ABSTRACT

The feasibility of lidar (laser radar) for stack plume studies is established from the results of an experimental investigation of plume behavior from a 245-m power plant stack in western Pennsylvania. During this study a total of 175 vertical plume cross sections containing about 3800 separate lidar observations were obtained, of which 64 cross sections representative of various types of plume behavior were selected for detailed analysis. Each vertical cross section was built up from 15 to 30 lidar shots at 5 to 8 second intervals and at elevation angle increments of $1/3°$ to $10°$. The selected cross sections are grouped into series which show the spatial (downwind) and temporal variations in plume geometry and relative particulate concentration distributions.

The factors involved in interpreting the lidar data in terms of plume rise and diffusion are discussed and exemplified. Although calculated plume-rise values agree reasonably well with the observations, it is clear from inspection of the cross sections that the important effects of vertical wind direction shear (plume tilting and fanning) and vertical changes in stability (plume trapping) should be taken into account when predicting plume rise and diffusion. Close correspondence between plume tops and levels of increased atmospheric stability was found. Several cross sections are shown of fumigating plumes, which occurred frequently. In a tilted plume, different portions apparently fumigate at different times. Optimum use of lidar for diffusion studies requires provision for obtaining 30-minute or hourly plume concentration distributions, as well as allowances for the effect of the lidar noise level upon plume size.

To investigate the potential of lidar for making quantitative measurements, a sample cross section of absolute mass concentration was computed on the basis of Mie scattering theory and independent particle size measurements. The cross-axial integrated mass concentration represented by this cross section is 680 g/m. The corresponding value calculated from the gross power-plant data and wind speed is 875 g/m.

The advantages of the mobile lidar technique stem from its ability to obtain measurements remotely and at a high density in space and time. The quantitative application of the technique for obtaining absolute particulate mass concentrations is limited mainly by the accuracy with which the optical characteristics of the aerosol are known. An improved lidar system for plume studies would incorporate better signal-to-noise characteristics and a higher pulse repetition rate than present equipment provides. In addition, an expanded data processing capability with "real-time" output is necessary.

CONTENTS

ILLUSTRATIONS

a = particle radius

A = effective receiver area

c = speed of light

C = particle number concentration; also parameter in formula for Junge fit to particle-size data

$\overline{C}$ = optical cross section averaged over particle size interval

E = lidar site elevation

F = buoyancy flux

g = acceleration of gravity (= 9.8 m/s)

G = stability parameter

H(R) = magnitude of magnetic disk-recorded signal return from atmosphere as a function of range

H_p = height of plume axis above lidar

H_s = height of top of stack above lidar

H_t = height of plume top above lidar after maximum rise

ΔH = plume rise (height of axis of plume above stack top after reaching equilibrium)

ℓ = distance along the laser pulse propagation path

i = complex operator ($\sqrt{-1}$)

k = slope parameter in equation for Junge fit to particle-size data

$\log^*$ = logarithmic amplifier transfer function

m = refractive index of particles

M = plume mass concentration

M_o = background mass concentration in "clean" air

n = number of particles per unit volume per unit radius interval

n_r = relative density of particle-size distribution (fraction of number of particles per unit radius interval)

N = cumulative particle number concentration (number of particles larger than a given radius)

P_N = detector output component due to background and internal noise

P_S = detector output component due to backscattered signal return

P_T = peak power emitted into the atmosphere

xiii

Q_b = backscatter efficiency factor

Q_e = extinction efficiency factor

r = radius of stack orifice (= 4.25 m for Keystone)

R = range

R_o = reference range

ΔR = range increments of digitized lidar data

S = normalized, range-corrected signal return function

T = atmospheric transmission factor

T_a = ambient atmospheric temperature at stack top

T_c = beam convergence factor

T_s = stack gas exit temperature

T_t = air temperature at height of plume top

$\overline{U}$ = mean wind speed over height interval where plume rise occurs

U_a = wind speed at height of stack top (H_s)

U_t = wind speed at height of plume top (H_t) after maximum rise

V_s = stack gas exit velocity

x = particle size parameter (= $2\pi\, a/\lambda$)

β = volume backscatter coefficient (per steradian)

λ = wavelength of the laser energy

μ = 10^{-6} m; also used generally as 10^{-6}( )

ξ_b = backscattering optical cross section per unit mass per steradian (= β/M)

ξ_e = total scattering (extinction) optical cross section per unit mass (= σ/M)

π = 3.1416

ρ = density of the particulate matter

σ = volume extinction coefficient

τ = pulse duration

FOREWORD

This work was carried out as part of the Large Power Plant Effluent Study (LAPPES) conducted by the National Air Pollution Control Administration, and was sponsored by the Division of Meteorology of that agency under Contract PH 22-68-33.

We are grateful for the logistical and meteorological support and experimental coordination provided by Frank Schiermeier, LAPPES Field Manager, and by Larry Niemeyer and Charles Hosler of the Division of Meteorology, National Air Pollution Control Administration.

We also acknowledge the able assistance of the following Stanford Research Institute personnel: Hisao Shigeishi, Charles Brabant, and Stephanie Briggs in the computer data processing and analysis phase; Al Smith and John Alder in the manual analysis phase; and John Oblanas, Norman Nielsen, and William Dyer in the experimental program. Thanks are also due to Ron Collis, Director of the Aerophysics Laboratory, for his helpful suggestions in the writing of this report, and to William Evans for the contribution of his ideas on data display and analysis techniques.
FRONTISPIECE   MARK V LIDAR IN OPERATION DURING
KEYSTONE STACK PLUME STUDY NEAR
SHELOCTA, PENNSYLVANIA

I INTRODUCTION

The lidar, or laser radar, which was developed for meteorological use by Stanford Research Institute in 1963, has important applications in air pollution research and control activities (see Johnson, 1969; Hamilton, 1966; Barrett and Ben-Dov, 1967).[*] This report covers a recent experimental program, carried out for the National Air Pollution Control Administration, involving mobile lidar observations of the diffusion of the smoke plume from a 245-m stack at Keystone Generating Station in western Pennsylvania. Such tall stacks are becoming increasingly necessary in order to lower the ground concentrations of pollutants from large plants. However, these stacks cost in excess of $3000 per meter to build, and it is important to determine their efficiency, in practice, in preventing high air-pollution levels. In addition, in order to refine diffusion models used to predict pollutant concentrations from high stacks, more data are needed. Most existing diffusion models were developed before the advent of the tall stack, and the accuracy of the theoretical predictions for this application has not yet been adequately verified due to the shortage of suitable data (Smith, 1968). The new lidar technique promises to fill this need and facilitate advances in the theory of high-stack diffusion.

Using a mobile, truck-mounted lidar system, a field team from Stanford Research Institute participated in the LAPPES[†] experimental program during two periods: 25 May-1 June and 15-24 October 1968. Lidar observations of the smoke plume from the stack of coal-burning Keystone Generating Station were obtained on 17 days; a total of 175 vertical plume cross sections, consisting of 3806 individual lidar observations, were collected. The quality of about one-third of these data were degraded by poor weather conditions. Of the remainder,

[†] Large Power Plant Effluent Study.

approximately 10 percent were selected for detailed manual analysis (first field program) and 46 percent were analyzed objectively using computer techniques. Representative examples of these derived plume cross sections will be presented here to illustrate the significant information which lidar observations can furnish regarding plume geometry and behavior. Although particulate emission is not the major air pollution problem associated with power plants because of the efficacy of modern ash removal devices, the smoke serves as a convenient tracer for the study of diffusion processes. Since the particles are small, their diffusion should be essentially identical with that of a gas such as SO_2.

II SUMMARY AND CONCLUSIONS

The results of the Keystone plume study with regard to plume be-
havior in particular, and lidar capabilities and limitations in general,
are briefly itemized below, with conclusions included as appropriate.

A. Plume Characteristics

In general, the lidar observations confirmed and underscored the
known and suspected complexities of plume behavior. Complicating fac-
tors--such as those mentioned below--that have been largely ignored in
present theories should now be intensively studied for possible incor-
poration, if the theory is to stay abreast of the experimental state of
the art.

Plume tilting and fanning caused by vertical wind direction shear
probably affects plume rise, and definitely requires reconsideration of
the definition of plume rise.

Fanning is a very common feature of plumes from high stacks ob-
served under stable conditions and must be included in any realistic
diffusion theory.

The marked effects of elevated inversions and other levels of in-
creasing stability with height were observed frequently and need thorough
consideration. Close correspondence was found between such levels and
plume tops, as well as with haze tops when no plume was observed.

Plume fumigation occurs often, probably more often than previously
suspected. Typically, however, only a portion of the plume fumigates at
a given time, with the remainder tilted and elevated.

The meteorological regime best suited for model validation, namely
nonstable conditions, also presents the most difficult observational
situation for lidar. This is because of the diffuse, rapidly changing
nature of plumes under these conditions. (See the instrumentation dis-
cussion later in this section.)

B. Lidar Data Analysis Considerations

The value of lidar for observing plumes was clearly established. For many applications, such as the use of particulates in a plume as tracers for the study of diffusion processes, lidar-observed relative mass concentrations, uncorrected for attenuation, should be sufficient to furnish the required information.

However, quantitative results in terms of absolute mass concentration were also obtained. A computed sample cross section corrected for attenuation gave a cross-axial integrated mass concentration of 680 g/m of plume length, compared with 875 g/m as calculated from the power plant data and wind measurements.

Our method of calculation of absolute particulate mass concentrations from the lidar data is based on the following:

(1) The same particulate relative size distribution and optical properties are assumed to hold in the clean air and plume. (The MRI data appear to confirm this.) This is a convenient but not essential assumption for obtaining a solution.

(2) The relative size distribution and optical properties are assumed to be known (measured or estimated).

(3) Mie scattering theory is assumed to be valid (this is reasonable, since the fly ash particles are spherical). Thus ξ_e, the extinction optical cross section per unit mass, can be computed.

(4) The clean air outside the plume is assumed to be homogeneous and to have a known mass concentration M_o (measured or estimated).

The integration procedure used in this method is fairly sensitive to errors in the values used for the solution parameters ξ_e and M_o.

The known errors and limitations associated with the use of collecting-type particle samplers tends to make such data incompatible with lidar data. Optical particle samplers might give more comparable

4

results, although there could be difficulties with any direct-sampling instrument that disturbs the medium.

The best prospects for obtaining routine quantitative data seem to lie in the direction of deriving additional information on the solution parameters by means of advanced lidar techniques, such as multiple-wavelength instruments, which may be able to eliminate the need for independent particle measurements.

C.   Instrumentation Considerations

For plume cross sections built up from many individual lidar observations, an accurate shot-to-shot referencing system is essential to correct the data for pulse-to-pulse variations in transmitted power.

Higher pulse repetition rates, on the order of one to ten shots per second, are needed to observe rapidly changing plumes under unstable conditions adequately and faithfully. A water-cooled system is suggested by this requirement.

Better data handling, processing, and display capabilities are necessary to assimilate larger quantities of data properly. New techniques, ideally of the real-time analog type, are needed to provide a capability of averaging many cross sections to obtain an hourly mean concentration distribution with which to check diffusion theories.

The usefulness of lidar data would be considerably enhanced if instrumentation with higher power output and lower noise susceptibility, and thus greater range, were used. A lidar with an effective <u>above-noise</u> range (for the clear-air return) of about 8 km would be ideal for plume studies. The neodymium system used in this study has an effective range for clear-air return of about one to two km,[*] and thus could observe only the denser parts of "clean"[†] plumes at ranges greater than

_____

[*]This range is variable, depending upon the level of background illumination.

[†]When all electrostatic precipitators were operating.

5

this. The Mark V ruby lidar would give much better results in this respect due to its shorter wavelength, narrower spectral region, and greater receiver sensitivity, but the pulse repetition rate needs to be increased.

In this connection, it is encouraging to note that neither the ruby nor neodymium versions of the SRI Mark V lidar approach the limits of current technology, and systems with the recommended performance can readily be developed.

III DESCRIPTION OF THE EXPERIMENTAL PROGRAM

A. Instrumentation

The SRI Mark V lidar (Fig. 1) was used during both field programs in a mobile, truck-mounted configuration. The characteristics of this instrument are detailed in Appendix A. As are all lidars, the Mark V is basically composed of a laser transmitter, which emits a very brief, high-intensity pulse of coherent monochromatic light, and a receiver, which detects the energy at that wavelength backscattered from the atmospheric aerosol as a function of range.

The transmitter of this instrument employs either a neodymium-doped glass laser rod or a ruby rod, at wavelengths of 1.06 and 0.694 μ respectively. The neodymium laser was used for the plume study because of its faster pulse repetition rate (approximately 10 pulses/min vs 3 pulses/min for the ruby). However, due to the much lower quantum efficiencies and higher dark currents of the best available photomultiplier tubes at 1.06 μ, and the wider filter bandpass needed for this system, overall receiver sensitivity, signal-to-noise ratio, and thus range is significantly reduced over that obtainable with the ruby system.

The lidar data were recorded on both a video magnetic disk recorder[*] and on an oscilloscope equipped with a 35-mm recording camera. A second oscilloscope used in conjunction with the disk recorder permitted an "instant replay" of each lidar shot, thereby providing real-time monitoring of the data. A 3-MHz low-pass filter is used with the disk recorder to minimize noise; the range resolution[†] is about 40 m, while that for the 35-mm film record is less than 20 m. The 35-mm film records were used for the manual analyses, while the machine analyses employed the magnetic disk records.

---

[†]The range resolution as used here is defined as the minimum separation distance at which two individual targets can be resolved.
FIGURE 1   SRI MARK V LIDAR

B.   Experimental Procedures

For each series of observations, the lidar was situated at any one of a number of preselected points, depending upon the location of the plume. The sites used during the two observation periods are depicted in Fig. 2. Where possible, the lidar was positioned so that it could be aimed in a direction approximately perpendicular to the plume axis. At each site, vertical cross sections through the plume were normally obtained at several downwind distances from the stack.[*] The technique employed consisted of scanning vertically with elevation angle increments of 0.3° to 10°, depending upon the vertical extent of the plume as determined from preliminary observations. Such scans were then repeated at other azimuth angles. The neodymium lidar permitted observations at intervals as short as five seconds. A complete vertical scan of 20 to 30 lidar shots required about two to five minutes to complete, and a set of three cross sections could be obtained within 10 to 15 minutes.

When the lidar was located at a considerable distance downwind from the stack, such as at Sites 16 (9 km), 17 (14 km), and 21 (21 km), the vertical cross sections were limited to only one azimuth angle (i.e., one vertical plane), because of the extended width of the plumes and the frequently directly overhead plumes.

In order to make the stack plume visible for direct observations with aircraft associated with other experiments, 50 percent of the electrostatic precipitators at Keystone Generating Station were normally shut down during most of the observations. However, to test the capability of the neodymium lidar to observe the "clean" plume, all of the precipitators were put into operation during certain periods on 21 and 22 October. As shown in Table I, six lidar plume cross sections were obtained under these conditions, and the results are presented in Sec. V.

---

[*]Although the Keystone Generating Station has two stacks, each 245 m high, only one stack was in operation during each of the observation periods.

The lidar observation periods were limited in length by prior arrangement in order to forestall any possible interference between the lidar and other experiments utilizing aircraft. One of the considerations here was lidar eye-safety, which is discussed in Appendix E.

C.   Summary of Lidar Data

The lidar observations obtained during the two experimental periods, 25 May-1 June 1968 and 15-24 October 1968, are summarized in detail in Appendix B, and in condensed form in Table II, along with the distribution of the analytical effort among the data. Data obtained during several days during the May period when there was rain, low ceilings or fog have been omitted, since no analysis was attempted. Data obtained on occasions when the cooling tower plume merged with the smoke plume also were not analyzed.

*M--Manual Analysis, C--Computer Analysis.

IV BASIC ANALYSIS OF LIDAR BACKSCATTER SIGNATURES

A.   General Discussion

An example of an oscilloscope photograph of a typical lidar shot
recorded on the magnetic disk is given in Fig. 3. Here the magnitude
of the backscattered signal return from the airborne aerosol is log-
amplified and displayed on a logarithmic scale (in order to maintain a
wide dynamic range of recording) versus time (or range) on a linear
scale.
FIGURE 3   BASIC LIDAR OBSERVATION OF SMOKE PLUME

For inspection, inventory, and editing purposes, ten lidar observa-
tions are displayed simultaneously by the magnetic disk recorder, as
shown in Fig. 4. One complete vertical "slice," or cross section,
through the plume is represented by two to four of these ten-trace

15
FIGURE 4   EXAMPLE OF MULTIPLE-TRACE FORMAT USED
FOR EXAMINATION OF MAGNETIC
DISK RECORDS

photographs. The "artificial" peak in the received signal at close range in Figs. 3 and 4 is typical of a bistatic system,[*] and is due to the oppositely acting effects of signal increase with increasing degree of intersection of the transmitter beam and receiver field of view, and signal drop-off due to increasing range (a function of the square of the range).

These traces represent the basic raw lidar data, which can be used directly to obtain plume boundaries easily and accurately. However, meaningful quantitative information on the concentration distribution within the plume requires further reduction and analysis. For each plume cross section consisting of 20 to 40 lidar observations, the data must be adjusted and corrected for:

(1)   Range effect,

(2)   Log-amplifier transfer function, and

(3)   Pulse-to-pulse variations in transmitted power.

---

[*]Current lidars have separate, noncoaxial transmitter and receiver optics

16

Allowance for these factors is fairly straightforward, and results in a cross section of normalized signal return (S) values. These S-values are directly proportional to particulate mass concentrations (expressed in logarithmic units), if the particle size distribution and optical properties are spatially uniform, as is often a reasonable assumption (McCormick and Kurfis, 1966), and if attenuation is negligible. Correction for the attenuation effect requires considerable effort, and is detailed in Sec. VII.

Manual analysis was initially employed for the May data. Using a specially prepared gridded template, range-corrected values of signal return (in dB, relative to the background signal level from the ambient aerosol) were extracted from the 35-mm film record. These values were then corrected for the shot-to-shot variations in transmitted power, plotted, and the resulting cross sections analyzed by hand at a contour interval of 6 dB (representing an increase by a factor of four). In line with the preceding discussion, these S-contours represent (in logarithmic units) approximate relative mass concentrations within the plume.

These manual analyses are quite tedious, and an objective analysis procedure was developed to process the October data and to check the hand analyses of the May observations. This procedure is documented in Fig. 5 (and Appendix C) and is discussed below.

B.   Lidar S-Function Analysis

The signal received on the face of the Mark V detector, originating from backscattered energy at range R, may be expressed as

$$P_s(R) = P_T \, \frac{c\tau}{2} \, \frac{A}{R^2} \, T_c(R) \, \beta(R) \, T^2(R) \qquad (1)$$

where

P_T = peak power emitted into the atmosphere

c = speed of light

τ = pulse duration

FIGURE 5   LIDAR DATA ANALYSIS PROCESS. See Appendix C for additional details
on Steps 1 and 2.

A = effective receiver area

T_c = beam convergence factor

β = volume backscatter coefficient (per steradian)

T = atmospheric transmission factor.

As previously mentioned, the resulting detector signal was routed through a logarithmic (log) amplifier and recorded on a video magnetic disk, as well as on a backup 35-mm recording camera system.

All signal strengths were referenced to the detector level in the absence of the applied backscatter signal P_s, which is denoted by P_N. The atmospheric return level recorded on the disk may then be expressed (in decibel notation) as

$$H(R) = 10 \, \log^* \frac{P_s(R) + P_N}{P_N} \tag{2}$$

where $\log^*$ is the log amplifier transfer function, which differs slightly from the true log function. As indicated in Fig. 5 and detailed in Appendix C, the analysis phase was initiated by digitizing recorded $H(R)$ traces, using a CALMA Model 300 digitizer. Intensity values at the digitizer standard increment (equivalent to 4 m) were recorded on magnetic tape. A CDC6400 computer was then employed to obtain a range-corrected, normalized signal return (S) function defined as

$$S(R) = 10 \, \log \frac{P_s(R) \, R^2}{P_s\left(R_o\right) R_o^2} \tag{3}$$

where R_o is a reference range [normally chosen as the first data point of the $H(R)$ digitization], and $P_s \gg P_N$. This S function also incorporates a correction for the transfer function of the log amplifier.

From Eqs. (1) and (3), the normalized signal return function $S(R)$ may be related to the atmospheric optical parameters by

$$S(R) = 10 \, \log \frac{\beta(R) \, T^2(R)}{\beta\left(R_o\right) T^2\left(R_o\right)} \quad , \tag{4}$$

where $T_c(R \geq R_o) = 1$ is assumed; i.e., the H(R) digitization process was initiated at a point on the trace for which the transmitted beam is fully encompassed by the diverging receiver field of view. The S function then represents a relative backscatter function, which is uncorrected for atmospheric transmission losses.

S-function contours were generated from a computer program (developed at Stanford Research Institute) that uses linear interpolation of data gridded in polar coordinates. The polar grid of data points need not be equal-incremented in range or angle, thus permitting processing of lidar data collected at unequal increments of elevation angle. The output from the contouring program was subsequently machine plotted on a Benson-Lehner or Calcomp plotter, or electronically graphed on the CDC280 CRT/ film system. These contour plots and their significance are presented in Sec. V.

The lidar S function is dependent only on the atmospheric optical properties when $P_s(R) \gg P_N$. However, when $P_s(R) \leq P_N$ (i.e., when the atmospheric return is at or below the noise level), then $S(R) \propto 10 \log R^2$. Invalid data of this type were omitted from the contouring program. This omission, illustrated in Fig. 6, explains the open contours that may be expected when plume return occurs at a range for which the clear-air return would be below the noise level. While the S-function contour analyses give a surprisingly good picture of plume relative concentration distributions from laser energy returns (see Fig. 23), they are biased to varying degrees by the fact that some energy is lost from the laser pulse as a function of distance along the path, i.e., the atmospheric transmission of the laser energy varies along the pulse path. Accounting for this attenuation effect requires additional information on the atmospheric scattering particles and/or an explicit relationship between the atmospheric transmission and backscatter properties at the laser wavelength. This aspect of the analysis is discussed further in Sec. VII.

Since plume mass concentrations--and thus lidar echoes--cover such a wide dynamic range, contouring a plume cross section in linear units presents a problem. As illustrated in Fig. 7, the linear display (a)

RAW LIDAR DATA
FIGURE 6 EFFECT OF RANGE CORRECTION UPON PLUME SIGNAL RETURN AND RECEIVER NOISE LEVEL. For simplicity, a perfectly transmitting homogeneous medium has been assumed for the clear air.

(b) Logarithmic display—10 log$_{10}$ (M/M$_o$)— contour interval 3 db

TA-7289-13

FIGURE 7   COMPARISON OF PLUME CROSS SECTIONS CONTOURED
IN LINEAR UNITS (a) AND LOGARITHMIC UNITS (b)
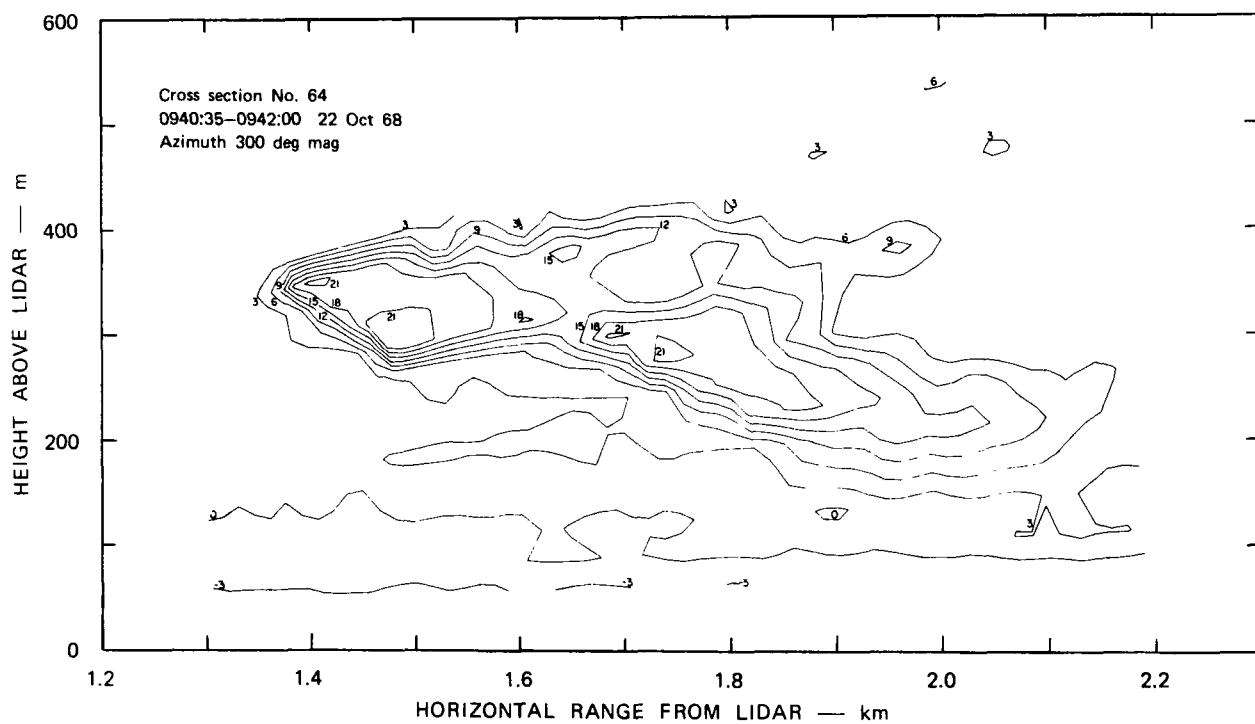

loses definition at the boundary of the plume, compared with a logarithmic display (b) with contours in decibels. The latter documents the plume edge more accurately, and permits reasonable contour spacing.

In the linear display in the figure, the contour units are in multiples of the clean-air background mass concentration (M_o), or M/M_o, where M is the plume mass concentration. [For this case, M_o was taken to be 100 $\mu g/m^3$, on the basis of the visibility estimate and the work of Noll, et al. (1968).] It may be seen that the contour spacing, and thus the outer contour value, must be set at no lower than about 25 in order to prevent contour crowding. On the other hand, the logarithmic display with units of dB $= 10 \log_{10} (M/M_o)$ has a contour spacing of 3 dB, which gives an outer boundary of $M/M_o \approx 2$ without excessive contour crowding. (Each contour increment of 3 dB corresponds to a change by a factor of approximately two from the adjacent contours.) Because of these advantages, logarithmic contour intervals have been used exclusively in the lidar cross sections.

Because of the effect of the finite above-noise range of the lidar as explained in Fig. 6, many contours in the cross sections to follow later do not close around the plume; with increasing range they begin contouring the background noise and become meaningless. In addition, contours frequently appear in the clear air beneath the plume, which are usually probably real, but have no particular value. Both of these effects are shown in Fig. 7(b). To add clarity to the plume cross sections, these extraneous portions of the contours have been deleted from the illustrations. Figure 33 in Sec. VIII shows the nature of this editing process. Considerable care was taken to ensure that this process did not remove any portion of the plume cross section or any other information of value.

V   RELATIVE CONCENTRATION CROSS SECTIONS OF KEYSTONE STACK PLUME

A.   May 1968 Observation Period

The emphasis during the May observation period was on lidar plume observations within five miles (8 km) of the stack. The analyses for the May data were performed manually. All lidar observations during this period were taken when one of the two precipitator banks for the active stack was shut down, allowing 50 percent of the effluent to pass out through the stack untreated. The resulting plume color was a light gray-brown.

In the plume cross section illustrations to follow, both for the May and October data, it should be noted that the lidar is at the point (0,0), and the horizontal range scale is usually discontinuous. Also, heights are taken above the lidar; Fig. 8 illustrates the height relationships involved. To facilitate height transformations, the height of the top of the stack is indicated on the ordinate scale for each cross section by means of a horizontal arrow. (Lidar site elevations are given in Table II, Sec. III.) Calculated plume rise heights (ΔH) are also shown for those cross sections for which reasonably concurrent temperature profiles were available, and will be discussed in Sec. VI.

Figures 9-12 show four sets of sequential vertical cross sections through the smoke plume during the mornings of 25 May (Figs. 9 and 10) and 26 May (Figs. 11 and 12). The contours in Figs. 9 through 12 represent range-corrected signal return in decibels relative to that from the ambient background aerosol, including background noise, and can be taken to represent (approximately) the relative particulate concentrations. The effects of attenuation are neglected. The inset in each figure indicates the geometry of the observations. Poor weather conditions prevailed during the 43 cross sections obtained during the remainder of the May period. The cross sections in Fig. 9 were obtained about 1-1/2 hours earlier than those in Fig. 10, while the observations in Fig. 11 precede those in Fig. 12 by almost three hours. Vertical temperature profiles closest in time

to the lidar cross sections are given in Fig. 13. On both mornings, the sky was essentially clear.
FIGURE 13   VERTICAL TEMPERATURE
              PROFILES ASSOCIATED
              WITH LIDAR OBSERVATIONS,
              25—25 MAY 1968

Several general features of these cross sections are apparent. The contours, which are in logarithmic units (decibels), represent approximate relative particulate mass concentrations as previously discussed. Maximum concentrations are usually observed near the top of the plume, apparently associated with the greater buoyancy there. This effect was also found by Hamilton (1966), who took ruby-lidar observations of the plume from an oil-fired power plant. There is considerably consistency in the observed shape and structure of the Keystone plume from cross section to cross section in each set, and individual features may be followed for several kilometers downwind from the stack. This is particularly pronounced for the early-morning, nondiffusive cases. For

31

example, in Fig. 9, the central clear cavity, or vault, on the bottom of the plume, evidently associated with the bifurcation process, is readily apparent in all three cross sections.

For the stable cases (Figs. 9 and 11), the characteristic horizontal spreading (fanning) and tilting of the plume due to vertical wind direction shear (wind veering with height) is evident.

In Fig. 11, there is some evidence that terrain channeling of the air flow acted to horizontally spread the effluent, in addition to the effects of wind direction shear. The northeastern portion of the plume (nearest the lidar) appears to follow a valley that is about 100 m lower than the hills which are traversed by the southwestern portion of the plume (farthest from the lidar), possibly accounting for part of the rapid increase in the cross-wind (or cross-axis) dimension[*] of the plume from 340 m at 0.8 km downwind to 1450 m at a downwind distance of 2.2 km. Lifting by the hills could explain the 160-m rise of the southwestern portion of the plume (at the extreme right in Fig. 11) from Cross Section 12 to Cross Section 14.

The cross sections pictured in Fig. 10 probably represent a case of fumigation, in that downward diffusion is fairly strong, while upward diffusion of the plume apparently is limited. This situation could be caused by a temperature inversion at 900-1000 m, above the maximum height of the observed temperature profile. Note that relatively high concentrations are brought to very low levels within 3 km from the stack.

The rapid upward diffusion of a looping plume is illustrated in Fig. 12. For the most part, the relative concentrations in Cross Section 19 are less than those in Cross Section 17 by about 6 dB, which represents a decrease to about one quarter of the previous levels. The temperature sounding for this time (Fig. 13) shows an approximately dry-adiabatic lapse rate up to the maximum height sampled, 1000 m above the base of the stack.

---

[*]This dimension is indicated on the secondary abscissa scale for each cross section during the May period.

Since these cross sections were built up from lidar observations spanning a period of two to five minutes, some distortion is unavoidable when the plume structure is changing with time, as during unstable conditions (Figs. 10 and 12). In the future, lidar systems capable of one or two pulses per second and with automatic positioning should eliminate such problems by furnishing essentially instantaneous plume "slices."

B.   October 1968 Observation Period

Due to the large quantity of lidar data obtained during this period, an objective, computer-oriented data reduction and analysis process was developed, as described in Sec. IV. This process permitted the analysis of about half of the cross sections observed. A number of illustrative examples have been selected for presentation here. There are various minor flaws in these analyses that would not have occurred if the work had been carried out by hand, but the time saving is quite significant.

For example, occasional small areas of the cross sections (indicated in the figures) were not contoured due to a minor program error. In addition, the cross sections illustrated do not always represent the total plume width as recorded on the original data records (photographs), although the portion shown is correct. This truncation occurred because of a problem in digitizing and processing those photographs that were obtained with an oscilloscope sweep speed of 5 μs/cm, corresponding to a full-scale range of 7.5 km.

Because of this difficulty, which could not be overcome within the time and effort limitations of the project, the photographs taken at 2 μs/cm were used exclusively, which limits the ranges of the analyzed data to 3-km maximum. In order to retain the information on total horizontal plume extent, maximum distances of plume return were scaled off the original 35-mm film and are indicated on the figures by vertical arrows (horizontal arrows when off scale) labeled with the range to the farthest observed edge of the plume.

Several of the May (hand-prepared) cross sections were reanalyzed by machine for comparison purposes. An example is given in Fig. 14. The agreement is good, despite the fact that two different data records

33
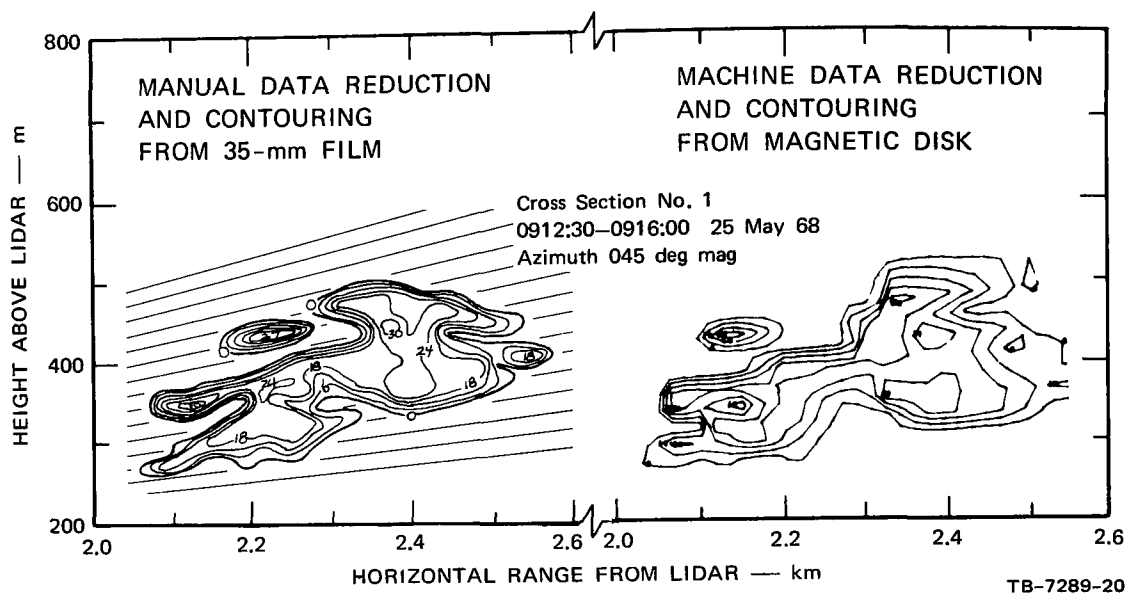

FIGURE 14   COMPARISON OF MANUAL AND MACHINE ANALYSES. Note that
two different records are used, with the 35-mm film having considerably
better spatial resolution than the magnetic disk. One lidar observation
is missing at the top of the machine cross section.

were used: the 35-mm film (spatial resolution about 20 m), and the mag-
netic disk (spatial resolution about 40 m). In addition, it was later
discovered that some data (the uppermost lidar observation) was missing
from the disk record; this caused the shape of the machine cross sec-
tion to differ at the top of the plume from that in the manual analysis.

The cross sections in Fig. 15 are in the same (approximately cross-
wind) vertical plane at the same azimuth angle from the lidar, and are
spaced about one hour apart; thus, they document the changing crosswind
structure of the plume with time during the morning of 15 October. The
direction to the stack is into the paper. (See Appendix D for plan views
of the horizontal plume positions, to clarify visualization of the lidar/
stack/plume orientation.) The typical tilting and fanning of the plume
in stable conditions, due to veering (clockwise rotation) of the wind
direction with height, is apparent. By 1147 EDT, the height of the
mixed layer had apparently increased to the level of the lower part of
the plume, causing fumigation of that portion. Unfortunately, no tem-
perature profiles are available for this day.
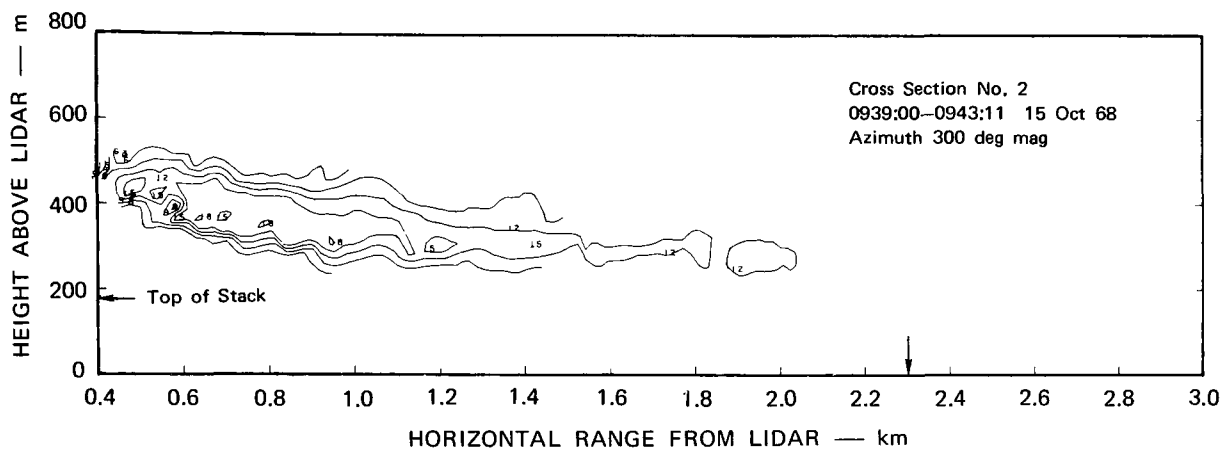

FIGURE 15   TIME SERIES OF LIDAR-OBSERVED VERTICAL CROSS SECTIONS FROM SITE 6, 3.8 km

horizontal extent of plume as indicated by original record. See also Figure D-1.

35

Figures 16-18 illustrate the large plume widths at 8.5 and 14 km down-
wind caused by stratification and fanning of the plume during the early
morning hours of 16-18 October, respectively. The "lumps" appearing in
these cross sections (and in those of other stratified plumes) are caused
by a bias effect in the computer contouring program[*] due to the particu-
lar gridding technique used. This bias effect only occurs for very shal-
low plumes. The vertical plane covered here is directly over the lidar.

The plume cross sections in Fig. 19 are the farthest downwind (21 km)
that were observed during the experimental program. These cross sections
are in a vertical plane directly over the lidar. Of special interest
here is Cross Section 42, which shows no plume, but does show the haze
top associated with the temperature inversion. Evidently the tenuous
plume either meandered away or lost its identity by mixing downward.

Figures 20 and 21 illustrate the effect on plume density of all
precipitators being in operation (Fig. 21) compared with 50-percent
operation (Fig. 20 and others). In each figure, the cross sections are
at different azimuth angles and thus different downwind distances from
the plume. Cross Sections A44 and 46 are about 3.5 km downwind, Cross
Sections B44 and 47, 4.5 km downwind (and approximately crosswind), and
Cross Sections 45 and 48 are 6 km downwind. (It should be kept in mind
that as illustrated in Appendix D, these cross sections are sometimes
elongated and do not represent true plume width, except when oriented
in the crosswind direction. Plume height, however, is always truly
represented.)

Examining Cross Sections B44 (Fig. 20) and 47 (Fig. 21), the dirty
and clean plume, respectively, we see that the maximum normalized signal
return above the reference for the clean plume is 12 dB, which is 6 dB,
or four times, lower than that for the dirty plume. The apparent size
of the plume, as observed by the lidar, also shrinks, due to less of the
plume return being above the receiver noise level (see Fig. 6, Sec. IV).

---

[*]The contouring program, developed recently by S. Briggs of SRI, was
used in its available form for this work. This bias effect, as well as
the cause for the contouring skips, could be eliminated from the program
in future studies.

42

Later during the same morning, the cross sections in Fig. 22 were observed on the same azimuth angles. Here the lower portion of the plume is fumigating, while the upper portion remains relatively intact, probably due to the temperature inversion at 470 m.

Figures 23-26 illustrate various stages in the structure of the plume during the morning and midday of 22 October. In these figures the stack location is into the paper. Considering the cross sections located nearly crosswind (Cross Sections 58, 64, and 73), we see that at 0904 EDT the plume is compact and level (Cross Section 58), at 0941 EDT wind shear has set in and the plume is tilted, and at 1232 EDT fumigation of the lower portion is occurring. For the clean plume (Fig. 24), essentially no plume is apparent in the cross sections due to the weakness of the return signal in relation to the background noise level. Possibly because of the 3-MHz bandpass of the disk recorder, the data for clean plumes do not show up as well on these cross sections as on the 35-mm film, from which the plan views in Appendix D were obtained.

In Fig. 27, the plume apparently cannot penetrate the $1°$ C inversion at 500 m above the lidar, and is spreading out beneath with fumigation of the lowest portion. Cross Section 79 shows an interesting bubble at the top, which could be a thermal which has risen through the plume.

A series of approximately crosswind-oriented cross sections at about 15-minute intervals is shown in Figs. 28-30. The rapidly changing structure of the plume is apparent, as well as the trapping of the effluent by the stable layer at 400-500 m above the lidar. On this date, 24 October, the particulate output of the stack was reduced by 25 percent from previous days, since two additional precipitator sections were operating. As shown in Cross Section 104 (Fig. 29), there is some downward diffusion of the plume, but the stable near-ground layer apparently prevents the plume material from mixing to the ground.

VI INTERPRETATION OF CROSS SECTIONS IN TERMS
OF PLUME RISE AND DIFFUSION

The new capability to "see" the detailed structure and geometry of plumes, which lidar makes possible, gives the instrument decided potential in plume rise and diffusion studies. However, as often happens when a new technique enables us to obtain detailed observations where only sparse data were available before, the lidar data have underscored the complexities of plume behavior and made apparent the weaknesses of certain of the present concepts and theoretical assumptions.

After examination of the plume cross sections in Sec. V, it is apparent that plume tilting and fanning caused by wind direction shear is a characteristic feature of plume behavior in stable conditions. It then becomes difficult to identify any one level of the plume for use in computing plume rise. The concept of plume rise also tends to lose meaning under fumigation conditions, which were frequently observed, and under unstable (looping) conditions. Equally important as complicating factors are the temperature inversions and stable layers, which regularly occur aloft and tend to trap the plumes and prevent further rise. The lidar data for October show several instances of this. Thus the data emphasize that there typically are significant vertical variations in stability and wind structure that have profound effects upon plume behavior, and that are not taken into account by the plume rise theories.

Plume-rise values (ΔH) for the stable cases were calculated from the formula recommended by the ASME[*] Committee on Air Pollution Controls (Smith, 1968):

$$\Delta H = 2(F/G\overline{U})^{1/3} \tag{5}$$

---

[*]American Society of Mechanical Engineers.

with

$$F = g \, r^2 \, V_s \left(T_s - T_a\right)/T_a$$

$$G = \left(g/T_a\right)(\Delta T/\Delta Z + 0.01)$$

and

$$\overline{U} = \left(U_t + U_a\right)/2$$

$$\Delta T = T_t - T_a$$

$$\Delta Z = H_t - H_s \qquad \text{(after Proudfit, 1969)}$$

where

F = buoyancy flux

g = acceleration of gravity (= 9.8 m/s)

r = radius of stack orifice (= 4.25 m for Keystone)

V_s = stack gas exit velocity

T_s = stack gas exit temperature

T_a = ambient atmospheric temperature at stack top

G = stability parameter

$\overline{U}$ = mean wind speed over height interval where rise occurs

U_t = wind speed at height of plume top (H_t) after maximum rise

U_a = wind speed at height of stack top (H_s)

T_t = air temperature at height of plume top.

The computed values, as well as the values of the input parameters used, are listed in Table III.

In view of the complications discussed previously with regard to defining plume rise in a manner that permits objective determination from lidar plume cross sections, the calculated plume rise values have been indicated directly on the cross sections, Figs. 9-12 and 15-30.

*Estimated.

In this way, detailed comparisons with the observed plume heights and shapes are possible.

In general, the ASME formula appears to predict plume rise reasonably well, although of course the frequent presence of temperature inversions at plume levels diminishes the relevancy of the theory in many instances. For the few cases where the vertical temperature gradient at plumes levels is approximately uniform with height, and vertical wind shear-- and thus plume tilting--is weak (e.g., Cross Section 58, Fig. 23), the agreement between the theory and the observations is excellent. On the whole, there appears to be a weak indication that the ASME formula may predict slightly lower plume rises than observed.

The capabilities of lidar in computing diffusion parameters are fairly obvious, at first glance, from inspection of the horizontal plan views of plume positions in Figs. 9-12 (insets) and in Appendix D, which show the horizontal spread of the effluent with downwind distance. Again, however, wind direction shear and the attendant spreading of the plume by shearing are not adequately covered by present theories. The best application of current theory is probably for the neutral and un- stable cases, when vertical wind shear is not usually so pronounced. Here another problem is encountered, in that most theories are only valid for mean concentrations over a period of 30 minutes to an hour (Gifford, 1961). To be most useful here, then, a lidar should be capable of taking fast, quasi-instantaneous cross sections through a plume at frequent intervals for extended periods on the order of an hour. The results of these cross sections would then be averaged to obtain a mean concentration distribution to compare with theory. The present equipment requires about two to three minutes for a complete cross sec- tion. Under unstable conditions when the plume position is rapidly changing, some distortion is introduced into the cross sections due to the lack of instantaneity of the individual lidar observations.

Another important consideration for studying plume diffusion with a lidar is the receiver signal-to-noise ratio at the range where the plume is observed. As seen in Fig. 6, a portion of the plume return is

truncated when the plume is observed at a range beyond that at which clear-air return is detected above the noise. This decreases the observed size of the plume, and hence affects the diffusion calculations unless suitable allowances are made. A prime example of this effect is shown by Figs. 20 and 21 and the corresponding plume plan views in Appendix D.[*] Here a series of six cross sections were obtained within a time period of 15 minutes. The precipitators were all on when the last three cross sections were observed, furnishing a clean plume. Due to background noise considerations, this clean plume is "seen" by the lidar to be considerably smaller than the dirty plume. However, the diffusion regime was the same.

The Mark V lidar has an effective above-noise range <u>for clear-air</u> return on a typical bright day of about one to two km in the neodymium version, but this could be readily improved by using a ruby or YAG[†] laser and/or additional signal-to-noise enhancement equipment and techniques.

---

[*]The effect is not as pronounced in the plan views due to the greater recording resolution of the 35-mm film system.

[†]Ytrrium aluminum garnet, wavelength 1.06 μ.

VII EVALUATION OF PARTICULATE MASS CONCENTRATIONS
FROM LIDAR NORMALIZED SIGNAL RETURN (S) VALUES

As discussed in Sec. IV, the conversion of S values to absolute mass concentrations requires allowance for the effect of attenuation of the laser beam as it passes through the atmosphere and the plume. This problem is best approached by solving the differential equation derived from Eq. (4) (Sec. IV):

$$\frac{dS}{dR} = 4.34 \ \frac{1}{\beta} \ \frac{d\beta}{dR} - 8.7 \ \sigma \tag{6}$$

where Bouquer's law of attenuation

$$T(R) = \exp\left[- \int_0^R \sigma(\ell) \ d\ell \right] \tag{7}$$

has been assumed and $\sigma(\ell)$ is the volume extinction coefficient at a distance ℓ along the path. The solution of Eq. (6) for particulate mass concentration along the laser beam path requires relating the optical parameters σ and β to the particulate mass concentration. For this purpose the ratio of each optical parameter to the particulate mass concentration M(mass/volume) is defined as

$$\xi_e \equiv \frac{\sigma}{M} \ , \qquad \xi_b \equiv \frac{\beta}{M} \ . \tag{8}$$

Substitution of Eq. (8) into the lidar differential equation [Eq. (6)] results in an expression relating mass concentration to the lidar normalized signal return:

$$\frac{dM}{dR} - \frac{1}{4.34} \ \frac{dS}{dR} \ M - 2 \ \xi_e \ M^2 = 0 \qquad , \tag{9}$$

where ξ_b has been considered independent of range. The validity of this assumption will be discussed later. This nonlinear equation may be solved by first employing the linearization transform $\eta \equiv M^{-1}$ with the

result

$$M(R) = \exp\left[C_1 S(R)\right] \left[M_o^{-1} - 2\, \xi_e \int_{R_o}^{R} \exp\left[C_1 S(\ell)\right] d\ell \right]^{-1} \qquad (10)$$

where $C_1 = 1/4.34$. This solution principally assumes that

(1) ξ_e and ξ_b are invariant with range and the value of ξ_e can be computed, and

(2) a boundary or clear-air particulate mass concentration, M_o, is known or can be estimated.

Microscopic analysis of the Keystone fly ash clearly shows that the particles are glass spheres, apparently formed from the mineral content of the coal by the intense heat of the combustion process; hence, the use of Mie theory in deriving estimates of ξ_e and ξ_b is justified. To a high degree of accuracy, the volume extinction coefficient at the lidar wavelength of 1.06 μ may be considered to be essentially dependent only on the atmospheric particulate matter, and the ξ values may be expressed[*] as:

$$\xi_e = \frac{\int_0^\infty \pi\, a^2\, Q_e(x,m)\, n(a)\, da}{\int_0^\infty \frac{4}{3}\, \pi\, a^3\, \rho\, n(a)\, da} \qquad (11)$$

$$\xi_b = \frac{\int_0^\infty \pi\, a^2\, Q_b(x,m)\, n(a)\, da}{\int_0^\infty \frac{4}{3}\, \pi\, a^3\, \rho\, n(a)\, da} \qquad (12)$$

_____

[*]To be precise, the parameters ξ_e and ξ_b defined by Eqs. (11) and (12) are exactly equivalent with those defined by Eq. (7) only when multiple scattering effects are absent. This is a good assumption for this study because of the narrow field of view of lidar systems (<1 mrad).

where

a = particle radius

Q_e = extinction efficiency factor

Q_b = backscatter efficiency factor

x = size parameter = $2\pi a/\lambda$

m = refractive index of particles

λ = wavelength of the laser energy

n = number of particles per unit volume per unit radius interval, and

ρ = density of the particulate matter.

The efficiency factors may be computed from Mie theory for a given particulate matter refractive index, the real part of which in this case was estimated to have a value of approximately 1.5, based upon the known mineral composition of coal. The requirement that ξ_e and ξ_b be independent of range is satisfied when the relative particle-size distribution is invariant with range; i.e.,

$$n(R,a) = C(R)\ n_r(a) \quad , \quad \quad \quad (13)$$

where $C(R)$ is the number concentration and $n_r(a)$ is the relative size distribution. Also, with this assumption only the relative particle size distribution is required to evaluate the ξ values. However, $n_r(a)$ is rarely completely independent of range, and the question may be asked as to how small changes in the relative size distribution are reflected in the ξ values. Since the ξ values are expressed in terms of integrals over the range of particle sizes, monodispersed (single-sized) particles would cause largest ξ variations with slight changes in the particle size. Mie computations of ξ_e and ξ_b are presented in Fig. 31 for the case of monodispersed particles consisting of material with a density of 2.1 g/cm^3 (as measured at the Institute from a Keystone fly ash sample) and a refractive index of $m = 1.5-i0$ for incident radiation of wavelength 1.06 μ.

62

As shown, slight variations in particle size can cause large variations in ξ_b and smaller but significant variations in ξ_e. Because of this, and the fact that P_s is more sensitive to variations in β than σ [Eq. (1)], the requirement that ξ_b remains constant with range also satisfies the less stringent requirement that ξ_e remains invariant.

A real aerosol contains particles of many sizes, so the variations in the ξ curves tend to be smoothed out when a weighted integral for all sizes present is computed. The next section will explain the methods developed to handle the supplementary particle-size data obtained during the Keystone study for use with the lidar observations.

VIII ANALYSIS OF ATTENUATION EFFECT
USING PARTICLE-SIZE CHARACTERISTICS

The Keystone stack plume particulates were sampled with an airplane-mounted Goetz moving slide impactor (Goetz, 1969) by Meteorology Research, Inc. (MRI), at times nearly concurrent with the SRI lidar observations. Tentative relative particle size distribution data for specified sampling periods were furnished SRI (see Table IV) along with information required to evaluate the number of particles per unit volume per unit radius interval for increments of 0.25 μ in radius. The relative size distribution is sufficient to evaluate the optical parameters ξ_e and ξ_b for use with the lidar data.

Ideally, however, one would like to compare mass concentrations measured by the MRI sampler with those derived from the lidar data. This was not possible, since our conversions of the relative particle-size data to absolute size distributions (using the furnished sample-volume values) and then to mass concentrations give unrealistically large values of concentration for the clear air ($M_o > 1000$ μg/m^3) upwind of the stack. Hence it has been necessary to use the empirical relationship derived by Noll, et al. (1968) to determine the clear-air background mass concentration (M_o) from visual estimates of atmospheric visibility.

The solution parameter ξ_e and the parameter ξ_b were evaluated from the furnished relative size distributions for each data sample listed in Table IV; these values are tabulated in Table V. In these computations, integrations over particle radii were performed by means of rectangular integration, with the size distribution assumed constant within each sampling interval. The parameters ξ_e and ξ_b were evaluated from sampling-interval-averaged optical cross sections defined as:

$$\overline{C} = \overline{\pi a^2 Q} = \left(\lambda^2/4\pi\right)\int x^2 Q(x)\,dx / \int dx \qquad (14)$$

where $x = 2\pi a/\lambda$ (see Sec. VII), and the integration was trapezoidal with 0.1 intervals in x (0.106/2π radius intervals at $\lambda = 1.06$ μ).

Table IV

It was indicated by MRI that the particle counting technique is insensitive to particles with radii less than 0.50 to 0.25 μ. The influence of this on the evaluated quantities, as well as the validity of the rectangular integration, was investigated by fitting a continuous Junge distribution function to the observed particle counts. Figure 32 illustrates the method used to evaluate the Junge parameters from the cumulative particle-size distribution of Count No. 21, which has been reduced to absolute values by the tentative MRI information. This particular sample has considerably fewer small particles (a < 1.0 μ) and also fewer large particles (a > 3 μ) than the indicated Junge model.
FIGURE 32 **SAMPLE CUMULATIVE PARTICLE SIZE DISTRIBUTION AND JUNGE-TYPE ANALYTICAL FIT**

Assuming that the Junge model is a satisfactory representation of the real aerosol, it can then be employed with a more exact trapezoidal integration of ξ_e (maintaining 0.1 increments in x). Integration with limits of a = 1.0 and 10.0 μ results in ξ_e = 0.37 m^2/g, slightly less than the rectangular integrated value (0.51), which is expected because of the increased number of larger particles in the Junge model. Integration with limits of a = 0.1 and 10.0 μ results in ξ_e = 0.87, the increase occurring because of the larger number of small particles in the Junge distribution.

68

The lidar and particle sampling of the Keystone plume were best coordinated for Cross Section 64, which is oriented approximately cross-wind, and this case was chosen to apply the mass concentration solution discussed in Sec. VII. The boundary parameter M_o was taken from the visibility estimate (7 to 10 miles), which gives $M_o = 100$ $\mu g/m^3$, using the relationship of Noll, et al. (1968). The value of ξ_e was chosen in accordance with the computation (Table V) for Particle Count 22 as 0.2 m^2/g.[*] The results of these absolute mass concentration computations are presented in Fig. 33, which also illustrates the manner of the removal of extraneous clear-air and background noise contours from the plume cross sections, which is normally employed in order to better define the plume boundaries and shape. Figure 33(c) represents the results of the graphical subtraction of Fig. 33(a) from 33(b), and thus shows contours of mass concentration in decibels added to the back side of the plume by the attenuation correction. It may be noted that the maximum correction is 9 dB, which means that the mass concentration at that point was almost 10 times too low in the uncorrected cross section, Fig. 33(a). It may be seen that although the attenuation correction does change concentrations significantly in one part of the cross section, the general shape and structure of the plume remain the same.

A planimeter was used to integrate the total mass per unit plume length (cross-axial integrated mass concentration) represented by the cross sections in Fig. 33(a) and (b). The results were as follows: uncorrected cross section (a), 350 g/m of plume length; corrected (b),

---

[*]A value of 0.3 m^2/g was tried also, but gave no solution due to the integration becoming unstable. Although solutions were not attempted for any other cross sections, many of the high values of ξ_e shown in Table IV would probably cause similar unsuccessful results. These high values are a consequence of the surprisingly small modal particle sizes reported by MRI. The cause of this apparent discrepancy between the lidar data and the particle-size data is unknown, but there are a number of possibilities, such as (1) the free-air particles could have a thin coating of water, which increases their optical size, (2) particle agglomerates may break up when introduced into the sampler, (3) some of the assumptions used in the lidar data analysis may be faulty, or (4) there may be an error in the particle-size measurements or analyses.

69
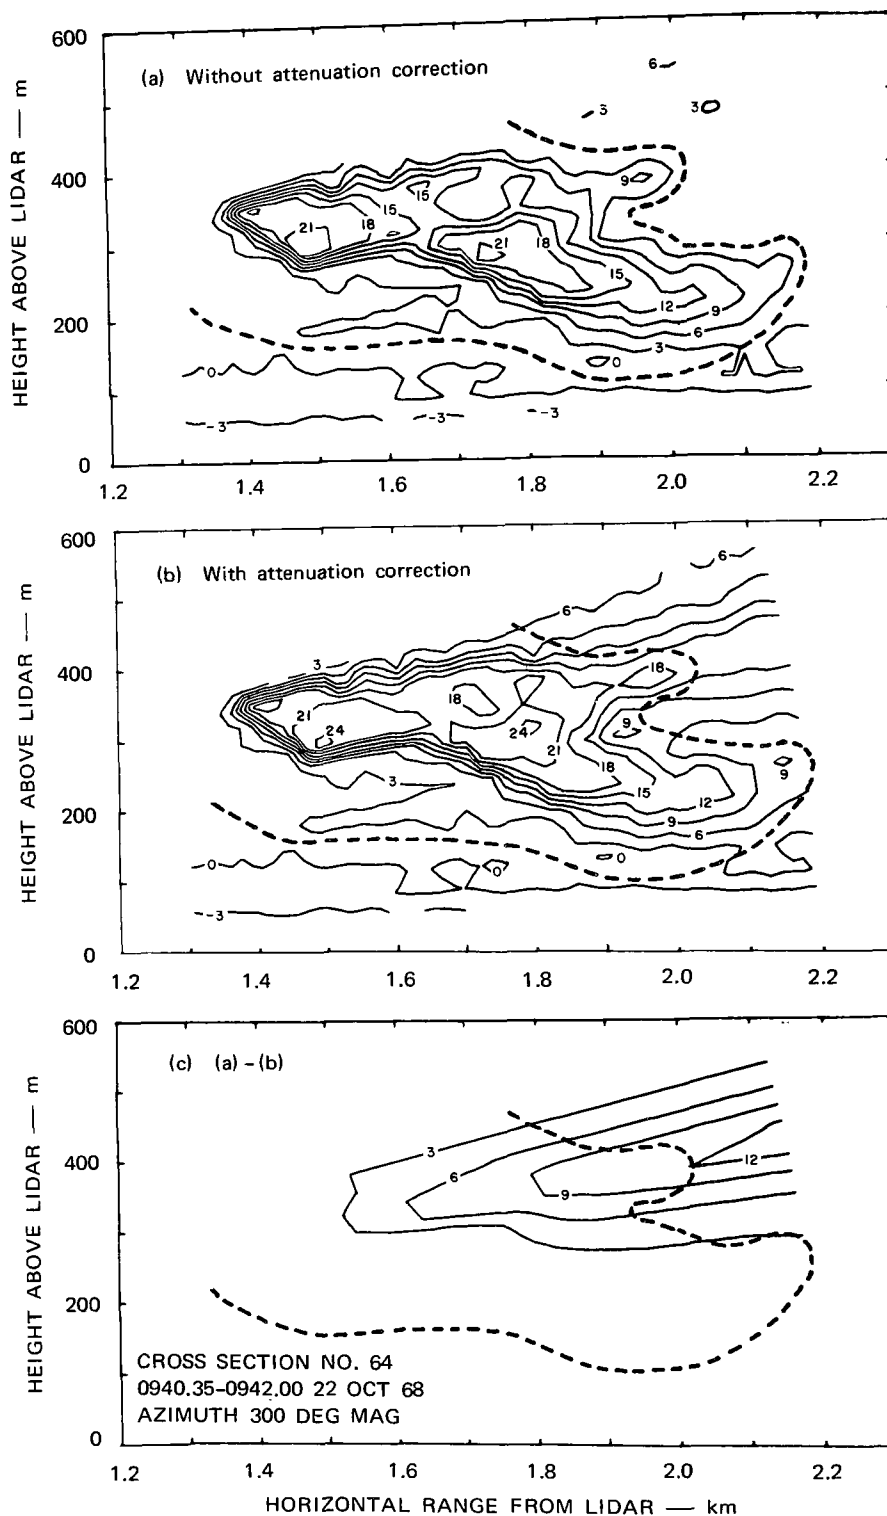

FIGURE 33 EFFECT AND MAGNITUDE OF CORRECTION OF PLUME MASS
CONCENTRATION DISTRIBUTIONS FOR ATTENUATION. Contours
represent 10 $\log_{10}$ (M/M_0) and thus are labelled in decibels. Solution
parameters for (b) are clear-air concentration M_0 = 100 x 10^{-6} g/m^3;
ξ_e = 0.2 m^2/g; dashed line faired in by hand separates clear-air and
background-noise contours from plume contours.

70

680 g/m, which shows that the mass correction was significant. These values were compared with an estimate of the particulate emission rate from the stack, obtained from the following parameters existing at the time the cross section was obtained:

Coal burning rate = 651×10^3 lb/hr

Fly ash content of coal = 17 percent[*]

Precipitator collection efficiency = 50 percent
(half in operation)

Wind speed at plume level = 8 m/s.

Using these values gives a stack source strength of 7000 g/s, and a plume cross-axial integrated mass concentration of 875 g/m, compared with the 680 g/m measured by the lidar, after allowance for attenuation Although further evidence will be necessary from other comparisons, the close agreement of this initial example does indicate strongly that the lidar technique is capable of useful quantitative measurements.

---

[*]Full conversion to gas-borne fly ash particles is assumed.

IX   RECOMMENDATIONS FOR FURTHER RESEARCH

This first feasibility study, although limited in scope and scale
of effort, has demonstrated that lidar is of significant value in plume
studies. The instrument can furnish information about plume rise and
dispersion from tall stacks that is unobtainable in such detail by any
other means. To take advantage of the full potential of the technique,
additional work is needed in a number of areas. These fall for the most
part within the general categories of

(1)   Lidar instrumentation improvements,

(2)   Additional data-handling and reduction capabilities,

(3)   Improved experimental and analytical techniques, and

(4)   Testing of advanced lidar concepts.

A number of specific suggestions for improving lidar usefulness in plume
studies are itemized below.

A.   Lidar Instrumentation

●   The observations described in this report were made with SRI's
general-purpose experimental Mark V lidar operating in its neodymium
configuration. Although this provided a higher pulse repetition frequency
(10-12 pulses/min) than the ruby version, the latter system is more sen-
sitive and could thus have acquired data at longer ranges, or better
information on "clean" plumes (i.e., with full precipitator operation).
The lower pulse rate of the ruby system (3-4 pulses/min) would have
seriously reduced the data rate.

These considerations well illustrate the problem confronting
the designer of an optimum system for use in plume observations. It is
important to recognize, however, that the SRI Mark V lidar is a rela-
tively modest unit, and that with current technology considerably higher
performance is readily attainable. The results of the present investi-
gation, even allowing for the limitations of the equipment, are so

encouraging that the development of a more advanced lidar system appears to be fully justified.

Such a system could be readily developed with state-of-the-art technology based upon the experience of the present study. In selecting an optimum system, it would be necessary to investigate carefully the relative advantages of lasers of different wavelengths. Prime candidates are 0.694 μ (ruby), 0.9 μ (gallium arsenide), near infrared at 1.06 μ (neodymium glass and YAG--ytrrium aluminum garnet), or 0.53 μ (the second harmonic of the latter), all of which are immediately available. In making the choice, the factors of pulse repetition rate, availability of adequately sensitive detectors, and, of course, cost would all have to be carefully weighed.

Although at the moment indications are that a well-cooled ruby laser system* with a PRF of 1 to 10 pulses per second would provide the best compromise, a detailed systematic study would be a most valuable preliminary to building an advanced lidar system for plume studies.

● A study should be made of the feasibility of calibrating the lidar on an absolute basis so that the energy output (in joules) of each pulse were known. A completely calibrated lidar could furnish objective estimates of one of the attenuation solution parameters, M_o, the absolute particulate mass concentration in the clear air.

B. Data Handling and Reduction Capabilities

● Even at the present lidar firing rates, the large quantity of data collected is on the verge of becoming unmanageable. Each lidar observation is not just a point measurement, but a complete profile. Making full use of this information, particularly when using higher-PRF instruments, requires new and better ways of handling and processing lidar data.

---

*Recent tests with the SRI Mark V ruby system indicate that relatively modest improvements could permit it to be operated at a pulse rate comparable to that of the neodymium version, which could make this system an excellent interim solution.

• A big step in the right direction would be the development of an intensity-modulated range-height oscilloscope display of plume cross sections. This would be similar to the familiar radar RHI display, as simulated in Fig. 34, and would give an immediate, operationally useful photograph showing the plume shape and boundaries, as well as the internal relative concentration distribution in terms of varying degrees of brightness. For a more quantitative record, the video magnetic disk recorder would be used to take photos of the same cross section with

(Each line represents one lidar shot; trace intensity is a function of plume particulate concentration)

FIGURE 34   VISUALIZATION OF INTENSITY-MODULATED RANGE/HEIGHT
OSCILLOSCOPE DISPLAY OF PLUME CROSS SECTION
OBSERVED BY LIDAR

different oscilloscope intensity settings, giving a contour representation. Such a display would require that each lidar observation be corrected electronically for range and for equipment nonlinearities. These real-time analog techniques would greatly simplify the data-processing problem and reduce the number of digital computer analyses required.

• Since some of the lidar data will always need to be retained in quantitative form, an on-line analog-to-digital conversion and recording capability in the field would vastly facilitate later digital analyses.

75

C. Experimental and Analytical Techniques

● For better time continuity of the lidar plume observations, the limitations on duration of the observation periods, which were in effect during the experimental phase of this study, are undesirable and future arrangements should permit uninterrupted operations, if at all possible.

● Observations should also be obtained during the night hours, when lidar performance is optimum due to the low background illumination (noise) levels.

● Most of the effort in this study went into lidar data collection, processing, and analysis. More work is needed on the interpretation and use of plume cross sections in checking plume rise formulas, testing diffusion models, studying terrain effects, etc.

● In particular, a rationale is needed to deal with the effect of the background noise threshold in plume cross sections upon the testing of diffusion models using lidar data. This methodology could be similar to that developed by Gifford (1959) for use in diffusion estimates from smoke plume photography.

● Some provision for time averaging of the lidar data is required for use in testing diffusion models, which generally are designed to furnish one-half- to one-hour averages. This capability is especially needed for checking models for neutral and unstable conditions. It is possible that an analog means to do this can be devised using the previously discussed intensity-modulated range-height display.

● In future absolute concentration analyses, an attempt should be made to treat ξ_e, the ratio of the optical volume extinction coefficient to particle mass, as a variable with range.

D. Advanced Lidar Concepts

● There is great potential for exploiting the wavelength characteristics of laser energy in lidar applications for plume studies. Two possibilities warrant early investigation:

(1) The use of multiwavelength systems to determine
     absolute mass concentrations without independent
     information of the particle size distribution,
     and

(2) The extension of the multiwavelength differential
     absorption technique that has been applied to the
     determination of water-vapor (Schotland et al.,
     1962) to the evaluation of plume constituents.

In this connection the development of new types of lasers, such as the
tunable dye laser, holds great promise.

Appendix A

DESCRIPTION OF MARK V LIDAR

Appendix A

DESCRIPTION OF MARK V LIDAR

The optical system of the Mark V lidar is illustrated in Fig. A-1.
The transmitter consists of a Q-switched, air-cooled, pulsed ruby or
neodymium-doped glass laser with wavelengths at 6943 Å[*] (deep red) or
at 10,600 Å (near infrared), respectively. Since the angular resolution
of the lidar is determined by the transmitted beam divergence, 6-inch-
diameter collimating optics are used to reduce the laser beam divergence
and to produce an output beamwidth of 0.35 mrad. The corresponding
spatial resolution of this beam is 0.50 m at a range of 1 km in the
cross-beam direction, and about 2.3 m in range. The pulse repetition
rate of the Mark V lidar is primarily limited by the cooling rate of the
laser cavity. At present, the maximum firing rate is 3 to 4 pulses per
minute for the ruby laser, and 10 to 12 pulses per minute for the neo-
dymium. The characteristics of the Mark V lidar are summarized in Table
A-I.

The lidar receiver consists of a 6-inch-diameter Newtonian tele-
scope, identical to the transmitter optics. An adjustable field stop
at the focal plane limits the receiver field of view to a maximum of 6
mrad. A multilayered narrow-band filter with a wavelength interval
(bandwidth) of 13 Å (ruby) or 100 Å (neodymium) is inserted in the re-
ceiver optical path to reduce the output noise level produced by solar
radiation scattered into the receiver field of view. The detector con-
sists of an RCA 7265/S-20 photomultiplier tube for the ruby laser, and
an RCA 7102/S-1 for the neodymium system.

The major electronic components of the lidar and the data-recording
system are illustrated in the block diagram shown in Fig. A-2. A
compressed-air-driven turbine rotates the laser Q-switching prism at

Postdetection Filter Bandwidth (MHz)	30	30

500 revolutions per second. Upon receipt of a fire signal, the synchronizing generator triggers the flash lamp in step with a signal from the rotating prism. A capacitor bank charged to 3 kV supplies energy for the laser flash lamps. A photodiode senses the occurrence of the laser pulse and produces a trigger pulse to start the oscilloscope sweep. The output of the photomultiplier in the lidar receiver is fed to a pulse amplifier having a logarithmic transfer function, and then to an oscillo-scope. A Polaroid recording camera mounted on the oscilloscope photographs the lidar return signal. Other data-recording options available include the use of an automatic recording 35-mm camera and a magnetic disk video recorder. The latter device furnishes a steady display on the face of the oscilloscope immediately after each shot, as well as a permanent record, and is very useful for real-time monitoring of observations.

FIGURE A-2   ELECTRONICS SYSTEM OF MARK V LIDAR

Although the pulse-to-pulse variations of laser power output are not unduly severe, the presence of this random variation introduces a corresponding uncertainty in the amplitude of the received signal unless provision for monitoring the transmitter power is made. The Mark V lidar incorporates an optical feedback arrangement, using fiber-optic light guides, that samples the transmitted energy and injects it into the receiver optical path ahead of the narrow-band predetection filter (see Fig. A-1). This arrangement produces a pulse occurring at zero range on the receiver output. The pulse height is proportional to transmitted power. A variable neutral-density filter is inserted in the fiber-optic path to allow adjustment of the pulse height.

The use of a logarithmic video amplifier in the receiver is almost essential in order to compress the wide dynamic range of the detector (typically four or more orders of magnitude) to enable the received signal to be displayed on a single oscilloscope trace without loss of detailed information.

LIDAR DATA DIGITIZING AND CONDITIONING DETAILS

Appendix C

LIDAR DATA DIGITIZING AND CONDITIONING DETAILS

(by C. E. Brabant)

1. <u>Photographic Processing</u>

The lidar returns were recorded on Polaroid photographs and on magnetic disk tracks in analog form. These signals were then reproduced from the magnetic recordings and displayed repetitively on the screen of a standard laboratory oscilloscope (Tektronix Model 555). A photographic transparency on 35-mm film was made of each oscilloscope trace with an illuminated graticule superimposed on the background to provide reference axes for scaling the photograph. The time scales used in the photographic frames were 2 μs/cm (3-km range full scale), and when appropriate, 5 μs/cm (7.5-km range full scale). The vertical amplitude scale was set at 100 mV/cm.

2. <u>Graphical-to-Digital Conversion</u>

A Model 300 CALMA Co. digitizer was used to convert the optically enlarged photographic trace to numerical increments recorded on digital magnetic tape. The data on the photographs were automatically digitized when the cursor was manually traced over the image of the lidar return signal amplitude. Scaling was performed at the beginning of each digitizing-recording session and immediately preceding a change in scale whenever this occurred.

Engineering values in millivolts and microseconds were entered via the digitizer keyboard, as were all other special control characters. These were recorded on magnetic tape along with the records of the incremental digital values describing the X and Y Cartesian coordinates of the analog signal. These values were recorded for equal increments in time at a resolution of approximately 25 ns, corresponding to 3.8 m in range. The vertical scale resolution was 0.75 mV. General accuracy obtained in curve tracing is estimated to be no worse than one-half of

the trace width, which varied from approximately 10 to 20 mV, although it is possible that larger deviations from the curve occurred infrequently.

3. Transformation to Engineering Units and Conditioning

A standard CDC 6400 computer program developed by the CALMA Co. was used to recover the data, scaled in engineering units. Much of the data required special handling because of operator errors in entering control characters via the keyboard, foot-treadle, and console pushbuttons of the digitizer. This step produced the first intermediate digital magnetic tape and a control listing of the decimated data points. This listing also provided data for verifying the scaling factors used to convert incremental values into scaled engineering values.

A pair of special CDC 6400 computer programs were developed to select data between predetermined starting and ending ranges (travel time values for lidar return signals) at equally spaced intervals. Adequate spatial resolution was obtained by selecting every fifth point in the data record, yielding an increment of approximately 100 ns (15-m range) between selected sample points. The second program of the pair listed the entire output tape, point-by-point, as a check for subsequent processing.

PLAN VIEWS OF HORIZONTAL PLUME POSITIONS

FROM LIDAR OBSERVATIONS

To help clarify the plume cross sections from the October period
that are presented in Sec. V, plan views of horizontal plume positions
derived from these cross sections are shown on the following pages
(Figs. D-1 to D-9). By referring to these plan views, the elongation
in the cross sections caused by the lidar azimuth angle being nonper-
pendicular to the plume axis may be determined.

For those observation series where the azimuth angle was held constant and the plume structure observed as a function of time, the first cross section in the series is shown at the proper position, and subsequent cross sections are displaced slightly for graphic purposes to avoid superposition.

The horizontal plume boundaries interpolated between cross sections are indicated by dashed lines in the figures. It should be remembered that these illustrations show the total horizontal projection of the plume. At any given height, the plume would normally be narrower than this.

The cross section number and time (EDT) are shown beside each horizontal plume position.

LIDAR EYE-SAFETY CONSIDERATIONS

Appendix E

LIDAR EYE-SAFETY CONSIDERATIONS

Although often exaggerated, the question of safety in the use of experimental lidar systems should be carefully considered.

The series of observations described in this report were carried out with careful adherence to the safety procedures that have been developed and practiced by SRI teams over the last six years of field experiments. Some of the more important aspects of the safety question are described below.

The Mark V lidar pulse is harmless to the skin, but could cause eye damage in the form of a minute retinal lesion if the pulse were viewed directly. The lidar pulse takes the form of a cylinder of light, initially 15 cm in diameter and 6 m long, traveling through the atmosphere at the speed of light. Each pulse is only 0.00000002 s (0.02 μs) in duration, and the pulses occur approximately 5 s apart. The lidar is designed to totally prevent any emission of stray laser light from any direction other than that in which the unit is pointed.

Thus an eye hazard exists only at the exact instant of firing and only in the precise direction the lidar is aimed. The lidar is highly directional: the increase in diameter of the pulse with range (travel distance) is very slight--from 15 cm at the transmitter to 1.3 m at two miles range--so that the spatial extent of the hazard is confined to a very narrow cone. In this sense, the hazard from a lidar is directly analogous to that from a rifle or other firearm, except that the magnitude of the danger is considerably less for the lidar. This is because the pulse can only cause eye damage, and even then, only a partial (localized) loss of vision could result. Generally this loss would take the form of a blind spot ten times smaller than the natural one already present (and unnoticed) in every human eye at the location of the optic nerve.

Our standard general safety procedures for field experiments (which have proven worthy by use in many projects) are as follows:

(1) Mechanical stops are placed on the equipment to con-
fine the pointing angles to a specific field of view.

(2) Aiming and firing is accomplished manually by an
operator who uses an aiming telescope to monitor
the field of view, as well as a large surrounding
area. This operator is the only person who can
fire the lidar, and he does not trigger the unit
until he is sure the area is clear.

(3) A separate observer equipped with binoculars also
keeps the entire firing area under surveillance.
This observer is equipped with an override switch
to prevent firing of the lidar when any human
activity (airplane, ship, etc.) is sighted in the
firing area.

(4) When not being fired, the lidar is always rendered
completely safe by a switch which discharges the
capacitor bank furnishing high voltage to the laser
flash lamps. Without this high voltage supply, the
lidar cannot be fired.

(5) As an additional precaution, the stowage position
of the lidar is such that it is never pointed at
eye level.
