The ENVIRONMENTAL HEALTH SERIES of reports was established to report the results of scientific and engineering studies of man's environment: The community, whether urban, suburban, or rural, where he lives, works and plays; the air, water, and earth he uses and re-uses; and the wastes he produces and must dispose of in a way that preserves these natural resources. This SERIES of reports provides for professional users a central source of information on the intramural research activities of programs and Centers within the Public Health Service, and on their cooperative activities with state and local agencies, research institutions, and industrial organizations. The general subject area of each report is indicated by the two letters that appear in the publication number; the indicators are

- AP — Air Pollution
- AH — Arctic Health
- EE — Environmental Engineering
- FP — Food Protection
- OH — Occupational Health
- RH — Radiological Health
- WP — Water Supply and Pollution Control

Triplicate tear-out abstract cards are provided with reports in the SERIES to facilitate information retrieval. Space is provided on the cards for the user's accession number and additional key words.

Reports in the SERIES will be distributed to requesters, as supplies permit. Requests should be directed to the Center identified on the title page or to 5555 Ridge Avenue, Cincinnati, Ohio 45213.

ABSTRACT

Rates of emissions of polynuclear hydrocarbons were measured at several sources considered likely to produce such emissions. The sources included heat generation by combustion of coal, oil, and gas; refuse burning; industrial processes; and motor vehicles. The annual emissions of benzo(a)pyrene in the United States were estimated for each of the sources surveyed, to provide a rough gauge of the importance of each source. Small, inefficient residential coal-fired furnaces appear to be a prime source of polynuclear hydrocarbons; other sources may be of local importance. Production of polynuclear hydrocarbons was generally associated with conditions of incomplete combustion.

INTRODUCTION

Concern with the health effects of carcinogenic substances dates back at least to 1775, as reflected by the writings of Pott.¹ It was discerned that among persons employed as chimney sweeps in Europe the rate of skin cancer was higher than that of the general population. Since that time, considerable progress has been made in isolating and identifying individual compounds from many suspected cancer-causative agents such as soot and coal tar. The isolation of benzo(a)pyrene (3,4-benzpyrene) from coal tar in 1933² has particular significance. Although this compound has not been definitely identified as the etiological agent responsible for many of the so-called industrial cancers, laboratory experiments with animals have shown that it is one of the more biologically active organic compounds in the group termed "polynuclear hydrocarbons." The carcinogenic effects of benzo(a)pyrene on animals are well documented in the published literature.³⁻⁵ The biological activities of the other polynuclear hydrocarbons discussed have been reported. Some of these compounds are weakly carcinogenic; some are not carcinogenic; some may inhibit or accelerate the activity of benzo(a)pyrene.^{3,6}

Surveys by the Public Health Service

In the late 1950's, the U.S. Public Health Service, Division of Air Pollution, surveyed concentrations of polynuclear hydrocarbons in the atmosphere of 103 urban and 28 nonurban areas of the United States.^{7,8} The air in all of the 103 urban areas contained benzo(a)pyrene. Concentrations ranged from 0.11 to 61 micrograms per 1000 cubic meters of air, with a geometric mean concentration of 6.6. Concentrations in nonurban areas were much lower, ranging from 0.01 to 1.9 micrograms per 1000 cubic meters, with a geometric mean concentration of 0.4. The relatively large quantities found in the air of urban areas are logically attributed to the higher density of domestic, commercial, and industrial activities.

A very limited amount of published data is available, either on concentrations of polynuclear hydrocarbons in effluent streams from specific air pollution sources or on the atmospheric concentrations to be expected in the vicinity of such sources. Because of the need for information of this type, the U.S. Public Health Service inaugurated a program in 1960 to survey selected processes to evaluate emissions of polynuclear hydrocarbons. The main purpose of the survey was to "screen" processes likely to produce emissions of polynuclear hydrocarbons and thereby to indicate the probable origin of the polynuclear compounds contained in urban air. Individual studies, comprising portions of the over-all survey, have been reported for heat-generation and incineration processes,⁹⁻¹² industrial processes,¹³ and motor vehicles.¹⁴ This report compiles and summarizes the entire survey and presents some previously unpublished data on residential furnaces and petroleum catalytic-cracking catalyst regenerators.

Significance of the Data

A review of the published literature indicates that no definite atmospheric concentrations of polynuclear hydrocarbons constituting hazards to human health have been established. Therefore, no attempt is made herein to interpret the hygienic significance of the polynuclear hydrocarbon concentrations. The results are presented simply to indicate the relative importance of the processes studied as contributors of polynuclear hydrocarbons to the atmosphere.

SOURCES SURVEYED

The processes to be surveyed were selected from a list of probable potential sources of polynuclear hydrocarbon emissions. The categories of the sources tested are listed in Table 1.

Table 1. SOURCES SURVEYED FOR EMISSIONS OF POLYNUCLEAR HYDROCARBONS

Heat generation: coal, oil, and gas

Refuse burning: municipal and commercial incineration; open burning

Miscellaneous industrial processes:

Petroleum catalytic cracking – catalyst regeneration: FCC, TCC (air lift), TCC (bucket elevator), and Houdriflow

Asphalt air blowing

Asphalt hot-road-mix manufacture

Carbon-black manufacture

Steel and coke manufacture

Chemicals manufacture

Motor vehicle exhaust (gasoline): automobile; trucks

POLYNUCLEAR HYDROCARBON COMPOUNDS DETERMINED

The individual polynuclear hydrocarbons that were quantitatively analyzed are classified in Table 2 in two groups corresponding to the relative reliability of the analytical determinations. Because of interferences that occur during chemical analyses, values for the compounds in Group 2 are of lower quantitative reliability than those for Group 1.

Table 2. PROPERTIES OF POLYNUCLEAR HYDROCARBONS³

SAMPLE COLLECTION AND ANALYTICAL TECHNIQUES

Data were collected in three ways: by direct sampling of stationary sources, by atmospheric sampling near stationary sources for which direct sampling was not practical, and by sampling of exhaust from motor vehicles. The principal items of special equipment were the sample collection trains illustrated in Figures 1 and 2. These sampling trains, designed to minimize loss of condensed polynuclear hydrocarbons from volatilization, have been described in previous publications. 9, 13-15

Stationary Source Testing

In testing of stationary sources (Figure 1) the sample gas stream passes through a series of water bubblers kept at 32°F and then through a series of freeze-out traps immersed in a dry-ice alcohol bath, from which it exits at 0°F. Finally, the sample gas stream passes through a high-efficiency glass-fiber filter. Isokinetic sampling rates ranged from 2.1 to 6.0 standard cubic feet per minute (70°F, 1 atm), and all sources were sampled continuously over periods ranging from 80 minutes to 3 hours.

Figure 1 Polynuclear hydrocarbon sample train for stationary source testing.

Figure 2. Polynuclear hydrocarbon sample train for motor vehicle testing.

Atmospheric Testing

Some installations were not amenable to direct source testing (e.g., slot-type coke ovens). In addition, some processes are so complex that proper evaluation of emissions of polynuclear hydrocarbons would require the sampling of many related installations (e.g., chemical manufacture). In this survey, such processes were evaluated indirectly by collection of atmospheric samples in urban residential areas near the installations.

Atmospheric samples were collected with high-volume air samplers.¹⁶ Usually, air samplers were operated simultaneously at

three to five urban residential sites near each installation. All samplers were located at least 15 feet above ground level to minimize the possibility of sampling dust-laden air. Samplers were operated for periods of 1 to 3 days at flow rates ranging from 20 to 65 cubic feet per minute. Tests were conducted over an interval of 2 weeks.

Motor Vehicle Testing

Figure 2 is a diagram of the apparatus used in sampling exhausts from automobiles and trucks. Total exhaust is piped into an ice-chest condenser and then through a filter. Sample volumes ranged from 675 to 1120 standard cubic feet (70°F, 1 atm) of dry exhaust. Maximum instantaneous temperature at the filter ranged from 37° to 80°F for automobiles and from 40° to 60°F for trucks.

Analysis

All of the samples were analyzed by the same technique, which involved benzene extraction of the particulate matter, the condensate, and the rinse liquids. The benzene-soluble fraction of the samples was separated by column chromatography, and the analyses made by ultraviolet-visible spectrophotometry.^{17, 18}

The analytical scheme is believed to be accurate to within ± 20 percent for benzo(a)pyrene, not including possible variations attributable to sample collection and extraction. This degree of variation is consistent with the complexity of the analysis and the small amounts of material present in samples containing many similar compounds.

HEAT-GENERATION PROCESSES

Combustion units that burn conventional fuels were designated as heat-generation processes. Design and operation data for these units are given in Tables 3, 4, and 5. Data on emissions are summarized in Tables 6, 7, and 8.⁹⁻¹²

Coal-Burning Units

The largest units tested were coal-fired boilers with rated capacities ranging from 1,300,000 down to 70,500 pounds of steam per hour (Tables 3 and 4). The larger boilers in this range incorporated pulverized and cyclone firing and were used to generate electric power. The smaller boilers in this size range supplied steam for industrial process heating and electric power generation. Firing was accomplished with pulverized coal, chain grates, or spreader stokers. Smaller coal-burning units tested were rated by Btu input. Units in this group supplied steam for smaller industrial-process heating systems as well as

Rates of emission of polynuclear hydrocarbons from coal-burning units varied widely, depending on the quality of combustion achieved. The highest emission rates were found in small domestic furnaces used to heat single-family homes. For example, tests on hand-fired and underfeed stoker-fired domestic units, with essentially no combustion control, showed emissions ranging from 3800 to 3,300,000 micrograms of BaP* per million Btu gross heat input (Table 8). Intermediate-sized and large-sized units incorporating chain-grate stokers, spreader stokers, pulverized feed, and cyclone firing achieved better combustion and produced appreciably lower emissions of polynuclear compounds (17 to 370 micrograms of BaP per million Btu gross heat input) at normal operating conditions (Tables 6 and 7). Among the other large, fully instrumented, coal-fired steam power plants, the cyclone-fired unit, which burns crushed coal, showed the highest emission rate (76 to 370 micrograms of BaP per million Btu gross heat input).

In Figure 3, BaP emission rates are plotted against size of the coal-, oil-, and gas-fired units. Because of the many variables affecting the formation of this compound, a wide range of emissions can be

*Benzo(a)pyrene; abbreviations for other compounds are given in Table 2.

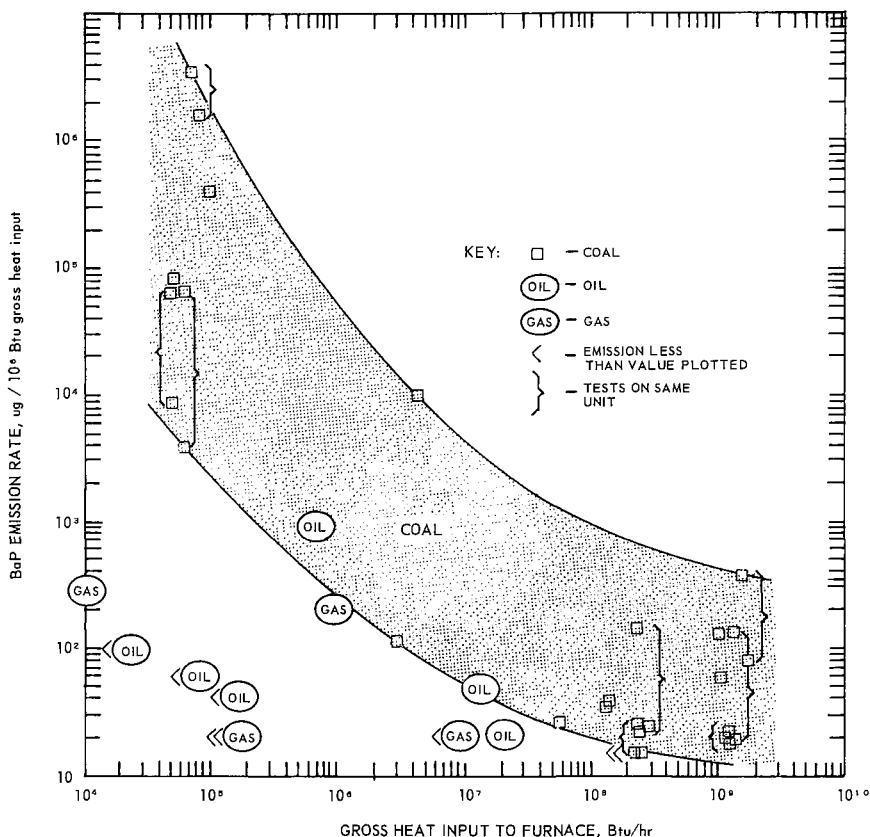

Figure 3. Range of benzo (a) pyrene emissions from coal, oil, and natural gas heat-generation processes.

expected from a given size of unit and the results do not lend themselves to a straight-line relationship. Emissions of BaP from units operating with relatively good combustion conditions would be expected to fall near the lower boundary of the range, whereas emissions from less efficient combustion processes would fall near the upper boundary. Although it is constructed with limited data from oil- and gas-burning sources, the plot in Figure 3 emphasizes that heavier emissions are to be expected from coal-burning units than from gas- or oil-fired units of comparable sizes.

The lower emission rates from the large coal-fired units can be attributed to the more efficient combustion of fuel attainable with closely regulated air-fuel ratios and uniformly high combustion-chamber temperatures.

Among the seven polynuclear hydrocarbons for which the analytical technique was most reliable, pyrene, BaP, and benzo(e)pyrene were detected in all coal-fired units tested (see Tables 6 through 8). In all

but two tests, the ratio of pyrene to BaP was greater than 1, varying from 0.6 to 23. Ratios of BaP to benzo(ghi)perylene ranged from 0.9 to 6.6 except for one power plant for which the ratio was 0.13. Ratios of BaP to coronene ranged from 1.0 to 94. Average ratios for the residential coal-fired furnaces are as follows: P/BaP, 2.6; BaP/BghiP, 1.7; BaP/Cor, 19. These results tend to confirm the data reported by Sawicki¹⁹ regarding the ratios of these compounds in particulate samples collected from the atmosphere. Sawicki states that particulate pollution from coal-burning sources (as opposed to auto exhaust) might be characterized by ratios of BaP to benzo(ghi)perylene greater than 0.6 and ratios of BaP to coronene greater than 1. He further suggests that the ratio of pyrene to BaP might indicate the "age" of the particulate pollution, since pyrene is less stable in the atmosphere than is BaP and tends more to be lost by volatilization. This interpretation is substantiated by the finding that ratios of pyrene to BaP in particulate matter collected from the atmosphere in cities throughout the United States were less than 1 in most cases reported.⁸

Comparison of polynuclear hydrocarbon emissions with other products of incomplete combustion indicates that polynuclear emission rates are generally high when carbon monoxide and total gaseous hydrocarbons are high.⁹

Oil-Burning Units

The capacities of the oil-burning units tested ranged from 0.09 to 30 million Btu per hour gross heat input (Table 4). The largest of these boilers produced steam for process heating and was fired by steam-atomizing burners. The smaller units (up to 4.2 million Btu/hr, heat input) produced hot water and hot air for institutional and home-heating uses; most of these units were fired by air-atomizing and pressure-atomizing burners.

Polynuclear hydrocarbon emissions from oil-burning sources were generally much lower than from coal-burning sources of equivalent size (Table 7). Detectable BaP concentrations were found in only two of the six oil-burning units tested, but pyrene was present in all sources. Ratios of pyrene to BaP for the two BaP-emitting units averaged 6.6. Ratios of BaP to benzo(ghi)perylene were >2 and 3.0, and ratios of BaP to coronene were 0.4 and >5. The highest BaP emission rate from oil-burning occurred in a unit with an air-atomizing burner.

Low BaP emissions from liquid-petroleum-fired units have also been reported by Howe.²⁰ In a study of household-sized units (12,000 to 250,000 Btu per hour) and small industrial-sized units (6,000 pounds of steam per hour), no BaP was detected in the samples collected. Two of the small household-size units produced smoke during testing.

Gas-Burning Units

The gas-burning units tested ranged in capacity from 0.025 to 7.2 million Btu per hour gross heat input (Table 4). The larger units provided steam for process and institutional heating; the smaller units (0.21 million Btu per hour gross heat input and below) provided hot water and hot air for single-family home heating.

Polynuclear hydrocarbon emissions from gas-fired units were generally lower than from coal-fired units and were about the same as emissions from oil-fired units (Table 7). For three of the five gas-fired sources the only compound of consequence was pyrene. Two gas-fired sources (Samples ISS-9 and ISS-47) produced more polynuclear hydrocarbons than the others, apparently because of improper adjustment of the air-fuel ratio as evidenced by high concentrations of CO and total gaseous hydrocarbons. The ratio of pyrene to BaP for these sources averaged 75. The ratios of BaP to benzo(ghi)perylene and BaP to coronene averaged 0.1 and 0.2, respectively; these values contrast with the higher ratios obtained in tests of coal-fired units and are more similar to the lower ratios for auto exhaust. ¹⁹

REFUSE BURNING

Incinerators

Waste materials burned during the incinerator tests were typical of present-day municipal and commercial wastes collected from households, grocery stores, and restaurants. Municipal units included a continuous-feed 250-ton-per-day furnace and a batch-charged 50-ton-per-day furnace equipped with water spray scrubbers. Commercial incinerators included a 5.3-ton-per-day unit and a 3-ton-per-day unit equipped with an auxiliary gas burner. (See Table 9).

Polynuclear hydrocarbon emissions produced by municipal and commercial incinerators are summarized in Tables 10 and 11. BaP and benzo(e)pyrene, both of which have demonstrated carcinogenic qualities, were detected in the flue gases from every incinerator tested. The concentrations of pyrene from each unit were higher than those of any of the other polynuclear hydrocarbon compounds detected, and ratios of pyrene to BaP ranged from 6.0 to 120. Ratios of BaP to benzo(ghi)perylene ranged from 0.3 to more than 2, and ratios of BaP to coronene ranged from 0.3 to 2.5. Following the pattern of the coal-fired sources, the small-sized commercial incinerators with relatively poor combustion emitted more polynuclear hydrocarbons than the intermediate- and large-sized municipal units. The largest municipal unit, operating at relatively constant temperatures above 1600°F and with longer gas retention times in the high-temperature zone, produced the least of these compounds in terms of emissions per pound of refuse charged. In additional tests run with less underfire air (50 and 20 percent versus 80 percent) this low emission rate was reduced only slightly.

^bAdditional filter used before the bubblers in the sampling train as shown in Figure 1 for tests 40 through 44).

A water-spray scrubber used to control fly ash from the smaller municipal unit proved highly effective in reducing the level of polynuclear hydrocarbons emitted to the atmosphere. Emissions of BaP, for example, were reduced 98 percent by use of the scrubber. Additional tests with a combination of lower-than-normal underfire air (19 percent versus 50 to 60 percent) and higher excess air (220 percent versus 108 percent) also reduced emissions at a rate equivalent to that obtained with the scrubber.

Open-Burning Sources

Emissions from open fires were evaluated by two different methods: on-site sampling and sampling at a special test facility. In on-site sampling a high-volume air sampler attached to the end of an 8-by-10-inch duct collected particulate samples on MSA 1106-BH glass-fiber filters. The open end of the duct was positioned in the smoke plume. Separate samples were taken from the open burning of municipal refuse, automobile tires, grass and tree branches, and automobile bodies. Refuse burning rates and combustion gas flow rates were not obtained during these tests because of the difficulty of making such measurements in the field. Hence, results can be compared only on the basis of the amounts of polynuclear hydrocarbons in the particulate matter collected. Table 11 summarizes the results.

The facility designed specifically for research on open fires was made available by the Air Pollution Research Center of the University of California at Riverside. This facility consists of a "burning table" with an inverted conical hood suspended above it to collect and funnel the combustion products into a stack. Instrumentation allowed the measurement of flue-gas flow, weight of fuel remaining, and temperature, and the analysis of gases. Quantitative emissions were determined for the open burning of municipal refuse, grass and tree branches, and automobile components. Results are given in Tables 10 and 11.

The comparatively high emissions of polynuclear hydrocarbons from open burning, especially of automobile components, is consistent with the general pattern that has developed for other combustion processes; i.e., the inadequate combustion conditions typical of uncontrolled burning processes consistently produce the highest levels of these compounds. Ratios of pyrene to BaP ranged from 1.2 to 2.6, BaP to benzo(ghi)perylene from 1.7 to >20, and BaP to coronene from 6.6 to >60. These ratios are similar to those for residential coal furnaces.

INDUSTRIAL PROCESSES: DIRECT SAMPLING

Petroleum Catalytic Cracking -- Catalyst Regeneration

Concentrations of polynuclear hydrocarbons in the waste gases of catalyst regenerators were measured for each of the major types of petroleum catalytic cracking units: Fluid catalytic crackers (FCC);

Thermoform catalytic crackers (TCC), both air lift and bucket elevator catalyst carriers; and a Houdrifiow catalytic cracker (HCC).

The objective of catalytic cracking is to upgrade heavier petroleum fractions by breaking up long-chain hydrocarbons to obtain high-octane gasoline and distillate fuels. The most common feed-stock is the gas-oil fraction obtained from the crude distillate unit.

Although the catalytic cracking units surveyed may differ somewhat in equipment, geometry, and actual operation, the cracked products and basic chronology of the process are the same. Preheated gas-oil and silica-alumina type catalyst are charged into a reactor maintained at about 900°F and 15 psig. The cracked products are separated by fractionation and further processed. The spent catalyst, laden with coke, is rejuvenated in a catalyst regenerator kiln. Here the coke is burned off the catalyst at temperatures near 1000°F and pressures ranging from 2 to 20 psig, depending on the type of unit; the catalyst is recycled to the reactor. The regenerator flue gases, high in carbon monoxide and unburned hydrocarbons, are then exited directly to the atmosphere or to a carbon monoxide waste heat boiler. Typical flow diagrams of the units tested are given in Figures 4, 5, and 6. Table 12 summarizes the operational data.

The emission rates measured are presented in Table 13. High concentrations were present in the regenerator waste gases from the HCC and TCC air-lift units. Emissions of BaP, pyrene, benzo(e)pyrene, and benzo(ghi)perylene were especially high. The average BaP emission rates for the HCC and TCC air-lift units were 218,000 and 90,000 micrograms per barrel of oil charged. By comparison, the highest BaP emission rates from TCC bucket elevator and FCC units were 31 and 460 micrograms per barrel of oil charged. These large variations in emission rates cannot be explained by analysis of data from the small number of tests performed in this screening program.

Concentration ratios for the high-emission units are as follows:

<u>Unit</u>	<u>P/BaP</u>	<u>BaP/BghiP</u>	<u>BaP/Cor</u>
HCC	0.58	0.65	15
TCC, air lift	1.1-4.3	1.7-1.2	

The HCC and FCC units incorporated CO waste heat boilers to effect complete combustion of the regenerator flue gases. The CO boilers, providing combustion with auxiliary fuels or a catalyst, greatly reduced emissions of carbon monoxide and total gaseous hydrocarbons. In addition, all the polynuclear hydrocarbons detected in the HCC regenerator waste gases, including BaP, underwent more than 99 percent reduction upon passage through the CO boiler. BaP emissions were reduced from 218,000 to 45 micrograms per barrel of oil charged. The CO boilers on the FCC units further reduced the low emissions.

The TCC air-lift units were equipped with plume burners. The plume burner is a secondary stage of combustion built into the regenerator kiln. This type of burner has successfully increased the clarity of plumes from regenerator waste gases; however, compared to a CO waste heat boiler, the plume burner is ineffective as a control device for reducing emissions of polynuclear hydrocarbons, total gaseous hydrocarbons, and carbon monoxide.

In 1964, CO boilers in the United States burned regenerator gases from 65 percent of the total HCC capacity and 31 percent of the total

air-lift TCC capacity. Fifty-one of a total of approximately 113 FCC units are equipped with CO boilers. The use of plume burners on air-lift TCC units amounted to 45 percent of total capacity.

Asphalt Air-Blowing Process

The asphalt plant surveyed processed about 140,000 gallons of asphalt per day (24 tons per hour). The air-blowing operation involved charging 10 enclosed reactors of 5,000- and 10,000-gallon capacity each with petroleum-base asphalt; the material was then heated externally by gas burners and maintained at temperatures ranging from 430 to 500°F. Air then was bubbled through the hot asphalt continuously for periods ranging from 8 to 16 hours. The partially oxidized end products, more viscous and less resilient than ordinary asphalt, are termed either flexible coating, linoleum saturate, or shingle material. A summary of the polynuclear hydrocarbon emissions and a flow sheet of the asphalt-blowing process are given in Figure 7.

The gaseous emissions from the 10 reactors in operation were vented to the atmosphere through a system consisting of a common duct, oil knock-out tanks, and a stack. The individual reactors are charged on a rotating schedule; hence, the gases vented to atmosphere at any given time represent materials emitted at different stages of the air-blowing process.

The lower section of the stack was equipped with a steam spray-baffle arrangement. Pyrene was detected in large quantities in samples collected at the inlet and outlet sides of this baffle arrangement. The pyrene emission rate at the inlet was 3.5 grams per ton of material processed. Anthracene was present in smaller quantities. Phenanthrene and fluoranthene were detected in trace amounts. BaP, if present, was not detected because of interferences from unknown compounds. On the basis of the threshold concentration for this analysis, the BaP concentration in the gases would be at most 10 milligrams per ton of processed material. At this concentration, the daily contribution of BaP from this asphalt-blowing source would be less than that from two hand-stoked residential coal furnaces. By comparison, an equivalent emission of pyrene would require 250 hand-stoked furnaces (see Table 8).

Simultaneous with collection of the source samples, atmospheric concentrations of polynuclear hydrocarbons were measured in the immediate plant vicinity. For this purpose, high-volume air samplers were situated 1/4 to 1/2 mile from the plant in five residential areas of the city. Benzene extracts from the collected atmospheric samples (July 1962) were composited for a single analysis. BaP from this analysis measured 0.42 microgram per 1000 cubic meters air. This concentration is considerably lower than the 3.9 micrograms per 1000 cubic meters (July 1958) reported previously⁷ for the downtown area of the same city.

Not Detected: Benzo(e)pyrene, perylene, benzo(ghi)-perylene, anthanthrene and coronene

Figure 7. Flow sheet of effluent gases from asphalt air-blowing process-batch operation.

Thus, both the source samples and the air samples indicate that polynuclear hydrocarbons larger than pyrene are not volatilized to any significant extent by the air-blowing process. This process does not appear to emit significant amounts of BaP or other polynuclear hydrocarbons of equal or greater molecular weight. One other point of significance is that Sawicki²² has found that the samples contain large quantities of alkyl-type polynuclear hydrocarbons (the analytical technique did not permit the determination of specific compounds of this type). Alkyl polynuclear hydrocarbons such as 9,10-dimethyl anthracene and 1,2,4-trimethyl phenanthrene have been shown to be carcinogenic in studies with animals.^{4,5} Because of the nature of the asphalt air-blowing process, one would also expect the presence of oxygenated hydrocarbons. Epstein²³ has shown that the oxygenated fraction of the benzene extract from atmospheric particulate samples produces skin cancers on mice.

In summary, asphalt air blowing does not appear to be an important source of BaP. The source surveyed did emit large quantities of unidentified alkyl polynuclear hydrocarbons. Future identification of these alkyl compounds, and determination of oxygenated polynuclear hydrocarbons or the absence thereof, should define more precisely the importance of asphalt air blowing as a source of carcinogenic compounds.

Asphalt Hot-Road-Mix Plant

An asphalt hot-road-mix plant with a capacity of 3 tons per batch was tested for polynuclear hydrocarbon emissions by direct measurements. The plant was operating at a rate of 133 tons of finished mix per hour. A typical weighed 3-ton batch consisted of 6 percent asphalt and 94 percent sand and crushed stone. The mixture of sand and crushed stone was dried and charged to a mixer at 400°F. Asphalt at 250°F was then added to the mixer, and the materials were blended for 1 minute or less before being discharged to waiting trucks. A flow sheet of the process and a summary of emissions during the test are given in Figure 8.

Effluent gases from both the mixer and the rotary drier (45, 000, 000 Btu per hour) were passed in sequence through a cyclone and a water spray tower to remove process contaminants. Samples were collected simultaneously before and after passage through the spray tower. Duplicate samples were taken at each sampling location and combined for one analysis at each location.

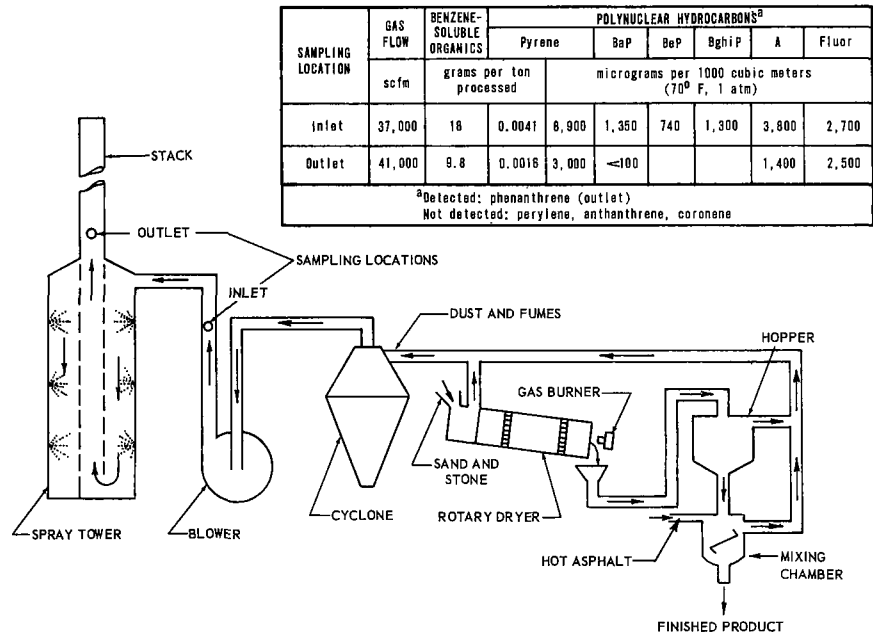

Figure 8. Flow sheet of effluent gases from asphalt hot-road mix process—batch operation.

Nearly all the emissions reported from this hot-road-mix plant are attributed to combustion gases emitted from the rotary dryer and not to effluent gases from the mixing chamber. This is evidenced by the results for a sample of the suspended particulates collected

directly from the mixing chamber. Of the 10 polynuclear hydrocarbons under consideration only anthracene was qualitatively identified. In the sample collected from the gas stream prior to the spray tower, however, six polynuclear hydrocarbons, including BaP, were detected. At this sampling location, the gas stream consisted of flue gases from the dryer and effluent gases from the mixing chamber.

Concentrations of the Group 1 polynuclear hydrocarbons are reduced considerably by the scrubbing effect in the spray tower. For example, the BaP concentration was reduced from 630 micrograms per ton of processed material to less than 50 micrograms per ton.

Because of the low inlet concentrations and the ease with which pollutants are removed, the asphalt hot-road-mix process does not appear to be a potentially important contributor of polynuclear hydrocarbon emissions to the atmosphere.

INDUSTRIAL PROCESSES: ATMOSPHERIC SAMPLING

The remaining industrial processes were evaluated by collection of atmospheric samples in urban residential areas in the vicinity of the installation. General atmospheric samples do not, of course, indicate anything about the relative distribution in the atmosphere, e.g., high concentrations that may exist only a few feet from a source having relatively small total emissions. For example, in one case reported by Sawicki, et al.,²⁴ BaP concentrations as high as 78,000 micrograms per 1000 cubic meters of air were found a few feet downwind from a sidewalk tarring operation in which coal tar pitch was being used.

Carbon-Black Manufacturing

Samples of suspended particulates were collected at several urban residential sites in the vicinity of carbon-black manufacturing plants. The sites were located 1 to 3 miles from two adjacent carbon-black plants. Figure 9 (City A) shows the general location of sampling sites.

Carbon black was manufactured primarily from incomplete combustion of natural gas by both the furnace and channel processes. Some residual oil was burned intermittently with natural gas in the furnace process. One plant used both the furnace and channel methods whereas the other used only the furnace method. At the time of testing, one plant operated 360 burner houses for channel black and 2 production-size units for furnace black. The other plant operated five production-size furnace units.

The degree of carbon-black buildup on the filters varied from heavy loadings when the sampling sites were fumigated by the carbon-

black plume to light loadings at other times. All samples showed the presence of carbon black.

Concentrations of polynuclear hydrocarbons in atmospheric particulate samples collected in winter and summer are summarized in Tables 14 and 15. In Figure 10 the BaP concentrations near the three processes investigated indirectly are compared with the average winter and the average summer concentrations for a number of cities. These comparisons can be used very generally to determine the BaP emission potential of the three processes surveyed.

The winter BaP concentration in City A was well below the arithmetic mean winter concentration calculated from previously reported

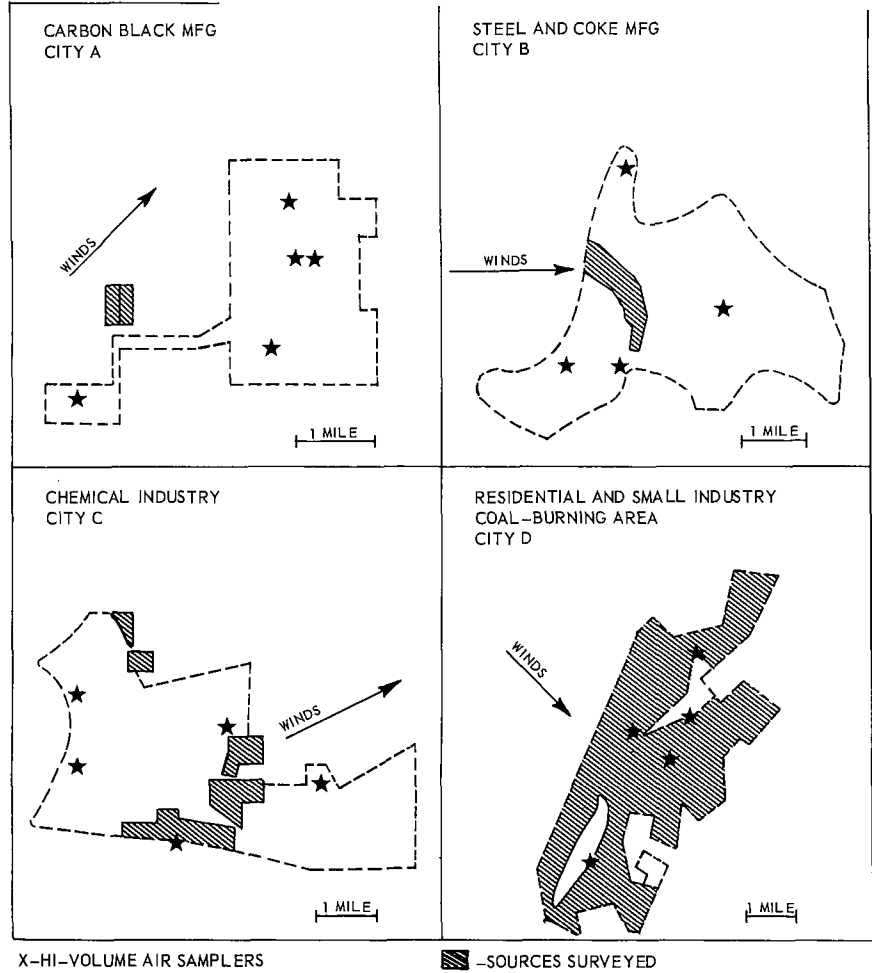

Figure 9. Maps of cities and sources included in the atmospheric survey.

data⁷ for 102 United States cities (Figure 9). In fact, the BaP concentration of 0.58 microgram per 1000 cubic meters air in City A would be the fourth lowest concentration if it were included in this 102-city survey. On the basis of micrograms of BaP per gram suspended particulate, the concentrations in City A would rank eighth lowest.

Table 14. SUMMARY OF CONCENTRATIONS (BY VOLUME) OBTAINED IN ATMOSPHERIC SAMPLING NEAR AIR POLLUTION SOURCES
(micrograms per 1000 cubic meters of air)^a

Air pollution source		Carbon black		Steel and coke	Chemical

	Phenanthrene				
	Fluoranthene	0.43	0.07	3.2	0.30

^aA blank indicates that the compound was not detected in the sample.

Carbon-black manufacture does not appear to be an important source of polynuclear hydrocarbon emissions for the following reasons: (1) the industry is relatively small; (2) although 87 percent of the carbon black in 1961 was manufactured by the furnace process, only 20 percent of the furnace black was classified as either "semi-reinforcing" or "high modulus" furnace black, the classes shown by Falk, et al, 26, 27 to contain the most polynuclear hydrocarbons; (3) low BaP concentrations were detected in the vicinity of the furnace-black plant tested. These results might be expected since published data by Lindsey, et al, 28 show no detectable BaP in a carbon-black sample of American origin manufactured for industrial use. Other data reported by Lindsey, et al, 29 show BaP concentrations as high as 1 percent by weight in two carbon-black samples of European origin.

Other previously reported studies also appear to support the conclusion that carbon-black manufacture is not an important source. Nau,

et al, 30, 33 showed that whole carbon black manufactured by the channel and furnace processes in the United States produces no appreciable carcinogenic effect on animals. Ingalls³⁴ concluded from a statistical study that the carbon-black worker faces no more than the ordinary risks of cancer encountered by other groups of the male working population.

Table 15. SUMMARY OF CONCENTRATIONS (BY WEIGHT) OBTAINED IN ATMOSPHERIC SAMPLING NEAR AIR POLLUTION SOURCES

Steel and Coke Manufacturing

Samples of atmospheric suspended particulate were collected at four urban residential sampling sites in the vicinity of an integrated steel and coke manufacturing plant. Sampling sites were located 1/4 to 1-1/2 miles from the source in City B. Figure 9 shows the general location of the sampling sites.

Air pollutants from the steel and coke processes come primarily from two sources: (1) slot-type coke ovens and (2) oxygen-lanced open-hearth furnaces. During the test period the coke ovens, with an average capacity of 18 tons per charge, were operated at the rate of 383 oven charges per day. Meanwhile 11 of the 14 oxygen-lanced open-hearth furnaces (420 ton average size) were in operation. The open-hearth furnaces did not utilize control equipment to reduce dust emissions.

The BaP concentration during the spring test period in City B approximates the average winter concentration of 102 United States cities (Figure 10). Since samples were collected during the spring

season, the contribution from the periodic use of residential coal furnaces would be included in the measured result. Residential-size coal furnaces, as previously mentioned, are important sources of BaP emissions.

Figure 10. Comparison of atmospheric benzo (a) pyrene concentration in the United States.

The relative contribution of polynuclear hydrocarbons from the coking operations and the steel operations in City B cannot be ascertained by atmospheric sampling. No data were found in the published literature on polynuclear hydrocarbon emissions from steel manufacturing, but BaP concentrations ranging from 120 to 1700 micrograms per gram particulate have been reported by Yanysheva³⁵ in discharge gases from coke ovens in the U. S. S. R. These samples were aspirated from the upper areas of the coke oven.

Slot-type coke ovens are normally equipped with a chemical recovery system, and polynuclear hydrocarbon emissions result mainly from gas leakage. Therefore, even though high BaP concentrations have been reported in the particulates from coke ovens, the use of chemical recovery systems on the coke ovens operating in City B unquestionably restricted emissions of BaP to the atmosphere.

Higher polynuclear hydrocarbon emissions would be expected from the now-obsolete beehive coke ovens. Since production by this method amounted to only 6 percent of the total United States coke production in 1960,³⁶ no attempt was made to sample a beehive oven.

Chemical Manufacturing Complex

Atmospheric suspended particulate samples were collected at five urban residential sampling sites within a chemical industry complex in City C (Figure 9). This chemical complex produces graphite products, metallurgical products, inorganic acids and alkalies, and many organic compounds including organic polymers.

Concentrations of polynuclear hydrocarbons in the atmospheric particulate samples, which were taken during the summer, are summarized in Tables 14 and 15. The BaP concentrations on a volume basis and on a weight basis are only 80 percent and 70 percent higher, respectively, than the average summer concentrations⁷ for nine larger United States cities (population greater than 150,000). On this basis, benzo(a)pyrene emissions to the atmosphere from such a chemical industry complex do not appear to be unusually high.

MOTOR VEHICLES

Eight automobiles and four trucks, representing two popular vehicle makes, were tested. To avoid obscuration of any relationship between emissions and the combined effects of age and mileage, automobiles of a given make were selected with the same type of engine: vehicles of Make A were powered by in-line 6-cylinder engines; those of Make B, by V-8 engines. All trucks tested were powered by in-line 6-cylinder engines. All automobiles were equipped with automatic transmissions and all trucks with standard transmissions. This choice was a compromise in the attempt both to represent typical usage and to exclude the influence of transmission type in comparisons of emissions from individual passenger cars and individual trucks. Each vehicle was carefully checked to ascertain that the mileage on the odometer was correct and that no major engine work had been done. Vehicle statistics and operating data are given in Table 16.

After a brief warmup to give a "hot start," all vehicles traversed the same 11.8-mile route, which consists of a realistic composite of business, arterial, and rapid-transit driving. Average run times were 31.9 and 34.4 minutes for the automobiles and trucks, respectively, at average speeds of 22.2 and 20.6 mph. Trucks were loaded with barrels of water to a weight representing 50 percent of rated payload capacity. All vehicles burned the same regular-grade fuel having medium aromatic content of 25 percent.

Emission data for polynuclear hydrocarbons are given in Table 17. The average BaP emission for the eight automobiles tested equals 11 micrograms per vehicle mile traveled. The average emission rate for Make-B automobiles (V-8 engines) was 14 micrograms per mile; the average rate for Make-A automobiles (6-cylinder engines) was 8.6 (see Table 17). The higher total emissions for Make B are expected in view of the larger engine displacements, but the average emission rate is also higher on the basis of micrograms of BaP per gallon of fuel. In

view of the limited quantity of data and the possibility of a strongly skewed distribution of emission rates with mileage, the nonparametric outside-count and sign tests were applied to the data to determine whether the BaP emissions from Make A were statistically different from those from Make B. ³⁷ These tests indicate no difference at the 10 percent level of significance.

A large jump in BaP emission rates at about 50,000 miles (1957 model or older) was observed for both makes of automobiles. Emissions averaged 28 micrograms per mile, whereas the average for the newer, lower-mileage automobiles was 5.5. A clear trend is not discernible at lower mileages. These values may indicate that at some stage in engine life changes occur that cause higher emissions. The character of the emissions for the two high-mileage automobiles is anomalous in one respect. For Make A, both the BaP and total benzene-soluble organic emissions were high (Table 17); but for Make B, the BaP emission was high although the benzene-soluble organic emission was not high.

BaP emissions from trucks averaged more than 40 micrograms per mile. The average rate for the Make-B trucks is probably low because total mileages were relatively low on both trucks.

^aMicrograms per gram of benzene-soluble organics.^bMicrograms per gallon of fuel input.^cMicrograms per 1000 cubic meters of dry exhaust at 68°F and 1 atmosphere.^dCompound not detected in sample.^eInterference prevented determination.^fEstimate based on average of pyrene to BaP ratios for tests 57, 58, and 59.

Nearly every sample contained all of the polynuclear hydrocarbons for which analyses are reported, and the emission trends in general followed those reported for BaP. In addition, the compounds benz(a)-anthracene and chrysene were detected. Pyrene was present in the greatest quantities; the average ratios of pyrene to BaP were 9.4 and 12.5 for the Make-A and Make-B automobiles and more than 90 and 48 for Make-A and Make-B trucks, respectively. Ratios of BaP to benzo(ghi)perylene and BaP to coronene averaged approximately 0.2 and 0.6 for both makes of automobiles. These values are consistent with ratios reported earlier by Sawicki:⁸ BaP to benzo(ghi)perylene, less than 0.6; and BaP to coronene, less than 1.0.

Two sets of preliminary tests yielded less substantial, but still comparable data. The first series of measurements was designed to determine which modes of operation of an automobile produced the greatest quantities of polynuclear hydrocarbons. A portion of the exhaust gas was sampled from an automobile having a 6-cylinder engine, mounted on a chassis dynamometer. Tests were made at constant-speed conditions of 20-mph cruise, 40-mph cruise, 20-mph deceleration, 40-mph deceleration, idle, and 20-mph acceleration. On the basis of micrograms per vehicle-mile, the 20-mph acceleration produced the highest BaP emission rate, 14 micrograms per mile.

The second series of preliminary measurements consisted of road tests similar to those described earlier. Total exhaust flow was sampled from three automobiles: two with V-8 engines (283 cubic inches, 5600 miles and 292 cubic inches, 32,000 miles). Emissions of BaP ranged from an average of 5.3 micrograms per mile for the V-8 engines to 77 micrograms per mile for the 6-cylinder engine.

Larsen³⁸ reports an estimated BaP emission rate of 49 micrograms per mile* determined by simultaneous particulate sampling and measurements of ventilation air flow and traffic flow in the Sumner Tunnel in Boston.

Begeman³⁹ reports a BaP emission rate of 9.6 micrograms per minute from a dynamometer-mounted V-8, 364-cubic-inch gasoline engine operated on a simulated city-driving cycle. At the average cycle speed of 23 miles per hour,³⁹ the reported emission rate equals 25 micrograms per mile. Samples taken over successive mileage intervals showed the possibility of increasing BaP emissions.^{39, 40, 41}

Mileage Interval		BaP Emission Rate,	
		$\mu\text{g}/\text{min}$	$\mu\text{g}/\text{mile}^{\text{a}}$
8,000	12,000	9.6	25 ^b
19,300	25,500	6.2	16
25,500	29,000	9.0	24
29,000	33,000	27 ^c	74 ^c

^a Calculation based on 23-mph average cycle speed.

^b Takes into account high BaP content of condenser collected tar.

^c Malfunction of engine reported reference 40.

*Corrected value; emission rates for polynuclear hydrocarbons as given in this reference are in error by a factor of 10.

The higher aromatic content of the gasoline used in Begeman's tests (36 percent versus 25 percent aromatic by fluorescence indicator analysis) may have contributed to the slightly higher emission rates.

More recently, Hoffman ⁶ reported BaP emission rates at two levels of oil consumption for the same dynamometer-mounted V-8 engine. BaP emission rates equivalent to 19 and 250 micrograms per mile were determined for oil consumptions of 1 quart per 1600 miles and 1 quart per 200 miles, respectively. The 13 times greater emission for the high-oil-consumption test suggests a partial explanation of the high BaP emission rates for the older, higher-mileage vehicles.

SUMMARY AND CONCLUSIONS

A screening survey of likely sources of emissions of BaP and other polynuclear hydrocarbons has produced some semi-quantitative data on possible major contributors of these compounds to the atmosphere. The sources were evaluated either by direct sampling of the effluent gases from the process or by atmospheric samples taken in residential areas in the vicinity of the process. The survey was not intended to establish statistically sound average emissions for every source category; such a study would have required many times the effort and funds expended. Enough emission data are available, however, to reveal the probable major sources, when annual consumption or production figures are considered. Table 18 is presented for this purpose. In interpreting the significance of this information, one should keep in mind that the calculation of total emissions involved considerable estimating and a number of assumptions, with respect to both emission rates and annual consumption or production figures. Also, the aggregate emissions from a number of small sources not considered in this study, although probably small, cannot be calculated.

The sources were classified in four major categories: heat generation, refuse burning, industrial processes, motor vehicles. This study has revealed that each category must be considered a factor affecting the atmospheric loading of BaP. Generally, the importance of a particular category or source has been evaluated in terms of the United States as a whole, but the importance of a particular source relative to concentrations found in the atmosphere undoubtedly varies considerably with locality; e.g., no coal is burned in Los Angeles County, but that city has areas of exceptionally high traffic density. Other factors may also influence the concentrations of BaP and other polynuclear hydrocarbons found in the atmosphere, e.g., decomposition or reaction with smog constituents in the atmosphere.

Heat Generation

Although each process surveyed undoubtedly contributes to the atmospheric loading of BaP, the most important source of BaP is the inefficient combustion of coal, typified by residential and small indus-

trial coal-fired furnaces. BaP concentrations were determined during the winter and summer in a city in which the number of residential and small-industry coal-burning units was unusually high (Figure 9, City D). In Figure 10 these concentrations are compared with averages for United States cities and with the concentrations measured in the vicinity of processes surveyed by atmospheric sampling. This figure shows that

the atmospheric concentration during the winter for City D is considerably higher than the other concentrations shown.

The efficient combustion of coal in modern industrial process heating boilers and power plants and the combustion of fuel oil and natural gas do not appear to be significant contributors.

Replacement of inefficient coal-fired furnaces would greatly reduce emissions attributable to heat-generation.

Refuse Burning

In refuse burning, as in coal burning, efficiency of combustion governs the emission of polynuclear compounds. Inefficient combustion in small incinerators and open burning results in considerable formation of BaP and other polynuclear hydrocarbons, whereas good combustion in municipal incinerators leads to very little BaP formation.

The burning of all refuse, especially that which has a high ratio of hydrogen to carbon, in modern municipal incinerators or disposal by noncombustion methods would almost eliminate emissions attributable to refuse burning.

Industrial Processes

Results from direct and indirect sampling of industrial sources, although not conclusive, indicate that the following are not major sources of BaP: (1) an asphalt air-blowing process (pyrene emissions were high), (2) an asphalt hot-road-mix plant, (3) a carbon-black manufacturing area, (4) a steel and coke manufacturing area, and (5) a chemical industry complex.

Direct samples of the effluent from the catalyst regenerators of petroleum catalytic cracking units indicate that Houdrifiow and Thermo-for (air-lift) units can be significant sources of BaP and other polynuclear hydrocarbons among industrial sources. Emissions of these compounds can be and frequently are reduced to negligible amounts through the use of CO-waste heat boilers on individual "cat-cracker" catalyst regenerators. Thermo-for (bucket lift) and Fluid units incorporate catalyst regenerator designs that result in only minor emissions. Considerable additional testing would be necessary to report contributions from catalyst regenerators with statistical assurance, as is the case for all of the sources tested.

Motor Vehicles

Consideration of the emission rates determined for gasoline-powered automobiles and trucks and the annual fuel usage leads one to

believe that motor vehicles are a major contributor of BaP to the atmosphere. This is confirmed by Colucci, ⁴² who reports automotive BaP contributions of 5 to 42 percent based on ratios of lead to BaP in exhaust and in the atmosphere. Evidence indicates that the older, higher-mileage vehicles and those with poorly adjusted engines yield the highest emission rates.

Limited data indicate higher emission rates for gasoline-powered trucks. Diesel-powered trucks may also yield higher rates; ^{43, 44} however, diesel fuel usage by trucks and buses accounts for only about 4 percent of the total petroleum consumption for motor vehicles. The over-all contribution from trucks and buses possibly exceeds that from automobiles, even though the total fuel usage for this category is about half that for automobiles.

Control systems applied to automobiles and trucks for the purpose of reducing emissions of total gaseous hydrocarbons should reduce emissions of BaP and other polynuclear hydrocarbons, but no data are available to confirm this.

ABSTRACT: Rates of emissions of polynuclear hydrocarbons were measured at several sources considered likely to produce such emissions. The sources included heat generation by combustion of coal, oil, and gas; refuse burning; industrial processes; and motor vehicles. The annual emissions of benzo(a)pyrene in the United States were estimated for each of the sources surveyed, to provide a rough gauge of the importance of each source. Small, inefficient residential coal-fired furnaces appear to be a prime source of polynuclear hydrocarbons; other sources may be of local importance. Production of polynuclear hydrocarbons was generally associated with conditions of incomplete combustion.
