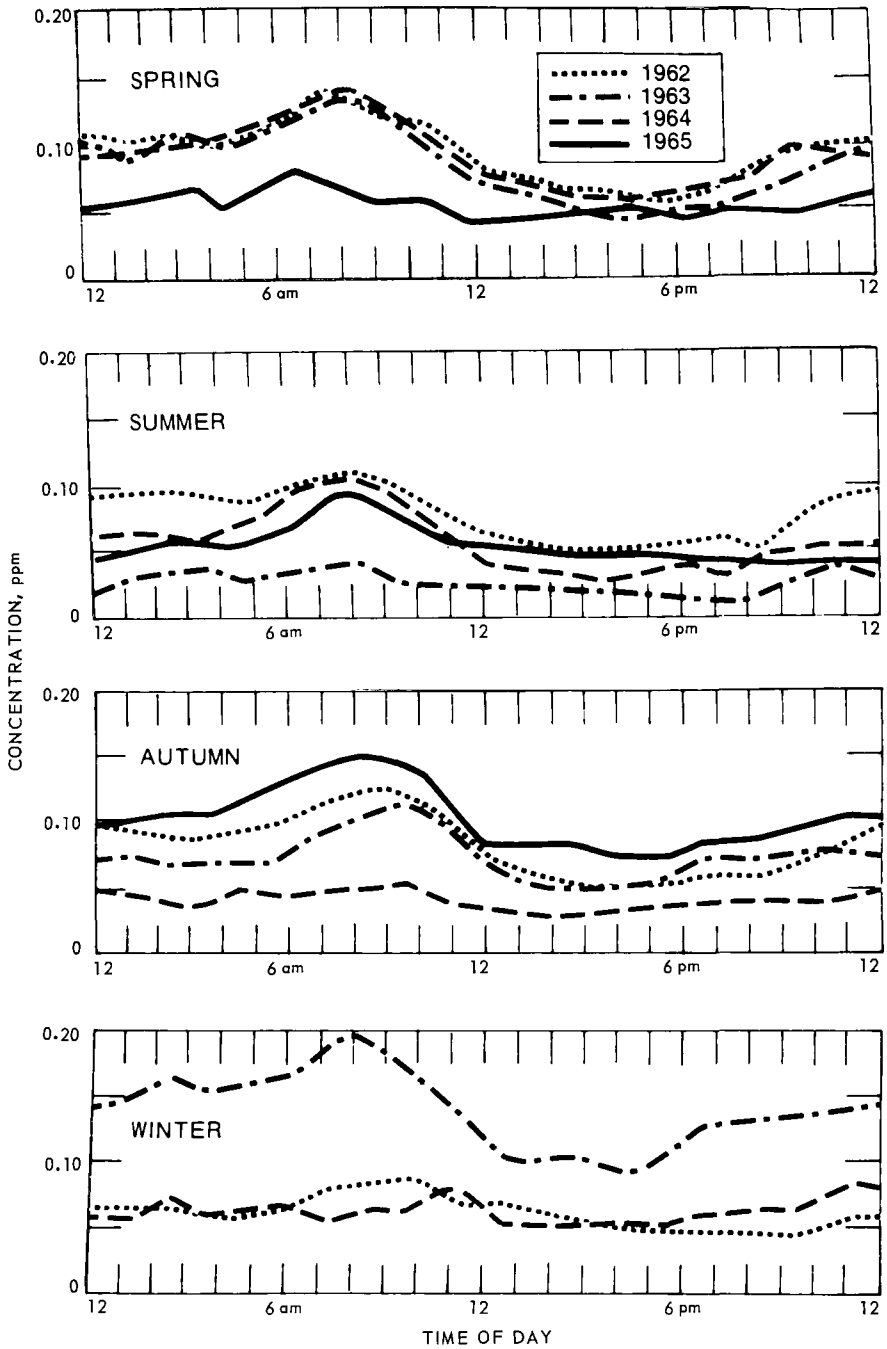

Figure 2-5. Diurnal variation of sulfur dioxide levels by individual season.

electric power generation or from industrial process losses. The Schuylkill electric generating plant, located about 1-1/2 miles to the southwest of the CAMP station, consumes some 2-1/2 million barrels of oil per year - oil with a sulfur content of 2 to 3 percent. The stack gases, therefore, include about 55 tons of SO_2

per day. The Delaware and the Southwark electric generating plants, about 2-1/2 to 3 miles east and southeast, respectively, from the station, together consume about 1.2 million tons of coal per year, again with a 2 to 3 percent sulfur content. The combined SO_2 yield from these two stations is about 165 tons per day. Almost directly to the west of the CAMP station, about 3/4 mile away, is a steam-electric plant operated by the Pennsylvania Railroad to generate electric power for commuter trains. The plant is a relatively minor consumer of coal, but because of its proximity, it can contribute significantly to SO_2 concentrations measured at the CAMP station.

Six major petroleum companies operate refineries in the Philadelphia area. Two are located from 2-1/2 to 5 miles southwest of the CAMP station, along the lower reaches of the Schuylkill River; two more are located 6 to 8 miles south of the station, along the New Jersey side of the Delaware River; and the remaining two are located about 16 to 18 miles southwest of the station, below Chester on the Pennsylvania side of the Delaware River. Emissions of SO_2 from these sources result from both process losses and fuel combustion. Total annual SO_2 emission from these refining operations is estimated to average about 400 tons per day.

Because of these significant point sources, the concentration of SO_2 at the CAMP station is more strongly related to wind direction than are the concentrations of other pollutants. To portray the relationship between wind direction and SO_2 concentration, directional pollutant profiles are superimposed on radial wind roses for each of the four seasons in 1963 (Figure 2-6). For this use, the winter "season" is considered to consist of January, February, and December of 1963. In calculation of a directional pollutant profile, each hourly average pollutant concentration is related to the prevailing wind direction (one of 16 sectors) for that hour, and the concentrations observed in connection with each directional sector are averaged. The average concentration for each of the 16 directions is plotted on a polar graph as a vector corresponding to the wind direction, and a smooth line is drawn through the endpoints of the 16 vectors to produce the directional pollutant profile. Directional lines in the wind roses are divided into two segments indicating two wind speed categories: 0 through 7 mph and greater than 7 mph. The length of each segment corresponds to the number of hours that winds in the indicated speed category were observed. Together, the lengths of the two wind speed segments give a relative indication of the total number of hours during which wind blew from the direction indicated.

Some of the highest average pollutant concentrations in each season are associated with the relatively frequent winds from the southwest quadrant. In the winter months (January, February, December), high average concentrations also occur

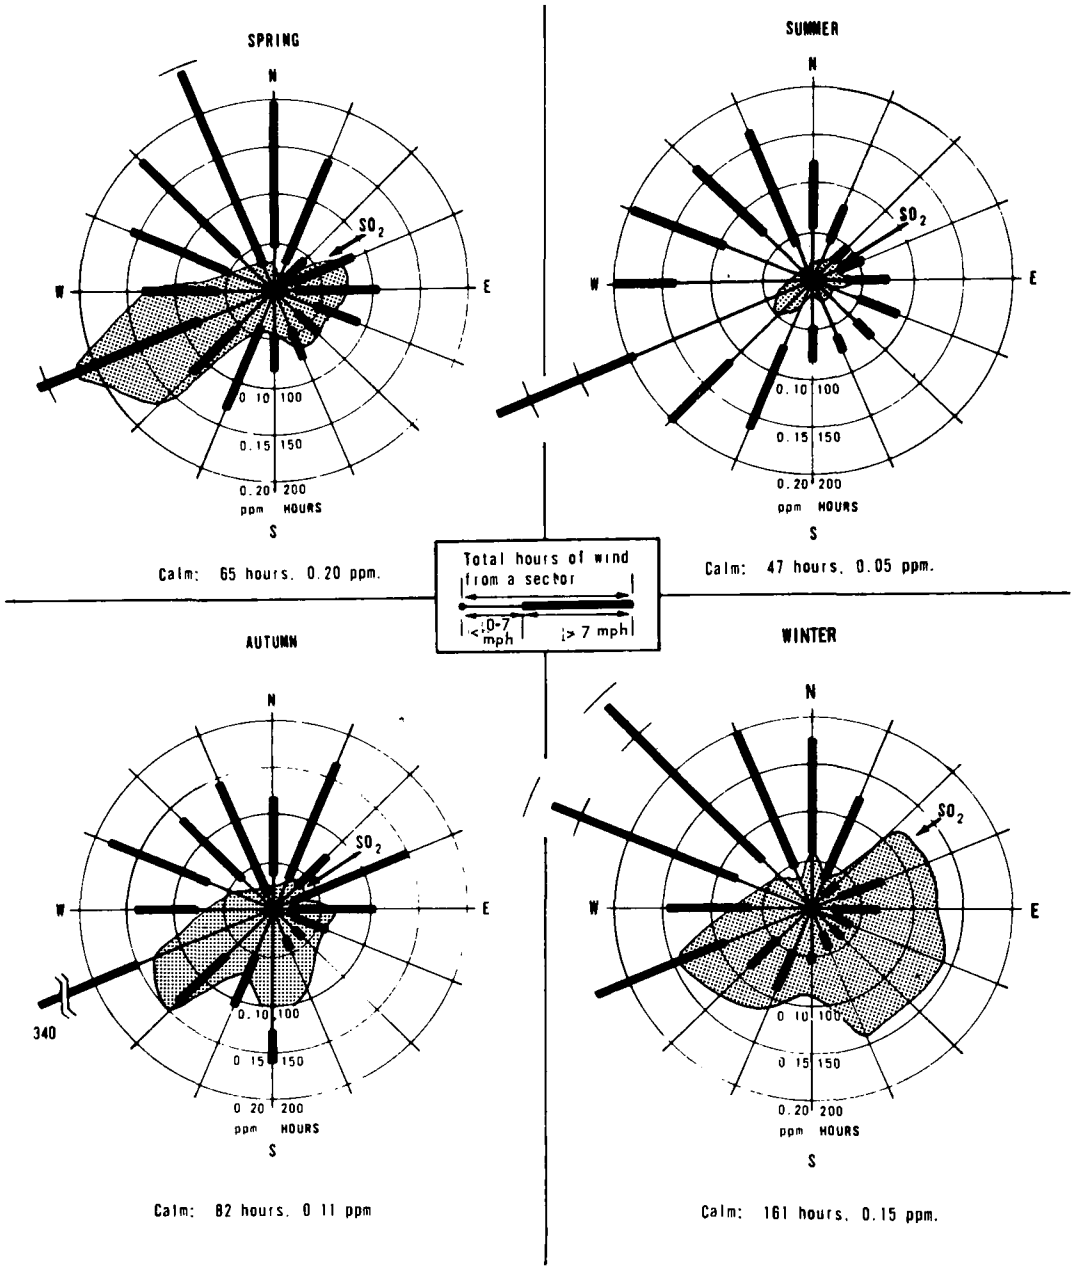

Figure 2-6. Sulfur dioxide concentrations and wind direction, Philadelphia - 1963.

with winds from the northeast through the south-southeast sectors, but winds from these directions are relatively infrequent. These high winter averages from the south-easterly quadrant are attributed to the operation of space heating equipment in buildings of the central business district of Philadelphia, which lies mainly to the south and east of the CAMP station. In the other three seasons, the average concentrations from the easterly directions are much lower. A suggestion of a small

peak in the profiles corresponding to winds directly from the east is most noticeable in the summer and fall profiles. This peak may be due to operations at the Philadelphia Electric Company's Delaware plant, situated on the Delaware River slightly north of east from the CAMP station and about 2-1/2 miles distant, and at other industrial sources located along the river in this general area.

Although the highest average SO_2 concentrations occur with winds from the west-southwest, the major nearby sources (the Schuylkill power plant and the closest of the petroleum refineries) lie more to the southwest or south-southwest of the CAMP station. The appearance of a shift in these vectors toward the west may be due to the fact that wind direction data are obtained from the Greater Philadelphia Airport, which is located adjacent to the Delaware River, some 6 miles south of the CAMP station. Ideally, the wind data should be obtained where the pollutant measurements are taken. Additional studies of pollutant concentrations in relation to wind parameters can use meteorological data from wind-recording instruments installed in mid-1963 at the Franklin Institute, on whose grounds the CAMP station is located.

Although seasonal variations in SO_2, as measured at the CAMP station, tend to be erratic, concentrations tend to be higher in winter than in summer. This tendency is probably due to space heating since the major point sources operate rather steadily all year.

Oxides of Nitrogen

Nitric oxide (NO) and nitrogen dioxide (NO_2) are produced by any high-temperature combustion process using air as an oxygen source. Concentration levels of these oxides of nitrogen depend upon source strength and atmospheric dilution; the relative levels of NO and NO_2 are influenced by atmospheric reactions that convert nitric oxide to nitrogen dioxide at rates related to the intensity of solar radiation. Because of the influence of solar radiation, nitrogen dioxide levels exhibit essentially no seasonal pattern, but the nitric oxide pattern is quite pronounced (Figure 2-2). During the summer, the high rate of conversion of NO and NO_2 subtracts from the NO concentrations during the season when levels are already low, thus accentuating their variation. In turn, this high rate adds to the concentrations of NO_2 during the season of reduced emissions, thus reducing their variation.

Nitric oxide concentrations exhibit pronounced diurnal variation (Figure 2-7), because of the same factors that contribute to the seasonal pattern: (1) strength of combustion sources, (2) dilution capacity of the atmosphere, and (3) rate of photochemical conversion to NO_2. These factors combine to produce three consistent features in the diurnal NO pattern for each month:

1. The minimum concentration during the afternoon (like the low summer

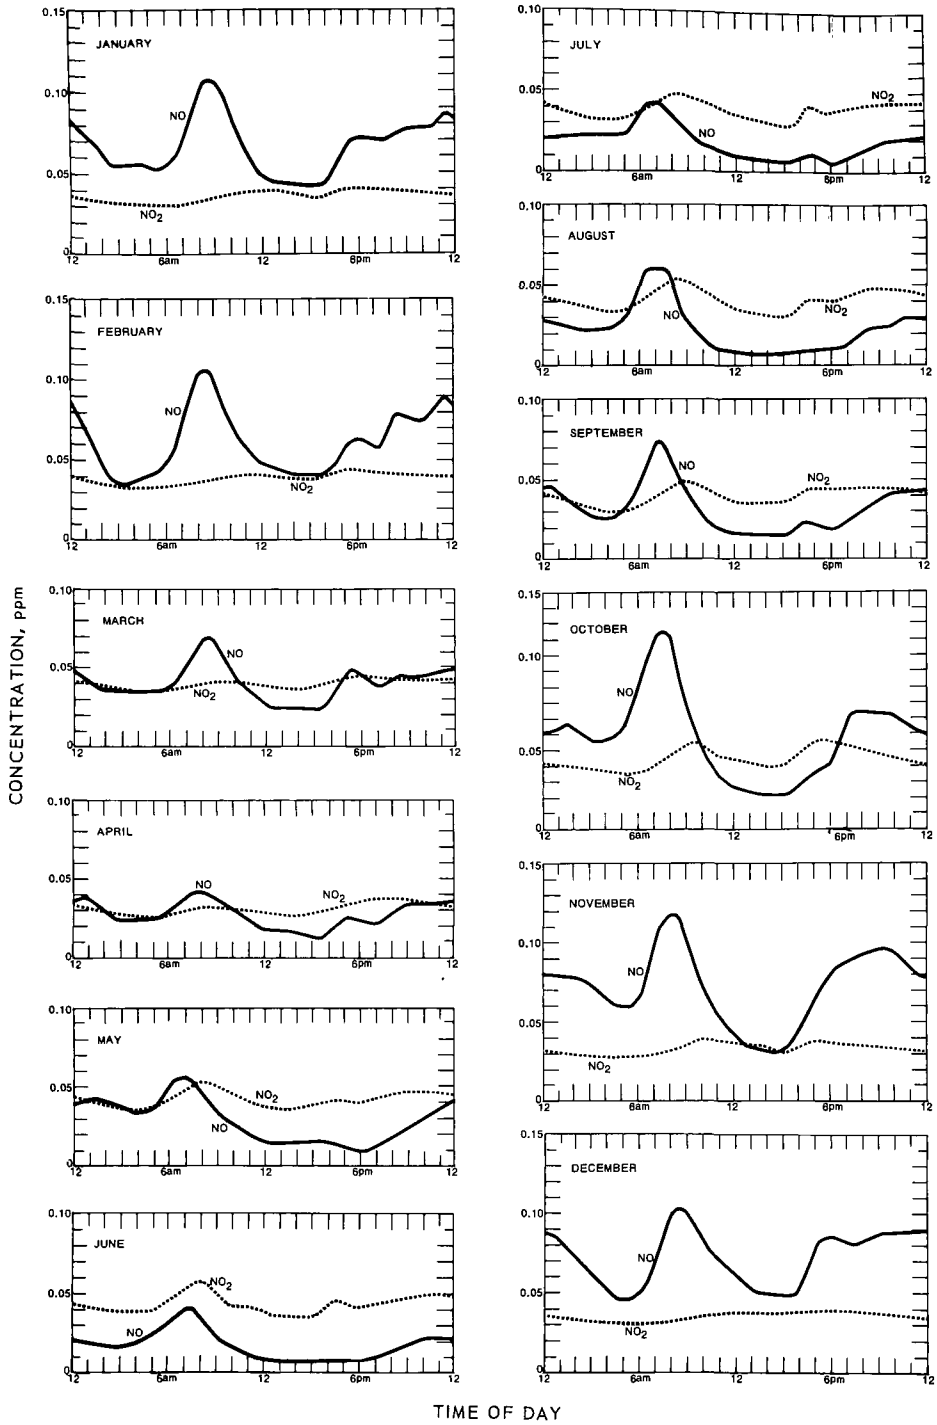

Figure 2-7. Diurnal variation of nitric oxide (NO) and nitrogen dioxide (NO_2) levels by month.

levels) is attributable to maximum conversion of the NO to NO_2, to enhanced atmospheric dilution potential, and to minimum emissions. The level of this afternoon minimum varies with the season from near zero in the summer to 0.05 ppm in January.

2. The high overnight concentrations of nitric oxide are the result of a reversal of these three factors: source strength, dilution capacity, and conversion rate. The level begins to increase in late afternoon and peaks between 5 and 7 p.m., most prominently during late fall and winter. With the decrease in human activity later in the evening, the concentration of nitric oxide decreases to a secondary minimum around 3 to 4 a.m.

3. The characteristic morning peak results from increased emissions at the beginning of the day's activities. Low-level inversions, which frequently form overnight, confine the increased morning emissions, to further increase morning concentrations. With the breakup of the inversion, around 7 a.m. in the summer and as late as 9 a.m. in the winter, the mixing volume increases and the ambient concentration begins to decline even though the emissions of NO may continue at a high rate beyond the peak in concentration.

During the warmer months (May through October), the diurnal patterns for NO_2 levels (Figure 2-7) are similar to those of NO; however, the photochemical conversion of NO to NO_2 has a smoothing effect. The morning peak, when it can be discerned, varies from about 8 a.m. during the summer to about 11 a.m. in the winter. The 1- to 2-hour lag between the NO peak and the NO_2 peak is attributed to the time required for the photochemical conversion. The conversion of NO to NO_2 contributes to the afternoon concentrations by sustaining the NO_2 level when dilution conditions are best.

The relationships between NO concentrations and seasonal wind patterns during 1963 are portrayed in Figure 2-8. The average concentration, indicated by the outlined area, is noticeably higher in winter than in summer, but no consistent relationship to wind speed or direction is apparent. This absence of pronounced directional features is characteristic of a pollutant that emanates from a multitude of small sources broadly distributed over a large area, in this instance automobiles.

Although some NO_2 is emitted in automobile exhaust, a significant amount is produced from NO by reactions in the atmosphere. Consequently profiles of wind direction and pollutant concentration for NO_2, having no prominent directional features, have not been included.

Total Oxidant

Most atmospheric pollutants capable of oxidizing are produced by photochemical reactions in the atmosphere rather than by specific sources. Ozone, the principal

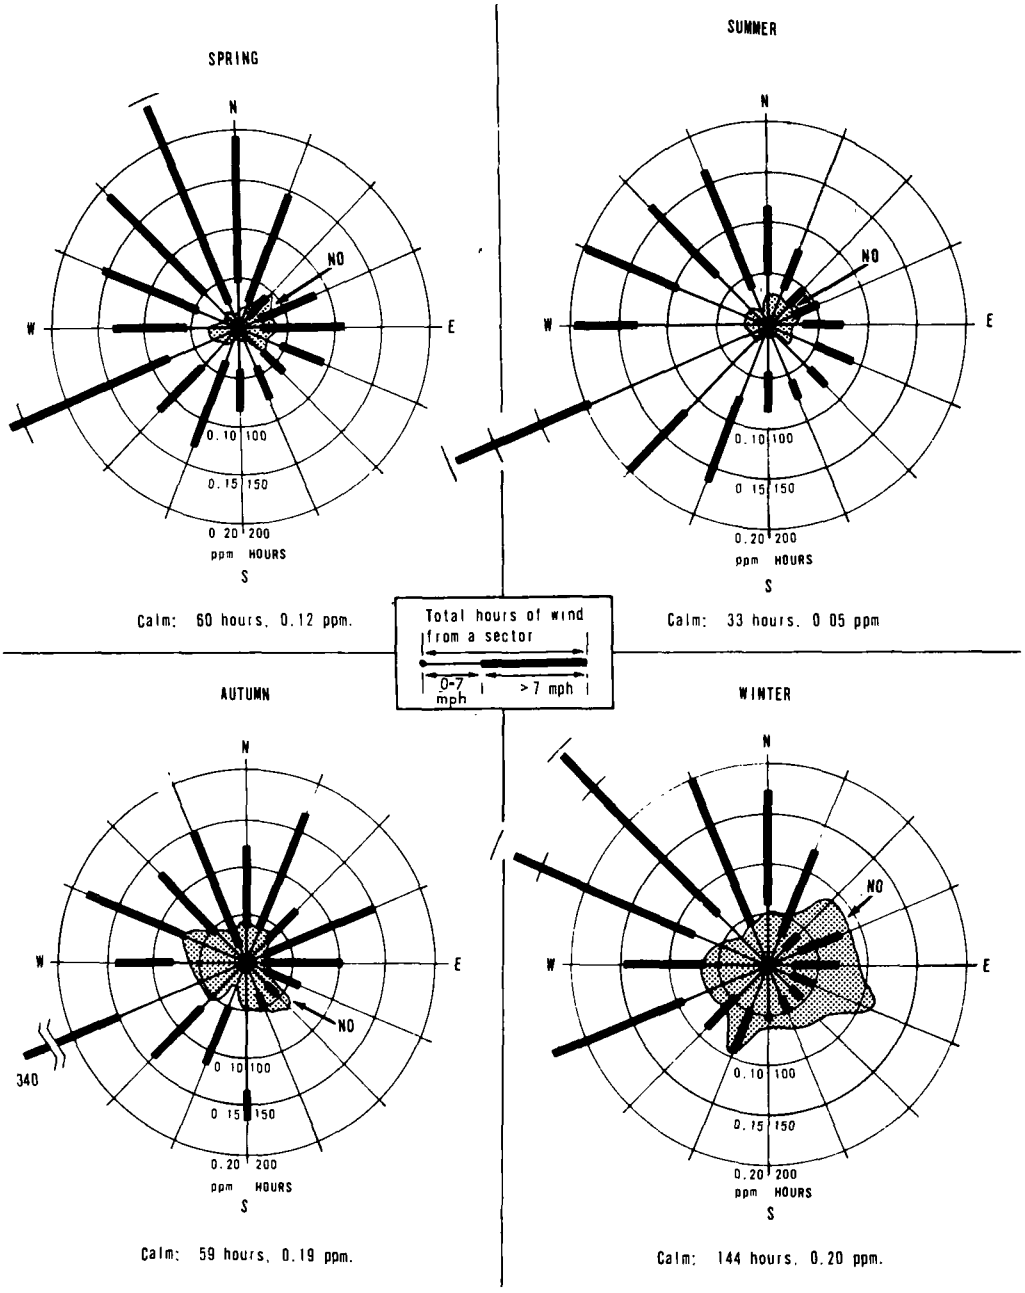

Figure 2-8. Nitric oxide concentrations and wind direction, Philadelphia - 1963

oxidizing compound, is formed at high altitudes by high-energy solar radiation and is carried to lower levels by air currents. Ozone is also formed at low altitudes as a product of photochemical reactions involving the oxides of nitrogen and the various hydrocarbons. NO_2 itself produces a small oxidizing effect, and photochemical reactions among emitted pollutants produce more complex oxidizing compounds.

The oxidants produced by photochemical reactions among the oxides of nitrogen and the hydrocarbons are of primary interest in air pollution. To them have been attributed the adverse effects (plant damage, rubber cracking, etc.) associated with photochemical smog.

Because of the previously mentioned negative interference from SO_2 in 1962 and 1963, only the 1964 and 1965 data, which give dependable information on actual concentrations of oxidants, are graphed (Figures 2-9 and 2-10).

Both daily and seasonal variations in oxidant concentrations depend upon variations in solar energy; levels are higher in the daytime than at night and higher on summer days than on winter days (Figure 2-3). In general oxidant concentration starts to rise about 9 a.m. in the winter and as early as 6 a.m. in the summer, reaches a peak between noon and 2 p.m., and then declines smoothly to an overnight minimum (Figure 2-9). The highest hourly average for the summer was 0.081 ppm; the corresponding winter maximum was 0.020 ppm.

Data for daytime (6 a.m. through 6 p.m.) and data for nighttime (6 p.m. through 6 a.m.) are graphed separately in Figure 2-10. Separate patterns of monthly averages for day and for night both resemble the pattern in Figure 2-2 for combined day and night oxidant data for 1964 and 1965. As Figure 2-10 shows, although nighttime averages are significantly lower than daytime averages, both follow similar seasonal patterns.

Total Hydrocarbons

Gaseous hydrocarbon compounds in the atmosphere are of two types: stable hydrocarbons, such as methane; and reactive hydrocarbons, such as olefins and aldehydes, which participate in photochemical reactions that produce photochemical smog. The stable hydrocarbons include a background level, thought to be about 1 ppm, of methane from natural decay processes plus methane and other stable hydrocarbons from motor vehicle exhaust, gas main leaks, sewage treatment, and other sources. The reactive hydrocarbons in the atmosphere are produced mainly from incomplete combustion and from evaporation of organic compounds, primarily gasoline.

The patterns of diurnal variation of total hydrocarbon for each month (Figure 2-11) show a fairly consistent rise between 7:00 and 8:00 a.m., coincident with the morning traffic surge, after which the levels decline because of reduced emissions and increased dilution later in the morning. The afternoon peak, around 4:00 to 5:00 p.m., about the time of the homebound traffic surge, is smaller because the dilution capacity is usually greater during the evening rush hour than during the morning rush hour.

The concentrations of total hydrocarbons show little variation with season or wind direction (Figure 2-12). This lack of relationship is consistent with the

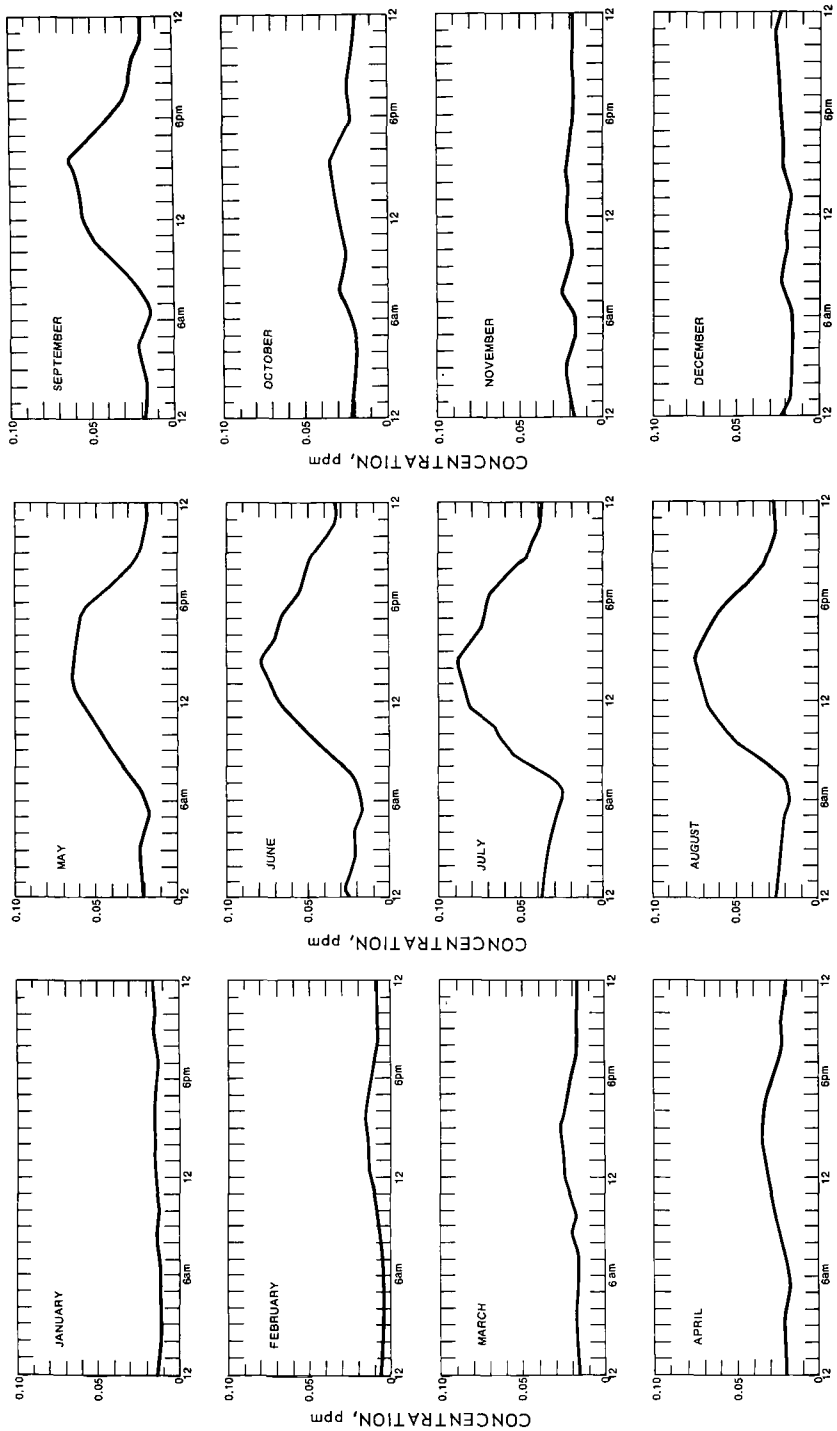

Figure 2-9. Diurnal variation of oxidant level, by month (1964-1965 only).

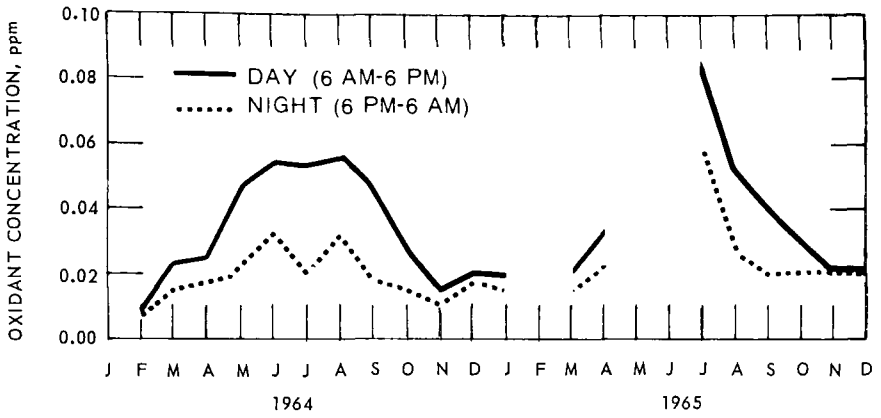

Figure 2-10. Daytime versus nighttime oxidant.

origin of hydrocarbon emissions, chiefly the automobiles that thread the city in all directions at all seasons.

Carbon Monoxide

Carbon monoxide is produced by the incomplete combustion of any organic fuel. Combustion is relatively complete in steam boiler burners and in other fuel-burning equipment that operates with an excess supply of air. The outstanding exception, the gasoline-powered internal-combustion engine, delivers the performance demanded of it only when operated with less air than is needed to burn all the hydrocarbons to carbon dioxide. Thus, the ubiquitous automobile is the principal source of carbon monoxide.

Difficulties with the carbon monoxide monitoring instrument invalidated all but 3 months of data during 1962 and 1963. Most of the monthly diurnal patterns of 1964 and 1965 (Figure 2-13) show a consistent peak between 6 and 8 a.m. and lesser peaks between 4 and 6 p.m. These peaks coincide with the weekday surges of commuter traffic, as do the peaks of the other two pollutants that derive principally from automobiles, total hydrocarbon and nitric oxide.

Average Concentration as it Depends on Averaging Interval

When a maximum 5-minute pollutant concentration for a month is combined with 11 contiguous 5-minute values to arrive at an hourly average, that hourly average also may be the maximum hourly average for the month. Similarly, the maximum hourly value may contribute to the maximum daily average for the month. The variations in maximum concentrations and in concentrations exceeded by given percentiles of readings with progressively longer averaging intervals are depicted in Figure 2-14. The long-term average, of course, is not affected by averaging time.

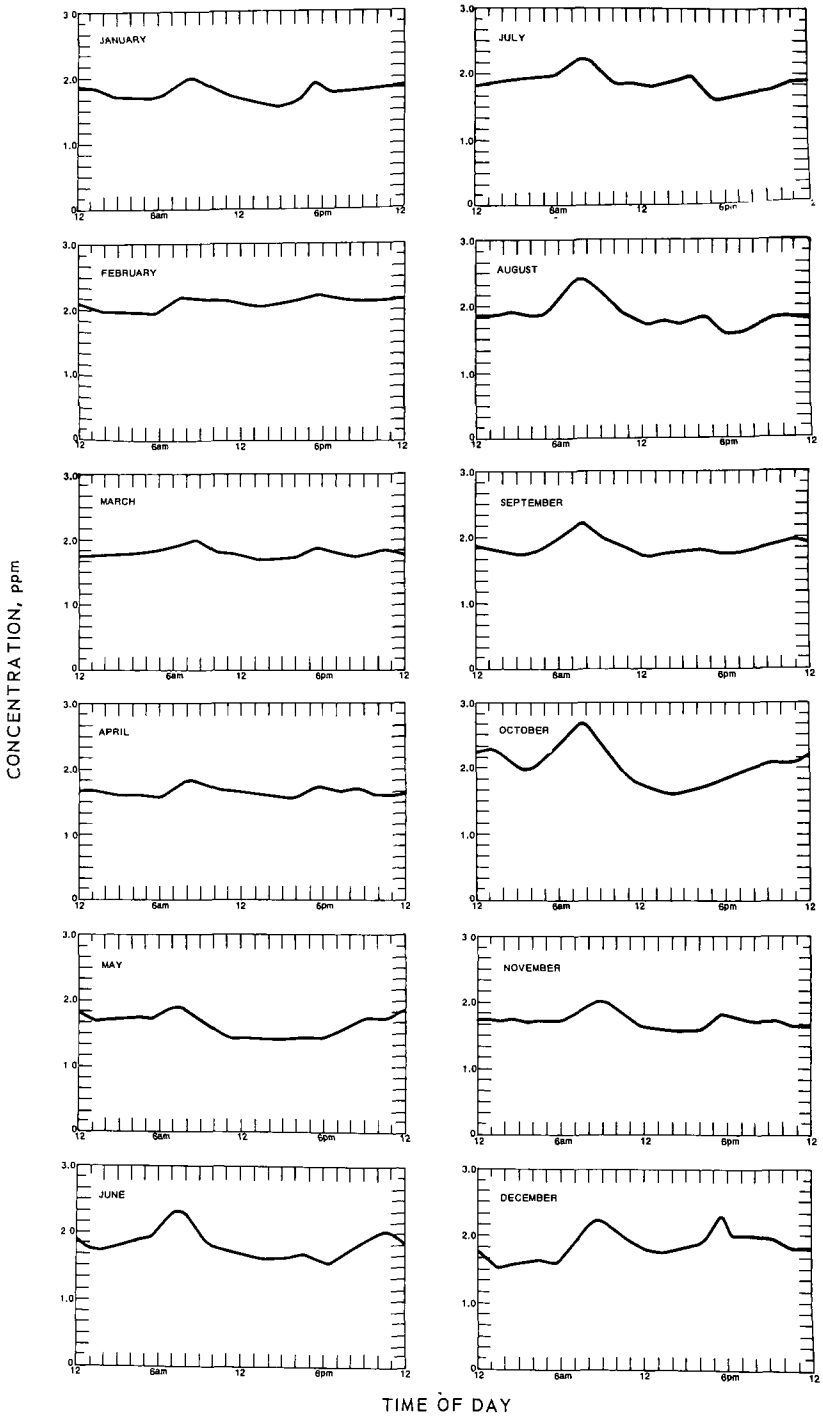

Figure 2-11. Diurnal patterns of total hydrocarbon concentrations by month.

The percentile curves are relatively flat from the 5-minute to the 1-hour averaging interval. For example, for all six gaseous pollutants, the concentration

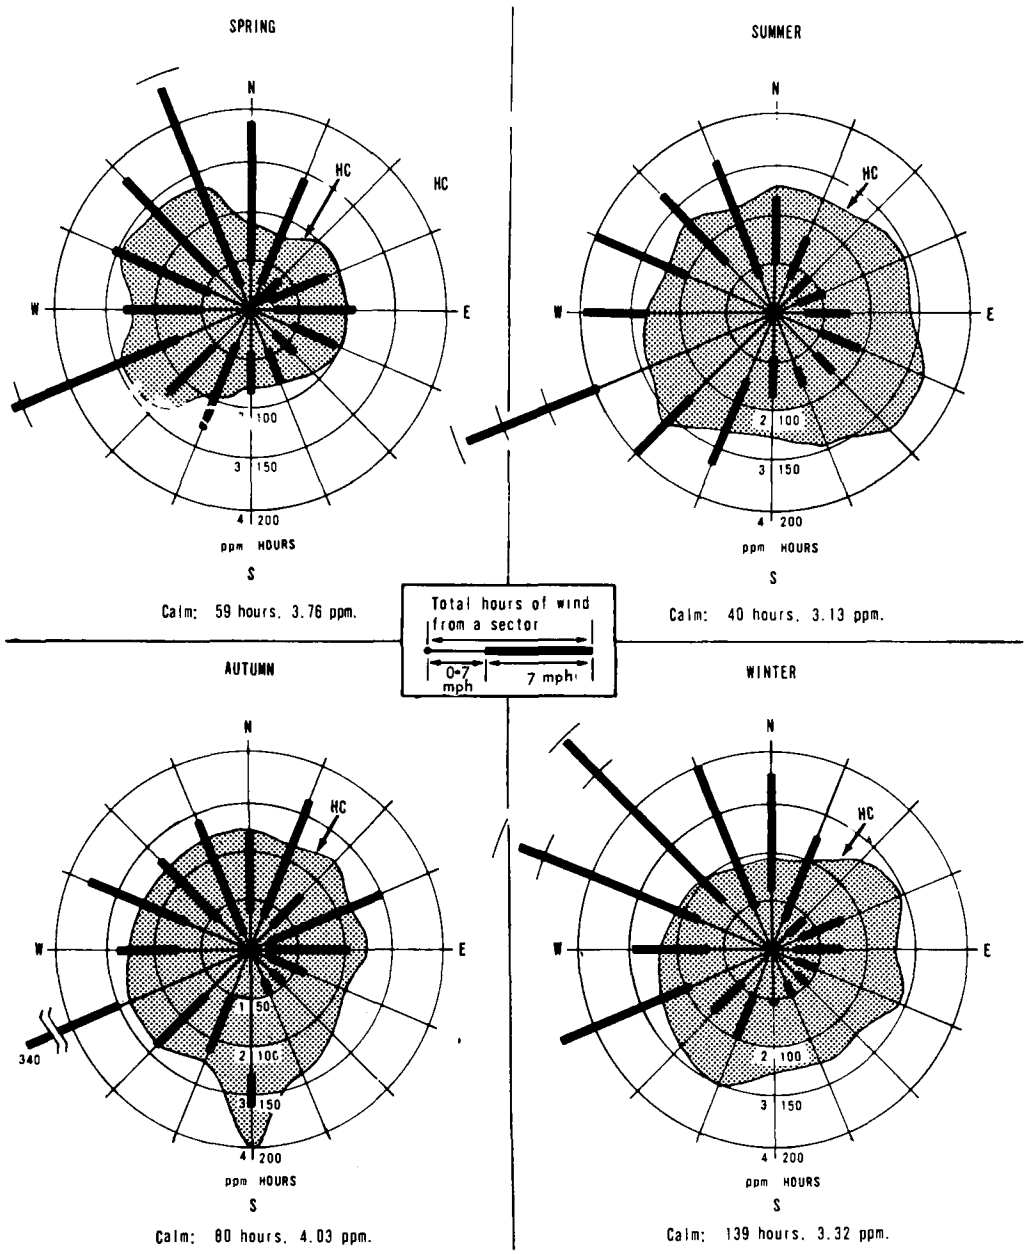

Figure 2-12. Hydrocarbon concentrations and wind direction, Philadelphia - 1963.

exceeded by 1 percent of the hourly averages differs only slightly from the concentration exceeded by 1 percent of the 5-minute values. Since this difference is slight, instruments with a 1-hour integrating time probably would provide sufficient information about air quality at less expense than the stations now operated by CAMP. Although the curve of the maximum value rises for averaging intervals of less than 1 hour, it soon levels out, appearing to reach a peak of at least 10 or 15 minutes duration. To some extent, however, the duration of this peak is a

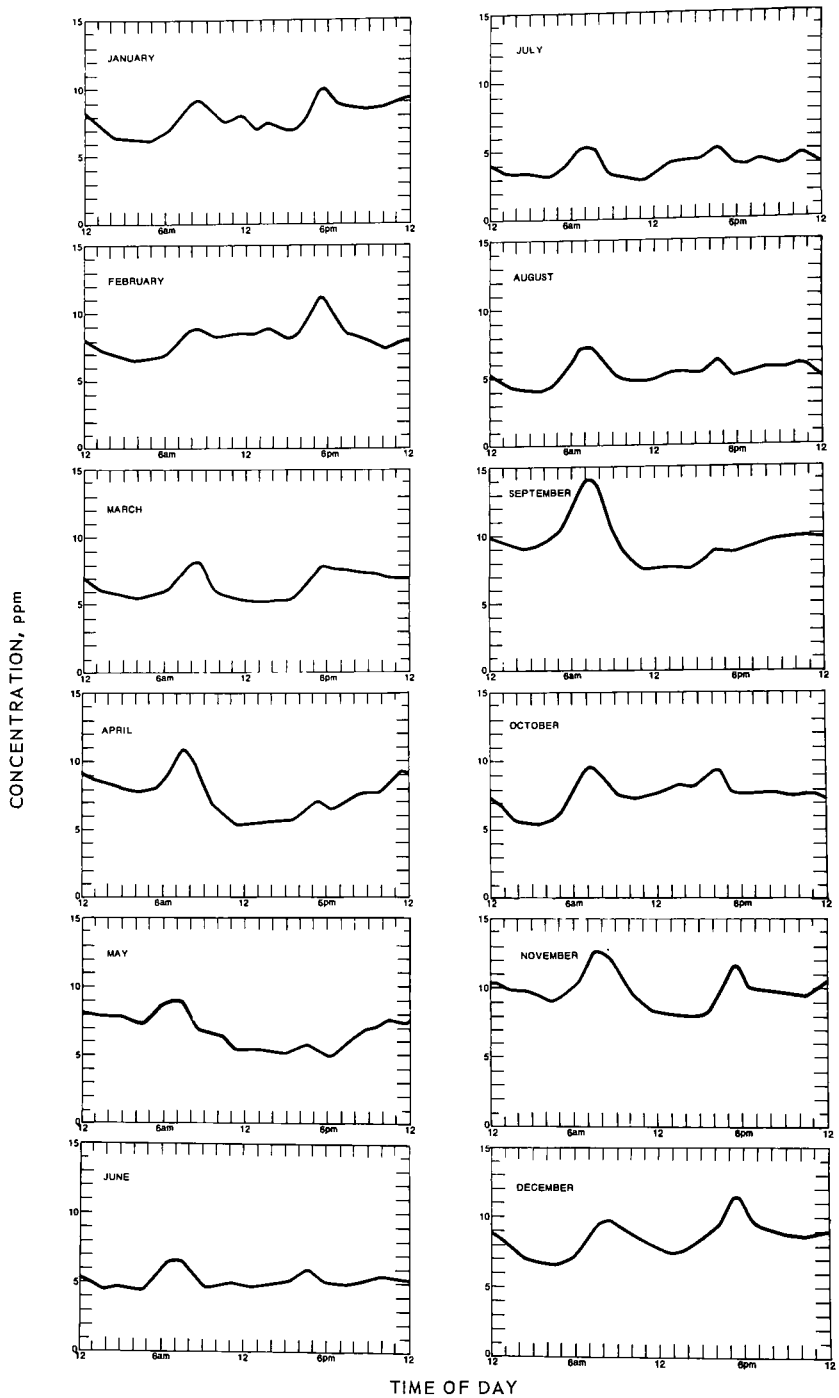

Figure 2-13. Diurnal variation of carbon monoxide level, (1964 - 1965 only).

consequence of the response times of the instruments. (See Appendix A: Instrumentation and Methods). Once these characteristic curves of the distribution of values for various averaging times have been established for an area, more extensive

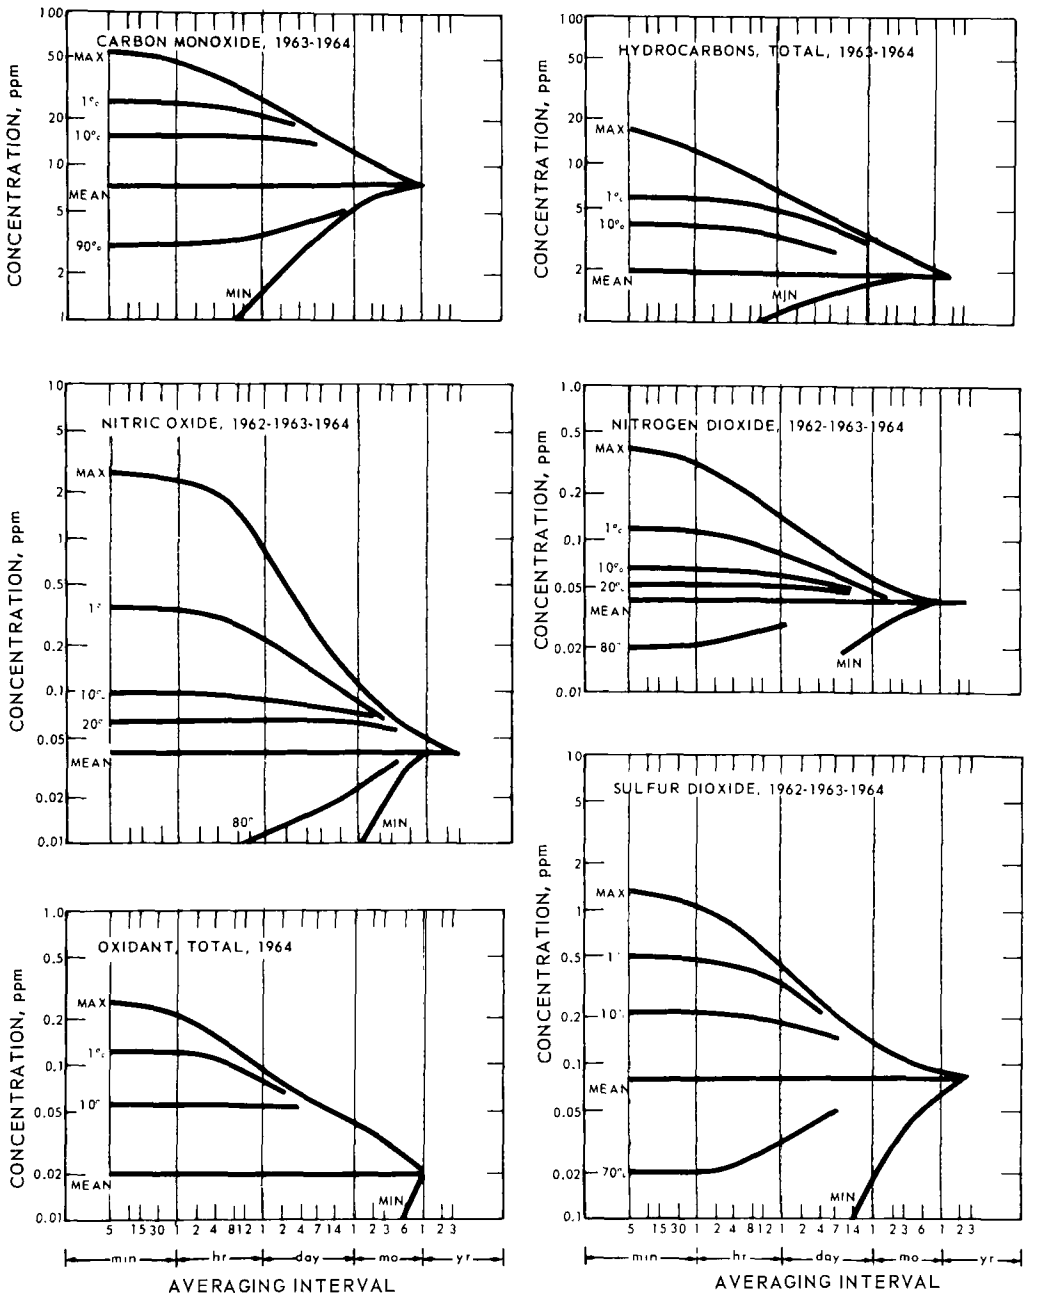

Figure 2-14. The concentration exceeded by a given percent of the value varies with the length of the averaging interval.

sampling should be possible with simpler and less expensive equipment such as liquid impingers. Also, an expected distribution of values at short intervals might be extrapolated from a known distribution of values at longer intervals. For example, 1-hour and 5-minute maximums could be estimated from the known 24-hour maximums. An extensive analysis of these curves for all CAMP data is being conducted. If

consistent relationships between distributions of values for various sampling intervals can be defined, complicated short-interval monitoring might be eliminated.[13]

Diurnal Patterns for Weekdays, Saturdays, and Sundays

Previous discussions of some pollutants, have referred to the relationship between emissions and the pattern of daily activities, and in previous diurnal patterns, all days of the week have been averaged together. However, since patterns of human activity are not the same every day, diurnal patterns can be analyzed more precisely if data are grouped according to day-of-the-week. For this summary, weekdays are grouped together, and Saturdays and Sundays are considered separately (Figure 2-15).

The most prominent distinction among these curves is the presence or absence of a morning peak. The weekday morning peak for emitted pollutants regularly exceeds the Saturday morning and Sunday morning peaks. NO, NO_2, and CO have no discernable morning peaks in the Sunday patterns and have intermediate morning levels in the Saturday patterns. NO and CO patterns indicate that traffic is heavier on Saturday night than on other nights.

The similarity among weekday, Saturday, and Sunday patterns for total oxidant suggests that even though the levels of oxides of nitrogen and total hydrocarbons are lower on Saturday and Sunday, amounts of these pollutants in the atmosphere are still adequate for undiminished photochemical production of oxidants.

Incidents of High Pollution

Some exceptionally high concentrations of one or two pollutants are traceable to a strong, nearby source, but such concentrations generally affect only a small portion of the community and involve only those pollutants characteristic of the source. The more familiar incident of high pollution lingers or recurs over a period of several days, is characterized by similar patterns of build-up and decline in concentrations of most or all of the emitted pollutants, and affects the entire community. Such an incident is the result of minimum natural ventilation due either to a prolonged nocturnal inversion or to a general atmospheric stagnation. Whether the resulting pollution includes discomforting amounts of photochemical smog depends on the intensity of solar radiation reaching the polluted layer of the atmosphere.

Table 1-4 lists all of the U.S. Weather Bureau's Air Pollution Potential Forecasts from 1962 through 1965 that included the Philadelphia area. These predict stagnations that if confirmed are expected to persist for at least 36 hours beyond the routine announcement time of 12 noon. The highest 5-minute concentration and the highest hourly average concentration of each pollutant during each period are listed in Table 2-9. A comparison of these maximums during forecast

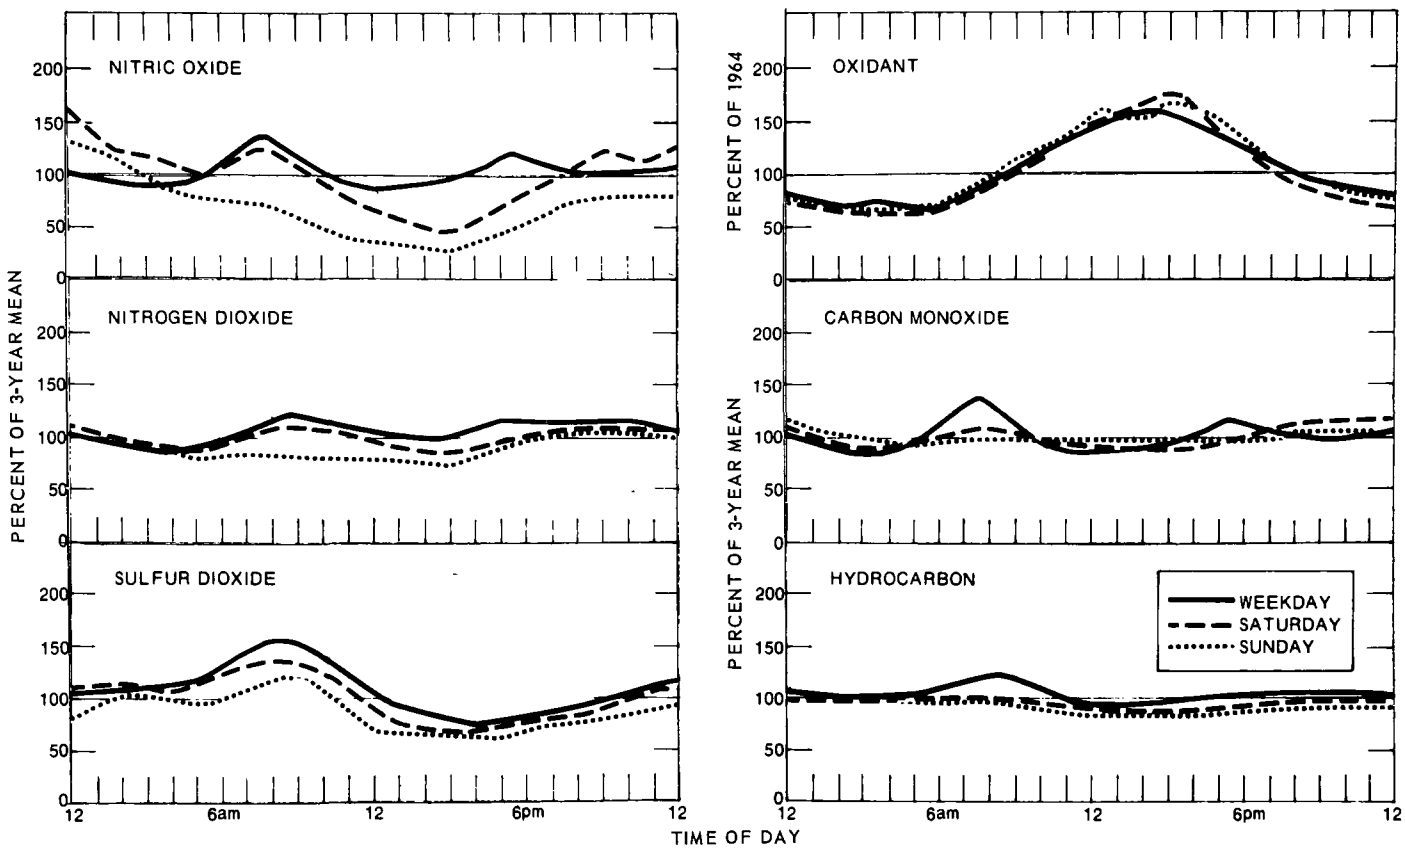

Figure 2-15. Diurnal patterns of gaseous pollutants for weekdays, Saturdays, and Sundays.

stagnations with the 5-minute and hourly maximums for the entire 4 years (shown at the bottom of Table 2-9) shows that the highest values do not always occur during the extended stagnations. However, a comparison of the stagnation period maximums with the 99th percentile concentration (also shown in Table 2-9) indicates that the maximums reached during a stagnation often are among the highest 1 percent of the measured concentration.

At least one stagnation, which because of its brevity was not included in the high pollution potential forecasts, deserves some discussion. At noon on February 6, 1963, Philadelphia was under a stagnating air mass, but ventilation was expected to, and in fact did, improve in less than 36 hours. However, during this brief episode, the CAMP instruments recorded the highest 5-minute NO concentration (1.72 ppm) of the entire 4-year period. Figure 2-16 depicts the variations in the hourly average concentrations of NO, NO_2, SO_2, and total hydrocarbons for February 4 through 8, 1963. The peak concentrations of these pollutants were recorded on February 6, a cloudless Wednesday when wind speeds averaged 2.6 mph and low-level smoke and haze were reported during the entire day.

The hourly average concentrations of NO and of total hydrocarbons reached maximums of 0.77 ppm and 8 ppm respectively at about 8 a.m. on February 6. During a second, broader peak from 8 p.m. to 10 p.m. the same day, NO concentration reached an hourly average of 1.51 ppm, and hydrocarbon concentrations again averaged 8 ppm. The following morning, the concentrations of these two pollutants rose to a third peak, again about 8 a.m., with NO averaging 1.06 ppm and hydrocarbons averaging 7 ppm.

The pattern of hourly average NO_2 concentrations for this period shows three peaks about an hour after the NO and hydrocarbon peaks. Sulfur dioxide concentrations reached a 5-minute maximum of 0.98 ppm around 10 a.m. on the 6th but exhibited only minor, low-level fluctuations during the rest of this period. Because of SO_2 interference, oxidant concentrations could not be determined.

Shortly after noon on the 7th the wind began to strengthen from the NE and the air quality improved.

Soiling Index

An AISI* tape sampler, used to determine soiling capacity of the atmosphere, was installed at the CAMP station in January, 1963. This sampler collects fine suspended particulates on segments of a filter tape for consecutive 2-hour periods. The soiling index, reported in COH (coefficient of haze) units per 1000 feet of air,

*Mention of a commercial product does not imply endorsement by the Public Health Service.

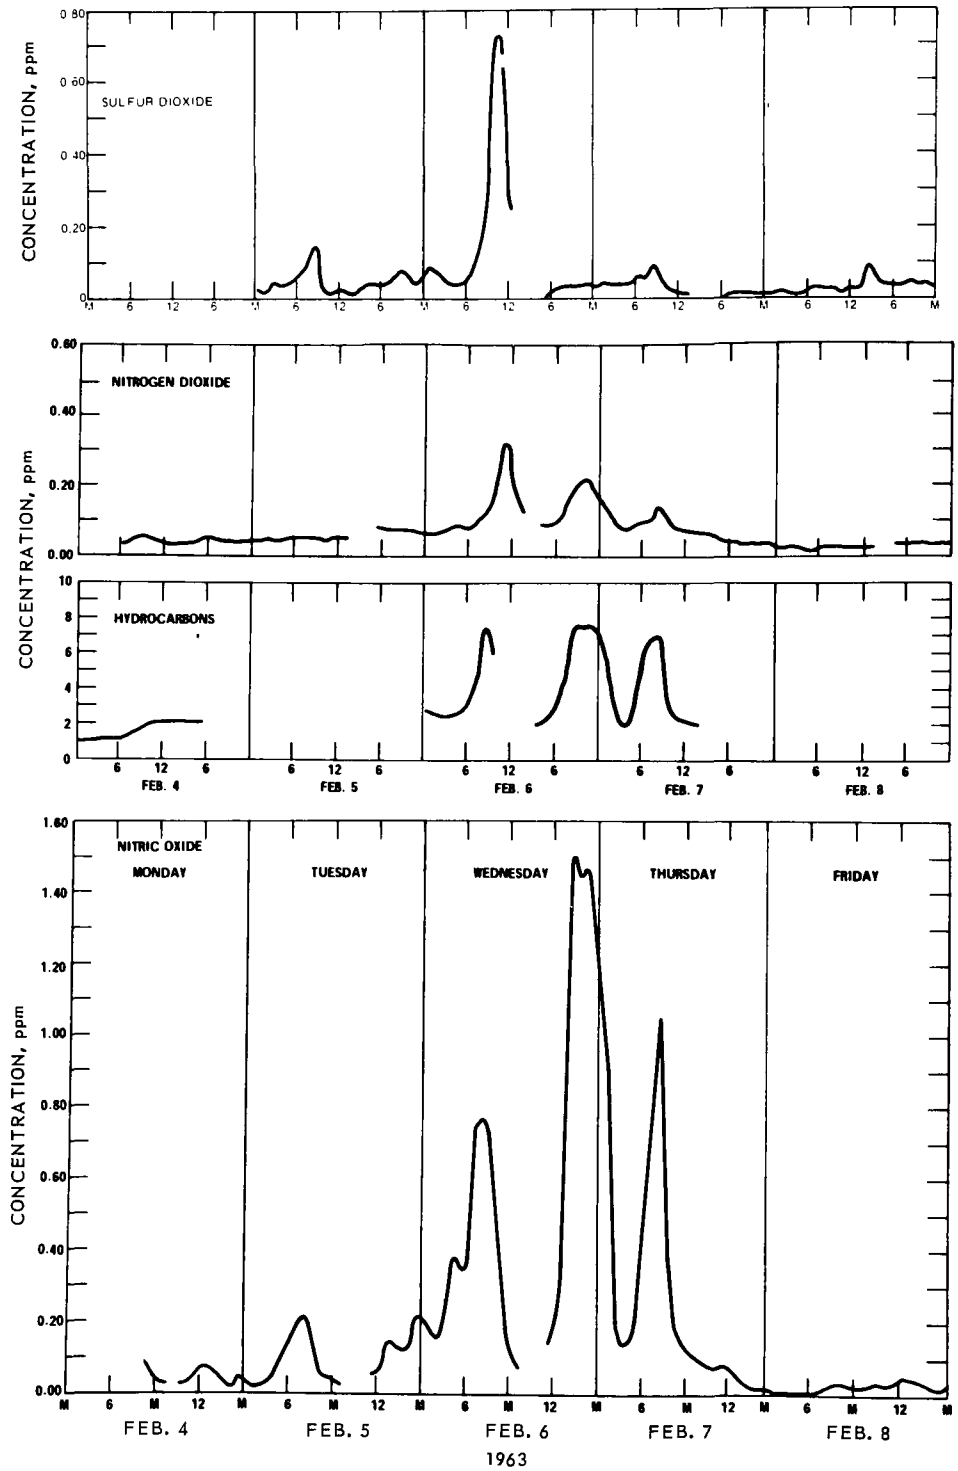

Figure 2-16. Diurnal variation of gaseous pollutants during a period of restricted ventilations, Philadelphia, Feb. 4-8, 1963.

is determined from the amount of reduction in the transmission of light through the tape caused by the deposit of particulate matter.

The seasonal averages (Figure 2-17) follow the general pattern of heating fuel consumption; highest in winter, lowest in summer, and intermediate in spring and fall. The diurnal pattern follows the general pattern of the emitted gaseous pollutants, an early morning maximum followed by a midafternoon minimum and a rise in the late afternoon.

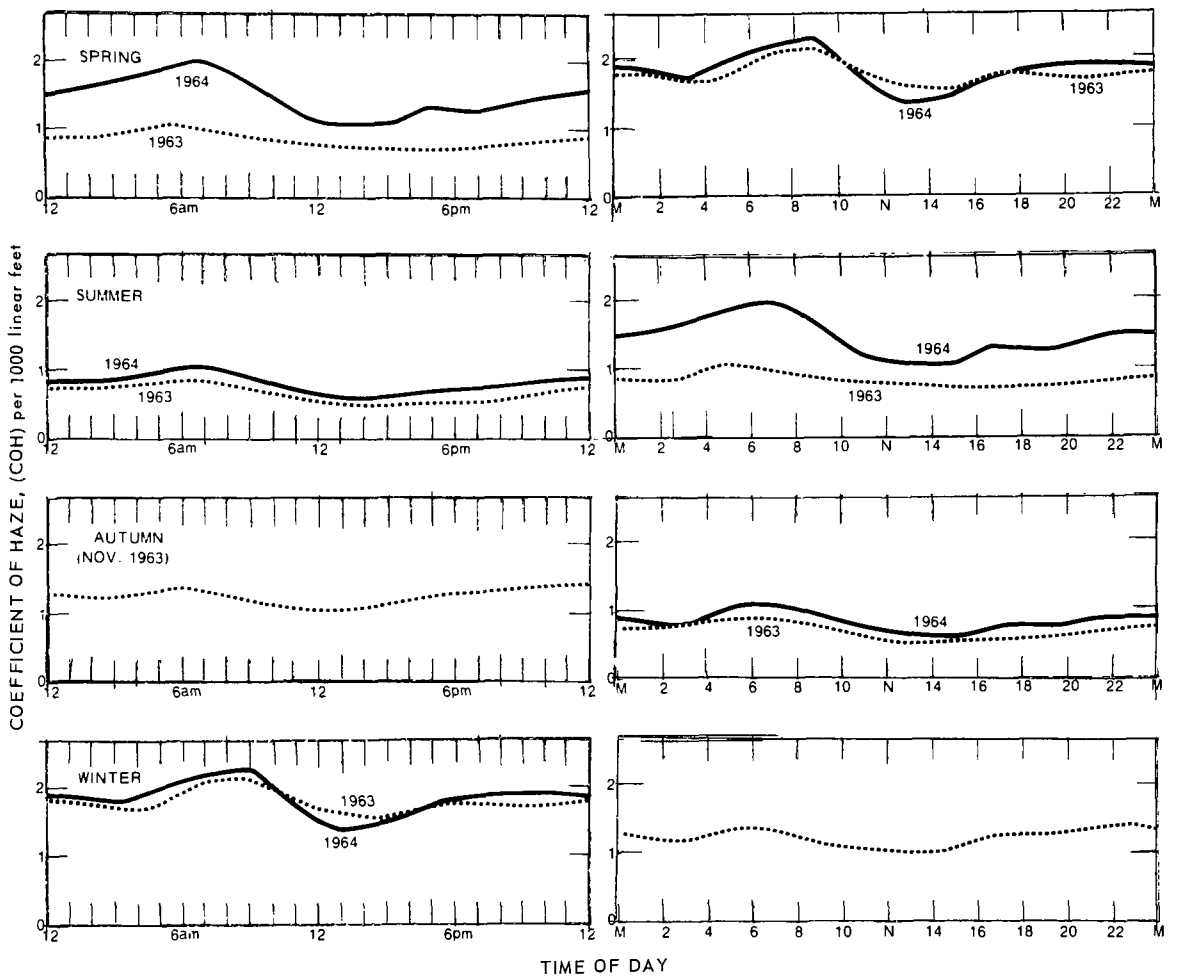

Figure 2-17. Diurnal variation of soiling index (COH) by season.

PART 3. DATA TABLES

The data gathered during the first 4 years of CAMP operation in Philadelphia are summarized in the following tables. Although these tables are intended as references, the data are necessarily condensed. Anyone desiring further information should contact the Chief, Division of Air Quality and Emission Data, National Air Pollution Control Administration, Consumer Protection and Environmental Health Service, DHEW, 801 North Randolph Street, Arlington, Virginia 22203.

GASEOUS POLLUTANTS

Tables 3-1 through 3-250 list hourly pollutant concentration averages by month for the six pollutants:

Carbon monoxide	Tables 3-1 through 3-27
Nitric oxide	Tables 3-28 through 3-73
Nitrogen dioxide	Tables 3-74 through 3-120
Sulfur dioxide	Tables 3-121 through 3-165
Total hydrocarbons	Tables 3-166 through 3-204
Total oxidant	Tables 3-205 through 3-250

Values in each table are the arithmetic means of the 5-minute values in the clock hour beginning at the time indicated in the table. No average is calculated if the hour is considered invalid, i.e., if fewer than seven 5-minute values are valid. Similarly, if a calendar day had fewer than 13 valid data hours, it is considered invalid and no averages are listed for that day. Although this procedure results in the loss of a few valid hourly averages, the data thus lost are usually concentrated at the beginning or end of a day. Since pollutant concentrations show considerable diurnal variation, the inclusion of data for partial days would introduce a definite bias into the monthly mean concentrations.

The first summary line at the bottom of each table (titled Monthly Mean) contains the arithmetic means of the hourly averages, representing the pattern of diurnal variation for the month. This average is not calculated unless 16 or more hourly averages are given. The number of hourly averages and maximum hourly average in each column are given in the second and third summary lines respectively.

The first summary column at the right of each table (titled Daily Mean) lists the arithmetic mean* of the 13 or more hourly averages comprising each row, and

*All summary calculations in the tables are performed before the hourly averages are rounded.

the second lists the number of valid hourly averages in each row. The third summary column lists the maximum 5-minute value included in valid hours of the day. The largest of these, printed in the extreme lower right corner, is not necessarily the maximum for the month, since some valid hours may have been deleted as parts of invalid days; the maximum 5-minute concentration during the month is best obtained from the tables of frequency distributions, which are compiled without consideration of the validity of any hour or day.

Two summary figures appear in the lower right corner. The first is the monthly average, an arithmetic mean, and appears only if 16 or more days (a valid data month) were valid. The second is the total number of valid hours included in the table, which offers some basis for judging the representativeness of the monthly average. (A 31-day month has 744 possible hours; a 30-day month, 720; and a 28-day month, 672.)

SOILING INDEX

Tables 3-251 through 3-276 present monthly soiling index values recorded at the CAMP station. Each value was obtained from a 2-hour integrated sample beginning at the time indicated in the column heading. A missing value indicates that the sample was not taken or was invalid because of instrument malfunction.

The first summary line (titled Monthly Mean) represents the arithmetic mean of the 2-hour average values in the column, and is calculated only if 16 or more days are represented. The first summary column (titled Daily Mean) is the arithmetic mean of the 2-hour values for the day; if fewer than seven such values are present, the daily mean is not calculated, and the data are not included in the summaries, but the component 2-hour values for the day are not deleted from the table as with data on gaseous pollutants.

Three summary figures appear in the lower right corner; the mean and maximum values for the month are the upper left and lower right figures respectively, and the center figure is the total number of values. (A 31-day month could have 372 such values; and a 30-day month, 360; and a 28-day month, 336.) The monthly mean and the summary rows at the bottom are not presented if there were fewer than 16 valid data days during the month.

APPENDIX A
INSTRUMENTATION AND METHODS

INSTRUMENTATION

The gaseous pollutant instrumentation was developed and fabricated by Beckman Instruments, Inc., under contract with the Public Health Service, and the calibration techniques were developed by the CAMP staff. Because of difficulties encountered in field operations, CAMP personnel subsequently modified all instruments, some extensively. In addition, calibration techniques, particularly for the wet instruments, have been continuously studied and frequently revised.

The gas-measuring instruments, as modified, are thus unique. The spot tape particulate samplers at the CAMP stations are, in contrast, identical with many others used throughout the country.

SULFUR DIOXIDE

The SO_2 instrument performs conductometric analyses. A sample air stream is passed through a dilute sulfuric acid solution containing hydrogen peroxide which oxidizes SO_2 in the sample stream to H_2SO_4. The added H_2SO_4 further ionizes the solution so that any change in solution conductivity, compared to that of a reference cell, is proportional to the SO_2 concentration. The range of this instrument is 0 through 2 ppm of SO_2.

This instrument is very stable and presents few calibration difficulties. The electronics are checked daily by means of a built-in circuit that simulates 1.5 ppm SO_2. At least weekly, the air flow is manually eliminated to produce a zero condition, and at least monthly, the upscale range is statically calibrated with standard solutions. Very little drift has been experienced. At least once a year, the instrument is dynamically calibrated with standard gas mixtures. The response time of the SO_2 instrument, about 8 to 12 minutes, causes some smoothing of any concentration peaks that may occur of 10 minutes duration, or less.

The conductometric analysis is considered very accurate. Although it is sensitive to any ionizable substance, it is essentially specific for sulfur oxides (principally SO_2 but sometimes including small amounts of SO_3) since other ionizing substances probably do not occur to any significant extent in the normal urban atmosphere.

OXIDES OF NITROGEN

The NO_2 instrument is a colorimetric analyzer, incorporating Saltzman reagent to produce a magenta color that intensifies as concentration increases. The color

is measured by a ratio photometer (operating at 545 millimicrons). The system has a 90 percent response equivalent to 1 ppm of NO_2. Such colorimetric analysis is considered accurate within 10 percent.

After the NO_2 has been extracted, the sample air stream is bubbled through an acidified potassium permanganate solution to convert NO in the stream to NO_2. It then passes into an identical NO_2 instrument which measures the original NO concentration as NO_2.

These instrument systems are subject to considerable zero drift; thus, they are purged (with carbon-filtered air) daily at a time of normally low pollutant levels. The zero correction is recorded daily and reset when drift becomes excessive. The scale range is calibrated with colored optical filters as needed, and both instruments are dynamically calibrated periodically with standard gas mixtures.

The response time of the NO_x instrument is about 15 to 20 minutes. Part of this time is required for the reaction that produces the reagent color change; the remainder is due to engineering features necessary to insure precision. Although this response time is longer than that of any other CAMP instrument, it is not considered a major problem because NO_x levels fluctuate less rapidly than those of other pollutants.

TOTAL OXIDANT

The total oxidant instrument system passes a sample air stream through a 10 percent neutral potassium iodide (KI) solution from which free iodine is released in the presence of oxidizing agents. A ratio colorimeter (operating at 345 millimicrons) measures the color intensity of the liberated iodine against a reference. The instrument, with a range of 0 through 0.5 ppm of oxidants, records the presence of any substance capable of oxidizing iodide in the KI solution, such as ozone, the peroxyacetyl nitrates, and, to a lesser extent, nitrogen dioxide, and others.

Sulfur dioxide, a reducing agent, produces a negative interference by driving the iodine released by the oxidation reaction back into solution as iodide. This interference affected the CAMP data gathered during 1962 and 1963; in 1964 the oxidant instruments in most of the CAMP cities were equipped with devices which remove SO_2 from the sample air stream to prevent the interference. These devices consist of glass U-tubes filled with filter paper saturated with a sulfuric acid solution of chromium trioxide (CrO_3).

Figure A-1 presents recorded traces of oxidant levels from two instruments operating side by side, one with and one without the SO_2 absorbing device; the simultaneous trace of SO_2 levels is also included. The interference effect is obvious; during the morning, when SO_2 levels were high, the oxidant instrument without the absorber recorded essentially no oxidant, although the other instrument

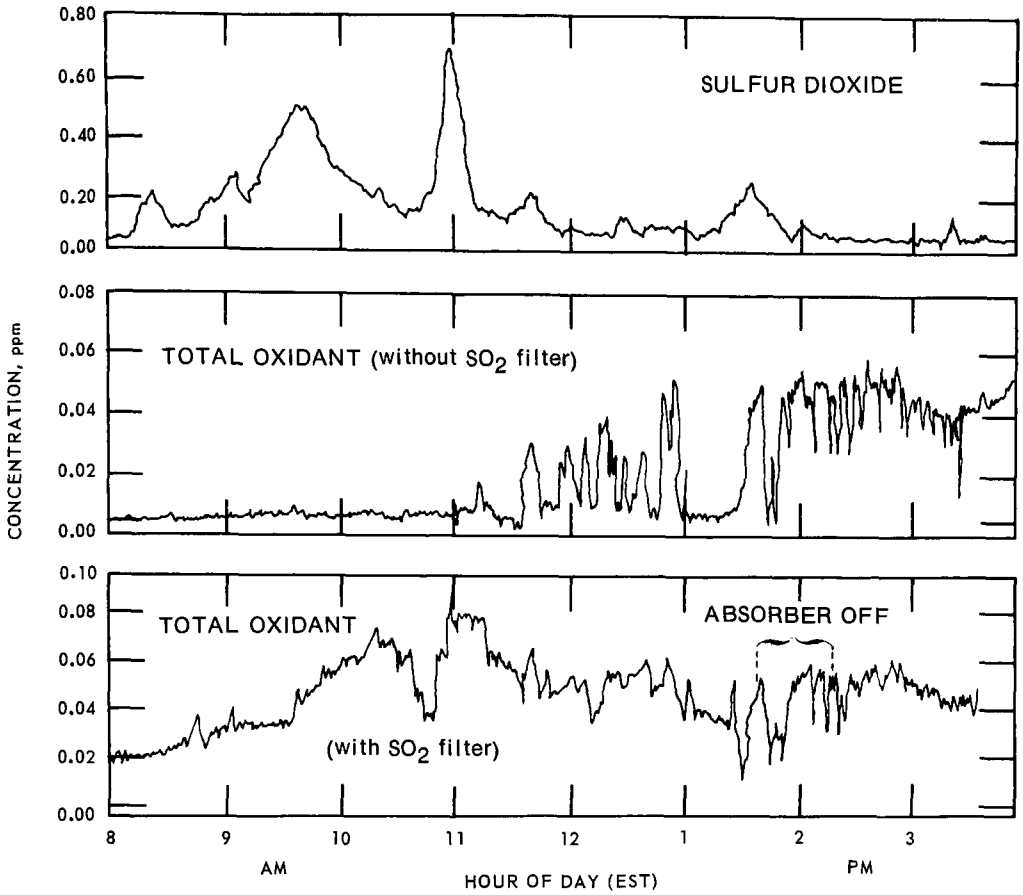

Figure A-1. Effect of sulfur dioxide on recorded total oxidant measurements.

indicated levels up to 0.08 ppm. As SO_2 levels decreased, the unfiltered instrument began to record the oxidant, and by midafternoon the two instruments were responding similarly.

The absorbing device introduced a secondary interference, however. The CrO_3 in the absorber oxidizes any NO, which normally would not react in the instrument, to NO_2, which does react with the KI solution to a slight extent. The exaggerated oxidant concentrations thus obtained are corrected to the proper level by subtraction of a certain percentage of the concurrent NO concentration. If NO data are invalid for one hour or less, the oxidant data for that time are corrected on the basis of interpolated NO concentrations; if NO data are invalid for more than an hour, the oxidant data are invalidated. This procedure is followed to prevent consistent loss of the afternoon oxidant peak because of the 2- to 3-p.m. NO instrument check. However, since the NO instrument check occasionally losts longer than one hour, a disproportionate amount of oxidant data still is lost during the early afternoon.

Nevertheless, the oxidant data gathered during 1964 and 1965 are believed to be quantitatively accurate. The data gathered during 1962 and 1963 are not comparable to subsequent data and must be used with considerable caution. Since the 1962 and 1963 data do convey some information, they are reported; however, the only definite conclusion that can be drawn from the data is that any oxidant value recorded indicates the presence in the atmosphere of a concentration that high or higher.

The total oxidant instrument system also presents sensitivity and stability problems and satisfactory data are acquired only with extensive and careful maintenance. Frequent calibration, similar to that described for the oxides of nitrogen system, and including a daily instrument purge from 1 to 2 a.m., is required.

TOTAL HYDROCARBON

The total hydrocarbon instrument uses a flame ionization detector in which the sample air stream is introduced into a hydrogen-air flame whose intense heat dissociates the hydrocarbons. The positive carbon ions produced by the dissociation are collected by an electrode above the flame, and the current produced is proportional to the number of carbon atoms ionized. The instrument sensitivity allows a scale range of 0 to 10 ppm (carbon atoms), although during 1962 through 1964 CAMP operated the instrument on a scale of 0 to 40 ppm to insure inclusion of all peak levels.

Since experience has demonstrated that a scale of 0 to 20 ppm accommodates peak values at the current sites, the hydrocarbon instruments were reset in 1965 to give a full scale reading of 20 ppm. This change also warranted increased precision; thus, beginning with the 1965 data, the 5-minute values for total hydrocarbons are reported to the nearest 0.1 ppm.

The flame ionization technique is well established and is considered very precise. Although the instrument system is normally almost instantaneous, CAMP has incorporated an integrating flask into the system to provide data averaged over about 5 minutes. The system is dynamically calibrated weekly on standardized air-methane mixtures in the near-zero ppm and 20 ppm ranges.

CARBON MONOXIDE

The CO instrument is a short-path, monobeam infrared analyzer, based on the molecular absorption of infrared radiation by carbon monoxide; it is an interesting variant of the more conventional long-path infrared analyzers. The single infrared energy beam is directed in series, as indicated in Figure A-2, through a sample cell through which the sample air stream flows, and through sample and reference compartments of a dual detector unit charged with CO-argon mixtures.

The sample detector compartment is charged with a low concentration of CO, which

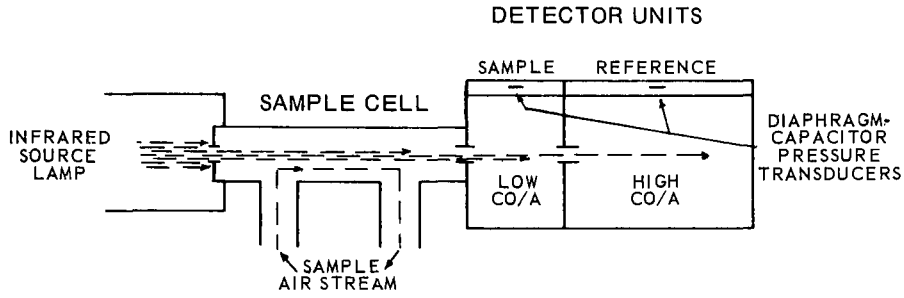

Figure A-2. Short-path monobeam infraraed analyzer.

absorbs radiant energy in an amount dependent upon the amount previously absorbed by the sample air stream. The reference detector compartment contains a high CO concentration that absorbs enough radiation to be largely unaffected by the slight fluctuations in incident energy produced by varying absorption in the sample cell and in the sample detector unit. This concentration thus provides a very stable reference, with which absorption in the sample detector is compared. In each compartment, the energy absorbed is measured by pressure transducers.

The CO instrument can have a very rapid response, but an integration time of about 5 minutes has been introduced in the same manner as in the hydrocarbon system. It is extremely sensitive along the entire range (0 to 100 ppm) and is dynamically calibrated weekly in the manner used for the hydrocarbon instrument.

Both water vapor and carbon dioxide absorb infrared radiation at wavelengths very near the absorption wavelength of CO. During 1962 and 1963, the degree of such interference was periodically measured by filtration of the sample stream through columns of silica gel and ascarite. When interferences were significant, the CO data were declared invalid and were not reported. Because of such interference, valid CO data were often sparse, and on occasion non-existent, during 1962 and 1963. In early 1964, this problem was largely eliminated by addition of an infrared filter, which narrows the radiation band to converge on the CO absorption wavelength.

DATA RETRIEVAL SYSTEM

Each of the gaseous pollutant instrument systems produces an electric output signal that drives a strip chart recorder. At 5-minute intervals, the signal is momentarily diverted to an analog-to-digital recorder that records on punched paper tape the magnitude of the signal. Thus, the basic data represent the instantaneous instrument response value recorded at 5-minute intervals.

The raw data are transferred by an automatic translator from punched paper tape to punched cards for computer use. The actual pollutant concentrations are calculated by computer from the raw data, from the station operator's logs, and from the known instrument parameters, and the results are stored on magnetic tape for subsequent analysis. Throughout the several steps of this process, the time synchronization and completeness of the data are checked by hand. All unusually high concentrations or abrupt changes in concentrations are manually checked against the recorder charts before the data are accepted as valid.

DATA ANALYSIS

The information presented in this volume is derived from the data by several analytical techniques. Some of these are common statistical methods, but others have been modified specifically for use with the CAMP data. The tremendous quantities of data have necessitated the programming of even the simplest operations for the digital computer facilities of the Robert A. Taft Sanitary Engineering Center. The application of frequency distribution analysis to the CAMP data is sufficiently specialized to warrant its description here, both as a background for the results reported in Part 2 and as an illustration of the type of additional material available on request.

A frequency distribution analysis summarized the frequency of occurrence of the various pollutant concentrations recorded. Each pollutant concentration tabulated in the frequency distribution tables is the concentration that was not exceeded by the specified percentage of the total data considered. Although such a distribution is properly termed a relative cumulative frequency distribution, the phrase "frequency distribution," or merely "distribution," is used in the text for convenience. Frequency distributions of this type provide a convenient means for determining the median pollutant concentration and the data for specific frequencies, such as the concentration exceeded 2 percent of the time, the concentration below which the pollutant level fell 10 percent of the time, etc.

The graphic presentations of frequency distributions are drawn to logarithmic-probability scales; if the logarithms of the pollutant concentrations were distributed according to a normal probability distribution, the resulting curve would be linear, and the data would be described as being log-normally distributed. The slope of a curve plotted to such scales is a function of the variance of the population of data included, with a steeper slope representing more variable pollutant levels. The curve's vertical position is determined by the magnitude of the pollutant concentrations. Thus a curve that has an inflection represents data recorded from two relatively distinct populations with differing variances or levels.
