Hazardous Materials Control Research Institute

Preface

The rigorous control and management of hazardous materials and wastes is an urgent necessity for safeguarding the public health, our environment and natural resources, while at the same time, fostering the continued economic growth of the nation. Since 1980, the Hazardous Materials Control Research Institute has organized an annual conference and exhibition to review, update, and exchange information on the latest research and technical findings from the laboratory, industry, and the field concerning hazardous materials and hazardous waste management. With the cooperation of our affiliates, this annual Superfund Conference and Exhibition has become the most comprehensive gathering and information exchange available on the complex of technical and policy issues that flow from the Superfund program. These proceedings include the most up-to-date technical developments, the impact of federal and state policies as well as the legal, health and economic issues that emanate from the Superfund program.

CERCLA (The Comprehensive Environmental Response Compensation and Liability Act) or "Superfund," as it is now commonly known, was first passed in 1980. This Trust Fund, administered by the U.S. Environmental Protection Agency (EPA), was created to help pay for cleanup of hazardous waste sites that, due to its contents and its terrestrial and/or hydrogeologic setting, threaten the public health or environment.

Under CERCLA, EPA developed a strategy composed of three major elements. The first called for assessing the uncontrolled hazardous waste sites in the Agency's current inventory. Second, those sites which presented an imminent threat to public health or the environment were to be stabilized. Third, using the National Contingency Plan (NCP) for guidance, the NPL sites were ranked to receive priority attention for remedial cleanup action.

The "Superfund" extension, the Superfund Amendments and Reauthorization Act (SARA), signed into law in October 1986, was funded at a level of $9 billion. The extension represented a much increased funding level over the previous five-year period, 1980-1985. A significant portion of these resources will be devoted to remedial construction projects at existing and additionally listed NPL sites.

SARA is designed to achieve greater effectiveness by intensifying all activities under CERCLA and adding more facets to the scope of Superfund activities. Within the total program, SARA stipulates that states will be placed in the implementing role and greater responsibilities will be delegated to the EPA Regional Administrators. Through the implementation of SARA, new sites will be identified and new technologies will be developed and employed. There are now approximately 1,100 sites on the National Priorities List (NPL) plus other sites administered directly by the affected states.

In addition to EPA's program responsibilities, there is now an even larger involvement of other federal agencies concerned with hazardous materials control or cleanup at federal facilities. Chief among them are the Department of Defense and Energy. To gauge the extent of their involvement, EPA is slated to spend approximately $9 billion through 1990, while DOD and DOE have admitted to requiring $120 billion and $170 billion, respectively, over the next 30 years.

This year's *Proceedings* include 192 papers and lecture outlines that emphasize the latest developments and cumulative experiences gained from the spectrum of Superfund activities. This knowledge and experience can serve as an immediate technology transfer for solutions to your areas of concern.

ABSTRACT

This paper discusses Massachusetts' innovative approach for recovering the costs it incurs to clean up sites, including its staff and overhead costs for overseeing PRP actions. On June 9, 1989, the Massachusetts Department of Environmental Protection (DEP) promulgated new cost recovery regulations (310 CMR 40.600) as an amendment to the Massachusetts Contingency Plan (MCP). The new regulations describe how DEP will recover the costs it incurs in performing or arranging for the cleanup of releases of oil and hazardous materials under the authority of the Massachusetts Oil and Hazardous Materials Release Prevention and Response Act (Massachusetts General Laws Chapter 21E).

This paper provides background on the statutory basis for the regulations, summarizes their key provisions and describes changes that the Department has made in its existing cost recovery program to implement them. It explains to whom the regulations apply, how costs are calculated and the challenges DEP has faced in implementing this innovative program.

INTRODUCTION

In March 1983, Massachusetts enacted the Massachusetts Oil and Hazardous Material Release Prevention and Response Act (M.G.L. c.21E). This statute, although similar in many respects to the Federal Superfund law, is broader in scope, regulating not only the cleanup of hazardous wastes covered by the Federal statute, but also the cleanup of oil and other hazardous materials that are not waste products. In November 1986, Massachusetts voters overwhelmingly passed an initiative petition on the ballot commonly referred to as "Question 4." This initiative petition expanded the site cleanup program to incorporate a number of new features including cleanup deadlines, an emphasis on permanent remedies and expanded requirements for public involvement.

Partially as a result of its early enabling legislation and the overwhelming citizen support expressed through passage of Question 4, Massachusetts has one of the most extensive site cleanup programs in the country. As of July 1990, Massachusetts had identified more than 1700 confirmed sites and an additional 2300 locations to be investigated for potential contamination by oil or hazardous materials. Currently, approximately one half of the confirmed sites on the state's list involve only petroleum contamination, often as a result of leaks from underground storage tanks. Massachusetts also actively participates in cleanup activities at the 25 NPL sites located in the state. DEP is particularly proud of its record of involving PRPs in the cleanup process. At over 90⁴ of the confirmed sites, PRPs perform most cleanup activities themselves, subject to DEP's review and oversight .

In 1988, in response to a requirement in M.G.L. c.21E, Massachusetts

promulgated the Massachusetts Contingency Plan (MCP). This document, which is similar in some respects to the NCP, establishes the ground rules for the site cleanup process. Currently, most sites must proceed through a multiphase cleanup process with DEP approvals required at significant decision points.

In June 1989, the Massachusetts Department of Environmental Protection (DEP) promulgated revisions to Subpart F of the Massachusetts Contingency Plan (310 CMR 40.600—Enforcement and Cost Recovery). These revisions contain DEP's interpretation of its statutory authority to recover, pursuant to M.G.L. c.21E, 5a(i), "all costs of assessment, containment and removal that DEP incurs on behalf of the Commonwealth in performing or arranging actions in response to releases or threats of release of oil or hazardous material." The regulations accomplish this purpose by establishing a formula for calculating these costs and a procedure for recovering them through administrative action. They provide a framework for DEP to enhance recovery of "response costs from persons responsible for releases" (Acts of 1983, Ch.7).

The regulations emphasize recovery of the costs DEP incurs in planning, managing and directing (overseeing) response actions that are actually conducted by PRPs. This emphasis, which is an expansion of past DEP cost recovery practices, has resulted in both the new regulations and the program to implement them being commonly referred to as "Oversight Cost Recovery." However, the regulations define recoverable response action costs (hereinafter "costs" or "recoverable costs") as having two components: (1) the costs of direct personnel hours, including the cost of labor and expenses needed to support those hours (so-called oversight costs) and (2) payments made to the Department's agents (contractor costs). Each component is explained in more detail later in this paper. The regulations contain provisions for the recovery of both types of costs through a single action.

The cost recovery regulations promulgated in June 1989 apply to recovery of costs DEP incurs performing or overseeing remedial response actions at disposal sites; provisions for recovery of costs DEP incurs performing or overseeing emergency response actions at spills have been reserved for later promulgation at 310 CMR 40.630. PRPs who qualify for a streamlined agency review process under 310 CMR 40.537, commonly called the "waiver" program, are subject to different cost recovery provisions as long as they comply with the terms and conditions of the waiver program. Applicants for the waiver process pay a one-time charge of $1200 to cover the average costs of agency review and audit of waiver sites.

KEY PROVISIONS OF THE REGULATIONS

As discussed above, response action costs include two major components: (1) personnel costs, often referred to as oversight costs and (2) contractor costs. This portion of the paper explains how the regula-

tions define each of these components and how they are combined to calculate total response action costs.

Oversight Costs

Oversight costs for a particular site are based on DEP's actual costs of supervising response actions at that site. Oversight costs are composed of the costs of direct labor and indirect costs.

The costs of direct labor are the salary-related expenses for DEP staff who plan, manage, direct or perform activities associated with site cleanup. Direct labor hours (which are defined in 310 CMR 40.020) include, for example, time DEP staff spend reviewing reports submitted by PRPs, meeting with PRPs and their representatives and inspecting a site. The costs of these direct hours include each employee's actual hourly salary plus other salary-related costs such as fringe benefits and paid leave (see the definition of hourly rate of compensation in 310 CMR 40.020).

The regulations exclude certain site-specific activities that might otherwise be classified as direct labor from the definition of direct hours. These activities include all time spent on public participation and reviews of preliminary assessments, limited site investigations and site classification reports submitted by PRPs or their agents (except to the extent this review is part of the approval of a short-term measure, i.e., a rapid action to abate or eliminate a release that poses an imminent hazard).

Indirect costs include labor and other expenses needed to support the direct labor described above. Specifically, indirect labor costs include costs for DEP employees such as supervisory, clerical and administrative staff who support direct site-specific activities. Indirect expenses include the portion of DEP's space and equipment rentals, office supplies, telephones, field and laboratory equipment, training expenses, utilities, maintenance and repairs, printing and miscellaneous noncapital expenses that support direct site-specific activities. Only those indirect costs that are closely related to direct labor are recovered.

Indirect costs are allocated to individual sites by using an indirect rate (defined in 310 CMR 40.020). At the end of each fiscal year (which runs from July 1 through June 30), DEP totals its indirect costs (both labor and nonlabor) and its direct hours, based on actual expenses in that fiscal year. DEP then calculates the ratio of its total indirect costs to its total direct hours (310 CMR 40.621(1)). This ratio (called the indirect rate) may be used during the next calendar year to calculate indirect costs for a specific site by multiplying the number of direct hours for that site by the indirect rate (310 CMR 40.620(2)(b)).

Beginning July 1, 1989 and continuing until DEP changes the indirect rate pursuant to 310 CMR 40.621(1), the regulations (310 CMR 40.621(2)) establish an indirect rate of $18.40 per direct hour. DEP developed this rate based on budget and program planning information and on information from its existing fiscal and time tracking systems. If the actual indirect rate for a particular fiscal year is lower than the current rate established under the regulations, DEP must amend the regulations to decrease the indirect rate. If DEP's actual indirect rate for a particular fiscal year is higher than that specified in the regulations, DEP can amend the regulations to increase the rate or continue to use the lower rate already established in regulation.

Contractor Costs

The regulations (310 CMR 40.620(2)(c)) require PRPs to reimburse the Commonwealth for all payments DEP makes to contractors, grantees or agents who perform or oversee response actions at a site. PRPs are not required to reimburse the Commonwealth for any activities performed by contractors, grantees or agents that are excluded from the definition of direct hours (e.g., public participation and reviews of preliminary assessments, limited site investigations and site classifications submitted by PRPs).

Total Costs

DEP uses the following formula to calculate the total response action costs for a site: total response action costs + total costs of direct labor + total indirect costs + total contractor costs.

Total response action costs will vary significantly from site to site. In general, these costs will be higher if the site presents complex assess-

ment and cleanup problems (e.g., it is contaminated with many different substances and/or threatens to contaminate a drinking water supply or other sensitive environmental resource). They also will be higher if PRP submittals are inadequate or incomplete and therefore require substantial DEP review and/or many rounds of revision.

IMPLEMENTATION

DEP has spent considerable effort developing new computer systems and management procedures to implement its cost recovery regulations and training its staff in the use of these new systems and procedures. Much of this effort has focused on the three areas described below:

- Tracking and management of response action costs
- Recovering response action costs from PRPs
- Administrative review of costs disputed by PRPs

Tracking and Management of Response Action Costs

Although DEP has always had procedures for managing its site cleanup activities, the new cost recovery regulations make the Department accountable to the public in a way that few public agencies ever are. DEP believes that it is the only public agency in Massachusetts that effectively "bills its time by the hour" similar to the way that law, engineering and other consulting firms bill for their services. To ensure that its response action costs are fair and reasonable, DEP has revised or developed a number of time-tracking and site management procedures. These procedures include:

- Having employees fill out weekly timesheets that provide a detailed record of the activities they perform
- Having supervisors review these timesheets before the information is entered into the computerized time management system
- Making one person, usually the site manager, responsible for reviewing all recoverable activities performed at each site
- Having the supervisors of site managers review response action costs whenever oversight costs exceed a specified amount

The Department has conducted numerous training sessions and developed guidance manuals to explain these new procedures to its staff and answer any questions they might have.

Several of the new procedures are designed to improve communication among the many DEP programs involved in site cleanup and provide site managers with more information on the activities performed by DEP personnel at their sites. These procedures require site managers to sign off on all recoverable time spent on a site and to document through a work order process any recoverable activities performed by DEP staff outside the Bureau of Waste Site Cleanup.

To support the implementation of its new cost recovery regulations, DEP substantially revised its existing computerized time-tracking system, developed new computerized accounting systems to track all site-specific costs and revised its procedures for updating basic site information.

The revisions to the time-tracking system enable DEP to track time spent on site cleanup in several different ways:

- By the type of activity performed (e.g., report review, meetings with PRPs, enforcement activities, etc.)
- By the DEP Division, Office or individual employee that performed the activity
- By the time period when the activity was performed (week, month, quarter, etc.)
- By the particular site or spill for which the activity was performed
- By the phase the site was in when the activity was performed

The revisions also enable the Department to cross-reference its time-tracking data with payroll information maintained by the State's Personnel/Payroll Management Information System (PMIS). This new reporting flexibility helps insure that salary information used to calculate costs for each employee is accurate and up-to-date and that the employee costs recovered from PRPs have, in fact, been paid by the State.

The new site accounting system allows DEP to calculate total costs for a site, (i.e., to add together all direct labor costs, indirect costs and contractor costs for each site) and to distinguish between those costs

that can be recovered under the provisions of the new regulations and those that cannot.

Although the primary motivation for developing these new systems and features was to implement the oversight regulations, they also enhance DEP's ability to understand and manage its site cleanup program. For the first time, DEP can easily compare information on the time spent on various activities with data on site characteristics. The agency is just beginning to exploit the potential of this management resource to analyze questions such as how much time or money has been spent on certain types of sites (or activities), or how do patterns of site activities vary across the state's four regional offices.

Recovering Response Action Costs from PRPs

The new cost recovery regulations contain several provisions describing administrative actions DEP can take to recover response action costs from PRPs. These administrative actions include sending requests for payment of response action costs to PRPs, implementing an administrative review process to resolve PRP disputes about the accuracy or reasonableness of costs included in requests for payment and using consent orders to establish "caps" on costs that will be recovered from certain PRPs. Although DEP has the discretion to decide not to use administrative actions to recover costs, it hopes using administrative cost recovery approaches will encourage more negotiated settlements and help avoid costly and protracted litigation. This section focuses on DEP's new systems and procedures for requesting payment from PRPs while the next section discusses the administrative process DEP has established to review costs disputed by PRPs.

The new accounts receivable system developed by DEP produces computerized requests for payments for most sites. This system includes several special features needed to implement the provisions of M.G.L. c.21E and the new cost recovery regulations. Because liability under M.G.L. c.21E is joint and several, each PRP at a site will receive a request for the entire amount of DEP's response action costs at that site, unless there is some formal agreement between the Department and the PRPs to allocate costs. However, total payments from PRPs cannot exceed the total costs incurred by the Department. The new accounting system tracks costs and payments for each site and also for each PRP (or group of PRPs) at the site. It then compare costs and payments to ensure that total payments by all PRPs do not exceed total costs at the site. The system also can produce computerized requests for payment that incorporate simple payment provisions that might be contained in consent orders (e.g., a proportional allocation of costs among several PRPs).

DEP staff can bypass the computerized system and produce requests for payment manually at sites with special circumstances (e.g., complicated payment schedules or allocation provisions among PRPs). The computerized accounting system enables DEP staff to identify and track those requests for payment that are produced manually. Requests for payments show: DEP labor costs (classified into two categories: costs associated with short term measures and all other costs); contractor costs; outstanding costs from previous bills and interest accrued; and a summary of payments made for the site by PRP. Requests for payment also provide the names and addresses of all PRPs receiving the request for payment at that particular site and instructions for making payments, requesting additional information on the response action costs incurred by DEP, or requesting a review of these costs (described in more detail below).

One innovative feature of Massachusetts' program is that PRPs are sent Requests for Payment on a regular basis, typically once every four months. This approach keeps PRPs informed of costs that are accruing at their sites as well as payments that they or other PRPs have made. Much of the information contained on the request for payment—such as the names of other PRPs and their payment history—is designed to encourage joint PRP action at sites with more than one PRP.

This approach and the new computerized accounts receivable system, also makes it possible to standardize DEP's procedures for assessing interest. Under the new regulations, DEP begins assessing interest on unpaid response action costs forty-five days after it has sent a request for payment (310 CMR 40.620(5)). Interest is assessed at the rate of 1% per month and will be compounded annually until the costs are paid or otherwise resolved. M.G.L. c.21E, 13 establishes an interest rate of 12% per year.

To minimize uncertainty about future oversight costs, DEP may consider including caps on response action costs in consent orders negotiated with PRPs (310 CMR 40.620(7)). The cap amount represents the Department's best estimate of the costs it expects to incur at the site. Decisions about whether or not to include such a cap in a specific consent order are made on a case-by-case basis.

Administrative Review

DEP has established a process for answering questions raised by PRPs regarding the accuracy or reasonableness of specific costs in a request for payment. This process, which implements the regulatory provisions contained in 310 CMR 40.620(4), works as follows.

First, PRPs may request information about how costs were calculated. The new accounting systems will enable DEP to provide PRPs who request it with detailed computerized reports on the costs contained in a request for payment. These reports may include some or all of the following items, depending on the type of costs incurred at the site:

- Breakdown of DEP labor hours and costs by activity, employee, time period and phase
- Breakdown of contractor costs by invoice
- List of all payments received for the site; the report will identify which PRP made the payment, the payment amount and the payment date
- Summary of interest assessments, showing the amounts and time periods used to calculate interest

PRPs who wish to dispute a specific cost must submit a written request outlining the nature of the dispute within the time limits established by the Department and include any evidence necessary to support the request. DEP staff review the disputed costs and consult with the appropriate DEP site manager and the PRP as necessary. Once the review is completed, the reviewer may approve the request, crediting the PRP's account for some or all of the disputed costs, or may deny the request, making the disputed amount due. If the PRPs disagree with the reviewer's decision, they still have the recourse provided in M.G.L. c.21E of filing an action in Massachusetts Superior Court. DEP may elect to waive its statutory right to seek treble costs from PRPs who participate in good faith in the administrative review process (310 CMR 40.620(6)(c)).

Time spent by Department staff on this administrative review process is intended to encourage voluntary payment of costs and is not included on requests for payment sent to PRPs.

ENFORCEMENT ACTIONS

If DEP does not recover its costs using the administrative procedures described above, it will seek to recover those costs through enforcement actions against PRPs. These enforcement actions may include filing a lien pursuant to M.G.L. c.21E 13 and/or asking the State's Attorney General to bring an action in State Superior Court pursuant to M.G.L. c.21E 11. DEP retains the right to seek these, or any other nonadministrative remedies, that are available to it at any point after costs have been incurred at a particular site.

Increasing Opportunities for State Involvement in the Superfund Program: A Review of Key Regulations, Changing Cleanup Roles and Flexible Funding Options

Jan H. Baker
U.S. Environmental Protection Agency
Washington, District of Columbia
Katherine T. Nakata, Ph.D.
Roy F. Weston, Inc.
Washington, District of Columbia

ABSTRACT

In 1980, when the U.S. Congress first enacted the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA), the law required States to be actively involved in Superfund response actions. Under CERCLA, States with technical and management capability to carry out a response action may be authorized to lead cleanup efforts at a site. Without elaboration from Congress, the U.S. EPA took a course of action that met with limited success due to States' lack of adequate resources, experience and legal authorities. In 1986, the Superfund Amendments and Reauthorization Act (SARA) mandated what the relationship at a minimum should be between the Federal Government and the States. These amendments provided further elaboration on the U.S. EPA/State relationship. In particular, the U.S. EPA is required now to provide an opportunity for "substantial and meaningful involvement by each State in the initiation, development, and selection of remedial actions to be undertaken in that State" by Section 121 (f) of CERCLA, as amended.

This paper reviews the U.S. EPA's short- and long-range strategy for increasing States' involvement in the Superfund program in the 1990s. Four building blocks for the new strategy include: (1) the U.S. EPA's program management goals; (2) efforts to foster increased State involvement based on the recent promulgation of two Superfund regulations—the National Contingency Plan (NCP) and 40 CFR Part 35, Subpart O; (3) increased financial support through Cooperative Agreement funding to help States move toward fully operational programs of their own; and (4) new opportunities for increased State flexibility to tailor environmental programs to meet State and local needs and benefit from a balance of U.S. EPA/State influence in the direction and implementation of program activities.

INTRODUCTION

When Congress first enacted the Comprehensive Environmental Response, Compensation, and Liability Act in 1980, it provided the U.S. EPA and the States with the authority and approach for responding to uncontrolled hazardous waste sites. Congress later amended CERCLA by passing the Superfund Amendments and Reauthorization Act in 1986. SARA was distinguished from CERCLA in its emphasis on State involvement in virtually every phase of response.

CERCLA, as amended by SARA, authorizes the Federal Government to assume lead responsibility for cleanup at a site (Federal-led) or to transfer the necessary funds and management responsibility to a State when it has the technical and administrative capabilities to lead all or part of a Superfund response (State-led). Regardless of the lead agency designation. Section 121(f) of the law mandates that the U.S. EPA provide "substantial and meaningful involvement by each State in the initiation, development and selection of remedial actions to be

undertaken in that State." The extent of involvement goes beyond remedial action. Section 121(f) lists a full range of activities to evaluate and respond to the problems at the hazardous waste sites to abate or permanently clean up waste threatening human health and the environment. The intent implicit in the law is to increase the opportunities for State involvement in all aspects of the Superfund program from listing to deletion from the National Priorities List (NPL) and during removal and enforcement as well.

In *A Management Review of the Superfund Program* (The Superfund 90-Day Study), the Agency's Administrator identified the need for the U.S. EPA and States to develop joint short- and long-term strategies to enhance State program capability, improve State performance at State-led Superfund sites and foster State remedial activities at sites not on the NPL. The U.S. EPA's short- and long-term program management goals and their implications for current efforts to encourage increased State involvement through promulgation of two Superfund regulations—the NCP[1] and 40 CFR Part 35, Subpart O[2] (hereinafter referred to as the "Assistance Regulation") - and financial support provided through Cooperative Agreements[3] are presented in this paper. This overview clarifies the Agency's overall rationale and strategy for providing a wide array of opportunities for States to assume increased responsibility and to provide input into the U.S. EPA's planning on future directions in State involvement.

BACKGROUND

The U.S. EPA's Changing Approach to Environmental Management

Since the 1970s, major environmental laws have assigned to the U.S. EPA most of the key functions involved in delivery of environmental programs, while providing for a State role in assuming day-to-day program implementation responsibilities. The U.S. EPA generally has issued regulations and standards, provided detailed guidance and financial/technical assistance and monitored State performance. As their capabilities and experience have increased, States have gradually applied for and received more operational responsibilities. Along with their greater program role and responsibilities, States have been seeking to establish an equal and balanced relationship with the U.S. EPA. An equal U.S. EPA/State relationship involves: (1) a clear and appropriate division of authority and responsibility; (2) State involvement/ participation in goal-setting, policy formulation and planning; and (3) reporting and other oversight mechanisms to provide management control and evaluative information that the U.S. EPA needs to assure management accountability. A more equitable U.S. EPA/State relationship based on increased State involvement will encourage improvements that will mutually benefit the U.S. EPA and the States by:

- Promoting delivery of more effective environmental protection by placing decision-making authority at the level of government closest

to the people most affected by the decisions
- Expanding the impact of program investments of limited resources and support by taking advantage of States' advances in staffing, expertise and experience
- Reducing duplication of effort and minimizing conflicts resulting from confusion and differing perspectives on appropriate roles and responsibilities

Thus, principles to fulfill the mission of the U.S. EPA's Office of Solid Waste and Emergency Response (OSWER) include:

- Assuring an effective and open dialogue and exchange of information with all "stakeholders in OSWER's mission" who include the general public, federal, State and local governments and other groups where the exchange of information includes the provision of technical assistance and opportunities for consensus-building
- Fostering a special relationship with States (and Indian Tribes)[4] in sharing responsibility for implementing OSWER's programs.[5]

To date, the historical evolution of the Superfund Program's approach to management of the Federal/State relationship has significantly differed from the U.S. EPA's implementation of other environmental programs due to certain characteristics of CERCLA and its legislative history. Differing U.S. EPA and State perspectives regarding State involvement in the Superfund program have also been based on certain of these characteristics. CERCLA does not clearly delineate a State role in implementation of the program. That is, CERCLA is not a "traditional delegated program" (i.e., in the same sense as the Resource Conservation and Recovery Act [RCRA] and the Clean Water Act programs, although Cooperative Agreements are being used as a mechanism for sharing responsibilities between the U.S. EPA and the States and designating States as the lead during a response action). The U.S. EPA's management approach for the Superfund program has also been influenced by a lack of clarity regarding Congressional intent to permit States to assume responsibilities originally assigned to the President (e.g., selection of the remedy and approval of major cleanup project deliverables).

Discussion of Early Regulations, CERCLA 104 (c) and Effects on Cooperative Agreement Funding

The early imbalance in the State/U.S. EPA relationship was exacerbated by a limited availability of Cooperative Agreement funding to support State involvement in remedial response coupled with demanding, yet restrictive, application requirements for such funding. Following the enactment of CERCLA in 1980, the U.S. EPA focused on site-specific cleanup activities while developing an understanding of the essential program components for effective response. In 1984, the U.S. EPA provided States with an opportunity to enter into Multi-site/Multiactivity Cooperative Agreements that enabled States to consolidate their resources under one funding mechanism covering site-specific State-led projects and/or State participation in site-specific Federal-led projects. In 1985, the U.S. EPA provided States with an opportunity to participate in the hazard ranking of sites to determine whether they could be placed on the NPL. Finally, in 1987, the U.S. EPA offered assistance for removals where a 6-month planning period exists. Over time, State involvement in the CERCLA-funded cleanup process continued to be defined primarily in terms of activities at single sites and a State's willingness to provide Section 104 (c) assurances required for cleanup. States were required to provide three types of assurances that included the following:[6]

- *Cost-sharing*: The State was required to share in the costs of the remedial action performed at a site. At privately owned sites, the State was required to pay 10% of remedial action costs. At publicly owned sites (owned by the State or a political subdivision thereof), the State was required to pay at least 50% of all response costs such as Removals, Remedial Investigation and Feasibility Study (RI/FS) and Remedial Design (RD) and Remedial Actions (RA). U.S. EPA policy permitted States to defer the cost-share for Remedial Planning until a remedy was selected. Then, if a CERCLA-funded RA was contemplated, 50% of these earlier costs plus 50% of the RA had to be assured.

- *Off-Site Treatment, Storage, or Disposal*: The State was required to assure the availability of a hazardous waste treatment, storage or disposal facility that had: (1) an applicable permit or had been granted interim status in accordance with RCRA; (2) a RCRA Part B permit or a RCRA compliance inspection within 12 months prior to its use for treatment, storage or disposal of site waste and had complied with the RCRA regulations; and (3) sufficient capacity to handle wastes from the site. In addition, the U.S. EPA had to find off-site treatment, storage or disposal to be the most cost-effective cleanup option in comparison to other proposed remedial actions to protect human health or the environment.

- *Operation and Maintenance (O and M)*: The State was required to assume responsibility for all future O and M for the expected life of each RA as determined by the U.S. EPA and the State. In accordance with prevailing policy in effect at the time, the U.S. EPA could, for a period up to 1 year after completion of remedial response activities, share in the costs of any required remedy. In these instances, U.S. EPA policies assumed that costs limited to the 1 year could be considered the first part/leg of O and M.

Versions of the NCP in effect before CERCLA was amended discussed assurances to be provided by States in a Cooperative Agreement or contract before a CERCLA-funded RA could begin. The NCP did not assign States any specific role during the course of remedial response.

Without an explanation of the State role in either CERCLA or the NCP, the Agency relied on guidance to explain Cooperative Agreements and the transfer of funds and cleanup responsibilities to States. Consequently, there were more U.S. EPA leads at the onset of the program because the U.S. EPA had access to resources, experience and expertise. The U.S. EPA had access to substantial cleanup expertise through its own contractors, the U.S. Army Corps of Engineers and Emergency Response Teams; the benefits of hazardous and solid waste cleanup and management experience gained from implementing RCRA and the Clean Water Act; and adequate legal authorities to go on any site and to conduct a response. In contrast, only a few States, such as New Jersey and New York, had a cleanup program, technical cleanup experience or legal mechanisms in place to meaningfully interact with the U.S. EPA on site matters. Most States had to rely on the U.S. EPA for funding to staff up to conduct responses. As a result of this imbalance in the U.S. EPA/State relationship, States with ready sources of funds were able to interact fully with the U.S. EPA, while States lacking such resources were limited in their ability to interact with the U.S. EPA or even to develop Superfund programs.

Congress provided a resolution for this inequity when it amended CERCLA. Section 121(f) (1) of CERCLA as amended by SARA requires the U.S. EPA to promulgate regulations that generally provide for:

- State involvement in decisions regarding performance of Preliminary Assessment/Site Investigations (PA/SIs) during pre-remedial activities
- Allocation of responsibility for Hazard Ranking System (HRS) scoring
- State concurrence on NPL deletions
- State participation in long-term planning for all remedial sites in a State
- A reasonable opportunity for States to review and comment on the RI/FS and data documents leading to its issuance, the planned remedial activities identified in the RI/FS, the RD, technical data and reports relating to remedy implementation and any applicable or relevant and appropriate provisions of other laws (ARARs) considered and/or adopted or waived during remedial activities
- Notice to the State of negotiations with Potentially Responsible Parties (PRPs) regarding the scope of any response action and an opportunity to participate in such negotiations and settlements during enforcement (for a complete list of requirements, see Section 121 (f) of CERCLA as amended)

Once the State role during response was mandated, the U.S. EPA was able to elaborate on the full array of tasks/activities that could support development of an equal U.S. EPA/State relationship because the base line (i.e., minimum requirements for "substantial and meaningful involvement") was specified in the law.

REVIEW OF CURRENT REGULATIONS

NCP and the Assistance Regulation

CERCLA, as amended, is the legislative initiative that provides for cleanup of hazardous waste. The NCP describes guidelines and procedures for implementing the law. Recently, all guidance and practical experience were taken into account when the U.S. EPA began implementing 121(f) of SARA. Consequently, there are now two regulations on Superfund guiding the U.S. EPA's strategy for increasing State involvement: the NCP (especially Subpart F on State Involvement)[7] and the Assistance Regulation. Moreover, in crafting these two regulations, the U.S. EPA assumed a complementary interaction between the two rules.

While Subpart F of the NCP specifies how the U.S. EPA will satisfy 121(F) of CERCLA as amended, the Assistance Regulation provides the mechanisms to foster the birth of State Superfund programs, support the State's development of its own program goals and sustain its effectiveness to respond at sites in a variety of ways. Most importantly, the U.S. EPA is now positioned to assist States in gaining more opportunities for substantially increased involvement in the Superfund program per se, rather than site response only. Consequently, most responsibilities regarding site cleanup and administrative management pertaining to State involvement that were in guidance are now specified in both regulations, and reliance upon voluminous amounts of program guidance to implement and administer the Superfund program is reduced.

The U.S. EPA's new approach to State involvement is based on a differentiation between: (1) the technical aspects of response that include State involvement throughout that response; (2) support intended to nurture and strengthen State involvement and (3) national consistency in the U.S. EPA/State relations with regard to environmental and public health protection. The different contributions of each regulation to the U.S. EPA's strategy for increasing State involvement in the 1990s are discussed below.

NCP's Delineation of Lead and Support Agency Roles During a Response

The NCP clarifies requirements for State involvement by specifying how the U.S. EPA will implement the 121(f) requirement for the U.S. EPA to provide "substantial and meaningful involvement by each State." The NCP delineates a structure for U.S. EPA/State interactions to assure consistency of communications and coordination when the States are assisting the U.S. EPA during the conduct of a response action. The NCP also responds to States' desires for an equal U.S. EPA/State relationship by fulfilling requirements that the U.S. EPA establish comparable processes for Federal- and State-led or support agency roles during the conduct of various response activities. The basic elements of the structure of interaction include specified decision points and communication and coordination points.

During a State-led remedial response, for example, decision points include State/U.S. EPA agreement on the acceptability of major project deliverables such as the RI/FS workplans and reports; concurrence with the Record of Decision (ROD) recommending a specific remedy for site cleanup; agreement with the RD and proposed plan for RA; and acceptance of the remedy at the conclusion of RA. Acceptance of the remedy involves acceptance of the technical report on the RA that the remedy is in place, working as designed and meets the cleanup requirements specified in the ROD. The final decision point involves the State's concurrence with the U.S. EPA's deletion of a site from the NPL. Communication and coordination points during a State-led remedial action include time frames for early joint identification of ARARs, specified time frames for review of key reports and advance notice of planned dates for important meetings, conferences and the fulfillment of State goals to address the concerns of its citizens.

Assistance Regulation's Requirements for Funding State-Led/Support Roles and Core Program Funding

The Assistance Regulation relies on the NCP for designation of a lead or support agency for response and the points of involvement during response and establishes the criteria for funding to support the State's

role in a variety of site-specific response activities. In addition, the Assistance Regulation contributes to the U.S. EPA's goal to increase opportunities for State involvement by providing the U.S. EPA's current requirements for Core Program funding — the solution to the constraints imposed by early assistance requirements which focused on site-specific activities.

Finally, the Assistance Regulation makes a substantial contribution to the U.S. EPA's efficient management of Hazardous Substance Superfund ("The Fund") dollars by providing uniform and consistent requirements for the obligation, fiscal management and expenditures to procure goods or services necessary to support cost recovery. Furthermore, the shift in emphasis from guidance to regulations provides for uniform treatment of States as the U.S. EPA's partners and national consistency in the program regardless of lead/support agency designation during site response. These different contributions are discussed in further detail below.

The Original Core Program Cooperative Agreement Concept

The concept of the Core Program Cooperative Agreement was implemented in 1987 through program guidance to fund nonsite-specific activities that could support a State's ability to assume an active role in site-specific responses. Basic Core Program functions considered essential for sustaining and/or enhancing State program abilities included:

- General program management and supervision necessary to direct a program to carry out CERCLA implementation activities
- Interagency coordination on all phases of response necessary to develop and sustain a consistent and concerted State effort
- Legal assistance associated with proper administration of the CERCLA program
- Development of fiscal and contract management procedures to ensure the financial integrity of CERCLA site-specific expenditures and CERCLA-related procurement administration
- General administration and clerical support
- Additional State-specific functions considered on a case-by-case basis once a State developed a viable Superfund program (including development of response training, base line medical monitoring programs, record-keeping guidelines to support cost recovery activities and 20-year hazardous waste capacity assurance plans)

The Core Program was initiated on a pilot basis with awards to three States in three different Regions. Each State (Illinois, Utah and Washington) provided practical insights into improvements for the Core Program concept, which facilitated nationwide implementation in 1988, when all States were eligible to receive Core Program funds.[8] In this process, the U.S. EPA learned several lessons regarding States' limited abilities to participate as "full partners" in the Superfund program. These lessons included the following:

- State programs lacked full capabilities
- States desired more integrated support
- States had difficulty justifying staff
- States have unique needs

During early implementation of the Core Program concept, financial awards fluctuated in response to the following:

- The number of sites a State had in the Comprehensive Emergency Response Compensation and Liability Information System (CERCLIS) inventory and on the NPL awaiting fund financing
- The number of State-led CERCLA-funded site cleanups underway
- The level of sophistication of the State's CERCLA implementation capability
- Whether or not State-specific additional functions were deemed appropriate

Because the public comment periods for both the NCP and Assistance Regulation overlapped, the U.S. EPA received many comments that provided practical advice on how individual requirements could be made more flexible to help States move toward fully operational programs of their own. In fact, during the public comment periods for both regulations, the Agency gained more insight into the future needs of States.

Consequently, when both became final, States were able to increase the degree of their involvement via Core Program Cooperative Agreements. As a result, all 10 U.S. EPA Regions are represented by awards to 41 States, the Territory of Puerto Rico, and the Navajo Nation.[9]

Now, the U.S. EPA is willing to fund:

- Procedures for emergency and long-term remediation of environmental and health risks at hazardous waste sites (including, but not limited to, the development of generic health and safety plans, quality assurance project plans and community relations plans)
- Provisions for satisfying all CERCLA requirements and assurances (including the development of a fund or other financing mechanism[s]) to pay for studies and remediation activities
- Legal and enforcement support associated with proper administration of the recipient's program and with efforts to compel PRPs to conduct or pay for studies and/or remediation (including, but not limited to, the development of statutory authorities; access to legal assistance in identifying ARARs; and development and maintenance of the administrative, financial and record-keeping systems necessary for cost recovery actions under CERCLA)
- Efforts necessary to hire and train staff to manage publicly funded cleanups, oversee responsible party-led cleanups and provide clerical support

Once a State has these necessary program functions in place, the U.S. EPA may provide funds to support other initiatives that support the uniqueness of each State. Program support activities have also been integrated throughout the Assistance Regulation. They include such activities as development and maintenance of central files for site-specific response to support cost recovery, interagency agreements with other State agencies and municipalities to obtain a variety of services such as consolidated reporting functions, development of long-range communication strategies and multiyear workplans and budgets to support strategic planning.

There are no Federal funding limitations imposed by the regulation; rather, awards are based on State program needs, demonstrated progress against previous scopes of work and the availability of funds.

Eligibility Requirements for State Roles in
Site-Specific and Other CERCLA Activities

In general, the Assistance Regulation provides eligibility requirements for States (as well as political subdivisions and Federally-Recognized Indian Tribes) seeking to apply for Superfund Cooperative Agreements. The regulation also identifies those entities eligible to apply for specific types of Cooperative Agreements. For example, States are eligible to apply for:

- State-led Pre-remedial Cooperative Agreements
- State-led Remedial Cooperative Agreements
- State-led Enforcement Cooperative Agreements
- State-led Removal (for 6 month planning period) Cooperative Agreements
- Core Program Cooperative Agreements
- Support Agency Cooperative Agreements where the U.S. EPA or a political subdivision is the lead for response

These eligibility requirements assure the consistent treatment of States across the range of available types of Cooperative Agreements and serve as the vehicle for their eventual attainment of true partnership with the U.S. EPA.

Consistent Application and Administrative Requirements

The comment periods for both the NCP and the Assistance Regulation were concurrent. Therefore, comments not applicable to the NCP were accommodated in the Assistance Regulation and vice versa. At the same time, the U.S. EPA gained a practical appreciation of how individual States viewed the requirements and their ability to interact with the U.S. EPA at all levels. Consequently, the requirements associated with applying for and receiving CERCLA funds increased the consistency of administrative requirements across the range of Cooperative Agreement types. By focusing on the type of entity (State,

political subdivision or Federally-Recognized Indian Tribe) in a lead or support role for a response, the U.S. EPA has increased the consistency of administrative requirements by providing:

- Consistent application and award criteria regardless of the type of response
- Flexible funding alternatives that support cost recovery yet reduce burdens of paperwork
- Reductions in the need for many special conditions for each Cooperative Agreement and thereby reducing confusion due to a substantial reliance on guidance
- Minimization of the potential for significant differences in treatment, from State to State and Region to Region
- Decrease in the potential vulnerability to misuse of Fund dollars during response and a subsequent decrease in audit problems
- Consistent criteria for evaluating requests to purchase equipment for State-involvement in site response, and enhancement of State capability to respond via the Core Program funding
- Consistent equipment disposition instructions that allow transfers of equipment from one site to another and one responder to another (e.g., State to County)
- Consistent reporting requirements and reporting schedules throughout the regulation to support cost recovery

FUTURE ACTIVITIES TO FURTHER DEVELOP STATE SUPERFUND PROGRAMS

Following promulgation of the two major Superfund program regulations, the U.S. EPA's strategy for increasing State involvement in the 1990s is being implemented through two types of activities:

- U.S. EPA's strategic plan
- Program-specific activities

The U.S. EPA's activities related to these types of activities are discussed below.

U.S. EPA's Strategic Plan

The U.S. EPA's mission is to protect human health and the environment from unacceptable risks posed by solid and hazardous wastes and by releases of oil and hazardous substances into the environment. To fulfill this mission, the U.S. EPA must meet four goals:

- Minimize the quantity and toxicity of waste created by commercial, domestic and governmental activities
- Ensure environmentally sound management of solid and hazardous wastes
- Prevent harmful releases of oil and hazardous substances into the environment
- Prepare for and respond in a timely and effective manner to releases of hazardous materials into the environment[10]

The U.S. EPA's strategic plan guides the Agency toward implementation of its principal purpose — to reduce risk to human health and the environment.

The Superfund Program's chief role lies in the fourth goal of the strategic plan—to respond to releases of hazardous materials in a timely and effective manner, which emphasizes:

- High-priority sites and releases first
- Effective remedies
- An efficient, well-managed Superfund program
- Increased role of others
- Building public confidence in Superfund
- Planning efforts to support the concept that enforcement is the preferred method of cleanup

Opportunities for State Involvement

In light of these general goals and objectives, States seeking involvement in the Superfund program may obtain:

- Increased opportunities for involvement in selected areas that are most important to them depending upon their own program needs
- Increased opportunities to become active partners in protecting the environment and public health by developing, or providing expertise

Opportunities for increased State involvement directly related to the U.S. EPA's strategic goals and objectives include the following areas.

Address the worst sites first

To meet this objective, the Superfund Program needs to develop, issue and implement operating guidance for pre-remedial, remedial, removal and enforcement activities that rely on common eligibility and performance criteria for each phase of response rather than separate and seemingly contradictory instructions. Such a consolidated initiative, wherever practicable, should increase the ability of States to work independently.

States have identified 32% of the total universe of sites in CERCLIS and 55% of the sites now on the NPL.[11] This contribution to the PA/SI and hazard ranking process has helped the U.S. EPA narrow the universe of sites that require attention.

Specifically, with States, the Superfund Program's activities include development and implementation of a site discovery policy and program. A recommendation has been made to fund State site discovery programs either under the Core Program or Preremedial Cooperative Agreements. The Assistance Regulation allows for this possibility which could mean that future problem sites will be assessed and cleaned up more rapidly.

Improve the operation and effectiveness of national preparedness and State involvement in response structure

To meet this objective, the U.S. EPA is examining ways to provide States with a larger role in emergency response efforts at sites where the U.S. EPA or Federal response contractors would respond. In addition, the U.S. EPA is exploring ways to share information on sites to help States respond where the U.S. EPA cannot. This goal can be accomplished only through a concerted effort with States to train State and local officials to respond rapidly and effectively to releases. Again, the Assistance Regulation allows for this possibility.

Control threats to human health and the environment by reducing costs and length of time from identification to response

Achieving this objective requires an improvement in all areas of Superfund response and program management, including a reliance on States to conduct the work and a reduction in the degree of oversight as States enhance their ability to respond. One must acknowledge that within the universe of sites, balancing priorities does not mean one entity does everything at a site; there is more than enough work for everyone.

Optimize U.S. EPA and State resources to secure maximal involvement by Responsible Parties

In order to meet this objective, the U.S. EPA intends to pursue a balanced, aggressive enforcement program that emphasizes participation by RPs in the design and implementation of a site's remediation. The Administration has continued to focus on enforcement in order to increase the number of sites that can be cleaned up; however, the U.S. EPA cannot carry out all these efforts alone. Specifically, the U.S. EPA will provide the support necessary to increase State involvement through the Assistance Regulation. States can now apply for Enforcement Cooperative Agreements for all CERCLIS sites and receive funding to pursue PRPs and oversee RP actions. In addition, States may receive funding through the Core program to develop the legal authorities necessary to establish an active and effective enforcement program of their own.

Establish effective State programs to respond to releases of hazardous materials

Overall, the Superfund Program intends to move towards a more delegated program by enhancing State programs and encouraging States to use local governments. The Core Program funding, training and other technical assistance from the Superfund Program and other sources within the U.S. EPA can be used to promote and support cohesive State programs that deal with all aspects of the hazardous waste cleanup and management per se from cradle to grave. States can optimize the U.S.

EPA's resources by more fully participating in areas where they have a comparative advantage, thereby enhancing the quality and quantity of response actions undertaken.

Program-Specific Activities

The Superfund Program is conducting an array of specific program activities to implement the two regulations including:

- Identifying and resolving administrative obstacles to national consistency between the regulations and existing program guidance
- Providing funding opportunities through expanded Core Program Cooperative Agreements
- Increasing State flexibility to tailor environmental activities to a States' unique needs and encouraging within the U.S. EPA a greater reliance on State expertise

Each of these activities is further discussed below.

Increasing National Consistency Between Regulations and Program Guidance

Regulatory or administrative obstacles may remain because the issuance of the NCP and Assistance Regulation did not automatically rescind operating guidance. Therefore, the U.S. EPA is evaluating State/U.S. EPA roles and the new eligibility requirements for assistance to foster consistent national implementation of the Superfund Program. This initiative includes an analysis of regulatory and program guidance requirements for Cooperative Agreement funding. Results of this analysis are being used for several purposes:

- To develop recommendations for streamlining and updating current program guidance and rescinding guidance that is no longer practicable
- To develop solutions for resolving existing administrative barriers
- To develop decision-making tools for States' use to satisfy eligibility requirements when applying for Superfund Cooperative Agreement funding. In the short-term, a review of these eligibility requirements will help identify State program capabilities that need enhancement. In the long-term, it should encourage development of a national cleanup program based on the collective contributions of many fully operational State programs - capable of responding to NPL and non-NPL sites.

Funding Opportunities and the Core Program Cooperative Agreements

In the future, the U.S. EPA will continue its existing practice of basing funding allotments on State program needs, demonstrated progress against previous scopes of work and availability of funds. In addition, the U.S. EPA plans to use the larger, more flexible Core Program offered by the Assistance Regulation to encourage States to respond creatively to their unique program needs. This procedure, in turn, should ensure that States progress toward fully operational programs of their own in the 1990s. The U.S. EPA will encourage these developments first, by allowing scopes of work and associated budget requests to cover more than one year; and second, by allowing funds to pay for "publicly-funded cleanups" to be used for oversight of cleanups funded by Superfund, State-funded cleanups and cleanups required and funded by other public entities.

Increased State Flexibility

Opportunities for increased State involvement in the 1990s will be based on the changing direction of the U.S. EPA/State roles in the Superfund program. The new direction is based on four recent developments:

- Opportunities for flexibility to tailor environmental programs to meet local and State needs are increasing
- The U.S. EPA is seeking to achieve a balance of the U.S. EPA/State influence in the direction and implementation of program activities
- States are providing innovative approaches to solving waste management problems
- The U.S. EPA is acknowledging the increasing U.S. EPA/State interdependence

FOOTNOTES

1. 40 CFR Part 300, National Oil and Hazardous Substances Pollution Contingency Plan; Final Rule. *Federal Register, 55* (46), March 8, 1990.

2. 40 CFR Part 35 Subpart O. Cooperative Agreements and Superfund State Contracts for Superfund Response Actions; Final Rule; *Federal Register, 55*(108), June 5, 1990.

3. A "Cooperative Agreement" is defined as the instrument for transferring money or services to a State (or political subdivision, or Federally-Recognized Indian Tribe) when a State assumes lead responsibility for all or part of a response activity and when substantial federal involvement is anticipated. A Cooperative Agreement under CERCLA also documents the U.S. EPA and State responsibilities and serves as an instrument for obtaining any required CERCLA 104 assurances when the State is the lead agency.

4. CERCLA Section 126 treats Federally-Recognized Indian Tribes substantially the same as States. The NCP Subpart F specifies circumstances under which substantially the same treatment is required of the U.S. EPA, and the Assistance Regulation tells these Indian Tribes how they can be supported in their role as a State. Section 104 provides political subdivisions with opportunities for participation in response activities and the Assistance Regulation specifies when and how they can be involved in response activities as a lead or support agency to the U.S. EPA and a State.

5. See the U.S. EPA, *OSWER Strategic Plan for FY 1992-1995*, November 30, 1989, pp. 5 and 6. OSWER includes (1) the Office of Emergency and Remedial Response, (2) Office of Solid Waste, (3) Office of Underground Storage Tanks and (4) Office of Waste Programs Enforcement. See also "Building an U.S. EPA/State Relationship for the Changing Management of Environmental Programs" in U.S. GAO, *Environmental Protection Agency: Protecting Human Health and the Environment Through Improved Management* August, 1988.

6. The SARA amendments added two additional assurances pertaining to siting/waste capacity (104 (a)(9)) and acquisition of property (104 (j)).

7. Although several sections of the NCP include requirements that are critical for State involvement in Superfund, e.g., Subpart E requirements on Removal Site Evaluations and Removal Actions, RI/FS and Selection of the Remedy, RD, RA and O and M; or Subpart I requirements for Establishment of an Administrative Record, Subpart F contains all regulatory requirements for State participation and involvement in CERCLA-authorized response actions.

Coordination of Site Cleanup with Natural Area Development

Daniel V. Markowitz

Ohio Environmental Protection Agency
Division of Emergency and Remedial Response
Columbus, Ohio

ABSTRACT

The New Lyme Landfill Superfund Site is a 40 acre site that was operated between 1968 and 1978 as a disposal facility for residential, commercial and industrial wastes. A Record of Decision (ROD) was signed by the U.S. EPA in 1985 after completion of the Remedial Investigation and Feasibility Study. The selected remedy described in the ROD included groundwater remediation and installation of a multilayer cap to prevent infiltration of water into the fill area. During the development of the Remedial Design project, the Ohio EPA developed and coordinated a unique solution to provide cover material for the site. The Ohio EPA project management staff suggested using an underdeveloped wildlife area adjacent to the site as a source for cover material. The Ohio EPA contacted the Ohio Department of Natural Resources (Ohio DNR) and jointly developed a plan to improve the habitat at the state-owned New Lyme Wildlife Area. That plan has been implemented through the U.S. EPA fund lead Remedial Design/Remedial Action with the oversite of the Army Corps of Engineers. The excavation of cover material was planned and executed to create a 60 acre lake in the 500 acre swampy forest area. The lake was designed in coordination with Ohio DNR to provide diverse habitat for waterfowl, shorebirds, furbearers and game fish. The project includes development of access roads and boat ramps to improve recreational use of the wildlife area. The lake is supplied by surface water that is not from the watershed of the landfill. Almost 900,000 cubic yards of soil were excavated from the wildlife area to provide materials for grading and development of the multimedia cap. The use of cover materials from the wildlife area has lowered the implementation cost of the remedy by at least $3,500,000. Additionally, use of soils from the adjacent wildlife area eliminated the truck traffic on local public roads that would have occurred if soils had been taken from other sources. The extra design efforts of the agencies involved has resulted in a greatly improved wildlife area and increased cost-effectiveness of the final remedial action at the New Lyme Landfill Superfund Site.

INTRODUCTION

In this paper, the authors present a brief history of activities at the New Lyme Landfill Superfund Site and a description of the implementation of the wildlife area enhancement that was integrated into the remedial project for the site. The authors also summarize the pre-remedial and remedial activities that occurred under the auspices of the U.S. EPA Superfund Program. The design and implementation of the wildlife area enhancement project is described in detail.

The case history presented here supports the importance of active and creative project management in the development and implementation of remedial projects at Superfund and state-led remedial projects. The remedial project at the New Lyme Site successfully implemented a protective remedy that was made more cost-effective by using borrow materials from an adjacent wildlife area. In addition to the expected benefit of mitigation of the long-term risk posed by the New Lyme Landfill, the community and the state has benefitted from the addition of a 60 acre lake to enhance a previously under utilized state owned wildlife area.

SITE HISTORY

The New Lyme Landfill was operated between 1968 and 1978. The facility accepted residential, commercial and industrial wastes. The facility accepted an estimated 27,500 cubic yards of waste monthly. Wastes disposed of at the site included paints, paint thinners, oils, coal tar, resins and other chemicals. The site was placed on the NPL in the fall of 1983 after initial investigation of contamination at the site.

A remedial investigation was conducted by U.S. EPA between August 1983 and August 1984. The RI concluded that site related contamination had migrated into the shallow groundwater. The area groundwater is yielded to wells from weathered fractured bedrock. The low permeability surface soils confine the groundwater and create artesian conditions. The mechanisms for groundwater discharge reported in the RI[1] are:

- Flow through fractures to the surface
- Flow through fractures to sand lenses and waste cells
- Flow directly from bedrock to waste cells excavated into bedrock
- Discharges from waste cells in the form of leachate

The discharge of contaminated groundwater and the possibility of contact with contaminated soils was evaluated in the 1985 feasibility study.

The feasibility study documented excessive cancer risks posed by exposure to contaminated on-site soils and contaminated groundwater.[2] The FS also documented an environmental threat to area wetlands and surface waters from the continued migration of contaminated leachate into area surface waters. Based on the exposure routes and risks evaluated in the FS, a source control remedy was proposed to mitigate the problems at the site. A multilayer (RCRA type) cap system was to be installed over the landfill and contaminated materials were to be consolidated onto the landfill. The landfill would then be dewatered by use of a groundwater and leachate collection and pumping system. Treatment of the extracted waters would include chemical precipitation, biological oxidation and granular activated carbon adsorption to remove contaminants prior to discharge. Groundwater treatment will continue until the landfill is dewatered and contaminated leachate is no longer being produced.

A ROD was signed on September 27, 1985 selecting the remedial alternative for the New Lyme Landfill.

REMEDIAL DESIGN

During the 10 percent design review conference on May 5, 1987, Ohio EPA project management staff discussed options for borrow sources for cover material with U.S. EPA and Army Corps of Engineers representatives. Many area soils apparently would have been available and met the performance criteria for cap material. In addition to area farmers who had been in contact with the Ohio EPA about providing borrow sources, the Ohio EPA staff had initiated investigation of using a state owned (Ohio Department of Natural Resources operated) wildlife area as a source of borrow material. Ohio DNR was contacted by Ohio EPA staff and negotiations were initiated in August 1987 to begin planning and implementation of the borrow area/lake.

U.S. EPA contractors developed the initial and final design plans for the on-site construction independently of the design of the lake. The design plans included: installation of monitoring and extraction wells, excavation and placement of contaminated perimeter soils and sediments onto the top of the landfill, construction of the wastewater treatment building and systems and construction of the multilayer cap.

The cap system required more soils than would be available on-site. The soils required for construction of the cap included an initial fill/grading layer, a clay liner and a vegetative support layer. The grading layer was placed over the existing landfill surface and would require up to 6 feet of compacted silty soils to fill in depressions and low spots and correct the existing grade to allow placement of the cap. The specifications for the clay liner required a minimum of 2 feet of recompacted clay with permeability less than or equal to 1×10^{-7} cm/sec. A synthetic membrane and drainage layer would be placed directly over the clay layer. A minimum of 2 feet of silt loam would be placed over the synthetic liner and seeded.

Although the contract documents called for 225,000 cubic yard of initial fill, 539,509 cubic yards were required to meet the grading specifications for the job. The contract required 163,000 cubic yards of clay and 163,000 cubic yards of topsoil. The requirements for these materials were considerably closer to the original estimates. The overage for clays and topsoil was less than 10,000 cubic yards.

LAKE DESIGN

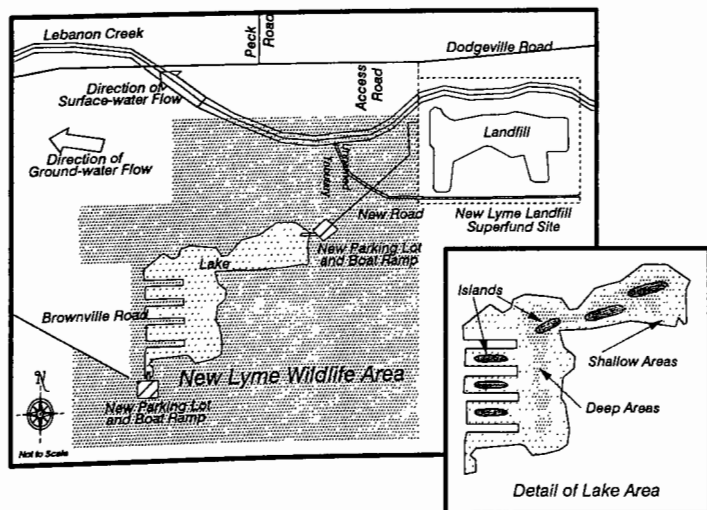
Ohio DNR personnel worked in conjunction with Ohio EPA, U.S. EPA and Army Corps of Engineers representatives to develop design plans for the lake borrow area that would meet the needs of both the remedial project and the development of the wildlife area. Figure 1 shows the outline of the lake and the adjacent landfill. The lake occupies approximately 80 acres of land and has 60 acres of open water. The wildlife area contains a total of 500 acres of mixed woodland and brushland.


Figure 1
New Lyme Wildlife Area

The Ohio DNR has designed the lake to optimize habitat for waterfowl and fish. The deeper portions of the lake are 17 to 20 feet deep. The stumps removed during the clearing of the land have been consolidated into stump "islands" that will provide subsurface habitat for fish. Additionally, two wooded islands were left intact and surrounded by stumps. The lake will be stocked with Bluegill, Channel Catfish and Largemouth Bass. The narrow fingers along the western end of the lake were designed to provide shallow surface water intermixed with woodland to provide habitat for wood ducks and other game species.

The wildlife area has supported limited populations of wood duck, mallard, black duck and blue winged teal in the past. The addition of the lake should allow larger populations to nest in the area. Access to the area will be improved as the haul road will be converted into a public entrance road, gravel parking area and boat ramp. The area used for access during clearing of the borrow area will be converted to a second small gravel parking area and boat ramp.

The landfill area is 1/4 mile from the lake, and the access road will pass adjacent to the western edge of the site. The landfill has been completely fenced to prevent any possibility of exposure to the public. The access road does not provide unlimited access to the site so better access should not promote excessive human interference with nongame wildlife in the area.

IMPLEMENTATION OF REMEDY

With the exception of some weather-related delays and some construction problems during construction of the water treatment plant, the implementation of the remedy proceeded according to planned schedules. The excessive spring rains of 1989 caused delays soon after the borrow area had been cleared and prior to placement of site fill. During the process of clearing the land, Corps of Engineers and Ohio DNR personnel identified nesting areas that were left undisturbed until nesting was completed.

After the beginning of summer weather, the contractors worked double shifts to put the project back close to its original schedule. The continuous streams of truck traffic for 17 hour days would have created substantial public relations and traffic problems had it been necessary to move the source material along public roadways. Even the number of truck trips would have been greater because the large off-road type trucks could not have been used on public roads.

As mentioned above, that the amount of initial fill material required had been underestimated substantially. Fortunately, the plans for the lake had been designed so that the size of the lake could be fairly easily changed if demands for borrow material changed significantly. The completed lake was somewhat smaller than the maximum possible size agreed to by the Ohio DNR had agreed to. The initial fill material exceeded the permeability standards required for the soil layer. As a result, many areas of the landfill have a low permeability clay layer that is considerably thicker than the required two feet.

The problems encountered during the construction of the cap were all site-related. No implementation problems were created or in any way caused by the use of the wildlife area as a borrow source. The early season, rain delays caused construction to continue past the normal construction season and an early winter storm caused damage to the landfill cover and liner over a portion of the edge of the landfill. The addition of the fill material and cover in a year of heavy spring rains apparently increased the pressure on the artesian system and caused leachate outbreaks that had to be handled during construction. Gas generation caused some problems during the installation of the HDPE liner material.

COST BENEFITS

The most obvious benefit derived from the use of the wildlife area as a borrow source was the decreased cost of acquiring borrow material. The Army Corps of Engineers estimates that the cost of purchasing soils would have been doubled had the soils been procured from an off-site property owner. Soil excavation and placement costs totaled more than $3,800,000 for the project as completed; purchase of those soils would have cost at least another $3,500,000.

Even if the soils had been donated in exchange for construction of a lake or farm pond in another location, the cost of transporting the soils over a greater distance would have been higher. Off-site transportation of soils over public highways would have caused considerable wear and tear on the road surfaces that would have added to the cost of the project. The on-site haul road was compacted and smoothed to a great extent by the passage of many trucks.

The intangible dollar benefit resulting from the construction of an improved wildlife area cannot be determined. Ecological cost or ecological benefit can not be assessed in simple terms. The environmental assessment of the project supported the decision to exchange terrestrial wooded habitat in order to enhance aquatic habitat in the area. After a few years of operation, the Ohio DNR should be able to begin to evaluate the effectiveness of the lake system in terms of improvements in local wildlife populations and improved hunting and fishing in the area.

CONCLUSIONS

It is much easier to present this information than it was to accomplish this project. In addition to all of the difficulties involved in coordination of a Superfund Remedial Design/Remedial Action, an additional effort was expended by Ohio EPA project management staff and personnel from the other agencies to implement a creative solution to a common problem. The fortuitous location of the state-owned wildlife area is something that cannot be planned, but it is something that can be investigated at other sites. One of the most difficult aspects of managing Superfund projects at the state level is the public perception that the program is not providing any tangible benefits and is much too slow to correct apparently obvious problems. When an obvious benefit can be derived through implementation of a remedial action, project management staff should be encouraged to coordinate creative solutions to reap those benefits. The New Lyme project has been well received by the local community and the local media, and the image of all of the agencies that were involved has been enhanced by their association with this project.

ACKNOWLEDGMENTS

We would like to acknowledge all of the people who have participated in this project. Most of the agencies involved have been listed in the text and the list of individuals whose individual and group contributions to this project have contributed to its success is too long to list without inadvertently omitting someone who deserves recognition.

Risk Assessment Versus ARARs in Wisconsin: A Case Study

M. Carol McCartney, Ph.D.
Stephen D. Johannsen
RMT, Inc.
Madison, Wisconsin

ABSTRACT

This case study illustrates conflicts between the application of state applicable or relevant and appropriate requirements (ARARs) for groundwater and the use of risk assessment for making remedial action decisions. The Algoma Landfill does not comply with state ARARs for benzene, iron and manganese in the groundwater. The state benzene standard (0.67 μ/L) is expected to be revised to the MCL (5 μ/L) and the timing of that change is critical to this site. If the ROD is signed before the revised ARAR is promulgated, the ARAR for benzene at this site will remain at 0.67 μ/L and the site will not comply. If the ARAR is promulgated before the ROD is signed, the site will not meet ARARs for iron and manganese, only. Wisconsin groundwater standards elevate federal secondary (public welfare) drinking water standards to enforceable status as groundwater protection standards. Under Superfund, these become ARARs and can then be applied as cleanup standards. In either case, risks at this site are low; but in spite of an endangerment assessment which shows risks within acceptable levels, Superfund remediation could be driven by standards that are fundamentally nonenforceable guidelines. Furthermore, such a remediation disregards results of the base line risk assessment in providing a basis for determining whether remedial action is necessary.

An RI conducted by the PRPs for the Algoma Landfill, in accordance with an agreement with U.S. EPA Region V, in 1988 and 1989. The RI Report included an Endangerment Assessment (EA) performed under the Risk Assessment Guidance for Superfund.[1] The results of that assessment included the following:

	Cancer Risk	Exposure Route	Hazard Index	Exposure Route
Current Land Use	1 x 10⁻⁶	soil ingestion	0.004	soil ingestion
Future Land Use	1 x 10⁻⁶	soil ingestion	0.02	groundwater ingestion

The risk estimates are at the 10⁻⁶ point of departure and the hazard index estimates are both below 1.0, the level of concern. Although some uncertainties exist, risk estimates for this site, based on maximum rather than reasonable maximum exposure, are within the target risk range for Superfund sites of 10⁻⁴ to 10⁻⁶.

INTRODUCTION

CERCLA Section 121 requires remedial action to meet promulgated state standards that are ARARs if they are more stringent than federal ARARs.[2] State criteria must be "promulgated" and "more stringent" to be potential ARARs. Promulgated requirements are defined as those of general applicability that are legally enforceable. When ARARs are not available or are not sufficiently protective, the 10⁻⁶ risk level is to be used as the point of departure for determining remediation goals. When the ROD is signed, ARARs become frozen for that site, unless the new ARAR is substantially more protective of human health and the environment.

The groundwater quality regulations in Wisconsin Administrative Code NR 140[3] are ARARs for Superfund sites in Wisconsin. NR 140 includes standards for substances of public health concern (e.g., aldicarb, arsenic, atrazine, etc.) that are similar to the Maximum Contaminant Levels (MCLs) under the Federal Safe Drinking Water Act. The NR 140 standard for benzene was 0.67 μ/L, but it has recently been revised to the MCL (5 μ/L). That revision, however, has not become effective; and if the ROD for the Algoma Landfill is signed before the effective date of the revision to NR 140, the ARAR for the site will be "frozen" at 0.67 μ/L. The maximum benzene concentration reported at this site was approximately 3 μ/L, which is a concentration between the old and the new ARARs.

NR 140 also includes standards for substances of public welfare concern (e.g., chloride, color, copper, etc.) that are equivalent to the Federal Secondary MCLs. Because NR 140 is an ARAR, the Federal SMCLs that are incorporated into NR 140 become ARARs, even though SMCLs are "nonenforceable limits intended as guidelines for use by states."[4] The Algoma Landfill does not comply with these standards for iron (300 μ/L) and manganese (50 μ/L). Wisconsin groundwater standards elevate Federal SMCLs to enforceable status as groundwater protection standards; and, under Superfund, these ARARs become enforceable cleanup criteria that are not related to public health risk.

The stated purpose of the base line risk assessment is to provide "a basis for determining whether remedial action is necessary and justification for performing remedial actions."[1] Because there are ARARs, risk (or its absence) is ignored and the CERCLA mandate to protect public health and the environment is superseded by the mandate to comply with state ARARs.

RISK ASSESSMENT

Site Description

The Algoma Landfill is located in Kewaunee County, approximately 2 miles west-southwest of the City of Algoma, Wisconsin. The City operated the landfill from 1969 until 1983 on seven acres of leased land. The landfill was licensed as a solid waste disposal facility and it accepted mainly municipal refuse during its operation; however, certain industrial wastes were disposed there.

The RI was conducted by the PRPs. RMT, Inc. of Madison, Wisconsin, was retained by the PRPs to provide consulting assistance for preparation of the RI/FS.

The RI was conducted to determine the nature and extent of the release or threatened release, if any, of hazardous substances at or from the Algoma Landfill.[5] Based on the findings of the RI, an FS was conducted to identify and evaluate alternatives for the appropriate extent of remedial action, if any, to prevent or mitigate the migration, release or threatened release of hazardous substances at or from the landfill.[6,7] The goal of the RI/FS is to gather information sufficient to generally characterize the site and support remedy selection.

The RI Workplan for the Algoma Landfill, which was approved by U.S. EPA Region V, identified air, surface water and groundwater as potential migration pathways for landfill-derived constituents. The air pathway was considered in the workplan to be of historical interest only, since the landfill was capped in October 1983.[8]

The RI Workplan identified surface water run-off as a potential transport mechanism of waste constituents by intermittent streams draining south and east from the landfill to wetlands and cedar bogs.[8]

A conceptual model of groundwater flow identified three potential mechanisms for transporting landfill constituents to human and environmental receptors. These mechanisms are: shallow groundwater transport discharging to surface water; groundwater movement through the shallow sand and gravel aquifer to private wells; and deep groundwater movement through the dolomite aquifer to private wells.[8]

Table 1
Summary of Risk Estimates

	CARCINOGENIC RISK ESTIMATES					
Exposure Scenario	Worst Case[a]			Reasonable[b]		
	Total Risk[c]	Route-Specific Risk[d]	Routes[e]	Total Risk[c]	Route-Specific Risk[d]	Routes[e]
Current Land Use	2×10^{-5}	2×10^{-5}	Soil ingestion	1×10^{-6}	1×10^{-6}	Soil ingestion
Future Land Use/RMEI	2×10^{-5}	2×10^{-5} 3×10^{-7} 1×10^{-7}	Soil ingestion GW ingestion VOC inhalation	1×10^{-6}	1×10^{-6} 3×10^{-7} 1×10^{-7}	Soil ingestion GW ingestion VOC inhalation
Future Land Use/MEI	2×10^{-5}	2×10^{-5} 3×10^{-6} 1×10^{-6}	Soil ingestion GW ingestion VOC inhalation	5×10^{-6}	3×10^{-6} 1×10^{-6} 1×10^{-6}	GW ingestion Soil ingestion VOC inhalation

	NONCARCINOGENIC HAZARD INDEX (HI) ESTIMATE					
Exposure Scenario	Worst Case[a]			Reasonable[b]		
	Total HI	Route-Specific HI	Routes	Total HI	Route-Specific HI	Routes
Current Land Use	0.02	0.02	Soil ingestion	0.004	0.004	Soil ingestion
Future Land Use/RMEI	0.04	0.02 0.02 0.0003	GW ingestion Soil ingestion VOC inhalation	0.02	0.02 0.0004 0.0003	GW ingestion Soil ingestion VOC inhalation
Future Land Use/MEI	0.2	0.2 0.02 0.002	GW ingestion Soil ingestion VOC inhalation	0.2	0.2 0.02 0.002	GW ingestion Soil ingestion VOC inhalation

[a] WORST-CASE estimates include some data that may not be representative of the site.

[b] REASONABLE estimates include reduction of total risk by removing contributions from questionable constituents or concentrations.

[c] TOTAL RISK is the total excess upper bound lifetime cancer risk summed across all appropriate routes for each exposure scenario.

[d] ROUTE-SPECIFIC RISK is the risk contributed by the individual exposure routes.

[e] ROUTES are the exposure routes that contribute to the risk.

GW   ground water

VOC   volatile organic compound

MEI   maximally exposed individual

RMEI   reasonable maximally exposed individual

The RI consisted of separate evaluations of soils, surface water and groundwater according to the U.S. EPA CLP. CLP analytical methods and associated QA/QC were used to analyze various samples for volatile organics, semivolatiles, pesticides/PCBs and metals.[5]

Discussion

The purpose of the risk assessment was to characterize the nature and estimate the magnitude of potential risks to public health and the environment caused by the constituents of concern identified at the Algoma Landfill. The assessment considered the risks which might exist to exposed populations under current site conditions and assessed potential future risks by evaluating assumptions of future events or land use which might increase exposure and, therefore, risk. In both the current and future land use scenarios, it was assumed that no corrective actions would occur at the site; thus, the assessment served as a base line risk assessment for the site. The risk analysis process was performed according to the Risk Assessment Guidance for Superfund: *Human Health Evaluation Manual (HHEM) Part A.*[2] The analyses were based on information collected during the Site Investigation in 1984, the RI conducted in 1988 and 1989 and the ongoing quarterly groundwater monitoring under Wisconsin solid waste authorities (NR 180).

Assessment of risks from environmental contaminants involves identification of constituents of concern, routes of migration and populations potentially exposed to the constituents of concern. This information is then integrated to estimate intake for a given population, which, in turn, can be compared to toxicological information to arrive at an estimate of health risk. Interpretation of the risk values must be made in light of the numerous uncertainties and assumptions incorporated into the risk calculation. Thus, risk values do not represent precise probabilities of the frequency of occurrence of disease. The risk values are most appropriately used to identify potential problems and to support an informed risk management decision regarding the remedy that appears to be most appropriate for a given site.

Risk assessments under Superfund are intended to "focus on providing information necessary to justify action at a site and to select the best remedy for the site."[1] The goal is to produce a streamlined assessment that facilitates determination of "what actions are necessary to reduce risks, and not to fully characterize site risks."[1] The risk assessment for the Algoma Landfill met these goals.

Results

Results of chemical analyses were used to develop a list of constituents of concern that were evaluated by the risk assessment following the guidance provided in the *Human Health Evaluation Manual (HHEM).*[1]

The risk and hazard index estimates for current and future land use exposure scenarios are summarized in Table 1. Worst-case and reasonable estimates are provided for each exposure scenario. The uncertainty in the worst-case estimates is high because some questionable data, particularly for arsenic in soils, are included in these estimates. If this questionable concentration is reduced to the next highest value, more reasonable estimates of risk result.

The reasonable estimates, while probably better estimates of total risk than the worst-case estimates, are still uncertain. The factors contributing to the uncertainty include the following:

- Using maximum concentrations to estimate average exposure concentrations

Table 2
Potential ARAR and TBCS*: Groundwater

Constituents of Potential Concern	Maximum Reported Concentration (μg/L)	WI[a] NR 140 ES (μg/L)	WI[a] NR 140 PAL (μg/L)	FED[b] DWS MCL (μg/L)	FED[c] DWS MSLG (μg/L)	DWEL[d] μg/L
Chloroethane	3	--	--	--	--	--
1,1-dichloroethane	2J	850	85*	--	--	--
Benzene	3.9	0.67	0.067*	5	0*	--
1,1,1-trichloroethane	18	200	40*	200	200*	1,000*
Butylbenzyl phthalate	22	--	--	--	--	--
Diethyl phthalate	3J	--	--	0*	--	--
Barium	166Bm	1,000	200*	1,000	5,000[g]*	--
Iron	13,100Em	300	150*	300[f]*	--	--
Manganese	400Em	50	25*	50[f]*	--	--
Potassium	26,100	--	--	--	--	--
Sodium	89,300Em	--	--	--	20,000*	--

Data Qualifier

J - Value is estimated below Contract Required Quantitation Limit (CRQL).
Bm = Reported value is below Contract Required Detection Limit (CRDL) but above instrument detection level (IDL).
Em = Value is estimated due to matrix interferences.
-- No standard, requirement, or criterion.
(a) WI NR 140 ES = Wisconsin Administrative Code NR 140 Enforcement Standard, October 1988.
(b) FED DWS MCL - Federal Drinking Water Standard Maximum Contaminant Level (USEPA, 1989a).
(c) FED DWS MCLG = Federal Drinking Water Standard Maximum Contaminant Level Goal (USEPA, 1989a).
(d) DWEL Drinking Water Equivalent Level (USEPA, 1989a).
(e) Proposed (other promulgated).
(f) = Secondary MCL.
* - TBC (To-Be-Considered Criteria).

- Exposure pathways, such as air, that were not dealt with quantitatively
- Generally using maximum exposure factors in the intake equation
- Using toxicity values with low confidence ratings and high uncertainty factors
- Not estimating risk or hazard quotient for the compounds with no toxicity values

Despite these uncertainties, the risk and hazard index estimates presented in Table 1 provide information sufficient to support an informed risk management decision regarding this site because the estimates are based on, wherever appropriate: the standardized assumptions, equations and values in the *HHEM*;[1] maximum exposure concentrations; and reasonable maximum exposure scenarios.

APPLICABLE OR RELEVANT AND APPROPRIATE REQUIREMENTS (ARARS)

A summary of the chemical-specific potential ARARs and TBCs for groundwater at the Algoma Landfill site is presented in Table 2. The ARARs assessment for the Algoma Landfill followed the protocols outlined in the draft U.S. EPA guidance *CERCLA Compliance with Other Laws Manual, Part I*[4] and *Part II*.[2] Where more than one ARAR exist for a chemical, the more stringent value is reported in Table 2. If no ARAR exists, a TBC is reported. If an ARAR and a TBC exist, the ARAR is reported.

The potential ARARs for groundwater at the Algoma Landfill are, according to U.S. EPA Region V and the Wisconsin NR 140 Groundwater Standards, as follows: 1,1-dichloroethane, benzene, 1,1,1-trichloroethane, barium, iron and manganese. There are no potential ARARs or TBCs for the following: chloroethane, butylbenzyl phthalate, diethyl phthalate, potassium and sodium.

At the Algoma Landfill, the concentrations of 1,1-dichloroethane, 1,1,1-trichloroethane and barium are below the ARARs.

The ARAR for benzene (0.67 μ/L) has been proposed by the Wisconsin Department of Natural Resources (WDNR) to be revised to the MCL (5 μ/L). This change is expected to become effective in October of this year. At that time, the Algoma Landfill will be in compliance with the ARAR for benzene. However, if the ROD is signed before that time, the ARAR for the site will be frozen at 0.67 μ/L for benzene.

The ARARs for iron and manganese are public welfare related standards (NR 140.12) rather than public health related standards (NR 140.10). Iron and manganese are both essential nutrients. The iron standard is based on the aesthetic effects of taste and iron staining of fixtures and clothing. The manganese standard is based on taste and color.

CONCLUSIONS

The risk estimates for the Algoma Landfill Superfund site are below the 10^{-6} point of departure for reasonable maximum exposure and are within the range of acceptable risks (10^{-4} to 10^{-6} as defined by U.S. EPA[9] for worst case maximums. For both scenarios, the hazard indexes are below 1.0, the level of concern.[1] The site does not meet ARARs, however, for iron and manganese in the groundwater and it may exceed the ARAR for benzene. The revised state benzene standard is not an ARAR until after its effective date, which may be after the ROD is signed. The remediation plan based on ARARs for this site does not address the CERCLA mandate to protect public health and the environment and it disregards the stated purpose of the base line risk assessment which is to provide "a basis for determining whether remedial action is necessary and justification for performing remedial actions."[1] ARARs drive the cleanup even though risks from the site are low. The justification for remedial action is to meet ARARs which could have as their basis nonenforceable guidelines like SMCLs.

Improving The Superfund Peer Review Process

Joanne M. Giordano
Sheila H. Conway
Steven T. Senior
ICF Kaiser Engineers
Edison, New Jersey
Karen A. Reed
U.S. Environmental Protection Agency, Region II
New York, New York

ABSTRACT

As part of the U.S. EPA efforts to implement the 90-Day Study, U.S. EPA Region II used the principles of Total Quality Management and worked closely with all U.S. EPA regional offices, 10 state Superfund programs and four U.S. EPA Superfund contractors to conduct a study of the Superfund program's peer review process nationwide. Some key recommendations for federal and state representatives and contractors which will enable them to improve the efficiency and quality of the peer review process include: early comprehensive planning; clear, documented and consistent communication; respect and understanding for different value systems and priorities; and achieving early agreement on applicable or relevant and appropriate requirements.

INTRODUCTION

In 1989, the U.S. EPA issued its report on the state of the Superfund program. The study entitled, *A Management Review of the Superfund Program* (also known as the "90-Day Study"), presented facts, observations and the best professional judgement of experts from U.S. EPA and several state Superfund programs, as well as information obtained through consultations with citizens, reporters, Congressional staff, industry and government representatives and communication professionals. The report contained a number of strategies and initiatives to improve the Superfund program, among them, the Superfund program's peer review process. As part of the U.S. EPA's efforts to implement the 90-Day Study, Region II was designated the lead for addressing how to improve the peer review process. ICF Kaiser Engineers (ICF KE) was retained by U.S. EPA Region II to study and analyze the peer review process nationwide and to develop recommendations for improving the process.

Designed to ensure QA/QC on both technical work and policy issues, the peer review process involves a series of internal (within the Superfund program) and external (i.e., other U.S. EPA divisions, the state and Trustees of the Natural Resources) reviews of work plans, investigative reports and decision documents. Ideally, it is a system of "checks and balances" to help guide U.S. EPA Remedial Project Managers' (RPM) activities and decisions. As we learned in the course of our interviews for this project, the term "peer review" has various interpretations. For this document, we use the term peer review as an all-inclusive term that applies to all phases and all groups and individuals involved in the review process for Superfund documents.

This paper describes the strong points as well as potential pitfalls of the peer review process and, more importantly, offers recommendations on how managers from federal and state environmental agencies and their consultants can improve this important area.

METHODOLOGY

Total Quality Management

In conducting this study, we utilized the principles of Total Quality Management (TQM): "a systematic approach to continuously improving the quality of services or products an organization produces." We defined the customers which include the U.S. EPA regions (primary customers) and the U.S. EPA Headquarters and the states (secondary customers). Our intent was to develop a document for the customers by soliciting customer input on program needs and project approaches. We relied on "the experts," or those who do the actual work--the RPMs, state representatives and contractors--because they are in the best position to know how the process can be improved. The tools that we used included analyzing and understanding work processes by creating flowcharts of each region's process; identifying causes of problems, or "cause and effect" using "fishbone" diagrams during interviews and brainstorming sessions; and focusing on improvement efforts by documenting success stories.

Region VII, Kansas City, Kansas
Region VIII, Denver, Colorado
Region IX, San Francisco, California
Region X, Seattle, Washington

Ten State Agencies:
California
Minnesota
New Hampshire
New Jersey
Oregon
Pennsylvania
South Carolina
Virginia
Washington

Four Environmental Consultants
CE Environmental/EC Jordan Company
ICF Kaiser Engineers, Inc.
Ebasco Services, Inc.
PRC Environmental Management, Inc.

Respondents and Survey Instrument

The following respondents were interviewed either in person or by telephone:

- 22 representatives from all 10 U.S. EPA regions
- 21 state environmental agency staff members from 10 states
- Four representatives from environmental consulting firms with extensive experience working with the U.S. EPA's Superfund program.

The participating entities are listed in Table 1.

Respondents were chosen based on personal knowledge of the investigators or from referrals. Given the schedule and need to collect candid, experiential information, this sampling method was considered most likely to yield high quality data. All those interviewed were in a position to know about U.S. EPA programs and policies. It is likely, however, that other viewpoints, problems and suggestions which we did not capture are available.

As a first step in this effort, U.S. EPA Region II requested information on the peer review process from designated leads within all 10 U.S. EPA regions. This information was used to develop a survey instrument with open-ended questions (Fig. 1). All responses were analyzed to uncover themes.

The U.S. EPA is looking at various Superfund processes and trying to effect improvements in Superfund efficiency. The 90-Day Study identified the Superfund peer review process as an area that needs improvement. U.S. EPA Region II has chosen to focus its attention on this area and plans to examine possible solutions to make the peer review process more efficient. This questionnaire will aid U.S. EPA Region II in learning about other regions' peer review processes and defining areas in need of improvement as suggested by the other regions.

1. What is your schedule for peer review activities from the FS stage through ROD; how does the process work; and who is involved?
2. Do you think that your region's current peer review process is adequate? Deficient? Excessive?
3. Are there places in the peer review process where you have consistently experienced delays and/or other problems? What do you attribute these delays/problems to?
4. Are there methods or procedures that you and/or your region have implemented or are planning to try to resolve these problems? What specifically has worked? What has not worked?
5. What could senior management either in your region or at headquarters do to assist you in the process?
6. Are there areas (e.g., administrative support, personnel, scheduling practices) that need improvement? What are they and how should they be improved?
7. If you could change one thing in the peer review process to make it more effective, what would it be?
8. Are there places in the peer review process where quality is lacking?
9. Does your region have a Regional Quality Assurance Officer? What QA/QC techniques does your region use? (e.g., document control)
10. Do you believe that your region's peer review process is consistent within your region? Consistent with other regions?

Figure 1
Regional Peer Review Processes for
Feasibility Studies and Records of Decision

RESULTS AND RECOMMENDATIONS

The following results and recommendations are divided into three categories: (1) general findings about the peer review process, (2) major delays and/or problems with the peer review process and (3) process-specific findings about each stage of the process. The general findings and major delays and/or problems are global in nature and pertain to all phases of the peer review process nationwide. The process-specific findings, on the other hand, pertain to particular characteristics of the peer review process from both a public and private sector perspective.

GENERAL FINDINGS

The Regional Peer Review Process Varies Significantly From Region to Region

The regional peer review process varies in both scope and focus from region to region. For example, many regions are dependent on both the management abilities and choices made by the RPM and the complexity of the site, for the design of site-specific review processes. Other regions rely on a more formal front-end peer review process that focuses on a comprehensive scientific internal scoping process of Work Assignments prior to issuance of the Work Assignments to the contractor.

Most Regions Are Streamlining Their Peer Review Process

Most regions are streamlining their process to promote efficiency and quality of review. For instance, one region is using standardized memoranda on which reviewers write their comments, while another has developed a transmittal form which accompanies review materials and identifies the areas for reviewers to focus on and time-frames for the review to be completed. Another region has developed a data base system and checklist of operating procedures to guide RPMs through the peer review process. Some regions rely on interim deliverables during the Remedial Investigation (RI) to troubleshoot problem areas early in the process.

Most Regions are Formalizing Their Peer Review Process

Many regions have restructured, or currently are restructuring, their peer review process to reflect a more formalized approach and to obtain greater internal consistency in their peer review process. One tool the regions are using to accomplish this formalization of review is a Standard Operating Procedures (SOP) document which outlines review procedures and key personnel.

RPMs Need to be Skilled Managers, Not Subject Matter Experts

Most regions said that the RPM needs to be a skilled manager, not a subject matter expert. The RPM is required to keep projects on schedule and within budget and to serve as the central contact between the internal reviewers, external reviewers, upper management and contractor. Therefore, RPMs need to have management training and experience with some environmental background and the support of an internal or external group of subject matter experts.

MAJOR DELAYS AND/OR PROBLEMS WITH PEER REVIEW PROCESS

RPM Management Experience and Training

Since the RPM is the primary decision-maker in the scoping, peer review and project specific management process, the success of the peer review process and remediation effort is very dependent on the abilities, experience and training of the individual RPM. Thus, lack of managerial ability, unfamiliarity with what is necessary to conduct an RI/FS and lack of training have been cited as leading to delays and/or problems with the peer review process.

State Review

Many regions reported that state agencies are reviewing the U.S. EPA's reports in more detail. The increased state review of Superfund documents has lengthened the time necessary to complete document reviews. This pattern can be expected to continue and become more pronounced throughout the regions as the Superfund programs within the state continue to develop.

Resource Constraints

Shortages of computers, copy machines and insufficient clerical and administrative support have been identified as a problem in several regions. Some of these problems are expected to be alleviated as additional resources resulting from the 90-Day Study become available to the regions.

Appropriate, Adequate and Timely Internal Review

Inter-divisional and inter-agency (e.g., U.S. Army Corps of Engineers)

reviews often are inconsistent. Specifically, since the peer review process is conducted with substantial discretion of the RPM, the variable level of guidance and direction for peer review given by the RPM to other non-Superfund divisions has resulted, at times, in inappropriate review by those divisions.

PROCESS SPECIFIC FINDINGS

Four key indicators have been identified as contributing components to a successful peer review process and, in turn, a successful remediation effort:

* Early comprehensive planning
* Clear, documented and consistent communication
* Respect and understanding for different agendas and priorities
* Achieving early agreement on Applicable or Relevant and Appropriate Requirements (ARARs)

Early Comprehensive Planning

One of the most important elements in ensuring timely, adequate and appropriate review of deliverables and an efficient and successful remediation effort, whether public or private sector initiated, is the early delineation of both a Project Team, to directly support the Project Manager/RPM in his/her efforts and a Review Team, to provide supplemental technical expertise and regulatory review (Table 2). It is crucial that a broad-based, multidisciplinary team be established in order to stimulate creative problem solving and to prevent narrow, provincial biases from dominating the planning process or to prevent an uninformed RPM from making decisions.

Table 2
Project/Review Team Members
Recommended members of the:

Project Team
Multi-disciplinary environmental personnel (hydrogeologist, civil/chemical engineer, risk assessment/toxicologist)
Senior management representation
Legal counsel
Public involvement specialist
Other appropriate parties within the federal or state agency

Review Team
Federal and state environmental agencies
U.S. Army Corps of Engineers
Department of the Interior
Trustees of the Natural Resources
Other Project Managers/RPMs with similar sites
Other appropriate parties within the federal or state agency
Local citizen groups (for sites with high public profile)
U.S. EPA Headquarters (for federal-lead sites)

For private-led cleanup projects, the Project Manager should request the lead government agency (i.e., U.S. EPA or the state agency) to schedule a meeting with those regulatory agencies that will be involved in the consultation and review process for the project. The entire Project Team and Review Team should participate in the meeting in order to facilitate team-building and to ensure clear, accurate communication of project goals, objectives, sampling protocols, expectations and regulatory requirements.

By designating a Project Team at the beginning of the project, the Project Manager/RPM would be creating a unified support network cognizant of every issue related to the site. The Project Team would vested interested in the site because of its "hands-on" involvement from the start of the project and would provide the Project Manager/RPM support, assistance and accountability through the life of the project.

In the case of federal- and state-led site cleanup, the Project Team would also help guide newer Project Managers during the peer review process, compensating for learning curves and inexperience. In the case of private party-initiated site cleanup the Project Team approach allows an early detection of federal and state preferences and ensures that costly delays and repetition of work plans and sampling events are avoided,

significantly reducing the cost of the site investigation.

The Review Team should be relied upon by the Project Manager/RPM to provide supplemental technical expertise and regulatory review. In addition, its involvement at the outset would give the Review Team more information on the site and the Superfund process itself, which, in turn, would enable the Review Team to give appropriate, substantive and specific comments to the Project Manager/RPM.

Clear, Documented and Consistent Communication

Contrary to popular historical practice, clear, documented and consistent communication amongst the various parties has been the single largest contributor to efficient, successful remediation efforts, whether federal, state or private parties initiate the response.

For federal- state-and private-led projects, Work Assignment (WA) and Work Plan Scoping Meetings should be held prior to retaining a consultant. The goal of the first scoping meeting, which will include the Project Manager/RPM and members of the Project Team, would be to develop a comprehensive WA and scope of work for the contractor and to discuss cost estimates and reporting procedures. The results of this scoping meeting and all subsequent meetings should be documented in a memorandum that is distributed to all attendees and placed in a centralized filing system. For subsequent meetings involving the Review Team, a request for exceptions to the meeting summary also should be included. This procedure will allow for early detection of miscommunication and will formally document legitimate differences. This technique will prevent avoidance behavior when faced with complex and controversial issues, for example Data Quality Objectives (DQOs), appropriate sampling techniques or ARARs.

Attendees at the initial Meeting should include the entire Project Team, Review Team, Project Manager/RPM and contractor. Issues and potential problem areas would be resolved during this meeting. Attendees also would discuss and verify the format, style and organization of each document clearly with the Project Manager.

Additionally, the team should consider potential remedial alternatives based on existing knowledge of the site. This point is important because the decisions made determine the type and quantity of samples taken during the RI and the level of quality assurance necessary to support the remediation objectives. The Project Manager/RPM would also provide the contractor, Project Team and Review Team with a schedule of upcoming activities and review cycles so that the contractor and reviewers could plan their schedules accordingly. In particularly large, complex and/or sensitive sites, the formal development of SOPs for coordination purposes has proven to be helpful.

Furthermore, the Project Manager/RPM in consultation with the Project and Review Teams should decide whether to direct the contractor to develop phased interim deliverable reports. This review method that has been successfully utilized, particularly in large and complex sites, to reduce costs and streamline schedules. Factors affecting whether to use phased interim deliverable reports during the RI/FS include:

* The size of the project, in terms of the duration of the RI/FS and the complexity of the site
* Public sensitivity and need to be regularly informed

Finally, the Project Manager/RPM and the Project and Review Teams should discuss and concur on the style, format and organization of all key documents thereby preventing disagreements late in the peer review process and multiple revisions.

A large component of the delay during the peer review process originates from inadequate direction to the contractor. By meeting with the contractor early and discussing components of the project with all the "key players," the Project Manager/RPM would provide the contractor with clear and accurate directions from which to develop the Work Plan and conduct the RI.

Respect and Understanding for Different Agendas and Priorities

One of the most significant miscommunications that occur during hazardous waste cleanups is the assumption that all parties have the same agenda, i.e., the successful remediation of a site. While in the broadest sense it is certainly true that all parties desire a successful

remediation effort, in today's complex and often contradictory regulatory climate, many differences, priorities and regulatory obligations may face federal agencies, private parties and even regulatory groups within one federal agency. It is naive to assume that good intentions and a broad public mandate to clean up the environment can or will mask the many contradictory priorities within and outside of government.

Successful Project Managers/RPMs are those that can integrate various agendas, priorities and administrative and regulatory obstacles into a schedule and plan for remediation. Recognizing these elements and then factoring them into the work plan and schedule early in the process, probably will be the single most effective technique in maintaining budget and schedule. Periodically, particularly at key milestones within the project, the priorities of the parties involved should be reevaluated.

While an agency such as the U.S. Army Corps of Engineers (COE) may express little interest at a project's outset, significant interest may be stimulated if the RI findings suggest an impact on wetlands. No matter how irrelevant or inappropriate other agendas may seem, the values, positions and authority of other state, federal and local agencies can either keep your project moving forward or stop it dead in its tracks.

Achieving Early Agreement on Applicable or Relevant and Appropriate Requirements

Agreement on ARARs and potential remedial alternatives is consistently a source of conflict between federal and state agencies, Trustees of the Natural Resources, environmental groups, potentially responsible parties (PRPs) and the general public. Typically, these conflicts occur at the very end of the process when the Proposed Plan is being developed and presented for comment.

To avoid the delays inherent in that conflict, ARARs and potential remedial alternatives must be discussed and agreed upon much earlier in the process. In fact, the Project Manager/RPM and Project and Review Teams should discuss ARARs as early as the Work Plan Scoping Meeting to mitigate "last-minute" conflicts or major changes, facilitate maintaining the project schedule and prevent any ARARs from being overlooked.

ARARs and potential remedial alternatives should be finalized by the Feasibility Study (FS) Scoping meeting. At this meeting, attendees would define the problem and concur on remediation goals, cleanup levels and affected media requiring cleanup. As was mentioned earlier, formal memoranda or letters of agreement for key decisions and ARARs agreed upon at these scoping meetings should be prepared and distributed to the attendees and upper management. Formalization of these decision points provides guidance to inter-divisional reviewers in delineating the parameters of their review and keeps the FS focused on project objectives.

Upper management officials, who are the key decision-makers, should be brought into the process of establishing ARARs, cleanup goals and remedial alternatives early so that they are familiar with the project goals, remedial objectives and areas of concern as voiced by the various agencies and division representatives present at the early FS meeting. By including the key decision-makers early in the project planning phase, the Project Manager/RPM will avoid time and cost delays, last minute disagreements and misunderstandings. Upper management, in addition to having a broad view of policy issues, often has significant preferences for presentation and organization. Consulting these key managers early will reduce the likelihood of substantial revisions at the last minute.

Lastly, lack of public acceptance of potential remedial alternatives can extend public comment periods and delay the peer review process. The public is not often considered a "key reviewer," though it actually is and public review and acceptance of the Proposed Plan is an important component to the successful and timely completion of a remediation effort. Early and clear communication of site issues during the process, including ARARs and potential remedial alternatives, allows the public to "own" portion of a proposed remedy and increase public acceptance. Public review can be accomplished by enlisting the aid of citizen advisory groups, conducting public or small group meetings after the completion of the RI but prior to the evaluation of alternatives in the FS and/or publicizing the availability of Technical Assistance Grants (TAG) which often are under-utilized.

Soil Cleanup Goals for Total Petroleum Hydrocarbons

ABSTRACT

Spills of petroleum product cause contamination of soil, surface water and groundwater and can lead to human health impacts. Soil is remediated at spill sites to prevent impacts to public health. This paper presents a survey of criteria used by the southeastern states to determine soil cleanup levels for petroleum releases and the rationale for selecting these levels. Experience at a site in North Carolina is used as an example to evaluate state cleanup levels for petroleum releases.

Total petroleum hydrocarbons (TPH) is an analytical test used to determine the presence and extent of spilled petroleum products (gasoline, waste oil, etc.). Cleanup levels usually are developed for a specific compound based on human health or environmental effects. Since TPH detects a mixture of hydrocarbons, different cleanup levels have been developed using various rationales. This variability presents a problem for owners, contractors and consultants implementing cleanup at petroleum-contaminated sites. Requirements differ from state to state, in different areas of the same state or in the field based on site conditions.

Cleanup guidelines for petroleum releases were obtained from the eight states within U.S. EPA Region 4. A comparison is made of the guidelines and rationales used for setting guidelines. All states indicated soil criteria were set to prevent impacts on the groundwater, as an existing or future drinking water supply. Evaluation of data from a case study indicates that TPH is useful in evaluating the extent of a spill but does not focus cleanup on areas of greatest public health concern as indicated by BTEX. A case study shows that the area indicated for remediation based on a state criterion of 10 ppm for BTEX (South Carolina and Tennessee) is less than half of the area indicated by a cleanup level of 100 ppm TPH (Alabama, Georgia and Tennessee) and about one fifth the area indicated by a cleanup level of 10 ppm TPH (North Carolina). Cleanup criteria are inconsistent between states, which can result in substantial differences in the extent and cost of remediation.

INTRODUCTION

Public health and environmental impacts from releases of petroleum products represent a significant problem. In the states within U.S. EPA Region 4, investigated in this report, as well as in many other states, petroleum releases have been shown to be the cause of the largest number of site investigations. Contamination by petroleum products is of concern due to potential health and environmental effects from some constituents which adsorb to soil or migrate into air or groundwater. This paper reviews established cleanup levels used to remediate organic compounds in contaminated soils. While criteria for metals are available, this paper only evaluates criteria for organic compounds.

There are no federal standards for soil cleanup. Individual states have promulgated their own standards or guidance levels to determine whether remediation of soils is necessary. Various factors go into the selection of cleanup levels. These include the composition of different petroleum products, geological and hydrogeological characteristics of the site and land and water uses in the area. TPH analysis has been used to determine if soil cleanup is necessary. This analysis does not specifically identify concentrations of contaminants that pose a health risk.

IDENTIFICATION AND CHARACTERIZATION OF CONSTITUENTS IN PETROLEUM PRODUCTS

Petroleum products include a wide range of fuels and oils such as crude oil; natural and liquified gases; gasolines; middle distillates such as kerosene, jet fuel, diesel fuel and heating oils; lubricating oils; and residual oils. This paper considers those in liquid form at standard temperature and pressure. The chemical composition of different fuels and oils varies and in most cases is not completely defined; the composition varies depending on the type of crude oil and fractionation process used to produce the product. Constituents include paraffinic, naphthenic, aromatic and sulfur-containing hydrocarbons; some nitrogen and oxygen-containing compounds; and a variety of metals.[1] From 100 to 150 compounds have been identified in gasoline, although more are known to be present.[2]

The most toxic components of petroleum products have been described by some as the aromatics, including benzene, toluene, ethylbenzene and xylene (BTEX), with toxicity decreasing from olefinics to naphthanes and paraffins.[1] Benzene in gasoline and carcinogenic polycyclic aromatic hydrocarbons (caPAHs) in certain heavy residual oils have also been identified as the components of greatest concern due to their carcinogenicity.[3] CaPAHs include benzo(a)anthracene, benzo(a)pyrene, benzo(b)fluoranthene, benzo(k)fluoranthene, chrysene, dibenz(a,h)anthracene and indenopyrene.

Given the range of chemicals that make up petroleum products, the behavior of oils and fuels in the environment is not fully understood. Components that are soluble in water and have low adsorption coefficients, such as aromatics (BTEX), have the greatest potential to migrate into the groundwater. Compounds with higher molecular weight (carcinogenic PAHs) are less water soluble, have higher adsorption coefficients and, as a result, tend to remain adsorbed to the soil for longer periods of time. Lower molecular weight compounds such as BTEX also have higher vapor pressures, indicating a tendency to volatilize into the air, resulting in surface contamination, or into soil pores.[3] Modeling by Fleischer et al.,[4] provides information on the environmental partitioning of thirteen petroleum constituents. Table 1 presents the partitioning of the thirteen constituents and Table 2 presents the migration pathways of the different compounds.

STATE CRITERIA

Soil cleanup criteria for Alabama, Florida, Georgia, Kentucky,

Table 1
Relative Environmental Partitioning of Petroleum Constituents

Petroleum Compound	Adsorption onto Soil Particles (%)	Volatilization (%)	Soluble Portion in Groundwater and Soil Moisture (%)
Benzene	3	62	35
Ethylbenzene	21	59	20
(n)Heptane	0.1	99.8	0.1
(n)Hexane	0.1	99.8	0.1
(n)Pentane	0.1	99.8	0.1
Benzo(a)anthracene	100	0	0
Benzo(a)Pyrene	100	0	0
Napthalene	61	8	31
Phenanthrene	68	2	10
1-Pentene	0.1	99.8	0.1
Phenol	9	0.01	91
Toluene	3	77	20
(o)Xylene	15	54	31

Mississippi, North Carolina, South Carolina and Tennessee (U.S. EPA Region 4) are summarized in Table 3. All of the states set soil criteria based on the prevention of groundwater contamination. In addition, certain states have also set criteria to protect surface waters and prevent exposures to contaminated surface soils. In most cases, states will consider variances or modifications of criteria based on land use, site-specific geologic and hydrogeologic conditions and results of a risk assessment. Soil criteria are available for:

* Total petroleum hydrocarbons - 7 states
* Benzene, toluene, xylene (BTX) or BTX and ethylbenzene (BTEX) 5 states
* Halogenated hydrocarbons - 1 state
* Polycyclic aromatic hydrocarbons (PAHs) 1 state
* Volatile organic compounds (VOCs) 1 state

Three states provide different soil criteria depending on the type of fuel contamination. State criteria are discussed in greater detail below.

Alabama

In Alabama, TPH cleanup levels are only used for underground storage tank (UST) sites.[5] The soil cleanup concentration is 100 ppm TPH, provided that the soil is at least 5 feet above groundwater. At non-UST sites, cleanup is determined on a case-by-case basis. Factors evaluated are background concentrations; surrounding site conditions such as land use and well supplies; and applicable or relevant and appropriate requirements. The state's goal is to develop a reasonable program using site circumstances and potential risk.[5]

Florida

Laboratory methods of determining contamination, as opposed to field screening techniques, were rejected by the state of Florida due to the turnaround time, cost and a lack of numerical standards, as is explained in the state's guidelines document.[6] Measurement of total hydrocarbons was selected over measurement of individual compounds because toxicological data are limited and additional health effects may be identified. A flame ionization detector (FID) was chosen for measurement because it is sensitive to hydrocarbons of interest. U.S. EPA data from gasoline spill sites were used to establish that a FID reading of 500 ppm was roughly equal to a total hydrocarbons concentration of 10 to

20 ppm in soil. This concentration has been shown by U.S. EPA and the state of California to not result in adverse groundwater effects.[6] The FID measurement is made in the headspace of a jar sample. State regulations are supplemented by more stringent criteria in different counties of Florida due to local aquifer protection plans. Cleanup levels as low as 10 ppm on the FID are required in some areas.

Georgia

The main factor in selecting soil-cleanup levels for Georgia is distance from well supplies.[7] If a public supply well is within three miles or a private supply well is within a half-mile, then the cleanup level is 100 ppm TPH or 20 ppm BTEX. Groundwater contamination is assessed only where soil remediation is required. When sites are not within the distances to well supplies given above, soil cleanup is required when TPH concentrations are above 500 ppm or BTEX concentrations are above 100 ppm. In these cases, monitoring of the groundwater is required.

Kentucky

Recent state regulations include a provision to propose soil cleanup levels based on the results of site-specific risk assessments; however, since the regulations are new, no risk-based cleanup levels have been submitted to date.[8] Historically, the state has required cleanup to background levels, generally meaning to nondetectable levels. The constituents to be monitored depend on the spill material: BTEX is required at gasoline spill sites; PAHs at diesel fuel and motor fuel sites; and TPH at waste oil sites.[9] State guidelines require sampling of soil, groundwater, surface water and sediment potentially affected by contaminant migration from the site.[9]

Mississippi

A soil criterion of 100 ppm TPH is used at virtually every UST diesel fuel site. For gasoline spills and leaks, there are no criteria for TPH; instead the criterion of 100 ppm BTEX in soil is used. Land use is considered and could result in higher cleanup levels. For example, at an automotive garage or a wood preservative plant, the criterion used could be higher, given sufficient technical basis.[10] Documents are not

Table 3
State Criteria

STATE	SOIL CLEANUP LEVELS	COMMENTS
Alabama	• 100 ppm TPH in soil if more than 5 ft above groundwater	Set to protect groundwater Variances from criteria based on risk assessments
Florida	• 500 ppm on FID • 10 to 500 on FID if groundwater affected	Set to protect groundwater Dependent on location in the state, aquifer conditions and future use of the site
Georgia	• 100 ppm TPH or 20 ppm BTEX within 1/2 mile of private well or 3 mi of public well • 500 ppm TPH or 100 ppm BTEX for other cases	Set to protect groundwater Dependent on proximity to well supplies
Kentucky	• Background levels or detection limits • Analysis for gasoline BTEX • Analysis for diesel/motor fuel PAH • Analysis for waste oil TPH	Set to protect groundwater and surface water Recent changes in the state regulations include a provision for a risk assessment
Mississippi	• Diesel fuel. 100 ppm TPH in soil • Gasoline 100 ppm BTEX	Set to protect groundwater. Value could increase on site-by-site basis, based on land use
North Carolina	• TPH - 10 ppm • Halogenated hydrocarbons - Det limit	Set to protect groundwater and prevent surface soil exposure Could increase based on site sensitivity evaluation • potential for direct exposure • proximity to water table • contaminant class • soil characteristics
South Carolina	• Gasoline and light products 10 ppm BTEX • Heating oil and heavy products 100 ppm TPH	Set to protect groundwater Variances based on site-specific conditions and a risk assessment
Tennessee	• Drinking water area BTEX 10 - 100 ppm TPH 100 500 ppm • Non-drinking water area BTEX 50 - 500 ppm TPH 250-1000 ppm	Set to protect groundwater Level based on soil permeability Variances based on land use, depth to bedrock, aquifer characteristics, chemical constituents, and toxicity

available to explain the technical basis for the criteria; however, ground-water cleanup goals are associated with soil cleanup goals, indicating that the soil criteria are based on preventing migration into groundwater.

North Carolina

State guidelines state "...soil remediation shall be conducted in order to eliminate potential threats to human health and/or welfare resulting from exposure to contaminated materials and prevent further environmental degradation resulting from leaching of contaminants into the groundwater."[11] Action levels are provided for TPH (10 ppm) and halogenated hydrocarbons (detection limit). The guidelines indicate that while screening methods for VOCs, including ion detectors, are useful in the field, they cannot replace recommended laboratory analytical methods for final cleanup. A site-sensitivity evaluation (SSE) allows for higher action levels where contaminated soils are five or more feet above the seasonal high-water table or bedrock and where direct contact with the soil does not occur.[11] The SSE is based on soil pH, grain size, contaminant class, distance from seasonal high water table and bedrock, presence of a confining layer, time since the release occurred, presence of sedimentary structures and textures and presence of artificial conduits within the zone of contamination. Criteria based on site-specific conditions or a risk assessment would also be considered.[12]

South Carolina

Cleanup levels for soil in South Carolina are guidelines, not legal regulations. Criteria were developed from those used by other states in the southeast.[13] Different analyses and concentrations are used for light and heavy petroleum products. The guideline for gasoline and similar substances is 10 ppm BTEX. For heating oil and heavy substances, the guideline is 100 ppm TPH. Other factors, such as groundwater use in the area, depth to the water table and soil conditions, are assessed to determine the necessary site cleanup.

Tennessee

State criteria are dependent on whether the site is located in a drinking water or nondrinking water area and the permeability of soil in the vicinity of the site. The state provides two technical documents outlining the determination for drinking water area and soil permeability classifications. The following criteria are available.

Criteria can be modified based on other site-specific variables, however no site-specific variances have been submitted to date.

DISCUSSION

Soil criteria for TPH are available for seven of the eight states investigated and range from detection limits to 500 ppm. Protection of groundwater for use as a drinking water supply is the basis for the criteria; however, a calculation of TPH levels in soils from safe groundwater levels is not available from the states. Instead, reference to criteria used in other states within and outside of Region 4 and an interest in being as protective or more protective is made.

Guidance provided by the state of California has been cited in conversations with personnel from agencies within the states investigated. The California guidelines are based on preventing migration of BTEX into groundwater. A model is used to predict the potential for leaching of BTEX and the percentage of BTEX in gasoline and diesel fuel is used to estimate a TPH level that prevents BTEX impacts on groundwater. Other investigators have evaluated whether a commonly used TPH criterion is likely to result in groundwater concentrations of BTEX below federal drinking water standards.[3] These investigation showed, through modeling, that soils with TPH levels of 100 ppm can result in benzene concentrations above groundwater standards for some petroleum releases, specifically petroleum naphtha, gasoline and waste oils.

Compound-specific analytical testing is required by four of the states. Criteria for BTEX and PAHs have been provided, with the goal of focusing cleanup efforts on chemicals that affect human health. In some cases, such as in the state of Kentucky, a requirement to analyze for specific compounds is dictated by the type of petroleum product released into the environment, with the intent to focus the cleanup on the toxic

components felt to be the most prevalent in the petroleum product.

The state of Tennessee provides a range of cleanup levels depending on the soil permeability at the site being investigated. North Carolina goes a step further by providing a range of cleanup levels dependent upon a variety of site conditions such as soil pH, grain size, contaminant class and other conditions described above.

CASE STUDY

In August and September 1989, an investigation was conducted at a fire fighting training area within an air force base in North Carolina. The primary petroleum product used at the site was jet fuel, a middle distillate similar to kerosene with some components of light distillates like gasoline. Thirteen borings and five monitoring wells were completed. A total of 57 soil samples from the borings and monitoring wells and a groundwater sample from each of the wells were analyzed. Several seeps were observed issuing from the hillside below the site; three samples of the seeps and their associated sediment were collected. All samples were analyzed, using the U.S. EPA methods for total petroleum hydrocarbons, volatiles and semivolatiles. The data were used to write a preliminary report on site contamination.

Geologic and hydrogeologic conditions at the site are fairly simple. There is a surficial sandy aquifer 20 to 30 feet thick comprised of 90% fine to medium sand and 10% silt and clay. Underlying this is a relatively impermeable unit at least 40 feet thick comprised of 55% clay, 31% silt and 14% fine sand. The groundwater table ranges from 2 to 5 feet below ground. Flow direction is downhill in the direction of the topography. Slug tests in two wells indicate the velocity of flow is approximately 0.06 feet per day in the upper sandy aquifer.

Analysis of soil and sediment samples indicated that concentrations of TPH were present at numerous locations. Of the 60 samples of soil and sediment analyzed, 10 had TPH levels below the detection limit (4 ppm), 8 had TPH between the detection limit and 10 ppm, 15 had TPH concentrations between 10 and 100 ppm, 8 had concentrations between 100 and 999 ppm and 19 had concentrations of 1,000 ppm or higher. The highest concentration measured was 44,000 ppm.

In spite of such widespread TPH concentrations, almost no benzene was detected in the soil. Of the 60 soil samples analyzed, only 6 had a benzene concentration greater than 1 ppm and only two had a concentration greater than 5 ppm. These samples contained 6.4 ppm and 9.9 ppm benzene and occurred near the highest TPH concentrations. A review of total BTEX data indicates that 8 soil samples had a concentration greater than 10 ppm and 2 of these were greater than 100 ppm.

The high TPH concentrations did not reflect high caPAH concentrations in the soil. CaPAHs were detected in only one sample at low concentrations of 1.8 ppm for chrysene, 1.6 ppm for benzo(a)anthracene, 1.2 ppm for both benzo(b)fluoranthene and benzo(a)pyrene and less than 1 ppm for benzo(k)-fluoranthene and indenopyrene. The sample containing caPAHs was in a different location from those containing benzene.

Prior to drilling borings and monitoring wells, a soil-gas survey was conducted to determine the area of contamination. An area of approximately 55,000 ft^2 contained OVA readings greater than 500 ppm. This area is similar in size and location to the one containing BTEX readings greater than 10 ppm (Table 4). Although an OVA is nonspecific in measuring organic vapors, it was sensitive to the BTEX compounds in soil.

To illustrate how the criteria from states within Region 4 would affect

Table 4
Approximate Cleanup Areas in the Case Study

Criteria	Area (ft^2)
BTEX over 100 ppm	16,000
BTEX over 10 ppm	55,000
VOC over 500 ppm*	55,000
TPH over 100 ppm	140,000
TPH over 10 ppm	265,000

* Total volatile organic compounds as measured with an OVA.

the level of cleanup at this site. Table 4 presents criteria for BTEX, TPH and total volatile organic compounds (VOCs), as measured on an OVA and the corresponding areas of remediation. The areas indicated for cleanup based on BTEX concentrations greater than 10 ppm and OVA readings greater than 500 ppm are similar. The TPH cleanup levels of 100 ppm and 10 ppm would result in a cleanup of an area 2.5 and 5 times larger than the area required using a BTEX cleanup level of 10 ppm.

Data from the site have shown:

* Soil at petroleum-spill sites can have high TPH levels and little or no benzene present. This contain may be due in part to partitioning of the benzene so that almost all is either volatilized into air or leached into groundwater.
* High TPH levels do not indicate high caPAH levels in soil at this site where the release is mainly jet fuel.   The OVA data greater than 500 ppm correlated well with data on BTEX concentrations greater than 10 ppm. This supports work presented by Florida and its use of this field-screening method. This method provides no specific information on BTEXs and would not be suitable where a mixture of petroleum spills and solvents has occurred.
* The extent of site remediation required varies greatly depending on which state's criterion is used. Soil remediation of 140,000 ft² area would be necessary at the case study site based on state criteria of 100 ppm for TPH. Less than half that area would be remediated using a cleanup criteria of 10 ppm BTEX and about one tenth the area using 100 ppm BTEX.

CONCLUSIONS

States within U.S. EPA Region 4 have established different soil cleanup levels, using various rationales, for petroleum release sites. Soil cleanup criteria generally are based on laboratory analysis of TPH or FID measurements of VOCs. A few states provide chemical-specific criteria for BTEX and PAHs. Additional criteria are based on the type of petroleum product released, groundwater use and soil permeability. TPH criteria have been estimated based on the percentage of and the leaching potential of BTEX in petroleum products and precedence set by other states.

Cleanup criteria are inconsistent between states which can result in substantial differences in the extent and cost of remediation. Data from a site in North Carolina indicate that a soil cleanup criterion of 10 ppm for BTEX will limit the cleanup to less than one half the area required if a TPH criterion of 100 ppm were used and approximately one fifth the area required if the TPH criteria of 10 ppm were used.

If soil cleanup levels are to be based on health concerns, then analysis of toxic components of petroleum products and cleanup criteria for the

same components are needed. At sites with gasoline and light and middle distillate products, samples should be analyzed for BTEX. Evaluation of caPAH was found not to be useful at a site contaminated with jet fuel. Others have indicated that sites with oils and heavier products samples should be analyzed for caPAHs. Given the number of petroleum release sites investigated and the variety of site conditions and petroleum products encountered, a range of criteria for different chemicals in different solutions should be established.

Hanford Site Past Practice Investigation Strategy

K. Michael Thompson

IT Corporation
Richland, Washington

ABSTRACT

The Department of Energy's Hanford Site contains over 1000 CERCLA and RCRA past practice mixed waste sites which must be cleaned up under the Hanford Federal Facilities Agreement and Consent Order. These sites have been grouped into 78 source and groundwater operable units and many of the units also contain RCRA TSD units which must be closed or permitted to operate under Washington State's Dangerous Waste Regulations. Each operable unit must undergo either a RI/FS under CERCLA or a RCRA Facility Investigation/Corrective Measures Study (RFI/CMS) under the RCRA Corrective Action Program.

The complexity of working with mixed wastes, the need to conduct numerous RI/FSs simultaneously and the focus on obtaining large quantities of data to provide a high degree of certainty for decision-making, has caused the schedules to become very long (ranging from 3.5 to nearly 7 yr) and the costs to grow well beyond initial expectations. Further, because the initial efforts have shown that excessive time is required to gather data, the parties to the Agreement have become concerned that actual cleanup could not begin in an appropriate and timely manner. In response to these problems, a new strategy is being developed to integrate CERCLA and RCRA requirements into a singular process for Hanford, to provide for expedited response actions and to provide a streamlined study process which maximizes use of existing data for decision-making and at the same time manages uncertainty effectively.

INTRODUCTION

In May 1989, the U.S. EPA, the Washington Department of Ecology (WDE) and the U.S. Department of Energy (DOE) entered into an Interagency Agreement to provide a legal and procedural framework for cleanup and regulatory compliance at numerous hazardous waste sites at the DOE Hanford Facility located in southeastern Washington State. This Interagency Agreement, called the Hanford Federal Facility Agreement and Consent Order (Agreement), divided the Hanford Facility into four aggregate areas (the 100, 200, 300 and 1100 Areas), each of which has been included on the U.S. EPA's NPL.

Under the Agreement, the more than 1000 inactive waste disposal and unplanned release sites have been grouped into 78 past practice operable units (74 source operable units and four groundwater operable units which underlie the source units). The contamination, a result of past disposal practices and other releases, is in the form of solely hazardous waste, radioactive mixed waste and other hazardous substances defined by CERCLA.

Also covered by the Agreement are 55 RCRA TSD groups which will be closed or permitted to operate under the state's RCRA authority. Some of these RCRA TSD groups are physically located within the past practice operable units. Past practice operable units which contain a RCRA TSD unit as the primary contributor to the contamination have been designated as RCRA Past Practice subject to cleanup under the RCRA Corrective Action authority. Conversely, those operable units which involve primarily CERCLA releases are designated as CERCLA Past Practice subject to cleanup under CERCLA authority.

The Agreement requires that Hanford cleanup programs integrate the requirements of CERCLA, the federal RCRA/HWSA and the dangerous waste program enforced by the state. The Agreement includes all CERCLA removal and remedial actions and RCRA/HSWA corrective measures and requires integration of RCRA interim status compliance, RCRA permitting and RCRA closure activities which apply to the TSD units.

While the U.S. EPA maintains authority for CERCLA, WDE has received authorization from the U.S. EPA to implement the state's dangerous waste program in lieu of the federal RCRA program. In addition, the state has received authorization to implement the U.S. EPA's radioactive mixed waste program. The state does not yet have HSWA authority, and that authority remains under the U.S. EPA. The U.S. EPA is the lead regulatory agency for CERCLA Past Practice operable unit cleanup and WDE is the lead agency for RCRA Past Practice cleanup.

As a result of the complex regulatory involvement coupled with the sheer size of the cleanup program, a major challenge of the Agreement is to coordinate, in a cost-effective and timely manner, the different requirements of CERCLA, RCRA corrective action and RCRA TSD activities, in many cases at the same physical location.

The Agreement requires that comprehensive work plans for conducting either RI/FS or RFI/CMS be submitted for each of the 78 operable units according to a predescribed priority defined in the Agreement and that each operable unit be treated as a separate entity for the purposes of conducting the RI/FS. The Agreement requires that 20 RI/FS or RFI/CMS work plans be submitted to the regulatory agencies by April 1992 and that six per calendar year be submitted thereafter until all operable units are covered. RCRA Part B permit applications and/or closure plans must be submitted for all 55 RCRA TSD units by May 1996. Specific milestones are defined in the Agreement for the near-term work plans and RCRA permit/closure plans. A major milestone is included in the Agreement for completion of all RI/FS (RFI/CMS) by 2018.

Experience to Date

The experience gained to date on developing the work plans and permit applications has shown a need for refining the strategy of RCRA/CERCLA integration beyond that specified in the Agreement to provide for greater uniformity in the applicability of requirements

to the Hanford Facility. Because of the complexity of working with mixed wastes, because the need to conduct numerous large RI/FSs simultaneously strains available resources, and because the Agreement requires data collection which provides a high degree of certainty for decision-making, the schedules for the initial few RI/FSs have become very long, ranging from 3.5 to nearly 7 yr. For the same reasons, the costs of the RI/FS programs have shown growth well beyond initial expectations. Further, because the initial work plans have not provided for any cleanup actions to commence until after the ROD following the RI/FS, DOE and the regulatory agencies have become concerned that too much time and resources would be spent before evidence of actual cleanup could be demonstrated.

The lessons learned from development of the first few work plans have also shown that there is a need to more closely integrate source and groundwater operable units such that the information gained from each of the investigations is in sync and available for input into the source and groundwater risk assessments to be conducted in parallel. Also, since a groundwater operable unit covers an area which encompasses several source operable units, many of which are scheduled for investigation much later in the program, there is a need for early identification of the specific sites within each operable unit which are significant contributors to groundwater contamination. The three parties to the Agreement acknowledge that these significant contributor sites, even though not scheduled to be addressed for a long time, should be brought forward into the overall investigation and risk assessment for the aggregate area.

All parties to the Agreement have now recognized that past practice investigations must be managed and implemented under one characterization and remediation strategy regardless of the regulatory agency lead and the applicable regulations (CERCLA or RCRA Corrective Action). A need also has been identified to better coordinate and integrate past practice investigations and schedules with RCRA permitting and/or closure activities.

Finally, the long schedules and resultant high costs associated with traditional past practice investigations have given the parties a new perspective on the need to streamline the RI/FS and RFI/CMS processes.

Armed with the knowledge gained by past experience, the parties to the Agreement have set out in a cooperative effort to formulate a new strategy for addressing Hanford's cleanup problems which would streamline the programs for greater schedule and cost-effectiveness while minimizing lengthy investigations and paper studies.

STRATEGY

The acceptability and use of existing environmental data is a pivotal element to making the RI/FS process work more efficiently. There is a huge body of existing environmental information at Hanford dating back to the beginnings of the facility in the early 1940s. While much of the data were not collected under the rigorous procedures in use today, there exists a wealth of information. Although the data utility could be limited if viewed only for the utility and validity of individual data points, taken as a whole, the data are good for showing trends, for use in planning and possibly for making action decisions. Making maximum use of existing data and providing for uncertainties in the decision-making process would reduce the number of new samples required, which would in turn allow expediting treatability and feasibility studies as well as cleanup actions. Accepting that a level of uncertainty will ultimately exist in the data and data analyses for each decision is imperative if the process is to be streamlined.

Remedial investigations tend to be conducted for long periods of time because data uncertainty makes the highly subjective decision of when to stop sampling very difficult and hard to defend.

Methodical approaches for addressing the issues of data acceptability and uncertainty will draw from two existing concepts: the U.S. EPA's Management Systems Review[1] (MSR) and the Observational Approach.[2] The MSR concept proposes to limit field sampling episodes by defining objectives and acceptable uncertainty through structured planning and quantification. The Observational Approach proposes to address uncertainty of data and data analyses in the decision-making process by first defining the expected (probable) conditions and reasonable deviations to those conditions. The decision can then be

proposed with contingencies defined to address the probable deviations. The uncertainties remain, but the uncertainties are now quantified and contingencies are in place such that timely action can proceed without first having to conduct lengthy investigations and studies.

Three basic tenets of the observational approach are:

- Characterization should be undertaken for a specific purpose, such as the selection of a remediation technology, not just to study contamination or site characteristics
- More data do not necessarily lead to less uncertainty
- Convergence on a response action as early as possible is the goal.

Acceptance of uncertainty, within reasonable constraints, and reasonable contingency planning are synergistic in this approach.

The U.S. EPA Management System Review identifies a process to expedite the feasibility and treatability study processes. Feasibility studies are proposed to be initiated in the scoping stage, where possible, and are limited to as few realistic technologies as possible. In this way, evaluation of remedial alternatives becomes a process of starting with what is likely to work (based on existing information) and making adjustments later if significantly different contaminants or conditions are found. This approach has considerable advantage over the traditional methods of identifying and screening large arrays of alternatives and justifying why the unselected alternatives are unlikely to work. Early consideration of probable remedial technologies and alternatives thus allows focused data collection to obtain only the data needed to evaluate and implement the most probable remedial alternatives, thus limiting multiple field sampling episodes.

The MSR also proposes to conduct treatability studies during the early stages of the RI. Since treatability testing is costly and time consuming, a limited number of promising technologies, identified in the early feasibility studies, would be tested.

Another major aspect of the Hanford strategy is the initial evaluation of existing data on an aggregate area basis. These aggregate areas would provide the basis for detailed assessment of all operable units contained within the aggregate area prior to the development of RI/FS or RFI/CMS work plans. The aggregate area would be delineated to encompass the geography necessary to define and understand the local hydrologic regime, the distribution and migration of contaminants emanating from the target source terms, the interaction of those source terms and the area necessary to provide defensibility for both conceptual and numerical models. Existing data would be gathered and interpreted for the entire aggregate area. These data include all that are normally presented in RI/FS reports. The quality of existing data would be assessed and any need for verification would be identified. Conceptual models would be developed. Data needs would be assessed for: full development of the conceptual model; input to numerical models that assess performance and risk; and completion of site characterization, treatability studies, etc. Process information for the facilities would be gathered and assessed so that contamination potential is factored into site characterization.

Having defined the key concepts to be followed, the strategy now ties the concepts together into a methodical approach to decision-making. Paths are defined for conducting the decision process to tailor studies to site-specific conditions, situations and regulatory requirements. The objective here is to find the shortest path to a decision on a permanent solution to the problem and the shortest path to interim remedial actions or removal actions which start solving the problem as quickly as possible. Each path in the decision process constantly searches for the minimal amount of validated data adequate to justify the decision and provide confidence that the proposed solution will solve the problem. Uncertainty is recognized, but a process is in place to manage that uncertainty by providing contingency solutions.

The approach thus developed, which is referred to as the Hanford Past Practice Strategy, is embodied in the decision flow chart given in Figure 1. The decision chart encompasses an aggregate area as the basic unit for study and application of the principal concepts of the strategy. Each of the major elements and decision blocks of the chart is described below:

The Aggregate Area Management Study

In the first element of the strategy, an Aggregate Area Management Study (AAMS) is performed for a given aggregate area. The AAMS is similar in nature to a scoping study as defined in 40 CFR 300.430(b) and proposed 40 CFR 264.511. Both of these regulations are designed to characterize the release of hazardous substances at sites considerably less complex than Hanford. The intent of the AAMS is to:

- Assemble, validate and evaluate existing data
- Identify the need for interim response actions
- Identify likely contaminants, response scenarios and likely remedial technologies, i.e., perform a limited feasibility study
- Focus and minimize new work
- Identify data gaps and uncertainties
- Provide for the opportunity to perform limited new site characterization work if critical data gaps exist and/or uncertainty needs to be reduced. This procedue is similar in concept to Preliminary Assessment/Site Investigation (PA/SI) studies or the RCRA Facility Assessment (RFA) process
- Build defensible conceptual models for further site characterization and for the development of performance assessment models and proposed remedial actions

A key element to the AAMS process is conduct of a limited FS. Existing site and contaminant knowledge would be used to identify and screen likely remedial alternatives as early as possible. Early identification of remedial alternatives and technologies allows for focused data collection during early preliminary studies or during the early RI phase.

The AAMS culminates with the AAMS Report. This document, similar to RI/FS or RFI/CMS reports, contains the knowledge gained from the AAMS. The intent of the report is to present to the regulators and to the public data and analyses so that specific additional studies and analyses can be agreed upon.

If an AAMS Report is prepared, it would be fully integrated with subsequent operable unit work plans which would be focused on confirmatory or verification studies. The AAMSR would address the entire aggregate area, whereas the RI/FS (RFI/CMS) work plan would only address those sites or operable units for which additional work is necessary.

Expedited Response Actions

Concurrent with the AAMS, and throughout the duration of the AAMS, the question of whether an expedited response action is justified would be addressed. The assessment of this question would be iterative and continuous as new data are collected and analyzed. Expedited response actions (ERA) are one of several methods the U.S. EPA is looking at to improve the efficiency and effectiveness of Superfund response actions.[3] Revisions of the NCP redefine the response categories of removal actions and remedial actions so that removals now include all activities formerly considered immediate removals, planned removals and Initial Remedial Measures (IRMs). The purpose of the ERA is to accomplish rapid cleanups by streamlining the RI/FS process for operable units or sites where the most effective mitigation method is readily evident.

If there is justification for an ERA, then it must be decided whether immediate action is justified because of an imminent and substantial endangerment situation or whether an expedited response action is necessary but not time-critical.

The data would be assessed and judgement would be applied to evaluate the potential threat to human health (public and Hanford workers) and the environment. Consideration would be given to the immediacy and the magnitude of the threat, the nature of available actions and the implications of delaying the action until after the ROD is issued. In addition, the value gained from implementing the action would be evaluated in light of impacts to the overall Hanford cleanup effort.

If an imminent and substantial endangerment situation is found to exist and the decision is made to perform a removal action, the action would not preclude continuation of the AAMS. The AAMS would proceed in tandem with the abatement process. To respond rapidly,

activities would be carried out in parallel. These activities would include collection of data relating to selection and design of the preferred remedial alternative. Performance standards would be set by the regulators within their regulatory authority.

An assessment would be made of the removal action performance when it is possible to do so. If performance is judged adequate to justify terminating the remedial investigation process, a limited feasibility report and a risk assessment adequate to support the no-further-action decision would be prepared to support the record of decision. The decision to terminate the RI process would be made by the lead regulatory agency in consultation with the other regulatory agency.

A removal action which does not involve an imminent and substantial endangerment situation could cover a wide range of actions. Such action might involve relatively simple actions such as removal of surface contamination or buried drums. Other cases might involve relatively complex and more significant actions such as pump-and-treat groundwater cleanup efforts for source containment or mass reduction, in situ stabilization of waste sources, or managing groundwater injection and withdrawal to stabilize contaminant plumes. Such actions might also be designed to assist in gathering data useful in later feasibility or treatability studies if and when further action becomes necessary. Analogous to the previous discussion concerning imminent and substantial endangerment abatement decisions, these non-time-critical removal actions would not necessarily stop the ongoing investigation process. The investigation would continue in parallel to the removal action.

RI/FS

Once the AAMS Report is issued, a decision would be made whether to proceed with a full RI/FS or whether one or more elements could be bypassed depending upon the state of knowledge at that point. If sufficient validated data exist from the AAMS to complete a more formal FS without conducting a full RI, then the path diverts to completing the FS and writing the FS report. If necessary, additional focused field work could be done to obtain only those validated data necessary to support and complete the FS.

The fundamental principle involved here is that it is not necessary to fully characterize a site before cleanup decisions can be made. The NCP and proposed RCRA Subpart S regulations do not actually require completion of the RI/FS or RFI/CMS before taking corrective actions, i.e., these are only means to an end. The requirement is only that sufficient information be known from which a defensible decision (the ROD) can be made. This requirement means that the process can be streamlined with a certain degree of risk taking shared by all parties involved.

If the AAMS shows that substantial additional validated data are necessary before the FS could be completed, then the path reverts to a more typical RI/FS or RFI/CMS process requiring a complete work plan. The objectives of the work plan would be to describe the field and interpretive techniques needed to fill gaps in the available data, provide verification of data quality (existing and new) and, if necessary, refine the conceptual model identified in the scoping studies. Information gained through removal actions, remedial actions and expedited feasibility and treatability studies also would be factored into the work plan.

Groundwater investigations would be performed under a groundwater (or aggregate area) operable unit work plan. A parallel effort covering vadose zone investigations would be included in the priority (most significant contributor) source operable unit work plan. The groundwater/aggregate area work plan would provide for a screening investigation of potentially significant source term areas outside the priority source operable unit. This approach would be taken when there is a high probability that such source terms are contributing or may significantly contribute to near-term groundwater contamination. Reprioritization of operable unit rankings might result from this process. In such a situation, it would be appropriate to consider performing a definitive and exhaustive RI/FS on the first operable unit of each type. Subsequent investigations would use the findings of the definitive RI/FS to refine data needs for investigations of similar operable units.

These subsequent operable unit studies would be used to verify

findings and assumptions of the primary RI/FS or RFI/CMS investigations as they apply to similar operable units, in addition to providing site-specific information necessary to support a ROD or permit modification. Documentation in work plans, investigation reports, RODs and associated review requirements would thus be reduced. Additionally, reviews of work plans and reports would be performed in parallel by DOE and the regulatory agencies. This process could significantly reduce the time required to produce these documents, thus accelerating the decision-making process.

The U.S. EPA has recognized efficiencies in expediting treatability studies when obvious technologies can be selected early in the process.[1] Once the need for treatability testing is identified in the AAMS, collection of samples needed for bench-scale treatability tests can be scheduled to occur early in the RI. Results could be available for use during detailed evaluation of remedial alternatives and would indicate whether a technology would or would not meet ARARs and other risk-based criteria. If not, there would be less time lost in the evaluation of other alternatives.

CONCLUSION

The Hanford cleanup is a highly complex and massive effort involving compliance with a great number of laws, regulations and procedures whose application and integration are virtually unprecedented on this scale. Cleanup will be long and costly. Existing regulatory frameworks for conducting studies and for making decisions must be reshaped to allow for more efficient use of existing data, for more timely cleanup actions and for better management of uncertainty.

Waste Reduction Technical Assistance Programs: Supporting Business & Industry in Ensuring A Sustainable Future

Robin A. Day
Roger L. Price, P.E.
Center For Hazardous Materials Research
The University of Pittsburgh Trust
Pittsburgh, Pennsylvania

INTRODUCTION

Waste minimization, waste reduction, source reduction and pollution prevention are terms with one underlying philosophy: it makes far more sense not to produce waste than to develop costly schemes to control it. This concept is receiving a tremendous amount of attention these days. William Reilly has stated that pollution prevention is one of the U.S. Environmental Protection Agency's top priorities, several corporate pollution prevention programs are being highly publicized, including 3M's Pollution Pays program, and several states are considering legislation to enforce waste reduction by industry. It appears that pollution prevention will be the environmental issue of the 1990s.

Indeed, pollution prevention is an environmentally sound strategy for companies to control their waste production. But pollution prevention is not just an environmental issue; pollution prevention is an economic issue. Pollution prevention is the premier waste management strategy because, unlike pollution control which costs money, pollution prevention saves money. Reduction in the production of wastes reduces treatment, transportation and disposal fees, energy and fuel costs, water and raw materials expenses, long-term liability and insurance, and the administrative costs of record-keeping and reporting requirements. The "waste" in waste minimization is not just waste material, but wasted resources and money. It is rather self-evident that producing less waste reduces all the costs associated with wastes. However, less evident is the fact that the analysis of industrial processes involved in identifying pollution prevention opportunities almost always results in a higher quality product, greater process efficiency and less process downtime. These process advantages all favorably affect the bottom line of a business.

Why then have not all businesses implemented pollution prevention programs? A common response by industry is that pollution prevention is a highly technical issue requiring research to identify new and innovative methods to institute pollution prevention techniques. Pollution prevention thus is viewed as requiring major process changes and the installation of capital-intensive equipment. Yet experience has shown that some of the greatest gains in pollution prevention are made with little or no capital expense, and data indicate that waste generation across all industries can be reduced by 50% with existing technology.

What has become apparent is that the greatest barrier to pollution prevention is old attitudes. For many years, we have thought of waste management as an unfortunate cost of doing business. We grudgingly hired engineers to handle waste control problems and invested a great percentage of our revenues into environmental compliance. As the regulations grew in number and complexity, we increased our environmental staff and budget. We are finding, however, that this is not a road which leads to a sustainable future. Industry cannot afford the costs and liabilities associated with coping with unabated pollu-

tion. The old attitudes must be replaced by the new attitude that waste reduction is a sound investment both ecologically and economically.

Where then does this scenario lead us? Very few companies can implement a pollution prevention program without assistance. The initial need is for technical assistance programs to supply the support system needed to reshape the long-held end-of-pipe perspective of today's businesses. Education, information and tools will enable the industrial community to effectively reduce their wastes. Technical assistance programs cannot provide all the answers. Pollution prevention methods are highly case-specific, and there is no single technology applicable in all situations even within a specific industrial process. Therefore, taking advantage of the enormous opportunities for pollution prevention requires that the desire to reduce waste be part of the everyday consciousness of all employees. What technical assistance programs can, and should, provide are the tools and the methodology for implementing pollution prevention techniques.

In response to the urgent need for nonregulatory technical assistance in waste minimization and pollution prevention, the not-for-profit Center for Hazardous Materials Research (CHMR) at the University of Pittsburgh operates a comprehensive, state-wide technical assistance program in Pennsylvania. Although there is room for all sectors of society to become involved in pollution prevention, there is a particularly great need for nonregulatory technical assistance programs to provide pollution prevention assistance. The fear of federal regulation authorities that permeates most of the business and industrial community continues to frustrate the best intentions of many pollution prevention programs in regulatory agencies.

CHMR was established in 1985 to provide users of hazardous materials and generators of hazardous waste with cost-effective, practical information on waste management and waste reduction. Since then, the program has expanded to include cross-media pollution prevention. Pennsylvania has a particular obligation to provide solutions to some of the pressing hazardous waste problems. Pennsylvania currently is ranked fourth in the nation in the production of hazardous waste and second in the number of Superfund sites. As an agricultural state, Pennsylvania is a major user of pesticides and fertilizers, and 60% of the population depends on groundwater for drinking water.

Funded by $35,000 in seed money from the University of Pittsburgh, CHMR set out to solve these problems in partnership with industry and government. CHMR now has a staff more than 50 drawn from industrial, regulatory and academic communities. In 1986, CHMR was awarded a $259,000 grant by the U.S. EPA to create and implement the state-wide Technical Assistance Program. This program, currently funded in part by a grant from the Pennsylvania Department of Environmental Resources, continues to focus on waste minimization as the primary method of pollution abatement.

The experience of CHMR's Technical Assistance Program has demonstrated that technical assistance services are needed to respond to businesses whether they are completely unaware of pollution prevention or have already instituted a successful program. Pollution prevention assistance can be divided into three phases: motivate, educate and support.

First, businesses that are unfamiliar with pollution prevention most often request a definition of the concept and its application. This definition of what the words mean is essential as a first step, as is preaching the pollution prevention ethic. If you do not succeed in motivating a company to pursue pollution prevention opportunities, a successful program, even if instituted by coercion or enforcement, is unlikely to be successful. It cannot be overstated that committed management and employees are essential to any pollution prevention program. Inspiring businesses, government officials or employees to embrace pollution prevention is a key challenge involving the human component of the pollution prevention picture.

Second, once inspired to pursue pollution prevention, businesses need to be educated in the tools and resources with which to proceed. It is not enough to haphazardly apply pollution prevention techniques. An understanding of the thought processes involved in pollution prevention is essential.

Third, once businesses proceed with instituting a pollution prevention program in their facility, ongoing technical support is necessary. Inevitably, questions will arise as to the availability of particular chemical substitutes or alternative technologies. CHMR's Technical Assistance Program has informational services, training and engineering services that provide a complete support system including motivation and education for pollution prevention.

MOTIVATE

To inform the business and industrial community of both the existence of CHMR's technical assistance program and to motivate companies to investigate the benefits of pollution prevention, CHMR has established a network of organizations assisting in an outreach effort including trade associations, manufacturing associations, chambers of commerce, small business development centers, industrial resource centers, Pennsylvania Department of Environmental Resources and U.S. EPA Region III.

Trade associations have proven to be a major vehicle for reaching the business community. Press releases describing the Technical Assistance Program and announcing new services are sent periodically to associations which, in turn, publicize the program in their organization's publications.

CHMR also publishes articles on pollution prevention in journals, association publications, bulletins, magazines and newsletters. CHMR's speakers' bureau provides experts on pollution prevention to speak at conferences and meetings. In these ways, CHMR reaches out to the business community to promote the value of pollution prevention.

CHMR's quarterly newsletter, *The Minimizer*, currently is mailed to more than 2,000 business people, researchers, legislators, regulatory officials and other states' waste minimization personnel. This four-page publication includes articles written primarily by CHMR staff on waste minimization techniques, recycling, new CHMR services and publications, and other environmental and health and safety issues.

The goal of these services is to inspire businesses to pursue the benefits of pollution prevention.

EDUCATE

Businesses often become convinced of the benefits of pollution prevention, but do not know where to begin. To meet this need, CHMR has established a pollution prevention clearinghouse containing fact sheets, articles, government publications, reports and manuals. The clearinghouse includes CHMR's publications such as industry-specific pollution prevention packets and fact sheets and CHMR's 300-page *Hazardous Waste Minimization Manual for Small Quantity Generators* which received the U.S. EPA Region III's Environmental Education Achievement Award. This easy-to-read manual covers topics such as: how to conduct a pollution prevention audit, financing a pollution prevention program and sources for waste reduction and recycling equipment.

CHMR's pollution prevention seminars and workshops have been attended by more than 400 regulatory personnel, industry representatives and members of the academic community. The first state-wide conference in Pennsylvania addressing waste minimization issues, held by CHMR in the fall of 1987, attracted representatives of government, business, academia and public interest groups. The second conference is being planned for the spring of 1991.

For more complete training, CHMR has developed a 16-hour pollution prevention workshop designed to improve participants awareness and ability to incorporate pollution prevention concepts in their day-to-day job functions. Workshops have been customized for the U.S. EPA regulatory personnel, industry representatives and students. Participants receive a mix of classroom instruction and interactive group exercises with an emphasis on learning the thought processes required to identify pollution prevention opportunities and on recognizing the role of human attitudes in implementing pollution prevention in the workplace. Through workshop activities, participants gain the tools and resources necessary to perform a pollution prevention assessment and institute a pollution prevention program in their own facility.

SUPPORT

Once a business has embraced the pollution prevention perspective, an avenue for ongoing support is essential. The lifeline of the Technical Assistance Program is a confidential, toll-free telephone number (1-800-334-CHMR) which receives more than 150 calls per month. Callers receive answers to their questions on pollution prevention issues as well as regulatory and other environmental and health and safety topics. The Center's telephone is staffed by CHMR technical staff who can either provide the technical assistance immediately or, in the case of more complicated questions, research the particular problem and provide the necessary information within an average of 2 hours.

The telephone center uses a computerized data base system for the logging and tracking of calls. This data base allows the staff to search previous calls for information obtained which may be applicable to other calls. The database includes information about the caller's business such as address, number of employees, business type (SIC code) and inquiry topic. As CHMR develops new services or obtains more updated information, specific mailing lists are developed to target mailings to callers who are in need of the particular service or information.

By providing CHMR with a direct communications link with the business community, the telephone center enables CHMR to design programs in response to the needs that are identified through the calls. Each month internal reports are produced which summarize the types of callers and their concerns or questions. This information is then used to target additional support programs to meet the needs identified by the callers.

The toll-free number is particularly useful to individuals who have specific questions that develop concerning the institution of a pollution prevention program or specific techniques. This type of ongoing support is essential. If a question or problem is too complex to answer by telephone, CHMR provides on-site pollution prevention consultations and assessments. CHMR pollution prevention specialists review facilities' waste streams and processes, identify pollution prevention options and advise facilities how to begin or continue a pollution prevention program. Assistance may include training for employees or the development of guidance manuals. In some instances, research into available alternative technologies for a particular process may be conducted.

To address the need for financial support in demonstrating and instituting pollution prevention technologies, CHMR is managing the U.S. EPA's Office of Small and Disadvantaged Business Utilization's "Pollution Prevention By and For Small Business" grant program. Under this program, approximately $800,000 in grants will be made available to small businesses over a 2-year period.

CONCLUSION

The key challenge for business and industry today is ensuring a sustainable future. Economic development and environmental protection

cannot remain mutually exclusive. To support the business and industrial communities in this effort, technical assistance programs must supply the necessary services for motivating, educating and supporting these communities in their pollution prevention efforts. The opportunities for pollution prevention are great, and it will be through the cooperation of business, government and academia that full advantage of these opportunities can be taken. The present and future role of technical assistance programs is pivotal in this venture. With the support systems in place, all sectors of the business community can discover and implement this lucrative alternative to waste control.

Regulating Hazardous Waste on Indian Lands

Sarah Joyner
PRC Environmental Management, Inc.
Chicago, Illinois

ABSTRACT

Enforcing RCRA Subtitle C regulations on Indian lands is a challenge for both the U.S. EPA and for Indian tribes. The task is to define Indian land, determine regulatory authority and identify hazardous waste on Indian lands. These issues have not been properly addressed by either the Indian tribes or by the regulatory community. As a result, hazardous waste has gone largely unregulated on Indian lands.

To correct these problems, U.S. EPA Region 5 initiated a study of Indian lands. The key goals of Region 5's study are to identify hazardous waste on Indian lands and to educate the tribal governments about RCRA. Information request letters will be sent to the tribal environmental contacts, to the Indian Health Service and to the Bureau of Indian Affairs.

INTRODUCTION

Enforcing RCRA Subtitle C regulations on Indian lands is a challenge for both the U.S. EPA and for Indian tribes. Tribal governments are considered to be sovereign entities, subject to federal jurisdiction. U.S. EPA holds a federal trust responsibility to protect human health and the environment on Indian lands. The challenge is to define Indian land, determine regulatory authority, identify hazardous wastes on Indian lands and promote technology transfer to the Indian tribes.

The term "Indian land" refers to all land within the exterior boundaries of an Indian reservation. Within each Indian reservation, however, there are several types of land ownership, including ownership by non-Indians. This variety of ownership complicates the problem of defining regulatory authority. In addition, most information about hazardous waste operations is tracked by the Hazardous Waste Data Management System (HWDMS). Partly because of errors in HWDMS, there is very little information available on the types of hazardous waste operations on Indian lands. The lack of technology transfer to Indian tribes is a problem because even if RCRA clearly delegated authority to tribal governments, the tribes would need to meet training and health and safety criteria in order to become authorized to regulate RCRA on the reservations. Currently, it would be nearly impossible for most tribes to meet such criteria.

Because of the complexity of these issues, hazardous waste on Indian lands has been addressed at only a few sites, typically after problems have been identified.

To meet the challenges described above, U.S. EPA Region 5 initiated a study of Indian lands. The key goals of Region 5's study are to identify hazardous waste on Indian lands and to educate the tribal governments about RCRA. Information request letters will be sent to the tribal environmental contacts, to the Indian Health Service and to the Bureau of Indian Affairs.

What Is Indian Land?

The problem in defining Indian land is that both Indians and non-Indians can own land on the same reservation. The Indian reservations that were created by Congress during the mid-1800s have undergone significant changes in the intervening years. Non-Indian ownership of land within reservation boundaries is a result of the General Allotment Act of 1887 (also known as the Dawes Act). The Dawes Act divided up land within reservation boundaries and allotted ownership of land to individual tribal members. The concept of property ownership was completely foreign to the Indians, and the concept of property tax was even more so. Many individual Indians subsequently sold their lands to non-Indians or lost their lands because of failure to pay their property taxes. Although allotment ceased by the 1930s, the legacy of policy legacy can be seen today in the checkerboard pattern of Indian and non-Indian ownership that characterizes most reservations.[1]

This complexity of property ownership on Indian lands adds to the problem of determining regulatory authority on Indian lands.

Who Holds Regulatory Authority On Indian Lands?

Although Indian reservations and tribal governments are considered to be sovereign entities, the question of who actually holds environmental regulatory authority on Indian lands is a very complicated issue. Until recently, there has been no clearly defined authority set forth in the environmental regulations. For example, although Section 1004(13) of RCRA includes Indian tribes within the definition of "municipality" and Section 3006 gives state hazardous waste management programs authority over municipalities, Section 3006 does not grant states authority over Indian lands.[2] The Indian Self-Determination and Education Act of 1975 clearly illustrates the intent of Congress to delegate Indian regulatory programs away from the federal government and to the tribal governments as much as possible. The contradictory language between these and other regulations creates the perception of a regulatory "gap" on Indian lands. Despite this perceived gap, the U.S. EPA still holds a federal trust responsibility to regulate hazardous waste on Indian lands. The U.S. EPA's federal trust responsibility extends over more than 83,807 square miles of Indian land and more than 100 federally-recognized tribal governments throughout the United States.

The U.S. EPA has taken the lead among federal agencies in developing policy to interpret regulations such as the Indian Self-Determination and Education Act of 1975 and the President's Federal Indian Policy (January 24, 1983). On November 8, 1984, the U.S. EPA established an Indian lands policy pursuant to the President's Indian policy. The U.S. EPA's Indian policy is based on a nine-point approach that stresses that the Agency will work directly with the tribes on a government-to-government basis, and that the Agency recognizes tribal governments

as "the primary parties for setting standards, making environmental policy decisions and managing programs for reservations, consistent with agency standards and regulations." The overall goal of the U.S. EPA's 1984 Indian land policy fits within the overall Agency goal to protect human health and the environmental quality for all people and all geographic areas in the nation.[4]

In addition to the U.S. EPA's Indian policy, several legal decisions have served to reinforce federal and tribal government authority as opposed to state jurisdiction over Indian lands. For example, in the case of the *State of Washington vs. U.S. EPA*, the Ninth Circuit Court of Appeals affirmed that the U.S. EPA, not the state, is responsible for "ensuring that federal standards are met on the reservations."[3]

Although the U.S. EPA arguably holds both the responsibility and the authority to regulate hazardous waste on Indian lands, very little work has been done on Indian lands to date. Environmental problems can be found in all media on Indian lands. On most Indian reservations, the only types of solid waste disposal are open dumping and burning of garbage, and many reservations are not able to restrict access to the dumps. The potential magnitude of this problem is just beginning to be realized by the regulatory community. There is growing concern that the magnitude of the unregulated waste may be larger than previously anticipated.

In order to address these waste problems, the U.S. EPA and the tribal governments must be able to located and identify hazardous wastes on Indian lands.

Identifying Hazardous Waste on Indian Lands

Identifying hazardous wastes on Indian lands is difficult because the Hazardous Waste Data Management System (HWDMS) data base system, which often is used to track hazardous waste generators, transporters and disposal facilities, has proven to be inadequate for tracking facilities on Indian lands. This is often because either the original Notification of Hazardous Waste form or the Part A Application form was filled out incorrectly. These two forms are the source of much of the HWDS data, and therefore the source of most errors in the data base.

A common HWDMS error that interferes with tracking waste on Indian lands is in the area of property ownership. Both the Notification and Part A application forms include codes that specify the type of ownership - whether a facility is privately owned Indian land (PI), federally owned Indian land (FI) or (M) municipal property. On the Notification form, the "M" code is used to indicate municipally-owned land. However, on the Part A Application form the code "M" is used to indicate that a facility is operated on "public, other than federal or state" land. Therefore, the M code is often incorrectly substituted for the PI or FI codes for facilities or operations located on Indian lands.

This error and other errors commonly found in the HWDMS data base make tracking hazardous waste operations on Indian lands difficult. Most RCRA implementation has been conducted through the states' programs, and since states do not have regulatory jurisdiction on Indian lands, there are very little data available to indicate what types of hazardous waste operations and facilities may exist on Indian lands.

Technology Transfer

Even if RCRA clearly delegated authority to tribal governments, the tribes still would need to meet training and health and safety training criteria in order to enforce RCRA on the reservations. Most tribes currently do not meet the equivalence and capability requirements as stated in RCRA (CITE REG), owing to a lack of resources and the absence of a program of technology transfer from the U.S. EPA to the tribes. To correct this shortfall, technical assistance must be made available to the tribes so that they can exercise their sovereign right to self-regulation. The same resources that have been made available to the states during their regulatory development should now be made available to the tribes.

REGION 5's APPROACH

PRC Environmental Management, Inc. (PRC) was asked by the U.S. EPA Region 5 RCRA Enforcement Branch (REB) to identify opera-

tions located on Indian lands that are subject to RCRA Subtitle C. These operations might then be the subjects of compliance evaluation inspections (CEI).

To identify RCRA Subtitle C operations, the U.S. EPA sorted the HWDMS data base by the ownership codes. Of the 32 Indian reservations in Region 5, seven facilities or operations were found to show either PI, FI or M codes.

PRC contacted each of the identified facilities or operations and determined that of the seven facilities or operations, only two were actually located on Indian lands and subject to RCRA Subtitle C. For five out of the seven facilities or operations, the Notification forms had been completed incorrectly. Table 1 below summarizes the data collected by PRC and the U.S. EPA. The table shows the names of the facilities or operations as they appear in the HWDMS data base. In some cases the names appeared as specific facilities, and in some cases the Notification appeared to be for the entire reservation.

Table 1
Summary of Indian Land Facility Status

Facility Name	State	U.S. EPA Notification Form Code	Located on Indian Lands?
Bookcrafters, Inc.	MI	PI	No
Champion International	MN	M	Yes (Leech Lake IR)
Fort Howard Paper Company	WI	M	Partially (Oneida IR)
Hagglunds Dennison Corp.	OH	PI	No
Koch Fuels	MN	PI	No
Lac Du Flambeau	WI	FI	Yes (Lac Du Flambeau IR)
Red Lake PHS Hospital	MN	FI	Yes (Red Lake IR)

Note:
PI = Privately Owned, Indian Land
FI = Federally Owned, Indian Land

In July 1989, PRC performed CEI inspections at the Lac du Flambeau Indian Reservation in Wisconsin and at the Red Lake Indian Reservation Public Health Service (PHS) Hospital in Minnesota. These inspections identified two small quantity generators that were previously unknown to the EPA. Both of these facilities are located on the Lac du Flambeau reservation. No additional RCRA facilities were identified on the Red Lake Indian Reservation. Both of the reservations inspected had completed their Notification of Hazardous Forms incorrectly.

The project approach was revised after the screening and inspection activities described above. The revised approach involves direct contact with reservations and coordination with various Indian related agencies, such as the Bureau of Indian Affairs and the Indian Health Service. The reservations and concerned agencies will be sent a questionnaire which will request information and assistance in identifying hazardous waste generators on Indian lands. This information request is consistent with Section 3007 of RCRA, which authorizes the U.S. EPA to collect information for enforcement purposes, and it also qualifies as a government-to-government request under the U.S. EPA's 1984 Indian policy.

The approach of coordinating among various agencies and involving the tribal governments directly is a more efficient approach than trying to access information about hazardous waste operations through HWDMS. This approach will also facilitate technology transfer to the reservations.

CONCLUSION

The issues raised in this paper have implications that reach beyond the scope of regulating RCRA Subtitle C on Indian lands. These questions must be addressed in enforcing any environmental statute on Indian lands.

The U.S. EPA Region 5 REB has initiated a study to collect data on the types of operations located on Indian lands and subject to RCRA Subtitle C. As part of this study, an information request letter will be sent to all tribal environmental contacts. This letter will be written both to request information and to provide information and should serve to educate the Indian tribes about RCRA and waste problems in general.

The study conducted by Region 5, and other programs being im-

plemented by Regional Indian Work Groups in other Regions, will help to close the "regulatory gap" on Indian lands. By identifying hazardous waste generators on Indian lands, and promoting technology transfer, the U.S. EPA to can better meet its objectives of working on a "government-to-government basis" with tribal governments, while protecting human health and the environment on Indian lands.

Active Site Discovery Using a Geographic Information System

Karl A. Morgenstern
Peter V. Witt
Ecology and Environment, Inc.
Seattle, Washington
Deborah Flood
U.S. Environmental Protection Agency
Seattle, Washington

ABSTRACT

Concerns about the potential universe of CERCLA sites has led the U.S. Environmental Protection Agency to take a more active role in determining those sites currently not included in the U.S. EPA site inventory. As a result, Ecology and Environment, Inc. (E & E) was tasked to develop an active site discovery mechanism in the State of Oregon.

The discovery mechanism developed by E & E consisted of: utilizing several discovery methods to obtain a complete inventory of active or abandoned potential Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) sites; screening and locating the new sites; and focusing on vulnerable areas as defined by the revised Hazard Ranking System (rHRS) model. To accomplish the latter, a Geographic Information System (GIS) was used to store, manage, manipulate and display the gathered data necessary to model rHRS factors. Preliminary Assessments (PAs) were performed on a representative fraction of the discovered sites in an attempt to evaluate the correlation between the GIS model vulnerability values and the rHRS model scores.

INTRODUCTION

The U.S. EPA is in the process of evaluating different mechanisms for discovering potential Superfund sites. Ecology & Environment (E & E) was tasked by the U.S. EPA to develop an active site discovery mechanism to be applied in the State of Oregon. The main objective of the Region 10 Pilot Site Discovery Project was to identify potential CERCLA sites in areas considered vulnerable based on rHRS model factors (proposed Rule 53 FR 51962).

Current methods of site discovery used by the U.S. EPA typically consist of identifying potential Superfund sites through a combination of citizen's complaints, referrals from other government branches and agencies and identification through the Preliminary Assessment/ Site Inspection (PA/SI) work (Table 1). These site discovery methods are considered passive since they do not require regions or states to use a systematic approach in identifying potential hazardous waste sites. This system of site discovery has worked reasonably well to date, given the U.S. EPA's current inventory of potential hazardous waste sites. However, passive methods are dependent on random site discovery and on individuals to channel the information to the appropriate agency. Active site discovery requires the dedication of resources to find previously undiscovered hazardous waste sites (Table 1). Previous active discovery efforts have been limited to specific geographic areas (i.e., cities, counties and sole-source aquifers) and/or specific contaminant/facility types (i.e.,

known area-wide problems related to wood preserving, coal gasification, coal fields, and solvent and TCE contamination).[2][4][7]

Table 1
Passive versus Active Discovery Methods

Passive Site Discovery Mechanisms	Active Site Discovery Mechanisms
Citizen Complaint	Remote Sensing
Referrals by Other Agencies	Aerial Photograph Interpretation
PA/SI Byproduct	Selected Geographic Area
Responsible Party Report	Historical Searches
Property Transfer Regulations	Selected Pollutant Searches
Solicitation of Information (Random)	Solicitation of Information (Specific)
Response to Emergency Situation	Selected Industry Study
Survey Review	File Review
	Documentation Search

The active discovery mechanism developed targets a variety of industries as potential CERCLA sites. This mechanism utilized several discovery methods to obtain a complete inventory of active or abandoned potential CERCLA sites, screened and located the new sites, and delineated vulnerable areas using a Geographic Information System (GIS).

SITE DISCOVERY CONCEPT

A GIS was used to store, manage, manipulate and display data necessary to model and map the air, surface water and groundwater pathway factors of the rHRS model. Areas mapped using GIS were ranked in an attempt to correspond with rHRS model values so that areas delineated as highly vulnerable correspond to areas most likely to receive significant weighting under the rHRS model if contamination is present at a site located in these areas.

Site discovery methods consisted of using a general documentation search for all active facilities in Oregon by specified Standard Industrial Code (SIC) and an abandoned site search in areas considered highly vulnerable. The SICs selected for general documentation search represent those facilities commonly found on the NPL and the CERCLA Information System (CERCLIS), and typically generate hazardous wastes. Sites discovered using the various methods were screened in a series of steps to generate a final list or universe of potential CERCLA sites.

This paper provides a summary of the site discovery mechanism completed for the Willamette Basin, Oregon. The Willamette Basin was selected as the first basin in Oregon to implement this concept

since it contains approximately 70% of the discovered sites on the final list and 80% of Oregon's population.

IMPLEMENTATION OF SITE DISCOVERY CONCEPT

GIS Model Development

A GIS can be defined as an organized collection of computer hardware, software, geographic data and personnel designed to efficiently capture, store, update, manipulate, analyze and display all forms of geographically referenced information.[6] ARC/INFO GIS software was used to develop the GIS vulnerability model. In ARC/INFO software, a digital version of a single map sheet layer is the basic unit of storage and is termed a "coverage." A coverage contains both the locational data and thematic attributes for map features in a given area.[6] In this paper, a "coverage" and a "map" are interchangeable terms.

Data used in the GIS vulnerability model were acquired from several sources, such as: the U. S. Geological Survey (USGS); the United States Census Bureau; Oregon Fish and Wildlife; and the U.S. EPA. The rHRS model uses site-specific and waste-specific information; therefore, it was necessary to simplify the model in order to integrate rHRS factors into the GIS vulnerability model.

The rHRS model groundwater, surface water and air migration pathways were evaluated for nonsite-specific factors. The pathway factors were grouped into two primary categories: contaminant migration factors and target factors. For a given migration pathway, a GIS pathway module was developed to account for contaminant factors. Target factors were then integrated into the GIS pathway modules. Each migration pathway was developed independently resulting in a pathway vulnerability coverage. For each pathway map (i.e., groundwater, surface water and air) the pathway vulnerability values were standardized to a 0 to 100 point scale. These three pathways were then overlayed to produce an overall vulnerability coverage. Five ranking categories were chosen for each vulnerability coverage. Table 2 summarizes these ranking categories.

Table 2
Ranking Categories of GIS Vulnerability Coverages

Category	Percent Distribution of Pathway Vulnerability Values
Low Vulnerability	Lower 10
Moderately Low Vulnerability	Lower 20
Moderate Vulnerability	Middle 40
Moderately High Vulnerability	Upper 20
High Vulnerability	Upper 10

Groundwater Pathway Module

Two options exist for evaluating the groundwater contaminant migration factors. The first is to use the rHRS environmental factors (i.e., net precipitation, depth to aquifer, hydraulic conductivity and sorptive capacity), weight them according to the rHRS model and combine the weighted factors. The second option is to use the parameters in the DRASTIC model to map groundwater contaminant migration factors. The DRASTIC parameters (i.e., depth to aquifer, net recharge, aquifer media, topography, impact of vadose zone and hydraulic conductivity) reasonably correlate with the rHRS factors (Table 3). DRASTIC was selected because of wide use of the model by USGS, the U.S. EPA and other government agencies.

DRASTIC parameters were weighted and combined to create a contaminant migration coverage. Table 4 summarizes groundwater pathway factors and weights. Since the data were not available, two DRASTIC factors (depth to aquifer and topography) were not used.

The groundwater pathway target factor was accounted for by using a coverage of population served by municipal wells. The well locations were "buffered" to a 1-mile radius by changing a point representation to an area representation of a circle with a 1-mile

radius. A 1-mile radius buffer was chosen by examining the rHRS distance weights. The groundwater drinking population necessary to maximize the rHRS groundwater target score is 32,000 at a 1/2-mile distance; 62,000 at a 1-mile distance; and 115,000 at a 2-mile distance. It was determined that the 1-mile radius was the best compromise distance for rHRS dilution weights.

Table 3
rHRS Model and Drastic Model Weight Comparison

rHRS Parameter Weights (%)*	DRASTIC Parameter Weights (%)*	
Depth to Aquifer (35%)	Depth to Aquifer (22%)	
Hydraulic Conductivity (35%)	Aquifer Media (13%) Vadose Zone (22%) Hydraulic Conductivity (13%)	(48%)
Net Precipitation (20%)	Net Recharge (16%) Topography (4%)	(20%)
Sorptive Capacity (10%)	Soil Media (9%)	

* Numbers in parenthesis represent the percentage of the total maximum value possible for the rHRS and DRASTIC models.

Table 4
Groundwater Vulnerability Pathway Factors

Contaminant Migration Factors/DRASTIC (PGV)	Weights

Contaminant Migration Factor/DRASTIC (PGV)	5

- Not used.

This groundwater-use population coverage was then overlaid with the contaminant migration coverage (DRASTIC) to create a groundwater pathway vulnerability coverage (Maps 1 and 2). Figure 1 illustrates the development of the groundwater pathway vulnerability module.

Surface Water Pathway Module

To incorporate the surface water pathway contaminant migration factors, a model was developed that takes into account rHRS factors for which data were available. This model incorporated soil texture, 2-year 24-hour rainfall and land-use type. These factors were overlaid and weighted according to rHRS factor weights to develop a surface water contaminant migration coverage. In order to define run-off limits, it was necessary to incorporate an areal hydrographic boundary. This hydrographic boundary, a sub-sub-basin coverage, represents drainage areas on a 1:24,000 scale.

The contaminant migration coverage was overlaid with the hydrographic boundary coverage, and an area weighted average score of the contaminant migration factor was developed for each sub-sub-basin.

The rHRS target factors used in developing the surface water pathway vulnerability module consisted of surface water use population, fish production and sensitive environments. Each target factor was overlaid with the hydrographic boundary coverage. The value of each target factor was summed per sub-sub-basin.

The target coverages were then combined with the contaminant migration coverage to produce a surface water pathway vulnerability coverage (Map 3). Figure 2 illustrates the development on the surface water vulnerability module.

Figure 2
Schematic of Module Development,
Surface Water Route

Air Pathway Module

The air pathway contaminant migration factor used in the rHRS model is the Thornwaite Precipitation-Effectiveness Index (P-E Index).[3] The P-E Index is a surrogate measure of the relative moisture content of surface material. The P-E Index is constant throughout all of the Willamette Basin; therefore, it was not necessary to develop this data layer at this time.

The target factors incorporated into the GIS air pathway vulnerability model are population density and sensitive environments. The population density coverage was developed using Geographic Exposure Model (GEMS) data. The GEMS data base has a population per municipality variable. These point data were processed into area data with a population density attribute by creating polygons around each point and dividing the population variable by each polygon area. A more complete U.S. Census data layer will be used when made available.

As demonstrated in Figure 3, the sensitive environments coverage was then overlaid with the population density coverage to produce an air pathway vulnerability coverage (Map 4).

The groundwater, surface water and air pathway vulnerability coverages were overlaid and all module vulnerability factors were added to create the overall vulnerability coverage (Map 5). Figure 4 illustrates the development of the overall vulnerability coverage.

Universe Development

Categories of facility types that were targeted for site discovery were identified by the U.S. EPA based on past definitions, regulatory authority, site activity, waste type and NPL and CERCLIS characterization of sites. The hazard potential associated with these facility categories can be evaluated based on a typical site in each category. The hazard potential rank (i.e., low, medium or high hazard) is determined by evaluating four major factors:
• Documented evidence of hazards/risks associated with inclusion or absence of sites in the category on the NPL, the number and type of documented damage cases caused by releases at sites in the category, and previous conclusions by the U.S. EPA or other government agencies regarding hazard or risk
• Characteristics of the generated waste, such as waste quantity, concentration, and toxicity

• Typical containment and management practices associated with sites in the category
• Potential for exposure, given a release

The following is a list of facility categories considered to be high and/or medium hazard potential.

Categories With High/Medium Hazard Potential
1. Closed Municipal Solid Waste Landfills (High Hazard)
2. Hazardous Waste Generators (Medium Hazard)
   • Large quantity generators such as:
     - Fabricated metal facilities
     - Metal manufacturing facilities
     - Chemicals and allied products
       Electrical equipment
     - All other manufacturing
3. Subtitle D Industrial Process Waste Facilities (Medium Hazard)
   • Manage waste on-site such as:
       Pulp and paper
     - Inorganic and organic chemicals
       Transportation equipment
     - Rubber and miscellaneous products
     - Leather products
       Plastics and resins manufacturing
     - Fertilizer and agricultural chemicals
       Petroleum refining
4. Other Site Categories (Medium Hazard)
   • Nonfuel mining and processing
   • Class IV and Class V
     (industrial/commercial/utility) disposal wells
   • Open/illegal dumps
   • Coal gasification plants
   • Wood-preserving facilities
   • Tanneries
   • Pesticide formulators
   • Electroplating facilities
   • Aerial pesticide applicators
   • Drycleaners
   • Metal/transformer salvage yards

Overall Vulnerability Module

These types of facilities were targeted for the site discovery process. Not all individual sites in the categories listed above are sufficiently hazardous to warrant priority U.S. EPA concern under Superfund. In fact, there probably are few if any site categories in which all individual sites will require U.S. EPA attention, and some categories may have very few sites that warrant concern. The two main methods used in the discovery process were documentation search and geographic survey.

A documentation search consists of researching available data sources to obtain information regarding the existence of potential hazardous waste sites. The sources of data used include: U.S. EPA regional files, state files, commercial data bases and trade group publications. Abandoned sites can be identified by using County Business Patterns (U.S. Bureau of Census) and Directory of Chemical Producers (SRI) data bases to establish business patterns from 1961 to the present. State files were reviewed to locate closed municipal landfills. The facility information contained in the different data bases was cross-checked to eliminate facility duplication.

A geographic survey consists of canvassing specific areas in an effort to locate potential hazardous waste sites. The abandoned site search for closed landfills was limited to highly vulnerable areas as defined by the GIS vulnerability model. Geographic surveys were used to confirm potential waste sites identified through the documentation search and to identify other potential sites in the area.

Site discovery by documentation search uses five different data sources to obtain a thorough listing (i.e., universe) of active facilities and closed municipal landfills. These sources include: the American Business List (ABL), the Oregon Department of Environmental Quality site inventory (ODEQ list), the U.S. EPA Facility Index Numbering Data System (FINDS) and Title III data bases and the ODEQ Solid Waste branch files.

The ABL data base is a yellow page listing of active manufacturers by SIC code. The types of facilities acquired from the ABL correspond to the categories discussed earlier. The ODEQ list consists of active and abandoned facilities currently on the ODEQ site inventory. The FINDS data base includes all active and abandoned sites currently on the U.S. EPA's site inventory. Title III data contain a list of facilities with emissions of chemicals reported under Title III of the Superfund Amendments and Reauthorization Act (SARA) of 1986. Files from the Solid Waste branch of the ODEQ were reviewed to obtain a list of closed municipal landfills located in/near highly vulnerable areas as defined by the GIS vulnerability model.

The five data sources of potential CERCLA sites were processed to produce the final Universe of "discovered" sites. The first stage of the site discovery screening process was to compare each data source with an inventory of current CERCLA sites to eliminate those facilities already on CERCLIS. Following the purge of CERCLA facilities from each data source, the data bases were compared with each other to eliminate duplication. By eliminating U.S. EPA FINDS, ODEQ and Title III duplicate sites from the ABL data base, the ABL list represents potential CERCLA sites that are currently in neither the state nor the U.S. EPA site inventories. The U.S. EPA FINDS data base was processed by selecting RCRA generators not on CERCLIS and selecting those U.S. EPA sites not under RCRA or CERCLA (Other U.S. EPA).

The second phase of the screening process is to eliminate those facilities that do not fit the medium and high hazard categories discussed earlier from the ODEQ list, the U.S. EPA FINDS (i.e., RCRA generators and Other U.S. EPA sites) and the Title III list. The remaining ABL, ODEQ list, U.S. EPA FINDS, Title III and closed landfill sites comprise the universe of "discovered" sites. The final screening is designed to prioritize "discovered" sites. Sites in cities that are located in highly vulnerable areas are prioritized for confirmation and review.

Approximately 6,000 potential sites were discovered in Oregon using the screening process discussed above. The U.S. EPA emphasizes that the vast majority of sites may not contain hazardous waste or be of concern to the U.S. EPA. Seventy percent (4,198) of the discovered sites were located in the Willamette Basin. A summary of the number of sites contributed by each data source for the Willamette Basin is as follows:

- ABL = 3,072 sites (73.2 %)
- RCRA = 637 sites (15.2 %)
- Other U.S. EPA = 316 sites (7.5 %)
- ODEQ List = 98 sites (2.3 %)
- Closed Landfills = 48 sites (1.1 %)
- Title III = 27 sites (0.6 %)

In a study that summarizes discovered sites by industrial category (SIC code) and vulnerability rankings (as defined by the GIS model), the majority of the sites (97%) are located in the moderate to high vulnerability rankings. This could be a result of the fact that the moderately low and low vulnerability areas represent rural or low population centers. Fabricated metals and industrial machinery manufacturers comprise 38% of the sites. It was also noted that the

federal data sources have incomplete SIC designations for approximately 57% of the sites. To account for the lack of SIC codes in federal data sources, all facilities without SIC codes were included in the "discovered" universe.

PAs were performed on 79 of the 4,198 potential sites in an attempt to evaluate the legitimacy of the universe of "discovered" sites. A second objective of the PAs was to provide a field check for the GIS vulnerability model. Three criteria were used in selecting PA candidates from the 4,198 potential sites. The first criterion was to select PAs from each of the vulnerability rankings (high, moderately high, moderate, moderately low and low) in an attempt to test the GIS vulnerability model. The next criterion in the PA selection was to choose facilities from each of the data sources (ABL, ODEQ List, RCRA, Title III, Other U.S. EPA and closed landfills). Finally, PAs were selected to represent a cross section of industry type by SIC code.

A summary was compiled of 57 PA sites. Of the remaining 22 sites, drive-by surveys were performed on 19; the other three sites could not be located. It was determined that of the 57 sites evaluated, 27 sites generating hazardous waste were recommended as no further action (NFRAP), 19 facilities did not generate hazardous waste and were recommended as NFRAP and 11 sites were recommended as requiring a PA evaluation.

Table 5 summarizes the industrial code (SIC) and vulnerability ranking of the 11 facilities recommended for PA evaluation. Factors that determined which sites warranted a PA evaluation include: waste quantity, disposal practices, waste type, years of operation, spill history, visual appearance and past agency involvement.

Table 5
Summary of Preliminary Assessment Facilities

Industry Type	Data Source	Vulnerability Class
Pesticide Appl.	RCRA (1 site)	Moderately High
Chemical Products	RCRA (1 site)	High
	ODEQ (2 sites)	High
	Title III (1 site)	High
Lumber and Wood	ABL (2 sites)	High
Electronic Products	RCRA (1 site)	Moderate
Primary Metals	RCRA (1 site)	High
Drycleaners	ABL (1 site)	High
	ABL (1 site)	Moderate

CONCLUSIONS

Of the 79 potential PA candidates, PAs were performed on 11 sites. This indicates a success rate of 14% for the initial PA screening effort in the Willamette Basin. Based on this success rate and the current Level of Effort (LOE) expended to date, the cost of implementing this active site discovery mechanism in the Willamette Basin is approximately 7 LOE hours per discovered site. Nine of the 11 PA evaluations were recommended for Screening Site Inspections (SSIs).

The SSI results will be used to further evaluate the correlation between the GIS vulnerability model and the rHRS model.

PAs were performed on sites from four of the five data sources (ABL, RCRA, ODEQ List and Title III). This indicates that the data sources used to generate the universe of "discovered" sites appear to contain potential CERCLA sites. PA sites that scored the highest (i.e., rHRS potential scores of 31.80 and 30.07) are located in highly vulnerable areas. However, a site scored in the moderate vulnerability class exceeded some site scores in the moderately high and high vulnerability categories. Additional tests on the GIS vulnerability model are necessary to correlate vulnerability rankings with rHRS scores.

Since environmental and target type data are already in the GIS system, this allows for a reduction of resource requirements to calculate rHRS scores and perform PAs. Based on the 11 PAs performed in this study, a 40% reduction of LOE hours was achieved by using rHRS data in the GIS system, as opposed to collecting rHRS data in the field.

These GIS environmental and target data layers can be used for other agency applications, such as risk assessments, environmental impact statements and specific environmental studies (pesticide groundwater vulnerability study). The developed GIS data layers also are accessible to the State of Oregon for use in prioritizing state resources.

The results of the Willamette Basin project will be incorporated as this active discovery mechanism is applied to the remaining basins in Oregon. This discovery mechanism also can be applied, partially or as a whole, to other areas or states.

Highway Right-Of-Way Considerations
Near Superfund Sites in Delaware

ABSTRACT

State transportation departments are responsible for state ownership of roadway right-of-way and for acquiring new right-of-way and related properties. Some state-owned highway right-of-way properties lie adjacent to uncontrolled hazardous substance release sites. Due to potentially high implementation costs (from construction scheduling, operations impacts and future liability associated with acquiring portions of an uncontrolled hazardous substance release site or encountering contaminants on existing right-of-way), the Delaware Department of Transportation (DOT) has instituted a program to evaluate environmental constraints before purchase decisions are made. Where possible, phased environmental investigations are performed on properties considered for acquisition. The ultimate objectives are: (1) to provide right-of-way negotiators with cleanup cost estimates for consideration in the purchase agreements and (2) to evaluate design and construction constraints should the property be purchased. Most of the properties investigated to date have been underground storage tank (UST) sites, although a number of industrial and commercial facilities have been evaluated. This paper examines case studies of Delaware DOT highway projects planned near three Superfund sites: Sealand Limited, Tybouts Corner Landfill (NPL No. 2) and Dover Air Force Base. Substantial technical and legal effort are is associated with addressing right-of-way issues near each of the three sites. Due to the complexity of the issues and considerable time required for resolution, early attention to Superfund impacts by environmental professionals is recommended.

IMPACTS TO STATE RIGHT-OF-WAY

State-owned roads and highways exist adjacent to, or near, many uncontrolled hazardous substance release sites. Most commercial and industrial facilities require road access or frontage to conduct business. The nature of vehicular transportation attracts some environmentally sensitive businesses, i.e. to road frontage gasoline stations. In planning, acquiring, constructing and maintaining roadway right-of-way, increasing attention is being given to resolving matters related to impacts from environmental regulations and releases of hazardous substances on State-owned rights-of-way. State transportation departments (the planners and custodians of state-owned rights-of-way) must confront the issues of environmental compliance and responsible management of affected road projects and properties.

The right-of-way development process is important when evaluating environmental impacts and actions. Figure 1 illustrates a five-stage development process of a roadway from its conceptualization to completion.[1] Note that eventual property management (Stage 5) is only one stage of concern. The first four stages—location planning, design, acquisition and construction—are associated with development of a new or expanded roadway. These four stages may be significantly affected

by environmental considerations. Generally, the earlier that potential environmental problems are recognized and evaluated, the less disruptive they are to later stages. For instance, discovering an environmental problem during the construction stage may not only delay the construction and require special operations, but the road design (Stage 2) might require modification and the value/liability of the subject state-owned property (Stage 3) may change at the taxpayers' expense. Furthermore, if the environmental condition is known earlier, a more feasible and potentially more cost-effective roadway alternative may be selected (Stage 1). Unforeseen environmental problems can cause substantial time and cost impacts to the roadway project.

Often with existing road upgrades, it is not feasible to avoid a problem site because of the high cost of developing a totally new road corridor. Recently in Delaware, upgrade projects have constituted the majority of new road projects and have been the most affected by hazardous substance environmental problems. For these projects, environmental issues are assessed with regard to liability of ownership and design and construction impacts.

Property owners could be liable for necessary environmental compliance (e.g., site cleanup), handling and disposing of special or hazardous wastes generated by site development (e.g., being named as a responsible party due to the link with state-generated waste, third party law suits by construction workers exposed to waste) and additional administrative costs (e.g., negotiation or litigation). Historically, efforts have been made to quantify environmental compliance cost and to avoid, rather than estimate, potential liabilities associated with waste issues and additional administrative costs.

Environmental impacts to road design and construction have motivated Delaware DOT to establish a hazardous substance evaluation program. The presence of contaminated soil or groundwater on a right-of-way construction site can significantly disrupt planned operations and cause delays and contractor claims.

ENVIRONMENTAL EVALUATION PROCESS

Delaware DOT has instituted a multiphased right-of-way evaluation process that is similar to the environmental evaluation process for real estate property transfers. A number of other states, including California and New Jersey, have similar programs.[2]

Delaware DOT is in the midst of a Relief Route Project, a new 46-mile, north-south limited access highway. Due to the size and complexity of the project scope, Delaware DOT retained Century Engineering, Inc. International (CEII), a civil engineering consultant, to manage the design and construction.[3] CEII subcontracted with EA Engineering, Science and Technology, Inc. to perform environmental services for the Relief Route Project. CEII and Delaware DOT representatives screened the proposed road alignment for suspect sites based on current site usage

and Delaware DOT records.

Other state road projects are managed internally by the Location Studies group of Delaware DOT. Traditionally, this group has administered the environmental impact aspects of road preconstruction activities (e.g., wetlands and noise). In 1988, their responsibilities were expanded to include administering hazardous substance evaluations. Between 1987 and 1988, the Delaware DOT retained EA to provide technical assistance for selected projects. After fulfilling several small contracts dealing only with individual sites during 1987, EA was contracted in 1988 by Delaware DOT under a task-order basis to provide investigative and remedial design/implementation environmental services. Currently, environmental specialists in the Location Studies group screen various road project right-of-way acquisition plans and proposed subsurface construction. Properties designated as environmentally suspect are assigned to EA for phased investigation. For major new corridor projects requiring an Environmental Impact Statement (EIS), the Location Studies group now requires more consideration of hazardous substances release sites by the EIS consultant.

The multiphased approach is designed to identify and evaluate potential areas of contamination on the suspect properties.[3] A three-phased approach is used:

- Phase I—Preliminary assessment
- Phase II—Site characterization, remediation assessment
- Phase III—Remedial design and implementation

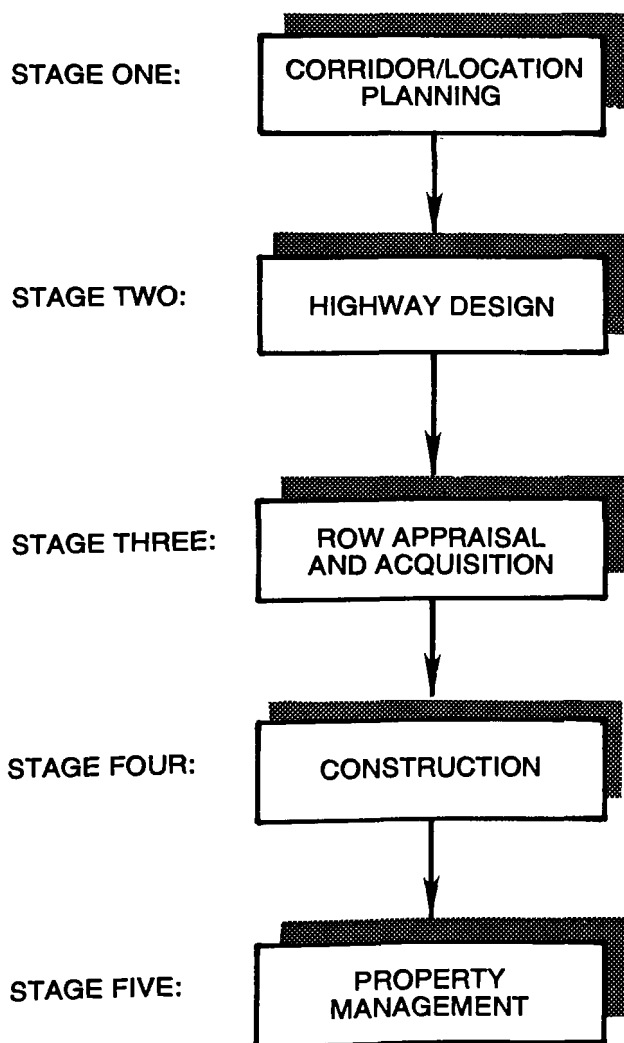
Figure 2 illustrates a sequential flow of environmental activities.


Figure 1
Right-of-Way Development Process

STAGE ONE: CORRIDOR/LOCATION PLANNING

STAGE TWO: HIGHWAY DESIGN

STAGE THREE: ROW APPRAISAL AND ACQUISITION

STAGE FOUR: CONSTRUCTION

STAGE FIVE: PROPERTY MANAGEMENT

The purpose of Phase I is to establish whether or not an environmental problem exists on the subject property. Often the right-of-way to be acquired is a "strip-take," that is, a strip of property adjacent to the existing road. Investigation may be limited to that strip. Records, site inspections and interviews, limited sampling and metallic tank location surveys are used in Phase I investigations. Because many of the sites (e.g., gas stations) are associated with volatile organic compound usage or storage, soil vapor surveys are a valuable investigative technique. Often during Phase I, several shallow soil samples are obtained by hand-augering in proposed trench lines. In some cases, existing information is sufficient to omit some or all of the Phase I components and proceed directly to Phase II or III.

Phase II investigations are implemented if contamination is identified or suspected and further characterization is necessary. Detailed investigations, such as hydrogeologic assessments, may be performed. Once the site is adequately characterized to evaluate hazards and/or remediation needs, a cleanup cost estimate is generated to assist Delaware DOT property acquisition personnel. The cost estimate is used to help appraise the value of the property if Delaware DOT purchases it unremediated. In some cases, the responsible party has initiated cleanup and site closure. In other cases, the estimated cleanup costs are used to establish escrow funds deducted from the purchase price, pending future cleanup.

Phase III, remedial design and implementation, can be implemented if Delaware DOT accepts responsibility for the identified environmental problem. Delaware DOT has pulled a number of USTs at various sites, some with associated soil excavation and above-ground remediation. Delaware DOT has not initiated any multimedia site cleanups, such as pumping or venting, although such projects are possible in the future.

Delaware DOT (through EA) has performed Phase I investigations at 50 properties, Phase II investigations at 17 properties and tank pull oversight with some soil remediation at 10 sites. The majority of properties investigated are UST-related; however, several road project locations are affected by Superfund sites. Presently, environmental issues are being evaluated for road projects adjacent to three NPL sites. Due to the technical and administrative complexity associated with environmental issues of Superfund sites, these cases are good illustrations of how such sites can affect the road right-of-way development process.

CASE 1—SEALAND LIMITED

The Sealand Limited site located in New Castle County, Delaware, was recently added to the NPL. Prior to 1983, the Sealand facility recycled waste oils, coal tar, inks and other waste organics. The property was owned by Conrail and leased to Sealand. Operations closed in 1983 when a U.S. EPA Emergency Removal Action was initiated. Past analysis of site groundwater and soil have indicated the presence of trace metals, VOCs and base neutral organic compounds (notably polycyclic aromatic hydrocarbons—PAHs). The property is narrow, approximately 100 ft wide and 1,000 ft long. An RI/FS is being conducted now with numerous off-property sampling locations. Delaware DOT is planning a road upgrade near Sealand. The route is heavily used by commercial and commuter traffic. Figure 3 depicts three road upgrade alternatives, Alternates 2, 3 and 4 (Alternate 1 is not discussed here). All three alternatives have hazardous substance concerns, as well as other substantial considerations (e.g., wetlands, property cost). The favored Alternate, No. 4, skirts the north end of the Sealand property on a new alignment. An effort was made by Delaware DOT planners to avoid potential property acquisition of the Superfund site itself, due to legal ramifications, delays and association with an NPL-listed site. However, subsurface contaminants may be migrating toward the Alternate 4 right-of-way. Alternate 3 is an upgrade of the existing road, but requires acquisition of property strips along the Sealand site and other environmentally suspect sites. Alternate 2, the southern-most route, bisects an operating grainery.

Investigations on each alternative have discovered subsurface contamination. Aside from the legal aspect of acquiring a section of a Superfund site, Delaware DOT is concerned about purchasing neighboring properties with contamination sources and ultimately being drawn into the Superfund process due to mingling contaminants. Although in some

cases the contamination has been small and probably of low risk to human health or the environment, the proximity to the Sealand site exacerbates future liability concerns.

A significant quantity of oil-stained soil was discovered on Alternate 4, possibly related to former asphalt batching operations. The discovered compounds of concern are the same as those on Sealand—PAHs and total petroleum hydrocarbons. The oily soil lies near a stream headwater and wetland, so road construction through the area would require careful design and construction to minimize surface water impacts.

Alternate 3 requires strip-takes of the Sealand property, a former gas station and an operating grainery. Soil and groundwater samples at the former gas station showed aromatic petroleum hydrocarbons (benzene, toluene and xylenes) in the former tank field area. The former tank field may be upgradient of the Sealand site. Past sampling at Sealand

has shown benzene and toluene in soil. Soil vapor and shallow groundwater samples at the grainery indicate the presence of 1,1,1-trichloroethane. From the limited sampling to date, the compound appears to be ubiquitously distributed across the site. Solvents may have been used in the past as carrier agents for grainery pesticides. This environmental condition also affects Alternate 2.

Environmental evaluations of the right-of-way development process began more than 1.5 years ago (during Stage 1) for this project; the final alternative still has not been selected, partially due to the complexity of the above environmental issues.

CASE 2—TYBOUTS CORNER LANDFILL

Tybouts Corner Landfill is located in New Castle County, Delaware and was originally No. 2 on the NPL. The 50-acre site originally was a sand and gravel pit and subsequently was used as a landfill for

1. Site characterization may include hydrogeologic assessment, waste distribution assessment, and ecological assessment.

2. Hazard assessment is a qualitative mini-risk assessment.

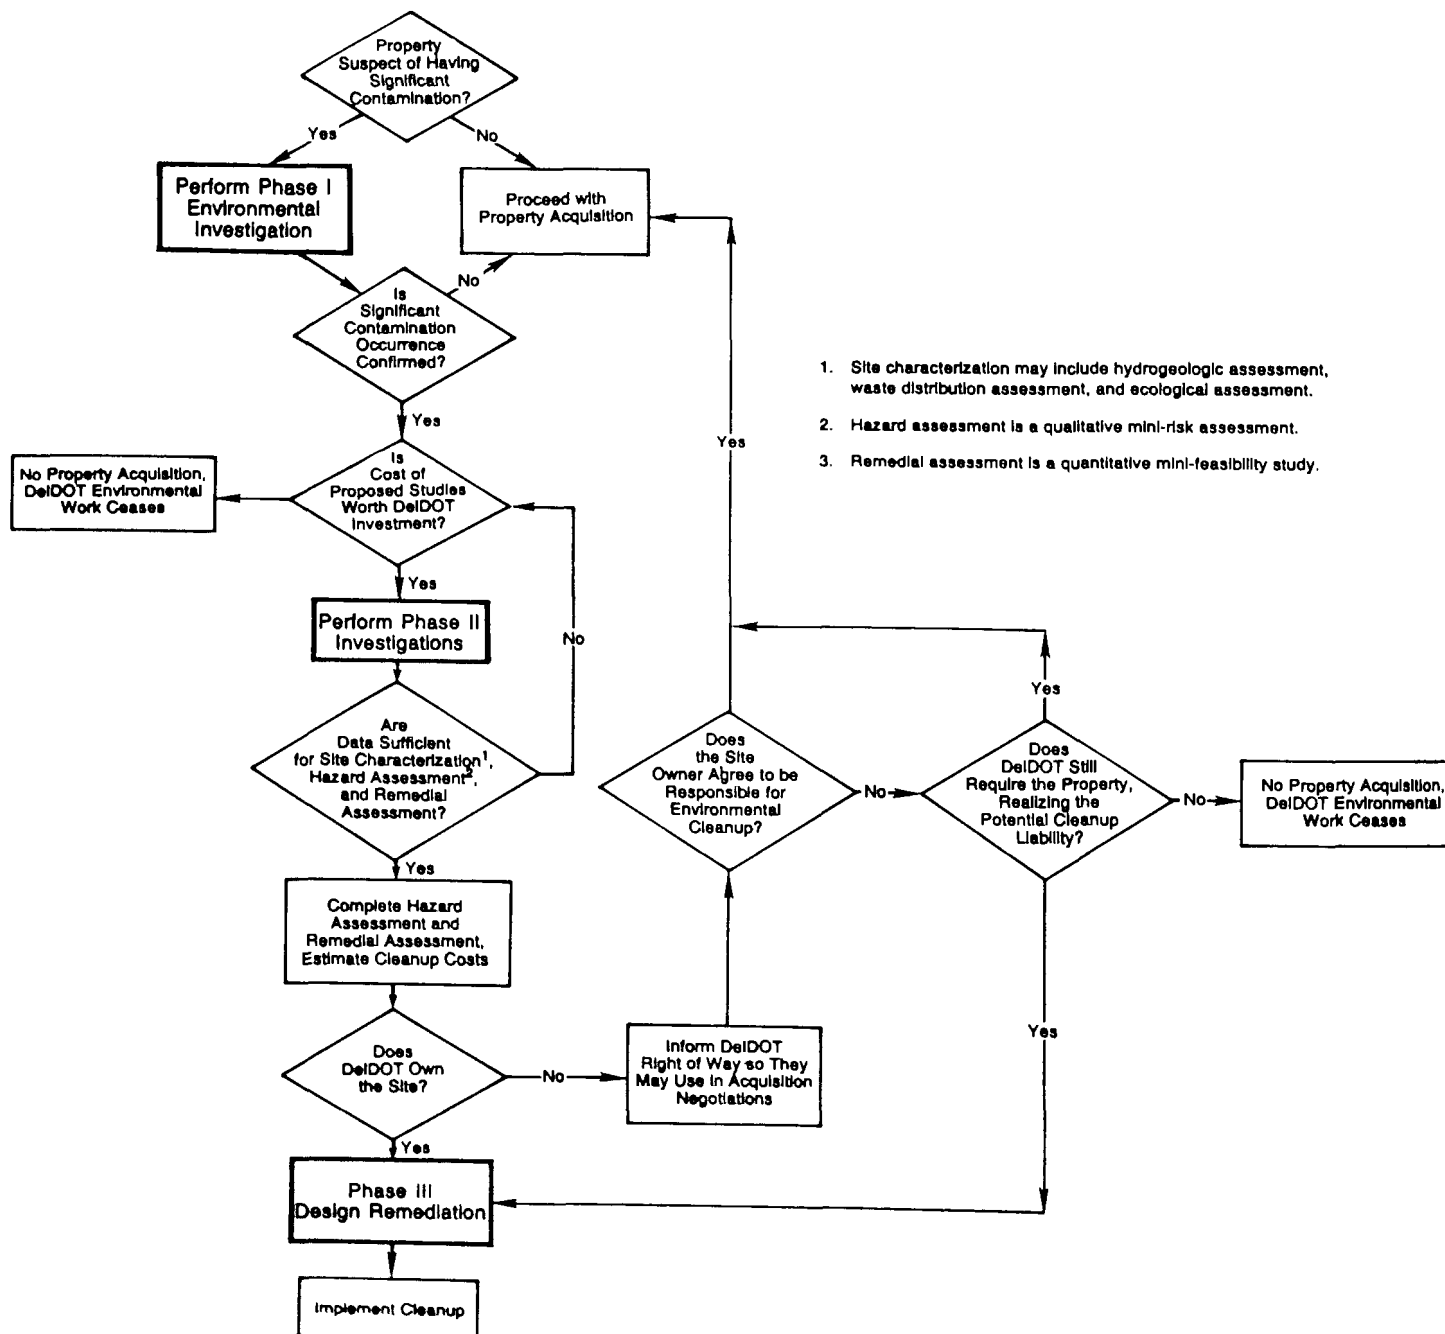
3. Remedial assessment is a quantitative mini-feasibility study.


Figure 2
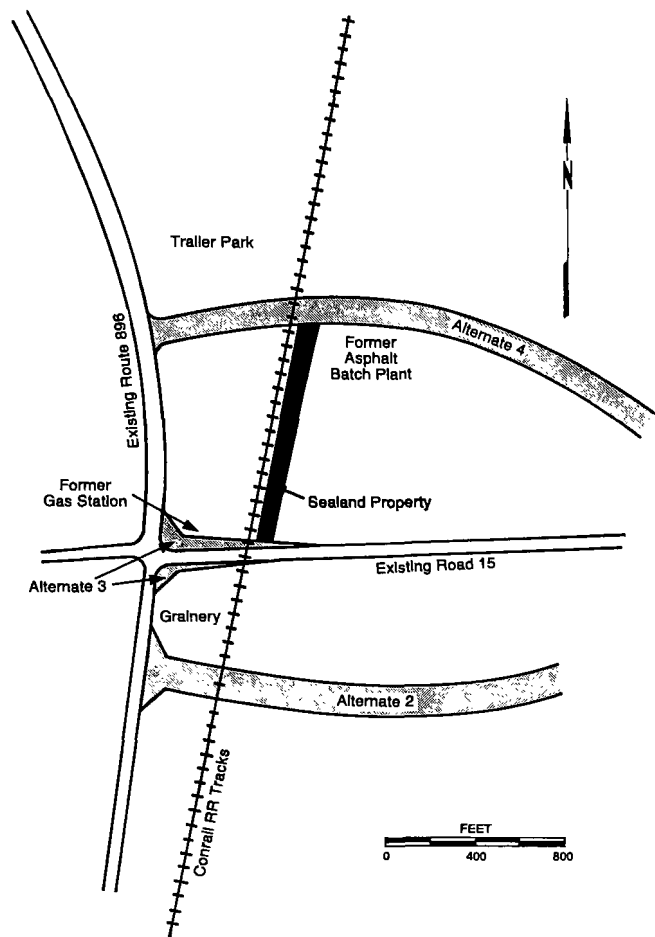
Environmental Activities Flow Chart

Figure 3
Road Alternatives Near Sealand Limited

penetrated, so stringent borehole sealing and decontamination procedures were required. Because drilling was performed in the existing highway right-of-way (shoulders and median), special attention was given to maintaining traffic. After several iterations of a work plan, geotechnical borings were completed in Spring 1990, almost two years after they were originally planned.

Subsurface samples were obtained during drilling to evaluate other design and construction operation considerations. Concerns include foundation design, road and bridge drainage design, waste generation and disposal, health and safety for construction operations and construction materials compatibility. These issues are being evaluated now. Because driven piles were an original foundation design alternative, consideration will be given to methods that may minimize cross-contamination of subsurface units if retarding units must be penetrated. Many of the issues still require discussion with regulators and PRPs. For instance, it is still uncertain as to which party should be responsible for wastes generated (e.g., soil and groundwater from excavations). Also, construction health and safety measures will be established by assessment of the chemical data, but it has not been determined if road construction should fall within the Tybouts Corner Landfill approved Safety and Health Plan.

CASE 3—DOVER AIR FORCE BASE

Dover Air Force Base (DAFB) is a large military cargo handling facility. The base recently was included on the NPL: it has numerous uncontrolled hazardous substance problems, including jet fuel and motor fuel spills and leakage of dissolved organic compounds from surface impoundments. RT. 113, part of the Relief Route Project, borders the base. To expand the existing roadway into a limited access highway, numerous property acquisitions are necessary near the base. A commercial strip exists on the southwest side of the road, across the operational part of DAFB and several subsurface contaminant sources have been or will be acquired as part of the Relief Route (Fig. 4). Namely, parts or all of two former gas stations and one active gas station, several


municipal and industrial waste in the 1960s and 1970s. A number of refineries are nearby and solvent and hydrocarbon wastes were documented to be disposed at the site. The RI/FS was completed in 1985 and the ROD was signed in 1986. The PRPs are now in the design phase of remediation. The cleanup will ultimately incorporate capping, excavation and pump-and-treat technologies.

Route 13, a major north-south highway, lies immediately east and downgradient of the landfill. Expansion for the limited access Relief Route will require acquisition of only the property to the east of the existing right-of-way. No Tybouts Corner Landfill property will be acquired. The problems associated with road development thus far have centered on design considerations and impact on future road construction. The road work also may affect the off-site remediation and monitoring, such as compliance well placement. The project has required substantial coordination effort between Delaware DOT and its consultants, The Delaware Department of Natural Resources and Environmental Control (DNREC), U.S. EPA Region 3 and the PRPs and their consultants.

Problems began in the summer of 1988, when a geotechnical drilling crew encountered suspicious odors while drilling in the road median downgradient of the site. The drillers were pulled off the site and EA and CEII performed an environmental evaluation using existing information. It was discovered that an existing right-of-way area near a bridge over a creek probably was underlain by aqueous leachate plumes from the landfill. Also, underlying aquifers had varying degrees of hydraulic confinement and contamination from the landfill. These conditions present several potential problems for road design and construction.

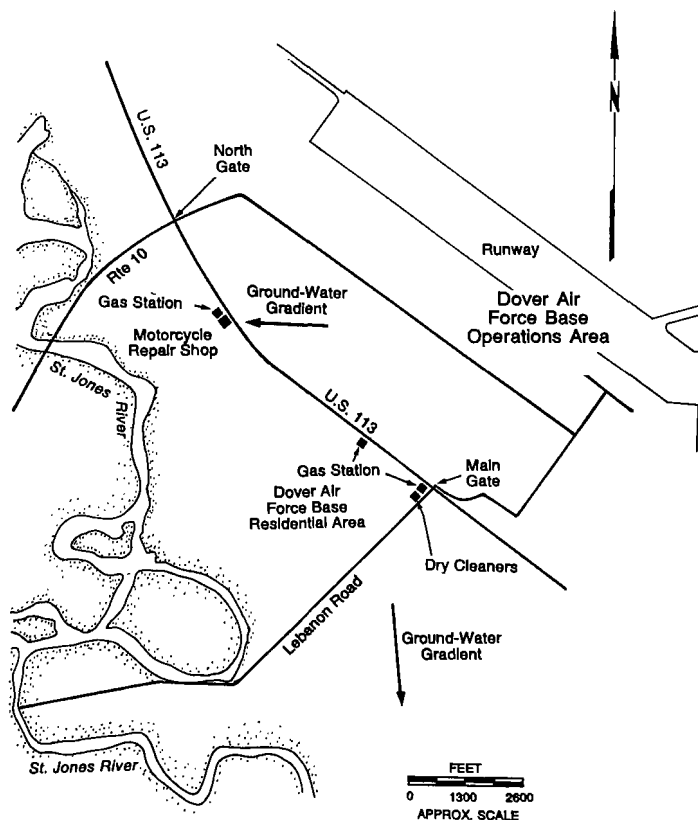
First, the geotechnical borings, which were necessary for new bridge design, had to be completed with regard for environmental considerations. Several retarding units separating subsurface hydraulic units were


Figure 4
Properties Considered for Acquisition Near Dover Air Force Base

former drycleaners and a large motorcycle repair and salvage business are included in the project.

The three gas stations are documented to have had leaking USTs. Two sites are being remedied by the PRPs, while one is being handled by Delaware DOT under an escrow arrangement. All gas station environmental activities fall under Delaware DNREC UST Management Group primacy. Subsurface chlorinated solvent contamination existing on a former drycleaner site and motorcycle facility fall under Delaware DNREC CERCLA Management Group primacy. The U.S. Air Force is presently completing RI/FS activities at DAFB under state and U.S. EPA scrutiny.

A central issue in developing the subject properties is the potential mingling of aqueous plumes from the right-of-way sites with DAFB plumes and the possibility of having to jointly allocate plume responsibility. Near the highway, the shallow groundwater gradient is from the DAFB operations area toward the subject properties. DAFB sources with similar contaminants have been documented to be migrating toward one gas station and the motorcycle business. Preliminary results of investigations near the drycleaners have found contaminated shallow groundwater upgradient of the known source sites. A substantial amount of site characterization work is being performed just to obtain a baseline of contamination location and the costs of investigation and probable remediation are greater than the value of the assets of some of the responsible properties. Delaware DOT is now weighing how best to appraise and acquire the properties. A large uncertainty exists as to what corrective action objectives and criteria will be set for DAFB and how they may affect cleanup requirements from other downgradient sources. The value of properties and future liabilities can differ substantially different from those perceived now if stringent corrective action is required. Where possible, Delaware DOT is altering plans to avoid acquisition of potential source areas.

LESSONS LEARNED

Subsurface contamination originating on the right-of-way of highways and migrating from off-site sources can pose a problem. Dealing with uncontrolled hazardous substance impacts to the right-of-way development process takes more time and effort than that to which highway planners are accustomed. Confronting the environmental issues as early as possible during the staged right-of-way development process will minimize disruptions to plans, designs and construction operations. Environmental expertise is essential to understanding the complex technical and regulatory environmental issues as they apply to the highway process, as well as prudently managing the public's property and interests.

Road development near Superfund sites has been especially sensitive due to the complexity of regulatory and multiple-party interaction and uncertainties in how the Superfund process may affect right-of-way projects. Furthermore, the thoroughness and QA/QC requirements of field and laboratory activities necessary for work associated with Superfund sites often exceeds that for other programs, such as state UST investigations. Therefore, an extra effort must be made to communicate environmental plans to the appropriate regulators and interested parties and to coordinate a mutually agreeable action.

Conducting Remedial Investigations/Feasibility Studies at CERCLA Municipal Landfill Sites

Susan M. Cange
U.S. EPA
Washington, District of Columbia

John D. Rendall, P.E.
CH2M HILL
Boston, Massachusetts

ABSTRACT

Approximately 20% of the sites on the National Priorities List (NPL) are municipal landfills which typically share similar physical and chemical characteristics. Because of this similarity, the Superfund Program anticipates that their remediation will involve similar waste management approaches.[1]

As stated in the National Contingency Plan, the U.S. EPA expects that containment technologies will generally be appropriate for waste that poses a relatively low long-term threat or where treatment is impracticable [NCP Sec. 300.430(a)(iii)(A)]. Therefore, containment has been identified as the most practicable alternative because of the volume and heterogeneity of waste within CERCLA municipal landfills, which often makes treatment impracticable. In addition, the U.S. EPA expects treatment to be considered for identifiable areas of highly toxic or mobile material that constitute the principal threat(s) posed by the site [NCP Sec. 300.430(A)(iii)(C)]. Treatment of hot spots within a landfill should therefore be considered and evaluated. The similarity in landfill characteristics and the NCP expectations make it possible to streamline remedial investigations and feasibility studies for municipal landfills with respect to site characterization, risk assessment and the development of remedial action alternatives.

INTRODUCTION

A broad framework for the Remedial Investigation/Feasibility Study (RI/FS) and selection of remedy process has been created through the National Contingency Plan and the *EPA RI/FS Guidance*.[2] With this framework now in place, the U.S. EPA's Office of Emergency and Remedial Response's efforts are being focused on stream,lining the RI/FS and selection of remedy process for specific classes of sites with similar characteristics.

One such class of sites is municipal landfills which compose approximately 20% of the sites on the Superfund Program's National Priorities List (NPL). Municipal landfill sites currently on the NPL typically contain some combination of municipal and hazardous waste and range in size from 1 to 640 acres. Nonhazardous waste disposed in municipal landfills is a heterogeneous mixture of materials primarily composed of household refuse such as yard and food wastes, and commercial waste such as paper, plastic, glass and metals. There are four ways in which hazardous wastes may have been disposed in municipal landfills. First, landfills that operated before the implementation of RCRA in 1980 typically accepted and codisposed of both liquid and solid hazardous waste; second, small quantity generators contribute varying quantities of hazardous wastes to municipal landfills; third, some household wastes such as batteries and paints are hazardous; and fourth, biodegradation of wastes within the landfill can create new compounds that are hazardous.

Potential threats to human health and the environment resulting from municipal landfills may include:

- Leachate generation and groundwater contamination
- Soil contamination
- Landfill contents
- Landfill gas
- Contamination of surface waters, sediments, and adjacent wetlands

A conceptual model of the potential pathways of exposure that may exist at municipal landfill sites is presented in Figure 1.

Because these sites share similar characteristics, they lend themselves to remediation by similar technologies. The National Contingency Plan (NCP) contains the expectation that containment technologies generally will be appropriate remedies for wastes that pose a relatively low long-term threat or where treatment is impracticable. Therefore, because of the volume and heterogeneity of waste within CERCLA municipal landfills, treatment often will be impractical. The NCP also contains an expectation that treatment should be considered for identifiable areas of highly toxic and/or mobile material (hot spots) that pose principal threats. Therefore, treatment of hot spots within a landfill will be considered and evaluated.

With these expectations in mind, a study of municipal landfills was conducted with the intent of developing methodologies and tools to assist in streamlining the RI/FS and selection of remedy process. Streamlining may be viewed as a mechanism to enhance the efficiency and effectiveness of decision-making at these sites. The goals of this study to meet this objective include: (1) developing tools to assist in scoping the RI/FS for municipal landfill sites, (2) defining strategies for characterizing municipal landfill sites that are on the NPL and (3) identifying practicable remedial action alternatives for addressing these types of sites.

STREAMLINING SCOPING

The primary purpose of scoping an RI/FS is to divide the broad project goals into manageable tasks that can be performed within a reasonable period of time. The broad project goals of any Superfund site RI/FS are to provide the information necessary to characterize the site, define site dynamics and develop a remedial program to mitigate current and potential threats to human health and the environment. Scoping of municipal landfill sites can be streamlined by focusing the RI/FS tasks on just the data required to evaluate alternatives that are most practicable for municipal landfill sites. Scoping of municipal landfill site RI/FS tasks can be streamlined by:

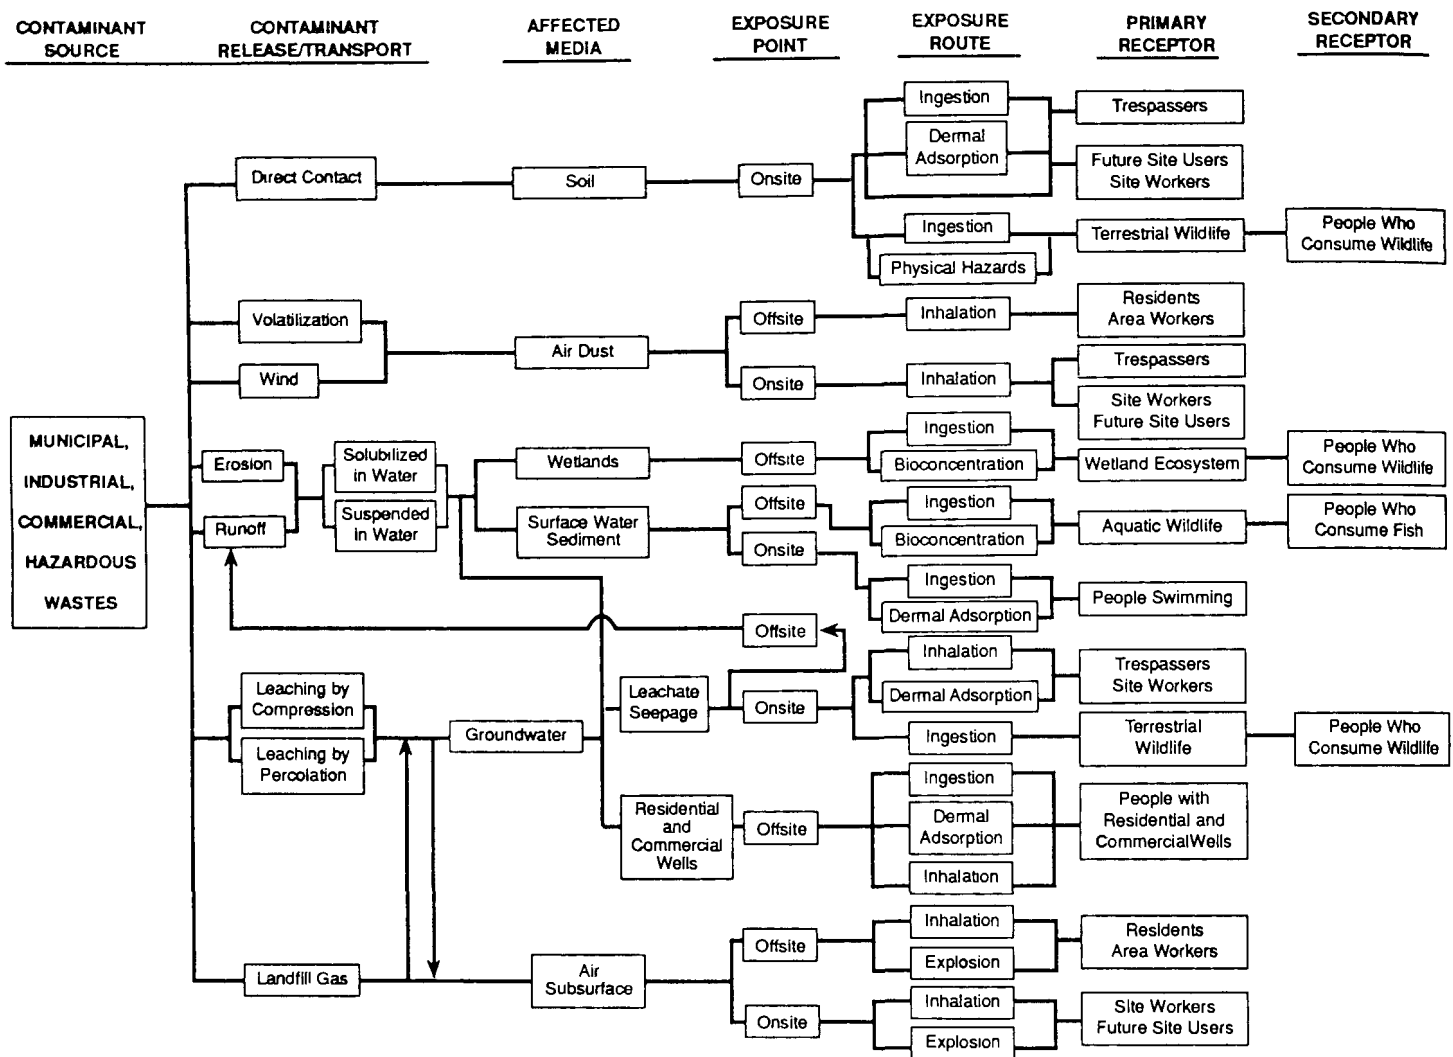
- Developing preliminary remedial objectives and alternatives based on the NCP expectations and focusing on alternatives successfully implemented at other sites


Figure 1
Potential Exposure Pathways for Municipal Landfills

- Using a generic conceptual site model developed for municipal landfill sites (based on their similarities) and modifying it as necessary to reflect site conditions
- Conducting limited field investigations to assist in targeting future fieldwork (Table 1)
- Identifying clear, concise RI objectives in the form of field tasks to ensure sufficient data are collected to adequately characterize the site, perform the necessary risk assessments(s) and evaluate the practicable remedial action alternatives
- Identifying data quality objectives (DQOs) that result in a well-defined sampling and analysis plan, ensure quality of the data collected and integrate the information required in the RI/FS process
- Limiting the scope of the baseline risk assessment as discussed below

Streamlining the Baseline Risk Assessment

The purpose of the baseline risk assessment is to determine whether a site poses risks to human health and the environment that are significant enough to warrant remedial action. Because options for remedial action at municipal landfill sites are limited, it may be possible to streamline or limit the scope of the baseline risk assessment by:

- Using the conceptual site model and RI-generated data to perform a qualitative risk assessment that identifies contaminants of concern in the affected media, contaminant concentrations and their hazardous properties that may pose a risk through the various routes of exposure.
- Identifying pathways that are an obvious threat to human health or the environment by comparing RI-derived contaminant concentra-

tion levels to standards that are potential chemical-specific applicable or relevant and appropriate requirements (ARARs) for the action. These ARARs may include:

— Non-zero maximum contaminant limit goals (MCLGs) and MCLs for ground water and leachate
— State air quality standards for landfill gas

- When potential ARARs do not exist for a specific contaminant, risk-based chemical concentrations should be used.
- Where established standards for one or more contaminants in a given medium are clearly exceeded, the basis for taking remedial action is clearly warranted (i.e., quantitative assessments that consider all chemicals, their potential additive effects or additivity of multiple exposure pathways are not necessary to initiate remedial action).
- In cases where standards are not clearly exceeded, a more thorough risk assessment will be necessary before initiating remedial action.[3,4]

This streamlined approach may facilitate early action on the most obvious landfill problems (groundwater and leachate, landfill gas and the landfill contents) while analysis continues on other problems such as affected wetlands and stream sediments. However, the effect of early action on obvious problems should be factored into any ongoing risk assessment. For example, if leachate seepage that had been contaminating surface water and wetlands is stopped as a result of an early action, then the risk assessment developed subsequently for the stream sediments and wetlands should assume no further loading. Any early actions also need to be designed for flexibility so that they will

Activity	Objectives	Action
Hydrogeologic Investigation	Evaluate usefulness of existing monitoring well network	Conduct a well survey for all wells (residential, commercial, industrial). Determine local uses of groundwater and accessibility of existing wells. Obtain permission for use. Determine, by sounding to the bottom of the well if existing wells are obstructed.
	Review preliminary locations for new monitoring wells	Perform fracture-trace analysis in areas with fractured bedrock (can be done through EPIC study).
	Determine location of residential wells and their construction	Perform well survey for all residential wells adjacent to, and downgradient from, the landfill. Obtain well logs from federal, state, local utilities, or municipal agencies.
	Determine direction of groundwater flow and estimate gradients	Record water level measurements from existing wells.
	Determine rate of groundwater flow in strata and bedrock fractures	Perform hydraulic conductivity tests on existing wells.
	Confirm previous sampling results for both existing monitoring and residential wells and collect additional data as necessary. Identify areas of groundwater contamination and types of contaminants.	Collect and analyze samples from monitoring and residential wells. Record quality parameters for the samples analyzed. Compare new results with values from previous studies.
	Determine if residential wells adjacent to, and downgradient from, the landfill are contaminated	Collect and analyze tap water samples before any filtration unit and conduct preliminary risk assessment.
General Investigation	Identify previous site owner/operators and delineate site boundaries. Estimate uncertainties in boundaries	Conduct property survey or perform a title or identify property ownership from tax records, or plat maps.
	Locate existing monitoring wells	Perform location and elevation survey of existing monitoring wells.
	Evaluate site drainage patterns	Perform a topographic and hydrologic survey.
	Evaluate site-cover conditions and surface water drainage	Perform visual surface inspection with topographic maps. Conduct surface emissions survey.
	Evaluate gas migration, potential, if applicable	Measure explosive gas levels in nearby residences, or onsite buildings, if present. Also measure in water meter boxes and utility corridors, if landfill gas poses a threat.
	Locate sampling locations	Survey a grid for the site and cross-reference to sample locations.
	Determine landfill subsidence, if survey is otherwise required	Measure elevations along crown of fill or install benchmarks in areas of potential subsidence (requires repeat visits by surveyor).
Geotechnical Investigation	Describe geologic features, classify soil	Conduct visual observation of mechanical erosion, slope instability, differential settlement,, and ponding caused by subsidences and cracking.

be consistent with subsequent actions. For example, it may be necessary to adjust a groundwater pump-and-treat early action designed to attain MCLs to achieve even lower levels, determined to be necessary under a subsequent risk assessment, in the interest of protecting environmental receptors in the wetlands into which the groundwater discharges.

Ultimately, it will be necessary to demonstrate that the final remedy,

once implemented, will in fact address all pathways and contaminants of concern, not just those that triggered the remedial action. The approach outlined above facilitates rapid implementation of protective remedial measures for the major problems at a municipal landfill site.

STREAMLINING SITE CHARACTERIZATION

Site characterization for municipal landfills can be expedited by focusing field activities on the information needed to sufficiently assess risks posed by the site and to evaluate practical remedial actions. Media-specific recommendations to help streamline site characterization of media that are unique to landfills are discussed below.

Leachate/Groundwater Contamination

Characterization of a site's geology and hydrogeology will affect decisions on capping options as well as on extraction and treatment systems for leachate and groundwater. Data gathered during the hydrogeologic investigation are similar to those gathered during investigations at other types of NPL sites. Groundwater contamination at municipal landfill sites may, however, vary in composition from that at other types of sites in that municipal site groundwater often contains high levels of organic matter and metals.[5,6]

Leachate generation is of special concern when characterizing municipal landfill sites. The main factors contributing to leachate quantity are precipitation and recharge from groundwater and surface water. Leachate is characteristically high in organic matter as measured by chemical oxygen demand (COD) or biochemical oxygen demand (BOD). Information to be gathered during characterization of leachate may be limited to:

* Surface water drainage patterns
* Climatological characteristics (for example, precipitation and evapotranspiration)
* Leachate characteristics [for example, TCL organics, TAL metals, BOD, COD, pH, total dissolved solids (TDS), total suspended solids (TSS) and oil and grease]
* Identification of Class I and II aquifers and their associated water levels, flowrates and chemistry

In many landfills, leachate is perched within the landfill contents, above the water table. Placing a limited number of leachate wells in the landfill is an efficient means of gathering information regarding the depth, thickness and types of the waste; the moisture content and degree of decomposition of the waste; leachate head levels and the composition of the landfill leachate; and the elevation of the underlying natural soil layer. Additionally, leachate wells provide good locations for landfill gas sampling. It should be noted that, without the proper precautions, placing wells into the landfill contents may create health and safety risks. Also, installation of wells through the landfill base may create conduits through which leachate can migrate to lower geologic strata, and the installation of wells into landfill contents may make it difficult to ensure the reliability of the sampling locations.

Landfill Contents

Characterization of a landfill's contents generally is not necessary because containment, which often is the most practical technology, does not require such information. Certain data, however, are necessary to evaluate capping alternatives. The needed data include:

* Contour maps
* Fill thickness, lateral extent and age
* Estimate of landfill settlement rate
* Estimate of rate of landfill gas production and landfill gas composition
* Soil characteristics, including permeability, grain size, Atterberg limits and erosion rates
* Climatic conditions, including frost depth, and the appropriate storm event to assess the potential for significant erosion
* Geologic and hydrogeologic characteristics, particularly the permeability of the layer underlying the landfill; depth to groundwater; thickness of waste below the water table; and groundwater flow through the waste, if the waste is partially below the water table
* Physical characteristics of any existing cap, including thickness, area,

slope stability, evidence of freeze/thaw protection and soil characteristics
- An evaluation of the ability of an existing cap to reduce surface gas emissions and odors, prevent oxygen intrusion into the refuse, prevent surface water infiltration, provide erosion control and improve site aesthetics
- Potential future uses of the site

Hot Spots

Hot spots may lend themselves to more extensive remedial alternatives such as thermal treatment or stabilization.[7] In order to consider treatment of hot spots, a waste type or mixture of wastes must be in discrete, accessible locations of a landfill and must be highly toxic and/or highly mobile and present a principal threat to human health or the environment. A hot spot should be large enough that its remediation would significantly reduce the risk posed by the overall site, but small enough that it is reasonable to consider removal or treatment. A landfill containing a low to moderate volume of waste (for example, 100,000 cubic yards or less), and where treatment of the entire landfill contents might be practical, may be treated as a hot spot.

To determine if treatment is practicable, hot spots should be characterized if documentation and/or physical evidence exist to indicate the presence and approximate location of the hot spots. Hot spots may be delineated using geophysical techniques or soil gas surveys and typically are confirmed by excavating test pits or drilling soil borings. When characterizing hot spots, soil samples should be collected to determine waste characteristics, including target analytes list metals, target compound list organics, RCRA waste characteristics, total BTU content and weight of the material. Treatability or pilot testing may be required to evaluate treatment alternatives.

Landfill Gas

Several gases typically are generated by decomposition of organic materials in a landfill. The composition, quantity and generation rates of the gases depend on such factors as refuse quantity and composition, placement characteristics, landfill depth, refuse moisture content and amount of oxygen present. The principal gases generated in municipal landfills are carbon dioxide, methane, nitrogen, trace thiols and, occasionally, hydrogen sulfide. Volatile organic compounds may be present in landfill gases, particularly at co-disposal facilities. Data generated during the site characterization of landfill gas should include:

- Contour drawings and rate of settlement
- Geologic and hydrogeologic characteristics, including permeability, moisture content, geologic strata, pH, depth to bedrock and depth to groundwater
- Presence of off-site subsurface migration
- Surface emissions
- Ambient air monitoring
- Landfill gas characteristics, including composition, moisture content, quantity, temperature and methane content

STREAMLINING THE DEVELOPMENT OF ALTERNATIVES

Figure 2 identifies remedial technologies and process options that frequently have been implemented for achieving remedial action objectives at CERCLA municipal landfill sites. The following points should be considered in order to streamline the development of remedial action alternatives for landfill contents, hot spots, landfill gas, contaminated groundwater and leachate:

- The most practicable remedial alternative for landfills is containment (capping). The type of cap would likely be either a native soil cover, single barrier cap, or double barrier cap. The appropriate type of cap to be considered will be based on remedial objectives for the site. For example, a soil cover may be sufficient if the primary objective is to prevent direct contact and minimize erosion. A single or double barrier cap may be necessary where infiltration is a significant concern. Figure 3 is a simplified decision-tree for selecting the appropriate type of cap.
- Treatment of soils and wastes may be practicable for hot spots. Consolidation of hot spot materials under a landfill cap is a poten-

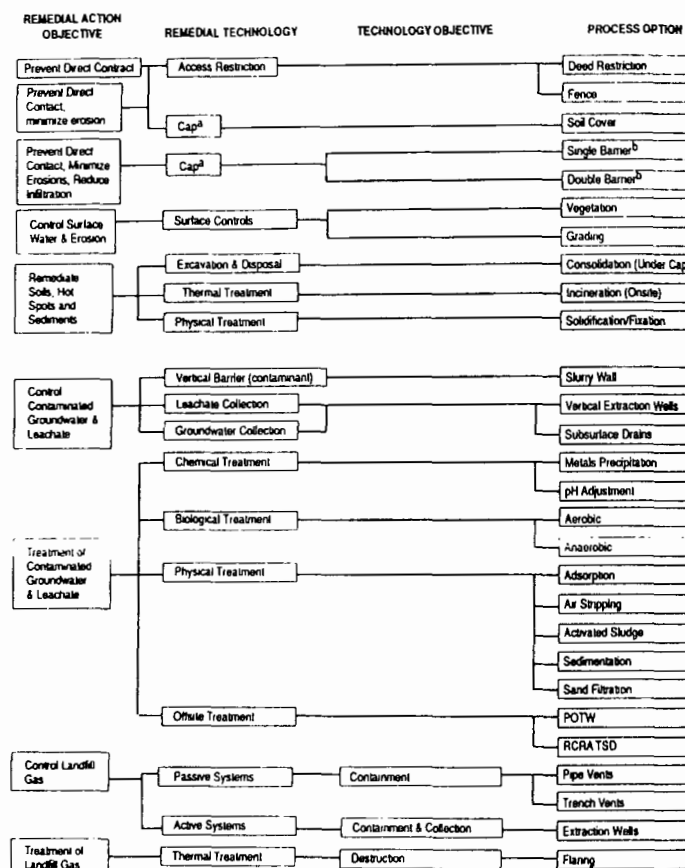
tial alternative in cases when treatment is not practicable or necessary.
- Extraction and treatment of contaminated groundwater and leachate may be required to control off-site migration of wastes. Additionally, extraction and treatment of leachate from landfill contents may be required. Collection and treatment may be necessary indefinitely because of continued contaminant loadings from the landfill.
- Constructing an active landfill gas collection and treatment system should be considered when: (1) existing or planned homes or buildings may be adversely affected through either explosion or inhalation hazards, (2) final use of the site includes allowing public access or (3) the landfill produces excessive odors. Most landfills will require at least a passive gas collection system (venting) to prevent buildup of pressure below the cap and to prevent damage to the vegetative cover.


Figure 2
Technologies Frequently Implemented for Remedial Action at CERCLA Municipal Landfill Sites

CONCLUSIONS

Evaluation and selection of appropriate remedial action alternatives for CERCLA municipal landfill sites are functions of a number of factors including:

- Sources and pathways of potential risks to human health and the environment.
- Potential ARARs for the site.[8,9] Significant ARARs might include RCRA closure requirements (Subtitle D requirements will be applicable unless Subtitle C is determined to be applicable or relevant and appropriate)[8] and federal or state requirements pertaining to landfill gas emissions.
- Waste characteristics.
- Site characteristics (including surrounding area).
- Regional surface water (including wetlands) and groundwater characteristics and potential uses.

LANDFILL CHARACTERISTICS	REMEDIAL OBJECTIVES	COVER TYPE

Minimal Hazardous Substances in Landfill and Minimal Contamination of Groundwater

Significant Percentage of Hazardous Substances in Fill Are Below the Water Table, And Lowering the Water Table Is not Practicable

Leaching of Hazardous Substances to Groundwater Is Expected to Contribute to Unacceptable Human Health or Environmental Risks, and Reliability of Single Barrier Is Considered Adequate c

Significant Contaminant Mass in Fill, and Risks of Hazardous Substances Leaching to Groundwater Are Great

High Degree of Reliability Needed in Method of Minimizing Leaching of Hazardous Substances to Groundwater

Prevent Direct Contact; Minimize Erosion a → Native Soil Cover

Prevent Direct Contact; Minimize Erosion; Minimize Infiltration → Single Barrier Cap b

Prevent Direct Contact; Minimize Erosion; Prevent Infiltration → Double Barrier Cap

a Primary objective is to prevent direct contact, although the soil cover can be designed to reduce infiltration.

b Single barrier caps may include additional layers that provide protection to that barrier.

c Examples include situations where infiltration is not the primary concern and may include sites containing a small volume of contaminant mass, regions with low annual precipitation, or sites where groundwater is not being used as a source of drinking water.

Figure 3
Landfill Cover Selection Guide

Because these factors are similar for many CERCLA municipal landfill sites, it is possible to focus the RI/FS and selection of remedy process. In general, the remedial actions implemented at most municipal landfill sites include: (1) containment of landfill contents (i.e., landfill cap) (2) remediation of hot spot areas, (3) control and treatment of contaminated groundwater and leachate and (4) control and treatment of landfill gas. Other areas which commonly require remediation include surface waters, sediments and adjacent wetlands.

NOTICE

The policies and procedures set out in this paper are intended solely for the guidance of response personnel. They are not intended, nor can they be relied upon, to create any rights, substantive or procedural, enforceable by any party in litigation with the United States. The U.S. EPA officials may decide to follow this guidance, or to act at variance with these policies and procedures based on an analysis of specific site circumstances, and to change them at any time without public notice.

Improving the Remedy Selection Process:
An Explicit and Interactive Process

Douglas J. Sarno
Clean Sites, Inc.
Alexandria, Virginia

ABSTRACT

This paper summarizes the results of a year-long project to study the process of selecting remedies at Superfund hazardous waste sites. One key to getting a larger number of sites cleaned up is making the remedy selection process work as effectively and rationally as possible. The choice of a remedy determines the total cost of cleanup and the level of protection it will afford. The current process has been widely criticized as inconsistent.

The Clean Sites project identified that a key problem with the current process of selecting remedies is that it works backwards—the U.S. EPA explores in depth all the alternative cleanup methods it plans to consider before it determines the level of protection necessary for the site. Part of the problem is that program goals and requirements of site cleanup are poorly defined.

In its report, Clean Sites recommends that the U.S. EPA move to a process that explicit defines cleanup requirements and requires cleanup objectives be developed for each site before alternatives are developed. Clean Sites also recommends that the U.S. EPA adopt a more interactive approach to decision-making that elicits and responds to citizens' and states' comments as part of setting site cleanup objectives and before selecting a preferred alternative.

INTRODUCTION

Following the October 1986 reauthorization of the Comprehensive Environmental Response, Compensation and Liability Act (CERCLA), members of the Superfund community criticized many of the remedies being selected by the U.S. Environmental Protection Agency (U.S. EPA) for Superfund sites. The U.S. Office of Technology Assessment (OTA) and a number of other government, industry and environmental organizations released reports charging that the U.S. EPA was not complying with the specific provisions for remedy selection developed as part of the Superfund Amendments and Reauthorization Act of 1986 (SARA).

In light of these criticisms, Clean Sites developed a project to bring together representatives from all areas of the broad Superfund community to discuss their concerns regarding Superfund remedy selection and to identify improvements to the current process. The project was initiated in the summer of 1989 under grants from the U.S. EPA and the Andrew W. Mellon Foundation, with additional support from private contributions. Nearly 100 individuals participated in a series of meetings and workshops in 1989 and 1990 to generate ideas for improving remedy selection in Superfund. The input of the many individuals who participated in this project was invaluable to the development of our recommendations. However, the recommendations presented in this report are those of Clean Sites.

As expected, the project revealed a great deal of continuing disagree-ment among the many participants in the Superfund program regarding the key requirements and goals of remedy selection—and of the Superfund program itself. Fortunately, there is also a great deal of common ground from which to build an effective remedy selection process.

THE CHALLENGE OF REMEDY SELECTION

For any remedy selection process to be effective, it must direct decision-makers to answer two fundamental questions at each Superfund site:

- What level of cleanup is required to achieve overall protection of human health and the environment?
- How will this level of cleanup be achieved?

The answers to these questions are not straightforward. The factors that are taken into consideration vary among sites and include risks to public health and the environment, statutory preferences, available technology, cost, liability and political sensitivities. Very often these issues create conflicting considerations for site cleanup.

At every site there are a number of interested parties with a stake in the decision. At most sites, these parties include the U.S. EPA, state environmental agencies, local citizen groups and potentially responsible parties (PRPs). Additional stakeholders may include other federal and state agencies, local governments, and national environmental groups. Naturally, each group approaches site cleanup from a different perspective. These different perspectives often result in differing opinions as to the cleanup requirements of the site.

In addition to the challenge of balancing the many issues and the range of interests involved in remedy selection, the U.S. EPA faces several fundamental challenges as a result of its decision to implement the Superfund program in a decentralized fashion. Paramount among these challenges is the tension between the desire for program consistency and the need for site-by-site flexibility. The challenge confronting the U.S. EPA as it attempts to implement a successful remedy selection process is to balance all of the site-specific and program-wide considerations of Superfund to protect human health and the environment, meet statutory directives and respond to stakeholder concerns — without creating a bureaucratic quagmire.

The U.S. EPA's current approach to remedy selection is presented in the National Oil and Hazardous Substances Pollution Contingency Plan (NCP). The U.S. EPA remedy selection process centers on the application of nine evaluation criteria representing the statutory requirements for Superfund cleanups and other considerations identified by the U.S. EPA for remedy selection. The overall process was developed to provide a great deal of flexibility to the site decision-maker.

MAJOR ISSUES

The results of Clean Site's project indicate that a number of specific

impediments exist to the implementation of effective and consistent remedy selection. The most significant issues and the resulting problems created in remedy selection are summarized below.

Issue 1

There is no program definition and little consensus among stakeholders as to "overall protection of human health and the environment." Overall protection is the primary objective of Superfund, yet there is no overall program definition or comprehensive site-specific process to establish this level of protection. In fact, the current remedy selection process does not require determination of site-specific cleanup levels to achieve protection of human health and the environment until after a remedial alternative has been selected.

The use of applicable or relevant and appropriate requirements (ARARs) in conjunction with site-specific risk assessment to establish cleanup levels has not been sufficiently developed or consistently applied at Superfund sites. The use of ARARs is confusing and time-consuming because most of these standards were developed to address different types of environmental problems. More specific guidance is needed before site-specific risk assessment can be used with any consistency to establish cleanup levels.

The results that remedy selection decision-making often works backwards—potential remedies are developed and evaluated before the level of cleanup necessary to achieve protection of human health and the environment is established. The lack of explicit standards or an explicit process to determine "how clean is clean" at specific sites results in insufficient attention to this issue. As a result, decision-makers are often inexplicit and local citizens and other interested parties are not informed as to the level of cleanup that is required to protect human health and the environment.

Issue 2

The nine criteria approach does not provide for the explicit evaluation of the statutory requirements for Superfund remedies. In particular, insufficient definitions exist for "permanence," "treatment," "long- term effectiveness" and "cost-effectiveness." The current process makes little distinction between long-term effectiveness and permanence and defines both concepts on a continuum. No specific process exists to guide the decision-maker in making the determination of cost-effectiveness. The use of treatment has been much debated and often has focused on the use of treatment for its own sake. The result of the above-cited problem is that the application of the statutory requirements is inconsistent and ambiguous. Inexplicit definitions have generated semantic arguments that obfuscate program objectives. Focus is often diverted from the actual results that the overall site cleanup will achieve. The outcome is a lack of consistency in the application of "permanence," "treatment," "long-term effectiveness" and "cost-effectiveness." In particular, the preference for permanence is often ignored.

Issue 3

The use of "modifying criteria" to formally address state and community concerns focuses much of the site communication at the end of the process in the record of decision (ROD). Currently, the U.S. EPA does not communicate the majority of important information regarding remedy selection until a remedy is proposed. Communities are not involved in the setting of objectives or goals for the site. The result of the foregoing is that communities generally believe they have no opportunity for meaningful input into decision-making. Because of the focus of communication in the ROD, important site information and decision-making rationale is not communicated in a clear and timely fashion. The use of the "modifying criteria" has created unnecessary friction between the U.S. EPA and states and communities by creating the impression that the only chance for input occurs after the U.S. EPA has proposed a remedy. As a result, communities often are reluctant to accept any remedy that may be proposed.

RECOMMENDATIONS FOR IMPROVING REMEDY SELECTION

Clean Sites believes that a long-term view of the hazardous waste cleanup problem should be adopted. Initiatives taken today may not assist the cleanup of those sites currently on the National Priorities List, but there are thousands of sites to be cleaned up and the more effort put toward the problem now, the faster the cleanups will be in the future, not just for Superfund but for all waste site cleanups. In response to the issues identified as a result of the project activities, Clean Sites believes that for remedy selection to be effective, the U.S. EPA approach to decision-making must do the following:

- Require the explicit determination and communication of site risks and objectives for cleanup as early in the process as feasible
- Clearly define the statutory requirements of Superfund and identify how they are to be achieved
- Enforce a consistent process which recognizes the need to incorporate site-specific considerations
- Provide for interactive communication throughout the process to generate input from all stakeholders, particularly the community

To address each of these desired characteristics, Clean Sites has developed the following recommendations:

1. U.S. EPA should establish an explicit process to focus on the identification of the level of cleanup necessary to achieve site-specific protection of human health and the environment. Such a process is presented in the following section. The purpose of an explicit process is to clearly identify the goals of the program and explain for each site how those goals have been achieved or why they cannot be achieved.

2. U.S. EPA should improve the usefulness of ARARs by more clearly identifying which standards apply to Superfund sites. A clearly applicable subset of available environmental standards will be much more useful than the current approach by allowing for quicker and more consistent application. Also important, this will allow for the comprehensive identification of specific site conditions for which no usable standards exist.

3. U.S. EPA should set a long-term goal, and focus the necessary resources, to develop standards to fill the gaps in currently available ARARs wherever possible. A practical set of nationally-developed standards applicable to the cleanup of even some categories of hazardous waste sites would greatly improve the cleanup process by reducing the time and conflict of selecting cleanup levels.

Clean Sites recognizes the time and effort that creating such standards would entail, but believes the size of the cleanup program and the long-term nature of the problem warrant a significant investment in investigating its feasibility. At least, the U.S. EPA should attempt to develop concentration levels for that subset of chemicals that are most commonly encountered. Setting the development of standards as a national long-term goal with the appropriate resource commitment will help to stimulate the development of the fundamental scientific base that ultimately can contribute to the quantification of risks to human health and the environment. During the life of Superfund, which may well exceed the professional careers of many current decision-makers, this effort would improve the certainty with which site cleanups are performed.

These standards would need to operate within a total framework that allows for different levels of site use and recognizes the highly variable conditions at hazardous waste sites. Part of developing standards should be to focus more strongly on the cleanup levels that are being selected at specific sites. When conditions are encountered at a site for which no standards are available, decisions made at that site should guide future decisions at similar sites. It is time to incorporate much better use of past experience into Superfund decision-making. The use of each site decision as a potential precedent for future decisions will result in a greater focus on the cleanup levels being selected and speed up future decision-making.

4. The U.S. EPA should develop a specific and detailed approach to using risk assessment procedures to establish site cleanup levels. Clean Sites recognizes that there are many conditions for which national standards are not feasible. Site-specific risk assessment will continue to be one of the primary tools for setting cleanup levels. The U.S. EPA should develop specific procedures and specific exposure scenarios that

provide the flexibility to select different future land uses.

5. The U.S. EPA should give greater weight to the so-called "point of departure" in the residual risk range. To increase the consistency of using risk assessment and to increase the explicitness of remedy selection, more stringent rules should be developed for deviating from the excess upperbound lifetime cancer risk of one-in-one-million (10^{-6})—the U.S. EPA's "point of departure." The current risk range of one-in-ten-thousand (10^{-4}) to 10^{-6} provides a very large variance in cleanup levels. By calling the entire range fully protective, the U.S. EPA has created a source of contention. Many PRPs logically take the position that if 10^{-4} is "fully protective," then they should not be required to achieve a higher level of protection. The NCP identifies 10^{-6} as a "starting point," which suggests that its attainment will be an exception. Clean Sites believes the point of departure should be viewed more seriously. Deviations should be permitted based upon site conditions, but the reasons for these deviations should be clearly explained and objectives for the site (including the future land use) should be revised as necessary.

6. The U.S. EPA should clearly define permanence as a goal of Superfund cleanups. Permanence will not be achieved at every site, but the statutory requirement to achieve permanence "to the maximum extent practicable" suggests that the feasibility of achieving a permanent solution should be specifically evaluated at each site. Permanence for Superfund should present a stringent but attainable goal. The dictionary definition of "permanent" is "intended to last indefinitely without change." Clean Sites believes this concept should be transferred to the evaluation of permanence with regard to Superfund sites. The application of permanence Clean Sites proposes is as follows:

> "Permanent solutions return the site to a usable condition by irreversibly eliminating the threat of any future release that would increase the risk to human health or the environment above cleanup levels identified for the site. Permanent solutions must conform with the statutory preference that waste not be disposed off-site without treatment."

This definition does not allow containment remedies to be considered permanent, but does allow remedies that achieve less than pristine levels of cleanup to be considered permanent when justified by site conditions.

7. Because permanence will not be achieved in many cases, long-term effectiveness should be the primary criterion in the evaluation of remedial alternatives. Long-term effectiveness is the ability of a remedy to maintain the desired level of protection over time. This, in effect, represents the "next best thing" to a permanent solution if a permanent solution is not practicable. In order to fully evaluate the long-term effectiveness of each alternative, the expected useful life of each alternative should be calculated (in years).

8. Treatment should not be used as a stand-alone criterion, but rather evaluated as a means to achieve permanence or long-term effectiveness. It is not the use of treatment, but the result of using treatment, that is important. Treatment options should be developed to clearly demonstrate the increased protection and long-term effectiveness they provide relative to containment remedies.

9. The consideration of cost should be more clearly evaluated against the overall result of site cleanup. Consideration of costs should be the last step in remedy selection. A cost-benefit approach for Superfund should compare costs against the primary benefit of long-term effectiveness. This approach would provide a relative measure of the long-term value of each alternative from which to make a decision.

10. The U.S. EPA should establish an interactive remedy selection process to incorporate the views of both the community and the state throughout remedy selection. The only way for these viewpoints to be fully considered is to involve the community and state in decision-making activities by regularly discussing issues and options regarding site cleanup. Round table discussions among all parties should be used to promote a greater understanding of site conditions and a mutual understanding of the concerns of each of the parties.

11. The U.S. EPA should disclose all site information as soon as it is available. The community needs detailed information early in the cleanup process. In order for an interactive process to work, all stakeholders must be well informed about site problems and activities.

12. U.S. EPA should develop a headquarters task force to assist in remedy selection. In a delegated program seeking consistency, some central source of guidance and assistance needs to be created to ensure quality and consistency in remedy selection. This group would not second-guess decisions, but would provide a clearinghouse for information and assistance and monitor the consistency of decision-making among U.S. EPA regions.

AN EXPLICIT PROCESS FOR REMEDY SELECTION

Remedy selection is influenced by all site characterization activities. Community relations, the remedial investigation (RI), the feasibility study (FS), and the ROD are all interrelated and should be considered components of a single remedy selection process. However, the current timing of these activities does not promote a logical decision-making process or provide discrete points for communication and interaction. The remedy selection process should promote an understanding of how all these activities are linked and focus decision-makers on the relevance of these activities to the overall determination of the appropriate response action.

To help achieve this goal, Clean Sites recommends that the decision-making process used by the U.S. EPA for remedy selection be reoriented to focus on the major issues that must be resolved at every site. These are:

* What are the risks to human health and the environment that require remediation?
* What is the level of cleanup necessary to achieve protection of human health and the environment in response to these risks?
* What alternatives are available to achieve the identified level of cleanup?
* Which alternative best fits the site conditions?

Clean Sites recommends that the U.S. EPA adopt a four-step process directed at explicitly answering these questions. Such a process would not require changing the content of the RI or the FS, but would simply reorient key decision-making points. The application and importance of each of the nine criteria would be strengthened through their explicit consideration at appropriate points throughout the process. The process Clean Sites recommends is presented below.

Step 1: Clearly Define the Problem

The site characteristics and risks identified in the RI and the base line risk assessment need to be clearly and consistently communicated because they play a key role in remedy selection. Site risks will guide the development of site cleanup objectives by focusing the decision on what specific problems of the site require remediation. A clear description of site risks also provides the community with a basis of understanding for subsequent site decisions. Early communication of these risks to the community should provide the U.S. EPA a vehicle to gain an understanding of the fears and concerns of the community.

Step 2: Establish Site Cleanup Objectives

The most critical point of remedy selection is establishing site-specific cleanup objectives. These objectives are: (1) the level of cleanup necessary to protect human health and the environment and (2) the expected use of the site. Clean Sites recommends that the U.S. EPA's "threshold criteria" (overall protection of human health and the environment and compliance with ARARs) be specifically identified and evaluated through explicit objective-setting.

Cleanup objectives should be detailed and explicit enough to guide the development of alternatives and to provide outside parties an understanding of what is to be achieved at the site. Developing cleanup objectives is an iterative process. Initial objectives should be realistic and sensible in light of the site conditions and, therefore, achievable. However, there will always be instances when initial objectives are determined not to be feasible from a technical or cost standpoint once alternatives are developed. In these cases, the objectives should be revised

and new objectives developed in light of the new information.

The revision of objectives should be as explicit an activity as the original development of objectives. It should also be recognized that there are cases when a higher level of cleanup is achievable at a small incremental cost, and this also must be considered as the process progresses. It is important that final cleanup objectives be developed before a remedy is selected.

Step 3: Develop Remedial Alternatives

Comprehensive cleanup alternatives should not be developed until after the objectives are established so that all alternatives, at a minimum, meet the site objectives. (This does not mean that all of the activities of the FS must wait until after the RI, as there are many data gathering and preliminary design steps that can proceed prior to the development of objectives.) Also at this point in the process, explicit consideration of permanence, treatment and long-term effectiveness is required so that these criteria can be fully considered in the evaluation of alternatives. At least one permanent remedy should be developed.

Step 4: Evaluate Alternatives and Select a Remedy

Alternatives should be evaluated considering cost, permanence, long-term effectiveness and the concerns of the community and state. To frame the problem, Clean Sites recommends a cost-benefit approach which compares the cost of alternatives to their overall long-term effectiveness. Permanent solutions represent the highest level of long-term effectiveness.

Since all of the alternatives under consideration must achieve site objectives, the task of selecting an alternative will be to select the alternative that achieves the greatest long-term value (protection over the longest number of years for the lowest cost). In some cases, one alternative will stand out. In other cases, several alternatives may provide similar long-term value. In such cases, community and state preferences would then be used to choose among the remaining alternatives.

CONCLUSION

The remedy selection process presented by Clean Sites forces the explicit communication of important site decision-making information early in the process. It is directed at eliciting and incorporating the views of all stakeholders. As such, much of the site controversy will occur earlier in the process than currently. Clean Sites believes this will force the U.S. EPA and the stakeholders to focus more deliberately on the difficult issues that must be resolved and be more explicit about the decisions that are reached. While this may slow the process somewhat in the beginning, it will ultimately lead to better decision-making, more community trust and more effective implementation of remedial actions.

Title III Of SARA: The Facts You Need To Know

James M. Buchert
Kenneth L. Mitchell, Ph.D.
GEO/Resource Consultants, Inc.
Washington, District of Columbia

INTRODUCTION

Any business that handles or uses chemicals is potentially regulated by Title III of SARA, the Emergency Planning and Community Right-to-Know Act (EPCRA). This paper is designed to help facility owner/operators comply successfully with all of EPCRA's requirements and avoid enforcement actions.

The discussion will concentrate on each reporting requirement with significant detail. For the emergency planning requirements under Section 302 of EPCRA, the paper focuses on the responsibilities given to facilities and also to local emergency planners.

The EPCRA, Section 304 emergency release reporting requirements encompass both the extremely hazardous substances and the CERCLA hazardous substances subject to the CERCLA Section 103(a) provisions. The paper discusses the differences between the two reporting requirements and how to correctly report releases. Under Sections 311 and 312 of EPCRA, any facility that is subject to the Occupational Safety and Health Administration (OSHA) Hazard Communication Standard (HCS) is subject to the inventory reporting requirements of EPCRA.

The EPCRA, Section 313 toxic chemical release reporting is probably the most well-known and most complex of the EPCRA requirements. The discussion will explain how to make an accurate threshold determination and how to properly complete U.S. EPA Form R. Under Section 322, of EPCRA there are provisions to claim and substantiate as trade secret a particular chemical identity an owner or operator wants withheld from the public or competitors. Lastly, there is a brief section on how the information collected is made available to the public under EPCRA.

SECTION 302: EMERGENCY PLANNING

According to SARA Title III, the Local Emergency Planning Committee (LEPC) is primarily responsible for developing and maintaining an emergency plan for its district. The State Emergency Response Commission (SERC) is responsible for coordinating the district plans together into a comprehensive statewide emergency plan. Section 302 of EPCRA was developed because no matter how broad-based the membership of the LEPC and SERC, it would be very difficult for them to identify every potential chemical hazard in their community. EPCRA, Section 302 provides a mechanism for identifying facilities that the planners should take into account in their planning efforts.

Who Is Subject

Since emergency planning is important to entire communities, the EPCRA, Section 302 requirements apply to all sectors of the community, from private residences to large businesses. There are very few facilities not included in the scope of Section 302 of EPCRA.

Exemptions

Ships and federal facilities are the only types of facilities not subject to Section 302 or any other section of EPCRA. Federal facilities are not included in the scope of EPCRA due to the following regulatory language: a "facility" for SARA Title III purposes must be "owned or operated by the same person" (40 CFR 355.20). The definition of "person" at 40 CFR 355.20, however, does not include the federal government. This unintentional exclusion applies only to federal facilities operated by Federal employees. This exclusion does not include government owned-contractor operated facilities (GOCOs) even though these GOCOs may be operating on Federal property.

Similarly, there is only one category of substances excluded from Section 302 and the other sections of EPCRA, except Section 304 emergency release notification. The substances in this category are those in transit. These substances in transit were given a statutory exemption by Congress. Section 327 of EPCRA reads: "Except as provided in Section 304, this title does not apply to the transportation, including the storage incident to such transportation, of any substance or chemical subject to the requirements of this title, including the transportation and distribution of natural gas." Therefore, if a substance is under active shipping papers, whether it is actively in transit, in storage during transit or in a distribution pipeline, it is considered to be in transit and not included in the scope of EPCRA (except for Section 304). However, once the substance is delivered and the shipping papers are signed, that substance is no longer exempt under the above provision. The substance must then be included in any applicable threshold determinations. Similarly, once a substance in a pipeline reachs an end-of-the line holding tank and is no longer in the pipeline, it is no longer part of the transportation exemption and must be included in any applicable threshold determinations.

De Minimis

In order to make threshold determinations for mixtures and solutions easier to calculate, the U.S. EPA set a minimum concentration level below which a person can disregard the EHS. This level is called the de minimis. The de minimis for Section 302 of EPCRA is 1%. Any amount in a concentration greater than 1% must be factored into a threshold determination. Any amount less than or equal to 1% can be excluded from the threshold determination (40 CFR 355.30(e)(1)).

Facilities (excluding ships or vessels and Federal facilities) are subject to the emergency planning provisions of Section 302 of EPCRA if they are a facility at which there is present an EHS equal to or exceeding its Threshold Planning Quantity (TPQ) or if they are a facility that has been designated by the SERC under the authority of SARA Section 302(b)(2) to become subject to the requirements of emergency

planning. The following discussion will focus on the substances covered and the thresholds for reporting.

The Extremely Hazardous Substances (EHS) List

The EHS list was originally developed by the U.S. EPA under the voluntary Chemical Emergency Preparedness Program (CEPP) as the acutely toxic chemicals list. The purposes of the EHS list were, and still are, to identify substances which, if released, could cause serious, irreversible health effects and to provide emergency planners with a starting point for their efforts. In order to identify these substances, the U.S. EPA developed criteria that would be used to identify short- and long-term health effects resulting from short, term exposure. These criteria were then applied to the Registry of Toxic Effects of Chemicals Substances (RTECS) data base. Any substance that met one or more of the criteria was then included on the EHS list.

Threshold Planning Quantity (TPQ)

In order to further assist emergency planners, the U.S. EPA developed a Threshold Planning Quantity (TPQ) for each EHS. This TPQ does not represent a cutoff above or below which a substance is or is not a danger. Rather, the TPQ was developed as a preliminary cutoff that local emergency planners could use to further prioritize facilities for their planning efforts. The TPQ was developed by assigning each EHS an index that accounts for the potential of the chemical to become air-borne and for the toxicity of the substance. Each index then corresponded to a TPQ level. The TPQ for any EHS can be found on the list in 40 CFR 355, Appendices A and B. It is the TPQ that determines whether or not a facility is subject to Section 302 of EPCRA.

When doing a threshold determination, the EHS amount must be aggregated for all sources of the EHS at the facility (every container, drum, etc.) regardless of the method of storage or the number of containers. There are no exemptions given in the regulations in 40 CFR 355 for uses or storage of EHSs and, therefore, if an EHS is present at the facility, it must be included in the threshold determination. When doing threshold calculations, a facility owner/operator must consider the issues discussed below:

Mixtures And Solutions

If the EHS in question is present at the facility in a mixture or solution, the TPQ is calculated based on the weight percent of the EHS in the mixture or solution.
Substances With Two TPQs

Some substances on the EHS list have two TPQ values: a low TPQ and a 10,000 pound TPQ. These double thresholds were developed to account for solid substances which, when they exist in different physical states, represent different hazards.

EHS List Issues

Two substances appear on the EHS list with qualifiers. These substances are hydrogen chloride (gas only) and hydrogen peroxide (concentration > 52%). These qualifiers indicate the only conditions under which the substance is extremely hazardous. Therefore, hydrogen chloride is an EHS only when it exists as a gas and is subject to a threshold determination under Section 302 of EPCRA only when it is in a gaseous state. Similarly, only if hydrogen peroxide is present in concentrations above 52% by weight is it an EHS and subject to a threshold determination under Section 302 of EPCRA.

What To Submit

Once a facility becomes subject to the emergency planning requirements of EPCRA Section 302, the owner/operator must notify the SERC and LEPC that the facility is subject to emergency planning. This notice originally was required to be given by May 17, 1987, and since then is required within 60 days after the facility first becomes subject to Section 302 of EPCRA (40 CFR 355.30(b)). This notification can be verbal, but is strongly preferred in writing. The notice must specify the name and an accurate and current address of the facility (April 22, 1987; 52 FR 13379). The facility owner/ operator also must provide the name of a facility emergency coordinator who will assist the SERC and LEPC when developing a plan for their facility (40 CFR 355.30(c)).

This initial notice is not required to include information on what substances are present or what amounts are present. If the SERC or LEPC needs additional information, they will request it using their authority under Section 303(d)(3) of EPCRA. This section stipulates that if a SERC or LEPC requests any information that it feels is necessary to the development of its emergency plan, the facility owner/operator must provide the information and is subject to penalties if he does not.

Therefore, if a facility has an EHS present at any one time in an amount equal to or exceeding the TPQ (40 CFR 355.30 (a)) or has been designated by the SERC as a facility subject to emergency planning (40 CFR 355.30(a)), then the owner/operator must notify his/her SERC and LEPC that his/her facility is subject to emergency planning, provide the name of a facility emergency coordinator (40 CFR 355.30(b) and (c)) and provide any information to the SERC or LEPC that it requests under Section 303(d)(3) of EPCRA.

SECTION 304: EMERGENCY RELEASE NOTIFICATION

Under EPCRA, the SERC and LEPC are responsible for developing an emergency plan to be used when responding to emergencies in their district. In order to provide a mechanism for notifying the SERC and LEPC about emergencies needing response, Congress enacted EPCRA Section 304, the emergency release notification requirements. Unlike most other release reporting requirements, Section 304 of EPCRA requires notification to be given to the state and local authorities. These are the persons most likely to respond to and be affected by a release and are the persons with knowledge of the emergency plan and how it works.

Who Is Subject

The emergency release notification provisions of Section 304 of EPCRA apply to any facility "at which a hazardous chemical is produced, used or stored" (40 CFR 355.40(a)(1)(i)). A hazardous chemical is defined by OSHA as any substance that presents a physical or health hazard (29 CFR 1910.1200). Since a facility must produce, use or store a hazardous chemical to be subject to Section 304 of EPCRA, very few facilities will be excluded from its scope. Any facility that has any hazardous chemical in any amount is included in the scope of Section 304 of EPCRA.

An important difference between Section 304 and the rest of the EPCRA regulations is the definition of "facility." The definition of "facility" usually includes "all buildings, equipment, structures, and other stationary items which are located on a single site or on contiguous or adjacent sites and which are owned or operated by the same person..." (40 CFR 355.20). However, for Section 304 of EPCRA, the definition of "facility" is expanded to include "motor vehicles, rolling stock, and aircraft." Although the definition of "facility" was modified to encompass the majority of transportation related releases, it still does not include vessels or Federal facilities.

Substances Covered

There are two lists of chemicals covered under Section 304 of EPCRA. They are the Extremely Hazardous Substances (EHS) found in 40 CFR 355, Appendices A and B and the CERCLA Hazardous Substances found in 40 CFR Table 302.4. The EHS list was developed under the voluntary Chemical Emergency Preparedness Program (CEPP) as a list of substances that when released, could cause serious, irreversible health effects. The CERCLA hazardous substances were identified based on other environmental statutes. Section 101(14) of CERCLA designates hazardous substances pursuant to Sections 307(a) and 311(b)(2)(A) of the Clean Water Act, Section 3001 of the Resource Conservation and Recovery Act, Section 112 of the Clean Air Act and Section 7 of the Toxic Substance Control Act. If the substance in question does not appear on either list, then regardless of the amount released, it is not a reportable event under Section 304 of EPCRA.

Reportable Quantities

For each chemical that appears on either the EHS or CERCLA hazardous substance lists, an amount has been determined (based on the chemical's individual properties) which when released triggers the Section 304 notification requirements. This amount is known as the Reportable Quantity. An RQ is established under the authority of Section 102(b) of CERCLA which states that the RQ shall be equivalent to the RQ established under Section 311 of the Clean Water Act, or one pound, until such time as the U.S. EPA establishes a final RQ for the substance.

The final RQ is determined by evaluating the substance for six "primary criteria" (50 FR 13466). These criteria are: aquatic toxicity, mammalian toxicity, ignitability, reactivity, chronic toxicity and potential carcinogenicity. Each property is ranked on a scale of 1, 10, 100, 1000 or 5000 pound RQs. The lowest RQ becomes the primary criteria RQ. The primary criteria RQ is then evaluated against the following "secondary criteria" (50 FR 13468): biodegradability, hydrolysis and photolysis. The primary criteria RQ is then raised one level (to the next higher RQ) if the secondary criteria shows that the substance will degrade relatively rapidly to a less harmful compound when released.

The authority for establishing an RQ is under CERCLA Section 102(b). The U.S. EPA only has the authority to establish an RQ for substances on the CERCLA hazardous substances list (no such authority was written in EPCRA). Any EHS that is also on the CERCLA hazardous substances list was required by EPCRA to have the RQ that was established under CERCLA. Any EHS that does not appear on the CERCLA hazardous substances list was given a statutory one pound RQ under EPCRA Section 304(a)(2).

As of February 1990, there were 134 EHSs that also appeared on the CERCLA hazardous substances list. As a result, if an RQ of one of these substances is released, two notification requirements potentially must be fulfilled: one under EPCRA Section 304 and one under CERCLA Section 103(a).

In order to simplify release reporting requirements, the U.S. EPA had proposed to add the remaining 232 EHSs not listed on the CERCLA hazardous substances list to the CERCLA list (January 23, 1989, 54 FR 3388). On August 30, 1989 (54 FR 35988), the U.S. EPA then proposed to establish final RQs using CERCLA Section 102 (b) authority for these EHSs. On February 15, 1990 (55 FR 5544), the U.S. EPA took final action to delete six of the EHSs from 40 CFR 355, Appendices A and B. Therefore, the final rule to add the EHSs to the CERCLA hazardous substance list will only include the 226 remaining chemicals. These EHSs are expected to be added to the CERCLA list with their final RQs sometime during 1990 in a final rule encompassing both proposed rules mentioned above. When the final rule is published, all the substances on both lists will be subject to both release reporting requirements.

Mixtures

For Section 304 of EPCRA, the U.S. EPA is concerned only with the actual amount of EHS released when a mixture is released. Since that is the case, a mixture calculation is made in the same manner as in any other section of EPCRA, by using the weight percent of the EHS present in the mixture (April 22, 1987; 52 FR 13392). For CERCLA Section 103 (a), the Clean Water Act mixture rule is applied. If the concentrations of the constituents are known, a weight percent calculation may be made. If the concentrations are unknown, the weight of the entire mixture spilled is compared to the lowest component RQ (April 14, 1985; 50 FR 13463).

De Minimis

Unlike the rest of EPCRA, there is no de minimis exemption for Section 304. The de minimis, the minimum amount of concern, is the RQ. Therefore, no matter how low the component concentration is in a mixture, a weight percent calculation must be made.

Release

The definition of "release" is very broad to encompass all possible actions, both intentional or accidental. "Release means any spilling,

leaking, pumping, pouring, emitting, emptying, discharging, injecting, escaping, leaching, dumping, or disposing into the environment (including the abandonment or discarding of barrels, containers, and other closed receptacles) of any hazardous chemical, extremely hazardous substance, or CERCLA hazardous substance." (40 CFR 355.20).

Both the EPCRA Conference Report and the EPCRA statute stipulate that a release is to be reported under EPCRA in the same manner as under CERCLA Section 103(a). This has been interpreted by the U.S. EPA to include the 24-hour RQ time frame for reportable release amounts. Therefore, if a facility has a release of an EHS or CERCLA hazardous substance in an amount equal to or in excess of its RQ in a 24-hour period, the release is potentially subject to the reporting requirements of EPCRA Section 304 and CERCLA Section 103(a).

Exemptions

Even though there may have been a release from the facility, it still must be determined if it is a reportable release. Title 40 CFR 355.40(2) specifically exempts six types of releases from the reporting requirements of Section 304 of EPCRA. These release are: (1) any release which results in exposure to persons solely within the boundaries of the facility, (2) any release which is a "federally permitted release" as defined in Section 101(10) of CERCLA, (3) any release which is "continuous" as defined under Section 103(f) of CERCLA, (4) any release of a pesticide product exempt from Section 103(e) of CERCLA, (5) any release not meeting the definition of release under Section 101(22) of CERCLA, and therefore exempt from Section 103(a) reporting and (6) any radionuclide release which occurs: (A) naturally in soil from land holdings such as parks, golf courses, or other large tracts of land; (B) naturally from the disturbance of the land for agricultural or construction activities; (C) from the dumping of coal and coal ash at utility and industrial facilities with coal-fired boilers; and (D) from coal and coal ash piles at utility and industrial facilities with coal-fired boilers.

The preamble to the April 22, 1987 final rule (52 FR 13384) discusses three releases not included in the scope of Section 304 reporting. Although they are not spelled out in the regulations, these releases are exempted because they do not meet the definition of a release under Section 101(22) of CERCLA. They are: releases from engine exhaust, normal application of fertilizer and releases of source, byproduct or special nuclear material from a nuclear incident at a nuclear power plant. If the release is covered by one of the above exemptions, there is no reporting requirement under Section 304 of EPCRA, even if a listed substance is released in an amount equal to or in excess of its RQ.

Reporting Requirements Under EPCRA Section 304

Under Section 304 of EPCRA, if an EHS or CERCLA hazardous substance is released in an amount equal to or in excess of its RQ in a 24-hour period, it is a potentially reportable release. If the release is not exempted from the requirements, it is a reportable release and the owner/operator of the facility must immediately notify the SERCs and the community emergency coordinators for the LEPCs for all areas likely to be affected by the release. The time period for a facility owner/operator to immediately notify is intentionally not defined in the regulations to encourage prompt reporting.

The information that must be included in the initial notification is listed in the regulations at 40 CFR 355.40(b)(2) and includes the following information: the chemical name or identity of any substance involved in the release; an indication of whether the substance is an EHS; the time and duration of the release; the medium or media into which the release occurred; any known or anticipated acute or chronic health risks associated with the emergency (and, where appropriate, advice regarding medical attention necessary for exposed individuals); precautions to take as a result of the release, including evacuation (unless such information is readily available to the community emergency coordination pursuant to the emergency plan); and the names and telephone numbers of the persons to be contacted for further information. The U.S. EPA strongly recommends that the location of the release also be included in the initial notification.

Unlike CERCLA, as soon as practicable after a reportable event has

occurred, a written follow-up notice must be submitted to all EPCRA entities which received the initial verbal notice. The time frame involved is not specified in the regulation to encourage prompt submissions. The information that must be included in the written follow-up is set forth in 40 CFR 355.40 (b)(3). The written follow-up must set forth and update the information given in the initial notice as well as include additional information regarding: actions taken to respond to and contain the release, any known or anticipated acute or chronic health risks associated with the release and, where appropriate, advice regarding medical attention necessary for exposed individuals. Additionally, the U.S. EPA recommends that the cause of the incident be included in the written follow-up notice as well.

Transportation-Related Release

For purposes of EPCRA Section 304, the definition of facility includes motor vehicles, rolling stock and aircraft. If the release is a transportation-related release, the transportation vehicle is a facility and it is the responsibility of the owner/operator of the transportation vehicle to report the release.

In the case of a transportation-related release, the owner/operator of the vehicle may meet the requirements of EPCRA Section 304 by providing the required information to the 911 emergency service or, in the absence of a 911 emergency service, to the telephone operator. Also, no written follow-up report is necessary for a transportation-related release (40 CFR Section 355.40(b)(4)(ii)).

Reporting Requirements Under CERCLA Section 103(a)

Under CERCLA Section 103(a), if a CERCLA hazardous substance is released in an amount equal to or in excesses of its RQ in a 24-hour period, it is a potentially reportable release. The exemptions from the CERCLA 103(a) reporting requirements are found in Section 101 (22) of CERCLA.

If the event is reportable, any person or persons in charge of a facility or vessel with knowledge of the reportable release must notify the National Response Center (NRC) immediately. The notice information is not specified in the CERCLA regulations. It is up to the NRC to ask the procedural questions about the event and to evaluate if the event warrants federal intervention.

Differences Between EPCRA Section 304 and CERCLA Section 103(a)

Along with the obvious difference between the EPCRA Section 304 and CERCLA Section 103(a) reporting requirements, there are three other important differences which are: (1) CERCLA Section 103(a) requirements include vessels in the definition of facility and EPCRA Section 304 does not; EPCRA Section 304 only covers releases that have the potential to migrate beyond the facility boundaries (40 CFR 355.40 (a)(2)(i)); CERCLA Section 103(a) only requires that a release go into the environment to be reportable, and (3) Petroleum products are exempted from the notification requirements of CERCLA Section 103 (a) because they are not included in the definition of "Hazardous Substances" found in CERCLA Section 101(14); no such exemption exists under EPCRA Section 304. Therefore, if a petroleum product containing an EHS is spilled and an RQ of that EHS is released, it is potentially reportable under EPCRA, Section 304.

Overlap Between the Two Laws

Regardless of the differences, the potential for having to report a release under both authorities does exist. Assuming no exemptions have been met for the event, there are three possible scenarios to consider:

Release of an EHS That Is Not a CERCLA Hazardous Substance

Since the substance is listed on the EHS list only, the release is only subject to EPCRA Section 304 requirements. Therefore, a notification (and subsequent written follow-up) must be given immediately to the SERCs and LEPCs for all areas likely to be affected by the release.

Release of an EHS That Is Also a CERCLA Hazardous Substance

Since the substance is on both the EHS list and the CERCLA hazar-

dous substances list, the release is subject to both the EPCRA Section 304 and CERCLA Section 103 (a) requirements, respectively. This is because even though the CERCLA Section 103(a) requirements apply only to the CERCLA Hazardous Substance list, the EPCRA Section 304 requirements apply to both the EHSs and CERCLA hazardous substances (40 CFR 355.40(a)(1)(ii)). Therefore, a notification (and subsequent written follow-up) must be given immediately to the SERCs and LEPCs for all areas likely to be affected by the release (EPCRA Section 304) and a notification must be made to the National Response Center (NRC) (CERCLA Section 103(a)).

Release of a CERCLA Hazardous Substance That Is Not an EHS

Since the requirements of EPCRA Section 304 apply to both the EHSs and CERCLA hazardous substances, this scenario would be reportable in the same manner as Scenario number 2.

The U.S. EPA has proposed to add all the EHSs not currently on the CERCLA hazardous substances list to that list. When that occurs, Scenario number 1 will no longer exist and all releases will be reported in the same manner as Scenario number 2. Until that time, releases are reported as stated above.

SECTIONS 311 AND 312: COMMUNITY RIGHT-TO-KNOW

Sections 311 and 312 of EPCRA were designed to provide the public with important information about the types and quantities of hazardous chemicals present in their communities. This information can enhance community awareness of chemical hazards and facilitate development of state and local emergency response plans.

Sections 311 and 312 of EPCRA require facilities to make public their MSDSs or lists of their hazardous chemicals and Tier I or Tier II inventory forms which detail the quantities, hazards and storage information about these chemicals. OSHA's Worker Right-to-Know law requires employers to communicate chemical hazards to persons within the facility. Sections 311 and 312 of EPCRA expand this concept of right-to-know to the communities surrounding the facility.

The LEPCs and SERCs receive the information on hazardous chemicals from the facilities and then make it available to the public upon request. Facility owner/operators must also submit the EPCRA Section 311 and 312 information to the local fire department, but the fire department has no obligation to provide this information to the public.

Who Is Subject

Any facility which is required to prepare or have available an MSDS under the Federal OSHA Hazard Communication Standard (HCS) is regulated by EPCRA Sections 311 and 312 (40 CFR 370.20(a)). Originally, the OSHA HCS only applied to manufacturers in Standard Industrial Classification (SIC) codes 20-39. OSHA expanded its HCS to cover all non-manufacturers other than the construction industry on June 24, 1988 (53 FR 27679). It was expanded again to include the construction industry as well on January 30, 1989 (54 FR 6886). The HCS now covers all employers who handle hazardous chemicals, unless those employers are exempted.

Substances Covered

OSHA's definition of "Hazardous Chemical" is broader than many people expect. OSHA does not have an inclusive list of all hazardous chemicals, rather, they have a performance criterion: "Hazardous Chemical" means any chemical which is a physical hazard or a health hazard as defined at 29 CFR 1910.1200(b). Any of over 500,000 products may meet this criterion.

The easiest way to determine which chemicals are hazardous chemicals is to take an inventory of the facility MSDSs. OSHA requires that manufacturers and importers ensure that distributors and employers are provided with an appropriate MSDS with their initial shipment of a hazardous chemical (29 CFR 1910.1200(g)(7)). There is a good chance that every hazardous chemical on the site will be represented by an MSDS in the MSDS file which the facility owner/operator must maintain under the OSHA regulations.

It is possible that a manufacturer or supplier has been negligent in

supplying copies of MSDSs. If a chemical comes on-site without an MSDS, but that chemical has been labeled as a hazardous chemical, the facility owner/operator has an obligation to obtain an MSDS from the chemical manufacturer, importer or distributer as soon as possible (29 CFR 1910.1200(g)(7)). As the facility owner/operator goes through his/her MSDSs, he/she should take note of hazardous chemicals which contain EHSs because he/she must give them special treatment when calculating thresholds. There are certain exemptions from OSHA's MSDS requirement and from the definition of "Hazardous Chemical" under Section 311 and 312 of EPCRA. These shall be addressed later.

Thresholds

OSHA requires that an establishment maintain MSDSs for all hazardous chemicals present at the establishment, regardless of the quantity of chemical present. Under SARA, Title III, the U.S. EPA only regulates those chemicals which are present in quantities capable of significantly effecting the surrounding community. The only hazardous chemicals which need to be reported under Sections 311 and 312 of EPCRA are those present in a quantity of 10,000 pounds or more, unless the hazardous chemical is (or contains) an EHS. An EHS needs to be reported if it is present in a quantity of 500 pounds or its TPQ, whichever is lower. These thresholds apply to the amount of the hazardous chemical present at the facility at any one time. They do not apply to the amount of chemical purchased or used throughout the year.

Many hazardous chemicals are contained within mixtures. A mixture is a combination of two or more different chemicals, each retaining its own chemical identity. Under Sections 311 and 312 of SARA, the owner/operator of a facility can choose to provide the required information on each hazardous chemical component in the mixture or to provide the required information on the mixture as a whole. The decision should be made by the facility owner/operator on the basis of the situation at the facility.

The choice of how to report determines how the owner/operator must calculate his/her thresholds. If the reporting is on each hazardous component of the mixture, then the concentration of the hazardous chemical is multiplied by the total weight of the mixture to determine the quantity of hazardous chemical in the mixture. If the reporting is on the mixture itself, the total quantity of the mixture shall be reported. The owner/operator must be careful to determine if the mixture contains an EHS, because in these cases the U.S. EPA does not allow a choice in the threshold calculation. If mixtures at a facility contain EHSs, the mixture(s) or the EHS components must be reported when the TPQ or 500 pounds, whichever is less for that EHS, is reached. Quantities of each EHS must be considered individually and then aggregated to determine if the quantity at the facility exceeds the reporting threshold.

Exemptions

Certain facilities are exempt from OSHA's MSDS requirements, certain uses of chemicals are exempt from OSHA's MSDS requirements and other chemicals and uses are exempt from Section 311 and 312 of EPCRA even though they might require an MSDS. OSHA's coverage is very broad, but there are three main categories of employers which are outside of OSHA's jurisdiction. The first is state and local governments. Because OSHA excludes states and political subdivisions of states from its definition of "employer" (29 USC 652(4)), the OSHA HCS cannot apply to state or local agencies. States and local governments may be required to have available MSDSs under a state-approved plan; however, since they are exempt from federal OSHA, they are exempt from Sections 311 and 312 of EPCRA. State agencies may, however, subject their state and local governments to state community right-to-know laws under their own authority.

The next group of facilities which are not covered by OSHA are those covered by some other federal safety act, in lieu of OSHA. This situation occurs at mining facilities. Mining extraction operations are covered by the Mining Safety and Health Act (MSHA) rather than OSHA. Even though they must have MSDSs under MSHA, mining facilities would not be covered by Sections 311 and 312 of EPCRA because they are exempt from OSHA.

Special loopholes in the law exempt a final group of facilities from OSHA. A special congressional rider exempts farmers with fewer than 10 employees from OSHA. This is a special case and does not apply to any other industry. Because farmers with fewer than 10 employees are exempt from OSHA, they would be exempt from Sections 311 and 312 of EPCRA.

The U.S. EPA's EPCRA regulations have some facility exemptions as well. Federally-owned and operated facilities are exempt from EPCRA since the federal government is not included in EPCRA's definition of person. Federal facilities, therefore, would be exempt from Sections 311 and 312 since they are exempt from all sections of EPCRA.

Section 327 of SARA states that EPCRA does not apply to the transportation, including the storage incident to such transportation, of any substance, except for Section 304 reporting. Therefore, materials being distributed or stored incident to transportation would not be included in a facility threshold determination for any portion of SARA, Title III except Section 304. This exemption may apply to chemicals in a warehouse, provided the chemicals are still under active shipping papers (SARA Conference Report, October 3, 1986, p.311).

Another U.S. EPA exemption is the de minimis concentration level. This exemption is for hazardous chemicals in mixtures or solutions where the concentration of the hazardous chemical is so low that the mixture or solution does not present a significant physical or health hazard at the facility.

For mixtures which contain hazardous chemicals in amounts below the de minimis concentration, the amount of the hazardous chemical is not counted toward the threshold for reporting that substance. The de minimis for reporting hazardous chemicals is the same as the de minimis used by OSHA. OSHA states at 29 CFR 1910.1200 that the de minimis concentration is 1% by weight unless the chemical is a carcinogen or a suspected carcinogen, in which case the de minimis cut off would be 0.1 percent by weight.

In addition to the exemptions noted above, OSHA's HCS contains eight exemptions from MSDS requirements. These are defined at 29 CFR 1910.1200(b)(6) as: (1) any hazardous waste as such term is defined by the Solid Waste Disposal Act, as amended by the Resource Conservation and Recovery act of 1976, as amended (42 U.S.C. 6901 et seq.) when subject to regulations issued under that Act, (2) tobacco or tobacco products, (3) wood or wood products, (4) articles as defined under 29 CFR Section 1910.1200(b), (5) food, drugs, cosmetic or alcoholic beverages in a retail establishment which are packaged for sale to consumers, (6) foods, drugs or cosmetics intended for personal consumption by employees while in the workplace, (7) any consumer product or hazardous substance, as those terms are defined in the Consumer Product Safety Act (15 U.S.C. 2051 et seq.) and Federal Hazardous Substances Act (15 U.S.C. 1261 et seq., respectively, where the employer can demonstrate it is used in the workplace in the same manner as normal consumer use, and which use results in a duration and frequency of exposure which is not greater than exposures experienced by consumers and (8) any drug, as that term is defined in the Federal Food, Drug and Cosmetic Act (21 U.S.C. 302 et seq.), when it is in solid final form for direct administration to the patient (e.g., tablets). If the chemical meets one of these exemptions, then the facility owner/operator does not need to maintain an MSDS for it. Therefore, the chemical would be exempt from Sections 311 and 312 of EPCRA.

Section 311(e) of EPCRA contains five additional exemptions from the definition of "Hazardous Chemical." These exemptions apply above and beyond the previously listed eight OSHA exemptions, so these chemicals are exempt from Sections 311 and 312 of EPCRA even if an MSDS is required for them under federal OSHA. The definition of a hazardous chemical under Title III of SARA specifically excludes the following substances: (1) any food, food additive, color additive, drug or cosmetic regulated by the Food and Drug Administration (FDA), (2) any substance present as a solid in any manufactured item to the extent exposure to the substance does not occur under normal conditions of use, (3) any substance to the extent it is used for personal, family or household purposes, or is present in the same form and concentra-

tion as a product packaged for distribution and use by the general public, (4) any substance to the extent it is used in a research laboratory or a hospital or other medical facility under the direct supervision of a technically qualified individual and (5) any substance to the extent it is used in routine agricultural operations or is a fertilizer held for sale by a retailer to the ultimate customer. These exemptions do not exclude all amounts of the chemical on-site, but only the amount which is used in a manner consistent with the exemptions. Also, the exemptions do not take a chemical off the EHS list, they only exempt it from the definition of a "Hazardous Chemical."

Section 311 of EPCRA requires the submission of MSDSs or a list of each hazardous chemical present at the facility in quantities equal to or greater than their threshold. If a list is submitted, the chemicals must be "grouped by hazard category," meaning the facility owner/operator must indicate which of the U.S. EPA's five hazard characteristics the chemical exhibits. The U.S. EPA's five categories are based on the 23 OSHA HCS categories for physical and health hazards (29 CFR 1910.1200(c)). MSDSs usually will be standardized according to the 23 OSHA categories.

The U.S. EPA hazard category definitions (40 CFR 370.2) that follow may be used to convert the OSHA categories to the U.S. EPA categories. "Fire hazard" means any chemical defined by OSHA as a flammable, combustible liquid, pyrophoric or oxidizer. "Sudden release of pressure" means any chemical defined by OSHA as an explosive or compressed gas. "Reactive" means any chemical defined by OSHA as an unstable reactive, organic peroxide or water reactive. "Acute health hazard" means any chemical defined by OSHA as a highly toxic, toxic, irritant, sensitizer, corrosive and any other hazardous chemical with an adverse effect on a target organ that generally occurs rapidly as a result of short-term exposure and with a short duration. "Chronic health hazard" means any chemical defined by OSHA as a carcinogen and any other hazardous chemical with an adverse effect on a target organ that occurs as a result of long-term exposure and with a long duration.

Although the regulations do not require a set format for the list submission, the U.S. EPA has recommended a method of organizing the list. The facility owner/operator may list the reportable chemicals in a column on the left-hand side of a sheet of paper. Make five more columns and label each with one of the hazard categories. Then put check marks in the appropriate columns beside the chemicals which exhibit the characteristics.

It is up to the facility owner/operator to decide whether to submit MSDSs or a list of chemicals. He/she must consider the following points when choosing between the list versus the MSDS submission for Section 311 of EPCRA. The list usually is preferred by the LEPC, fire department and SERC because it reduces their information burden. The production of a list may require some additional analyses of the MSDS to determine the appropriate hazard categories of each chemical. This analysis, however, would need to be done to complete the EPCRA Section 312 requirements anyway, so sending MSDSs would only postpone this burden. Submission of MSDSs requires copying, in triplicate, all required MSDSs. Any MSDS submitted under EPCRA Section 311 must be updated if any significant new information concerning the chemical is discovered. Some states charge a higher reporting fee for MSDS submissions than they do for list submissions.

Whichever method of reporting is chosen, the report must be sent to the LEPC, SERC and local fire department. The original EPCRA Section 311 submission is due within three months after the facility owner/operator first becomes subject to OSHA's MSDS requirements. After that, the owner/operator must update the list or submit a new MSDS within three months after a new hazardous chemical requiring an MSDS becomes present in an amount exceeding the threshold (40 CFR 370.21(c)).

Section 312 of EPCRA requires the submission of a Tier I or Tier II inventory form. Copies of these forms and instructions for completing them appear in the July 26, 1987, final rule in the *Federal Register* on pages 30632 through 30656. To determine which hazardous chemicals to include on the Tier I or Tier II form, the facility owner/operator must first calculate the maximum amount of each chemical that was on-site during the reporting year. The reporting year is the calendar year preceding the year of the submission of the form. Any chemical which met or exceeded the threshold at any time during the year would be reported.

Although the Tier I form is less detailed than the Tier II form, the Tier II form can be used as a worksheet for the Tier I form. Discussion will therefore begin with the Tier II form before addressing the Tier I form.

Completing the Tier II Form

Most of the information requested on the Tier II form is self-explanatory. For questions such as the average daily amount, an educated approximation of the average amount of the chemical stored at the site is usually accurate enough for the form. Generally, the facility owner/operator can simplify the average daily amount calculation by comparing the most a facility would have with the least they would have. The average falls somewhere in between these figures. Often this observation is enough to determine the appropriate range code to enter on the Tier II form.

The storage code has three parts. The first part describes the storage type. The second part indicates the temperature and the third part indicates the pressure. The appropriate codes are found in Table II and III of the instructions.

The U.S. EPA has not mandated specific requirements for the method of expressing storage locations. Simply provide a brief description of the precise location of the chemical, so that emergency responders can locate it easily. Providing an optional site plan or site coordinates may be advantageous. A narrative form or a map with appropriate site coordinates or abbreviations also may be used.

If for some reason, revealing the locations of the chemicals would put a company at a competitive disadvantage, the owner/operator may include the confidential location sheet with the submission. Using this option, the facility owner/operator also must submit the nonconfidential form but in the location section write the word "confidential."

The easiest way to fill out a Tier I form, in most cases, is to fill out the first three rows of the Tier II form as discussed above. Then for each hazard type of physical and health hazard, add the maximum weights of all chemicals indicated as the particular hazard type, find the appropriate range value code and enter this code as the maximum amount. Finally, in the general location section, record the locations of all applicable chemicals for each hazard class. The general locations should include the names or identifications of buildings, tank fields, lots, sheds or other such areas.

The owner/operator or an authorized representative of the owner/operator must sign the certification at the bottom of the form. The form sent to the SERC should have an original signature. The forms sent to the LEPC and the fire department can be photocopied.

There are advantages and disadvantages to using each type of form. Although only the facility owner/operator can determine which form best suits his/her needs, the Tier II form is generally both easier and more useful.

SECTION 313 OF SARA:
TOXIC CHEMICAL RELEASE INVENTORY

Section 313 of SARA is a release reporting requirement which applies to certain owners/operators of manufacturing facilities. The covered owners/operators are required to report annual releases of certain toxic chemicals to the U.S. EPA and to their designated state contact. If the facility does not meet the basic applicability requirements, then they are not required to report their releases of these toxic chemicals under Section 313 of SARA, regardless of the amount released. If the applicability is met for one or more of the toxic chemicals, then the filing of release information is required for each chemical which was used at or above an applicable threshold.

Who Is Subject

Owners or operators of facilities are subject to the EPCRA Section 313 reporting requirements if their facility meets all of the following

criteria: (1) The facility is in Standard Industrial Classification (SIC) major group 20 through 39 (a facility would fall into an SIC major group 20 through 39 if the facility is primarily engaged in manufacturing operations); (2) the facility has 10 or more full-time employees or the hourly equivalents (because the U.S. EPA defines a full-time employee as someone who works 2,000 hours per year, a facility would meet this second criterion if 20,000 hours or more were worked at the facility during the reporting year); and (3) the facility meets or exceeds an applicable threshold for usage of a Section 313 toxic chemical during a calendar year.

Thresholds

The thresholds were established by Congress under Section 313 of EPCRA to be: 75,000 pounds for calendar year 1987, 50,000 pounds for calendar year 1988 and 25,000 pounds for calendar year 1989 and every year thereafter for any toxic chemical which is manufactured or processed at the facility or 10,000 pounds for calendar year 1987 and every year thereafter for any toxic chemical which is otherwise used at the facility. A Form R is required to be submitted for each toxic chemical manufactured, processed or otherwise used at a covered facility at or above an applicable threshold.

What Substances Are Covered

The toxic chemicals subject to the reporting requirements of Section 313 of SARA are those chemicals on the list in Committee Print Number 99-169 of the Senate Committee on Environmental and Public Works. The list was codified at 40 CFR 372.65 on February 16, 1988. The toxic chemical list contains more than 300 specifically listed chemicals as well as 20 chemical categories. This list is a combination of lists from the state implemented community right-to-know laws of Maryland and New Jersey. When EPCRA was enacted on October 17, 1986, Congress provided this list to the U.S. EPA. The list then contained 308 chemicals plus 20 chemical categories with a provision that the list could change based on the criteria given in the law. As of August 1990, six chemicals had been removed from the list, several more were pending or proposed for deletion and 16 had been added to the list bringing the total to 318 chemicals plus 20 chemical categories.

Threshold Determinations

The thresholds for reporting are based upon the amount of the Section 313 toxic chemical that was manufactured, processed or otherwise used during the calendar year. These thresholds were discussed previously. The amount of the toxic chemical that was released during the calendar year has no effect on the determination of whether or not the facility met or exceeded the applicable threshold for reporting. A facility owner/operator needs to do three separate threshold determinations for each toxic chemical based on the activity of the toxic chemical at the facility. The three types of activities are defined at 40 CFR 372.3 as:

* Manufacture: to produce, prepare, import, or compound a toxic chemical. This would include any activity which creates the toxic chemical or causes the toxic chemical to enter the United States (Imported)
* Process: the preparation of a toxic chemical, after its manufacture, for distribution in commerce. If the intent is to incorporate the toxic chemical in whole or in part into the final product, it is considered processed for EPCRA Section 313 purposes.
* Otherwise use: use of a toxic chemical not covered by the definitions of manufacture or process. This catch-all phrase includes any active use of a toxic chemical that would not fit the definition of manufacture or process. Toxic chemicals in storage are not counted for EPCRA Section 313 threshold determinations until they are used in some manner. The storage itself is not considered manufacture, process or otherwise use.

The following special circumstances are considered when doing a threshold calculation are discussed below.

Mixtures And Solutions

For mixtures and solutions containing the EPCRA Section 313 toxic chemicals, threshold determinations are based on the weight percent attributable to the toxic chemical, not the entire weight of the mixture or solution.

Metal Compounds

There are several metal compounds listed under the chemical category section of the toxic chemical list. For metal compounds, the entire weight of the compound is used in making the threshold determination for reporting the compound; however, release estimates are based only on the amount of the compound attributable to the parent metal.

Qualifier

Certain chemicals are only subject to reporting if they are used in the specific form listed parenthetically next to their entry. These qualifiers, with the exception of fibrous, were on the toxic chemical list when it was given to the U.S. EPA. On February 14, 1990, (55 FR 5220) the U.S. EPA added the qualifier "fibrous" to the entry for aluminum oxide. The qualifiers are: (1) fume or dust, (2) solution, (3) manufacturing by the strong acid process, (4) manufacturing, (5) friable and (6) fibrous.

Exemptions

Section 313 of SARA contains several exemptions for toxic chemicals used at a facility. Toxic chemicals that meet these exemptions do not have to be considered for either threshold determinations or release reporting requirements. These exemptions are outlined below:

* De Minimis: If a toxic chemical is present in a mixture at a covered facility and the concentration of the toxic chemical is below the de minimis, a person is not required to factor the amount of the toxic chemical in that mixture into either threshold determinations or release reporting. The de minimis levels for the Section 313 toxic chemicals are 0.1% for carcinogens or suspected carcinogens and 1% for all other toxic chemicals. There are a couple of exceptions to this exemption. First, the U.S. EPA has indicated that while the de minimis applies to unintentional impurities, it does not apply to byproducts of the manufacturing process. Also, the de minimis would not apply in the case where a toxic chemical is discharged into a waste stream where it becomes diluted to below the cutoff level.
* Article: If a toxic chemical is present in an article at a covered facility, a person is not required to consider the quantity of the toxic chemical present in such an article for threshold determination and release reporting. An article is defined at 40 CFR Section 372.3 as a manufactured item: (1) Which is formed to a specific shape or design during manufacture, (2) Which has end use functions dependent in whole or in part upon its shape or design during end use, and (3) Which does not release a toxic chemical under normal conditions of processing or use of that item at the facility or establishments.
* Laboratory: If a toxic chemical is manufactured, processed or otherwise used in a laboratory at a covered facility under the direct supervision of a technically qualified individual (defined in 40 CFR 720.3(ee)), the facility owner/operator is not required to factor that amount of the toxic chemical into threshold determination and release reporting. However, if the laboratory is engaged in specialty chemical production or operates on a pilot-plant scale, the exemption does not apply, and any toxic chemicals used at the laboratory must be included in threshold and release determinations.
* Owners Of Leased Property: The owner of a covered facility is not subject to the EPCRA Section 313 reporting requirements if the owner's only interest in the facility is the ownership of the real estate upon which the facility is operated.
* Multi-Establishment Facilities: The owner or operator of an establishment at a multi-establishment facility would not have to report for a particular toxic chemical if his/her establishment does not manufacture, process or otherwise use that toxic chemical. However, if the establishment does use a toxic chemical, then the establishment owner/operator must determine if the entire facility has exceeded an applicable threshold. If this is the case, the entire facility may report or each establishment may report, accounting for their releases of the toxic chemical.

- Specified Uses: For certain uses of a toxic chemical, the particular amount used which is consistent with one of the following exemptions is not included for threshold determinations or release reporting. These exempt uses are: (1) use as a structural component of the facility, (2) use of products for routine janitorial or facility grounds maintenance, (3) personal use by employees or other persons at the facility, (4) use of products containing toxic chemicals for the purposes of maintaining motor vehicles operated by the facility and (5) use of toxic chemicals present in process water and noncontact cooling water as drawn from the environment or from municipal sources or toxic chemicals present in air used either as compressed air or as part of combustion.

What To Submit

Each owner or operator of a covered facility must complete and submit a Form R (Toxic Chemical Release Inventory Form) to the U.S. EPA (Reporting Center) and the designated SARA, Section 313 contact for the state. A Form R is required for each toxic chemical which is manufactured, processed or otherwise used at the facility above an applicable threshold during a reportable calendar year. All Form Rs are due by July 1 of each year and cover activities at the facility that occurred during the previous calendar year. A complete Form R submission will include at least five pages of information for each toxic chemical being reported.

Filling Out The Form

After completing threshold determinations and deciding which toxic chemicals require reporting, the next step is the completion of a Form R for each toxic chemical used at or above an applicable threshold. A complete Form R must contain at least five pages of information.

Page 1 of the form contains facility identification information. Page 2 lists the names and addresses of off-site locations to which toxic chemicals are transferred in wastes. Most of the information requested on page 1 and on page 2 is self-explanatory.

Page 3 requires the following information: (1) chemical identity: the name of the chemical being reported, (2) activities and uses of the chemical: how the chemical is used at the facility and (3) estimates of release of the toxic chemical into the environment. This is where the amount of the chemical released (in pounds per year) is reported on the form. The chemical identity is simply the name and the associated CAS number of the toxic chemical being reported. For the reporting of one of the 20 chemical categories, the chemical identification would be the category name and the CAS number would be "NA." The second section of page 3 which requires information on how much of the chemical is released requires more detail and more time to complete. Fugitive and point air emissions usually are obtained from monitoring data or from general industry guidelines specific to certain manufacturing processes. Generally, these figures will be expressed as the release of so many pounds per ton of material processed. Barring any more specific information on release estimates, a facility owner/operator would multiply this number by the amount of the toxic chemical processed to arrive at an estimate that could be used when completing the Form R. Water discharges usually are monitored because of NPDES permit requirements under the Clean Water Act (CWA), and the amount of material sent to a landfill also usually is very carefully monitored.

Page 4 of the Form R requires the following information: amounts of the toxic chemical in waste sent to off-site locations, waste treatment methods and the associated efficiencies for treating the toxic chemical on-site and optional information on waste minimization.

Page 5 provides additional space if necessary to complete sections on: discharges to receiving streams or water bodies, transfers of the chemical in water to off-site locations, and waste treatment methods and efficiencies. This page must be included as part of a complete Form R submission even if blank.

SECTION 322: TRADE SECRETS

When Congress enacted EPCRA, they realized the importance of proprietary information to the regulated community. At the same time, Congress realized the importance of ensuring that the intent of EPCRA, providing information to the community, was not hindered in any way. As a result, provisions for claiming a trade secret were included in EPCRA. These provisions, found in EPCRA Section 322, ensure the protection of proprietary information and specify what information can be claimed as a trade secret.

What May Be Claimed As Trade Secret

Section 322(a)(1)(A) of EPCRA specifies that a person may withhold as trade secret only the "specific chemical identity (including the chemical name and other specific identification)." Therefore, when filing a report under EPCRA, the only information that is allowed to be withheld is the chemical identity and the corresponding CAS number. All other information must be provided.

Sections Of EPCRA For Which A Claim May Be Filed

Section 322 (a)(1)(A) of EPCRA also specifies that a trade secrecy claim may only be filed for a submittal under Sections 303 (d)(2), 303(d)(3), 311, 312 or 313 of EPCRA. It is important to realize that when reporting an emergency release under EPCRA, Section 304, no trade secrets claims can be made.

How To File A Claim

In order to claim a trade secret under EPCRA, a person must submit a trade secrecy claim package to the U.S. EPA. This claim package will provide the necessary information to substantiate the person's claim. The claim is then reviewed by the U.S. EPA and must be approved before it is considered valid.

The trade secret package that must be submitted to the U.S. EPA contains the following four documents: (1) an unsanitized version of the report, (2) a sanitized version of the report, (3) an unsanitized version of the trade secret substantiation and (4) a sanitized version of the trade secret substantiation.

Unsanitized Reports

An "unsanitized" report is the version of the reporting form that contains the trade secret chemical identity. This version of the form is sent only to the U.S. EPA, is viewed only by U.S. EPA personnel with trade secrecy clearance, is kept under lock and key and is used to evaluate the claim.

Sanitized Reports

A "sanitized" report is the version of the reporting form that does not contain the trade secret identity; in other words, it has been wiped clean. Instead of filling in the trade secret identity, the person must provide a generic class or category. This generic class or category must be one that adequately protects the trade secret identity and also provides enough information to assess the chemicals risks and hazards. The rest of the report is filled out in the same manner as if no claim has been filed.

Unsanitized Substantiation

In order to substantiate a claim of trade secrecy, a person must supply supporting information to the U.S. EPA using U.S. EPA form 9510-1, "Substantiation To Accompany Claims of Trade Secrecy Under the Emergency Planning and Community Right-to-Know Act of 1986." This substantiation form was published, with the final rules and regulations, in the *Federal Register* on July 29, 1988 (53 *FR* 28772). The substantiation form requires information regarding what steps the person has taken to guard the trade secret identity from competitors. This information includes: if the identity has ever been disclosed; the use of the substance at the facility; and what harm could come to the company if the identity of the substance is disclosed.

In order to support a trade secrecy claim, many companies are prepared to disclose confidential business information (CBI) to substantiate their claim. To protect the CBI from disclosure, the U.S. EPA will allow companies to claim supporting information confidential. When completing a trade secrecy substantiation, to claim CBI as confidential, the submitter must clearly mark the CBI contained therein. This

mark can be a stamp of "confidential" across the paragraph or any other clear indication of what is to be held confidential by the U.S. EPA.

Just as the unsanitized reporting form contains the chemical identity, the unsanitized substantiation also contains the trade secret identity. The unsanitized substantiation also contains the company's supporting CBI. This unsanitized version is submitted only to the U.S. EPA, is viewed only by U.S. EPA personnel with trade secret clearance, is kept under lock and key and is used to evaluate the claim.

Sanitized Substantiation

In order to submit the sanitized version of the trade secret substantiation, a person would again use U.S. EPA form 9510-1. Just as with a sanitized report, the sanitized substantiation would only include the generic class or category and not the trade secret identity.

As stated above, CBI that is clearly marked on the unsanitized substantiation will be held strictly confidential by the U.S. EPA. This is accomplished by allowing the submitter to delete any clearly marked CBI from the sanitized version of the substantiation form (40 CFR 350.7(d)).

The complete trade secrecy claim package includes: (1) the unsanitized version of the reporting form which contains specific chemical identity and other specific identification, (2) the sanitized version of the reporting form which contains a generic class or category in place of the specific chemical identity and does not include other specific identification, (3) the unsanitized version of the substantiation form which contains specific chemical identity and other specific identification and may contain CBI, clearly marked as confidential according to 40 CFR 350.77(d) and (4) the sanitized version of the substantiation form which contains the generic class or category in place of the specific chemical identity, does not include other specific identification and does not include any CBI that was marked as confidential in the unsanitized substantiation.

Submitting a SARA Title III Report Which Contains Trade Secret Information

When submitting a report form which the submitter has claimed the chemical identity trade secret, the submitter is only required under Federal law to submit the sanitized reporting form and the sanitized substantiation to the appropriate state and local agencies. The unsanitized versions of any form containing the trade secret identity or CBI is sent to the U.S. EPA only.

Valid And Invalid Claims

If the claim has been reviewed and it was found to be a valid claim, the U.S. EPA will notify the submitter. If the claim is found to be insufficient, the U.S. EPA will contact the submitter, inform them of the U.S. EPA's intent to deny the claim and ask if they want to submit more information or withdraw the trade secrecy claim.

Disclosure Of Trade Secret Information

Section 323 of EPCRA allows the trade secret identity to be released to health professionals only, in the following circumstances. The information will be released if it is needed for diagnosis or treatment in both emergency and non-emergency situations, for purposes of conducting preventative research studies or for providing medical treatment by a health professional who is a local government employee (53 FR 28797, July 29, 1988).

For more information, the regulations found in 40 CFR 350.5(b) through (e) explain how to file a trade secrecy claim under each applicable section of EPCRA.

SECTION 324: PUBLIC AVAILABILITY

The second part of the Emergency Planning and Community Right to Know Act provides, as the name implies, the vehicle by which the community can exercise their "right-to-know" about the hazardous chemicals being used, stored and released all around them. Most of the rules governing the public availability of data are contained in Section 324 of SARA. Essentially, the LEPC, SERC and the U.S. EPA must make available to the general public, during normal working hours

at some location, all of the EPCRA information which they have received.

The LEPCs must make available the emergency response plan, MSDSs, lists, inventory forms and followup emergency notices. The LEPC also must publish a notice of public availability concerning this information at least once each year. The SERCs must make available MSDSs, lists, inventory forms, follow-up emergency notices and Toxic Chemical Release Inventory forms (the Form R).

Typically the SERCs and LEPCs will have a room which contains all of the information they have collected. They allow visitors to examine the records and often provide a photocopy machine for duplication. The LEPC or SERC usually responds to written requests for information, and a number of LEPCs and SERCs have computerized their data, making them even more accessible.

In certain cases, the public can request and receive information above and beyond what was submitted by industry to the LEPC and SERC. The regulations at 40 CFR 370.30(a) state that if a person requests an MSDS for a facility's hazardous chemical and the LEPC does not have it, the LEPC shall request the MSDS from the facility. The regulations at 40 CFR 370.30(b) state that the LEPC must obtain the Tier II form for any facility if a person asks for it. Generally, the request is limited to chemicals present above 10,000 pounds. However, if the LEPC decides that the person's need is justified, or if the person is a state or local official acting in his or her official capacity, the LEPC can request Tier II information for all hazardous chemicals present at a facility, regardless of quantity on-site.

The Toxic Release Inventory information is available from the U.S. EPA, as well as from the state contact in several ways. To obtain TRI data, persons can access the TRI Database through the National Library of Medicine. Additionally, persons can request individual forms from the SARA, Title III Reporting Center or the state contact. Also, state data are on microcomputer diskettes and a magnetic tape containing the national data are available from the National Technical Information Service. Finally, CD-Rom disks and COMfiche will be placed in certain government depositories and county libraries.

CONCLUSION

The Emergency Planning and Community Right-to-Know Act (EPCRA or Title III of SARA) is a law which requires various facility owner/operators to report their chemical inventory and releases. The information is collected by various state and local entities and is made available to the public through different media. The information is used to enhance emergency planning and to increase community awareness of the presence of hazards in their area. Because the information is made available to the public, the law allows certain information to be withheld and claimed as trade secret by the reporting facility. In this case, the community is given information concerning the physical and chemical properties of the substance, but the chemical identity is withheld.

A summary of the EPCRA reporting requirements follows. Section 302 requires the reporting of Extremely Hazardous Substances (EHSs) at or above their Threshold Planning Quantity (TPQ). Most facilities will be subject to the reporting requirements of Section 302. Section 304 requires the reporting of releases of EHSs and CERCLA hazardous substances at or above their Reportable Quantity (RQ). Any facility that produces, uses or stores a hazardous chemical is covered by Section 304 reporting. Sections 311 and 312 require the reporting of the presence of any hazardous chemical at or above 10,000 pounds or hazardous chemicals that are EHSs present at or above 500 pounds or their TPQ, whichever is less. The Section 311 and 312 requirements apply to any facility that is covered by the Occupational Safety and Health Act (OSHA). Section 313 requires the reporting of annual emissions of toxic chemicals used by manufacturing facilities with 10 or more full-time equivalent employees. These reports are filed if the amount of any toxic chemical manufactured or processed at a covered facility exceeds 75,000 pounds for calendar year 1987, 50,000 pounds for calendar year 1988 or 25,000 pounds for calendar year 1989 and beyond. Reports also are filed for any toxic chemical otherwise used at or above

10,000 pounds for calendar year 1987 and beyond.

There are a multitude of exemptions from the requirements. Some of the exemptions were designed to reduce the burden on reporting facility owners and operators without significantly impacting the community awareness of the hazards present in their local area. The second reason for some of the exemptions is that the materials and activities are already regulated under some other act or by some other agency and additional regulation under EPCRA would not be necessary.

Additional sections of EPCRA apply to specific situations. For example, Section 322 establishes mechanisms for the claiming of trade secret information, and Section 324 provides a mechanism for public availability to any and all of the information (with the exception of trade secret information) collected under the EPCRA program.

The requirements of EPCRA are very broad in scope and may encompass a multitude of facilities. The information that is collected under EPCRA, however, may be used for a multitude of purposes, including emergency planning which, if properly used, could be of vital importance to the community.

Total Quality Management in the Site Assessment Program

Joseph Kruger
Penelope Hansen
Office of Emergency and Remedial Response
U.S. Environmental Protection Agency
Washington, District of Columbia

ABSTRACT

The Superfund program has developed an innovative management strategy that will help address the staggering cleanup challenges of the 1990s. The U.S. EPA believes this renewed emphasis on quality and efficiency, known as Total Quality Management (TQM), will quicken the process of evaluating and addressing the nation's worst hazardous waste sites.

The objective of this paper is to describe the application of TQM principles to one part of the Superfund program - the process for placing sites on the National Priorities List (NPL). The paper analyzes past problems in the NPL process from a TQM perspective and discusses measures taken to resolve these problems.

INTRODUCTION

This paper discusses a Superfund program initiative to improve the process for placing sites on the National Priorities List (NPL) through the use of Total Quality Management (TQM) principles. The paper begins with a brief explanation of TQM principles and tools and a description of the NPL process. Next, we discuss our analysis of problems in the NPL process and some of our initial findings. Finally, we address improvements we have begun to make to the NPL process and our plans for future improvements.

BACKGROUND

Total Quality Management is a collection of management theories and principles that emphasizes the need to build quality into a work process from the very start. Based on the writings of W. Edwards Demming, Joseph Juran and others, the TQM philosophy was adopted by the Japanese after World War II and is believed to be one of the significant factors leading to Japan's remarkable economic revitalization. The teachings of Demming and others were largely ignored by most American corporations until the late 1970s, when several companies such as Ford Motor Company began to experiment with some of the changes advocated by TQM.

TQM and Superfund

In 1988, the Office of Management and Budget issued a draft order encouraging Federal government agencies to adopt TQM. The U.S. EPA has enthusiastically embraced this suggestion and is beginning to apply TQM principles in all of its environmental programs. In the Superfund program, a number of activities are underway, including TQM training for all Headquarters management and staff and several pilot projects. One of these pilots is the application of TQM to the process of placing sites on the NPL.

The Fundamentals of Total Quality Management

Fundamental Principles

TQM stresses many general principles. Those of particular importance to improving the NPL process are:

- **Continuous improvement in the work process.** TQM theory holds that the best way to improve a work product is to focus on the process by which that product is produced. TQM emphasizes that small and continual increments of process improvement often buy more than one time "great changes."
- **Customer orientation.** Demming and other quality management theorists repeatedly argue that each part of an organization must identify and understand its customers and their needs. This process includes both customers outside the organization as well as internal customers, i.e., other parts of the organization that depend upon it for resources, information or intermediate inputs to a final product.
- **Statistical analysis of data.** Advocates of TQM note that team-work and group problem solving alone are not enough. Solutions to quality problems must be based upon a thorough analysis of data rather than anecdotes and opinions.
- **Built-in quality.** One of Demming's most important teachings is to stop reliance on inspection "after the fact" to achieve quality. Demming argues that quality must be built into a process from the very first step.

Analytical Tools

TQM emphasizes that collection and analysis of data, rather than reliance on "conventional wisdom," is necessary to understand how a process is working and where it needs to be improved. Although a variety of analytical tools are used in a TQM analysis, the Superfund Site Assessment Branch (SAB) has found these the most useful:

- **Flow charts:** A flow chart is a picture that describes all of the players and steps in a process. Detailed flow charts help to identify steps that do not add any value to a process.
- **Pareto Charts:** Pareto charts are simple bar graphs that present the frequency with which problems arise in a work process. Based on the principle that 80% of the trouble comes from 20% of the problems, these charts help managers rank present problems and future opportunities for improvement.
- **Time Management Analysis:** With this type of analysis, data are

collected on the proportions of staff time spent on different activities. Activities are then analyzed to determine whether they add value to a final work product. Once unproductive activities (e.g., the continual reworking of products) are cataloged, efforts can begin to identify ways to reduce the amount of staff time spent on these activities.

USING TQM TO IMPROVE THE NPL PROCESS

The NPL Process

The process for screening and subsequently placing the most serious hazardous waste sites on the NPL is probably less well known than other parts of the Superfund program. The following description outlines the major steps that have characterized the process in the past.

Based on a variety of factors, the Headquarters NPL staff decides that an appropriate time to propose additional sites to the NPL has arrived. Headquarters announces the expected date of the rulemaking and issues a "call for packages" to the Regions. Regional Offices have the primary responsibility for prioritizing and then nominating sites to the NPL. To nominate a site, a Region must determine its preliminary Hazard Ranking System (HRS) score and submit an "HRS package" that documents the basis for the site's score. HRS packages usually are compiled by the Field Investigation Team (FIT) - the Regions' site assessment contractors - or by a State and are based on the technical and historical information found in Preliminary Assessments and Site Inspections. Regional Offices conduct varying degrees of quality control (QC) on the packages, depending on the technical expertise of the individuals involved, the number of sites the Region wishes to propose and the amount of time before packages must be received at Headquarters to begin Quality Assurance (QA). Once packages are received at Headquarters, U.S. EPA Headquarters NPL staff and QA contractors conduct a QA review to ensure accurate and consistent application of the HRS model. After site packages are judged acceptable, the U.S. EPA publishes a list of sites proposed to be added to the NPL in the Federal Register. These proposals are called "Updates." Public comment is accepted for 60 days, followed by technical evaluation of the comments and eventual placement on the final NPL of all sites that continue to score above the HRS cutoff for listing.

Why Apply TQM to the NPL Process?

The Superfund program has been criticized for the speed at which the nation's hazardous waste sites are being cleaned up. Although significant strides have been made in streamlining the process over the last few years, the process remains complex and time-consuming. The site assessment phase alone is extremely lengthy. Table 1 shows the range of time from discovery to listing for 71 sites added to the NPL in February 1990 and the one site dropped. Approximately 43% of these sites took more than 10 years to go from discovery to final listing on the NPL. Approximately two-thirds of these sites took 2 years or more between completion of the SI and proposal to the NPL, and approximately 87% took 2 years or more between proposed and final listing.

The length of the site assessment process is of concern because the quicker sites are assessed, the sooner those with significant hazards can be addressed. In some cases, quick assessment may lead to earlier actions which can limit the migration of contamination and reduce the cost and difficulty of site cleanup. Congress recognized this problem in Section 116(b) of the Superfund Amendments and Reauthorization Act of 1986 (SARA), which requires the U.S. EPA to create an assessment process that requires no more than 4 years to go from discovery to listing.

In addition to the general need to speed up the NPL process, there are two other important reasons to apply TQM:
• The new HRS, about to be revised as required by SARA, is a more comprehensive and complex model for ranking sites than the

original HRS. A new soil exposure pathway and a number of new subpathways and factors have been introduced, each with additional data collection requirements and QA concerns.
• After all sites in CERCLIS are assessed, a substantial universe of undiscovered sites still may require the Agency's assessment. Although estimates of the size of this universe vary, there is agreement that its screening will require significant time and resources.

Table 1
Sites Added to the NPL in February 1990

Discovery to Promulgation		Discovery to SI		SI to Proposal		Proposal to Promulgation	
Years	No. Sites	Years	No. Sites	Years	No. Sites	Years	No. Sites
0-4	8	0-1	13	0-1	23	1	9
5	10	2-3	18	2-3	28	2	47
6-8	9	4-5	16	4-5	7	3-4	13
9	14	6+	18	6+	4	5+	1
10+	31	Not Known	7*	Not Known	10*	Not Known	2*
Total	72		72		72		72

* Insufficient data in CERCLIS to permit analysis.

ANALYSIS OF THE LISTING PROCESS

Data Collection

To obtain a complete picture of the NPL process and to identify problem areas, data were collected on how the process works and participants in the listing process were asked to suggest improvements. Interviews were conducted in six Regional Offices, and files and the CERCLIS data base were reviewed for sites within those Regions. In addition, Headquarters NPL staff and staff of Mitre Corporation, the U.S. EPA's primary QA contractor, were interviewed.

Detailed flow charts were constructed for the six Regions visited and for the Headquarters portion of the process. In addition, information was collected on the time spent by Headquarters staff on activities related to NPL Update 10 and final rules promulgated in 1990. Finally, data were collected and arrayed on Pareto charts on the technical and procedural issues raised in QA for Updates 7, 8 and 10.

Summary of Findings

Our initial efforts at data collection and analysis turned up three major findings:
• Insufficient communication led to inconsistent understanding of the responsibilities of all participants and wide variation in what various participants considered to be "quality products." It also led to suspicion and mistrust between Headquarters and the Regions. Regions felt that once packages were sent to Headquarters they "disappeared"; i.e., they were not informed on either progress or problems, while Headquarters felt that some Regions generally submitted incomplete or inadequate packages.
• The NPL process was characterized by substantial variation, complexity and general unreliability. Perhaps the most important aspect of this variability was the irregular scheduling of Updates, which undermined attempts to rationalize the NPL process.
• The NPL process has been overly dependent on inspection, i.e.,

QA after packages are submitted, to achieve quality, rather than building it into the process from the start.

The TQM Response

In response to these problems, TQM theory offers several general approaches:
- Break down barriers between groups and improve communication
- Regularize processes and reduce variation
- Reduce dependence on inspection to achieve quality by building quality into the process from the start

The specific application of these approaches to the NPL listing process follows.

Finding #1: Inadequate Communication Hampers the Process

Our most important finding was that communication between the different groups involved in the process has been inadequate. In the past, neither SAB nor the QA contractor clearly identified the Regional offices as the their prime "customer," and little time or effort was spent on keeping the Regions informed. Regions complained that they were unaware of the status of packages for sites in their Regions and that no comprehensive tracking system was in place. In addition, roles and responsibilities of the Regional offices were unclear and no explicit, standard process for Regional QC of packages existed.

Regions felt that with the complexity of the NPL process and with relatively high staff turnover rates, they often had to struggle to decipher the rules of the listing process. Moreover, there was considerable confusion of the Regional staff over where their activities fit into the overall NPL process. This confusion is understand-able given the huge numbers of steps and participants in the process. For example, Figure 1 shows the numerous steps and participants involved in the three week period between OMB review and publication in the Federal Register for NPL Update #10. A complete flow chart of the NPL process would take 6 to 7 pages to present!

TQM Approach

The TQM approach to these problems is to break down the barriers between the groups involved in the NPL process and to build communication into the process. TQM emphasizes collegial problem solving from all levels of the organization and establishes clear roles and expectations for all participants.

Changes Underway

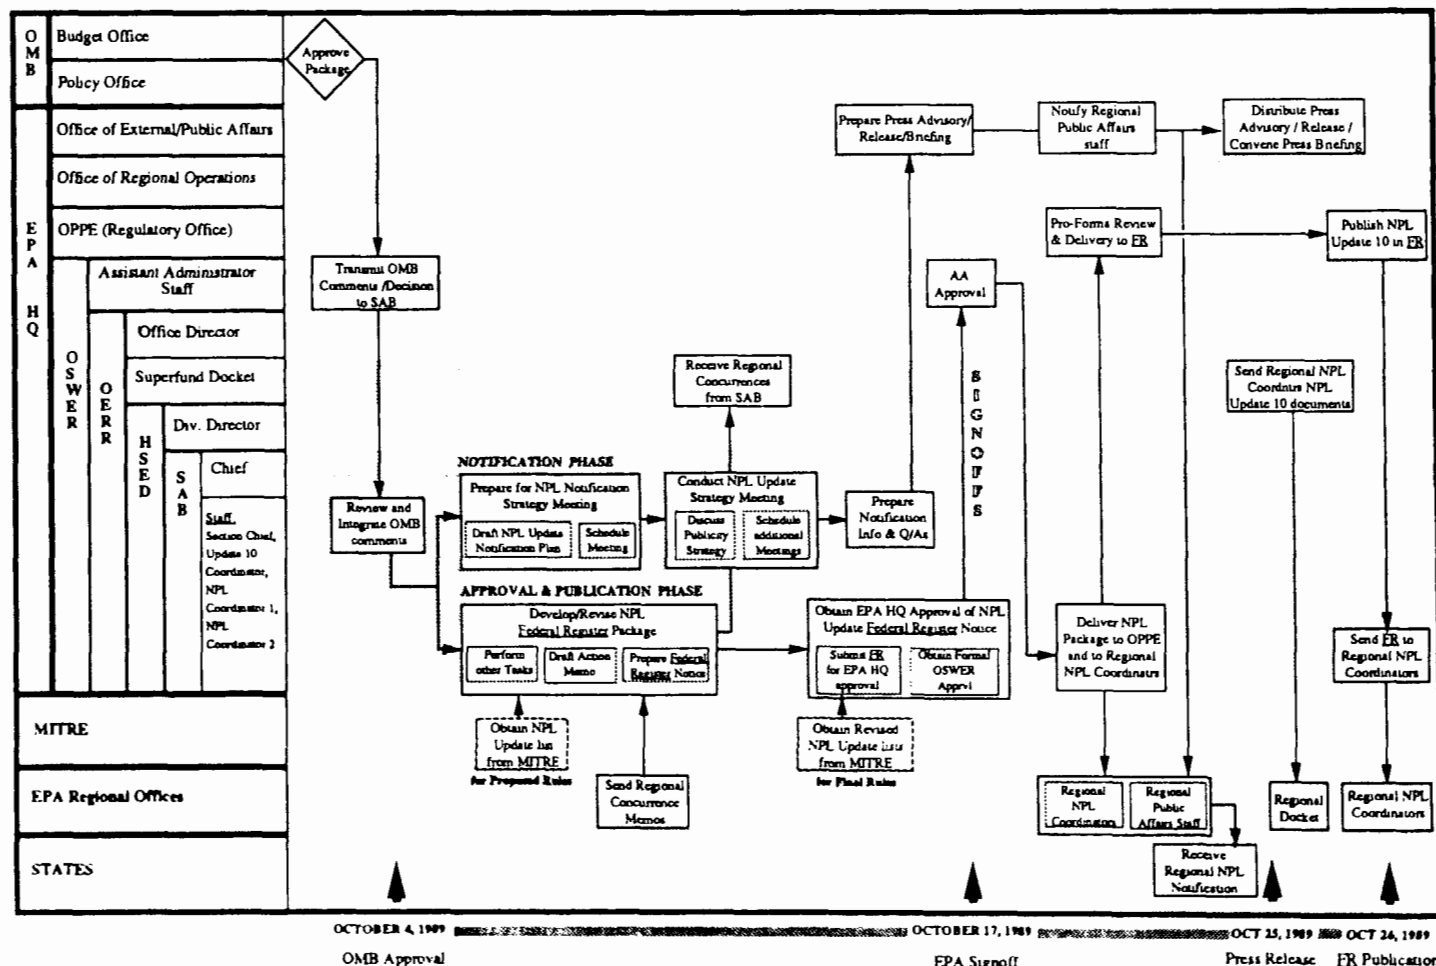
SAB has introduced several new measures to improve communication for Update 11, the first update under the revised HRS:
- **QA visits:** SAB and Mitre staff are conducting large portions of HRS package review and QA in the Regional offices. With this new system, all the players involved in the production of an HRS package (the Region, FIT, States, Mitre and SAB) sit around the same table and work through any issues raised. The Regions receive immediate feedback on emerging technical and policy issues, and Headquarters and Mitre staff are directly exposed to a field perspective on sampling and other HRS requirements.
- **Regional Coordinators:** SAB has assigned one staff person to coordinate QA for each Regional Office. This person will be the point of contact for the Region and will be familiar with all of the candidate NPL sites for that Region. Mitre has also designated a single QA contact for each Region. These three individuals are expected to stay in communication throughout the year on all sites


Figure 1
Proposed Update 10

under consideration for the NPL. The 10 SAB Regional Coordinators meet weekly to compare notes on emerging areas of Regional concern, QA problems and common communication needs.

- **Tracking system**: SAB has instituted a new computer based tracking system for NPL sites, which will allow us to accurately convey the status of packages as they move through the approval process.
- **Regional Quality Control Check-Off List:** To assure that Regions understand their role in providing quality HRS packages, a workgroup, made up of Headquarters and Regional staff, has created a check-off list of steps necessary for a complete HRS package. This list and a signature must accompany all NPL packages.

A number of additional measures are planned for the near future including:
- **A Guidance/Policy Hotline for Regions and States**
- **Guidance on the NPL process** - a complete description of the NPL process with flow charts illustrating the different steps.
- **Regional QC Guidance** an expansion on the QC checklist mentioned above that will elaborate upon the Regions' role in providing quality HRS packages. This guidance document is being written by Regional site assessment staff.

Finding #2: Variations in Scheduling Led to Inefficiencies

Unpredictability in the scheduling of NPL Updates has affected the quality of HRS packages produced by the Regions and the efficiency of the entire site screening process. The time intervals between NPL proposals have been sporadic over the history of Superfund, ranging from 2 to 13 months (Figure 2). Not knowing if Updates will be months or a year apart sets up numerous responses that substantially alter the site assessment process. Some Regions have responded to this irregularity by "clearing the shelves"; i.e., sending in everything that could remotely be called an NPL package no matter how incomplete, just to get it in the queue before the deadline. Other Regions stopped all other site assessment work, no matter how important, to work on scoring sites. The process has also suffered from the "hurry up and wait" syndrome where tight deadlines were imposed for the submission of packages, but were repeatedly changed, leading to a lack of trust in Headquarters schedules and to a general casualness about the process in the Regional offices. Finally, the lack of a predictable schedule for Updates sometimes led Regions to plead for delays so that they could add "just one more site" before the door was closed. In some cases, Regions were justifiably concerned that they would have a considerable wait before they received another chance at proposing the site to the NPL.

Meanwhile, back at Headquarters, the entire NPL staff (three people) was struggling to see over the stacks of dozens of packages that had all arrived on the same day! It is not hard to understand why Regional queries on the status of individual sites went unanswered for long periods of time. Moreover, where Regions had sent in incomplete or poor quality HRS packages, it was necessary to go back and correct mistakes, thereby creating additional delays.

Changes Planned or Underway

SAB is committed to making NPL Updates and final rules regular, predictable events. In the future, Updates to the NPL will be submitted to the Office of Management and Budget (OMB) every 6 months, no matter how many sites are ready. In addition, there will no longer be a "call for packages" before each Update. Regions will submit HRS packages on a rolling basis as they are completed (i.e., QC signed by Regions).

Finding #3: Dependence on Inspection

Demming's concern about dependence upon inspection to achieve

quality was particularly relevant for the QA process. In the past, QA focused on spotting mistakes in HRS packages so that these packages could be returned to the Regional offices for correction. Although the "final products" (HRS documentation packages) were of good quality (i.e., sites were scoring above the HRS cutoff and packages were well-documented and legally defensible), the process was time-consuming and inefficient. It was not uncommon for Regional offices to prepare and send to HQ three, four or even more versions of a documentation package before it was considered acceptable.

Number of Months
Figure 2
Lapsed Time Between Proposed Rules
September 1983 through October 1989

Figures 3 and 4 are Pareto charts that portray some of the recurring problems caught during QA review of HRS packages. Figures 3 illustrates the most common QC problems identified during reviews of 125 sites from several NPL Updates. Figure 4 breaks down the largest category from Figure 3, "Documentation," into smaller subcategories. Many of the problems identified in this chart could have been avoided had there been adequate written standards for HRS packages.

Quality Control Issues
125 Sites
Figure 4
Documentation Issues
125 Sites

TQM Approach

TQM theorists argue that relying solely upon this "last chance" inspection of products wastes time and effort. The need for rework that results from this type of QA is wasteful and is, as one TQM expert notes, "like scraping burnt toast." Rather than relying solely upon inspection, TQM advocates providing participants a process with written standards and other tools that allow them to avoid errors in the first place. In addition, TQM theory encourages all groups involved in a process to be responsible for quality, not just the QA staff. By involving representatives from different groups in the collection and analysis of data, an organization can create a system that provides for continuous improvement in a process.

Changes Planned or Underway

SAB is initiating a number of measures intended to wean us from our dependence upon inspection to achieve quality. These measures can be divided into two categories. The first is guidance documents and other tools that will help guarantee high quality HRS packages, among them:

- **Regional Quality Control guidance** QC guidance is being developed that will provide explicit written standards for the quality of HRS packages.
- **HRS "Rules-of-Thumb" scoring manual** - This document will be a users manual for those who are scoring sites with the HRS.
- **Short sheets and guidance updates** - SAB is planning to issue guidance short sheets on a variety of policy and technical issues involved in HRS scoring. In addition, application of the revised HRS probably will require updating or changing the guidance.
- **Training** - SAB is developing HRS training sessions for State,

Regional, FIT and Federal Facility personnel.
- **Prescore** - A computerized HRS scoring package is being developed that will greatly reduce the time needed to calculate HRS scores and will eliminate math errors. In addition, the program will help field staff develop sampling plans by allowing them to test how different scenarios might affect a site's HRS score.
- **Chemical data base keyed to the revised HRS** - This computerized data base is designed to provide easy access to toxicity and mobility information for 330 chemicals.

The second category is a data collection and analysis system that helps monitor the vital signs of the process and spot problems. Although a certain amount of "last chance" QA will continue to be necessary, SAB has begun to institute a new role for its contractor QA staff. Rather than looking solely at changes to the HRS package required for a final product, the QA staff will also collect data on the types of problems that arise and recur in HRS packages. For example, Figures 3 and 4 provide an example of information on documentation problems to be collected on a continuous basis as QA proceeds on HRS packages. SAB also expects to be able to analyze problems in implementing other aspects of the HRS such as analytical data quality issues, aquifer issues and pathway- or factor-specific issues. In this way, SAB will "monitor the pulse" of the process. Pareto charts and other tools will help identify the most significant problems, both systemwide and in specific Regions. Once problems are identified and priorities are set, guidance or training can be targeted to specific areas or to specific Regional Offices.

Our prime customers, the Regions, will be actively involved in this effort to analyze data and resolve problems through their involvement in project teams and data collection. Several changes have already been made for Update 11 to facilitate this involvement:

- **Analysis of technical and procedural issues:** SAB is cataloging and analyzing technical and policy issues that arise in this first update to identify guidance needs. A project team consisting of Headquarters and Regional staff is meeting after each Regional visit to coordinate the resolution of guidance questions.
- **Evaluation of the NPL process after visits**: After each Regional visit, interviews are conducted with Regional and contractor staff to identify aspects of the new QA process that need improvement.

Ultimately, a Headquarters/Regional project team will analyze data collected by the QA staff after every update to answer questions such as:

- Which procedures worked and which did not?
- What technical issues are consistently causing confusion or need to be resolved?
- Are the worst sites being listed first, in less time, with less wasted effort?

NEXT STEPS

SAB has only just begun to reexamine the process for placing sites on the NPL. TQM is a long-term strategy, and the U.S. EPA plans to continue to make improvements to the NPL process. Thus far, we have focused our efforts on the process for proposing sites to the NPL. In the future, we plan to reexamine and revise the next phase of the process, i.e., responding to public comments on proposed sites and placing these sites on the final NPL.

Overview of the Revised Hazard Ranking System (HRS)

Suzanne Wells
Steve Caldwell
Agnes Ortiz
Office of Emergency and Remedial Response
U.S. Environmental Protection Agency
Washington, D.C.

ABSTRACT

The Comprehensive Environmental Response Compensation, and Liability Act of 1980 (CERCLA) required the Federal government to establish criteria for setting priorities among releases of hazardous substances, pollutants and contaminants. The U.S. Environmental Protection Agency (U.S. EPA) responded by developing the Hazard Ranking System (HRS), which is a scoring system used to establish the National Priorities List (NPL). The Superfund Amendments and Reauthorization Act of 1986 required the U.S. EPA to amend the HRS so it will more accurately assess relative risks and take into account certain specific elements of risk, e.g., potential air releases of hazardous substances and contamination of the human food chain. On December 23, 1988, a proposed rule to revise the HRS was published in the Federal Register by the U.S. EPA. After reviewing public comments, U.S. EPA published the final rule. This paper describes the major revisions made from the original to the revised HRS.

The HRS revisions change the way the U.S. EPA evaluates potential and actual threats to public health and the environment from hazardous waste sites, and may affect the types of sites to be included on the NPL.

BACKGROUND

In 1980, Congress enacted the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA or "Superfund") to establish a Federal program to respond to the risks posed by uncontrolled releases of hazardous substances, pollutants and contaminants (hereafter referred to as "hazardous substances").[1] Section 105(8)(A) of CERCLA required the U.S. Environmental Protection Agency (U.S. EPA) to establish criteria for determining priorities for response actions among releases or threatened releases.

CERCLA Section 105(8)(B) specified that those criteria be used to establish the National Priorities List (NPL), a list of at least 400 releases and potential releases. To meet these requirements, on July 16, 1982, the U.S. EPA revised the National Contingency Plan (NCP) to include the Hazard Ranking System (HRS) as the primary criterion for establishing the NPL.[2] Only sites that are on the NPL are eligible for Superfund-financed remedial action.[3]

The HRS is a scoring system which evaluates the relative threat to public health and the environment from releases (including potential releases) of hazardous substances. In the 1982 version of the HRS (hereafter referred to as the "original HRS"), the score for a site was developed by evaluating a set of "factors" for three pathways: groundwater, surface water and air, that are related to risks to public health, welfare and the environment. Within each pathway, those factors were combined into factor "categories" that evaluate the potential for a site to release into the pathway, the inherent hazards of the site or release (e.g., toxicity, persistence, quantity of the hazardous substances present at the site), and the presence or proximity of targets (e.g., drinking water wells, wetlands, or residential areas) that could be affected by a release in the pathway being evaluated. The individual pathway scores were calculated by multiplying the category values and normalizing the results to a 100-point scale. The three pathway scores were then combined using a root mean square, and the resulting value was normalized to a 100-point scale. The U.S. EPA has used this value, the "HRS score," to establish the NPL. Sites receiving scores of 28.50 or greater under the original HRS were eligible for the NPL.

The original HRS also included an evaluation of direct contact and fire/explosion hazards. Those scores, although not used in determining NPL eligibility, were intended to help identify candidates for short-term response under the removal authorities of CERCLA.

Since 1982, the U.S. EPA and the States have applied the original HRS to thousands of sites posing threats due to hazardous substance releases. Of those, as of September 1990, 1,187 sites are on the final NPL.

SARA REQUIREMENTS

Section 105 of the Superfund Amendments and Reauthorization Act of 1986 (SARA) required U.S. EPA to amend the HRS to assess, to the maximum extent feasible, the relative degree of risk to human health and the environment posed by facilities under review. SARA specified several areas that must be addressed in developing the revised HRS:
- Damage to natural resources that may affect the human food chain
- Contamination or potential contamination of ambient air associated with a release or threatened release
- Contamination or potential contamination of surface waters used for recreation or as drinking water supplies

In addition, SARA Section 118 specified that the revised HRS should assign a high priority to facilities where the release of hazardous substances from a site results in closing of drinking water wells, or contaminates a principal drinking water supply. SARA Section 125 required revisions to the HRS to address facilities that contain substantial volumes of wastes, as defined in Section 3001 (b)(3)(A)(i) of the Solid Waste Disposal Act (Resource Conservation

and Recovery Act), i.e., fly ash and other wastes from coal-fired power plants.

While SARA required that the HRS accurately assess relative risk to the maximum extent feasible, the Conference Committee Report on SARA clarified that the degree of accuracy required is to be consistent with the data collected during preliminary assessments and site inspections. In other words, Congress did not expect the Agency to undertake long-term monitoring or studies to determine the full nature and extent of contamination at the time of HRS scoring. Also, Congress did not expect the HRS to achieve the level of accuracy of risk assessments performed in support of remedial actions. As stated in the Conference Committee Report, the HRS should perform "with a degree of accuracy appropriate to its role in expeditiously identifying candidates for response actions."[4]

ROLE OF THE HRS

The role of the HRS is to serve as the primary decision tool for determining which sites are appropriate for remedial investigations based on information developed during preliminary assessments and site inspections (Figure 1). The HRS functions primarily as a screening tool and provides useful information for meeting the Superfund program's strategic goal of addressing the highest priority releases first.
Figure 1
Typical Phases of the Superfund Process

The need to base the HRS on data available from preliminary assessments and site inspections places constraints on the factors that can be used and, consequently, on the degree of accuracy that can be expected at the site assessment stage of analysis. This places certain limits on the types of models or approaches that can be used. However, in order to fulfill its role within the Superfund program, the HRS need not establish an absolute ranking of NPL sites for remedial investigations based on risks. This approach is consistent with the Conference Committee Report[4] and the need to consider other factors besides risks (e.g., urgency, availability of State matching funds) in scheduling remedial actions.

MAJOR CHANGES BETWEEN ORIGINAL AND REVISED HRS

In developing the revisions to the HRS, the Agency undertook a comprehensive review and analysis of various sources of information. Comments to the Advance Notice of Proposed Rulemaking (52 FR 11513, April 9, 1987) and Proposed Rule Notice (53 FR 51962, December 23, 1988) were reviewed and considered while developing the final revised HRS. In addition, the U.S. EPA conducted a field test for the proposed revisions to assess the cost and implementation concerns associated with the modifications. The U.S. EPA announced the availability of the field test report and requested public comments, which were also considered (54 FR 37949, September 14, 1989).

The original and revised HRS differ substantially (Figures 2 through 5). The revised HRS is more flexible than the original HRS in that it can address a broader range of problem types and can accept a wider variety of types of data. While the factors have undergone wholesale revision, the structure of the model has largely been retained. Some of the more important changes are described briefly in the following paragraphs; more detailed descriptions and the underlying rationale are presented in the revised HRS preamble and final rule.

Groundwater Migration Pathway

Soil Exposure Pathway

The revised HRS adds a new pathway, the soil exposure pathway which is similar to the direct contact pathway of the original HRS. This pathway, named on-site exposure in the proposed HRS, evaluates the possibility that people or sensitive environments will have direct physical contact with hazardous wastes or contaminated soil. The Agency's experience at sites such as Love Canal in Niagara Falls, New York, and Times Beach, Missouri, suggests that contaminated residential or school properties need to be addressed as special situations. The soil exposure pathway considers two groups potentially at risk, those living, working or attending school on property with hazardous wastes or contaminated soils, and those living nearby with access to the property. The pathway is evaluated only on the presence of contamination and not on release potential, as in the other pathways, because contaminants do not have to migrate off-site for exposure to occur (Figure 4).

Food Chain Threat

To address the requirements of SARA Section 105 and to more accurately evaluate relative risks, the U.S. EPA developed the food chain threat within the surface water pathway. This threat addresses human exposure to contaminated fish and shellfish resulting from hazardous substance releases. Most notable in the methodology are the use of a bioaccumulation factor (BCF) and a food production factor to estimate relative population exposure levels. BCF is based on bioconcentration values reported in the U.S. EPA's water quality criteria documents, where available, or peer-reviewed literature. Where bioconcentration studies are insufficient to calculate BCFs, the logarithm of the n-octanol-water partition coefficient can be used. Food chain production is based on fish catch or commercial landing data, where available. The approach allows an estimate of relative exposures from fish consumption, which is calibrated to values developed in the drinking water threat of the surface water pathway.

Distance/Dilution Weights

The original HRS assigned values to potentially affected populations, based on the number of people using wells, or drinking water intakes within the target distance limits - 3-mile radius for groundwater or 3 miles downstream for surface waters. Only in the air

pathway was there some further adjustment of target population values based on distance from the site. The revised HRS weights potentially-exposed targets on the amount of dilution expected in the exposure medium. In surface waters, dilution weights are based on mean annual stream flow at the point of potential exposure. For the groundwater and air pathways, dilution weights were established for various distances from sites using analytical models with relatively conservative input parameters. General dilution values were developed for concentric rings around sites (e.g., 0 to 0.25 mile, 0.25 to 0.5 mile). Applying those weights in scoring a site requires counting the number of residents residing or using wells within a given ring and multiplying that number by the distance weights for the ring.

Documented Human Exposures

While the original HRS did not differentiate between potential exposures and actual exposures, the revised HRS assigns a higher value to target populations where actual exposures can be documented. Where data indicate that promulgated health benchmarks (e.g., drinking water standards) have been exceeded, the revised HRS assigns higher values to targets than where contamination is observed, but below benchmarks, or where contamination is only potential. These changes respond to SARA Section 118(a), which requires that releases causing the closing of drinking water wells, or

contamination of a principal drinking water supply, be given a high priority. A similar approach of taking into account environmental benchmarks has been developed to evaluate sensitive environments.

Sensitive Environments

In revising the HRS, one of the U.S. EPA's goals was to improve the evaluation of sensitive environments by addressing a broader range of sensitive ecosystems and to afford a higher weight for sensitive environment factors. The original HRS addressed threats to sensitive environments through air and surface water releases, but the weights were assigned such that even a worst case problem (e.g., a release that contaminates the habitat of an endangered species or harms a National Park) could not score high enough to be placed on the NPL on that basis alone. In addition, only a limited number of sensitive environments were considered. The revised HRS substantially increases the number of sensitive environments evaluated to include all specifically identified under Federal and State statutes and regulations as requiring legal protection. The revised HRS assigns sensitive environments that are seriously threatened, or affected by releases, a higher relative weight than the original HRS. The intent of the changes is that serious environmental threats can score above the NPL cutoff. The relative weights for sensitive environments versus human health factors were established based on

Figure 3
Surface Water Migration Pathway

consensus within the U.S. EPA workgroup developing the revised HRS; U.S. EPA solicited public comment on those relative weights in the preamble to the proposed rule.

Soil Exposure Pathway

Waste Quantity

In the original HRS, hazardous waste quantity was the amount of waste containing hazardous substances present at the site, because it is generally easier to estimate than hazardous constituent quantity, which may require extensive concentration measurements. In cases where hazardous waste quantity could not be determined, a default value of 1 was assigned.

The revised HRS substitutes a tiered approach for the hazardous waste quantity factor. The tiered approach arrives at a single hazardous waste quantity value based, in order of preference, on:

- Hazardous constituent quantity, which represents the actual quantity of hazardous substances deposited on the site
- Site wastestream quantity, which is similar to the original HRS

hazardous waste quantity factor, and represents the quantity of hazardous wastes deposited on the site
- Site disposal capacity, which represents an estimate of the quantity of hazardous substances the site could have received as indicated by the sizes of the sources identified

The tiered approach allows the scorer the flexibility to move within the tiers depending on data availability. This approach permits a more accurate evaluation at many types of sites without imposing significant new costs.

Finally, in response to public comments, the hazardous waste quantity is now multiplied by toxicity and other factors, instead of being added as they were in the original HRS. This is one of several changes that make the revised HRS more consistent with risk assessment principles.

Toxicity

The original HRS scored the toxicity factor based primarily on acute toxicity of the hazardous substance, evaluated by either of two rating systems: Dangerous Properties of Industrial Materials or the National Fire Protection Association guidelines.[3] Factor values were developed for each substance in each migration pathway and combined with persistence factor values. The substance with the highest combined toxicity/persistence value for a pathway was used to assign that pathway's toxicity/persistence factor value.

However, based on risks identified at NPL sites, it is likely that most risks at these sites result from chronic exposures to hazardous substances. To consider such risks in the revised HRS, the toxicity factor evaluates the hazardous substance and assign scores for three kinds of toxicity: (1) acute toxicity, (2) carcinogenicity, and (3) chronic noncarcinogenic toxicity. The highest of the three scores for a hazardous substance becomes the toxicity factor value assigned to that substance. The score is based on the Reference Dose for chronic noncarcinogenic toxicity; cancer potency factors combined with a qualitative weight-of-evidence for carcinogenicity; or, when these factors are not available, the ED_{10} and LD_{50} or LC_{50} values for acute toxicity. Aquatic toxicity is also considered when assessing potential risks to aquatic ecosystems.

Mobility

The original HRS did not directly consider properties of substances that affect their ability to be released and migrate through environmental media. The revised HRS adds mobility factors to both groundwater and air pathways and modifies the persistence factor in the surface water pathway to consider a greater number of potential degradation mechanisms. The groundwater mobility factor is intended to reflect the fraction of a hazardous substance expected to be released from the source, migrate through the porous media, and contaminate aquifers and drinking water wells that draw from them. Mobility in the groundwater pathway involves both release and transport concerns, and is evaluated based on solubility and distribution coefficient values for the hazardous substances present at the site. The air pathway evaluates gaseous mobility (on the bases of vapor pressure) and particulate mobility (on the basis of the Thornthwaite P-E Index).

Radionuclides

The revised HRS includes a special section on scoring radionuclides. Essentially, radionuclides are treated in a parallel manner to hazardous substances with certain special characteristics that are accounted for by separate scoring rules for some HRS factors. The revised HRS evaluates radionuclides within the same basic structure, and the evaluation of many individual HRS factors is the same whether radionuclides are present or not.

CUTOFF SCORE

One of the more challenging tasks in revising the HRS was selecting the cutoff score. The Agency has used the cutoff score as

a management tool to identify the top priority sites in the nation. In 1982, when the first sites were being considered for the NPL, approximately 700 sites had been scored. The cutoff score of 28.50 under the original HRS was chosen because it yielded an initial NPL of at least 400 sites, as suggested by CERCLA Section 105(8)(B) (now CERCLA Section 105(a)(8)(B)). Out of the approximately 700 sites, 418 were actually proposed to the NPL. The cutoff score was not chosen because it represented a threshold of unacceptable risk posed by the sites.

In the Conference Committee Report on SARA[4], Congress asked the U.S. EPA to address the relationship between risks at NPL sites and the cutoff score. The U.S. EPA performed several studies on the cutoff score.[5] While the studies were limited in scope, and definitive conclusions were not possible, they supported the continued use of cutoff score as a useful management tool in identifying priority sites. However, the studies indicated sites with scores below the 28.50 cutoff could also pose potential dangers to human health and the environment.

The U.S. EPA believes the cutoff score, under the original HRS, has served its purpose as a management tool. In general, NPL sites that scored greater than 28.50, under the original HRS, present significant risks to public health and the environment, and have necessitated some form of response.

Because the cutoff of 28.50 served as a useful management tool, the Agency proposed that the cutoff score for the revised HRS be functionally equivalent to the 28.50 cutoff under the original HRS. The Agency proposed the following approaches for determining functional equivalency:

* **Statistical equivalence** - determine what revised HRS score best correlates to 28.50, i.e., score a sample of sites with the original and revised HRS, and adjust the revised HRS cutoff score to reflect changes in values so that the original and revised HRS scores would be equivalent.
* **Numerical equivalence** - determine what percentage of CER-CLIS sites score above 28.50 under the original HRS, and set a cutoff that yields the same percentage under the revised HRS.
* **Risk equivalence** - determine the quantitative risk level that, on average, corresponds to a HRS score of 28.50 under the original HRS, and then determine what revised HRS score best corresponds to that risk level.

To perform the above analyses, the Agency scored 110 sites with both the original and revised HRS. These 110 sites were composed of:

* **Phase I Field Test Sites (30 sites)** - sites selected to test specific features of the proposed revised HRS. The field investigation on these sites was relatively complete, and generally all pathways were scored.
* **Phase II Field Test Sites (40 sites)** - these sites were scheduled to have preliminary assessments performed on them. The field investigation on these sites was less complete than for the Phase I field test sites, but still all pathways were generally scored.
* **Region IV Sites (40 sites)** - sites generally expected to be likely candidates for the NPL. A number of these sites were thought to have either groundwater or surface water contamination.

The Agency's analysis on the 110 sites indicated:

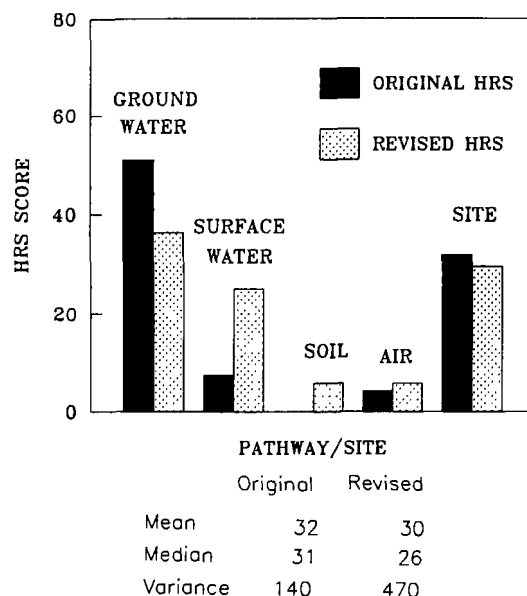
* **Statistical equivalence** - the average site score dropped from about 32 on the original HRS to 30 on the revised HRS, the median site scores dropped from 31 to 26, and the variance associated with site scores increased (Figure 6).
* **Numerical equivalence** - 72 sites scored at or above 28.50 on the original HRS versus 54 on the revised HRS. The cutoff would have to have been lowered to 13.5 in order to get 72 sites above the cutoff under the revised HRS (Figure 7).
* **Risk equivalence** - because quantitative risk information was not available for the 110 sites, the Agency looked at the qualitative risks of the revised HRS scores, particularly at theoretical sites scoring around 28.50.


Figure 6
Pathway and Site Score Comparison
for the Original and Revised HRS

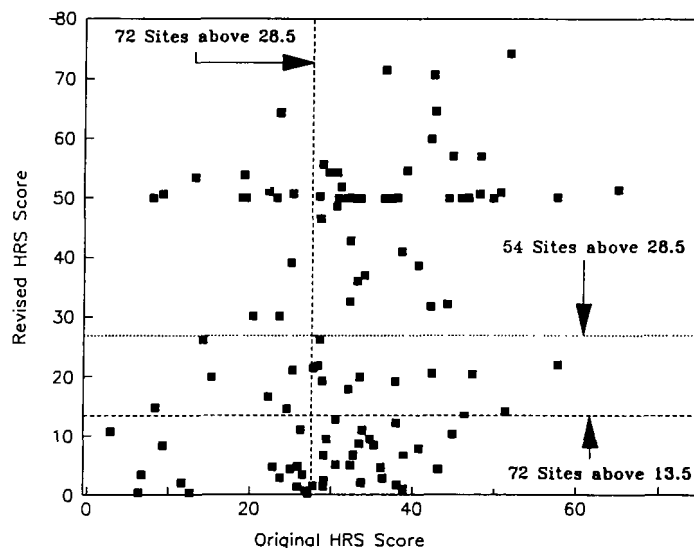
	Original	Revised
Mean	32	30
Median	31	26
Variance	140	470


Figure 7
Scatter Plot of Site Scores for the
Original and Revised HRS

In general, the U.S. EPA found:
* Of sites that scored between 40 and 60:
  -90% had observed releases and 10% had potential releases, moderate to large amounts of waste, and large target populations
* Of sites scoring between 30 and 40:
  -70% had observed releases and 30% had potential releases, moderate to large amounts of waste, and moderate target populations.

Around 28.50, several scenarios were examined. A site with these characteristics scored 28.80:
* Observed contamination in a drinking water well above a health-based benchmark, a substance with a toxicity value of 10,000 and a waste quantity value of 100, and 22 people served by the well.

Another site with these characteristics scored 33.70:
* Observed release in a monitoring well on the site, a substance with a toxicity value of 1,000 and a waste quantity value of 100, and a distance weighted population between 10,000 and 30,000 people.

Because of the large number of changes between the original and revised HRS, it was difficult to infer a correlation between how sites scored. The statistical and numerical approaches to determining equivalency suggested that, if anything, the cutoff score should be lowered, but did not indicate a specific number. The risk analysis indicated that the types of sites scoring above 25 to 30 pose the types of risks that warrant designation as a national priority, recognizing that the cutoff score does not reflect a point below which no risk is present.

Because the statistical and numerical analyses did not point to a specific number, and because the qualitative risk analysis indicated that sites scoring around 28.50 appear to pose significant risks, the Agency decided to retain 28.50 as the cutoff score under the revised HRS.

ANTICIPATED EFFECTS ON THE NPL

The revisions made to the original HRS are likely to place new types of sites on the NPL. For example, since the revised HRS considers contamination of natural resources that can affect the aquatic human food chain, some sites that discharge substances that bioaccumulate in aquatic organisms will be listed. Also, the addition of the soil exposure pathway makes it likely that certain soil contamination problems, especially those involving contamination of residential or school property, will be listed. Because the revised HRS expands the types of sensitive environments considered and increases their weighting, some sites causing serious environmental impacts are likely to score above the cutoff score. The addition of distance weighting in the groundwater pathway is expected to lower groundwater pathway scores, and result in fewer sites being placed on the NPL on the basis of groundwater impacts. Finally, because of the addition of health-based benchmarks, sites that result in high levels of known exposure, even if only small populations are involved, will score relatively higher on the revised HRS.

The Superfund Site Assessment Process: A Status Report

Penelope Hansen
Caroline Previ
Office of Emergency and Remedial Response
U.S. Environmental Protection Agency
Washington, D.C.

ABSTRACT

The Agency's evaluation list (CERCLIS) now contains about 32,000 sites. The decision process for determining which of these are among the nation's most seriously contaminated sites, and therefore warrant the expenditure of the Fund for long-term remediation, is managed by the U.S. EPA's Site Assessment Program. The U.S. EPA's goal for this program is to expeditiously identify the worst sites at each step of the evaluation process and move them on to the next stage, ultimately to the National Priorities List (NPL), or to the decision that they will not be cleaned up by Superfund. This year marks a major transition time for the program. Publication of the revised Hazard Ranking System, finalization of all proposed NPL sites, and the imminent completion of site inspections at all sites in CERCLIS, prior to the Superfund Amendments and Reauthorization Act (SARA) of 1986, have brought the site assessment program to a natural opportunity for evaluation and change. This paper describes the status of the program at the time of SARA enactment, its changes under SARA, and projects where the program is headed.

In addition to this programmatic discussion, the paper will explore what the Agency has learned through an extensive statistical analysis of a random sample of 2,300 CERCLIS sites and all NPL sites. Data ranges from site ownership at time of contamination to wastes and management types present to impacted populations and environments. The results of the study will be used by the Agency for a variety of policy and resource issues, the most important of which will focus on the design of discovery strategies to be instituted next year.

INTRODUCTION

Under the Superfund program, three major categories of activities take place: (1) emergency or removal actions; (2) evaluation of sites for actual or potential releases, and (3) remediation of sites. In managing this sizable program, the U.S. EPA's general philosophy is to address the worst sites first.

Prior to determining if a site will be addressed under Superfund, the Agency:
- Discovers the site
- Determines its emergency status
- Assesses its potential for contaminating the environment
- Scores the site using the Hazard Ranking System (HRS)
- Proposes it to the National Priorities List (NPL) determines that there is No Further Remedial Action Planned (NFRAP)

Once the decision is made for a site to be addressed by the Federal Superfund Program, the following steps occur:
- Final listing on the NPL
- Comprehensive site evaluation and risk assessment
- Selection of cleanup methodologies
- Initiation of cleanup actions
- Final determination of cleanup

This paper will cover the progress to date of the U.S. EPA's Site Assessment Program.

SITE ASSESSMENT PROGRAM GOALS AND FRAMEWORK

The decision process for determining which sites are among the nation's most seriously contaminated, therefore warranting the expenditure of the Fund for long-term remediation, is managed by the U.S. EPA's Site Assessment Program. The program utilizes the talents of some 800 professionals through 46 State Multi-Site Cooperative Agreements, 10 Field Investigation Teams, 10 Regional Office staffs and a U.S. EPA Headquarters branch.

The U.S. EPA's goal for this program is to expeditiously identify the worst sites at each step of the evaluation process and move them to the next stage, ultimately to the NPL or to the decision that they will not be cleaned up by Superfund. This year marks a major transition time for the program. Publication of the revised HRS, finalization of all previously proposed NPL sites and the imminent completion of site inspections at all sites under consideration, prior to the passage of the Superfund Amendments and Reauthorization Act (SARA) of 1986, have brought the site assessment program to a natural opportunity for evolution and change.

Sites are identified for evaluation through a wide variety of mechanisms, including such diverse sources as formal notification requirements and citizens' telephone calls. After the Agency is notified of a possible release, the site is entered into the Comprehensive Emergency Response, Compensation and Liability Information System (CERCLIS), Superfund's computerized data base that contains information on potential hazardous waste sites as well as information on Superfund removal, remedial, and enforcement activities. With entry into CERCLIS, the site begins an evaluation process that consists of:
- A Preliminary Assessment (PA). The PA acts as an initial screening of the site in which all available data - past industrial activity, permit history, location of drinking water wells/intakes, surface water bodies, sensitive environments, etc. is collected and

reviewed so that the U.S.EPA can decide if the site poses a potential hazard to public health or the environment.

- **If warranted by the PA, a Site Inspection (SI).** The SI involves on-site work that usually includes collection and analysis of suspected impacted soil, surface water, groundwater and air samples, as well as wastes, if feasible. In serious cases where listing is considered likely, wells may be dug and extensive historic aerial photography analyses, as well as more extensive investigation activities, may be conducted, as well as other, more extensive investigation activities.

- **If warranted by the SI, an HRS scoring.** The HRS is the evaluation framework for the entire site assessment program, and all sites are assessed with the key factors of the model as a template. The model is not a risk assessment, but serves to give relative indications of risk posed by individual sites to surface and groundwater, air and, under the revised version of the model, soil. Informal scores are generated throughout the process; formal scores are generated prior to proposal to the NPL.

SITE ASSESSMENT PROGRAM IN 1986

In October 1986, when SARA was signed by the President, the Site Assessment universe consisted of approximately 25,000 sites (Figure 1). The Agency had:

- Completed PAs on more than 19,800 of the sites in CERCLIS
- Conducted SIs on approximately 6,500 sites
- Made decisions on about 6,000 sites; 5,100 had received a NFRAP decision, 703 were on the final NPL, and another 185 were proposed
- A backlog of about 4,400 sites that had not received any evaluation, with another approximately 12,400 sites that had had a PA, but no SI or NFRAP decision

	1980	1981	1982	1983	1984	1985	1986	1987	1988	1989
Sites in CERCLIS	8,000	10,500	13,366	16,309	18,864	22,621	25,194	27,571	30,013	31,904

NOTE: The graph represents the number of PAs and SIs completed during each fiscal year, and depicts the increase in the number of sites in the CERCLIS inventory as of the end of each fiscal year.

Figure 1
Historical Pre-Remedial Accomplishments
by Fiscal Year

MAJOR SARA REQUIREMENTS AND MESSAGES - OCTOBER 1986

Four major SARA requirements directly impacted the Site Assessment Program: (1) all pre-SARA PAs were to be completed by January 1, 1988; (2) all necessary pre-SARA SIs were to be completed by January 1, 1989; (3) the site assessment process was to be redesigned so that sites would have an NPL decision in no more than 4 years from the time they were entered in CERCLIS, and (4) the Agency was to revise the HRS to give higher priority to actually contaminated drinking water supplies; assess hazards to surface water used for recreation or drinking; assess food chain impacts;

assess potential air contamination, and give special considerations to fly ash wastes.

These Congressional requirements were sending the Superfund program two specific messages for the operation of its site assessment activities: (1) Get rid of the backlog and speed up the process of finding "worst sites", and (2) Make the HRS more comprehensive in addressing a variety of hazardous waste release problems, and more accurate in assessing relative risk (without making it a risk assessment).

SARA SITE ASSESSMENT IMPLEMENTATION PLAN

In order to comply with the SARA message to clean up the backlog of sites and speed up the evaluation process, the Site Assessment Branch, in the Hazardous Site Evaluation Division, developed a 5-year implementation plan. The goal of this plan was to implement basic programmatic changes that would escalate the rate at which decisions were made regarding the disposition of sites, while simultaneously expanding the HRS through the normal Agency rulemaking procedures.

In summary, the plan created the following schedule:

- **FY 1987:** Define problems for all parts of the program; achieve the PA goal for all pre-SARA sites; obtain Science Advisory Board approval of the revised HRS approach
- **FY 1988:** Reassess all PAs that did not have decisions; institute a policy of completing all PAs within 1 year of CERCLIS entry; propose the revised HRS
- **FY 1989:** Work at addressing the SI goal; reassess all SIs that were without decisions; complete public comment, issue analysis for revised HRS
- **FY 1990:** Achieve the SI goal; publish the revised HRS as a final rule; conduct training for all participants
- **FY 1991:** Achieve full-scale revised HRS implementation; institute 4-year, CERCLIS entry to NPL listing process

In order to have any chance of achieving this ambitious undertaking, U.S. EPA Headquarters realized that coordination, consultation and overall communication with the 10 Regional offices involved with the program would have to be substantially improved. The Regions needed Headquarters guidance to carry out a nationally consistent program; Headquarters needed Regional guidance to create a process that would work in the real world. To a very substantial degree, this partnership has produced the results outlined below.

SITE ASSESSMENT PROGRAM ACCOMPLISHMENTS

Clearing out the Backlog

As of September 21, 1990, CERCLIS contained 32,755 sites (Figure 2). To date, 93% of those sites have been evaluated through the PA stage. Because all sites now receive PAs within 1 year of CERCLIS entry, there is no backlog at this crucial first step. SIs have been conducted at almost 12,800 sites; Regions 6 and 10 met the actual SARA SI goal date of January 1989. All other Regions have made substantial progress at this difficult job over the last 4 years. Regions 3, 7, 8 and 9 are within a few sites of finishing. The Regions with large backlogs (1, 2, 4 and 5), expect to take another year. As Regions finish their pre-SARA SI work, their focus moves to determining which of the remaining sites need to be placed on the NPL and to instituting discovery projects to determine if all sites have been found.

It is expected that, by the time of publication of this paper, no sites will remain proposed on the NPL (at writing, 20 sites out of 1207 remained proposed). Since SARA passage, almost 400 sites have been proposed in 6 rulemakings, and 500 sites have been finalized or dropped for technical or policy reasons in 8 rulemakings. In FY90 alone, five final rules were published, as many as had been published in the previous nine years of the program combined.

Promulgating the Revised HRS

In response to SARA, the Agency undertook a comprehensive review and analysis of ways to improve the HRS. The paper "Overview of the Revised Hazard Ranking System" discusses the differences between the original and revised HRS. While the factors have undergone wholesale revision, the structure of the model has largely been retained. The revised HRS is more flexible than the original HRS in that it can address a broader range of problem types and can accept a wider variety of types of data.

NEW PROGRAM FACETS

At the same time, spurred on by the concept of Total Quality Management (TQM), the Site Assessment Program has begun to look at ways to improve the technical decision-making process and reduce the time-consuming facets of actually placing sites on the NPL. In the past, the decision on whether a site should continue on for HRS scoring or receive a NFRAP decision may have been delayed for some time after the completion of each evaluation step.

Currently, the thrust of the program is to improve both the quality and timeliness of all steps within the site assessment process. Our paper on TQM improvements, entitled "Total Quality Management in the Site Assessment Program", outlines many of the problems that our studies have identified and some of the approaches that are being tried to address them.

The PA has been tripled in scope to include numerous factors that had formerly been acquired in the SI, such as the identification of human and environmental targets, and establishes potential pathways of concern. New PA guidance, based on the most important factors of the revised HRS, will provide the Regions, States and contractors with a standardized and effective approach for conducting PAs, and continue to include the requirement for a site reconnaissance. This approach will continue to result in more efficient screening decisions earlier in the process, more site information available to conduct any subsequent SI and contribute to an overall streamlining of the decision-making process.

Standard operating guidance is being developed, and training packages to guarantee rapid and consistent application of the revised HRS will be published. The computer will play a large role in increasing the efficiency of the program. The HRS is being automated. The HRS has numerous technical factors which must be taken into account when developing the data collection plan. The Site Assessment Program has developed the "PreScore" computer program which performs the calculations required by the HRS. This allows quick sensitivity analysis to focus SI sampling on the most important HRS factors, resulting in more nationally consistent, focused, and better-quality decisions. In another of today's papers, the PreScore program for keeping site records, postulating scoring scenarios, and calculating scores will be explained, along with the recently completed Chemical Database program that will automatically supply all HRS factor data for 330 chemicals to PreScore.

CONCLUSION

The Agency believes that the expressed will of Congress to have Superfund carry out high quality, comprehensive, but expeditious, site assessment is an ambitious, but achievable, goal. Since SARA articulated this goal, the Agency has devoted substantial resources, both monetary and human, to achieving it. We expect that the next few years will be challenging and difficult, but in the end, successful.

Automation of Revised Hazard Ranking System Scoring

ABSTRACT

The Hazard Ranking System (HRS) has been revised to reflect the requirements of the Superfund Amendments and Reauthorization Act of 1986 (SARA), to address public comments on the HRS and to improve the overall Superfund process. These changes increased both the number of calculations needed to score sites, and the requirements for chemical data to support site specific scoring. This paper describes three "user-friendly" computer programs that can aid in scoring sites using the revised HRS:
- PreScore, a program to calculate revised HRS scores from "raw" data supplied by the user
- Superfund Chemical Data Matrix (SCDM), a source of chemical data to support the revised HRS, as well as other environmental assessments
- Chemical Scoring Matrix (CSM), a module within SCDM, to output revised HRS chemical factor values to PreScore

The purpose and design of the computer program, as well as the process for compilation of chemical data, are also described in this paper.

INTRODUCTION

The U.S. Environmental Protection Agency (EPA) recently revised the HRS to reflect the requirements of the Superfund Amendments and Reauthorization Act of 1986 (SARA), to address public comments received after proposal of the revised HRS and to improve linkages in the Superfund process between site assessment and remedial activities. Under the original HRS, calculations were performed using pocket calculators and were generally a paper exercise. With the revised HRS, it was necessary to develop an automated system to assist users in performing HRS calculations. Similarly, few chemical-specific data were required with the original HRS. The revised HRS uses substantially more chemical data. Public comment on the proposed revised HRS recommended that the U.S. EPA adopt a single source of chemical data in order to implement the model consistently. The Agency agreed that compilation of a single source of chemical data was needed to ensure consistency and improve site scoring efficiency.

The proposed revised HRS was field tested. The field test results reported that significant scoring errors, generally computational in nature, could result. These scoring errors confirmed the need for a standard, automated form of HRS scoring. The U.S. EPA anticipates that proper use of PreScore, the SCDM and the CSM by the large user community of States and contractors will significantly decrease or eliminate the vast majority of computational errors.

PRESCORE OBJECTIVES/USER NEEDS

The Site Assessment program objectives for PreScore were:
- Reduce the time involved in calculating scores
- Increase consistency of supporting information used in scoring

PreScore meets these objectives. The field test results showed that PreScore can calculate a score in half the time it takes a site reviewer using a pocket calculator, thus reducing the time needed to document supporting information. The use of PreScore is also expected to greatly enhance the consistency with which sites are evaluated and users will be able to immediately document data within the program itself. The program found that PreScore filled yet another regional need. It allowed users to improve the quality of decision-making by allowing the testing of multiple scoring scenarios easily and quickly and made more efficient sampling decisions based on the expected contribution of data to overall scores.

PreScore users can test how assumed (or judgment) values will affect a pathway or overall score. A specific factor's contribution to the overall score can be tested with PreScore prior to planning what data will be gathered at the site inspection phase. If certain data will not contribute significantly to the overall score, site investigators will not pursue those data as part of the sampling effort.

PROGRAM SPECIFICATIONS

Considering the varying computer equipment in the Regional, State and Field Investigation Team (FIT) offices involved in the Site Assessment process, the U.S. EPA decided to develop a system that would meet the following specifications in order to account for the equipment differences:
- IBM PC, PC-XT, PC-AT, PS/2, or compatible
- One 5.25 inch or 3.5 inch double sided disk drive (double or high density)
- Parallel or serial printer (necessary for output functions)

In addition, the C language was chosen as the program language for three primary reasons:
- Speed - C produces a "fast" program for this application
- Efficient memory use - C allows PreScore to run on computers with as little as 384 KB of RAM
- Small size - C produces a compact code, allowing PreScore to be installed on hard disks with limited free space

OPERATION

PreScore uses an innovative menu-driven approach to allow users to enter data quickly and efficiently in any sequence. A hierarchy of menu screens accessed through a Summary Screen (Figure 1) reveals progressively greater detail on a selected HRS factor, showing intermediate scores and the raw data on which the overall score is based. The Summary Screen depicts the four HRS pathways vertically on the left portion of the screen, while the three factor categories are displayed horizontally across the top of the page. Cursor keys (left, right, up, down) are used to move around the screens and access different factor categories. The 'Status line' at the bottom appears on each screen and displays key-stroke options available to the user. The F8 key, for instance, accesses the file system, which enables the user to create, select, save, delete or copy PreScore data files in any directory or drive (Figure 2). Another important feature displayed on all factor screens is a constant display of the current site score. PreScore uses a combination of spreadsheet-like forms for easy data entry.

Figure 2
PreScore File System Screen

The Summary Screen is the 'main menu' for PreScore. Each progressive level of screen information gives greater detail regarding a particular factor. In Figure 3, for example, the 'Location Line' near the top indicates this particular screen is in the Air Pathway, in the Targets factor category and asks for population information in the distance rings the HRS requires to document potentially-affected population.

This screen also exhibits a valuable property of PreScore: the ability to accept raw data values to calculate scores. Without this property, users would need to calculate these HRS factor values using a pocket calculator and then input this information into the program. PreScore simplifies HRS scoring by taking the raw data (e.g., population figures) and performing the appropriate factor

calculation internally. In the 'Status line' at the bottom, the F10 key is a Help function that provides basic information about each factor including the applicable section number of the HRS (Figure 4).

Population data (bottom screen) are accessed by cursoring to the population factor value (top screen) and pressing <ENTER>.

AIR PATHWAY -> POPULATION   Section 2.3.2

The population factor value reflects the population actually or potentially exposed to air emissions from the site. For each of the distance categories listed, determine the number of people within that distance category. The distance for an individual is measured as the shortest distance from any on-site emission source to the place at which the individual is located (e.g., place of residence or work. The population count should include persons residing within the distance categories specified as well as others who would regularly be present, such as students and workers. Exclude transient populations such as customers and travelers passing through the area in autos, buses, or trains.

Use exact population counts where possible. If actual residential population figures are not available, the population for a distance category should be estimated by determining the number of residences located within the distance category and multiplying each residence by the most recent U.S. Census factor for number of persons per residence for the county in which the residence is located.

Figure 4
Example of PreScore Help Screen

An important function of the program is a "built-in" Documentation Record which allows the user to type in the reasoning for scoring a factor in a certain way. Additionally, a Print function is available to print both scoresheets and the text of the documentation. One other feature to ease user interaction is pop-up windows that allow selection of different sources (e.g., landfills, surface impoundments) and selection of various concentration units for chemical information.

CHEMICAL DATA COMPILATION--PURPOSE AND OUTPUTS

The chemical information the U.S. EPA is compiling provides consistent sources of chemical information to support implementation of the revised HRS. The Superfund Chemical Data Matrix

(SCDM) and the HRS Chemical Scoring Matrix (CSM) are the two distinct modules that contain this chemical specific information.

The CSM is designed to support PreScore. The SCDM compilation includes all the information compiled in CSM and much of the information from which the factor values in CSM are derived. Moreover, SCDM is packaged with a "user-friendly front-end" to aid users in extracting combinations of chemicals or chemical parameters. SCDM contains a module to output an ASCII file of revised HRS chemical factor values to be used by PreScore.

The U.S. EPA will also provide a user's guide to support these two compilations. At this time, data for about 300 chemicals have been compiled. Additional chemicals, as well as new data and revisions for chemicals, are expected to be added. Both CSM and SCDM are to be updated on a regular basis.

The development of both the CSM and SCDM modules has been coordinated with the development team of PreScore. The SCDM module includes a "user-friendly front-end" that has been constructed using Turbo-C, which facilitates use on an IBM-PC without any additional software. Because the CSM is derived from SCDM, the two modules will be consistent in terms of data. Whenever possible, function keys have been identified so that they would reflect similar functions in the PreScore and SCDM programs. The SCDM contains options for including "flag" markers to indicate changes in chemical values, sources or other fields, and a "notes" field to facilitate documentation of sources.

SELECTION OF CHEMICALS

The chemicals compiled to date, shown in Table 1, represent both the most likely substances found at Superfund sites, and chemicals known to be toxic to human health and the environment. This list was developed hierarchically using three sources.[1][2][3] Several additional sources were also reviewed to aid in selecting chemicals.[4][5][6]

Zinc phosphide	1314-84-7
Zinc sulfate	7733-02-0

These additional sources are commonly used by Superfund Regional field personnel to identify and classify hazardous wastes. While most of these substances appear on the CERCLA Reportable Quantities list, they are not found in the Integrated Risk Information System (IRIS). Furthermore, the next set of chemicals to be evaluated includes radionuclides that are currently included in the Health Effects Assessment Summary Tables (HEAST).[7]

Chemical Parameters

Chemical parameters were added to both the CSM and the SCDM modules to reflect the increasing data needs incorporated into the revised HRS and in health issues applications.

A list of chemical parameters and their sources is provided in Table 2. Examples of the HRS chemical parameters include water solubility and bioconcentration factors. Other chemical parameters

to assist with health issues applications include cancer potency, RfD (inhalation and oral) and LD50.

SUMMARY

Introduction of these automated components will aid in the implementation of the revised HRS in the site assessment process. This process is expected to facilitate Superfund's evaluation of the thousands of sites that must be considered yearly for possible inclusion on the National Priorities List (NPL).

ACKNOWLEDGEMENTS

The authors would like to acknowledge the valuable contributions and direction of Paul Beam to the early stages of PreScore development. Also, a special note of thanks is extended to Jan A. van der Eijk of NUS for his efforts in programming PreScore.

Providing Technical Assistance Under the U.S. EPA's TAG Program

ABSTRACT

SARA enabled the U.S. EPA to give technical assistance grants to citizens' groups representing populations affected by Superfund sites in their communities. This money is to be used to hire advisors to assist the citizens in understanding the technical details of site investigations and remedial actions and to help them articulate their concerns to the U.S. EPA.

One of the first grants was awarded to the Old Forge Toxic Waste Removal Committee, which represents the community in the vicinity of Pennsylvania's Lackawanna Refuse Site, a series of abandoned coal mine pits used for industrial and municipal waste disposal. A subsequent grant was obtained by the Greater New Bedford Environmental Community Work Group, neighbors of the New Bedford Harbor Superfund site in Massachusetts, an estuary and bay extensively contaminated with PCBs and heavy metals. Acknowledgement of the social, economic and emotional impacts associated with a Superfund site and addressing them in the decision-making process, is an acute challenge for today's environmental professional and an essential ingredient for a successful remedial action. The U.S. EPA's grant program is a step in that direction. Serving as technical advisor to citizens' groups provides an opportunity for environmental scientists and engineers to broaden their horizons and gain an appreciation for a different perspective on environmental issues.

INTRODUCTION

SARA provides Technical Assistance Grants (TAGs) up to $50,000 to citizens' groups to assist them in understanding the activities associated with cleaning up contamination at Superfund sites in affected communities. The U.S. EPA issued an Interim Final Rule on March 24, 1988 establishing the initial policies and procedures governing the TAG program. Additionally, Volume 40 of the *Code of Federal Regulations* (CFR) Subchapter B—"Grants and Other Federal Assistance", including 40 CFR Parts 30, 33 and 35, contains regulations applicable to the TAG program.

The U.S. EPA's Management Review of the Superfund Program, issued shortly after William Reilly was approved as its new Administrator, found that "The TAG program is not working well...Citizens are deterred from using TAGs...[and]...U.S. EPA financial managers are wary of potential risks..." When that report was published, only nineteen TAG grants had been awarded and advisors had been hired at just a fraction of those sites. The TAG program was criticized as having too much red tape and excessive matching-funds requirements. Recently, the U.S. EPA has moved to make the TAGs more accessible, and additional grants have been awarded and advisors hired.

The U.S. EPA is authorized to award grants to "...any group of individuals which may be affected by a release or threatened release at any facility which is listed on the National Priorities List..." Groups threatened by a site proposed for listing on the NPL where a response action has begun also are eligible. Some citizen groups chartered by government entities may be ineligible, as are PRPs, academic institutions, political subdivisions and corporations not incorporated for the specific purpose of representing affected individuals at the site. Once the U.S. EPA determines that a group is eligible for a TAG, the group's ability to manage a grant must be demonstrated, generally by establishing recordkeeping and financial management procedures. The group must be incorporated, or have plans to incorporate as a nonprofit organization for the purpose of representing affected individuals.

TAG funds may be used to pay technical advisors to review and interpret documents, meet with citizens' groups to explain technical information, assist in communicating the group's concerns, disseminate information to the community and perform site visits. Funds may not be used to prepare for or participate in any legal proceeding, to generate new data, to challenge final U.S. EPA decisions or for any political activity. The U.S. EPA initially required the citizens' group to contribute 35% of the total project cost, with administrative costs not to exceed 15% of the total cost. The 15% cap has been removed and in-kind services may now be used to meet the total matching funds requirements.

The TAG process consists of: (1) submission of an application for the grant to the U.S. EPA; (2) selection of procurement method if awarded (i.e., small-purchase method for grants up to $25,000 or competitive negotiation for more than $25,000; (3) selection of a technical advisor; and (4) development, approval by the U.S. EPA and ratification of a subagreement between the citizens' group and the technical advisor.

The technical advisor's role is to help the citizens in affected communities make significant contributions to the decision-making process of Superfund. The advisor's role involves interpretation of technical details so that nonscientists can understand the complex issues associated with site activities; the advisor also assists the citizens in articulating their concerns, fears and frustrations to scientists and engineers not accustomed to considering nontechnical factors in their evaluations. Activities performed on the TAG projects have included: review of site characterization data and feasibility study reports; site inspections; preparations of reports; attendance and participation at technical meetings with the U.S. EPA, responsible parties and their contractors; and presentations at public meetings. The advisor often acts as a mediator or facilitator in meetings and interpersonal communication and relation skills, as well as technical ability, are essential in these situations.

In the following pages, two case histories of TAG projects are presented and some highlights of this work are discussed.

CASE HISTORY I—LACKAWANNA REFUSE SITE, PENNSYLVANIA

According to the U.S. EPA's remedial investigation and subsequent studies, three former coal stripping cuts were used for waste disposal at the Lackawanna Refuse Site. One of these, known as Pit 5, contained numerous drums of hazardous waste. Additionally, three other features, known as the Paint Spill Area, the Access Road and the Borehole Pit, were found to contain surficial contamination which required remediation.

The proposed remediation process for the two coal stripping pits not containing hazardous waste (Pits 2 and 3) entailed construction of a cap, leachate collection and treatment systems and a gas venting system. Contaminated soil from the Paint Spill Area, the Access Road and the Borehole Pit would be removed for off-site disposal. All drums and wastes would be excavated from Pit 5. Uncontaminated material [i.e., material containing concentrations of key indicator compounds (KICs) below established threshold levels] would be used to backfill the pit, with contaminated material disposed off-site. A cap, leachate collection and treatment systems and gas vents would be installed at Pit 5. A groundwater monitoring system would be installed following remediation.

Mobilization of the remedial action contractors, establishing site facilities and the associated vehicular traffic represented a highly unusual situation for the small community. Moreover, the perceived threat of a release of hazardous or toxic contaminants into the air as a result of excavation activities was of great concern to nearby residents and to the community in general due to the relatively close proximity of a school.

A consulting firm had extensive involvement with the Lackawanna project working for the citizens' group prior to the TAG program. Beginning in 1985, a number of documents pertaining to the design, conduct and safety of the remedial action and the plans for post-closure care of the site were reviewed by the consultants at the request of the Old Forge Toxic Waste Removal Committee (Committee). The group used a variety of fundraising activities to pay for this work; however, such technical assistance is relatively expensive and funds were limited. Nevertheless, privately funded technical support of the citizens' group continued through the 90%-design phase of the remedial action project.

Remedial activities began in 1987 with cleanup of the Access Road, Paint Spill Area and Borehole Pit and the construction of haul roads to Pit 5. Excavation of wastes from Pit 5 and regrading of Pits 2 and 3 in preparation of cap placement commenced in 1988. In September 1988, at the Committee's expense, the consultant performed a site inspection, reviewed data and met with the U.S. EPA and Committee representatives concerning the status of the remedial action project. At last, in 1988 the Committee's efforts resulted in the award of one of the first $50,000 TAGs. Because of its previous involvement in the project, the Committee wanted to retain the consultant as technical advisor after the TAG was obtained. The small purchase procurement method was used to award a $24,000 one-year contract for Phase I technical assistance. The consultant then assisted the Committee in its efforts to help the local citizens understand the technical issues concerning remediation of the Lackawanna Refuse Site using U.S. EPA funds.

Numerous site inspections were performed and the advisor prepared written trip reports documenting the status of the remedial action with photographs noting the progress made in resolving outstanding items of concern to the community. Construction, waste excavation and removal activities were observed and results of waste analyses and post-excavation (i.e., after cleanup) soil sampling obtained during the inspections were reviewed for consistency with the remedial design. The Committee was kept informed on the progress of the remedial activities in a series of technical briefings.

At the end of the Phase I contract, the Committee solicited proposals from a number of prospective firms and chose the incumbent consultants to continue as their technical advisor. A fact sheet was prepared and distributed to the community as the technical advisor presented a slide show at a public meeting in Old Forge near the end of removal opera-

tions to show the progress made in cleaning up the site. Additionally, the advisor assisted the U.S. EPA's consultant with a magnetometer survey to investigate for additional buried drums; reviewed the post-closure groundwater monitoring system installed at the site; evaluated leachate and gas emission data; and continued to interpret technical details and to help the Committee articulate its concerns in several meetings with the U.S. EPA. All work was documented in quarterly progress reports to the Committee.

CASE STUDY II—NEW BEDFORD HARBOR

On June 6, 1989, the consultant entered into an agreement with the Greater New Bedford Environmental Community Work Group (Work Group) to provide technical assistance for the New Bedford Harbor Superfund site remedial action under the TAG program. The Work Group had issued a Request for Proposal (RFP) seeking interested parties for providing technical assistance after receiving a $50,000 TAG. The consultant had tracked this potential new business opportunity in a typical fashion, submitting a qualifications package to the Work Group, proposing a scope of work and cost estimate, traveling to the community to meet with the potential clients and finally winning the job after making a "best and final" offer.

New Bedford Harbor is an urban tidal estuary located at the head of Buzzards Bay in southeastern Massachusetts, approximately 55 miles south of Boston. The communities of New Bedford, Fairhaven, North Dartmouth and Acushnet border the harbor which is home port to one of the largest commercial fishing fleets in the United States. From the 1940s until the late 1970s, when use of PCBs was banned in the United States, factories along the Acushnet River discharged industrial process wastes containing PCBs into the harbor. In 1976, the U.S. EPA conducted a New England-wide PCB survey which included New Bedford Harbor. During the next five years, field studies conducted by the U.S. EPA and the Commonwealth of Massachusetts identified PCBs and heavy metals, notably cadmium, lead, copper and chromium, in the sediments and marine life throughout a 1,000-acre area of New Bedford Harbor and parts of Buzzards Bay. In 1977, testing of edible fish tissue samples revealed PCB levels in excess of the U.S. Food and Drug Administration's 5 ppm guideline (subsequently reduced to 2 ppm). As a result, the Massachusetts Department of Public Health restricted fishing by establishing fishing closure areas in New Bedford Harbor and Buzzards Bay.

The U.S. EPA estimates that the Hot Spot area (a five-acre portion of the estuary) contains approximately 10,000 yd^3 of contaminated sediment with PCB concentrations ranging from 4,000 ppm to over 100,000 ppm and heavy metal concentrations ranging from below detection to approximately 4,000 ppm.

In 1988, an Engineering Feasibility Study (EFS) being performed by the U.S. Army Corps of Engineers was expanded to include a Pilot Study at the site, allowing the Corps to conduct physical demonstrations of dredging equipment and construction and testing of disposal facilities in the estuary, while continuing to carry out site sampling, analysis and research. The Pilot Study took place in a cove in the upper estuary and involved the removal and disposal of approximately 15,000 yd^3 of sediments, including approximately 7,500 yd^3 of PCB-contaminated sediments. The shoreline disposal facility, called a Confined Disposal Facility (CDF), was used to contain 5,000 yd^3 of contaminated sediment dredged from the cove. An underwater disposal facility, known as a Confined Aquatic Disposal (CAD) cell, was constructed using the hole created when sediments were dredged for placement in the CDF. The CAD was partially filled with the remaining 2,500 yd^3 of contaminated sediments dredged from the cove and then capped with a clean layer of sediment excavated from below the level of contamination.

In May, 1989, the U.S. EPA made available to the Work Group a draft Hot Spot Feasibility Study report which presented the range of remedial alternatives considered for the Hot Spot area. The Draft Final Hot Spot Feasibility Study report was published in July 1989. Having the technical advisor under contract as these complex documents were released enabled the community to obtain a clear understanding of the remedial

alternatives and the significance of underlying assessments and evaluations made by the U.S. EPA and its contractors. The technical advisor reviewed all previous studies and reports, including the Public Health Risk Assessment, EFS reports and the Hot Spot FS report. This independent analysis helped the concerned citizens gain confidence in the U.S. EPA's risk assessment, although some technical flaws and questionable assumptions were brought to their attention.

The advisor assisted the citizens in articulating some of their concerns regarding cleanup of metals in the sediments, potential hazardous air emissions from incineration, the presence of heavy metals in residual ash, long-term stability of ash after chemical fixation and the potential for future environmental degradation and health effects from disposal of residuals in the unlined CDF. Some of these concerns were initially based on emotions and fueled by misrepresentation by interest groups or the media. The advisor's experience with these issues, however, enabled the concerns to be put forth on a technical basis.

The U.S. EPA held a public meeting at which time the proposed plan for cleaning up the Hot Spot was presented. The technical advisor accompanied members of the Work Group to the meeting and discussed the plan with the U.S. EPA and state agency representatives. The preferred alternative consists of removal of approximately 10,000 yd^3 of sediment by dredging, incineration of the dredged sediments in an on-site, mobile incinerator to destroy PCBs, possibly treating the incinerator residue to reduce the mobility of heavy metals and temporary storage of the treated sediments in the existing CDF used in the Pilot Study. This cleanup is estimated to cost approximately $14.4 million and would take approximately one year to complete.

Another meeting was held later to allow AVX, essentially the only responsible party, to discuss a plan for in-place containment of the sediments by capping the estuary from the Coggeshall Bridge upstream. The advisor was present at this meeting and interviewed the consultants for AVX in an effort to better understand their proposal. This involvement helped the Work Group to offer cogent comments into the public record concerning the U.S. EPA's and AVX's plans for remediation of the Hot Spot.

ENHANCING SUPERFUND

Based on the authors' experiences in working on these two TAG projects, providing groups of responsible and concerned citizens with financial assistance to retain technical advisors has enhanced greatly the Superfund program. First, the community gains an understanding of many technical details that were very mysterious before the advisor interpreted them in a context that could be understood by nonscientists. Many nonscientists, no doubt, do not grasp easily the significance of a risk of 3.17 E-7. Explaining what this means can ease the level of anxiety in a Superfund community; people generally are less fearful of things they understand. Moreover, a measure of trust appears when the citizens' advisor enters the picture. The public often feels they are given the "runaround" and many grow suspicious when faced with the complexities and procedures institutionalized in Superfund. The advisor must represent a readily available and unbiased source of information—someone not considered to have a "hidden agenda" for forcing a remedial action onto the community. These factors help bring the citizens on board as part of the solution and help keep them from becoming the opposition. The following anecdotes illustrate these benefits.

The citizens of Old Forge were able to learn from an impartial eyewitness of the progress made in removing hazardous waste from their community. In one instance, their advisor helped negotiate additional investigations to locate buried drums after some drums had been encountered in an area previously thought uncontaminated. The advisor was on-site during the subsequent magnetometer survey, thereby ensuring that the citizens would be comfortable with the U.S. EPA's

reported results. In another instance, the citizens were concerned that the cleanup was leaving unacceptable levels of PCBs in residual soils at the base of Pit 5. The technical advisor helped the citizens understand applicable PCB cleanup criteria, the negligible risk associated with deeply buried low-level PCB contamination and the impracticality of additional removal. Once, photographs of the newly constructed cap were offered by a disgruntled site worker, along with allegations of improper construction practices and escape of hazardous leachate from Pit 5. The advisor was consulted and his knowledge of the status of work at the site, based on a recent site visit, helped reassure the citizens.

On the New Bedford project, one area of concern to the community was the planned disposal of residual ash from incineration of Hot Spot sediments in the proposed unlined disposal cell along the shore. The feasibility studies had noted that the high concentration of metals in the ash may require chemical fixation to immobilize the metals. One of the treatability tests conducted on the sediments, however, enhanced the mobility of certain metals. The community was confused about the potential for future contamination if metals leached from the disposal cell. The advisor pointed out that Massachusetts regulations for solid waste disposal required liners and if residual ash contained metals at concentrations above hazardous waste criteria, it would have to disposed of in an appropriate manner.

During one public meeting in answering a question concerning PCB air emissions from incineration of Hot Spot sediments, a scientist referred to the incinerator's efficiency "six nines." This pronouncement resulted in many glazed-over eyes and expressions of bewilderment in the audience. The technical advisor later interpreted this to the non-scientists so that they grasped the level of destruction of the incineration process. Many individuals were concerned with dioxin and lead in emissions from incineration as well. The advisor helped the citizens understand the nature of these emissions and the technologies available to scrub incineration by-products.

In these cases, advice from the citizens' own consultant was accepted more comfortably than from the U.S. EPA. Furthermore, the advisor could be directed to perform evaluations that centered on the communities' concerns which may not have been provided by the U.S. EPA. For example, the Old Forge community was concerned about the potential release of hazardous vapors and the risk of fire or explosion from the gas vents installed through the cap at the site. The advisor commissioned a study of landfill gas emissions by a firm that specializes in landfill work. In this manner, the concerned citizens were provided with an evaluation of the quality of emissions from the Lackawanna site, a comparison of those emissions with other typical gases from municipal landfills and hazardous waste sites and an identification of applicable monitoring and pollution control regulations.

A similar study was performed by the advisor regarding the quality of leachate generated at the site. He illustrated that Lackawanna leachate was generally less contaminated than leachate from hazardous waste sites and in some cases it was more dilute than sanitary sewage. The results of this effort were taken into consideration as the community and the U.S. EPA agreed to disagree on leachate management options (i.e., construction of an on-site treatment plant or discharge through municipal sewer to the local POTW).

Regardless of whether or not communities have the financial ability to engage their own technical advisors to assist them on Superfund matters, uncertainty and apprehension will be a factor in the government's efforts to remediate hazardous waste sites. In fact, our experience has shown that even when expert technical advice is offered, emotional arguments can prevail. The technical advisor, however, can help close the gap between the risk perceived by the community and that actually presented by a Superfund site. Serving as community technical advisor offers today's environmental scientist or engineer the opportunity to expand one's horizons while helping society deal with the complex emotions associated with environmental issues.

The Pros and Cons of PRP Involvement in Superfund Community Relations

Ray Germann
Environmental Resources Management, Inc.
Exton, Pennsylvania

ABSTRACT

Dealing with the public is a frightening prospect for most companies. Many would rather ignore the public—and hope it goes away. It never does; at least not until after you are out of business. This paper examines Superfund Community Relations from the perspective of a company involved in a Superfund action. It discusses some benefits and pitfalls companies face and details some strategies to increase their chance for success.

The number of "enforcement-led" Superfund sites has grown far more quickly in recent years than the number of "government-led" sites. So-called PRPs have assumed an increasing role in financing studies and cleanups. However, PRPs have not taken as much initiative in the implementation of the accompanying community relations activities required by law. In most cases, the U.S. EPA or the state performs most or all community relations.

It is generally recognized that remedy selection should be interactive. All affected parties (federal, state and local governments, residents, environmental groups, PRPs, etc.) are encouraged to voice their viewpoints and concerns so that a consensus can be reached.

When PRPs communicate only with regulators and not with other affected parties, their influence over remedy selection is severely limited. Under the Superfund law, PRPs have no more influence over remedy selection than other affected parties—even at enforcement-led sites. Despite their expertise, they can become just one of many voices trying to influence remedy selection. However, if PRPs share their expertise and viewpoints directly with other affected parties (as well as the U.S. EPA and the state) they can increase their influence over remedy selection. This process can result in an environmentally sound, economically practical, privately funded and timely cleanup. Of course no amount of communication can force acceptance of a remedy that is patently inadequate.

There are obstacles to overcome, such as the perception that PRPs are only interested in cutting costs or the potential for negative publicity. However, if handled properly, PRP involvement in community relations can be valuable in selecting appropriate remedies at Superfund sites.

INTRODUCTION

Financial liabilities related to site remediation projects are becoming one of the biggest worries facing corporate America today. For most large manufacturers, there is no way to accurately predict how many sites a company will be involved with or the extent of their liabilities.

For companies involved in Superfund projects, how well they deal with the public almost invariably has a substantial impact on the cost of the project. The U.S. EPA chooses a remedy for each site based on factors such as protection of human health and the environment, compliance with applicable laws, long-term effectiveness, permanence and public opinion. It is a political reality that public opinion is often given much greater weight than is indicated in the regulations.

In Superfund, dealing with the public consistently and effectively can make the difference between paying $10 million and $100 million for a cleanup just as surely as a marketing strategy statement can make or break efforts to reach a sales goal.

This statement does not mean that every company involved in a Superfund cleanup must have a high public profile. In some cases, this clearly is not desirable. It also does not mean that PRP community relations efforts should always urge selection of the cheapest possible remedy. This tactic is impractical, unethical and bound to be counter-productive.

The goal of most companies involved in Superfund cleanups is to control overall costs while implementing an environmentally sound remedy. In fact, implementing the cheapest remedy may not be the best way to control costs. Issues such as third-party lawsuits, future costs to correct an inappropriate remedy and damage to public image may produce costs far in excess of the actual cleanup. Many issues that can produce additional cost are related to interaction with the public.

GOVERNMENT/PRP ROLES IN COMMUNITY RELATIONS

Superfund mandates detailed community relations planning and implementation. The purpose is to involve each affected community as an important part of the decision-making process—not simply to provide information on what the government or the company is doing at the site. Many Superfund cleanup plans have been changed as a direct result of community comments.

The new NCP, the blueprint for implementation of the Superfund law, places even greater emphasis on the role of the public.

According to U.S. EPA guidelines, the U.S. EPA or the state has the lead in all community relations activities at both government-led and enforcement-led Superfund sites. This requirement means regulators have primary responsibility for informing the public about site activity and for seeking public input on all aspects of the study and cleanup process.

Without going into too much detail on Superfund Community Relations requirements, key activities generally include:

- Community Relations Plan—Outlines plans and stratgegies for gathering and providing information
- Public meetings—Held at the Workplan and RI/FS completion stages
- Briefings—Informal meetings with community residents, local officials, news media and other interested parties
- Informational material—Fact sheets and brochures to summarize ongoing events and solicit comment
- Responsiveness summary—Describes comments received on the RI/FS and responses from regulators

While regulators claim primary responsibility for implementing community relations in Superfund, they also recognize that PRP involvement in community relations can be beneficial. From the perspective of the government and the public, it allows easier access to the study and cleanup process, especially at enforcement-led sites where PRPs are performing a study or cleanup work, they may be the best source for timely and accurate information on site activities. From the perspective of the affected companies, PRP involvement in community relations can promote an effective working relationship with the public and increase the chance for completion of a site study and cleanup with minimum opposition, intervention or delay.

Specific guidelines for PRP involvement in community relations are determined by the U.S. EPA Region (or state) involved —with the regulator in as overseer. Some regions are quite restrictive, while others encourage active interaction between companies and communities.

POTENTIAL BENEFITS TO COMPANIES

The core objective of any community relations efforts should be to establish and maintain an effective working relationship with affected groups and individuals. By initiating a community relations program in cooperation with regulators, a company can actively control its own destiny at a Superfund site rather than leave its destiny solely in the hands of regulators. Regulators will generally inform and involve the community as specified under the law. But, although regulators, companies and affected communities are all working toward an environmentally sound cleanup, a community relations effort implemented by the government alone is likely to lack certain aspects that can be very important to PRPs. Some of these aspects are discussed below.

Providing a True Picture of the PRP's Role in the Site

During its community relations efforts, the U.S. EPA will generally explain the Superfund process to the community quite thoroughly. But it is not a priority for the agency to explain how each PRP contributed to the problem, or their specific roles. By communicating directly with the public, a PRP can more clearly define its role in causing the problem and its involvement in the project. These issues may be important to the PRP—particularly if it has come forward voluntarily and assumed a role in cleanup of a site in which it had little actual involvement or where it was in compliance with current regulations when the contamination occurred. These people may be moot under SARA, but they can be very important in third-party lawsuits and maintaining the company's public image.

Virginia Fly Ash Site

At a Virginia fly ash site, corporate executives for a PRP assumed a visible role in the community relations process. They assumed financial responsibility for the cleanup, but took care to emphasize that they were operating within current regulations when the problems were created. The result was an ever-improving working relationship with a powerful environmental group involved in the project and more detailed media coverage of the company's actual role in the site. Ultimately, a cost-effective, privately financed, on-site containment remedy was chosen.

Opening Direct Channels of Communication Necessary to Complete Site Work

Particularly at enforcement-led sites, it is often necessary to deal with community residents in getting access to adjacent property, sampling residential wells and other activities. This can be cumbersome if all such activity has to be conducted through regulators. Regulators should be kept fully informed of any contact with community residents, but direct communication can be invaluable in keeping a sampling program, or other necessary activity, on schedule.

Pennsylvania Industrial Facility

At a Pennsylvania industrial facility, community relations contractors for the facility operator provided nearby residents with ongoing information on site activity, the Superfund process and the company's role in the problems and the solution. Information, closely coordinated with the Regional Office, was provided through mailings and in person. This groundwork helped simplify gathering more than 100 residential well samples necessary to the RI/FS.

Influencing Remedy Selection

When the U.S. EPA considers public comments on a proposed cleanup remedy, it can give comments from PRPs no greater weight than comments from the general public. By communicating directly with the public, PRPs can share their knowledge and expertise with the general public, which may influence comments. Especially if there is disagreement between the U.S. EPA and the PRPs over which cleanup remedy is most appropriate, PRPs can only ensure that their opinions are adequately expressed to the public by communicating directly with the affected community.

Pennsylvania PRP Group

A Pennsylvania PRP group had serious concerns about a U.S. EPA proposal for on-site treatment at a site they had formerly operated. The group expressed its concerns to the U.S. EPA, but also met with state and local officials and residents to explain the group's concerns. The results were a letter from local officials to the agency and other communication expressing concern over the proposed remedy. The agency decided to reexamine its preference for an on-site treatment alternative.

A secondary but potentially valuable benefit to PRP community relations activities is the broader benefits to corporate image that can be engendered by a credible and responsive community relations effort.

POTENTIAL PROBLEM AREAS

While there are few down sides to a well orchestrated community relations effort, there are some important issues to consider during planning and implementation.

Credibility

PRPs can have an even worse credibility gap in their dealings with affected communities than regulatory agencies. There may be a perception that, because they are the parties which caused the problem at the site, the PRPs cannot be trusted to implement an appropriate solution. Another common perception is that PRPs are not interested in the quality of the cleanup—only its price tag.

Reliability and accessibility are two of the most important ingredients in establishing and maintaining a credible relationship with any community. Since most Superfund sites are abandoned properties, it is unlikely that PRPs have an ongoing relationship with communities before becoming involved in study and cleanup plans. They also may be geographically distant from the site. These factors can aggravate credibility problems.

Overcoming these problems can be the most important step in establishing working relationships with an affected community, in

conducting an effective study and in ultimately choosing a cost-efficient remedy. It is essential that PRPs or their representatives make themselves readily available to the community beginning with their initial contacts. These contacts must be factual, objective, two-way exchanges. As most PRPs realize, it would be a poor business decision to cut costs by purposely working toward a remedy that is not environmentally sound. Discussing potential economic drawbacks to the company of implementing a cheap but environmentally unsound cleanup can help the community understand the company's rationales.

While it is important that the community understand the PRP's role in past and future site activity, discussions should focus on the best ways to find solutions to problems at the site. One sure way to lose credibility is to try to "sell" a remedy to a community.

Legal Issues

The effectiveness of relationships between a company's community relations professionals and its legal counsel can determine the success or failure of community relations efforts. Full disclosure of pertinent information can damage negotiations or other aspects of the company's legal position, but withholding pertinent information can severely limit a company's ability to communicate effectively with the affected community. A balance between the two cannot be reached if lawyers and communicators cannot find common ground on which to base a community relations strategy.

Community relations during enforcement actions should be conducted much like community relations during government-led actions—almost all information generated or considered is public information. However, there will be times when limits must be placed on information released during enforcement actions. Information about ongoing negotiations, confidential business information and other potential PRPs can be particularly sensitive. While community relations staff must have latitude to discuss site-related work and issues with the public, all written material that addresses legally sensitive topics should be reviewed by counsel. In addition, it is advisable to meet with counsel prior to major public appearances to identify subjects which cannot be discussed and go over other, less severe ground rules.

Generally, any information that does not specifically and clearly threaten a company's legal or negotiating position should be made available to the public with as little delay as possible. It is likely that such information will be released under the Freedom of Information Act (FOIA) anyway. Forcing community residents to go through the cumbersome FOIA process unnecessarily can create resentment.

Just as it is important for a company's technical staff and consultants to form a cohesive team early in the Superfund process, it is important that legal and community relations representatives be an integral part of that team. This relationship allows team members to agree on general guidelines for the project and minimizes the potential for future serious philosophical disagreements.

Internal Communication

Coordinating the flow of information among different PRPs and within individual corporations can be cumbersome when planning and implementing a community relations program.

Superfund cleanups often involve groups of PRPs represented by law firms and environmental consultants that manage projects on a day-to-day basis. While the lawyers and consultants may be empowered to make most technical decisions without extensive review from all involved PRPs, such PRP groups are often very sensitive to site-specific dealings involving the press or public.

If a group consists of only two or three companies, developing a consensus on most community relations issues may not be an insurmountable task. However, if the group includes four or more

PRPs, it can become impractical to solicit frequent input from each PRP. In such cases, a meeting of key group members should be organized early in the process to reach consensus on basic community relations guidelines. A community relations strategy can then be outlined, agreed upon and implemented with frequent status reports provided to the full group. In such cases, group concurrence on all but the most crucial or unusual community relations events should be kept to a minimum. The roles of in-house staff and consultants in this process are discussed later in this paper.

Even in cases where only one PRP is involved, site-specific community relations efforts can cut across a number of internal corporate organizational systems—particularly at sites which involve both a local facility and corporate headquarters.

Generally, site-specific community relations are best handled at the most local level of a corporation's structure. If individual facilities are involved, plant managers and their staff are most likely to have an ongoing relationship with the local community. In such cases, community relations efforts should be based there. However, possible media attention and political involvement will likely engender interest from the corporate office—so corporate communications managers will have to be kept abreast of developments at the site.

The quality of this communication process may seriously affect the relationship between a facility and its corporate office—particularly if there is negative media coverage regarding the site.

BEST USE OF RESOURCES FOR PRP COMMUNITY RELATIONS EFFORTS

In-House Staff

Corporate staff should generally be active in Superfund community relations as much as possible. Serving as the key point of contact for the community and media reinforces a company's commitment to a project. It also allows closer control over statements made and information provided to the public throughout a project.

But in some cases, such direct involvement may be impractical or undesirable. It may be impractical because other demands can prevent corporate staff from spending as much time on a project as is needed. A company's credibility will be judged more by how responsive it is, than by what it says. If a key contact is not accessible to a community, and, therefore, not as responsive as he or she should be, there is a serious risk to the company's credibility. A half-hearted community relations effort can be almost as bad as no community relations effort at all. It is generally better to surrender some direct control over the nuances of public interaction than to try to run a community relations program in your spare time. Selection of an experienced consultant can be the next best thing to doing it yourself.

There may be cases where it is undesirable for a company to take a visible role in community relations efforts. When several PRPs are involved in a project, it may be difficult to single out one as the point of contact. Most companies in this situation are reluctant to draw attention to themselves and away from the other members of the group—for a variety of reasons.

Unfortunately, there also are projects which generate a lot of negative publicity and controversy. It is a fact that this happens rarely when a well-planned community relations program is established. In such cases, companies may prefer to designate a third party as the primary community and media contact. Companies cannot stay out of the picture through this approach, but they can focus attention on the contact and the project, rather than on the company.

Consultants

Three types of organization generally provide community relations services for Superfund PRPs:

- Public Relations Firms—These firms are likely to have the widest array of capabilities, ranging from fancy graphics to video production. Many large firms have offices or affiliates throughout the world. Personnel at PR firms generally have responsibilities outside the realm of environmental issues and may not have extensive practical experience with Superfund.
- Management Consulting Firms—Several of the larger companies have developed departments that deal only with environmental communication issues. Personnel at such firms may be technically proficient and have a good grasp of how Superfund community relations fits into a company's management systems. Many such firms have contracts to perform Superfund community relations for the U.S. EPA, posing a possible conflict of interest with private sector work.
- Engineering Firms—Some of these companies have developed community relations capabilities, primarily to serve clients that have already hired them for technical work at Superfund sites. These people generally have extensive technical knowledge and good communication skills. This arrangement also simplifies communication between technical and community relations staff.

Engineering firms may have to use subcontractors for fancy graphics or video presentations.

The type of company used for community relations support depends on the specific needs and preferences of the PRPs involved.

TACTICS

There are several key community relations decision points at each Superfund site. Planning an approach to these decision points can help ensure that activities are most effectively carried out.

Initial Contacts with the Public

It is essential that close coordination between regulators and PRPs begins as early as possible. Roles should be defined and responsibilities identified before community contacts are made. Such coordination shows that, although the two sides may not agree on all issues, there is a cohesive plan for involving the public in the decision-making process. Since initial community contacts may be made before the Community Relations Plan (CRP) is completed, the parties should hold an organizational meeting as soon as the PRPs become involved in site study and cleanup.

Community Relations Plan

The CRP is a blueprint for community relations activities at a Superfund site. Regulators and PRPs should work together in preparing the CRP to explain the roles of each. Community interviews, required by law, help gather pertinent information from neighbors, local officials, environmental organizations and other interested parties. PRPs should participate in community interviews to answer any questions about their involvement in the site and to assist in identifying key concerns. The U.S. EPA generally assumes responsibility for actually producing the plan.

Meetings with the Public

A variety of public and small group meetings are generally held throughout the project. These meetings provide opportunities for two-way dialogue between those involved in study and cleanup and the community. PRP participation in these meetings conveys responsiveness to the community and a willingness to work with

regulators rather than against them. PRP representatives may be best prepared to answer questions and respond to requested changes in project plans—particularly if the site is enforcement-led.

Media Interviews

A company's discomfort over dealing directly with the public can be exceeded by its disdain for dealing with the press, but good media relations is generally essential to a company's efforts to project responsiveness and credibility during its involvement at a Superfund site. A company must appoint one spokesman who is knowledgeable about the site, informed about the Superfund law, experienced in dealing with the press and accessible to reporters. Of these four qualities, experience and accessibility are the most vital.

Informational Material

All information developed specifically to inform the public should be reviewed by counsel. Production of any fact sheets, brochures, press releases or other items should be scheduled to allow time for such review. Once community relations personnel and lawyers agree on basic guidelines for public statements (as described under Legal Issues) these reviews should involve only minor changes in wording and emphasis.

Responsiveness Summary

As a required part of all RODs, a responsiveness summary can have a substantial impact on remedy selection. The government prepares all responsiveness summaries independently. PRPs must submit comments on proposed cleanup alternatives along with the general public. Comments by PRPs are given equal weight with comments from the public. If comments from PRPs and the public agree, they are likely to have more impact than if they are divergent. PRP involvement in community relations will increase the likelihood of common ground with the public at the responsiveness summary stage. (This issue is also discussed under "Influencing remedy selection.")

KEY POINTS FOR A SUCCESSFUL EFFORT

A corporation can use community relations best to complete a timely site study and implement an environmentally sound, cost effective cleanup if it takes an approach which:

- Realizes that the PRP's relationship with the community can have a direct bearing on the amount of money it spends at the site
- Recognizes the community as a key factor in study implementation and remedy selection
- Includes community relations staff as a vital part of the project team
- Plans the community relations effort to make the best use of available resources and to be most responsive to site-specific conditions
- Devotes the necessary time and resources to building a credible relationship with the community
- Implements the community relations effort with special emphasis on critical decision points

This approach can take some of the fear out of dealing with the public by helping a company to better control the amount of money it eventually sinks into a Superfund site.

Partners in Remediation:
Making a "MESS" of Community Participation

Pamela A. Hillery, M.S.
U.S. Environmental Protection Agency
Helena, Montana

Brad Martin
Montana Public Interest Research Group
Missoula, Montana

ABSTRACT

The Milltown U.S. EPA Superfund Site (MESS) committee formed to monitor remedial progress at the Milltown Reservoir Sediments National Priorities List Site near Missoula, in western Montana. The Environmental Protection Agency remedial project manager recognized the community's need to voice their concerns as participants in the remedial process.

MESS is involved in the Milltown Endangerment Assessment Committee (MEAC). Citizen involvement at such a fundamental level is unique to the Superfund process and relies on the commitment of not only the citizens but also the U.S. EPA staff, the State of Montana and the potentially responsible parties. Early citizen involvement and acceptance is critical to successful remedy selection and implementation. The Superfund process can be, and has been, brought to a standstill by public rejection of a proposed plan or record of decision.

Still, many committee members believe there should be even more opportunity for involvement. The U.S. EPA has yet to attain the MESS committee's ideal of citizen participation in the Superfund remedial process.

INTRODUCTION

The community of Milltown lies at the confluence of the Clark Fork River and the Big Blackfoot River in western Montana. The town grew up around the William A. Clark mining company lumber mill. As the mill expanded, the rivers offered a cheap source of energy, and so Milltown Dam was constructed and went on-line in 1907. The resulting reservoir unintentionally served as a settling pond for contaminated sediments in the Clark Fork River.

The contaminated sediments entered the river starting from its headwaters in Butte, Montana, where the Anaconda Copper Mining Company and others mined and milled copper, gold, silver and other valuable minerals. More contaminants entered the river from Mill and Warm Springs creeks, which flowed past heavily contaminated areas of Anaconda, Montana, where copper was smelted into anodes for manufacturing uses. Additional hard rock mining activities throughout the Clark Fork drainage contributed to the heavy metals and metalloids sediment load in the Clark Fork River.

These contaminated sediments found a resting place in the quiet backwater of Milltown Reservoir and settled to the bottom. At last estimation (1990), approximately 6 million cubic yards of reservoir sediments are contaminated with heavy metals and metalloids.

In 1981, a 2-year old Milltown child contracted an intestinal disease of unknown origin. The Missoula City-County Health Department (MCCHD), in searching for a possible cause, tested her family's well and found elevated levels of heavy metals and arsenic. While it later was established that the disease was organic in nature and not a result

of heavy metals or arsenic ingestion, seven other wells were tested, and four showed elevated levels of arsenic. Thirty-five homes were served by these wells, and in August 1981, the residents were told to stop using their well water for drinking and cooking purposes.

The Milltown Reservoir site was put on the National Priorities List in 1983, and a citizens' advisory committee formed to provide public comment on the selection of contractors to perform the remedial action study and review progress reports. After various samples were taken at the reservoir and an abandoned riverside landfill in 1984, the source of contamination was traced to dissolution of heavy metals from mill tailings in the reservoir sediments.

For almost 3 years, affected community residents hauled their drinking and cooking water. Some families even refused to bathe in the water and went to the local school to shower. Concern among the citizens varied from very worried to not at all concerned. Most people resigned themselves to hauling water and hoped local, state and federal officials would expedite replacement of the water source.[1]

After intense pressure from public interest groups such as Missoula Peoples' Action (MPA), the Montana Public Interest Research Group (MontPIRG) and the Milltown Water Users Association (MWUA), the National Guard provided a water truck for the affected citizens. By 1985, the Montana Department of Health and Environmental Sciences (MDHES), with funding from the U.S. EPA, replaced the water source and replaced residential plumbing that showed concentrations of contaminants. However, that action ameliorated only the immediate threat to human health and the environment. The reservoir sediments awaited investigation.

The process of performing a remedial investigation and feasibility study was derailed when the State declared its contractor in default in 1987. The U.S. EPA took the lead and, under the policy of enforcement-first, began negotiations with the potentially responsible party, the Atlantic Richfield Company (ARCO). ARCO was deemed responsible for the cleanup because the U.S. EPA asserts that ARCO is the successor-in-interest to, and has assumed the liabilities incurred by, the Anaconda Copper Mining Company (which became the major operator in the Butte/Anaconda area). The U.S. EPA made plans for negotiating, with ARCO, terms of the remedial investigation and feasibility study, with the U.S. EPA retaining full oversight authority.

MILLTOWN DAM PROBLEMS

During this time, Montana Power Company (MPC), owner of the Milltown Dam since 1929, was told by the Federal Energy Regulatory Commission (FERC) to upgrade the dam. Several severe weather incidents in the past had weakened the dam structure. After consulting appropriate state and federal agencies, including the U.S. EPA, MPC had a drawdown of the reservoir, dredged some sediments and repaired

the dam. The sediments were removed to an upland disposal area that all agencies had approved. However, no official noticed the three homes directly east of the area. One resident insists that when she indicated where she lived, officials said, "No, where do you really live?"[2] Nevertheless, the residents noticed the disposal area and were told by a contractor that MPC was constructing a toxic waste dump. The residents immediately called the MCCHD and were told to call the Clark Fork Coalition (CFC), a Montana environmental watchdog group whose sole charge is protection of the Clark Fork River basin resource. The citizens did call CFC.

In turn, CFC called the U.S. EPA. The remedial project manager (RPM) at this time (August 1988) was Ken Wallace. Wallace's background was in the public interest/environmental field, and he had established a good working relationship with the Clark Fork Coalition. They, in turn, were looking at a model of citizen participation in the Superfund process that avoided the cumbersome application process for the newly instituted Technical Assistance Grant program.

After responding to the citizens near the "waste dump," and several months of discussion, Wallace proposed that a (new) citizens' advisory group meet with state and federal Superfund personnel on a regular basis, providing a forum for U.S. EPA and MDHES to present data, report on activity progress, discuss problems and solicit input. He promised monthly meetings in Milltown or Missoula (downstream approximately 5 miles). The few restrictions were that Bonner Junction and Milltown citizens be members, that it not be solely a technical group and that it not be a partisan political forum.[3]

Seldom has the U.S. EPA encouraged this level of involvement from the public. However, Wallace saw this as an opportunity to expand greatly public participation in the Superfund process and preclude incidents such as the citizen ignorance of the upland disposal area, and so he successfully lobbied the issue with the Region VIII Montana Office management and ARCO. After several memos and letters, all parties agreed on the terms of participation. Thus, in March 1989 the "MESS" Committee was born.

THE COMMITTEE

The Milltown U.S. EPA Superfund Site (MESS) Committee was the vehicle of citizens who had no great faith in the Superfund process, the agencies (U.S. EPA and MDHES) or ARCO. They had seen decisions made both slowly and with seemingly little regard for public opinion. The name they chose for themselves reflects a deep-seated cynicism with Superfund and the major players. "MESS" means what it spells: the group saw a mess at the Milltown site, as well as a mess in the way the cleanup and citizen concerns were being handled. One of the first successful gestures the U.S. EPA made to the group was to accept their name without dissent or attempt to exert any pressure to change the name, despite the overt cynicism.

MESS is comprised of the Clark Fork Coalition's staff scientist, the Montana Public Interest Research Group's executive director and chair of the board of directors, the Five Valleys Audubon Chapter, the Missoula League of Women Voters, representatives from the MCCHD and the conservation district and unaffiliated citizens from Milltown and Bonner Junction (the site of the upland disposal area). Leadership follows two lines with CFC providing exceptional technical expertise, and MontPIRG providing expertise on community organizing and citizen groups. The MESS Committee set a goal for their involvement, which is:

"The complete removal, or the equivalent, of all contaminants at the Milltown site showing metals concentrations above background or which pose a threat to public health or the environment, whichever is lower, and an equivalent level of cleanup of upstream sources which will result in the elimination of downstream transport of contaminants. Final remedies which do not involve complete removal of contaminants must not require continued societal maintenance or concern [i.e. no institutional controls (ed.)]. Contaminants which are removed must be treated such that they cannot pose a threat to human health or the environment."[4]

By September 1990, the MESS committee felt reasonably comfortable and competent in its role (although they may be no less cynical

about the agencies or potentially responsible parties). There still are areas with which the committee has difficulties. As one member metaphorically stated, "MESS is a two-year old child. It knows what it wants to ask, but the words don't always come out right. We don't have the ability yet to rephrase our question to get the right answer, so we just keep asking the same question, hoping the answer we want will appear. But, like a child, we learn fast, and we'll know how to ask the questions better!"[5]

MILLTOWN ENDANGERMENT ASSESSMENT COMMITTEE

As an outgrowth of the successful relationship between MESS, the agencies and ARCO, Wallace proposed that MESS be involved in endangerment assessment (EA) activities. Wallace stated that all meetings would be open to the general public, decisions would be consensus-based and "should the meetings become non-productive, the U.S. EPA will dissolve the committee."[6] All parties indicated approval of this idea.

In a letter from ARCO project manager Christiane Garlasco, she said, "ARCO endorses the EPA's involving potentially responsible parties and local citizens in the endangerment assessment process" and recognized that the U.S. EPA would retain the final decision-making authority and responsibility. She continued, "the proposed (endangerment assessment committee) process, while experimental, may provide a valuable forum for exchange of information. ARCO will work with EPA and the other participants to make it so."[7] Phil Tourangeau of the Clark Fork Coalition said the MESS committee saw the purpose of the committee to be "to produce...(a) workplan for the conduct of the EA" and proposed additional work groups, of which one was adopted.[8]

The Milltown Endangerment Assessment Committee (MEAC) has been working together now for over a year. There have been growing pains and disagreements involved with the process, but the citizen members have been able to influence regulators (and sometimes ARCO), and MESS is aware of most activities concerning the Milltown site. Ken Wallace believes a completely successful model would need to have been implemented earlier in the Superfund process, but given what he and Tourangeau of CFC had to work with, MESS and MEAC are effective models of citizen participation.[9]

THE IDEAL OF CITIZEN INVOLVEMENT

However successful this incarnation of citizen involvement at a Superfund sight might be, it falls short of the ideal. These shortcomings hinder competent involvement on the part of the citizens, and that causes frustration for all parties. Wallace gave one indication of an obstacle to overcome, that of starting the concerted effort to involve the public late in the process. In addition, change of agency personnel played a role in the ability of the citizens to participate.

Shortly after the formation of the endangerment assessment committee, Ken Wallace chose to leave the U.S. EPA. In doing so, he allowed enough time to introduce and integrate the new project manager, Julie DalSoglio, into both the technical and community issues that existed. Fortunately, DalSoglio shared Wallace's public interest background and desire to facilitate public involvement in the Superfund process. However, any new managerial face at a site causes a certain amount of perturbation among all remaining parties, and Milltown was no exception. Some resentment was directed at DalSoglio simply for being new and for replacing a project manager with whom MESS had established a working rapport. DalSoglio made it clear, however, that she intended to follow the lead that Wallace had set and pursue involvement at all possible points in the process.

The MDHES also has had changes in personnel; since the formation of MESS, three successive project managers have been assigned to the site. Due to the U.S. EPA lead, this turnover has had less impact than it might otherwise have had, but it still causes some procedural difficulties. At times, MESS members wryly have referred to themselves as the oldtimers on the site and the institutional memories.

Additionally, MESS has disputed their exclusion from the negotiations for the remedial investigation/feasibility study administrative order on consent and work plan. The U.S. EPA, MDHES and ARCO re-

jected the MESS committee's request to be allowed to observe or participate, citing federal rules of evidence and privacy issues. While the committee does not accept these reasons, they agreed to participate in the endangerment assessment and pursue the issue of negotiations further.

Also, there remain logistical problems with an agency or other group working with a citizen-based group; most meetings need to be conducted in the evening so that all citizen members have the opportunity to attend. Unfortunately, that limits the amount of work that agency, ARCO and other personnel can do.[10] Various permutations have been attempted, but no one group is satisfied completely and continually. Such a problem is endemic to agency-public interactions, and no truly satisfactory solution has been espoused.

Finally, the issue of an informed, competent citizenry has to be addressed. The uninformed citizen is like the stereotypical insensitive tourist in a foreign country: unable to speak the language, when the citizen asks for a hamburger and the vendor does not understand, he simply says again "I want a hamburger" loudly, as though the vendor were merely deaf. So too does the citizen; isolated from arcane technical information, he simply rails against agency decisions all the louder, never making much sense to the agencies or potentially responsible parties. Such a situation is frustrating for all involved, but especially so for the citizen, because citizens also are powerless to influence the decision-makers.

The impotence felt by a citizen up against the bureaucracy lends itself to blocking actions that impede remedial activities at Superfund sites. Sometimes that action takes the form of requesting congressional interference; at other times people will lie down in front of bulldozers. The public is not completely powerless. The agencies serve their own best interests when they actively encourage early citizen participation and work to make that participation as skilled as possible. One way to promote participation skills is to utilize workshops on Superfund early in the process.

Region VIII, in conjunction with U.S. EPA headquarters, has developed a prototype workshop for citizens. Called the "Citizens' Superfund Workshop," it leads citizens new to Superfund through the process, putting them in the place of the project manager, with exercises on site-related issues. The MESS committee made the trial run through this workshop in May 1990, long after their involvement in the Milltown site. While they were past the need for the information contained within the workshop, and resented what they perceived as an agency attempt to make them sympathetic to the plight of the project manager, they were able to look at it from the point of view they had a few years ago, and affirmed its value to the Superfund novitiate.

Yet competent participation extends beyond simply understanding what step of the process one is on and relies on project managers and others providing information that they themselves use to guide their actions. If the agency wants to avoid lengthy battles at the proposed plan stage, they must put citizens in the position where they are not expected to answer a year's worth of questions in a 30-day comment period. Such a level of knowledge requires a continuous effort to bring the public along with the process and give them some participation aids.

In the end, agencies, contractors or potentially responsible parties can either play the game and pretend to foster citizen involvement while their meetings and studies thwart this involvement, or they can take some fairly straightforward steps to actively encourage effective citizen participation.

The following steps are suggested as a means to ensure competent, effective citizen participation. While we may not be able to guarantee that the citizens will agree with our decisions at the record of decision stage, they may be able to better explain their opposition, and we may be able to better meet their needs.

FIVE SIMPLE STEPS TO COMPETENT CITIZEN INVOLVEMENT

These steps are geared to the project manager and community involvement coordinator at a site; they are applicable to the efforts a potentially responsible party makes to involve the public, also.

- Do whatever you can to help citizens establish a firm knowledge of the Superfund process. This includes setting aside time to give briefings on the particular site as well as the process. However, talk not only about the process, but also about policy debates, the politics they will face and other insider information critical to successful operation in the Superfund arena.
- Open the process itself. To do this, invite citizens to join in risk assessments, RI/FS meetings or other meetings exclusive of those to which legal convention prohibits access. Help citizens prepare for meetings by making the pertinent data available beforehand, distributing agendas beforehand and informing them on the time table.
- Encourage citizens not to rely solely on the RPM but to use other resources, including other local and national citizen groups. In addition, encourage them not to rule out going to the PRPs for information. As we use other agencies, so too can the citizen benefit from outside experts.
- Encourage citizens to research and utilize the skills of citizen involvement and organizing. This includes (at any step in the Superfund process) taking the time to meet with their own group and establish their goals, their mutual questions and a strategy for their successful involvement in the process.
- As agency personnel, make yourself available and encourage PRPs to make themselves available to citizens for one-on-one briefings or background. By opening up the process to citizens, you create a relief valve so all issues do not have to be addressed in the forum of infrequent, confrontational public meetings.

CONCLUSION

We have to ask ourselves an important, but hopefully rhetorical, question. Do we really believe in citizen involvement or is our sole purpose to mollify the concerned public and have them agree with our decisions? We are obligated to realize and accede that the local citizens are the ones who must live with any decisions we make. No matter how trustworthy we believe ourselves to be, these people have to have some ownership of the decisions that will guide their future. We are not "arming our enemies" if we follow the steps suggested above; rather, we are giving the citizens an opportunity to participate in a meaningful, competent manner in a process that often robs them of that opportunity.

Understanding Effective Community Organizations

ABSTRACT

Industrial firms and governmental agencies dealing with hazardous waste recognize that public information is a crucial element in the success of technical projects. Numerous articles and studies attest to the validity of this concept. However, these publications have consistently viewed the issue from a one-sided perspective: that of the industry/agency being forced to include the public in its operations. Writings are replete with suggestions on how industries and agencies can "break through public opposition" and "overcome public ignorance." The public is viewed as a forbidding presence that the industry/agency can somehow control during a project by feeding it a steady stream of information.

A steady stream of information from the industry/agency, however, does not necessarily ensure a successful community relations program. In some cases where frequent high-quality project information has been distributed, community organizations have been able to force the industry/agency to alter or abandon a technical project or decision in favor of community concerns and desires. A common response of the industry/agency is to ask, "What did we do wrong?" In this paper, we argue that it is equally, if not more, important to understand what the community organization did right.

Through an analysis of case studies, we have identified those strategies that community groups have used to successfully alter project plans. These strategies include common organizational goals; detailed knowledge of technical plans and documents; a strong legal and scientific understanding of the issues at hand; presentation of viable alternative technical plans; involvement of local and political officials; continued persistence by the group in the face of opposition; and the application of a calm, professional manner in dealings with the industry/agency.

We have studied several community groups and in this paper we present detailed descriptions of each of the strategies listed above. By doing so, we provide a thorough understanding of effective and ineffective community strategies. This understanding should contribute significantly to the formulation of community relations programs that allow technical teams to complete their work in a manner consistent with the concerns and desires of the industry/agency and the affected public.

INTRODUCTION

Daily newspapers, radio reports, television stories and magazine articles regularly feature stories of community groups interfering with, altering and even halting, technical progress at hazardous waste project sites. This constant flow of information about hazardous waste projects in the media is resulting in a public that is increasingly aware of the issues surrounding these projects, as well as a public that is educating itself to safeguard what it perceives as its current and future safety and well-being.

But incinerators must be built, hazardous waste recycling efforts must increase, landfills must be sited and hazardous waste sites must be controlled or cleaned up. In the face of increasing public knowledge and awareness of environmental issues, how can industries and agencies successfully complete these projects? How can they accomplish their goals in the face of public opposition?

In this paper, we maintain that the ultimate success of hazardous waste projects rests in understanding what makes certain community organizations successful in their campaigns against hazardous waste projects.

As consultants and strategists who establish and maintain effective community relations programs, our primary goal is to help companies and agencies complete their technical projects successfully and efficiently. As heads of families, homeowners and community members, we understand the most conservative efforts to keep all risk and health threats out of our lives and our communities. We are, therefore, "on both sides of the fence." As a result, we have concluded that there must be compromise on both sides of that fence.

Compromise often is not a popular concept with companies in position to earn millions of dollars through the successful siting of a hazardous waste landfill. Compromise is difficult for agencies responsible for investigating and making decisions about the best way to clean up a functioning or abandoned hazardous waste site. Compromise is rarely an acceptable concept with community members who view their property values at risk and their lives and their children's lives as imperiled by hazardous waste projects.

At the very least, the strategies used to successfully complete controversial projects must be responsive to real issues and threats, as well as to the political and passionate climate of a community. Even the most powerful company is not guaranteed success by the sheer weight of that power. The strongest and most valuable asset that community members have is their passion to protect and safeguard those elements of life most dear to them: property values, their health and the futures of their children and grandchildren. No amount of money or skill can equal the power and effectiveness of this passion.

Although the importance of compromise cannot be overlooked, it is not our focus in this paper. Our purpose instead is to examine those strategies used by community organizations to impose their will on that of an industry or agency attempting to complete an unpopular project in that community. By examining and understanding effective community strategies, we can assist industrial firms and governmental agencies to successfully complete controversial projects in the face of opposition. We had originally intended to examine those strategies on the basis of detailed descriptions of specific case studies. However, in examining the merit of that presentation, we have opted in favor of presenting the strategies themselves, rather than details of the case studies. We are doing this in an effort to protect the anonymity of the companies, agencies and individuals currently embroiled in heated battles.

INFORMATION GATHERING

An effective community organizational effort starts by gathering the information crucial to the issue: the technical, political and legal factors of the issue. That information is then analyzed and understood to develop effective action: action that will delay, modify or even halt an undesired project. The first vital step in a community's strategy is to gather the information necessary to determine the exact environmental threats and local implications of the proposed project. This process sometimes requires hiring technical experts or capitalizing on the technical skill of an organization member. Very often, however, information is gathered simply by going to the public library to research the issue and the applicable Freedom of Information laws. Technical knowledge can be accumulated by accessing information prepared by state and federal environmental agencies which is available as public documents, or by telephoning the public affairs offices of those agencies. Technical information also can be gained through polite and careful questioning of company officials who are attempting to do their best to be responsive and responsible to the affected community. Community organizations have long understood that the "enemy" in an issue can become the most valued "ally" when dealt with carefully and skillfully.

Successful community groups also research the legal issues involved in a project. They determine if zoning changes are necessary to complete the project or if permits and licenses are required to implement all the phases of the project. Rarely has it been necessary for a community organization to pay for legal counsel. Organizations frequently have been able to recruit competent attorneys to their cause; attorneys whose contributions are the donation of legal advice and service. However, groups which need legal representation in court may have to hire attorneys. Optimally, these attorneys are also members of their communities, who have the benefit of personal passion to the cause in addition to expertise in legal environmental issues.

Successful community organizations also recognize and use the expertise of other groups. They network heavily, eliminating the need to "reinvent the wheel." The methods used and knowledge gained by others are invaluable in determining what strategies will be most productive and effective in their particular community. One of the most widely acknowledged and successful nonprofit organizations offering advice and expertise to communities is the Citizens Clearinghouse for Hazardous Waste, formed by Lois Gibbs, a former Love Canal resident and activist. Ms. Gibbs is at the forefront of the grass-roots protest on environmental issues and has established a sophisticated network to assist other groups, based on previous successes and failures.

The other vital piece of information that groups acquire before any successful challenge begins is a thorough knowledge of the elected and appointed officials, from the local to the federal level. Not only do groups know who these individuals are, they also learn the officials' postures on environmental issues, their terms in office and when they are up for reelection. This information is one of the most vital tools a community group can have and is readily available to all citizens. The most effective groups also use political offices as key sources of information. U.S. congressmen and senators can offer citizens direct access to the resources of the Library of Congress; state representatives and senators can provide critical insights into the inner workings of the state. Also, most U.S. congressmen and senators have staff personnel knowledgeable in environmental issues who are available to personally answer questions. They can direct group members to the appropriate federal agency personnel when necessary, cutting through reams of red tape.

Successful organizations also become familiar with the form of local government prevailing in their area. The federal and state government may be fairly easy to understand, but town governments can be more complicated. It is crucial to know who the true decision-makers are.

As part of the information gathering process, the organization also determines the sentiment of the affected public. By learning this, they can determine whether education is needed regarding the issue, whether they have to "line up the troops" or if the support is already there. It is imperative to have a vocal majority on the side of the "cause" if politicians and officials are going to rally behind the community.

Also integral to group success is familiarity with the local media and a good working relationship with those reporters interested in and willing to cover news and events relevant to the group's cause.

MOVING INFORMATION INTO ACTION

We identified six strategies that have been especially effective in transforming the accumulated information into action.

Create Awareness of the Group and its Mission

Most effective groups have first successfully created an "inner" and "outer" awareness of their organization and its mission. Inner awareness is the belief among group members that "David can fight Goliath" and win. To challenge an agency or industry successfully, individual members must believe that they can win no matter how few they are in number, how small their town or community, how little they think they know or how late in the official process they have become involved. Although it is difficult to pinpoint specific strategies and techniques by which inner awareness is built, its importance must not be underestimated. Inner awareness is the cornerstone upon which successful organizations are built; it is often the sole motivator when their cause appears futile; and it is nearly impossible for an agency or industry to defeat.

The most successful groups do not rely on inner awareness alone, however. They also create an outer awareness of their membership and mission; that is, they create an awareness of the group and its purpose in the community. This has been most often and most effectively accomplished in relatively simple ways:

- Petitions. Circulating petitions requesting support for the group's mission is an inexpensive and very effective tool for spreading the word quickly over a large area. Taking petitions door-to-door, to shopping centers, to community centers and to churches, temples and synagogues helps to spread the group's message not only to a large geographic area, but also to a large number of community members.
- Fair/Festival Booths. Many groups set up booths at fairs, festivals and other neighborhood events that attract large numbers of people. This activity provides an excellent opportunity for recruiting new members because it allows for one-on-one discussion of the group and its purpose.
- Working with Other Community Organizations. As we mentioned earlier, successful groups have found it extremely useful to work with existing community organizations, even if the purpose of those organizations is not related to the group cause. Existing community organizations often are able to provide the fledgling group with valuable resources such as contact lists of possible volunteers, newsletter items publicizing the group and monthly meetings at which group members may speak.

Focus on "Service-raising" Rather Than Exclusively Fundraising

Groups challenging an agency or industry are, at heart, running a political campaign. And, like every other political campaign, a constant source of money is needed to purchase the services necessary. Because money is so important, it often is the area on which the agency or industry concentrates, and they always have the advantage. Many agencies and industries feel that they can stop a community organization by pouring funds into extensive media campaigns, supporting local schools and causes and hiring scores of lawyers, engineers and scientists. These same agencies and firms are often thrown into a quandary when this strategy fails.

Successful community groups focus more on "service-raising" than on traditional fundraising. Group leaders acknowledge that they would never be able to compete with an agency or industry in terms of dollars, so they do not try. Instead, they focus their fundraising efforts on gaining the services that money can buy. Rather than hiring a print shop to produce and copy flyers, they turn to members with home computers and easy access to copy machines. Instead of renting halls for community meetings, they turn to members who can access rooms at minimal or no charge. Rather than hiring photographers to record group

events, they turn to members with the equipment and expertise to do the job. By exploring the individual capabilities and hobbies of each member, these group leaders acquire, at a low cost, the elements they need to continue, counterbalancing many of the dollars spent by their opponents. By utilizing the abilities and services available in and through their members, they increase the feeling of involvement and worth of the members. This mode of operation translates into increased allegiance and dedication to the cause.

Gain the Attention and Enlist the Aid of Every Possible Politician

Individuals who have successfully challenged the agency or industry also have successfully gained the attention and assistance of as many politicians as possible. Communities appear to have better luck at this than do agencies or industries. This seems to be due to two main reasons. First, politicians (particularly mayors, state representatives, state senators, U.S. representatives and U.S. senators) are accountable to voters. They need public support to stay in office. Any other goals a politician may wish to accomplish while in office (such as becoming instrumentally involved in certain areas of public policy) will become impossible if that person does not remain responsive to his or her electorate.

Second, in the public's eyes, the organization represents the interests of the "people," but the agency or industry may not. For this reason, it usually is not difficult for the organization to mobilize citizen support to put effective electoral pressure on elected officials. Some strategies and techniques in this area include the following:

- Invitations. Every politician is invited to all group meetings and functions. Each presence or absence is widely publicized.
- Questions. Every politician is publicly asked his or her opinion on the issue with questions phrased to require a yes or no answer. The answers are widely publicized.
- Voter Registration. One member of the group is deputized to register voters. Groups then set up a clearly marked voter registration booth at every meeting or function so that it is visible to the politicians in attendance.
- Letter Campaigns. Letter-writing campaigns are organized to simultaneously flood a politician's office with mail.
- Telephone Campaigns. Telephone campaigns are organized to simultaneously flood a politician's office with phone calls.
- Demonstrations. Peaceful demonstrations are held outside political offices.

Gain the Attention and Enlist the Aid of the Media

Effective community organizations appoint one person as media spokesperson for the group. It is the ultimate luxury to have a group member who is skilled in media relations, has established contacts and is willing to utilize them as his/her contribution to the group efforts. However, even in the absence of this, one person is appointed to serve as spokesperson, regardless of previous experience. This person gains the skills needed "on the job." Media contacts prefer to deal consistently with the same representative. The most successful spokespeople make themselves available at all times and carry a beeper or pager so that they can be reached at a moment's notice.

The spokesperson has no problem arousing interest and procuring media coverage with a good, fresh environmental or political story. It is a different matter when there is no new or "hot" news. Effective groups create their own stories during lulls in the action to keep the story fresh in the minds of the community, the media and the politicians.

Successful organizations maintain control of the coverage of their issue in the media. Without that control, the reporters will turn to others involved in the controversy for news. When this happens, the group may find that the stories become slanted in a different light and its side is not presented fairly or correctly.

A creative mind is the only limitation on the possibilities of creating stories that gain media attention. One effective proven technique is the creation of an event, sometimes a group fundraiser. Local popular media personalities are invited to host and judge the event. This garners pre-event publicity, event coverage and post-event reports.

Remain Active Even if the Agency or Company Does Not

A common mistake made by many organizations challenging agencies or industries is to react rather than act. When the agency or industry appears to be doing nothing, the group also does nothing. The group then loses momentum, members drop out, press coverage disappears and politicians ignore the cause. It is then very easy for the agency or industry to "move in" and win the fight.

Effective organizations, therefore, have adopted a strategy of continuous action. They put particular emphasis on remaining active when the agency or industry does not appear to be active. This strategy not only allows the group to hang on to the advantages it has gained, but it also helps to maintain inner and outer awareness.

The group leaders we spoke with mentioned no specific techniques for accomplishing this strategy. Instead, they suggested carrying on "business as usual," whether through press conferences, political rallies, demonstrations or mass mailings. Their key is to always keep the group as active as possible.

Work Within the Law at All Functions

In some community fights, the agency or industry often is able to stop a group activity by finding a legal loophole that was missed, such as finding out whether there are more people in a meeting hall than the allowable limit or whether a group needs (and consequently has) a parade permit to conduct a rally. The most successful groups search out these loopholes before the agency or firm has a chance to do so. They ensure that every requirement of every applicable law has been met.

CONCLUSION

There are effective and ineffective community organizations. The effective groups accomplish their purposes through a variety of techniques, but the strategies that result in success and accomplishment of group goals are consistent. Agencies and industries need to understand those strategies thoroughly in order to most effectively respond, compromise and accomplish their end goals.

Successful groups first carefully gather information relevant to the site or issue. That information includes a thorough knowledge of the technical issues of importance, the local political structure and method of government, the elected and appointed officials from the local through the state to the federal level and the applicable legal factors. This information is then put into action in a robust, impassioned, yet rational plan of action. Effective community organizations have used the following tried and true strategies:

- Create awareness of the group and its mission
- Focus on "service-raising" rather than fundraising exclusively
- Gain the attention and enlist the aid of every possible politician
- Creatively gain the attention and enlist the aid of the media
- Remain active even if the agency or industry does not
- Work within the law at all functions

Hazardous waste projects will always generate controversy. The industrial firms and governmental agencies that develop effective methods of dealing with and responding to the controversy will be the most successful in accomplishing their goals. A flexible, thorough community relations program based on a complete understanding of successful community organizations will smooth the process and give the agency and industry the leading edge to accomplish project goals.

Communicating Risk to Communities

Terryn Barill
Brown and Caldwell Consultants
Hazardous Materials Division
Pasadena, California

INTRODUCTION

This paper will discuss the common communication problems encountered by environmental professionals when dealing with the nontechnical community. Environmental professionals need to understand the community's point of view. Once the community's viewpoint is understood, action can be taken to address their concerns.

The Federal Superfund program requires individual states to achieve the ability to dispose of hazardous wastes without depending on land disposal. This requirement has created a need for new facilities. California's Tanner Bill (AB 2945) requires each county to have the capability to dispose of its own hazardous wastes. This is a microcosmic view of what is (or will be) happening on a national level.

The siting of a new waste disposal facility depends heavily on the surrounding community's willingness to accept it. Even in states without a formal community participation plan, homeowners know they can veto the development of a new facility through political action. Who really wants a hazardous waste facility in their neighborhood?

There are several reasons for the breakdown of communications: technical language versus lack of technical knowledge and nonrecognition of age, gender, language and ethnic barriers. The project team can overcome these barriers with various techniques: the use of common images; informal interviews with residents; addressing community concerns instead of attempting to overcome objections; and recognition of local conditions (demographics, politics, etc.).

More problematic than technical communication problems is a difference in values. Each element viewed as a benefit by the environmental professional may be viewed in the opposite light by the community. Each side, and often there are more than two sides, may have a completely different perception of the potential impact of a proposed project. Community relations efforts usually focus on convincing residents to support the proposed facility. These types of efforts are generally ineffective against the risks perceived by the community.

The environmental professional needs to realize that the community is operating from a psychological response to the fear of loss of control. Perceived risk is more real to the community it affects than the statistical reassurances produced by technical experts. This predisposition to fear is what creates the grassroots movement against the proposed facility. Miscommunications energize this movement and give it its eventual political force.

The importance of understanding the community's point of view increases as effective community relations plans become more vital to the siting process. Environmental professionals will have to learn to communicate more effectively with the communities involved. Effective communication can diffuse political pressures and high levels of controversy which would result in the disapproval of a site.

COMMON COMMUNICATIONS PROBLEMS

Effective communication involves the transfer of ideas from one person to another. Simply using the same spoken language does not guarantee communication, as anyone who has ever been in a parent/child discussion knows. For example, my mother and I will stand at Point A. We will agree that we are at Point A. We will agree that we want to get to Point B. We will stand at Point A and argue about how to get to Point B. This discussion is not much different from agreeing that the site is contaminated, agreeing that it needs to be cleaned up and arguing about how it needs to be cleaned up. When two people have something at stake, it leads to communication barriers.

In risk communication, the most common communication barrier and the easiest to overcome, is the use of technical language with people who do not use technical language. There are environmental professionals who seem shocked to learn that not everyone knows that EP-CRA is a section of SARA which amended CERCLA. In fact, there probably are quite a few environmental professionals who do not know what these acronyms stand for and what they mean. In the same vein, members of the general public ordinarily have no need to understand the differences between stabilization and solidification, or bioremediation versus excavation and treatment. Translating technical information into nontechnical language is simply a matter of explaining the problem clearly. Common images are extremely useful here. The object is to get the basic functional idea across, not to train the listener in the nuances of the technology. A carbon adsorption unit is like a giant fish filter in an aquarium. Both units use carbon as the primary cleaning agent. Both may also use secondary filter material. The only functional difference is size. Once the basic idea has been understood, then technical language may be used.

Common images can be used to illustrate pieces of explanations as well. The images do not need to continue on a theme—they just need to get a picture into someone's head. As an example, when explaining asbestos affects on the lungs, several different nonrelated images can be used: the lung is like a sponge; asbestos fibers are very aerodynamic, like a spear; when asbestos fibers get down deep into the spaces in the lungs, they can do a great deal of damage; the passages into the deepest parts of the lungs are covered with cilia, which looks like wheat; when asbestos gets down into the lung, it is like a 747 landing in a wheat field; and the asbestos cuts a path in the cilia, which does not regrow, embedding itself in the side of the lung.

Certain words and phrases associated with environmental risks already create images in the public's mind. Words like cancer, asbestos, cyanide and toxic are guaranteed to get a reaction. Special care should be taken with the phrase "one in a million" when describing risk. The public perceives 10^{-6} to mean if one million people are exposed to this

substance, then one will die. In risk assessment, 10^{-6} means that daily exposure of a specific dose to a 70-kg person over the expected lifetime of 70 years would increase the chance of cancer by one person out of one million people.

Sometimes the problem with using technical language is that it may give more information than is necessary. The public may not need to know that EPCRA is a section of SARA which amended CERCLA. Communicating that the community has a right to know may be the only important information.

Environmental professionals should recognize that communities are fully capable of understanding the technical and scientific issues. "The public" includes doctors, scientists and teachers, as well as persons with less scientific background who are able to understand the intricacies of the problem.

A second barrier to effective risk communication is the communicator's lack of recognition of age, gender, language and ethnic barriers. Recognizing the demographics of the effected community may give an indication of the probable public reaction. Younger people and couples with children, especially younger children, will react the most strongly against health risks. Younger couples and families who have recently purchased their homes (less than five years) are the most likely to be financially tied to the area. This group feels that they have the most to lose financially. Long-time residents, especially those over 60, feel that they have the most invested in their homes, in memories and effort as well as money. In addition, if they depend on a fixed income, they also may be financially tied to their home. The health threat of carcinogens will have less effect on this age group, since the attitude seems to be that cancer takes 20 years to develop and they may not have 20 years of life left anyway. Women tend to be more vocal against health threats, especially when protecting young children. Many community activist movements are begun and coordinated by mothers of young children.

Overcoming these types of communication barriers can be accomplished by addressing community concerns instead of attempting to overcome objections. Too often, community communications are focused toward "selling" the community on the remedial action that has been selected. The public focuses on risk factors not found in the quantitative data. Dismissing public reactions without any attempt to understand them may lead to greater public opposition and, ultimately, a greater expenditure of resources trying to quiet the controversy. Not recognizing language differences will lead to complete miscommunication and will fuel anger in residents. In communities with large non-English speaking populations, communicating in their fluent tongue may be critical to responding to community concerns.

Another barrier that may hinder effective communication is a difference in values—that is, the difference between what is important to the community and what is important to the agencies and PRPs. An example of this barrier could be a decision to excavate and treat contaminated soils. Although this process would clean the area much more quickly than on-site treatment, the community may object to the transporting of hazardous waste through their streets. Another example could be the reverse scenario, when the community wants the soils excavated and the PRPs object and want to treat on-site. A way to overcome this barrier is through informal interviews with residents.

An interview is exactly the opposite of "public information meetings," where the idea is to give out information. In these interviews, the idea is to get information regarding any local condition which may impact the community's reaction to activity at the site. One should listen to the questions that the community asks. People ask about what will affect them. They ask, "Will I die?" not, "How many people have died from exposure to X?" They ask, "How will exposures be limited?" not, "What is the level of exposure?" Actions speak louder than words. One should focus on what is happening now.

The community needs to be considered a legitimate partner when planning the remediation of a site, especially a large Superfund site. Communities not involved during the planning stages often fight agency decisions. The lines of communication must be kept open at all times. Staff who will be interacting with the public must be trained to handle not only the questions, but also the strain of contact with an angry or upset community. All information should be filtered through one contact point, if possible, to avoid conflicting statements from different sources. All information disclosed to the community should be as honest and up-to-date as possible. Trust and credibility are the best tools in risk communication; once lost, they cannot be regained.

COMMUNITY'S POINT OF VIEW

Hazardous waste is a threat to a community. The common psychological response to a threat is fear, anger and a feeling of a loss of control.

In addition, the concept of risk is different between agencies, industry and communities. There is a kind of "chemophobia" running through society; if it is natural, it must be better than if it has chemicals. We see this concept promoted endlessly in advertisements for varying products. Industry, on the other hand, is dependent on chemicals and technical processes. Agencies are comfortable with proven cleanup technologies and certain levels of residual contamination. The public does not ordinarily have an understanding of the proposed cleanup technologies and will therefore consider them a higher risk. What is unknown is considered a higher risk than what is known. This fear of the unknown is also why risk comparisons between involuntary risks (such as living near a contaminated site) and voluntary risks (such as driving or smoking) usually are not accepted by the public. People know what cigarettes can do to them, but they choose to increase their chance of cancer by smoking. Given the choice, they would not choose to increase their chance of cancer by exposure to hazardous waste at a nearby Superfund site.

Risk perception is a learned fear. Communities have a predisposition to fear through their knowledge of other communities and their experiences with toxic contamination. Note the word **toxic**. In a community's mind, the contamination is always toxic, never just hazardous. This concept is perpetuated by the media. Toxic fits better in a headline. The environmental professional is aware that a site may be contaminated with a waste considered hazardous because of its flammability or reactivity. To the affected community, it is toxic. "It could happen here" is the true legacy of Love Canal. Risks that can be associated with other events, such as Love Canal or Bhopal, India are considered a higher risk.

As a proposed facility is publicized, the community associated with the hazard becomes stigmatized. The stigma is applied both to the hazard and to the community that contains the hazard. Many times this result is due in part to fiscal impacts and issues unrelated directly to hazardous waste. Hazardous waste facilities require more public funding and support than other types of facilities. The fiscal responsibility for closure, permits, emergency funds and training emergency response personnel takes money away from other areas of the community. In addition, the money spent on a hazardous waste facility, other than direct construction costs, is often invisible to taxpayers. So when the media relates the total amount spent (i.e., the $14,000,000 hazardous waste facility in Smalltown...) it creates a twisted perception of favoritism where the community with the hazardous waste facility has more money spent on it. As the controversy escalates, the stigmatized community has a higher stake in keeping the facility out.

The community may feel victimized by both the contamination and the system that is in charge of removing it. Once again, involving the community in the decision-making process may help to keep everyone's perception of the risk within a close range.

If a community feels that it has not been involved in a decision, its members feel a loss of power over their community and a loss of control over events in their own lives. This loss of control leads to an increase in fear and anger, which can translate into action by the formation of community activist groups. This response can create a deep sense of community, which will enable the community to focus on solving the problems important to them and making their concerns heard. The activist group serves to focus the anger and use it against the feelings of powerlessness. The greatest fears in a community surround the issue of health. To be sick is feared more than being hurt, so materials that have high probability for accidents (such as explosives

or reactives) are feared less than materials that have a high probability of causing cancer.

The community's point of view focuses on the people involved with the site and what they have to lose. When the lights go out and the flyers handed out at the public meeting litter the parking lot, the agency people can go home and try to forget about the problem. However, the community feels that a silent killer is stalking them in their own homes and they have nowhere safe to go. The community feels an invasion of home and territory, especially when the exposure pathways are through the air and the water supply. A site where the exposure pathway of concern is direct contact may generate this type of emotion against the process of cleanup, rather than the contamination itself.

THE POLITICAL FACTOR

In our democratic society we are aware that we have certain rights, among them the Freedom of Speech and the Freedom of Assembly. The community may understand the risks as they have been explained and simply not agree with that position. Although most community activist groups arise out of being ignored and the need to affect the decisions made through traditional channels, there are groups and consultants that are adept at using political strategies for issues beyond the specific site. Since the community's concern usually focuses on health issues and the agency and PRP view usually focuses on the economic issues, some legitimate disagreement is inevitable.

A primary disagreement may be over zero risk. The demand for zero risk may be made for several reasons: it may be a negotiation point for a risk that seems too high; it is what the community wants, regardless of its feasibility; it may be a symptom of the intense anger generated by the site; or it may be politically motivated. When the demand for zero risk is politically motivated, the situation presents special challenges to those attempting to communicate risks to the community. This may be the one time when the strategy in public and in private may be different. During public meetings when the emotion and rhetoric run high, the best strategy is to stay open and direct. Try to arrange private or semi-private meetings where honest discussion and negotiation might be possible.

On some occasions, there may be interference from local politicians for political gain. The agencies usually follow the traditional problem-solving approach to a site; in contrast the community usually favors a more democratic approach. In the environmental arena, majority rule may not protect the minority and this has to be made clear to the community. Community education is ordinarily aimed at convincing the community, not addressing their fears. Once again, listening to the community and searching for the qualitative factors that influence them and adapting the pattern of risk communication to address specific concerns may overcome barriers to effective communication.

CONCLUSION

The keys to effective risk communication are explaining technical jargon clearly, recognizing barriers, addressing community concerns and maintaining credibility and trust. The community is going to be concerned about risk and may reject the explanations of risk offered to them. They also are likely to have concerns that are not reflected in the quantitative risk assessment. All community concerns must be acknowledged and addressed.

It is vital to understand the community's point of view and the variables affecting the site in order to avoid political pressures and high levels of controversy which may result in the disapproval of a site. Although this concept may sound like common sense, in real-life the community's concerns are often overlooked and the resulting controversy is played out in the media. Everyone involved with a Superfund site, the community, agencies and industry, wants the same thing. They all want to know what is there and how much is there and what will be done about it. Effective risk communication can pave the way for the process to focus on correcting problems rather than how data were presented.

The NIMBY Syndrome: Environmental Failure and the Credibility Gap

Stuart A. Wright
Associate Professor of Sociology
Lamar University
Beaumont, Texas

INTRODUCTION

While environmentalists and industry disagree on many issues, one thing they are certain to agree on is the growing opposition of the Not-in-My-Backyard (NIMBY) Syndrome. Government officials and industry analysts now are suggesting that the most difficult obstacles to siting hazardous waste facilities may be sociopolitical, not technical. Public opposition to new hazardous waste sites has been stiffening in recent years as citizens in communities across the country have organized politically to block permits. Will Collette, director of the Citizen's Clearinghouse for Hazardous Waste, estimates that between 1986 and 1988 the number of groups protesting toxic disposal in the U.S. more than doubled, from 1,700 to 3,650.[1] A recent story in the *New York Times* declared the NIMBY Syndrome an emerging movement and "a potent anti-development force" leading to "a paralysis in effective corporate response to marketplace incentives."[2] One specialist recently lamented, " No major anti-pollution project in at least ten years has been able to proceed without intense public opposition."[3] Moreover, there is no indication that public opposition will abate in the near future. Most of the recent poles show that the public demands for a cleaner, safer environment have increased. For example, 1988 Gallup poll showed that 84% of Americans were "very concerned" about water pollution and 73% held similar views about air pollution. Both figures represented significant increases from polls in the 1970s when fewer than half of those interviewed expressed such concerns.[4] Ironically, the resurgence of the environmental movement has occurred during a period in which the federal government has spent billions of dollars to improve methods of hazardous waste treatment, disposal and remediation, primarily through RCRA and Superfund. The current impasse over siting raises some critically important questions about the effectiveness of these government programs, and about confidence in the new regulations and new technologies. Indeed, it even raises questions about the credibility of government agencies and industry to place public health and safety above profits and politics.

THE DAYTON SURVEY

Some of these questions were addressed specifically in a recent study of a proposed hazardous waste site near Dayton, Texas, a small community about 45 miles northeast of Houston. A Florida-based company, Hunter Industrial Facilities, Inc., has proposed storing hazardous wastes in a salt dome at that location. Salt dome storage of hazardous wastes is one of only two disposal methods approved by the EPA. Through a grant awarded by the Gulf Coast Hazardous Substance Research Center, a consortium of eight universities estab-

lished in 1986 through Superfund legislation and headquartered in Beaumont, Texas, this author was able to conduct a study of community reactions to the proposed site from the earliest stages of the project. Part of the two-year study included a public opinion poll of residents in four communities (Dayton, Liberty, Huffman and Atascoctia) adjacent to the proposed site. The affected area covers the far western portion of Liberty County and the northeastern portion of Harris County. The poll was conducted in January 1990 using a scientific sample of 439 adult residents randomly drawn from telephone listings and interviewed by a research team from Lamar University. Some of the findings culled from the survey are discussed in this paper, and should be a cause of concern to corporate and government leaders.

The Dayton survey revealed a widespread belief among area residents that the federal government legislation had not improved waste management practices in recent years. Only 32% agreed with the statement "federal government legislation in recent years has dramatically improved the safety and effectiveness of hazardous waste methods and practices." A majority, 52% of the sample, disagreed with the statement and 16% said they didn't know. Substantive comments by respondents indicated doubts about the government's ability to compel strict compliance, and about industry's lack of initiative to comply in the face of increased costs. Citizens' responses did not vary significantly with level of education or income. In effect, it appears that most of the general population in the sample area were not willing to give the government a passing grade on its record.

A similar pattern emerged with regard to the perceived viability of the technology to be utilized. Sixty-six percent of the public disagreed with the statement, "The technology to ensure safe and effective disposal of hazardous wastes in salt domes has been adequately developed." Approximately 16% agreed with the statement and 18% said they didn't know. Again there was no significant variation by education or income.

Industry representatives will argue, of course, that few respondents have the knowledge of expertise to make a technical judgement. No doubt that such an objection would be correct. What the survey suggests, however, is a paucity of confidence in those segments of industry and government responsible for safe disposal of hazardous wastes. In other words, it may be less a technical issue than one of credibility and public trust. People are not often able to separate a technology from the carriers of that technology. Though some companies have better track records than others, there is a tendency for the public to lump them all together, good/bad companies and good/bad methods. Since the average citizen does not have

the requisite specialized knowledge and training to make reliable assessments of technology, he or she must be able to trust those who do. Thus, the most salient issue is credibility, and it does not appear that industry and government officials have it. This was borne out by several other items on the survey.

To test the issue of credibility, three questions were posed to community residents essentially asking them whom they would believe regarding assurances of safe hazardous waste methods of disposal. We had to consider the possibility that the citizens might refuse to believe anyone, given the frequent complaints about radical NIMBYists. However, the findings revealed that credibility was selectively imputed to one of three groups mentioned. Most sample area residents tended to trust scientists and technical experts, while distrusting industry representatives and government officials. Sixty percent of the public said they would believe assurances given to them by scientists or technical experts, while only 26% would believe government officials and even fewer, 22%, would believe industry representatives. The exact wording of the questions and the response patterns are shown in Table 1. It is worth noting that questions are identical except for the phrase identifying the source of assurances being given (industry representatives, government officials, scientists and technical experts). It should also be mentioned that they would have to be independent - not company employees - in order to gain credibility.

Table 1
Selected Items on Credibility from 1990 Dayton Survey (N=439)

	(Response in Percent)		
	agree	disagree	don't know
If INDUSTRY REPRESENTATIVES assured me that the technology to ensure a safe and effective disposal of hazardous wastes in salt domes had been developed, I think I would believe them.	22	75	3
If GOVERNMENT OFFICIALS assured me that the technology to ensure a safe and effective disposal of hazardous wastes in salt domes had been developed, I think I would believe them.	26	71	3
If SCIENTISTS AND TECHNICAL EXPERTS assured me that the technology to ensure a safe and effective disposal of hazardous wastes in salt domes had been developed, I think I would believe them.	66	31	3

THE CREDIBILITY GAP AND THE ENVIRONMENTAL FAILURE

These data may be helpful in shedding some light on the NIMBY Syndrome. If the attitudes of the population in our survey reflect the attitudes of other communities, it would appear that refusal to accept a new waste site or facility is tied to widespread distrust of waste-related industry and government agencies to safeguard public health. A credibility gap exists that thwarts the efforts of these institutions to resolve the problems of treatment and disposal. This crisis of confidence is not entirely unwarranted. Environmental studies do not show marked improvements in the quality of air and water in the U.S. over the last decade. Furthermore, new studies that may entail

data on longstanding problems have served to heighten awareness and outrage. For example, the infamous Waxman report revealed that approximately 2.4 billion pounds of toxic waste were released into the air in 1987 causing considerable adverse reaction. However, many experts concede that emissions had probably declined from a few years earlier.

While there are some notable successes in the fight against pollution, the general public impression seems to be one of environmental failure. This is strongly evidenced in the growing apprehension of the public concerning environmental problems as measured by polls. In a 1986 CBS/*New York Times* poll, 66% agreed with the statement, "Protecting the environment is so important that requirements and standards cannot be too high, and continuing environmental improvements must be made regardless of cost." The number of people agreeing with this same statement increased to 80% in 1989. Evidence of heightened public anxiety, the growth of NIMBY groups, the increased demands for a cleaner environment, and our own finding from the Dayton survey are all indicators that the characterization of environmental failure is an accurate portrayal of public perception. The theme of environmental failure is echoed throughout the polls, the electronic media, popular books, through special features in major magazines, and wherever one finds a public forum on the environment. The affects of environmental failure have been articulated in a recent book by Barry Commoner, Director of the Center for the Biology of Natural Systems at Queens College, New York. Commoner writes in *Making Peace with the Planet*[5]:

> It hardly takes a sociological survey to determine the response to (environmental) failure. It justifies the polluter's inaction and intensifies the public's frustration. It erodes the integrity of regulation and diminishes the public faith in the meaning of environmental legislation.

A social scientific analysis of the NIMBY phenomenon suggests that future resolution of the impasse will come painfully slowly since the public demonstrates little confidence in the institutions that are most directly involved in the effective disposal of hazardous wastes. A credibility gap threatens to make any efforts by government regulators of industry laborious, protracted, conflict-ridden and ultimately ineffective. However, our data suggest that independent research scientists or technical experts may play a key role in providing the public with reliable information upon which to make decisions. While the introduction of neutral scientists does not guarantee resolution, it may help the facility siting process hurdle one very important obstacle. Industry representatives and government officials may welcome this as an opportunity to reclaim public trust if and when independent studies confirm the integrity of their own claims and statements.

Alternative Methods for Estimating Hydraulic Conductivity

John B. Rand, C.G.
Dirk R. Brunner, P.E.
E.C. Jordan Co.
(ABB Environmental Services, Inc.)
Portland, Maine

ABSTRACT

From the early 1930s until 1982, municipal, commercial and industrial wastes were deposited at a municipally operated 15-acre landfill in Maine. Following a RI/FS, a PCP contracted for consulting services to develop and implement a Remedial Action Plan (RAP). The RAP included a three-phase hydrogeologic investigation to provide site information on which to demonstrate Alternate Concentration Limits (ACLs). ACLs were to be used to determine if aquifer remediation was needed. Soil borings, monitoring well installations and groundwater sampling and analyses were used to identify chemical flow paths from the landfill to points of discharge in an adjacent lake to the south and a brook to the north. In order to estimate chemical travel times in groundwater, several Darcy-based methods were employed to estimate hydraulic conductivity (K). These calculational methods included a chemical travel time based on landfill operational history, a water balance approach supported by seepage meter measurements and, hydraulic conductivity testing. These estimates were confirmed by the results of groundwater modeling and an aquifer pumping test.

The chemical travel time estimate of K was based on a range of distances between alleged liquid chemical disposal areas at the landfill and known locations of chemical discharge to surface water. This range of distances was divided by the range of time periods when chemicals were dumped and estimated chemical arrival at groundwater discharge points. Using a miscible, nonretarding indicator chemical, the resulting range of velocities was considered representative of the average linear groundwater velocity. When combined with porosity and a known hydraulic gradient along the flow path, a range of values for K could be calculated using Darcy's Law.

The water balance estimate was developed from a groundwater surface contour map for the site and well-defined aquifer geometry. Based on estimated precipitation recharge and regional groundwater flow into the site area, flow volumes were identified. Using known depths and widths of chemical flow paths, the cross-sectional area of flow paths was determined. Knowing the gradient, area and volumetric flow rate, K was estimated.

At the south end of the site, seepage meter measurements confirmed water balance estimates. Rising head hydraulic conductivity testing performed at selected monitoring wells provided a third estimate of K within flow paths.

Three dimensional groundwater flow (and chemical transport) was simulated at the site using the Princeton Transport Code (PTC). The resulting calibrated head distribution was obtained using K values comparable to those estimated by the above methods.

Finally, a 30-hour, 115-gpm aquifer pumping test was conducted with water levels recorded at 35 monitoring wells with Hermit Data loggers. Aquifer parameter analysis using the Hantush leaky aquitard solution confirmed estimates of K obtained with the above methods. The results of these studies indicated that, for certain site settings, simple application of Darcy's law provided estimates of K that are consistent with the more rigorous (and costly) analytical estimates provided by numerical computer modeling and aquifer pumping tests.

INTRODUCTION

This paper summarizes three simple methods used to estimate K of sand and gravel aquifer materials beneath a former municipal landfill. The three methods provide comparable results with the more rigorous analyses of a three-dimensional groundwater model and are consistent with the results of a comprehensive aquifer pumping test. While local variability in stratigraphy can cause large changes in K, no substantial layering was observed in borings located within the sand and gravel chemical flow paths.

Accurate estimates of K are necessary to assess chemical migration rates and design a groundwater extraction system capable of capturing chemicals migrating from the landfill. It is believed that the methods are applicable to sites with good geologic definition (using traditional soil boring methods) and hydrogeologic understanding of groundwater flow paths (based on groundwater contour mapping), a general understanding of chemical travel times and site area water balances.

HYDROGEOLOGIC SETTING

The geology of the site consists of a deep (greater than 150 feet below ground surface) bedrock trough filled with morainal sand and gravel. Uniform fine sand overlies the sand and gravel which, in turn, is overlain by a confining glacial marine clay silt. An extensive monitoring well network (more than 70 monitoring well and piezometer screens) provides a detailed description of both groundwater flow conditions and the chemical distribution on a quarterly basis.

Groundwater flows from areas of high groundwater potential in silty soils immediately west of the landfill to areas of lower groundwater potential in sand and gravel soils that occupy the landfill and stretch southward to the lake (southern flow path) and northward toward the brook (northern flow path) (Fig. 1). Most of the groundwater flowing through the site is believed to originate from precipitation falling on the topographic high along and east of the road. A groundwater divide exists beneath the northern portion of the landfill between MW-106 and MW-108.

Some lateral inflow from the brook drainage basin to the northern site area is expected to occur north of MW-7A through very fine sand and silt soils present along the road (western site modeling boundary). South of MW-7A, a layer of saturated silt and very fine sand, along with higher topography, is interpreted to be a (second) groundwater divide limiting the amount of lateral (i.e., west to east) groundwater

inflow through soils into the site area. Lateral inflow to the site area through the upper fractured portion of the bedrock is interpreted to occur along the entire length of the western boundary.

Landfill chemicals are consistently detected in monitoring wells along the southern and northern flow paths (Fig. 2). The flow paths follow consistent patterns of decreasing hydraulic head and are bounded on either side by higher elevation groundwater. The southern flow path discharges to the lake shore in an area approximately 300 feet by 180 feet. The northern flow path discharges to the brook along an approximate 500 foot reach where the confining clay silt is absent. Where the clay silt is present, a small portion (10%) of the northern flow path discharges upward through the clay silt to the brook.

HYDRAULIC CONDUCTIVITY ESTIMATES

Chemical Travel Times

Groundwater velocities for the southern and northern flow paths were estimated based on landfill operational history (known periods of waste disposal) and distances to known groundwater discharge areas. Tables 1 and 2 list the range of calculated groundwater velocities for the southern and northern flow paths, respectively. Based on this distribution, the most frequently calculated groundwater velocities for the southern and northern flow paths are believed to be the most representative of actual groundwater velocities. Because the predominant site chemical (dimethylformamide or DMF) is infinitely soluble, has low volatility and has a low affinity for organic carbon, no substantial attenuation of DMF is believed to be occurring at the site.

The range of travel times for the southern flow path was selected based on the following site history:

- The maximum time of chemical travel would be 30 years from the early 1950s (the earliest time chemical wastes could have been deposited based on manufacturing plant operational history) to 1980, when residents complained of occasional odors in private well water.

- The minimum time of chemical travel would be five years, based on chemical wastes allegedly disposed of at the southern end of the landfill in 1975 when the plant closed and complaints of occasional odors in private well water in 1980.

The range of distances used for the southern flow path is a minimum of 800 feet (from MW-5A at the southern edge of the landfill to the discharge area in the lake), to a maximum of 1,700 feet from an interpreted groundwater divide near Area B where chemical wastes allegedly were deposited (Fig. 1). Using these ranges with the distances shown in Table 1, the most frequently calculated groundwater velocity for the southern flow path is 60 ft/yr.

The range of travel times used for the northern flow path was based on the following site history:

- The maximum time for chemical transport from the landfill to the groundwater discharge point in the brook was 30 years (i.e., early 1950s to 1983 when chemicals were first detected in the brook).
- The minimum time for chemical travel was eight years (1975 to 1983 when chemical analyses detected waste constituents at Hoyt Brook).

The actual travel time is expected to lie within but probably not at the extremes of this range.

The range of distances over which chemical transport occurred during this period is based on the following site conditions:

- Chemical waste disposal is known to have occurred in Area H (Fig. 1), a distance of 1,400 feet from the brook discharge area. This is the minimum length of travel.
- The maximum distance for chemical transport is estimated to be 2,400 feet from Area B (Fig. 1) which is where chemicals were allegedly deposited and which is near an interpreted groundwater divide between the northern and southern flow paths.

Based on data in Table 2, the most frequently calculated groundwater velocity for the northern flow path is 80 ft/yr.

NOTES:

1. Distances are based on lengths of flow lines originating from possible locations of chemical waste disposal at the landfill and discharging to Hoyt Brook at SP-114.
2. Frequency of velocity column indicates the number of calculated velocities that are equal to or less than the corresponding velocity range, but greater than the previous velocity range.

The following values were used for each flow path:

South	North
$V = 60$ ft/yr $= 0.16$ ft/day	$V = 80$ ft/yr $= 0.22$ ft/day
$n = 0.25$	$n = 0.25$
$i = 0.0017$	$i = 0.0015$
$K = 24$ ft/day (8.5×10^{-3} cm/sec)	$K = 37$ ft/day (1.3×10^{-2} cm/sec)

Water Balance

The water balance method of estimating K for each flow path relies on estimates of volumetric groundwater inflow rates to the southern and northern flow paths and a knowledge of the cross-sectional areas through which groundwater flows out of each flow path. Groundwater that naturally flows into the aquifer under the landfill comes primarily from precipitation recharge and, to a much lesser extent, from groundwater inflow from the west in bedrock. The basis for calculating flow rates from each of the two inflow sources is the groundwater surface contour map for the site. The map is used to measure the land area over which precipitation would infiltrate the landfill cover system and undisturbed soil and, in turn, percolate down to the groundwater system beneath the landfill (Fig. 3). Only areas within the landfill groundwater shed were included in estimating precipitation recharge. For each flow path, the area of the landfill cover system was given a groundwater recharge rate of 3 in/yr which was based on the design specification and simulation with the Hydrologic Evaluation of Landfill Performance (HELP) model. Uncapped areas were given a recharge of 14 in/yr based on discussion with the local watershed district and water balances calculated for the site. The cross-sectional areas of each flow path were determined from geologic profiles in Figure 4.

Using these calculated velocities, the average hydraulic gradient from the landfill (MW-5A) to the discharge area at the lakeshore (SW-8, near MW-212) and from the landfill (MW-10B) to the brook (at SP-114) in the north was calculated from quarterly water level data for the period from May 1988 to May 1990. Using an effective porosity value of 0.25, a hydraulic conductivity was calculated for each flow path by rearranging Darcy's law as follows:

$$V = \frac{Ki}{n} \; ; \text{ then } K = \frac{n}{i} \qquad \text{where} \tag{1}$$

V = average linear groundwater velocity (ft/day)
K = hydraulic conductivity (ft/day)
i = hydraulic gradient in the direction of flow (ft/ft)
n = porosity (dimensionless)

Figure 5
Simulated Sand and Gravel Head Contours

No groundwater inflow from the west in soils is expected to occur based on groundwater surface mapping at the site, which indicates the road approximates a groundwater divide. Larger site area mapping supports this interpretation. To estimate bedrock inflows from the west, a bedrock thickness of 20 feet was assumed to contribute groundwater from the west to the landfill flow path systems. The width of the zone along the road and the hydraulic gradient were based on the groundwater surface contour map (Fig. 1), which also indicates the proportion of inflow to the southern and northern flow paths (i.e., 70% to the south and 30% to the north). Bedrock K was based on the geometric mean of bedrock permeabilities measured sitewide (i.e., falling-head and packer permeability testing), and on the results of groundwater modeling.

Using Darcy's Law, K may be calculated knowing the volumetric flowrate, hydraulic gradient and area through which groundwater flows, as follows:

$$Q = KiA \qquad (2)$$

and, rearranging, $K = \dfrac{Q}{iA}$

where:
Q = volumetric flow rate (ft³/day)
K = hydraulic conductivity (ft/day)
A = area through which flow occurs (ft²)
i = hydraulic gradient (ft/ft)

The following values were used for each flow path:

South	North
Q = 6,300 ft³/day	Q = 3,000 ft³/day
i = 0.0017	i = 0.0015 ft/ft
A = 27,000 ft²	A = 52,000 ft²
K = 140 ft/day (4.9x10⁻² cm/sec)	K = 38 ft/day (1.4x10⁻² cm/sec)

Results of direct measurement of seepage flux (with seepage meters) into the lake at the southern discharge area were consistent with the volumetric flowrate Q calculated for the southern flow path system.

Hydraulic Conductivity Testing

The results of rising-head and pressure (packer) testing are presented in Table 3. Hydraulic conductivity values from rising-head test data were calculated using AQTESOLV Software.[1] Based on results of testing, K values for the soil units in which well screens are located were estimated to range from 0.28 to 280 ft/day (9.8x10⁻⁵ to 1x10⁻¹ cm/sec). Values estimated at well screens placed in bedrock ranged from less than 0.00037 to 57 ft/day (1.3x10⁻⁷ to 2.0x10⁻² cm/sec).

Of primary interest are K values measured at well screens within the southern and northern chemical flow paths. Based on a review of the chemical distribution in groundwater in the southern flow path, we concluded that MW-5A, MW-8B and MW-212B monitor groundwater within sandy soils. The geometric mean of K values measured at MW-8B and MW-212B is 24 ft/day (8.5x10⁻³ cm/sec). (No data are currently available for MW-5A.) Geometric mean is used to average hydraulic conductivity over a given area because horizontal values tend to be lognormally distributed.[2] A value of greater than 170 ft/day (6.1x10⁻² cm/sec) was calculated for MW-8C, which is screened in somewhat coarser sand than MW-8B. This estimate of 170 ft/day is considered more representative of K in the southern flow path, considering: (1) the coarse texture of soils present at MW-212 and MW-8, (2) the general tendency for single well K tests in soil to underestimate formation K, (3) the results of other methods of K estimates described above, and (4) the results of the aquifer pumping test.

In the northern flow path, well screens that monitor the sand and gravel include MW-10B, MW-208B,C, MW-15A, MW-210B,C and MW-306B. The geometric mean of calculated values for these well screens is 48 ft/day (1.7x10⁻² cm/sec). (No data are currently available for MW-15A.) This mean value is consistent with values calculated for other wells north of the landfill.

Groundwater Model

A three-layer groundwater flow and transport model was configured representing the bedrock (Layer 1), sand and gravel (Layer 2) and clay silt/fine sand (Layer 3) geology present at the site. The primary interest was in calibrating the Layer 2 (sand and gravel) heads to those observed at the site. To achieve the best steady-state match of computed and observed heads (Fig. 5), K in the southern flow path was adjusted to 175 ft/day (6.2x10⁻² cm/sec) and in the northern flow path was adjusted to 50 ft/day (1.8x10⁻² cm/sec). Simulation of the aquifer pumping test with the model indicated good correlation of observed and simulated heads at the end of pumping (Fig. 6) validating this portion of the model.
Figure 6
Measured and Simulated Drawdown Aquifer Pumping Test

Aquifer Pumping Test

Based on results of the aquifer pumping test, the geometric mean K was calculated from transmissivity (T) estimates for well screens within the southern and northern flow paths by dividing T by the aquifer thickness. These values were 140 ft/day (4.8×10^{-2} cm/sec) and 80 ft/day (2.8×10^{-2} cm/sec) for the southern and northern flow paths, respectively. Because pumping tests generally provide the most accurate measurements of bulk aquifer parameters and the pumping test values are comparable to the range of values calculated using the other methods, values derived from the pumping test are believed most representative of the actual flow path K.

Hydraulic conductivities and groundwater flowrates (assuming a porosity of 0.25 and a hydraulic gradient of 0.0017 for the south and 0.0015 for the north) estimated using the five methods described are summarized in Table 4.

Table 4
Permeability Estimates

| METHOD | SOUTHERN FLOWPATH | | | NORTHERN FLOWPATH | | |
| | PERMEABILITY | | GROUNDWATER VELOCITY | PERMEABILITY | | GROUNDWATER VELOCITY |
	cm/sec	ft/day	ft/yr	cm/sec	ft/day	ft/yr
Geometric Mean of Well Screens with Flowpath	8.5×10^{-3}	24	60	1.7×10^{-2}	48	110
Landfill Operational History	8.5×10^{-3}	24	60	1.3×10^{-2}	37	81
Water Balance	4.9×10^{-2}	140	350	1.4×10^{-2}	38	83
Groundwater Model	6.4×10^{-2}	180	450	1.8×10^{-2}	50	110
Aquifer Pumping Test	4.9×10^{-2}	140	350	2.8×10^{-2}	80	80

NOTES: cm/sec - centimeters per second
ft/day feet per day
ft/yr - feet per year

Groundwater velocities are calculated based on horizontal hydraulic gradients of 0.0017 ft/ft for the southern flowpath and 0.0015 ft/ft for the northern flowpath and a porosity of 0.25 (for both flowpaths). Gradients are the two-year arithmetic mean for the period May 1988 to May 1990.

CONCLUSIONS

Considering site histories of waste disposal and discharge, fluid mass balance of annual inflows and outflows from a site area and traditional hydraulic conductivity testing, simple Darcy-based groundwater flow calculations may be used to accurately estimate K of chemical groundwater flow path systems. Providing site hydrogeology does not indicate a highly stratified, nonuniform subsurface and the chemical distribution is well defined, estimates of K within a factor of 2 or 3 of calibrated groundwater model and pumping test derived values were obtained. Given the often high cost and effort associated with aquifer pumping tests at Superfund sites (e.g., considering water storage and treatment requirements), the alternative methods for estimating K presented herein are believed to be relatively accurate, appropriate and cost-effective.

Use of Groundwater Modeling During Superfund Cleanup

ABSTRACT

Numerical modeling for both groundwater flow and contaminant transport predictions has long been used during RI/FS at federal or state Superfund sites. The need for accurate predictive modeling does not end when the selection of the remedial alternatives is complete; rather, it becomes a necessary tool to design the remedial system, to assess the continuing applicability of the remedial design, to determine risks associated with remediation and to predict changes in the remedial approach that may become necessary through time.

At the Seymour site in Indiana, groundwater flow and transport modeling were used to help design the remedial action which consists of pumping-and-treating, a soil vapor extraction system, bioremediation of contaminated soils and a low permeability cap placed over the 13-acre site. The soils and groundwater are contaminated with a mixture of approximately 10 major contaminants with an additional 25 minor constituents. Because the compounds have different affinities for the aquifer materials, the vertical and horizontal distributions of chemicals in the groundwater change with distance from the source. Since the original pump-and-treat system was specified, after the FS was prepared, the hydraulic capture and treatment parameters have had to be modified because of changes in the plume configuration and the types of contaminants being extracted. A new three-dimensional model was constructed to predict the number and pumpage of extraction wells and to specify the final design of the groundwater treatment system. The model will continue to be used to refine the treatment process as the concentrations of various chemical constituents change during remediation. The model will also be used to optimize the extraction well flowrates so that the cleanup goals will be achieved within the specified time period.

Part of the groundwater treatment system consists of an air stripper to remove the changing mixture of VOCs from the groundwater. The stripper emissions are vented to the atmosphere in such a manner that the 1×10^{-6} excess cancer risk will not be exceeded at the site's nearest receptor. The groundwater model will, therefore, continue to be used over the entire period of remediation to predict concentrations emanating from the air stripper so that a risk assessment may be performed prior to the actual emission. The pumping system will be optimized based on the results of the risk assessment so that the air stripper emissions when added to the vapor extraction system emissions will not exceed the 1×10^{6} cancer risk.

INTRODUCTION

The purpose of this paper is to provide a case study example of the need for this practical approach to modeling activities. The case study is based on our experience with the remediation of the Seymour site in Indiana, one of the first sites to be placed on the NPL and also one of the first sites to reach the remediation stage. This paper will present the types of design applications of a numerical flow and transport model that were performed after the ROD was issued in response to changes in the understanding of the site geology and changes in the size of the area of concern surrounding the site.

DESCRIPTION OF THE SEYMOUR SITE

History

The Seymour site is a 13-acre facility that was formerly occupied by Seymour Recycling Corporation which recovered solvents and other organic products from industrial wastes. In 1980, the facility was shut down by the U.S. EPA due to releases of contaminants into surface water and the air and due to a series of explosions that occurred at the site.

Many different chemicals were handled at the Seymour site, including 1,2 dichloroethene, trichloroethene, tetrachloroethene, as well as tetrahydrofuran, acetone, phenol, benzoic acid, benzene, toluene, 1,4-dioxane, chloroethane and various alcohols. Considerable quantities of the liquid contaminants have migrated to the subsurface where they now form portions of a plume in the aquifer beneath and near the site.

In 1980, the U.S. EPA removed stored drums and tanks from the site and excavated approximately one foot of surface materials. These materials were replaced by a low permeability cap covering approximately 75% of the site. From 1984 to 1986, the U.S. EPA conducted a RI at the site and in 1986 the FS and the ROD were also issued. The recommended alternative in the ROD was modified during Consent Decree negotiations with the PRPs involved with the site and in 1988 construction began on the remedial facilities. The cleanup measures include a pumping-and-treatment system (initial plume stabilizing and long-term), a soil vapor extraction system, in situ bioremediation of contaminated soils and a low permeability, RCRA-type cap placed over the 13-acre site. A schematic of the site and its environs is shown in Figure 1. The plume as it was known in 1985 is shown in Figure 2.

Hydrogeology

The Seymour site is underlain by various facies of the Atherton Formation. A cross section of the geology is shown in Figure 3. Above the shale bedrock, which dips to the southeast, lies a 10 to 20 foot thick coarse sand and gravel layer known as the Deep Aquifer. This layer was probably deposited by fluvial action and it increases in thickness towards the southeast. Towards the northwest, the Deep Aquifer thins out until it is replaced by different glacio-fluvial deposits associated with the White River Flood Plain. The groundwater flows to the south-southeast in the Deep Aquifer and is heavily influenced by the pumping activities of nearby supply wells.
Figure 1
Site Location

Above the Deep Aquifer lies a lower permeability lacustrine deposit known as the confining layer. This layer is from 5 to 35 feet thick, acts as a confining unit to the Deep Aquifer and also thins out to the northwest where it is replaced by the White River Flood Plain Deposits.

Above the confining layer are located glacio-fluvial and eolian deposits known as the Shallow Aquifer. These are unconfined and finer grained than the Deep Aquifer and are similar to the White River Deposits into which they grade towards the northwest. In the vicinity of the site, the shallow aquifer is from 20 to 35 feet thick and it increases in thickness up to 60 feet towards the northwest. The groundwater flows north and west towards the White River in the Shallow Aquifer.

The White River Deposits were previously not known to be significantly different from the configuration of the aquifers to the south. However, recent geologic borings in this area have shown medium to coarse sands throughout the 60-foot thickness of the deposits without any indication of layering or lower permeability units. These changes have had to be incorporated into the flow model as will be described below.

Distribution of Contaminants

The major portion of the contaminants is located in a plume in the shallow aquifer as shown in Figure 4. Note that a change in gradient, which is caused by a change in the permeability of the deposits, occurs at the contact between the Shallow Aquifer and the White River Deposits. The plume shows evidence of this change by taking a sharp bend to the west at the contact.

In its movement north and west, the plume has been separated into its constituents according to the retardation factor of each chemical. This separation process has resulted in the leading portions of the plume being composed predominantly of 1,4-dioxane and several alcohols. Tetrahydrofuran occurs along with 1,4-dioxane closer to the site and contaminants such as chloroethane and the less mobile compounds like benzene and toluene, occur together at increasing concentrations closer to the site.

The plume of contaminants has also been sinking as it moves north and west. Cluster wells show that the plume occupies the upper portions of the Shallow Aquifer near the site and gradually sinks to approximately 60 feet (to the top of the bedrock) in the White River Deposits.

FLOW AND TRANSPORT MODELING

The knowledge of the geology of the site was limited during the FS and the White River Flood Plain formation was not known. At that time, a three-dimensional finite difference model was constructed and used to evaluate various alternative pumping scenarios. This process resulted in selection of the U.S. EPA's preferred alternative which was modified during the Consent Decree negotiations. The model and pumping system proved to be inadequate when later data showed that the plume was larger than had been thought and that significant changes in geology occurred along the plume's migration route.

Model Construction and Calibration

A new three-dimensional finite difference model was constructed in 1989 in response to the changed conditions at the site. This new model was made much larger than the model in the FS and included the changes in geology that had been recently observed.

Groundwater flow at the Seymour site was modeled with the USGS Modular Three-Dimensional Finite-Difference Groundwater Flow Code, also known as MODFLOW. MODFLOW is well-documented, publicly available and generally accepted within the scientific community.

Model Discretization

As shown in Figure 5, the model covers the Seymour site and a large amount of the surrounding area. The model grid covers 29 mi^2 around the Seymour site with an east-west dimension of 29,000 ft and a north-south dimension of 28,000 ft. The model is much larger than the area of interest in order to incorporate regional groundwater flow effects. The model boundaries extend to the topographic highs located south and west and to the East Fork of the White River to the north of the site. The eastern boundary of the model was planned to extend past the cone of depression caused by the City of Seymour's pumping wells located approximately 2,500 feet west of the site.

The maximum cell dimension in the model is 1,600 ft. These large cells were placed away from the areas of interest near the site, such as in the extreme eastern and western areas. Finer grid spacings were used near the location of the Seymour site. The smallest cells measure 200 ft on a side.

The model contains three layers corresponding to the Shallow Aquifer (Layer 1), the Confining Unit (Layer 2) and the Deep Aquifer (Layer 3). The Shallow Aquifer is assumed to be unconfined and the lower two layers are confined. The flow of groundwater between model layers is represented in the model using a leakance term. The leakance term incorporates the vertical permeability characteristic of each layer.

In the original model, Layer 3 pinched out north of Von Fange Ditch. During the later investigation northwest of the site, this was determined to be inaccurate. Layer 3 sediments continue as far as the furthest northwest drilled well point. With this new information, Layer 3 sediments are predicted to extend up to the East Fork of the White River. In the model, Layer 3 sediments continue north up to the East Fork of the White River as part of hydraulic conductivity Zone 4.

Hydraulic conductivity Zone 4 includes all three layers north of the site in the area where the confining unit disappears. Another leakance zone was set up in the northern portion of the grid to include the leakance due to the incorporation of Zone 4.

Boundary Conditions

Three primary types of numerical conditions were used in the model to represent these physical boundaries to the system. The model boundary conditions are termed constant head, constant flux and head-dependent flux boundaries.

Constant head boundaries in Layer 1 and the White River Deposits are used to represent all surface water features, including the East Fork of the White River and other small streams. Elevations for the surface water bodies were estimated from the USGS topographic maps of the area.

East-West Creek is represented by a head-dependent flux condition. The creek occasionally goes dry and so it could not be classified as a constant head boundary. It is termed a head-dependent flux boundary or, more specifically, a drain.

Von Fange Ditch and Heddy Run are represented by river boundaries. This configuration allows the groundwater to pass under the river nodes in Layer 1 and is more representative of field conditions.

Automatic Calibration Technique

The model was calibrated using a nonlinear least-squares technique known as the Marquardt Algorithm. This technique is often referred to as automatic calibration or inverse modeling. Inverse techniques determine optimum aquifer parameter values for a given model configuration (grid spacing and boundary conditions) that provide the best statistical calibration. The calibration for the model was arrived at through an iterating procedure involving inverse model runs and subsequent redefinition of aquifer parameter zones and boundary conditions.

The steady-state calibration was performed by comparing model-calculated water levels to those measured in the field on Sunday, April 18, 1990 between 1:30 p.m. and 7:30 p.m. The values of the residuals of all calibration targets used are shown in Table 1 and the modeled water-level contours along with the residual values are shown in Figure 6.

Contaminant Transport Modeling

The groundwater flow model was calibrated to steady-state conditions over an area much larger than the Seymour site. A regional flow model was developed in order to use realistic hydrologic boundaries. This large scale was not appropriate for analysis of contaminant transport near the site, however, where a smaller scale and much finer grid were required. Thus, a new model was developed that was applicable to an area north and west of the Seymour site in the area of groundwater contamination. Boundary conditions and aquifer properties were defined by the previous groundwater flow modeling effort.

This form of transport analysis has been called the Grid Refinement Approach or the Telescopic Mesh Refinement technique. This technique was developed to account for regional groundwater flow conditions at a local scale (Fig. 7).

No additional calibration was performed on the Seymour transport model. This includes both groundwater flow and contaminant transport analyses. In the transport model, contaminant concentrations were initialized in the model at observed concentrations and simulated into the future. The purpose of the analysis was not to determine how the plume developed, but to estimate the loading of contaminants to the recovery system and to determine the influence of the pumping on the plume's configuration as compared to monitoring well analytical results.

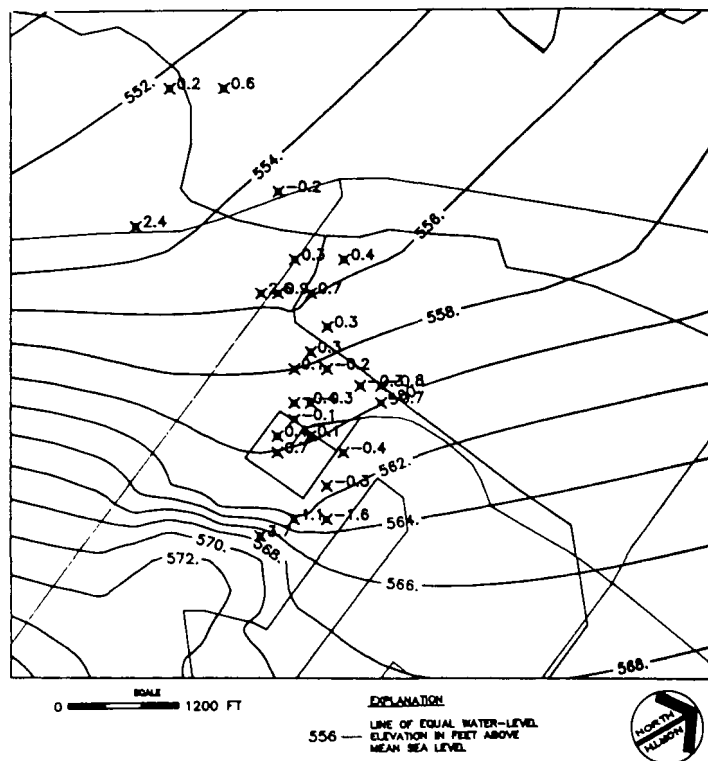
In all cases, the source of contamination was assumed to be controlled and its continued contribution to the groundwater was assumed to be negligible.


Figure 6
Calibrated Residuals in Layer 1

The transport analysis as described here proceeds in two phases after construction of the local scale refined model. In the first phase, an analysis of convective transport (particle-tracking) is used to determine the capture zones of several recovery well scenarios. After determining that the pumping rates for each scenario capture the area of the contaminant plume, a solute transport model is run to estimate contaminant concentrations in each recovery well.

Additional parameters required for the transport model included porosity, dispersivity and retardation coefficients. The porosity was estimated at 0.3 (30%). This value was chosen as a representative value for sand and gravel formations. No site-specific measurements were available. Longitudinal dispersivity was estimated to be 200 ft, with a transverse dispersivity of 20 ft. Dispersivity is a scale-dependent variable and is normally estimated to be 10% of the length of the contaminant plume. The Seymour plumes for mobile contaminants, such as tetrahydrofuran, are approximately 2,000 ft long. Retardation factors were obtained from the RI data for each contaminant simulated in the model.

Three example compounds that were simulated are as follows:

- Chloroethane $R = 2.1$
- Tetrahydrofuran $R = 1.02$
- 1,4-Dioxane $R = 1.0$

The spatial distribution of each compound was used as the initial conditions for the contaminant transport model. Two different sets of initial conditions were used for each compound representing average concentrations and maximum observed contaminations. The data used to determine the initial spatial distribution were the analytical results from the fall 1989 and spring 1990 sampling events. The raw data were contoured by hand by Geraghty & Miller personnel and the contours were digitized for input into the model.

APPLICATIONS OF THE MODEL
TO REMEDIAL DESIGN AND OPERATION

The new flow and transport model is being used to design the final pumpage and treatment system at the Seymour site. As shown in Figure 8, hydraulic capture analysis using particle tracking is helping to locate extraction wells and to specify their pumping rate. Concentration profiles such as shown in Figure 9 for chloroethane are helping to predict the concentration through time of each contaminant at each pumping well. The concentration vs time graphs are allowing the system designers to specify the appropriate mix of treatment technologies (air stripping, carbon adsorption and biological treatment) at the appropriate time. One alternative, for example, is that the extraction well (E5) that will intercept the 1,4-dioxane portion of the plume may be discharged directly to the city's sewers for treatment in the city's POTW provided that the concentration profile shows that no significant concentration of other contaminants will be intercepted by this well over the anticipated life of the remedial action. This information is critical to the continued discharge to the POTW from this portion of the plume. The presence of other contaminants could cause this portion of the remediation to be changed in the future, perhaps by adding a pretreatment system.

Similarly, the concentration profiles for the two other plume stabilizing extraction wells seen in Figure 8 closer to the site (E3 and E4) have been generated. These are shown for chloroethane and tetrahydrofuran in Figures 9 and 10. The operation of these wells is constrained by associated air and water emissions from the pretreatment facility. The object of the extraction system is to minimize these emissions while maximizing the rate at which contaminants are extracted from the

aquifer. The model is being used to generate the concentration profiles from which air risks and the level of carbon treatment may be evaluated depending on the pumping rates and locations of the extraction wells. The pumping rates will be adjusted to provide treatment of the groundwater in the most cost-effective manner while maintaining air emissions below the 1×10^{-6} excess cancer risk rate and while maintaining compliance with effluent discharge limitations. An alternative pumping scenario is shown in Figure 11. The predicted air risk from this pumping strategy is too great and therefore will not be feasible without treatment of the emissions. The cost of this treatment must be evaluated against the incremental decrease in cleanup time to determine the best course of action.

E5=100 gpm; E3=30 gpm; E4=50 gpm

As sampling is performed to verify that site cleanup is proceeding, the new monitoring data will be used to update the solute transport initial conditions annually. In this manner, the predictions of concentrations in the extracted groundwater will become increasingly more accurate.

CONCLUSION

It has become evident through our experiences at the Seymour site that numerical modeling at hazardous material cleanup sites will be used for other tasks in addition to selection of a remedial alternative. Modeling will be an indispensable tool for determining risks, for optimizing the operation of an extraction system and for designing various components of a groundwater treatment system. For these applications a model must be as accurate as possible, i.e., capable of being updated in terms of its construction for groundwater flow and in terms of its initialization for solute transport simulation. With these attributes, a model will incorporate the best possible information prior to its use as a basis for design.

ABSTRACT

This paper proposes a semianalytical model to estimate on-site air concentrations, based on the principle of mass conservation, continuous plume behavior and local meteorological conditions. The predictive scheme is based on the conventional "box" model, but is refined to incorporate considerations such as wind shear near the surface, development of plume thickness and atmospheric stability. The model has been tested against measurements of air concentrations utilizing the measured air emission rates for several Superfund sites. Preliminary findings indicate that the model predictions are in good agreement with direct measurements of on-site air concentrations at these sites. The proposed model is supported by a computer program that incorporates parameters utilized by the U.S. EPA in the UNAMAP6 Gaussian plume models.

INTRODUCTION

The ability to estimate on-site air concentrations with reasonable accuracy has assumed an increasingly prominent role in evaluating potential public health risks associated with activities at contaminated sites. The need for air concentration estimates may arise during: (1) assessment of base line risks associated with Superfund sites; (2) comparison of the risks associated with different remedial alternatives for contaminated site cleanups; (3) evaluation of on-site workers' health risks resulting from the development of contaminated industrial properties; and (4) determination of site cleanup criteria based on a prescribed acceptable public health risk. Errors introduced into the estimates of on-site air concentrations will extend into subsequent estimates of health risks and thus undermine the usefulness of the modeling effort and subsequent risk analyses. Accurate estimation of on-site air concentrations for a contaminated site is therefore essential to provide meaningful predictions of health risks for decision-makers.

Air emissions at contaminated sites normally are classified as continuous ground-level area-source emissions with negligible buoyancy effect and low source strength. Exposures to such emissions for on-site workers and nearby residents are of particular concern to the public and regulatory agencies. Estimation of the on-site air concentration by applying a conventional diffusion model, Gaussian or non-Gaussian, is inappropriate because the atmospheric dispersion mechanism for short-range dispersion is different from that for long-range dispersion. Taylor's theory of diffusion by continuous movements provides a typical illustration of this fact.[1] Furthermore, most dispersion models are derived with the given assumption that an infinite concentration, or some prescribed initial concentration, exists at the source location; these models fail to address the spatial variation of on-site air concentrations.

To address the limitations of applying conventional dispersion modeling techniques to the estimation of on-site air concentrations, a variety of approaches have been considered. The simplest approach to modeling the on-site air concentration is to modify the Gaussian point source solution and apply it to an area source by treating the area emissions as a concentrated point emission located either at the center of the actual source or upwind by a virtual distance. Turner[2] defined the virtual upwind distance by backcalculating the lateral dispersion coefficient from the Pasquill-Gifford curves using a reduced source width. Another similar virtual upwind point source dispersion equation was recommended by the U.S. EPA.[3] Both approaches, however, create an unrealistic estimate of the spatial variation of concentrations within the source area, depending on the size of the source.

A second approach is the "box" model which has been widely used in urban air pollution.[4,5,6] Gifford and Hanna[6] have proposed a formula with an empirical coefficient to correlate predicted concentrations to field observations. The empirical coefficient was derived from extensive air pollution data (average annual emissions and concentrations of particles for 44 United States cities and SO_2 data for 20 United States cities). This box model approach was greatly simplified in a document published by the U.S. EPA addressing the development of an advisory level for PCB cleanup,[7] by assuming a uniform mixing within a 2-meter high virtual box. The box model provides a useful tool in estimating the on-site air concentration. Its predictions, however, can be overly conservative if the model is not calibrated and validated by field measurements.

A third approach models short-range air dispersion from area sources based on K-theory.[8] K-theory involves application of the atmospheric diffusion equation using empirical eddy diffusivities for the time-averaged turbulent flux. The approach employs the solution of a two-dimensional atmospheric diffusion equation.[9,10] This model is more complicated than a Gaussian model and the expected improvement in accuracy has yet to be evaluated.

This paper proposes a simple but effective model[11] based on the principle of mass conservation, continuous plume behavior and local meteorological conditions. The model, referred to as the modified box model, has been developed to estimate the on-site air concentration that most Gaussian air dispersion models are unable to predict. The modified box model is refined from the conventional box model to incorporate considerations of wind shear near the surface, development of plume thickness, vertical concentration distribution and atmospheric stability while at the same time maintaining that model's simplicity. It calculates the on-site or near-field air concentrations from an area source utilizing emission estimates and on-site meteorological observations. The model's predictions have been compared with field observations of air emissions and on-site air concentrations. Preliminary findings indicate that the model predictions are in good agreement with direct measurements of on-site air concentrations at waste sites.

ESTIMATING ON-SITE AIR CONCENTRATIONS

If one represents the contaminated site of interest as a finite area source of strength E, the pollutants emitted can be considered to be contained within an imaginary plume boundary from the upwind edge to the down-wind edge of the area as shown in Figure 1. The height of the imaginary boundary, Zi, is a function of the downwind distance, oncoming wind velocity and atmospheric stability. Based on Gaussian distribution, more than 95% of the pollutants will be entrapped within a depth of 2.15 δ_z, where δ_z is the standard deviation of the vertical concentration distribution.
Figure 1
The Modified "Box" Model

If c(z) is the concentration at the downwind edge of the area source and c'a is the ambient concentration beyond the imaginary boundary layer, the conservation of mass states that

$$\int_s (c(z) \quad c_a) \; \vec{u}(z) \cdot \vec{n} \; dS \quad 0,$$ (1)

where:

$c(z)$ is the air concentration at the downwind edge, g/m^3
$u(z)$ is the atmospheric wind velocity at height z, m/sec
n is the unit vector normal to the imaginary boundary
S is the surface of the imaginary plume boundary, m

If the background air concentration, c_a, and the lateral dispersion are neglected, Equation 1 can be rewritten as:

$$\int_A E \; dA = \int_o^{z_i} \int_o^W c(z) \; u(z) \; dy \; dz,$$ (2)

where:

A is the size of the area source, m^2
W is the width of the area source, m
E is the area source strength, g/m^2-sec
y,z are the rectangular coordinates, with y the cross-wind direction and z the azimuth direction

The wind profile, u(z), in the above equation can be described by a power-law velocity profile:[12]

$$u(z) = u_{10} \; (\frac{z}{10})^P$$ (3)

where:

u_{10} is the surface wind speed at 10 m height, m/sec
z is the height above ground, m
p is the wind profile exponent

It is generally accepted that the vertical concentration distribution in a continuous plume follows the Gaussian distribution such that c(z) can be expressed in terms of the ground-level concentration:

$$c(z) = c_o \; exp(- z^2/2\sigma_z^2)$$ (4)

where:

co is the ground-level concentration downwind of the source, g/m^3

By substituting u(z) and c(z) with the relationships illustrated in Equations 3 and 4, respectively, Equation 2 can now be presented as follows:

$$E \cdot \Delta X \cdot W \quad \int_u^{2.15\sigma_z} \int_o^W c_o \cdot exp(-z^2/2\sigma_z^2) \cdot u_{10} \cdot (z/10)^P \; dy \; dz$$ (5)

where:

ΔX is the downwind distance from the upwind edge of the source, m. The integration can be manipulated and simplified to:

$$c_o = [\quad u_{10} \; \sigma_z^{p+1} \; I(p)]^{-1} \; E \cdot \Delta X$$ (6)

where:

$$I(p) = \frac{1}{10^P} \int_{\theta=0}^{\theta=2.15} \theta^P \; exp(-\theta^2/2) \; d\theta$$

The integration for I(p) can be performed with a simple numerical integration scheme. Figure 2 displays I(p) for various wind profiles. Default values for the wind-profile exponent as recommended by the U.S. EPA[13] can be readily incorporated into this refined box model. The standard deviation of the vertical concentration distribution can be defined under site-specific conditions or can be defined in accordance with many standard procedures.[13,14,15] A power-law expression for δ_z, which reflects the various atmospheric stabilities, is preferred in the current modeling for mathematical simplicity and consistency with U.S. EPA air dispersion models.

Figure 2
The Integration Function Utilized in Figure 6

Since Equation 6 takes into consideration the ambient wind speed and atmospheric stability, the real-time meteorological data and the joint frequency of occurrence of wind-speed and wind-direction classified by the Pasquill-Gifford stability categories [or STAR[17]] can be incorporated to yield an annual average concentration, c:

$$\bar{c} = \sum_{i=1}^{6} \sum_{j=1}^{6} \sum_{k=1}^{16} f_{ijk} \frac{\Delta X \; E}{(u_{10})_j \; (\sigma_z)_i^{P_i+1} \; I(p_i)}$$ (7)

where:

i is the wind speed category
j is the atmospheric stability category
k is the wind direction category
f_{ijk} is the frequency of time in a year for specified i, j and k

A computer program has been developed to perform the above averaging process.

MODEL COMPARISONS

On-Site Air Concentrations

Field observations of air emission rates were employed in Equation 6 to yield on-site air concentrations at two waste sites under undisturbed conditions. Predictions from the modified box model were then compared to the results of direct on-site air measurements in order to verify the accuracy of the model.

At the first site (Landfill 1), sulfur dioxide (SO_2) and total hydrocarbon (THC) concentrations were reported in a Superfund remedial investigation.[17,18] Air samples were collected 6 inches above the surface at 100 different locations at the site. Data consisting of 32 field observations and 10 background measurements (remaining after quality control on the sampling procedures) were examined in the current assessment.

For SO_2, 8 out of 32 surface samples and 7 out of 10 background samples were below the detection limit of the instrument. The observed background concentrations were all within 1.5 times the detection limit, which indicated that the true background concentration fluctuated around the detection limit. To yield a reasonable arithmetic mean, samples below the detection limit were assigned a value of 0.5 times the detection limit. For THC, all observations were above the detection limit. However, the average background concentration exceeded the average concentration of all surface samples. Table 1 shows the sample statistics for SO_2 and THC. To determine the statistical significance of the observed data, the Wilcoxon Rank Sum Test was conducted in addition to the analysis of variance for both chemical compounds. The average SO_2 concentration was concluded to be statistically significantly different from the background concentration based on the Wilcoxon Rank Sum Test with a p-value of 0.0101. The THC concentrations, however, were concluded to vary insignificantly from the background concentration, since they failed both the analysis of variance and the Wilcoxon Rank Sum Test (p-value > 0.5) and therefore were not considered further in this comparison.

Table 1
Statistics for Air Concentration Sampled from Landfill 1[17]

P - Value	0.0101		> 0.5	
Summary				
Mean	0.00933 ppmv or 24.88 ug/m^3		undistinguishable ...	

Direct emission measurements at the same site were performed using the surface flux chamber technique. The mean SO_2 emission rate computed from 18 measurements was 3.33 $\mu g/m^2$-sec, with a standard deviation of 9.05 $\mu g/m^2$-sec. Considering the inhomogeneity of soil contamination at a large waste landfill, such variation in the emission rate is not unexpected. Both the emission and ambient air measurements were conducted during the day. The annual average wind speed

of 3 m/sec, as reported from a nearby weather monitoring station, was employed as the ambient wind speed. Three average atmospheric stabilities were assessed to provide a comparison. Based on an annual mean wind speed of 3.0 m/sec and an atmospheric stability of D class that was considered to characterize the site, Table 2 shows that data for the measured mean SO_2 concentration differs from the modified box model prediction by only 2%.

Table 2
Comparison of the Predicted and Measured SO_2 Emission Rates at Landfill 1[17]

Atmospheric Stability	Ambient Wind Speed, m/s	Emission rate, ug/m^2·s		Air concentration, ug/m^3

D	4	3.33	12.38	24.88	55.28	18.32	68.09

* : High value is defined as Mean + 1 S.D.

In another recent Superfund site (Landfill 2) remedial investigation,[19] limited on-site air samples were taken at an undisturbed waste site with specified upwind/downwind sampling locations. Downwind samples collected during the day were statistically undistinguishable from the upwind sample. The nighttime samples, however, were distinguishable from the upwind sample and were adopted for the current analysis. Chemical vapor emission rates were also measured using the surface flux chamber technique. The chemical vapor emission rates are summarized from the report[19] and tabulated as follows:

Chemical Constituent	Number of Samples	Emission rate, μg/m^2-sec	
		Mean	S.D.
Benzene	7	9.98×10^{-3}	2.67×10^{-3}
Toluene	7	1.37×10^{-2}	4.35×10^{-3}
1,1,1-Trichloroethylene	4	1.00×10^{-2}	4.13×10^{-3}

Surface meteorological observations made concurrently with the emission rate measurements indicated that air samples were collected under a near calm condition with an average wind speed of approximately 0.8 m/sec.

The modified box model was used with F stability and a wind speed of 0.8 m/sec to yield on-site air concentrations. The results are presented in Table 3. The modified box model underpredicts the on-site air concentration by a factor ranging from 5 to 8. Given the experimental uncertainty involved in field measurements of emission rates and air concentration, the concentrations estimates are considered to be consistent with the field measurements.

Near-Field Air Concentrations

In addition to estimating on-site air concentrations, the modified box model can be used to estimate the near-field air concentrations provided that the receptor is located within a short distance from the area source (e.g., < 2.5 source-widths downwind of a source has been considered an appropriate distance) such that the cross-wind dispersion is insignificant. An examination of the model accuracy was conducted by com-

paring concentrations predicted by the modified box model with those predicted by a series of other air dispersion models. Ambient air concentrations for a California landfill (Landfill 3) reported in a study by Baker[20] were used as criteria for the comparison.

Ambient vinyl chloride concentrations were measured for 5 days at two receptor locations, Sites A and B, located within one source-width distance downwind of the landfill. Baker[20] compared the field observations to the predictions of four air dispersion schemes as follows:

• The maximum ground-level concentration resulting from a ground-level point source located at the center of the landfill

• The maximum ground-level concentration modified from Taylor[1] by utilizing a virtual upwind point source to represent a square area source

• A virtual point source approximation similar to Turner[2] but with modifications of the virtual downwind distance and empirical coefficients

• A simple box model developed for estimation of urban air pollution with adjusted downwind distance.

Hourly surface meteorological observations recorded at a nearby airport were employed to characterize the on-site meteorological conditions. Unfortunately, on-site air emission measurements were not conducted during the Landfill 3 air sampling program and 30 of the 120 hours measured at the nearby airport during the experiment were under conditions of no wind. In his model evaluation, Baker assumed that the receptors were directly downwind of the landfill and assigned an ambient wind speed of 1 m/sec for all no-wind conditions. Excluding the hours when winds were not upwind of the landfill, nearly 70% of the time that the receptors were assumed to be downwind of the landfill were under no-wind conditions. Although it is a generally accepted approach in air dispersion modeling to assign a wind speed for no-wind conditions, the uncertainty introduced in the concentration estimate by such meteorological adjustments should not be ignored.

Table 3
Statistics for Air Samples from Landfill 2 and Comparison of the Predicted and Measured Air Concentrations[19]

| Chemical Constituent | Emission rate (ug/m^2·sec) | | Stability | Wind speed (m/sec) | Air Concentration | | |

			F	0.5			1.48	2.09
			F	0.8			0.93	1.31
			F	1			0.74	1.05

Due to the lack of on-site emission measurements, emission estimates were developed from an analytical model.[21] The emission estimates were later supported by backcalculated annual average landfill emission rates using the ambient monitoring data, local meteorological data and the ISCST Gaussian air dispersion model.[22] Table 4 presents the measured and predicted vinyl chloride concentrations at receptor sites

A and B during the Landfill 3 air study as reported by Baker. Of the four models considered by Baker (Models 1 through 4), Models 1 and 4 were consistently found to perform less effectively than the other models and are not addressed further in this analysis. Estimates from three other models, a K-theory model (Model 5), a simple box model (Model 6) and the modified box model, are also included in Table 4 for comparison.

Table 4
Model Estimates and Measured Vinyl Chloride Concentrations (ppb) at Landfill 3

For Site A, concentrations predicted from the modified box model differ from the measured concentrations by 3 to 45%, as shown in Table 4. (Table 5 summarizes the predicted hourly vinyl chloride concentrations for all 5 days using the proposed model.) The modified box model and the K-theory model appear to provide similar concentration estimates to those estimated by the two virtual-point Gaussian approaches (Models 2 and 3) but with improved accuracy. In contrast, the simple fixed-height box model (Model 6) utilized in the development of U.S. EPA's PCB cleanup advisory overpredicts by approximately 20-fold.

For Site B, all models except the K-theory approach performed poorly in predicting the ambient vinyl chloride concentrations. A further examination of the site topography, however, indicated that a ridge north of Site B directs most nighttime draining air and emissions away from this site.[20] If one assumes that the air current was obstructed by the ridge during the calm condition and was able to pass over the ridge under other wind conditions, then the dispersion model should predict negligible concentration under the calm conditions. Table 4 presents the model predictions from the three Gaussian models incorporating these screened meteorological conditions. Using this more realistic representation of meteorological conditions, it is apparent that the modified box model performs well in predicting the near-field air concentrations.

DISCUSSION

While the concentrations predicted by the modified box model compare well with measured concentrations at the sites studied, the accuracy

of the model may vary depending on the specific site conditions. While the modified box model resembles the mathematical expression of the boundary-layer technology used in air emission estimation,[23] it differs in the vertical representation of the plume dispersion and dependence on the atmospheric conditions.

Figure 3 displays the variation of on-site concentrations in terms of emission source sizes. In general, the model is relatively insensitive to changes in atmospheric stability with the exception of stability classes A and F. Figure 3 shows that the on-site air concentration utilizing the wind-profile exponent for urban environments is almost independent of the source characteristic length (or the downwind distance from the upwind edge of the source) for all atmospheric stabilities except Stability A.

The effect of source sizes on the air concentrations becomes more apparent if one normalizes the on-site air concentrations by the concentration calculated for a 50-m long area source (Figure 4). The gradual variation of air concentrations with respect to source characteristic length is a result of the balance between the total emissions (source characteristic length), atmospheric stability (plume thickness) and wind shear.

In the modified box model, the plume thickness is represented by a power-law relationship, and the wind shear is implicitly conveyed by a power-law velocity profile. In an extremely unstable atmosphere (Stability class A), the power-law formula for δ_z may overestimate the plume thickness as much as 5-fold (based upon the ratio of plume thickness derived from the power-law formula and Briggs equations[14] at a distance of 3000 m). Thus, the modified box model may underpredict the air concentration for an area source under Stability A. In an extremely stable atmosphere (Stability Class F), the wind-profile exponent recommended by the U.S. EPA, which can be as high as 0.55, may not reflect the actual aerodynamic roughness characterized by the local topography. As a result, more rapid spatial variation of on-site air concentration with downwind distance is observed from the model estimates. More precise determination/selection of the dispersion coefficient,[24,25] mixing layer and wind shear would certainly improve the model's dependence on the source characteristic length.

The on-site or near-field air concentration is determined by on-site emission estimates and prevailing meteorological conditions. While emissions from a contaminated site are insensitive to the atmospheric conditions, the on-site or near-field air concentrations are inevitably affected by the atmospheric mixing. Table 3 shows how an arbitrarily

assigned atmospheric stability (e.g., Stability D), which did not represent the observed atmospheric conditions (Stability F) for Landfill 2, underestimated the air concentration by 40- to 60-fold. The extent of this underestimation was substantially reduced when the atmospheric stability was adjusted to reflect the nighttime no-wind conditions (Stability F). Accurate determination of the prevailing meteorological conditions is thus essential to yield a meaningful prediction of the on-site air concentration.

Relative Variation of On-site Air Concentration
with Respect to Emission Source Size

CONCLUSION

A modified box model has been developed to correlate the emission rates and the on-site or near-field air concentrations based on the principle of mass conservation, continuous plume theory and local meteorological conditions. It has been tested against measurements of air concentrations and emission rates for two Superfund sites and a waste landfill (with estimated emission rate). Preliminary findings indicate that the model results agree well with direct air measurements and that the model may provide enhanced accuracy over other predictive schemes.

The modified box model also can be used in conjunction with the STAR Summaries and other default values (wind profile exponents and

vertical dispersion coefficients) utilized by the U.S. EPA to yield an annual average concentration in the assessment of public health risks.

Arsenic Behavior in Soil and Groundwater at a Superfund Site: San Joaquin Valley

Palmer R. Ogden, Ph.D.
Environmental Science & Engineering, Inc.
Gainesville, Florida

ABSTRACT

Studies at a California Superfund site will determine whether arsenic in groundwater and soil is naturally occurring or the result of anthropogenic activity. As part of a contamination assessment ongoing since 1982, more than 3,700 groundwater samples from 240 monitor wells have been analyzed for arsenic, selenium, bromacil and 32 VOCs at the 2-mile by 0.5-mile site. Each well is screened in one of four aquifers: 0 to 50 ft, 51 to 100 ft, 101 to 150 ft and 151 to 200 ft. Arsenic concentrations in groundwater exceeding the U.S. EPA maximum contaminant level (MCL) (50 μg/L) have been measured at 50 of the 240 wells. Thirty-one of those 50 wells are screened in the surficial aquifer (0 to 50 ft). A key issue in this study is the fact that the arsenic is concentrated in the upper 50 ft of groundwater.

Variations of arsenic concentrations as a function of lateral distance and time and the suspended/dissolved nature of the arsenic have been measured. Arsenic concentrations of samples from the 50 wells vary from 20 to 1,100 μg/L. Variations of arsenic concentrations range from 50 to 500 μg/L at the same well within 3 months. The lateral variability of arsenic in groundwater is well demonstrated at a cluster of three wells separated by fewer than 100 ft, all screened in the surficial aquifer. These wells have arsenic concentrations ranging from 61 to 178 μg/L. Arsenic concentrations in dissolved and suspended fractions are being compared to total arsenic concentrations, time and the concentrations of other chemical species. The results will have important implications on the transport mechanism for arsenic at this site.

Adjacent to monitor wells with either high or low concentrations of arsenic, soil samples have been composited on 5-ft. intervals and analyzed for arsenic. Also, soil arsenic values have been compared to the groundwater concentrations. Off-site background samples have been collected, analyzed and compared to the on-site soil samples. There is no evidence that the arsenic on-site is related to anthropogenic activity. Naturally occurring minerals in the soil may be the sole source of arsenic in groundwater at this site.

INTRODUCTION

The potential for groundwater and soil contamination by VOCs, selenium, bromacil and arsenic at Sharpe Site (commonly referred to as SHAD), a Superfund Site in the San Joaquin Valley, was first recognized in 1980 by the U.S. Army Toxic and Hazardous Materials Agency (USATHAMA) during a preliminary record search.

The contamination assessment, which has been ongoing since 1982, now includes the results of 1,800 soil gas analyses for VOCs, 436 soil analyses for VOCs and arsenic and 3,760 groundwater samples from 240 monitor wells. The groundwater samples have been analyzed for arsenic, selenium, bromacil and 32 VOCs. This portion of the study was funded by USATHAMA to investigate the source of elevated arsenic in groundwater at SHAD.

Through a combination of record searches and field investigations, it has been determined that the VOCs were released to the ground as waste materials at several identified but unrelated locations at the study site. The soils at those locations are sources for VOCs that are being rinsed into the groundwater by infiltrating surface water. The addition of VOCs into the groundwater has resulted in plumes of contamination. The plumes of VOCs are significant to the study of arsenic contamination because the plumes are tracers which permit detailed mapping of groundwater flow regimes.

In addition to VOCs, arsenic is also present in the groundwater and soil beneath the study site. Arsenic concentrations in groundwater have been measured in excess of the U.S. EPA maximum contaminant level (U.S. EPA MCL) of 50 μg/L at 50 monitor wells. Arsenic concentrations in groundwater beneath this site vary within a range of 5 μg/L and 1,100 μg/L. Some of the wells have exceeded 50 μg/L arsenic only once in the 8-year sampling history. Others are consistently above the 50-μg/L concentration. Selected soils have been analyzed by the U.S. EPA's extraction procedure toxicity and California Department of Health Services Waste Extraction Test. Those soil samples did not meet the criteria for classification as hazardous waste.

The possible reasons for elevated arsenic concentrations in groundwater at this site are as follows:

- The elevated concentrations of arsenic in groundwater may be caused by the off-site or on-site use of arsenicals (i.e., rodenticides or herbicides).
- Arsenic, a component of naturally occurring minerals in the subsurface at this site, may be more soluble in the presence of the organic compounds known to exist here.
- The arsenic concentrations in the groundwater may be the result of naturally occurring mineral assemblages in contact with groundwater which reflect conditions unique to the San Joaquin Valley.

The data presented in this report are significant because the behavior of arsenic in groundwater has been well documented from more than 3,700 groundwater samples collected from 240 monitor wells and correlated with arsenic in 439 soil samples. The behavior of arsenic in soil and groundwater at this site may provide information relevant to arsenic behavior at other locations.

The San Joaquin Valley is underlain by several thousand feet of unconsolidated sediments which represent the distal fan deposits of clastics shed from the Coastal Range located west of the study site and the Sierra Range to the east. The Quaternary sediments have been reworked by rivers that have drained the San Joaquin Valley since the sediments were deposited.

Episodic deposition and contemporaneous reworking of the sediments by braided streams have resulted in an extremely complex cross section of discontinuous, intercalated lenses of sands, silts, clays and a minor amount of organic material beneath the study site (Fig. 1). In most cases, aquifers are laterally discontinuous within 1,000 ft. Pump tests have demonstrated that aquifers are connected vertically. The pattern of VOC contamination shows that the aquifers are connected horizontally.

Monitor wells have been installed in clusters of three or four wells, each screened in a successively deeper aquifer. The shallowest zone (A-zone aquifer) exists from approximately 10 ft to 50 ft below ground surface (bgs). The second zone (B-zone aquifer) extends from 50 ft to 100 ft bgs. The third zone (C-zone) extends from 101 ft to 150 ft bgs. The fourth zone (D-zone aquifer) extends from 151 ft to approximately 300 ft bgs. Water levels are recorded each time a groundwater sample is collected for chemical analysis. Additionally, most wells now have pressure transducers and automated telemetry systems that produce daily waterlevel measurements.

The seasonal changes in the groundwater gradient are well documented. The natural regional direction of groundwater flow is to the northwest. Intensive groundwater pumping for agricultural irrigation immediately west of the site during the summer months causes groundwater flow to become more westerly.

LAND USE

The study site is a military depot 2 miles by 0.5 mile used for the interim storage and repair of heavy equipment and aircraft. The land around the site is used primarily for growing row crops, most notably alfalfa. Irrigation of fields that are used for alfalfa production require intensive pumping of groundwater wells for irrigation during the summer months. The irrigation pattern is to pump water for 10 days each month during the summer to provide water for the alfalfa.

BEHAVIOR OF ARSENIC IN GROUNDWATER

Areal Distribution of Arsenic-Contaminated Groundwater

Fifty wells at this site have ever had arsenic concentrations in groundwater in excess of the U.S. EPA MCL. An average of 15 samples has been analyzed for arsenic from each well involved in this investigation. From those 50 wells, 13 wells have had arsenic concentrations in excess of 50 μg/L only one time. If the 13 wells are eliminated from consideration, the remaining 37 (of the total 240) with arsenic-contaminated groundwater represent only 15% of the wells (Fig. 2).

The mobility of arsenic relative to trichloroethene (TCE) can be inferred by comparing the locations of arsenic-contaminated wells with TCE-contaminated wells. TCE plume locations and concentration gradients have been established. Of the 240 total monitor wells, 118 (49%) have had concentrations of TCE in excess of 5 μg/L. If the dissolved arsenic is being transported by the advective flow of groundwater, the monitor wells downgradient from wells high in arsenic, as defined by the TCE plumes, should also have anomalous arsenic concentrations. Comparing the locations of arsenic-contaminated groundwater with the TCE plumes, there appears to be no correlation between the TCE plumes and arsenic-contaminated groundwater (Fig. 2).

The concentration gradient of arsenic in groundwater can be calculated at a cluster of monitor wells designated as the 439 series, all screened in the shallowest aquifer; these wells are located within 30 ft of each other (Fig. 3). At this location, the concentration gradient of arsenic is 390 μg/L per 100 ft. If this gradient is representative of this site and the background level of arsenic in groundwater is less than 50 μg/L, the maximum extent of the most concentrated arsenic-contaminated water (1,100 μg/L) would be on the order of 300 ft. Although arsenic is very soluble in the groundwater near certain wells at this site, it is not mobile.

Vertical Distribution of Arsenic in Groundwater

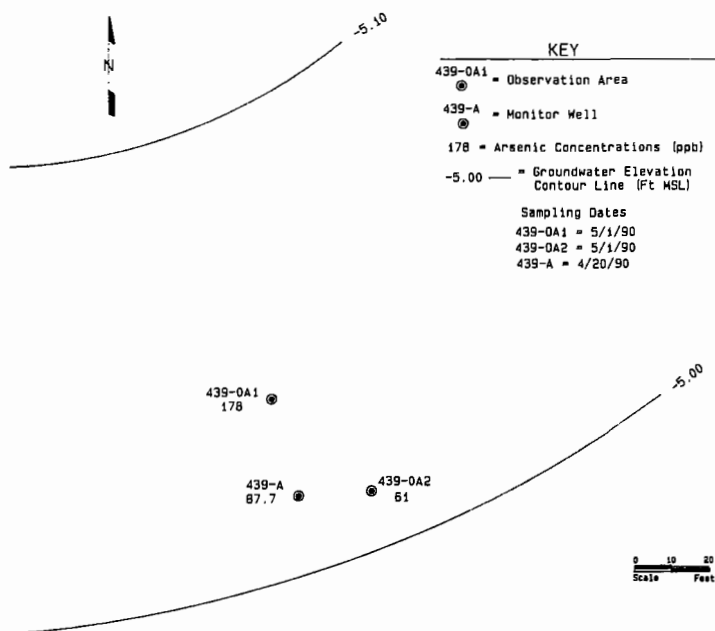
Groundwater samples have been analyzed from 240 wells and other sampling points on and off the site. The wells include 56 residential wells of unknown depth. The remaining monitor wells are distributed among the aquifer zones: A-zone 72, B-zone 52, C-zone 44, CD-zone 9 and D-zone 7. Arsenic-contaminated groundwater in excess of the U.S. EPA MCL has been measured at 50 of the 240 wells. Of those 50 wells, arsenic-contaminated groundwater exists primarily in the
Figure 1
Hydrogeologic Cross-Section Plume 1 and 3
Figure 2
Well and TCE Plume Locations


Figure 3
Arsenic Concentrations (ppb) in Groundwater at Well Cluster 439

shallowest zone. Arsenic concentrations greater than 50 μg/L were found in 31 wells in the A-zone, 7 wells in the B-zone, 3 wells in the C-zone and 2 wells in the D-zone (Fig. 4).

Prior to April 1990, groundwater samples from this site were analyzed only for VOCs, arsenic, selenium and bromacil. In April/May 1990, 66 wells were sampled and analyzed for 31 inorganic components that may be related to the behavior of arsenic, in addition to arsenic, VOCs, bromacil and selenium. The wells were selected on the basis of their historical arsenic concentrations. The wells with consistently high or low arsenic concentrations were selected.

The distribution of orthophosphate and vanadium are similar to arsenic. There are positive correlations between arsenic and orthophosphate and vanadium (Fig. 5 and 6). As with arsenic, the highest concentrations of dissolved orthophosphate and vanadium in these samples are restricted to aquifers within 50 ft of the surface (Fig. 7 and 8). Since phosphates, arsenates and vanadates have similar geochemical characteristics in general and similar distribution patterns at this site, the three components may have a similar source.

ARSENIC VARIATION WITH TIME

A total of 3,700 analyses of arsenic in groundwater has been recorded since 1984. Some wells have been sampled as frequently as twice a week, others once monthly, quarterly or annually. The wells with the highest sampling frequency have been sampled 66 times.

The wells with the highest average arsenic concentrations show the
Figure 4
Arsenic Concentrations vs. Well Depth

U.S. EPA Method 3050 and analyzed according to U.S. EPA Method 7060. It should be noted that U.S. EPA Method 7060 is intended to analyze contaminants rather than whole samples, which is necessary for geochemical modeling.

As a working hypothesis, it was assumed that the arsenic source in the groundwater is naturally occurring arsenic minerals within or adjacent to the aquifers. The relatively dense arsenic-bearing minerals should be heterogeneously distributed, reflecting the various energy environments of fluviatile deposition.

Soils were sampled adjacent to 10 monitor wells, half with high arsenic and half with low arsenic. The soil data were analyzed for correlation with the groundwater from those wells and for the variations of arsenic in soil with increasing depth.

The arsenic concentrations were grouped by depth interval (0 to 5 ft, 5 to 10 ft, 10 to 15 ft, etc. and 30 to 35 ft). The groups were assumed to be paired sets and tested for sameness using the sign test. At the 95% confidence level, it can be said that arsenic concentration increases with depth to 15 ft. The 30- to 35-ft interval has a higher median arsenic value than all of the intervals above it. The concentration of arsenic
Figure 6
Arsenic Concentrations vs. Orthophosphate Concentrations

Figure 5
Arsenic Concentrations vs. Orthophosphate Concentrations

greatest variability of arsenic concentrations. As an example, Monitor Well (MW) 407A has been sampled 21 times since 1982. The lowest concentration measured was 11 μg/L; the highest was 952 μg/L. The average arsenic concentration in groundwater in MW 407A has been 358 μg/L (Fig. 9). Wells with low mean arsenic concentrations tend to show less variation (Fig. 10).

Arsenic concentrations were measured in both filtered and unfiltered fractions in the 66 samples collected in the April/May 1990 sampling event. The arsenic dissolved varied between 50 and 99%. X-ray diffraction analyses have been performed on the filtered solids collected with these samples. Quartz, calcite, dolomite, feldspars, mica and minor quantities of expanding clay have been identified in the filtered solids. No naturally occurring arsenic phases were recognized.

ARSENIC IN SOILS

To evaluate the soil as a source for arsenic in groundwater, 439 soil samples have been collected and analyzed for arsenic. The samples were collected with 18-in long split-spoon sampling tubes and composited over 5-ft intervals. The 439 soil samples were prepared according to

Figure 7
Orthophosphate Concentrations vs. Well Depth

415A, 417A and 437A

Figure 9
Historic Arsenic Concentration Trends in Groundwater at MW-407A

more concentrated in the soil at this site than it is in the source rocks from which it was derived.

Recently, additional sampling was done in the immediate vicinity of the highest reading, 109 ppm, to test whether or not it is anomalous. A boring was completed within 0.5 ft of the first sample location. Additional samples were collected in a grid pattern around the sample location. Samples were collected with a split-spoon sampler and composited at 5-ft intervals. The results suggest that either the sample with 109 ppm is an extreme value in the natural distribution of arsenic in the subsurface at this site or error was introduced.

CONCLUSIONS

As a result of this investigation, the behavior of arsenic in soil and groundwater at this site can be summarized as follows:

- Arsenic concentrations in excess of the U.S. EPA MCL of 5 $\mu g/L$ have been measured in only 15% of the monitor wells at this site. The distribution of arsenic in the groundwater is not controlled by groundwater flow. Arsenic concentration gradients are approximately 400 $\mu g/L$ per 100 ft. Apparently, arsenic is not mobile in the groundwater at this site.
- Arsenic-contaminated groundwater is most soluble in the monitor wells that are screened within 50 ft of the ground surface, i.e., arsenic is more soluble in wells that are nearer the surface and probably in equilibrium with the atmosphere.
- The coefficient of variation of dissolved arsenic is related to the mean arsenic concentration at a given monitor well, i.e. a high percentage of variation in dissolved arsenic exists at most of the wells with high dissolved arsenic concentrations.
- The concentration of arsenic in soil increases with depth to 35 ft bgs. Either the depositional environment did not result in geochemical homogeneity, or infiltrating surface water is progressively leaching the arsenic-bearing minerals near the surface, or the source of the arsenic in the groundwater is not naturally occurring minerals.
- The arsenic concentration in shallow soil to a depth of 2 ft bgs beneath the study site is in the same statistical population as surface soil offpost.

The source of the excessive arsenic in the groundwater at this site is still being studied. The data will aid in evaluating potential sources.
in soil increases with depth.

A second hypothesis, that pesticides were the source materials for arsenic in the groundwater, was investigated by measuring arsenic in soils collected from surface depressions upgradient from monitor wells with consistently high arsenic concentrations. Samples from soil borings were also collected within the only known pesticide storage area at the facility. Off-site samples were collected to establish natural background values of arsenic in soil in the vicinity of the facility.

The frequency distribution and the mean of the arsenic concentrations of 20 off-site soil samples were compared to 39 soil samples collected from 0 to 5 ft on-site using the Wilcoxon rank sum test. At a 95% confidence level, the two samples are from the same population. No evidence exists that differences occur in arsenic concentrations between off-site and on-site soil.

The average concentration of all 439 soil samples was 5.7 ppm. The average arsenic concentration of granite = 1.5 ppm, basalt = 2.0 ppm and shale = 6.6 ppm. No evidence indicates that arsenic is significantly

Role of Environmental Fate and Transport Data in Health Assessments: Four Case Studies

Boston, Massachusetts

ABSTRACT

In health assessments developed by the Agency for Toxic Substances and Disease Registry, data and information on the release of hazardous substances into the environment are evaluated to assess any current or future impact on public health, develop health advisories or other health recommendations and identify studies or actions needed to evaluate and mitigate or prevent human health effects. Analyses of fate and transport data and information are primarily used in the health assessment process as a guide to highlight the significance or sensitivity of an environmental pathway that may lead to a human exposure. We describe four case studies to illustrate the use of fate and transport data in the health assessment process.

INTRODUCTION

The Agency for Toxic Substances and Disease Registry (ATSDR) is charged under CERCLA, as amended, to perform health assessments for each site listed, or proposed to be listed, on the NPL. In addition, ATSDR may perform a health assessment on a RCRA facility in response to a petition from a citizen. In an ATSDR health assessment, data and information on the release of hazardous substances into the environment are evaluated to assess any current or future impact on public health, develop health advisories or other health recommendations and identify studies or actions needed to evaluate and mitigate or prevent human health effects.

An ATSDR health assessment differs from a U.S. EPA risk assessment in several important details. Health assessments are qualitative, site specific and concentrate on medical and public health perspectives. U.S. EPA risk assessments are quantitative, compound-oriented and use statistical and biological models to calculate numerical estimates of risk.

Environmental engineers and health scientists who perform health assessments evaluate all available data and information on a hazardous waste site. These data and information come from three sources: environmental data bases, health outcome data bases and community concerns. The assessor first identifies the contaminated media and contaminant transport mechanisms (that is, environmental pathways). Then the chemical- and site-specific factors are evaluated to determine how they are influencing the environmental fate or transport of the contaminants in the environmental media.[1]

Analysis of the chemical- and site-specific factors that influence fate and transport of contaminants can lead to three different approaches within a health assessment. These analyses can be used to: (1) determine why or how contaminants have reached a certain monitoring location or exposure point; (2) rule out environmental pathways (for example, movement of contaminant "X" within the surficial groundwater will not occur because the organic carbon partition coefficient indicates it will strongly sorb to soil); or (3) highlight the sensitivity of an environmental pathway (for example, rapid and significant movement of contaminant "X" is highly likely because of the sandy nature of the subsurface geology). Analyses of fate and transport data and information, however, are primarily used in the health assessment process as a guide to highlight the significance or sensitivity of an environmental pathway that may lead to a human exposure. Furthermore, fate and transport analyses are not a substitute for quality monitoring data.

Using case studies, we illustrate how fate and transport analyses are not a substitute for quality monitoring data.

Using case studies, we illustrate how fate and transport analyses are used in the health assessment process to evaluate the environmental and human exposure pathways and to lead to recommendations to further evaluate public health implications and to protect public health. All case studies are based on actual site data and information.

CASE 1

The LMN site is the location of a former mixing and batching operation. The extensive contamination at the now closed site is the result of the disposal and release of many substances, including creosote. Two major constituents of creosote are naphthalene and 2-methyl-naphthalene. This discussion highlights the importance of the mitigation of groundwater as an environmental pathway for these two compounds at this site.

The groundwater became contaminated from the percolation of wastewater and the leaching action of rainwater on contaminants in the soil column. Free product consisting of creosote has been found floating on top of the water table. The groundwater contamination is comprised of many substances, including 2-methylnaphthalene and naphthalene. In the surficial groundwater, the maximum levels detected of both compounds combined exceed 20,000 ug/L.

Some of the chemical-specific factors that would influence the transport and fate of naphthalene and 2-methylnaphthalene are listed in Table 1.[2,3] Both compounds are bicyclic aromatic hydrocarbons and are relatively water soluble and volatile in comparison to the related polycyclic aromatic hydrocarbons (PAHs). Although less lipophilic than the PAHs, both compounds would tend to adsorb onto organic rich sediments and soils and to moderately bioconcentrate based on the log octanol-water partition

coefficients and bioaccumulation factor.

Site-specific factors favor the transport of both compounds in the groundwater. The former facility was situated on the eastern flank of a hill, which slopes eastward to a small river. The surficial groundwater flows to the east and downward until near the river and bordering wetlands where the hydrogeological gradient is upward. The competency of the bedrock in this area varies, but fracturing is apparent especially in the bedrock valleys and depressions. The available monitoring data for the shallow bedrock aquifer indicate a hydraulic connection between the overburden and bedrock aquifers, although the transfer of water from one aquifer to the other is impeded by a layer of till overlying the bedrock.

Table 1
Fate and Transport Data for Naphthalene and 2-Methylnaphthalene

FACTOR	NAPHTHALENE [2]	2-METHYLNAPHTHALENE [3]
CAS#	91-20-3	91-57-6
Molecular Formula	$C_{10}H_8$	$C_{11}H_{10}$
Molecular Weight	128.16	142.2
Log Octanol-Water Partition Coefficient	3.30	3.86
Water Solubility (mg/L at 25° C)	31.7	24.6
Vapor Pressure (mm Hg at 25° C)	0.082	0.068
Henry's Law Constant (atm-cu m/mol)	4.83×10^{-4} 5.53×10^{-4}	2.6×10^{-4} 5.18×10^{-4}
Bioconcentration Factor	39.8-1,000 aquatic animals	40-300 rainbow trout 470-2,800 starry flounder 28-190 coho salmon

Most of the contaminated surficial groundwater, and probably most of the shallow bedrock groundwater, discharges to the river. A component of the contaminant plume extends east of the river because: (1) the hydrogeological gradient from the east is more gentle than that from the west and (2) a thick layer of sediment in the river retards some of the discharge. The groundwater contamination is excessive but is mostly contained within the site boundaries because of: (1) the incoming groundwater flow from the other side of the river; (2) the slow rate of the northerly flowing surface water; and (3) the presence of a northward trending bedrock incline beneath the river.

Contaminated groundwater discharges into the river. Attenuation by the organic-rich sediments is likely a predominant fate of 2-methyl-naphthalene and naphthalene, rather than discharge to the river surface water. Based on the difference between the concentration of select contaminants detected in groundwater at a depth of 5 ft and that detected in a seepage meter, an estimated 90 to 100% of the organic contamination is trapped in the sediments. The results of monitoring of the sediments highlight the importance of the bioaccumulation pathway. Naphthalene and 2-methylnaphthalene were detected in sediments from all depths monitored (to 36 in.) at levels to 36,000 and 21,000 ug/kg, respectively.

Decreases in contaminant concentrations in the sediments at this location may occur by one of three mechanisms. First, biodegradation of these two compounds occurs, especially in sediments with acclimated microorganisms, and is expected to be a major route of loss from sediment.[2,3] Second, following resuspension, sediment-bound naphthalene and 2-methylnaphthalene can be transported downstream (and off-site) with surface water flow. Resuspended sediments will tend to resettle where surface water flow is reduced. In support of this interpretation, naphtha-

lene and 2-methylnaphthalene have been detected in the downstream surface sediments at levels to 1,200 and 920 ug/kg, respectively, and as far as 0.5 mi downstream in a pond.

Third, these compounds may be released in solution from the sediments to the surface water. Contamination of surface water is likely of less importance than contamination of sediments or groundwater. Any contaminant released or not trapped by the sediments will be rapidly diluted. Groundwater from the site is estimated to discharge to the river at a maximum rate of 0.03 ft³/sec and to represent less than 1% of the river's discharge upstream or downstream of the site. In addition, any naphthalene and 2-methylnaphthalene present in solution would tend to volatilize based on the calculations using Henry's Law constants. Decomposition via biodegradation and photolysis and adsorption to particulates are other mechanisms of loss from surface water for these chemicals.[2,3] Monitoring of the river's surface water has resulted in the sporadic, low-level detection of naphthalene (<21 ug/L) and 2-methylnaphthalene (<21 ug/L) and demonstrates that surface water is not a predominant pathway.

Although fish bioconcentrate naphthalene and 2-methylnaphthalene to moderate extents, fish also tend to metabolize these compounds.[2,3] Limited monitoring data are available for the fish in the river. Fish from on-site locations and the pond downstream were found to contain detectable levels of naphthalene and 2-methylnaphthalene. Not enough information is available to determine: (1) the effect of trophic level on contaminant concentration, (2) the distribution of these compounds to the edible fillet, (3) the relative contribution of sediment and surface water to the contamination and (4) the influence of distance from the site. A chain pickerel (*Esox niger*), however, from the site contained the highest level of contamination detected (1.2 mg/kg 2-naphthalene and 2.3 mg/kg naphthalene). Once fish are removed from naphthalene and 2-methylnaphthalene, depuration is rapid.[2,3] These compounds continue to be discharged from the groundwater to the river, however, and additional characterization of the fish contamination in the vicinity of the contamination should be considered.

The environmental pathways that can be highlighted as important are related to groundwater, sediment and, perhaps, fish. Human exposure to naphthalene and 2-methylnaphthalene might occur via ingestion of fish and incidental ingestion of sediment and dermal contact with sediments. Because no water supply wells intercept the overburden or shallow bedrock groundwater, exposure to these chemicals via ingestion of groundwater is unlikely. Details regarding groundwater and contaminant transport in deep bedrock are not available, but exposure appears unlikely because no deep bedrock wells are near the site and other wells are less likely to be installed in fractures bearing contamination from this source. Because surface water and probably ambient air are not contaminated to a great extent, humans are not likely to be exposed via these pathways at this time.

CASE 2

The QRS site is the location of a series of former dye manufacturers. During the production of some dyes, mercury was used as a catalyst. For 40 yr, 3,000 to 5,000 lb of unrecovered mercury were released annually. Most of the mercury was released in the effluent discharging into the nearby wetlands and in sludges discarded on top of a nearby hill.

Chemical-specific factors that would influence the transport and fate of mercury depend on the species of mercury present; however, the relative proportion of each species present is apt to change as local conditions change. Transport and fate data for some mercury species are given in Table 2.[3,4] This case example highlights methylated mercury in soil and sediments, although other environmental media also are impacted.

Surface run-off containing mercury-contaminated sludges and soils migrated down the hill and into the wetlands. From the wet-

land areas, soluble and particulate bound mercury were transported off-site from the wetlands via a brook to a nearby river. In the river, sediments, fish and, to a lesser extent, surface water are contaminated by mercury.

The potential exists for the methylation of mercury in the environment, particularly in wetland areas and river sediments.[3-5] Dimethylmercury and methylmercury are formed from inorganic mercury by both biotic enzymatic and nonenzymatic processes and abiotic mechanisms. Biological methylation of mercury can occur in aerobic and anaerobic environments and depends on: (1) the quantity of divalent mercuric ion present, which depends on the pH, redox potential and the presence of organic ligands; and (2) the abundance of microorganisms, which depends in part on the presence of wet, organic soils and specifics regarding microbial metabolism. A competing microbial process, demethylation, also can occur. Because of the various factors involved in methylation and demethylation, the amount of methylated mercury produced would be difficult to predict. The detection of dimethylmercury in the wetland soils/sediments and methylmercury in the surface water supports this interpretation; however, the available monitoring data are limited.

Table 2
Fate and Transport Data for Select Mercury Compounds[3,4]

FACTOR	MERCURY	MERCURIC CHLORIDE	METHYLMERCURY	DIMETHYL-MERCURY
CAS#	7439-97-6	7487-94-7	22967-92-6	593-74-8
Molecular Formula	Hg	$HgCl_2$	CH_3Hg	C_2H_6Hg
Molecular Weight	200.59	271.5	215.62	230.66
Water Solubility (mg/L)	56	7.4×10^{-4} at 25 C	NA	NA
Vapor Pressure (mm Hg)	2×10^{-3}	NA	NA	NA
BCF*	$10,000^1$ $63,000^3$	$10,000^1$	$40,000^2$	NA

NA– Not available.
* BCF, bioconcentration factor.
[1] Bioaccumulation factor for oyster and saltwater fish.
[2] Bioaccumulation factor for oyster.
[3] Bioaccumulation factor for freshwater fish.

Dimethylmercury and methylmercury have different chemical and physical properties. Methylmercury is both water and lipid soluble. Therefore, methylmercury tends to be found in surface waters and to bioconcentrate in fish and other organisms. Most of the mercury found in fish is in the form of methylmercury; however, methylmercury also may be formed from inorganic mercury in the intestine and liver of fish.[4,5] The recent monitoring of off-site fish for mercury and methylmercury indicates that more than 95% of the mercury found in the fish is in the form of methylmercury. The fish fillet contained more total mercury and methylmercury than did the remainder of the fish (that is, the offal).

Dimethylmercury is lipophilic, nearly insoluble in water and very volatile. Dimethylmercury would tend to remain bound to organic-rich soils or sediments until volatilized when exposed to air. Factors that might increase the chance of volatility are: (1) a lack of moisture in the vadose zone, (2) warm temperatures, (3) sunlight, (4) a decrease in the barometric pressure and (5) soil movement activities. Because the monitoring data are limited and site-specific factors would influence volatilization, the sensitivity of this pathway at this site would be difficult to predict; however, baseline monitoring of ambient air resulted in the sporadic

detection of dimethylmercury at levels near the method's detection limit.

Human exposure to methylated mercury may occur via ingestion of fish (methylmercury) and incidental ingestion of surface water, sediments and soils (methylmercury and dimethylmercury); via dermal adsorption from soils, sediments and surface water (methylmercury and dimethylmercury); and via inhalation (dimethylmercury). Special concern exists in the wetland areas if soils are disturbed because of the uncertainties mentioned previously.

In lieu of additional soil and sediment characterization, a near real-time monitoring method for dimethylmercury in ambient air was recommended and developed. This method is being used at the QRS site during remediation activities entailing soil and sediment excavation. Because of the elevated levels of mercury in fish, a health advisory was issued jointly by several state agencies warning against the consumption of fish obtained from the river.

CASE 3

The HIJ site is an inactive landfill that operated from 1963 to 1981. Various wastes were disposed of at the site, including municipal wastes, septage, industrial wastes and hospital wastes. Although many contaminants have been detected in sampling of the on-site media, toluene is considered a contaminant of concern—primarily because it was detected in shallow groundwater samples at concentrations up to 100,000 ug/L.

Some of the chemical-specific factors that could influence the fate and transport of toluene are listed in Table 3. Although toluene is a liquid at room temperature, it is sufficiently volatile (based on vapor pressure) that the majority of toluene in the environment exists in air. Furthermore, the Henry's Law constant for toluene indicates that it is moderately volatile when dissolved in water. Toluene that is released to surface water and soils tends to evaporate quickly. On the basis of the log values of the octanol-water partition coefficient and the organic carbon partition coefficient, toluene will be moderately retarded by adsorption to soils rich in organic matter, but will be readily leached from soils with low organic content. In addition, because of toluene's lipophilic properties, it also has a moderate tendency to bioaccumulate in the fatty tissues of aquatic species.[6]

Table 3
Fate and Transport Data for Toluene[6]

FACTOR	TOLUENE [6]
CAS#	108-88-3
Molecular Formula	$C_5H_5CH_3$
Molecular Weight	92.15
Log Octanol-Water Partition Coefficient	2.79
Log Organic Carbon Partition Coefficient	2.47
Water Solubility (mg/L at 20° C)	515
Vapor Pressure (mm Hg at 20° C)	22
Henry's Law Constant (atm-cu m/mol)	6.66×10^{-3}
Bioconcentration Factor	10.7 fish 4.2 mussels

The major site-specific factor that influences the environmental pathways is the hydrogeology of the site. Most of the unconfined shallow groundwater flows to the east of the landfill and is

discharged to a swamp and creek or forms leachate ponds. The confined deep aquifer underlying the site, which is the source of potable water in the vicinity of the site, was not contaminated. The hydrogeology of the site indicates that there is an upward hydrogeological gradient between the deep and shallow aquifers that causes groundwater to leak into the shallow aquifer and finally be discharged to the creek.

Because of the sandy nature of the soil at the site, toluene is not expected to be significantly attenuated by the sediment at the surface water discharge areas. Furthermore, since toluene tends to volatilize relatively rapidly from surface waters, the sensitivity of the air environmental pathway is highlighted. Sampling and analysis of on-site sediment and surface water were not performed. A photoionization detector was used to analyze ambient air around the surface water areas; results indicated elevated levels of organic vapors.

On the basis of the analysis of the chemical- and site-specific factors, the major potential exposure route to toluene at the site was determined to be through incidental inhalation by trespassers or through inhalation by residents living near the site. For that reason, on-site ambient air monitoring for toluene, under varying meteorological conditions, was recommended. Furthermore, if appreciable concentrations of toluene were detected in the air on the site, additional sampling at potential exposure points (residential areas), under varying meteorological conditions, was recommended. Although toluene is known to moderately bioaccumulate in aquatic species, this is not an environmental pathway of concern because it was determined that the creek and other potentially affected surface waters did not support edible aquatic organisms. Sampling of the surface water and sediment, to verify that these do not pose human exposure pathways of concern for incidental ingestion or dermal contact, was recommended.

CASE 4

At the KK site, filling operations reportedly occurred in 1978 after peat deposits were excavated. The landfill material consists of lead-acid battery casings that are buried in both the saturated and unsaturated zones. The layer of casings is estimated to be 6 to 12 ft thick. A thin layer of sand covers the battery cases.

The site lies just west of a freshwater marsh. Numerous aquatic organisms, including freshwater clams, live in the marsh. A canal cutting through the site connects this marsh with another march located west of the site. A large lake is located at the north end of the property. The groundwater flow direction in the surficial aquifer is toward the marsh east of the site. The surficial aquifer discharges to this marsh and has contributed to the contamination of the marsh. The marsh flows into a small stream to the southeast of the landfill, which eventually empties into a bay.

Some of the chemical-specific factors that would influence the fate and transport of lead are listed in Table 4. The chemistry of lead in aqueous solution is highly complex because it can be found in many different forms. Lead has a tendency to form low-solubility compounds with the major anions of natural water. In the environment, the divalent form is the stable ionic species of lead. Hydroxide, carbonate, sulfide and, sometimes, sulfate may act as solubility controls in precipitating lead from water. The amount of lead that remains in solution depends on the pH of the water and the dissolved salt content. A significant fraction of lead in water is expected to be in an undissolved form, which can consist of colloidal particles or larger undissolved particles of lead carbonate, lead oxide, lead hydroxide or other lead compounds incorporated in other components of surface particulate matter from run-off.[7]

Except for some shellfish, lead does not appear to bioaccumulate significantly in fish. The predominant fate of lead in surface water is sorption to sediments. The adsorption of lead is pH dependent, increasing with increasing pH.[7]

Table 4
Fate and Transport Data for Lead[7]

FACTOR	LEAD [7]
CAS#	7439-92-1
Molecular Weight	207
Water Solubility (mg/L at 25° C)	insoluble
Vapor Pressure (mm Hg at 980° C)	1

Surface water appears to be the primary environmental medium for migration of contaminants off-site. Lead was detected in water samples from the marsh. Only total lead was reported; the lead compounds were not differentiated. Unfiltered samples contained lead at a maximum of 46 mg/L; filtered samples, at a maximum of 1 mg/L. The water in the marsh has a pH near 7. The chemical-specific properties of lead suggest some possibly sensitive environmental pathways. Lead has a tendency to be adsorbed to sediments. Since lead was found in the surface water, an expected environmental pathway would be the adsorption of lead from the surface water to the sediments. Monitoring data confirm that lead is concentrating in the sediments at 17,741 mg/kg. Since the marsh discharges to a nearby stream, the contaminated water and sediments may be transported by this surface water flow. This lead transport process should be somewhat limited by the low flow of the marsh. Since lead has been shown to bioaccumulate in some shellfish, bioaccumulation of lead from the water and sediments by the claims is a potentially sensitive environmental pathway.

The vapor pressure of lead indicates that it is not volatile. Accordingly, volatilization of lead from the surface water to the air is not considered a sensitive environmental pathway. Site-specific characteristics rather than chemical-specific characteristics indicate that transfer of lead from surface water to groundwater is not a sensitive environmental pathway. Because the surficial aquifer discharges to the marsh, discharge from the surface water to groundwater is unlikely.

The possible human exposure pathways are ingestion of contaminated surface water and contaminated shellfish and dermal exposure to surface water. Because the site area is relatively uninhabited, exposure to surface water is expected to be infrequent and incidental. The clams are not consumed at all. Therefore, under current site use scenarios, the human exposure pathways are incomplete.

CONCLUSIONS

Analysis of the chemical- and site-specific factors that influence fate and transport of contaminants can lead to three different approaches within a health assessment. These analyses can be used to: (1) determine why or how contaminants have reached a certain monitoring location or exposure point; (2) rule out environmental pathways; or (3) highlight the sensitivity of an environmental pathway. Analysis of these factors, however, is primarily used in the health assessment process as a guide to highlight the significance or sensitivity of an environmental pathway that may lead to a human exposure. Fate and transport analysis, however, is not a substitute for quality monitoring data.

The four case studies illustrate how the analysis of fate and transport data is used in the health assessment process to highlight the sensitive environmental pathways. This analysis helps the assessor to determine the likely human exposure pathways. This guides further evaluation into the land use and behavior patterns around a site and helps to determine if the human exposure

pathway is complete, as shown in Cases 3 and 4. In Cases 1 and 2, where human exposure pathways are complete, potential public health implications can then be determined and appropriate actions to protect public health can be recommended.

Sensitivity Analysis of Surface Water Modeling Assumptions and the Impact On Risk Assessment

Case II: Seasonal Variation in Temperature and River Flow in Tidal and Nontidal Models

Linda Henry, Ph.D.

Athens, Georgia

ABSTRACT

This paper presents the second in a series of case studies on sensitivity analysis of parameters used in the Exposure Analysis Modeling System (EXAMS Version 2.92). The first case study presented the variability in the concentrations of three chemicals, vinyl chloride (VC), hexachlorobutadiene (HCB) and benzo(a)pyrene (BaP), in tidal and nontidal models with various values for dispersion and reaeration. This second case study presents the results of tidal and nontidal models using actual data on seasonal variation in flow and temperature in the Delaware River. High and low values for river flow and temperature were run in the tidal and nontidal models resulting in eight versions of the model.

The most significant effect of all variables tested was the more than 300-fold decrease observed in the upstream concentrations in the water column as a result of a 7-fold increase in flow in the tidal models. For all other scenarios (tidal versus nontidal, warm versus cold temperature and chemical properties), the changes in water column concentrations between model runs were either proportional to the changes in the value or minimal (less than 50%).

Risk assessors frequently use standard worst case assumptions to predict exposure concentration such as 7-day, 10-year flow values frequently used. For drinking water intakes in tidal systems upgradient from the source, the impact of flow on the exposure concentration is significant. Use of worst case data to represent lifetime risk can result in an overestimation of the average lifetime risk.

There were significant differences in the concentrations in the benthic and suspended sediment and the relative distribution of the mass of the chemicals between the water column and the benthic sediment due to differences in chemical properties.

INTRODUCTION

Risk assessors are aware that a single number cannot accurately represent risk because of the uncertainty inherent in predicting human health and environmental effects. Risk estimates are numerical values based on the concentration at the point of exposure and the potential of the chemical to have an adverse health effect on man or his environment. The focus of this paper is to examine the uncertainty present in estimates of exposure concentrations obtained from surface water models and the impact on estimates of risk.

Surface water models are frequently used to estimate exposure concentrations for drinking water intakes, recreational use of rivers and lakes and impacts to aquatic life. Data for site-specific model parameters such as flowrates and mixing characteristics require long-term base line data and/or are expensive to obtain. Therefore, risk assessors and modelers rely on data available in the literature for similar aquatic systems or estimation of several parameters from a limited data base. Frequently, there is a range of values to select from and a degree of

uncertainty is added to the model. Even when site-specific data are available, the variability in aquatic systems adds uncertainty.

These sources of uncertainty need to be understood by the modeler so that the risk assessor can develop a range of potential risk estimates around the variability in exposure concentrations. The uncertainly can be quantified by a sensitivity analysis which describes the effect of using several values for different model parameters in all possible combinations.

This paper presents the second in a series of case studies on sensitivity analysis of parameters used in the Exposure Analysis Modeling System (EXAMS Version 2.92).[1] The first case study presented the variability in the concentrations of three chemicals in tidal and nontidal models with various values for dispersion and reaeration. The model simulated the Delaware River using long-term low flow conditions reported in the literature. Low flow, worst case conditions are typically assumed for risk assessment purposes.

This second case study presents the results of tidal and nontidal models using actual data on seasonal variation in flow and temperature in the Delaware River. High and low values for river flow and temperature were run in the tidal and nontidal models resulting in eight versions of the model.

Flow rate is highly variable in all rivers and streams within and between years. Although the U.S. Geological Survey (USGS) maintains gauging stations throughout the United States, there still are many rivers and streams without sufficient information. Typically, modelers rely on estimating annual average flows for different periods based on the area of the watershed and flow/area relationships for nearby watersheds with a gauging station.

There are several ways that flow can affect the final concentration. Flow determines the flushing rate, velocity, depth, width, cross sectional area and, as a result, the reaeration rate. Temperature is also a critical parameter and controls the rates of many processes affecting the fate of pollutants in surface water such as volatilization and biodegradation. This study investigated the effect of temperature on volatilization. Other chemical-specific processes, biodegradation, photolysis and hydrolysis, were assumed to not occur.

METHODS

Model Construction

The EXAMS model parameters and values used for this study are presented in Table 1.

The EXAMS surface water model is built by dividing the river into a series of connected segments. Each segment consists of compartments that represent different media, e.g., benthic sediment or water column.

Table 1
Physical, Hydrogeological and Chemical Parameters Typically Needed for Surface Water Models

Physical	Hydrological
Bed geometry	- velocity of flow
- width	- rate of flow (advection)
- depth	- tidal and non-tidal mixing
- length	(dispersion)
	- reaeration rates
Sediment characteristics	
- total organic carbon	Chemical
- bulk density	
- percent water	- biodegradation
	- hydrolysis
Climate	- photolysis
- temperature	- sorption to sediments
- wind speed	

The segments and compartments are connected by advective and/or dispersive flow. In our model, the water columns of adjacent segments in a downriver direction were connected by advective flow, low or high rates of discharge. Advective flow entered the first segment only and no additions from tributaries were included.

Dispersion was used to connect the sediment and water in all forms of the model and to describe the effect of tides in the tidal models. The sediment and water columns were connected by a moderate dispersion factor, 0.00001 m²/hr in all models. This same factor was used to connect adjacent water column compartments in the nontidal model. In the tidal model, the upriver mixing induced by tides was described with a factor of 5 x 10⁴ m²/hr for dispersion between one water column and the adjacent upriver water column. This tidal dispersion factor is the highest of the two values used in the first case study.

The model consisted of 11 segments each with four media, sediment, pore water, water column and suspended sediments. EXAMS also allows for incorporation of biota, but this medium was not included. The segments were 2000 feet in length for a total of 22,000 feet or 3.6 river miles. A steady-state format of EXAMS was used assuming an infinite, continuous source of the three chemicals. For the tidal model, the chemical load was added as a diffuse source into the middle segment and to the first segment into the advective flow for the nontidal model.

Second order process models are used to describe the kinetics of the chemical reactions. The program is based on a series of mass balances for each compartment that give rise to a single differential equation for the contaminant in the water column and the benthic zone in each segment.

Changes Between Case I and Case II Models

The values used in Case I for model parameters for the dispersion coefficient and fraction organic carbon in the sediment of 0.1 m²/hr and 0.0001, respectively, were changed for Case II to 0.00001 m²/hr and 0.01, respectively. The changes were made to more accurately represent river conditions. The most important impact of the changes is likely to be an increase in the mass of chemical located in the sediments with lesser impacts to the concentration in the water.

Also, the load added via seep flow in the Case I model was changed to a drift load addition in Case II. The change was made to avoid exceeding the solubility limit for the chemicals at the cold temperature in the seep flow and to achieve strict comparability among cases. EXAMS will not allow the solubility to be exceeded.

Model Variables

High and low values for flow rate and temperature were used in the eight versions of the model prepared for this analysis (Table 2). Site-specific data were obtained from rating tables and discharge rates and temperature for 1986-1987 provided by the USGS for the Delaware River at Trenton, New Jersey. The river is not tidal at this point so that the tidal construct of the model does not strictly apply to this section. The

highest and lowest mean monthly rates of discharge and temperature, 4.1 x 10⁵ and 3 x 10⁶ m³/hr and 2 and 27 °C, respectively, were selected. The values for bed geometry, depth, width and cross-sectional area, were calculated from the rating tables provided by USGS.

Table 2
Model Variables

		LOW	HIGH
Flow / Geometry			
Water			
	volume (m3)	2.7 E+5	6.2 E+5

	depth (m)	1.3	2.3
River Flow			
	flow rate (m3 / hr)	4.1 E+5	3.0 E+6
Temperature (deg. C)		2	27
Tidal Dispersion (m2 / hr)		0.1	5.4 E+5

Since the width, depth and cross sectional area of the bed geometry change with flow rates, the variability in these parameters is automatically included in any study of the variation in flow. The reaeration coefficient, K_{o2}, was calculated from a value of 0.8/day and the depth. As a result, the coefficients for high and low flow were different because the depths at high and low flow are 2.3 and 1.3 m, respectively.

Study Chemicals

Each model was run with three chemicals, vinyl chloride (VC), hexachlorobutadiene (HCB) and benzo(a)pyrene (BaP). These three chemicals were also used in the first case study because they represent a range of chemical properties. The minimum information needed on chemical properties for EXAMS is molecular weight, Henry's Law constant, vapor pressure, solubility and octanol-water partition coefficient (Kow) (Table 3). Note that the first case study incorrectly suggests that molecular weight is not required.

Table 3
Chemical Properties of Study Chemicals

Chemical	Henry's Law Constant (atm * m * 3/ mol)	Water Solubility (mg / L)	Kow (mg / L: mg / L)	Molecular Weight
Vinyl Chloride (VC)	8 2 E-2	2.7 E+3	24	63
Hexachlorobutadiene (HCB)	4 75	1 5 E-1	6.0 E+4	2 61 E+2
Benzo (a) pyrene	1 6 E-6	1.2 E-3	1 2 E+6	2.52 E+2

Source EPA, 1986

VC is volatile and has little tendency to sorb to sediments as shown by the high Henry's Law constant and low Kow. HCB is both volatile and sorbs to sediments, while BaP has a low volatility and strong tendency to sorb to sediments.

These values for chemical properties were obtained from a variety of sources in the literature; however, they do not necessarily represent the average of the reported values. In particular, the value for vapor pressure for HCB used for this study is the highest reported for this chemical. The selection was biased to achieve a particular representa-

tion of different chemical properties.

Parameters to simulate biodegradation, hydrolysis and photolysis were set at zero to avoid multiple process effects. In a "real" world model, these processes, in particular photolysis for BaP, play an important role in fate and transport.

RESULTS

The most significant effect of all variables tested was more than 300-fold decrease in the upstream concentrations in the water column

VC - Vinyl Chloride
HCB - Hexachlorobutadiene
BaP - Benzo (a) pyrene

with a 7-fold increase in flow in the tidal models (Table 4). For all other scenarios (tidal versus nontidal, warm versus cold temperature and chemical properties), the changes in water column concentrations between model runs were either proportional to the changes in the value or minimal (less than 50%).

There were significant differences in the concentrations in the benthic and suspended sediment and the relative distribution of the mass of the chemicals between the water column and the benthic sediment due to differences in chemical properties (Table 5).

The following section discusses the variation in concentration of the chemicals in the water column and benthic sediment in the eight different forms of the model. All references to concentration in this paper apply to the water column unless otherwise specified. Also, the chemical load in the models was equal for all chemicals so that the total mass of chemical in each system is the same. Therefore, differences in the concentration of a chemical in any compartment can be directly related to chemical-specific processes.

Table 5
Distribution of Chemicals Between Benthic Sediments and Water Column

| | Percent of Total Mass | | |
	VC	HCB	BaP
Low flow (tidal and nontidal)			
Water	95	6	<1
Sediment	5	94	99.9
High flow (tidal and nontidal)			
Water	97	10	<1
Sediment	3	90	99.88

VC - Vinyl Chloride
HCB - Hexachlorobutadiene
BaP - Benzo (a) pyrene

Flow Rate

In the tidal model, the upstream concentration decreased 300-fold when the flowrate was increased by 7-fold, regardless of the temperature or chemical.

In both models, there was a 7-fold decrease in the concentration in the source and downstream segments when the flow rate was increased 7-fold from 410,000 m^3/hr to 3,000,000 m^3/hr. The decrease can be partially accounted for by the approximately 2-fold larger volume. The actual concentrations were approximately 3.3 x 10^{-10} mg/L for high flow and 2.3 x 10^{-9} mg/L, for low flow. In the tidal model, the downstream concentration was 2- to 3-fold lower than the source segment for all chemicals. In the nontidal model, the downstream concentration was reduced by 10 to 50% of the source concentration for all chemicals.

Temperature

The only impacts of temperature were slight decreases in the downstream concentrations for VC and HCB, approximately 10 and 5%, respectively, in the warm low flow models versus the cold low flow models. The impact of temperature in the high flow models was even lower for the volatile versus nonvolatile chemicals. This was true for both tidal and nontidal models.

The concentration of all chemicals in the source segment within the tidal or nontidal models, varied by less than 20%, regardless of temperature.

Chemical Properties

The main impact of chemical properties is on the relative distribution of the total mass between the water column and the sediment with small differences between the low and high flow models. For all three chemicals, the relative distribution did not change between tidal and nontidal. For VC, the water:sediment ratio was 95 to 5 at low flow and 97 to 3 in the high flow models. HCB was 6 to 94 at low flow and 10 to 90 at high flow. BaP was less than 1% in the water and greater than 99% in the sediment in both models.

In the water column, the concentration differences due to chemical properties were small. BaP concentrations were slightly, approximately 30%, lower than VC and HCB, which were generally similar. The slightly lower values for BaP water column are due to the higher concentration of this chemical in the suspended sediments.

Discussion and Comparison of Case I and II Results

Interpretation of the results of the model in terms of impact on the risk assessment process is simplified by the fact that risk for both carcinogenic and noncarcinogenic effects is proportional to the concentration for a single exposure pathway such as drinking water.[2] For carcinogens, the proportionality is direct so that a decrease in the concentration of 50% would cut a 2×10^{-6} probability of cancer risk (two cases of cancer in a million people) to 1×10^{-6}. For the index to describe noncarcinogenic health effects, the Hazard Index, the relationship is inversely proportional. Therefore, a HI value of 1 becomes 0.5 when the concentration is cut in half.

For multiple pathways where the risk is added across exposure routes such as ingestion of water while absorbing chemicals through the skin during swimming, the proportionality between risk and concentration breaks down.

Estimation of risk is inherently variable. Many of the exposure assumptions have a range of values associated with them. For purposes of this report, changes in the concentration of less than 50% or one half the risk level, are considered negligible.

The impact of dispersion and reaeration on the concentration and hence the risk were fairly low, 2- or 3-fold impacts within the range of literature values. Case I reported the results of the EXAMS model with variations in reaeration and dispersion. The models indicated that changes in the dispersion coefficient had a greater impact than changes in the reaeration coefficient for the tidal models. A 5-fold change in the dispersion coefficient results in a 3-fold change in concentration of the three chemicals. Two- and 4-fold changes in the reaeration coefficient resulted in minimal (less than 10%) changes in the concentration,

The results of Case II indicate that flowrate can have a significant impact on the concentration and hence risk estimate. A 7-fold increase in flow rate results in a 300-fold decrease in the upriver concentration in the tidal model.

Risk assessors should be aware of this impact when selecting the typical low flow rates used in a surface water model. They should be sensitive to use of standard worst case conditions for flow based on 7-day, 10-year flow values. For drinking water intakes in tidal systems upgradient from the source, the impact of flow is significant. Use of low flow data to represent lifetime risk can result in an overestimation of the average lifetime risk.

Potential Risks to the Marine Environment from Sunken Ships at Bikini Atoll

Catherine A. Courtney, Ph.D.
PRC Environmental Management, Inc.
Honolulu, Hawaii

ABSTRACT

This investigation examines the potential for release of fuel and oil from ships sunk at Bikini Atoll during the nuclear testing era. Historic data and site investigations provided a basis for determining the magnitude of the threat. A simple model was employed to estimate the dimensions, trajectory and duration of chronic oil spills at various release rates.

Historic accounts suggest that a significant portion of the available fuel load was released during the BAKER event, an underwater nuclear detonation. Current low rates of chronic release of product suggest that some fuel may still remain in the vessels. The highly deteriorated condition of the ships suggests the possibility of increased rates of release in the future. Potential impacts to the marine environment were assessed by estimating the dimensions and trajectories of minor, medium and major spills. A major spill (>4,000 gal/hr) occurring during normal trade wind conditions would result in an oil slick 3.5 mi wide by 67 mi long, extending beyond the boundary of the atoll in a northwesterly direction away from the sunken ships. Key ecological receptors to an event of this magnitude would be shallow reef flat environments and their associated fisheries, sea turtles and seabirds.

Attempts to recover the fuel could result in unacceptable short-term and long-term impacts to the marine environment. No remedial action is the recommended alternative for this site.

INTRODUCTION

Although health risks from radionuclide contamination of the islands remain the major concern of the Bikini people, they have expressed concern over the potential for a catastrophic release of fuel oil from the sunken ships in the lagoon and subsequent destruction of fisheries and coral reefs from which they derive subsistence. In addition, the draft Environmental Impact Statement for the Rehabilitation and Resettlement of Bikini Atoll[2] identified the need to conduct further investigations of this largely unknown threat. This investigation was initiated to gather historical information, conduct preliminary site investigations and provide qualitative estimates of the magnitude of this threat to the natural resources at Bikini Atoll.

HISTORICAL INFORMATION

Operation Crossroads consisted of two nuclear weapons tests, ABLE and BAKER, to assess the effects of nuclear weapons against naval war vessels.[1] The ABLE event, conducted on June 30, 1946, was an air drop nuclear device with a yield of 23 KT. The BAKER event, conducted on July 24, 1946, was an underwater detonation with a similar yield. As a result of these tests, 12 vessels lie within a one square mile area of the lagoon floor at a depth of 165 feet (Figure 1). The ships sank in battle-ready condition, loaded with fuel and ordnance. The

general location of the ships can be identified by an oily sheen on the surface of the water.

The target vessels used in Operation Crossroads included: attack transports, submarines, cruisers, aircraft carriers, destroyers and battleships. Major hull damage occurred to all types of vessels.[3] The vessels suffering the greatest damage during the ABLE Event were the *Carlisle* and *Gilliam*, which sank as a result of the test. The remaining vessels currently reported on the lagoon floor were sunk during the BAKER event. In a 1947 resurvey of several ships,[4] the *Saratoga* and *Pilotfish* were reported to have incurred much more extensive damage as a result of BAKER than previously estimated. Overall, ships sunk during BAKER received the most structural damage consisting of buckling of plates, breaching of hull and impairment of the boiler operation resulting in a reduced military efficiency.

A significant amount of fuel oil probably was released from the vessels that sank during Operation Crossroads. The amount of product released from the four most damaged vessels, *Carlisle*, *Gilliam*, *Pilotfish* and *Saratoga*, could account for a 50% reduction in the remaining estimated fuel load. Historical records, however, provide no information about the release of oil from specific ships.

Refined petroleum products are the major contaminants of concern in relation to potential risks to the marine environment from the sunken ships.[3] The vessels sunk in Bikini Atoll lagoon contained three types of refined petroleum products; gasoline, diesel oil (Fuel Oil No. 2) and Bunker C (Fuel Oil No. 6) (Table 1). Other potential contaminants include lead and sulfuric acid from batteries used on the submarines and radionuclides, principally cesium-137, strontium-90 and transuranics (plutonium and americium), remaining in the sediments surrounding the vessels. Overall, radionuclides in the marine environment have largely diminished by exchange of lagoonal water with the open sea. These other contaminants will not be discussed further in this investigation.

Bunker C, the predominant product, is an oil of high viscosity that must be heated to produce a more fluid consistency. It may be a residual oil from the distillation of crude petroleum, or it may be a mixture of two or more of the distillate cuts.[5] Based on the differences in physical and chemical properties of diesel oil and Bunker C, diesel fuel probably would be released to the environment more readily than the more viscous Bunker C.

Historical accounts of the fuel capacity and percent of capacity were used to calculate fuel load prior to Operation Crossroads.[3] The combined total volume of gasoline, diesel oil and Bunker C was estimated at slightly under 2 million gallons (Table 1).

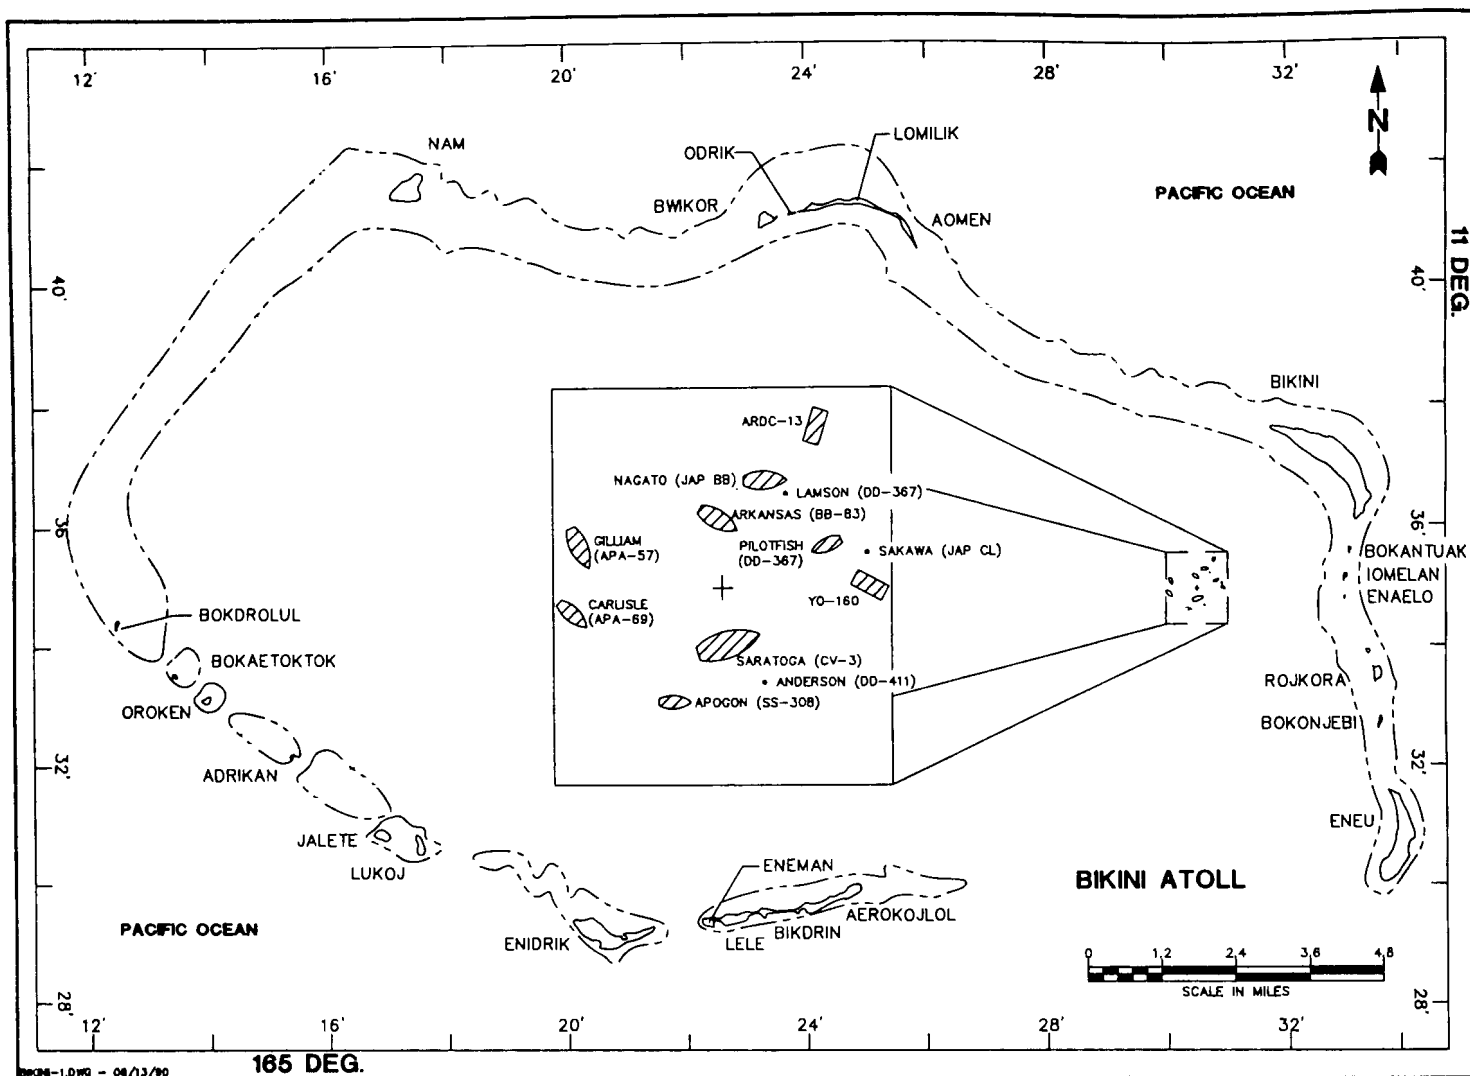
The amount of product lost during Operation Crossroads is unknown. The only historical account reported observations of a "great oil slick" resulting from BAKER.[6] The oil slick was discovered during a recon-


Figure 1
Location of Vessels Sunk During Operation Crossroads.
Stars Indicate Unverified Positions

naissance flight the day after the BAKER event when an area of high radioactivity was encountered on the surface ocean, miles north of Bikini Atoll. Historical accounts report that the oil slick, heavily impregnated with fission products, moved to the north from the target fleet, passed over the reef between Aomen and Bikini Islands and went out to sea. A "gummy emulsification" was noted smeared over the reefs and sandspits along the northern to northeastern flanks of the Atoll. The dimensions of the great oil slick were estimated to be greater than 1 mile in width and length, however, there was no mention of the thickness or color of the oil slick or estimate of the amount of product lost during the event.[6] If all the product, approximately 2 million gallons contained in the ships, was lost during the Baker event, an oil slick of the observed dimensions (estimated at 1.5 x 1.5 miles) would be approximately 1.3 mm thick. A surface slick with this layer thickness would be indicative of a significant surface concentration (Figure 2) and would not be unusual for oil slicks resulting from tanker or other types of petroleum product accidents.[5]

Recent observations of oil slicks emanating from the sunken ships suggest that not all product was released during the Baker event. Therefore, the estimated thickness of the slick, 1.3 mm, would have to represent an upper boundary. In addition, the observation that the oil slick had discrete dimensions suggests that the product was released fairly quickly after the BAKER event upon which little further release of product occurred.

In conclusion, these historical accounts suggest that a fairly significant amount of product could have been lost during the BAKER event; however, a quantitative estimate is unavailable. Furthermore, the remaining fuel load must be much less than the estimated 2 million gallons.

SITE INSPECTION

Location of Vessels

Prior to this investigation, the exact locations of the ships were unknown. A shallow water side-scan sonar and a shore-based navigational system were used to locate physical features, contacts, on the lagoon floor. These contacts were verified with visual observations made by diving. Nine of the 12 vessels known to have sunk at Bikini Atoll were located and marked (Figure 1). Included in the nine vessels found, the ARDC-13 is a concrete dry dock and the YO-60 is a concrete barge. The locations of two destroyers, *Lamson* and *Anderson*, and the Japanese cruiser, *Sakawa*, have not been found.

Long-term Deterioration of Vessels

The present condition of the vessels is the result of: (1) initial structural damage from Operation Crossroads, and (2) long term deterioration. Because no future catastrophic impact to the ships of the magnitude of Operation Crossroads is expected, long term deterioration is probably the most important factor influencing the rate of chronic release of product to the environment.

Table 1
Fuel Load of Ships at Bikini Atoll Prior to Operation Crossroads

SHIP	FUEL TYPE	CAPACITY	PERCENT CAPACITY	FUEL LOAD (gallons)

Figure 2
Approximate Classification of Slicks Based on Surface Concentration of Spill after Barger et al. (1974)

The ships have undergone significant deterioration over the past 44 years. Visual observations of the present condition of each ship were made by diving. An accelerated rate of decay of the vessels is suggested when compared with observations made of ships of the same vintage

sunk in similar oceanic conditions (e.g., the Ghost Fleet of Truk Lagoon).[7] Within a single year, significant structural changes have been observed on the flight deck and hangar deck of the *Saratoga*. In August 1989, four hellcat fighters were accessible along the starboard portion of the hangar deck. The most recent observations of this area (May 1990) revealed that the flight deck above had collapsed into the hangar deck crushing the third and fourth planes. Portions of the ship recorded as attached to the flight deck the previous year are now resting on the lagoon floor. Deteriorating metal particles rain from the ceiling of the hangar deck at the slightest disturbance to the surrounding water.

The factors influencing the rapid deterioration are unknown, but could be related to a number of variables, such as, initial blast effects to the metal and/or lack of significant marine fouling that serves to protect the surface of the ship from deterioration. Benthic invertebrate and algal growth on the ships is sparse in comparison with the heavy growth observed on the sunken ships at Truk Lagoon.[7] Significant coral growth was observed[7] on and about the sunken ships in Truk Lagoon, and no evidence of environment degradation was reported although fuel oils were slowly seeping from the ships. The deeper depths of the ships at Bikini Atoll (>130 feet) result in lower light levels when compared with the shallower sunken ships (<100 feet) found at Truk Lagoon. Although benthic invertebrate and algal growth covering the ships structure is sparse, adult and juvenile reef fishes are abundant on each ship. The composition of fish genera was similar to patch reefs at similar depths, suggesting that the ships are serving as artificial reefs.

Although the rate of deterioration of the ships cannot be measured, these observations suggest that an increased rate of chronic release of product from the ships could result from accelerated deterioration of the ships' internal compartments.

Chronic Oil Slicks

Small surface slicks have been observed frequently in the vicinity of the sunken ships. In particular, slicks have been routinely observed over the *Nagato*, *Saratoga* and *Carlisle*. Observed slick dimensions vary, indicating a variable release rate of product and/or variable surface dispersion rates which are dependent on wind conditions. These slicks appear as discrete iridescent to dull brown patches usually 5 to 10 feet in diameter, indicating a pulsed rather than continuous release of product.

Samples of surface water collected in the vicinity of the *Carlisle* were analyzed for soluble petrochemicals such as phenanthrene. Six samples were deliberately taken inside and outside the visible boundaries of the surface slick. Only one sample resulted in a concentration (0.15 mg/L) above detection limits (<0.008 mg/L), indicating a low concentration of soluble petrochemicals associated with the surface slick.

This type of chronic release has been observed over at least the last 10 years and probably has been occurring since 1946 when the maximum damage to the ships occurred as a result of nuclear testing.

Table 2
Time to Release Maximum Estimated Product (2 million gallons) from Sunken Ships at Four Spill Rates

RELEASE RATE	DURATION OF RELEASE	
CHRONIC SPILL (5 gal/hr)	16060 days	< 44 years
MINOR SPILL (40 gal/hr)	2083 days	< 5 years
MEDIUM SPILL (400 gal/hr)	208 days	< 1 year
MAJOR SPILL (4,000 gal/hr)	20 days	< 1 month

ESTIMATE OF THE IMPACT OF POTENTIAL CHRONIC RELEASES

The likelihood of a future catastrophic release of product from the ships is remote since these vessels already have incurred major physical impacts from nuclear testing. The potential for an increased rate of chronic release of product could occur, however, from ongoing structural deterioration. Impact to the marine environment is related to both spatial and temporal components of a release. Using different estimated rates of release of product, a simple model of dispersion was employed to provide an estimate of the potential lateral extent of a release to the marine environment.

Model for Estimating Oil Slick Dimensions and Trajectory

A rough estimate of the loss of product from a long-term chronic release was estimated using several approaches to provide a range of possible release rates. If the maximum volume of product, 2,000,000 gallons, were released continuously and totally over a period of 44 years (to present) and no other product remained in the ships after this time, the resulting release rate would be estimated at 5 gallons per hour (Table 2). Because small amounts of product continue to be released from the sunken ships, this estimate probably represents a high rate of current release from the ships.

The time to release the maximum product volume was also calculated for higher release rates (Table 2), assuming that a significant amount of product still remains in the sunken vessels. Release rates of 40, 400 and 4,000 gallons per hour were based on the total volume of oil discharged over a 24-hour period for three classes of spills: a minor spill of less than 1,000 gallons, a medium spill of between 1,000 and 10,000 gallons, or a major spill of greater than 10,000 gallons. The time to release the maximum estimated product at a rate for a major spill (4,000 gal/hr) would be 20 days. Order of magnitude estimates of slick dimensions for various release rates were calculated using the equations developed by Murray[8] and applied by Lukas.[9] The following equations for oil slick width (W) and length (L) were developed for a steady state oil slick emanating from a continuous source:

$$W = 2Q/(2\pi e)^{1/2} UC_b, \tag{1}$$

where

Q is the source strength (g/sec)
U is the current speed (cm/sec)
C_b is the concentration of the oil at the visible boundary (gr/cm^2)

Murray[8] found that the value of C_b was approximately 0.15×10^{-3} gr/cm^2. Using the relation Q= p oil x Volume discharge rate, and a value of 0.922 g/cm^3 for the density of oil, the width of the oil slick is found to be:

$$W \text{ (feet)} \quad 92.8 \times V(\text{gal/hr})/U(\text{cm/sec}) \tag{2}$$

For the length of the steady-state oil slick, Murray gives the expression:

$$L = Q^2/(4\pi KUC_b^2) \tag{3}$$

where

K is the turbulent diffusion coefficient (cm^2/sec)

As before, with the proper substitutions:

$$L(\text{feet}) = 8.89 \times 10^4 \times V^2(\text{gal/hr})/K(\text{cm}^2/\text{sec})U(\text{knots}) \tag{4}$$

Although the value of K should be determined experimentally for the conditions that prevail at the time of an oil spill, the value of K= 2 x 10^5 cm^2/sec that Murray found in his study can be used as an order of magnitude estimate to get:

$$L(\text{feet}) = 0.445 \times V^2 \text{ (gal/hr)}/U \text{ (cm/sec)} \tag{5}$$

Using these equations, slick dimensions were calculated for different release rates and surface current speeds (Table 3). The range of current speeds was calculated as 3% of a range of wind speeds representative of the Bikini area, in which average wind speed is 20 to 25 knots.

Table 3
Estimate of Steady State Dimensions
(after Lukas, 1978)

		Surface Current Speed (cm/sec)		
		40	20	10
Slick Dimensions	(feet)			
Chronic Spill	width	11.0	23.0	46.0
(5 gal/hr)	length	0.3	0.6	1.0
Minor Spill	width	93.0	185.0	371.0
(40 gal/hr)	length	18.0	35.0	71.0
Medium Spill	width	929.0	1855.0	3710.0
(400 gal/hr)	length	1780.0	3560.0	7120.0
Slick Dimensions	(miles)			
Major Spill	width	2.0	3.5	7.0
(4,000 gal/hr)	length	34.0	67.0	135.0
Wind Speed	(knots	30.0	13.0	6.0

This estimate is based on the largely substantiated wind stress/wind drift relationship described by Ekman.[10] A steady-state wind blowing over an infinite, homogeneous ocean, would result in a wind-induced surface current that is 3% of the wind speed at 10 m height in a direction 45° to the right of the wind direction (in the northern hemisphere).

The trajectory of a chronic release is dependent on surface currents. East to northeast trades are the dominant wind conditions at Bikini Atoll (Figure 3). Using the simple relationship above, surface drift of an oil slick would result in a net transport toward the north to northwest (326°).

SSMO   AREA 9

Figure 3
Wind Rose Summarizing Wind Direction
in Vicinity of Bikini Atoll
Estimated Dimensions and Trajectory of Chronic Oil Release

Estimated dimensions and trajectories of steady-state minor, medium and major oil slicks are shown in Figures 4 and 5 emanating from the general vicinity of the sunken ships. Only a major spill would result in a slick of significant surface dimensions that could possible impact natural resources. For this to occur, the chronic release rate would have to increase almost three orders of magnitude.

The dimensions for a major spill would extend beyond the physical boundaries of the atoll passing between Aomen and Bikini Islands. This trajectory is the same as that reported from historical accounts of the "great oil slick."

KEY ECOLOGICAL RECEPTORS AND DISTRIBUTION

Based on the estimated dimensions and trajectory of a major spill, the key ecological receptors impacted by a release of product to the marine environment would be shallow reef environments and their associated fisheries, seabirds and sea turtles. Direct contact by these receptors would be the principal exposure route of concern. A general summary of distribution of these receptors (Figure 6) was excerpted from an extensive environmental assessment of Bikini Atoll conducted in support of the draft Environmental Impact Statement.[2]

Shallow reef flat environments would be greatly impacted by the release of product to the marine environment. Reef flats connect islands and sand spits and are most developed in lateral extent on the windward (northeastern) side of the atoll. Significant subsistence fisheries inhabiting reef flat environments include numerous species of reef fish and giant clams.

Maintenance of the current diversity of Bikini Atoll seabirds would require the preservation of some or all of the islets on the northern and southwestern portions of the atoll.[2] The small southwestern islands which have well-developed forests constitute the only important breeding sites of Black Noddies and Red-footed Boobies on the atoll. The most important islands are Oroken, Lukoj, Bokdrolul and Bokaetoktok. Islands dominated by lower shrubs which have large breeding colonies of noddies, White Terns and Brown Boobies are Nam, Odrik/Lomilik/Aomoen and Jalete. Other islands harboring significant seabird populations are the Bokantuak/Iomelan chain between Bikini and Eneu Islands, Aerokoj/Aerokojlol Islands and Enidrik Island.

The distribution of the existing green sea turtle population at Bikini Atoll was estimated by visiting each islet and making visual observations of turtles, turtle tracks and nests. Turtle tracks and nesting sites were most abundant on islands in the southwestern part of the atoll, although turtles frequently were observed coming ashore on Bikini Island and some nests and turtles were sighted on Nam and Lomilik Islands.

Overall, the highest abundance of turtles and seabirds occurs in the

south and southwestern flanks of the Atoll and not in the vicinity of the proposed trajectory of the oil slick. Major reef flat environments, however, are found principally along the northern and northeastern flanks of the Atoll and would be the most impacted by an oil spill.

CONCLUSIONS

Based on historical accounts and site inspection of the sunken ships at Bikini Atoll, it is concluded that the potential for a catastrophic release of product from the sunken ships is extremely low. No remedial action is the recommended alternative for this site.

The vessels already have incurred maximum possible structural damages from nuclear testing. Accelerated deterioration of the vessels could result in an increase in the currently low chronic release rate of product. Historical accounts suggest, however, that a significant amount of fuel was lost from the ships as a result of the BAKER event, thereby greatly reducing the product available for long-term chronic release. The current low rate of release from the ships has not resulted in any apparent environmental degradation. An increased chronic release rate of product could result in impacts to the northern and northeastern flank of the atoll; however, estimated dimensions and duration of even a major spill would be limited in impact.

Fuel recovery would eliminate the long-term risk of chronic oil spill to the environment. This alternative could result, however, in short-

term impacts from the release of fuel during recovery operations. In addition, the deep depth, deteriorating condition of the ships and viscous nature of the predominant fuel, Bunker C, would make this alternative difficult to implement and extremely costly. Furthermore, the highly weathered nature of the petroleum products would probably make the recovered fuel unsalvageable.

Consideration of Non-Routinely Monitored Hazardous Substances for the Health Assessment

Eileen A. Furlong
Theresa A. Barry
Suzanne K. Condon
Division of Environmental Health Assessment
Massachusetts Department of Public Health
Boston, Massachusetts

ABSTRACT

When conducting Health Assessments of Superfund sites, an attempt is made to determine the specific human health outcomes that might be associated with exposure to site-related contamination. The possible human health outcomes are important for a variety of reasons, such as: (1) worker and public safety during remediation, (2) identifying sensitive subpopulations, (3) targeting specific health effects for the evaluation of health outcome data and (4) determining the need for a health advisory or other action. Therefore, information on the presence of nonroutinely monitored hazardous substances would increase the ability of the health assessor to identify public health problems.

This information can be obtained by examining various factors. The Massachusetts Department of Public Health (MDPH) has identified additional hazardous substances by reviewing information on the chemicals used at a site, chemical impurities and natural and unusual degradation processes. The four cases presented provide examples of how each chemical was identified, how exposure might occur, the possible health outcomes and the resulting public health recommendations or activities.

INTRODUCTION

The Massachusetts Department of Public Health (MDPH) was one of the original participants in ATSDRs Cooperative Agreement Program to conduct Health Assessments at Superfund sites. This paper describes, in part, the MDPHs approach when conducting Health Assessments.

The Health Assessment process considers: (1) the important contaminants at a site (2) the environmental fate and transport of those substances (3) the possible human exposure scenarios and (4) the public health implications (based on available medical and toxicological information) associated with a site. Emphasis is placed on the specific human health effects that might result from exposure to site-related contaminants. Two important parts of the Health Assessment are the evaluation of health outcome data and addressing community health concerns. Ideally, information on the possible human health effects is used in these analyses. The health outcome data analyses can target the health effects to better assess the possible impact of the site on local health; therefore, a thorough understanding of the contaminants present at a site would aid this process. Information on the contaminants present usually is obtained from the Remedial Investigations prepared as part of the cleanup effort as well as other site-specific documents. Most of the substances monitored during the Remedial Investigation are contained within the Superfund Target Compound List (TCL).

A TCL is a media-specific list of compounds that can be detected by a specific analytical method. The Superfund TCL is a list of compounds detected in soils, water and sediment by the analytical methods entailed in the Routine Analytical Services for the U.S. EPA Contract Laboratory Program. This list is periodically revised and, currently, contains 125 organic compounds and 24 inorganic compounds. Depending on site-specific factors and following U.S. EPAs preparation of a Special Analytical Request, other media and compounds can be monitored. Remedial Investigations frequently contain data from special analyses.

The TCL is designed as a tool for remediation purposes and not for determining the potential human health effects. Therefore, the health assessor should consider what other hazardous compounds might be present. Following this process, the findings might include: (1) the need for additional environmental monitoring or other information (2) the potential need for a health advisory or other public health intervention strategies and (3) the specific human health effects to be examined during the evaluation of health outcome data. These findings could be important later in the Health Assessment.

While preparing Health Assessments, the MDPH has used monitoring data for non-TCL hazardous substances contained within the Remedial Investigations and has shown the potential presence of other non-TCL hazardous substances. Selected non-TCL substances have included polychlorinated dibenzofurans, polychlorinated dibenzo-p-dioxin, phenoxy herbicides, methyl mercury compounds, arsine and methylarsines, naphthylamines and benzidine and its analogs. The following four cases are examples of the MDPHs experiences. Information presented includes: (1) the presence or potential presence of a non-TCL substance (2) the site-specific environmental and human exposure pathways (3) the possible human health outcomes or other toxicological information and (4) the conclusions and recommendations or the results of follow-up activities.

CASE EXAMPLES

Case 1: Polychlorinated Dibenzofurans

Site "A" is a granite quarry that was used as an industrial landfill for approximately 30 years. Waste deposited in the landfill included capacitors, transformers, organic solvents and tires. Contamination at the site consists of PCBs, VOCs and other chemicals. In particular, Aroclor 1254, a commercial mixture of PCBs, was detected in the sites soils at levels up to 2,200 mg/kg. Extensive fires occurred at the site, and the tires, solvents and various debris burnt for days before the fire was brought under control.

Laboratory investigations have determined that PCBs can be converted to polychlorinated dibenzofurans (PCDFs) by thermal processes.[1-5] PCDFs are more potent carcinogens than are PCBs. Based on laboratory experiments, the proportion of PCBs transformed into PCDFs is dependent upon PCB and oxygen concentrations as well as temperature and time of reaction, but, under certain conditions, can result in a conversion in the percent range.[1,4] A real life situation (i.e.,

the explosion and fire of an electrical transformer at the Binghamton State Office Building in Binghamton, New York) confirms that a percent range conversion to PCDFs can occur.[4] Although PCDFs are common trace contaminants of commercial mixtures of PCBs, the proportion (roughly 0.0002% for Aroclor 1254[4,6]) is much smaller than that from some thermal processes.

A limited amount of polychlorinated dibenzo-p-dioxin (PCDD) monitoring occurred at Site "A". No PCDDs (specifically 2,3,7,8-tetrachlorodibenzo-p-dioxin) were detected in the soil samples above the method detection limit of 1 ug/kg. PCDDs do not normally form from the heating of PCBs, but thermal reactions of polychlorinated benzenes result in the formation of both PCDFs and PCDDs.[4] The transformer in the Binghamton accident contained 65% Aroclor 1254 and 35% polychlorinated benzenes;[7] hence, the detection of PCDDs in the soot of this fire is not surprising. The level of total PCDDs (20 ppm) detected in the soot was approximately 100 times lower than the level of total PCDFs (>2,000 ppm) detected.[4] Whether polychlorinated benzenes are present at Site "A" is unknown; however, PCDD monitoring would not be an appropriate surrogate for determining if PCDFs might be present.

Whether conditions at the time of the on-site fires were appropriate for PCB conversion to PCDFs is unknown. However, because of the toxicity of PCDFs and the actual PCB levels detected in on-site soils, the possibility of past PCDF formation is of public health concern. No information is available for PCDF occurrence in the soils and sediments associated with the site. Based on a limited amount of experimental animal data and on in vitro studies of structure/activity relationships, PCDFs appear to express PCDD-type toxicity.[8] Like the PCDDs, the 2,3,7,8-congeners of the PCDFs are the more potent toxins and have been estimated to be 0.33 to 0.02 times (a 0.1 relative potency rate most frequently estimated) as potent as 2,3,7,8-TCDD.[8] Congeners other than the 2,3,7,8-PCDFs have been estimated to be 1,000-fold less potent than the 2,3,7,8-PCDFs.[8] The relative proportion of each PCDF formed is difficult to predict; thus, the following 2,3,7,8-congeners are of interest:

2,3,7,8-tetrachlorodibenzofuran
1,2,3,7,8-pentachlorodibenzofuran
2,3,4,7,8-pentachlorodibenzofuran
1,2,3,6,7,8-hexachlorodibenzofuran
1,2,3,7,8,9-hexachlorodibenzofuran
1,2,3,4,7,8-hexachlorordibenzofuran
2,3,4,6,7,8-hexachlorodibenzofuran

A recommendation was made within the Site "A" Health Assessment that soil and sediment monitoring be conducted for the 2,3,7,8-congeners of the PCDFs listed above. This additional monitoring will be implemented during a future remedial investigation.

Case 2: Naphthylamines and Benzidine and its analogs.

At Site "B," azo and anthraquinone dyes were produced for approximately 70 years. From the review of the company's purchasing and product lists and information from the Colour Index,[9] large quantities of benzidine, naphthylamines and related aromatic amines were known to have been purchased for the production of azo dyes. Both 2-naphthylamine and benzidine are human bladder carcinogens.[10-12] Other aromatic amines and benzidine-based dyes have been associated with bladder cancer in animals or humans.[10] However, at this site, monitoring data for these compounds did not exist.

Waste products and sludges were disposed on a hill and effluent was discharged into nearby wetlands and a brook. The soils, wetlands and water in the brook were often vividly colored. The brook discharges into an off-site river. Based on anecdotal information, the river was discolored until the early 1980s. In addition, the groundwater migrating from the site is highly contaminated with organics used in the manufacture of dyes. At various times, particulates, aerosols and vapors were emitted from the facility into the ambient air. As a result, nearby residents complained about: (1) dye-flecked belongings; (2) pitted automobiles, (3) noxious odors, and (4) irritated and burning eyes, noses and throats. The site also was a popular play area for neighborhood children, who often returned home with discolored clothes and skin.

Benzidine may be resistant to transformation and degradation, especially in anaerobic conditions, but microbial degradation can be substantial following acclimatization. However, high concentrations of benzidine are toxic to microorganisms.[12] Reduction of the azo bond(s) in benzidine-based dyes results in the release of benzidine.[12] Reduction can occur in the gut, on the skin surface and in the environment. Benzidine is more readily absorbed through the gut and skin than are the benzidine-based dyes.

Environmental monitoring for these compounds was recommended because: (1) there was a lack of monitoring data (2) benzidine and related compounds may be persistent in the environment (3) these compounds were purchased and dyes were produced (4) benzidine and 2-naphthylamine are human bladder carcinogens (5) waste disposal and emissions were extensive and (6) contaminants are transported to populated areas and human exposure occurred both on-site and off-site. Because remediation is currently occurring, on-site soils and sludges were not monitored for these compounds. However, groundwater and the rivers sediments and surface water were monitored. The preliminary data indicate the presence of benzidine in groundwater at levels exceeding 100 ug/L. None of these compounds were detected in the rivers surface water or sediment ten years after the facility closed.

An analysis of the cancer incidence and mortality data for the nearby community indicated a statistically significant elevation of male kidney cancer and a possible clustering of male kidney and bladder cases. A case series investigation was conducted to determine if the site or some other environmental exposure factor might have played a role in the etiology of disease among these individuals. The results of the investigation and the review by an expert panel are pending.

Case 3: Phenoxy Herbicides and Polychlorinated Dibenzo-p-dioxin.

Site "C" is the location of a former mixing and batching facility that operated for approximately 70 years. Products mixed, packaged and stored include herbicides, insecticides, disinfectants, soaps, floor waxes and wood preservatives. The herbicides processed at this facility were 2,4-dichlorophenoxyacetic acid (2,4-D) and 2,4,5-trichlorophenoxyacetic acid (2,4,5-T), the two components of Agent Orange. Both compounds are known to contain polychlorinated dibenzo-p-dioxin (dioxin) impurities, although only 2,4,5-T contains the potent toxin, 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD).

Dioxins and phenoxy herbicides are not currently on the Superfund TCL; however, during the Remedial Investigation of this site, monitoring was conducted for these three compounds. TCDD was detected mostly in on-site surface soils at levels to 48 ug/kg. Both 2,4-D and 2,4,5-T were detected in on-site subsurface soils and groundwater. In addition, 2,4-D was detected at a nearby municipal wellfield in the groundwater and in the subsurface soils below the water table. Because both herbicides are readily biodegraded in aerobic conditions,[13] their nondetection in surface soils was not unexpected.

The municipal wellfield operated from 1959 until 1982. The exact chemicals intercepted by the municipal wells are unknown as are the time period each chemical was intercepted and the concentrations delivered to the distribution system. However, a minimal amount of monitoring of the municipal wells indicated the presence of "phenols" as early as 1959 and of VOCs in 1980. No monitoring was conducted of the municipal well water for herbicides, insecticides, acid/base/neutral extractable compounds, inorganic compounds and certain volatile organic compounds. No aquifer test to determine the capture zone has been conducted.

By 1959, the soils beneath the water table of the wellfield were contaminated. In the 1985 Remedial Investigation, monitoring of subsurface soil borings and groundwater indicated the presence of site-related contaminants below the water table (pesticides, herbicides, creosote constituents and arsenic). Any of the site-related contaminants may have been captured by the municipal wells. The possible exception is 2,3,7,8-TCDD, which binds tightly to soils[14] and has been detected mostly in the surface soil.

The exact area receiving potable water from this wellfield is not known due to a lack of detailed information on: (1) the municipal distribution

system, (2) the relative contribution of the three existing water supply sources at any given time and (3) the effect of demand at any given time. Three observations were used to identify the consumers likely to have received water from this wellfield. First, the water flow within the pipes would tend to follow the path of least resistance; therefore, water from this source would not tend to travel towards the input of the other two water sources. Second, one of the other water sources contained high levels of manganese and iron, which would result in poor aesthetic qualities. This water source elicited strong complaints from the impacted consumers; as a result, the general area that received this water is known. Third, this community shares two water distribution system interconnections with a neighboring town. Because these two towns have the same water sources and treatment plants, the interconnections tended to remain open. The two towns have a total of five census tracts. Two census tracts (one from each town) are more apt to have received drinking water from the contaminated wellfield.

The carcinogenicity of 2,4-D and 2,4,5-T has not been classified by the U.S. EPA or IARC because inconclusive information is available.[13-15] However, based on occupational studies, 2,4-D may be associated with development of non-Hodgkins lymphoma and, to a lesser extent, soft tissue sarcoma and 2,4,5-T with soft tissue sarcoma and, perhaps, non-Hodgkins lymphoma and Hodgkins Disease. These studies cannot determine the relative contribution of the dioxin impurities to the toxic effects. Other site-related contaminants have been associated with non-Hodgkins lymphoma (benzene and arsenic) and Hodgkins Disease (benzene).[16,17] The cancers of the hematological system have been associated with various risk factors, including immuno-deficiency.[18] For example, primary, acquired and therapeutic immunodeficiency disorders have been shown to increase the risk of developing non-Hodgkins lymphoma. Site-related contaminants that may impair the immunohematopoietic system or depress immunity include chlordane, DDT, dieldrin, hexachlorocyclohexanes, 2,3,7,8-TCDD, benzene and arsenic. Whether the chemicals affecting immunity and those chemicals implicated in hematologic cancers interact in a synergistic manner to increase the risk of developing non-Hodgkins lymphoma or Hodgkins Disease is unknown.

Soft tissue sarcoma, non-Hodgkins lymphoma and Hodgkins Disease were added to the primary cancers usually considered by the MDPH for the health outcome study, because: (1) a number of site-related compounds have been associated with these cancers and (2) human exposure to a large population may have occurred via the municipal water distribution system. The two census tracts most likely to have received the water were targeted in the analyses of health outcome data. The health outcome analyses indicated statistically significant elevations in non-Hodgkins lymphoma incidence in the two targeted census tracts, but not in the three bordering census tracts. Statistically significant elevations in Hodgkins disease and soft tissue sarcoma incidences were not observed. As a result of these findings, physician and community education programs will be implemented. Currently, Site "C" is being evaluated by ATSDR for appropriate follow-up with respect to these potential health effects.

Case 4: Arsine and Methylarsines.

Another compound processed at Site "C" was sodium arsenite. Aqueous solutions of this compound were prepared for use as a potato top and weed killer. Arsenic has been detected in the sites soils, sediments, groundwater and surface water at levels to 380,000 mg/kg, 1,290 mg/kg, 3,850 ug/L and 87 ug/L, respectively. The on-site wetlands contain arsenic-contaminated soil at levels to 5,700 mg/kg.

Wetland soils tend to be relatively anaerobic, reducing environments and, under these conditions, arsenic could be reduced and methylated by microbial organisms to volatile species. The predominant forms found in similar environments (e.g., swamps and bogs) are methylarsines, arsine and elemental arsenic.[16] This process also could occur in other anaerobic/reducing environments, such as river or lake sediments and flooded areas. The species of arsenic present are dependent upon the physical and chemical characteristics of the soils and groundwater and the presence of microflora. The species present would change as con-

ditions change. Speciation of arsenic was not conducted during monitoring and, therefore, the presence of arsine and methylarsines has not been confirmed. However, volatilization of arsine and methylarsines should not be a factor unless soils are disturbed, such as during remediation.

Hemolytic anemia is known to occur following inhalation of arsine and, to lesser extents, methylarsines.[16] This disease is also known to occur in humans following oral, inhalation, dermal and transplacental exposure to naphthalene.[19] Naphthalene has been detected in the sites soils and groundwater at levels to 3,400,000 ug/kg and 13,000 ug/L, respectively. Individuals deficient in erythrocyte glucose-6-phosphate dehydrogenase (G-6-PD), an X-chromosome linked recessive trait, are susceptible to hemolytic anemia from exposure to naphthalene. Because this trait is X-linked, males express this disorder more often than females.[20] The severity and frequency of the deficiency varies between ethnic groups. Susceptibility of developing hemolytic anemia exists because reduction of NADP (and also GSSG) does not readily occur; thus, a challenge by an oxidant can result in depletion of GSH, oxidation of hemoglobin and hemolysis.

Whether individuals with G-6-PD deficiency are also susceptible to arsine- and methylarsine-induced hemolytic anemia is unknown, but appears probable. Both naphthalene and arsine act by depleting GSH and causing the oxidation of hemoglobin and hemolysis. In addition, symptoms of naphthalene and arsine toxicity are the same, i.e., jaundice, anemia and renal damage.[16,20]

Excavation of soils and wetland areas during remediation could result in the release of naphthalene and arsine/methylarsines, respectively. Without the proper safeguards, susceptible individuals could develop hemolytic anemia. Because arsine and methylarsines are oxidized to nonvolatile forms once released to the atmosphere,[16] human exposure and health effects from these chemicals are unlikely in off-site areas. Due to the concern from hemolytic anemia, a recommendation in the Health Assessment was to identify whether individuals who will be present during remediation have G-6-PD deficiency. To minimize the possibility of developing hemolytic anemia, particular care is needed to provide the appropriate personal protection equipment to any individual with this deficiency.

DISCUSSION/CONCLUSION

To predict the presence of non-TCL substances, a review of many factors is appropriate. The following factors have been examined by the MDPH, and examples are presented in the cases described above: (1) the chemicals used, made or disposed at a site, (2) the by-products or impurities of specific chemicals, (3) the natural degradation and transformation processes for specific chemicals, including microbial processes, and (4) the occurrence of fires at a site, which might result in chemical transformations.

By incorporating this review in the Health Assessment process, the MDPH has determined concern for specific cancers, including rare cancers and other adverse health outcomes. These cancers were then targeted in the review and analysis of health outcome data contained in each health assessment prepared by the MDPH. Another paper to be presented at this conference expands this idea and presents a case example.[21] In addition, the inclusion of non-TCL hazardous substances has led to various conclusions and recommendations in the Health Assessment, such as: (1) recommended environmental monitoring for specific non-TCL compounds, (2) the potential existence for specific cancers and other human health outcomes, (3) the potential existence of a sensitive subpopulation and recommended further identification of that population and (4) recommended worker and public safety precautions relative to specific non-TCL substances.

Ecological Assessment and Modeling of a Contaminated Wetland

Peter Boucher

U.S. Environmental Protection Agency
Boston, Massachusetts

ABSTRACT

Disposal practices at the Sullivan's Ledge Superfund Site in New Bedford, Massachusetts, have resulted in the transport of contaminants including PCBs to wetland areas downstream of the landfill. An ROD was signed on June 29, 1989 which outlined the remedial action to be undertaken at the site. However, there is concern that, if a portion of the PCB-contaminated sediments in wetland areas within the site are not excavated, they may continue to pose a long-term threat to a variety of aquatic and terrestrial organisms that inhabit the wetland areas. U.S. EPA has determined that additional studies, including biological testing, are needed before a final remedial action decision on the wetlands areas is given.

Determining appropriate remedial action in wetlands is complicated because of the need to: evaluate existing potential wildlife and other wetland values; identify ecological risk due to exposure to contaminated wetlands; and define the transport and distribution of contaminants in the wetland. For this site, additional wetland, hydrologic and ecological studies and soil/sediment sampling have been conducted to further define the nature and extent of contamination of wetlands areas within the site, with particular emphasis on a 12-acre wetlands area named Middle Wetland. These investigations indicate that the highest sedimentary PCB concentrations are located in low lying, frequently inundated areas of the wetland.

The ecological risk assessment indicates that there may be unacceptable ecological risk in the wetland as a result of exposure of organisms to contaminated sediments which support an aquatic food chain as well as exposure of associated terrestrial and semiaquatic food systems to contaminated soils. In order to identify cleanup levels for remediation of wetlands which are protective of the environment, numerous remediation criteria will be developed based on different ecological systems (aquatic vs. nonaquatic and exposures and associated risks). Finally, to evaluate appropriate remedial alternatives for the remediation of wetlands, a thorough examination of sediment and soil removal techniques will be performed to determine remedial options which shall achieve the cleanup objectives while, to the extent feasible, minimizing reduction of the existing wetland values.

INTRODUCTION

The U.S. EPA is conducting, through a contract with Metcalf & Eddy, a remedial investigation and feasibility study of Middle Wetland, a 13-acre palustrine forested wetland downstream of the Sullivan's Ledge landfill Superfund site in New Bedford, Massachusetts. The study area includes Middle Wetland and associated wetlands areas adjacent to the stream (Fig. 1). The landfill site is a quarry that was used between the 1930s and the 1970s as a disposal area for a variety of industrial wastes including capacitors and transformers. The Sullivan's Ledge landfill site

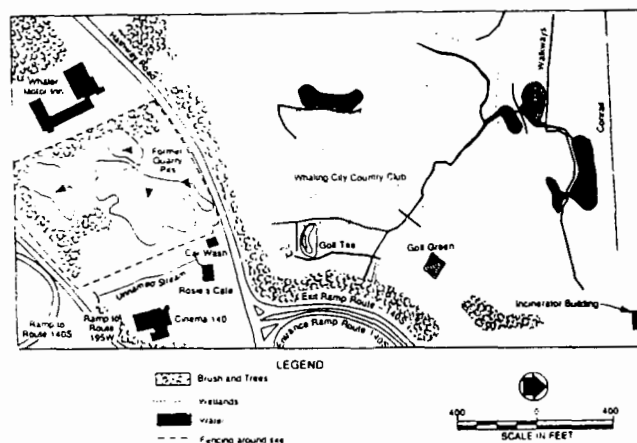
has been the subject of Phase I and Phase II RI/FS completed in January 1989.[1,2] These investigations revealed that contaminants, including PCBs, were present in high concentrations in the disposal area. Furthermore, soils and contaminated groundwater have migrated from the landfill to the adjacent stream.


Figure 1
Middle Marsh Study Area

The 1989 ROD which addressed the landfill and the unnamed stream further specified that the U.S. EPA would conduct additional wetlands, hydrologic, ecological and sediment/soil studies in Middle Wetland to determine whether the contaminants in the wetland posed a significant ecological threat warranting destruction of the valuable habitat in the wetland. These supplemental studies are the focus of this paper.

CONTAMINANT TRANSPORT HYPOTHESIS

The first step in conducting the additional studies was to develop a testable hypothesis concerning the transport of PCBs to and within the wetland. Once the hypothesis was confirmed, the distribution of PCBs could be understood and the areas of maximum contamination and thus greatest potential ecological risk, could be delineated with an efficient sampling program. An understanding of the transport and behavior of PCBs within the different media in the wetland (i.e., soil, sediment, pore water and standing water) would be useful in documenting the ecological risk and assessing various remediation strategies.

The unnamed stream adjacent to the disposal area appeared to be the most likely vehicle for transport of PCBs to Middle Wetland. The

transport would occur by erosion of contaminated soil particles, particularly smaller-sized particles, in the disposal area and then overland flow to the stream during rain events. Immediately adjacent to the disposal area, the stream gradient and thus the velocity, is great, and deposition of contaminated soils seemed reduced. However, once the stream enters Middle Wetland the topography flattens out and particles kept in suspension by the water velocity settle out. A transport hypothesis explaining how the PCBs got to Middle Wetland was posed based on this scenario.

A similar logic was used to develop a hypothesis for the mechanics of PCB distribution within the Wetland. During most hydraulic conditions the channel within Middle Wetland contains most of the flow, but during storms the channel overflows, inundating much of the wetland area. It seemed likely and initial observations confirmed, that when the channel overflowed, the suspended load was deposited in areas of the wetland. It appeared that there were two likely areas of deposition: one was immediately outside of the channel and in immediately adjacent low areas where the suspended load would be deposited in small frequent storms; the other area was at the inland boundary of inundated areas where, during larger storms, advective flow would cease and the remaining suspended load would be deposited. The first area would receive deposition relatively frequently and thus could have high concentrations of PCBs. The second area would receive less frequent deposition events, but because they would occur during larger storms carrying a greater suspended load, they also could have high PCB concentrations.

TESTING THE HYPOTHESIS

A program consisting of three critical elements was conducted to evaluate the PCB transport and distribution hypothesis. The first step was to define and reproduce the hydraulic conditions in the Middle Wetland watershed. The second step was to use this description and other information to predict areas of high deposition and, thus, potential PCB contamination. The final step was to measure PCB concentrations in the areas of predicted elevated PCB levels. The approach for each step is described below. The study is ongoing and not all results are available, but some general observations based on preliminary results are presented.

Middle Wetland Hydraulic Conditions

Preliminary baseline hydrology data were collected under the previous RI. These data, however, were limited with respect to the description of hydrologic conditions downstream of Hathaway Road. In order to support a detailed hydrologic and hydraulic analysis of Middle Wetland and the upstream wetland area, previous data were supplemented with additional hydrologic data collected during three wet weather events using the methods described below. Wet weather events were monitored on January 25, February 10 and April 3-4, 1990. The most definitive data were collected during the storm of April 3-4, when a storm of 3.17 inches of rainfall were measured from start to finish including measurements of peak flow. The April storm was approximately equal to the storm with a 1-year return frequency and resulted in flooding of most of Middle Wetland and golf course areas adjacent to the ponds between Middle Wetland and Apponagansett Swamp. Hydrologic measurements included flow velocity, stage or elevation and depth at preestablished stations in the unnamed stream. Field reconnaissance was conducted during December 1989 to plan the hydrologic surveys and to select cross-sections and flow monitoring stations. Fifteen cross-sections were selected in the unnamed stream for input to the hydraulic model.

During the hydrologic surveys, flows were measured at nine cross-sections. All measurements were taken within the effective cross-section (i.e., shallow areas of bank overflow were not considered). Elevation or stream stage measurements were collected by measuring the distance from the top of a stake of known elevation to the water surface. A rain gage was used to collect information on amount of rainfall. Readings were taken approximately every two hours during the sampling event in order to develop a hydrograph for the storm. These data were supplemented with data collected by the National Weather Service.

As soon as possible after the onset of each wet weather event, the survey crew commenced monitoring stream flow and elevation. Measurements were conducted at established cross-sections until stream flow and elevation had increased and stabilized for a significant period of time or until stream flow and elevation rose and subsided substantially. Monitoring of each cross-section station included measuring flow width and depth and recording observed water quality. The objective of the surveys was to measure peak wet weather flow data with which to calibrate the hydrologic model.

A detailed land survey was conducted focusing on the 13-acre wetland area known as Middle Wetland as well as extensive adjacent golf course areas and a previously unsampled upstream wetland area. The principal technical components of this survey included: (1) development of a 1-foot contour map of the areas described above, (2) surveying of 16 stream cross-sections located at all hydraulic control structures and in open and forested areas to support hydraulic modeling of the unnamed stream, (3) location of numbered perimeter wetland delineation and internal habitat delineation markers, (4) location of previous and planned sediment/soil sampling stations, (5) placement of surveyed stakes adjacent to the unnamed stream to enable measurement of water elevation and (6) establishment and field marking of a 100-foot grid to enable location of selected sediment/soil sampling stations in the field by triangulation. Data collected during the survey were used to produce detailed topographic mapping of the study area at horizontal scales of 1 inch equals 80 feet and 1 inch equals 40 feet, at a contour interval of 1 foot, annotated with numerous spot elevations. Subsequently, digitized contour data were downloaded into a geographic information system (ARC-INFO) and a detailed basemap was generated.

As stated above, the objective of the wet weather stream monitoring was to help describe the hydrologic characteristics of the study area. Stream flow data collected during this study were used, along with drainage catchment and culvert data, to develop a hydrologic model of wet weather surface run-off from subcatchments tributary to the study area. This model was used to predict flow in the unnamed stream for 24-hour storms with return periods ranging from less than 1 year up to 100 years.

Flow predictions in the previous RI were made using TR-55. For this study, TR-20 was used. TR-20 is capable of providing a more detailed approach involving the analysis of separate subcatchments and discrete reaches of stream. The input requirements of these two programs are compatible, thus some of the basic drainage basin and culvert data developed during the previous RI were verified or refined and then reused during this study. Storm distribution, times of concentration and curve numbers were developed using guidance set forth in the Soil Conservation Service National Engineering Handbook. Areas of subcatchments, hydraulic lengths and slopes were developed from the most recent USGS map of the area and city drainage plans.

TR-20 was calibrated using stream flow and rainfall data collected during the April 3-4, 1990 wet weather (storm) event. This storm was used because it was the largest storm monitored and because of the volume of data collected. In addition, data collected for this storm included distinct peak flow measurements. The calibrated model was then used to develop hydrographs for more severe, less frequent storm events with return periods between 1 and 100 years. Peak flows calculated for the 1, 2, 5, 25, 50 and 100 year 24-hour storms were 114, 181, 253, 420, 471 and 555 ft^3/sec, respectively. The flow of 555 ft^3/sec calculated for the 100-year 24-hour storm was used in the hydraulic analysis to determine the extent of the 100-year floodplain within the study area.

A qualitative hydraulic analysis of normal and flood conditions was conducted for the stream reach adjacent to the Sullivan's Ledge disposal area during the previous RI. However, the normal hydraulic regime and flooding within the study area downstream of Hathaway Road were not addressed in detail. Accordingly, a detailed analysis of normal and wet weather hydraulics, as well as extreme flooding, was conducted for the area downstream of Hathaway Road.

A one-dimensional hydraulic model was developed for the area between Hathaway Road and the Conrail railroad embankment. Although Middle Wetland comprises a relatively small part of this area,

the hydraulics within it are controlled by the response of the entire area. HEC-2 (published by the U.S. Army Corps of Engineers[3]) was used to simulate normal and wet weather hydraulics within the entire area. This model assumes gradually varied flow conditions.

HEC-2 requires the development of detailed cross-sections of the stream and overbank areas as well as for all culverts, weirs and bridges. Detailed stream cross-section and topographic mapping of overbank wetland and low-lying golf course areas were used to develop cross-section input data for HEC-2. Flow input to the model was developed from monitoring data collected during wet weather events and TR-20 hydrologic modeling predictions for 24-hour 1, 2, 5, 25, 50 and 100 year design storms.

One objective of the hydraulic modeling was to determine the frequency and extent to which different areas of Middle Wetland are flooded. This information was needed as the basis for selecting sediment/soil sample locations within the range of elevation intervals in the wetland to identify correlations between contaminant levels and elevation or flooding frequency. However, following an analysis of the 1, 2, 5, 25, 50 and 100 year storm flows, it was revealed that the majority of Middle Wetland flooded during all storms analyzed. Thus, it was necessary to evaluate smaller storms with return periods between 0 and 1 year. Since there are no established literature values for storms below a 1 year return period, various storms of less than a 1 year return period were selected by extrapolating from a plot of rainfall versus return frequency on log-probability paper. Peak flows calculated for the 3 month, 6 month and 9 month storms were 30, 68 and 90 ft³/sec, respectively. The results were used to evaluate the frequency with which the unnamed stream overtops its banks and floods depressed wetland areas near the bank of the unnamed stream.

Flood elevations for the 3, 6 and 9 month and the 1, 25 and 100 years storms were superimposed on the basemap of the Middle Wetland area. This analysis revealed that due to the low flat topography of Middle Wetland, the banks of the unnamed stream overflow at least once every 3 months for a 24-hour storm, flooding extensive areas of Middle Wetland. The 3 month storm floods areas below elevation 63 encompassing approximately 6 acres of the wetland extending into the extremities of the area on both sides of the unnamed stream. The 6- and 9-month 24-hour storms flood to elevations 63.92 and 63.34, respectively, encompassing smaller increments of the wetland due to the rising topography at the edges of the wetland, resulting in flooding of a 0.5 acre area not inundated by the 3 and 6 month storms. With a flood elevation over 64 feet, the 9 month storm also results in inundation of approximately 3 acres of golf course fairways adjacent to the hazards or ponds between Middle Wetland and the railroad embankment. The 25 and 100 year storms inundate the entirety of Middle Wetland and significantly larger areas of the golf course.

Prediction of Contaminated Areas

The objective of predicting contaminated areas was to follow the logic of the transport and distribution hypothesis and identify likely areas of contamination. Also, as an evaluation of the hypothesis, areas that could be contaminated as a result of alternative transport mechanisms were identified. Each area identified as potentially contaminated by the primary or alternative hypotheses was then slated for sampling.

As described above, the hydraulic modeling identified areas that were frequently inundated and thus potentially contaminated. It could be demonstrated that several of the areas were flooded due to run-off from the margins of the drainage basin and not from overflow of the unnamed stream channel. In these cases, contamination was not expected and they were not selected for intensive sampling. Some such areas were sampled and, if high concentrations of PCBs were found, the hypothesis tested would not fully explain the distribution and transport of contaminants.

The modeling predicted frequent inundation of a wetland area just upstream from Middle Wetland. Although there was no previous documentation of contamination in this wetland area, under the transport and distribution hypothesis, it met the conditions for potential contamination. Consequently, it was identified as a potentially contaminated area.

There were areas within Middle Wetland that supported different vegetation types indicating differences in elevation and thus frequency and extent of inundation. In several of these areas, the detailed topographic survey conducted for the hydraulic modeling did not identify the small differences in elevation and hydrology that can produce such vegetative differences. Also, areas that were historically low could have received significant deposition (and thus potential contamination) over time. Such areas might not now be active depositional areas now but the historic deposition could support different vegetation and these areas were identified as potentially contaminated areas.

A topographic high spot on the northern side of Middle Wetland is an example of an area supporting different vegetation that could be contaminated even though inundation from the stream channel was not predicted for the area. This area supports a stand of the Common reed *Phragmites* and is adjacent to a water hazard on the golf course just beyond Middle Wetland. Previous studies and observations have documented that the sediments in the water hazard are contaminated. Since the Common reed frequently grows in disturbed soils, such as dredged material, the presence of the reeds in this area could indicate potentially contaminated dredged material.

The final category of potentially contaminated areas was previously identified "hot spots." Neither the persistence or the cause of the areas of elevated PCB concentrations had been fully documented. If the "hot spots" correlated with predicted depositional areas and they were consistently higher in PCB concentration than surrounding areas, then the transport hypothesis would be advanced. Other results could indicate a different transport mechanism and/or a secondary source of contamination.

Measurement of PCB Concentration in Potentially Contaminated Areas

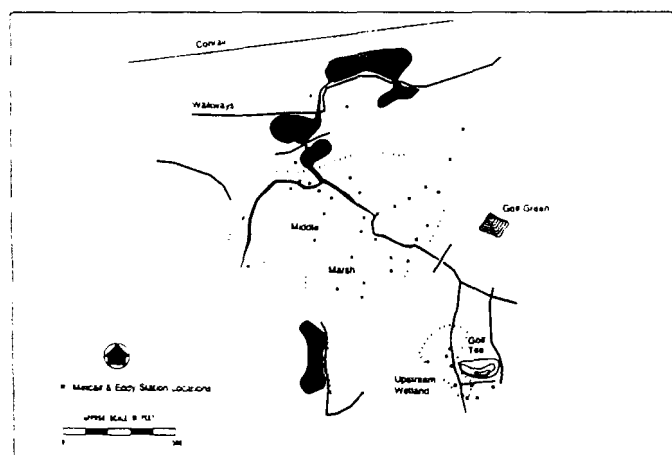
To evaluate the potentially contaminated areas, 42 stations were sampled (Fig. 2). At 12 stations, two-foot core samples were taken in four six-inch fractions to examine the vertical extent of contamination. As PCBs are hydrophobic and tend to adhere to organic soils, each sample was analyzed for total organic carbon. To examine partitioning of contaminants between the sediments and water, a pore water sample was extracted using a well point and bailer. If standing water was present at the station, a surface water sample also was collected.


Figure 2
Middle Marsh Soil/Sediment Sampling Stations

This sampling protocol allows not only the identification of contaminated areas, but also provides information which will aid in interpreting the transport and distribution mechanisms. The information also will be useful in understanding the potential bioavailability of the PCBs and thus lend insight into the ecological risk.

The data validation and interpretation are ongoing, but some preliminary results allow for some general interpretations. Sampling results showed a strong correlation between PCB concentrations and

frequency of flooding and supported the hypothesis that deposition occurs mostly in areas close to the stream and in the most upgradient areas of the wetland where stream flows heavy in sediment are expected to meet quiescent areas of Middle Wetland formed during periods of flooding. There is some indication that the most upstream areas of Middle Wetland, which would receive a higher proportion of sediments from Sullivan's Ledge disposal site, have the highest concentration of PCBs (Figs. 3 and 4).

The highest concentrations of PCBs were found in the wetland area upstream from Middle Wetland (Figs. 3 and 4). Subsequent observations during a major storm event indicated that under very high flow conditions the stream overflows the channel in this area and, thus, it is the first area where suspended particles can be deposited. This information lends strong support to the primary contaminant transport and distribution hypothesis. This finding has prompted additional investigations in the area to further define the extent and degree of contamination.

Perspective of PCB Concentration

REMEDIATION APPROACH

There are two elements of the Middle Marsh remediation that must be considered in a site-specific manner. The first remedial element is defining the ecological risk in Middle Marsh as it relates to contaminant concentrations, and the second element is alternative remediation techniques that minimize disruption to existing wildlife and other wetland values of Middle Marsh. Each of these element is discussed below.

Defining Ecological Risk

A critical element in defining the ecological risk is the development of appropriate remediation criteria. Potential criteria designed to pro-

tect biota include sediment quality criteria which are based on the equilibrium partitioning method and accumulation factor-based criteria developed from ecological modeling and estimates of bioaccumulation. In Middle Marsh, both of these approaches may apply and we are investigating the details and application of each process.

Sediment quality criteria are used to estimate sediment toxicity and the biological impact of in-place contaminated sediments. They are intended to be protective of the presence and uses of benthic organisms.[4] The method of calculating sediment quality criteria is based on: (1) the pore water concentration being controlled by partitioning between the liquid phase and the solid phase and (2) the fact that toxicity and exposure of benthic organisms are a function of the pore water concentration rather than the total concentration in the sediment. Partitioning is dictated by a partitioning coefficient that allows calculation of pore water concentration from known sediment concentrations. Organic contaminants, like PCBs, sorb to organic carbon in the sediments. The partitioning coefficient is based on the contaminant characteristic, the octanol-water partioning coefficient and the carbon fraction in the sediment. Hydrophobic chemicals tend to bind to colloidal organic particles. Thus, there is an inverse relationship between the organic content of soils and the bioavailability of PCB. Use of this method depends on the assumption that benthic organisms are as sensitive to contamination as are water column organisms.

Contaminant-specific criteria for sediments are derived from water quality criteria[5] through use of the partitioning coefficient. These data allow back-calculation of safe sediment levels in pore waters that will not exceed water quality criteria. These criteria are intended to protect benthic organisms from long-term exposure and bioaccumulation in higher levels of the food chain. For PCBs, the chronic water quality criterion for freshwater initially set forth by the U.S. EPA in 1980 is 0.014 ug/L and is based on protection of wildlife from long-term consumption of benthic organisms and their predators. Such benthic organisms exposure and accumulation of PCBs is based on intimate contact with the contaminated sediments and associated pore waters. This occurs in true benthic organisms through cutaneous or gill breathing as well as feeding. Many of the freshwater organisms are filter feeders and pump large volumes of water (or use currents for the same purpose) in the process of feeding.

In Middle Marsh, there are areas which support benthic organisms, and there are consumers of such organisms. Therefore, the exposure pathways and assumptions used to develop sediment criteria exist. In these areas the application of sediment quality criteria may be the appropriate method to establish remediation criteria. Efforts are currently underway to delineate areas that could support such aquatic communities. The delineation is being performed by evaluating the hydraulic information to define areas that support standing water most of the year. This information is being supplemented by observations of benthic organisms during the drier part of the year in the identified areas.

In much of Middle Marsh, conditions are not likely to support a self-sustaining aquatic community. In these areas, the hydraulic information does not indicate extended periods of standing water, the vegetation is not reflective of open water environments and the densely vegetated substrate inhibits a self-contained aquatic food chain. In these areas, there may not be the exposure pathway of true aquatic systems because the mechanisms do not exist to allow for the transport of PCB through the aquatic biotic environment to the sensitive wildlife species. In these areas, an ecological model is being considered to evaluate the potential ecological risk.

This model is being developed to investigate the potential for movement of contaminants through the ecosystem and to assist in documenting the importance of various areas in the wetland. Using species observed in the wetland and species expected to occur based on a habitat evaluation, a food chain model is being constructed. The model is being used to facilitate an understanding of the relationship between the biotic and abiotic components of the wetland such as the water and soil matrix. An extensive literature search was conducted to identify analogous studies and toxicity data and bioaccumulation factors for the species used in the food chain model.

Alternative Remediation Techniques

One of the critical elements of remediation in Middle Marsh is to access and remove contaminated material with minimal damage to existing wildlife and other wetland functions. This is being addressed by examining innovative removal techniques including:

- In-place capping to seal contaminated sediments particularly by increasing elevation to eliminate inundation and erosion during storm events
- Hydraulic flushing to remove contaminated surface soils with only minimal disruption of root systems
- Vacuum removal to minimize damage to plants
- Immediate replacement of clean soils to minimize exposure and damage to root systems

- Use of small equipment to minimize destruction of plants and the associated habitat

Modification of the Persistence Factor in the Hazard Ranking System

Patricia V. Cline, Ph.D.
Tom McLaughlin, Ph.D.
CH2M Hill
Gainesville, Florida
Reston, Virginia

ABSTRACT

The purpose of this paper is to show how the persistence factor in the Hazard Ranking System was modified to reflect the retention of hazardous substances in bed sediments by the process of sorption. The persistence factor is used to stratify chemicals on the basis of their anticipated losses during transport in the water column by decay mechanisms such as volatilization, hydrolysis, photolysis and biodegradation. Chemicals that are rapidly eliminated from the surface water system pose fewer risks to humans and ecological receptors and receive low persistence scores. Compounds that do not decay appreciably in the water column receive high persistence scores.

An assumption inherent in the definition of persistence is that a hazardous substance enters the water column in a dissolved state and remains there. Although this assumption is valid for highly water-soluble compounds, constituents with low water solubility sorb to suspended and shallow bed sediments and have reduced water-phase concentrations.

Steady-state models were used to understand the differences among chemicals and the relationship between degradation in the water column and retention in bed sediments. An exponential decrease in concentration between the source and target distance exists as a function of travel time and decay rate. Because the sediments and water are in equilibrium under steady-state conditions, the sediment concentration profile reflects the same first-order decrease as that of the water column.

This paper illustrates how the relative mass of a hazardous substance in the surface water system is a function of half-life and K_{ow} and how a substances' K_{ow} can be related to its persistence score.

INTRODUCTION

Persistence is the capability of a substance to resist reduction of its concentration despite the several decay processes imposed on it by the environment. The persistence factor is included in the surface water pathway to account for any reduction in concentration of a hazardous substance during transport from its source to a specified target distance. This factor is used to stratify hazardous substances and allows the calculation of the effective concentration at the target distance.

During the field testing of the Revised Hazard Ranking System (Revised HRS), it was discovered that several hazardous substances known to be extremely persistent in surface water (such as PCBs) were rated as being of low to moderate persistence. CH2M HILL was asked to review the persistence values assigned to hazardous substances to determine whether there is a need for changes in the method of scoring these substances, producing a support document for the changes made to the persistence factor leading to the scoring scheme promulgated in the current draft final rule.

The persistence of a substance is a function of its decay rate and travel time. In the original HRS, the persistence value for a hazardous substance was based solely on its biodegradability. However, the Revised HRS recognizes that decay processes other than biodegradation also affect the persistence of a substance; these processes are hydrolysis, volatilization, photolysis and free-radical oxidation. Sorption of hazardous substances onto particulates or sediment also is considered a decay process, but it is not included in the Revised HRS because the hazardous substances still could be available to ecosystems through uptake by benthic organisms or by resuspension.

The technical analysis of the Revised HRS persistence factor focused on the importance or contribution of each decay process to overall half-life, the actual travel time or residence of a hazardous substance in a water body and the effect that sorption to particulates or sediment has on persistence. Also, attempts were made to simplify the persistence scoring process by basing the values on factors other than the decay processes. This paper focuses on sorption. Instead of considering sorption to particulates or sediment solely as a decay process, it was studied as a process that can also enhance the persistence of hazardous substances. This possibility was investigated by looking at the relationship between degradation in the water column and retention in bed sediments.

PERSISTENCE IN THE HRS

The relative change in concentration of a pollutant downstream from its source determines its persistence. After discharge to surface water, the concentrations of many contaminants are reduced by decay mechanisms such as volatilization, hydrolysis, photolysis and biodegradation. Chemicals that are rapidly eliminated from the system pose fewer risks to humans and ecological receptors.

The persistence value assigned to a hazardous substance is based on the effects of decay processes and on the predicted time for the hazardous substance to travel from the source to the target 15 mi downstream. Only substances with half-lives much shorter than the travel time will decay significantly over the target distance. A hazardous substance with a half-life greater than the predicted travel time, or a decay rate of 0 to 50%, is scored as "persistent"; a hazardous substance that decays 50 to 90% is rated as moderately persistent; a hazardous substance that decays 90 to 99.9% is rated as having low persistence; and a hazardous substance that decays more than 99.9% is rated as nonpersistent. These ratings correspond to numerical persistence values (on a linear scale) of 1, 0.4, 0.07 and 0.0007. A travel time of 1.5 days was selected for use in scoring persistence as best representing the median stream velocity in the United States.

SORPTION

The retention of hazardous substances by suspended particulates or bed sediments by the process of sorption will result in changes in the

persistence scoring of these hazardous substances. Hazardous substances that sorb to suspended and shallow bed sediments will have reduced water-phase concentrations. Sorption not only decreases the rate of decay of a hazardous substance, but it also decreases mobility when the substance is retained in bed sediments. The hazardous substance is retained between the discharge point and the downstream 15-mi target for a longer period and typically releases slowly from sediments after the pollutant source is eliminated.

An assumption inherent in the definition of persistence is that a contaminant enters the water column in a dissolved state and remains so. Although this assumption is valid for highly water-soluble compounds, constituents with low water solubility sorb to particulates. Compounds that sorb to suspended and shallow bed sediments have reduced water-phase concentrations. Sorption not only decreases the rate of decay of a constituent, but it also decreases mobility when the substance is retained in bed sediments. The contaminant is retained between the discharge point and the downstream exposure point and typically releases slowly from sediments after the pollutant source is eliminated.

Examples of highly hydrophobic compounds that sorb to particulates are DDT, PCBs and many phthalates and polynuclear aromatic compounds. Hydrophobic compounds generally are carried with particulates into surface water from run-off or deposition and may, in some cases, be strongly bound to these particulates. Compounds such as acetone do not sorb to particulates and are present predominantly in the water phase.

The half-lives are relatively short for many chemicals with low water solubility, which typically are perceived as being persistent in surface water bodies because of their retention in sediments. The half-lives of hydrophobic chemicals appear short, in part, because of their rates of volatilization. Volatilization from water is a function of both vapor pressure and water solubility. Therefore, compounds with relatively low vapor pressures have enhanced rates of volatilization from water as a result of their low water solubility, as illustrated in Table 1.

Table 1

Compound	Estimated Volatilization Half-Life* (days)	Vapor Pressure (mm/Hg)	Water Solubility (mg/l)
Chloroform	1.2	151	8,200
Acetone	17.8	270	miscible
PCBs	2	7.7E-5	0.031

*Rivers.

The compounds with low water solubility, however, typically are reported in sediments that are not in the water column. Sedimentation was not considered a removal mechanism in previous analyses because of potential resuspension, dissolution and ecological impacts, including benthic uptake.

The sequence of instream events after the introduction and then the elimination of a source of hazardous substances has been described by the U.S. EPA[1] If a hazardous substance is discharged to the water column, pollutant concentration in the sediments at the bottom increases due to (1) the partitioning of the water and the sediments, and (2) the exchange between bed sediments and water column sediments. After a period of time, the net exchange diminishes as equilibrium is achieved. If the source is eliminated, the water column concentration decreases and the pollutant is desorbed from bed sediments.

Benthic organisms retard the burial of contaminated sediment fractions, and, according to Burns,[2] lacustrine oligochaete deposits can be active to a depth of 10 to 15 cm. In models presented by Neely and Mackay,[3] bottom sediments were represented by a completely mixed, active layer that overlays the inactive deep sediments.

Although surface water bodies are dynamic, steady-state models can be used to understand the differences among chemicals and the relationship between degradation in the water column and retention in bed sediments. The U.S. EPA model *Exposure Analysis Modeling System*

(EXAMS) describes the concentration profile for the continuous release of a constituent to a surface water body. The concentration profile results for steady-state conditions are illustrated in Figure 1 for two compounds with different first-order decay rates in the water column. An exponential decrease in concentration between the source and target distance exists as a function of travel time and decay rate. Because the sediments and water are in equilibrium under steady-state conditions, the sediment concentration profile reflects the same first-order decrease as that of the water column.

CONCENTRATION PROFILE - STEADY STATE
Mass of Containment in Surface Water
- Steady State Conditions -

● No decay, no sorption

$$M_o = C_o\,A\,X$$
where $X = 15$ miles

● Decay, no sorption

$$M = CoA\int_{x=0}^{x=15} e^{-kx} = CoA\left(\frac{e^{-kx_{15}}}{-k} - \frac{e^{-kx_{15}}}{-k}\right)$$

or:

$$M/Mo = (1 - e^{-kx_{15}})/15k$$

● Decay, sorption

$$M/Mo = ((1 - e^{-kx_{15}})/15k)\cdot(1/fw)$$

TERMS:
Co = initial concentration
A = Cross-sectional area of water body
X = distance
k = decay rate (1/mile)
M = mass of contaminant
fw = fraction of mass in water column

Figure 1
Surface Water Sorption and Decay

The relative concentration at the target distance (C/Co at 15 mi) depends only on the decay rate in the water column, and not on the sorptive properties of the contaminant. Once the bed sediments are in equilibrium with the surface water, there is no further net exchange and the sediments have no further influence on the decay processes in the water column. This calculation assumes negligible losses of contaminant from the bed sediments via biodegradation of the sorbed contaminant or burial to deep sediments.

Although the fraction of the total mass in the water phase (fw) is a function only of the partition coefficient and sediment/water ratio, the total mass accumulated in the sediments under steady-state conditions also is a function of the aqueous concentration. Thus, for two contaminants with the same source concentration (Co), the contaminant with the higher decay rate will have a lower overall mass in both the water column and the associated sediments.

The equations that describe mass in a river system are presented in Figure 1. The reference mass (Mo) is defined as the total mass of contaminant in the river from the source to the target distance with no decay and no sorption [that is, the river volume multiplied by the input concentration (Co)]. For constituents that decay in the water column, the mass in the river is reduced as a function of the concentration profile. The relative mass (M/Mo) is greater than the relative concentration

at the target distance (C/Co). As the rate constant (k) goes to zero, M/Mo approaches 1.

Sorption increases the mass retained in the system by the factor 1/fw or ($K_p S/W$ +1), where K_p is the partition coefficient, S is the mass of solids and W is the volume of water. For compounds that sorb and degrade, as k goes to zero, M/Mo approaches 1/fw, which is related to the equilibrium ratio of contaminant between solids and water phases. The relative mass (M/Mo) is shown in Figure 2 as a function of half-life and K_{ow}. This illustrates that sorption has a smaller effect on the retention of mass in the water body for compounds that decay rapidly relative to their travel time in the water body.
Figure 2
Sorption and Degradation
Relative Mass—Lake and River

Table 2 illustrates the relationship between K_{ow}, the increase of mass in the system at steady state (M/Mo) and the maximum increase (1/fw) for a compound at that K_{ow}.

Compounds are listed in order of decreasing partition coefficient, which corresponds to decreasing values of 1/fw. The relative mass (M/Mo) is also a function of the decay rate relative to the travel time in the system.

Several compounds have rapid decay rates relative to lake travel times. The M/Mo for hexachlorocyclopentadiene and heptachlor illustrate that highly sorbing compounds may not accumulate due to their high degradation rates.

SORPTION AND ADJUSTED HALF-LIVES

The half-life estimates in the HRS data tables are based on presence of the contaminant in the dissolved phase in the water column. It is generally assumed that the first-order decay processes degrade only this dissolved solute. Sorption reduces the water-phase concentration and decreases the rate of loss.

The partition coefficient describes the ratio of the concentrations of constituents in the phases; however, the distribution of mass also depends on the solids concentration. Suspended solids concentrations in surface waters are generally less than 500 mg/L. At this concentration, a contaminant with a K_{ow} of 4.13 would have 90% concentration in the

dissolved phase. Thus, the increase in half-life as a result of sorption to suspended solids is significant only for chemicals with high partition coefficients.

Half-life also can be calculated based on the total mass of contaminant in the system, including bed sediments. This adjusted term is used in the EXAMS model. It reflects the losses resulting from degradation processes in a static system and can be used with advective losses in modeling the dynamics of the surface water system. Using the assumption of 10 cm of bed sediments with an f_{oc} of 0.04, adjusted degradation half-lives (Table 2) illustrate the apparent increase in half-life as a result of sorption to bed sediments. However, under steady-state conditions, the mass of contamination in the bed sediments is a constant and the adjusted half-life does not appropriately reflect the decrease in concentration at the target distance. Thus, this adjusted half-life cannot be directly compared with travel time.

A nonsteady-state condition results when the source of a contaminant is eliminated. In addition to the extra mass in the system for the more strongly sorbing contaminants, the time it takes to purge the system of contaminant once the source loadings cease varies according to the partition coefficient.

A method of estimating desorption of hazardous substances from a river bed as presented in *Water Quality Assessment: A Screening Procedure for Toxic and Conventional Pollutants in Surface and Ground Water*[1] is shown in Table 3. This equation illustrates that the time required for removal is directly proportional to the partition coefficient. Therefore, an increase by a factor of 10 in the partition coefficient will also lengthen the time required for removal by a factor of 10.

SUMMARY OF EFFECTS OF SORPTION

Based on this evaluation, sorption has several effects. Sorption delays the arrival of contaminants; lower concentrations may arrive at the receptor over a longer time period. Sorption to bed sediments does not affect the mass reaching the receptor if degradation occurs only in the water column. If contaminants biodegrade in the sediments, the mass of the chemical reaching the receptor will be reduced.

Table 3
Estimating Desorption of a Hazardous Substance from a River Bed

Calculation:

$$T_d = K_p \, (x_L \, M_s / U \, d)$$

where

T_d	=	time required to desorb the hazardous substance
K_p	=	partition coefficient
x_L	=	length
M_s	=	mass of contaminated sediment/unit area
U	=	stream velocity
d	=	equivalent depth of water in sediment

Estimated removal times based on a stream velocity of 15 miles in 1.5 days and a contaminant depth of 10 cm.

Log K_{ow}	Time (years)
2.0	0.1
3.0	1.1
3.3	2.1
3.5	3.3
4.0	10.5
4.5	33.0
5.0	105.0

Sorption to suspended sediments increases the concentration reaching the receptor; however, since the concentrations of the suspended sediments is low, the effects will be minimal. Contaminants that sorb to sediments may be retained near the source and may not reach the receptor at a specified downgradient location. The presence of these constituents can result in exposures along the 15-mi distance of concern.

Contaminants retained in sediments are typically of low mobility or immobile in groundwater. The mechanism by which these constituents are released and distributed into the surface water body will differ from that of highly soluble components. According to relative mass calculations, the increase in mass (M/Mo) in lakes is lower than in rivers as a result of longer retention time relative to the half-life in the water column.

ESTABLISHING PERSISTENCE SCORES FOR SORPTION TO SEDIMENTS

The foregoing discussion indicates that compounds with higher partition coefficients retain a greater contaminant mass in the system. A ranking system for stratifying the persistence of chemicals found in sediments is proposed based on the previously discussed sorption effects.

Retention in sediments may be reflected by increasing the persistence factor for chemicals with high K_{ow}. However, some compounds would be ranked as persistent based on these criteria even if the relative mass retained in the system (M/Mo) would be low. These compounds include hexachlorocyclopentadiene, anthracene and heptachlor.

The following Log K_{ow} values are proposed to reflect the tendency to persist in sediments:

Log K_{ow}	Effect on Ranking
>4.5	1
4.0–4.5	0.4
3.5–4.5	0.07
<3.5	0.0007

If a higher persistence value can be assigned using this relationship between Log K_{ow} and persistence value, the higher value should be used as the score.

Estimating Cleanup Levels at Hazardous Waste Sites

Robert W. Schanz
Atul M. Salhotra, Ph.D.
Woodward-Clyde Consultants
Oakland, California

ABSTRACT

An important component of feasibility studies for hazardous waste sites is the development of remediation goals (cleanup levels) for contaminated soils. Ideally, these cleanup levels should be based on site-specific data and protective of human health and the environment. However, these levels often are arbitrarily related to the analytical detection limit, various federal and state water quality criteria, or natural background levels. Often such cleanup levels are much more stringent and, hence, more costly to implement than risk-based cleanup levels.

This paper describes methods for computing site-specific cleanup levels that are protective of human health and are based on an acceptable level of risk. Acceptable concentrations at the exposure point are determined from the site-specific exposure scenarios (i.e., ingestion of water, inhalation, dermal adsorption, etc.) and the chemical-specific toxicity. Contaminant transport models are then used in the "backward" mode to compute the cleanup level at the contaminant source. Two case studies are presented to illustrate the procedure.

INTRODUCTION

The goal of remediation is to clean up hazardous waste sites to a level that is protective of human health and the environment. Achievement of this goal requires the determination of the concentration of chemical that can be left in the environment without posing undue harmful effects to humans, i.e., the determination of "How clean is clean?" This maximum concentration level, defined as the cleanup level, has a direct impact on the selection, design and cost of remedial alternatives.

Although cleanup levels are conceptually defined in terms of human health, they are in practice often set to arbitrary levels such as the background concentration or the analytical detection limit. Both of these methods have serious limitations. Cleaning to background may be consistent with the concept of restoring contaminated sites to their pre-existing condition, but involves prohibitive costs. Detection limits depend upon the sample matrix and change over time as analytical methods improve. Thus, use of the detection limit as a cleanup goal can result in cleanup levels that differ from site to site. Further, there is no guarantee that either the background concentration or the detection limit is protective of human health.

This paper describes a risk assessment-based procedure for estimating cleanup levels that are protective of human health and the environment. Allowable concentrations are related directly to target risk levels, and contaminant transport models are used to back-calculate the corresponding cleanup level at the contaminant source. The paper presents a discussion of the method, including general considerations for calculating risk-based cleanup levels and guidelines for allocating risk among multiple chemicals. This is followed by a description of two case studies involving: (1) cleanup levels for a contaminated shallow aquifer and (2) cleanup levels for contaminants in the unsaturated zone.

ESTIMATING CLEANUP LEVELS TO MEET A SPECIFIED TARGET RISK LEVEL

Given a target risk level for a chemical, the cleanup level (or concentration) can be estimated using risk assessment procedures such as those recommended by the U.S. EPA.[1] These procedures are used in the "backward" mode to estimate allowable concentrations, as opposed to the usual "forward" mode to estimate risk. The procedure consists of the following steps:

- Compute the allowable chemical dose based on the target risk level
- Back-calculate the allowable concentration at the receptor location, based on the exposure scenario and chemical uptake parameters
- Back-calculate the corresponding source concentration (cleanup level) using a contaminant transport model in the "backward" mode

Estimating Allowable Dose

The allowable dose is related to the target risk level by the potency factor for carcinogens or the reference dose for noncarcinogens. For carcinogens, the allowable dose (assuming a linear dose-response model) is calculated by dividing the target risk by the potency factor:

$$D = TR/PF \tag{1}$$

where

D = the allowable dose (mg/kg-day)
TR = the target individual excess lifetime cancer risk (dimensionless)
PF = the chemical-specific potency factor (mg/kg-day)$^{-1}$

For noncarcinogens, the allowable dose is equal to the reference dose (RfD).

Estimating Allowable Receptor Concentrations

The allowable concentration in the receptor media (e.g. soil, water and air) is computed from the allowable dose and human exposure/uptake parameters. The procedure is dependent upon the exposure pathway, but generally can be applied using equations of the following form:

$$C_r = D/PEF \tag{2}$$

where

C_r = the receptor concentration (e.g., mg/L)
PEF = the pathway exposure factor (e.g., L/kg-day)

The PEF is a pathway-specific factor that is estimated from human uptake and behavioral parameters. For instance, for lifetime exposure to drinking water the PEF is given by:[1]

$$PEF = IR/BW \tag{3}$$

where

BW = body weight (kg)
IR = water intake rate (L/day)

The U.S. EPA[1] presents the relationships that can be used to estimate the PEF for other exposure scenarios. Note that the allowable receptor concentration also may be derived from federal or state action levels, such as drinking water standards or MCLs.

Estimating Cleanup Levels at the Source

Having estimated the allowable concentration at the receptor, the cleanup level at the contaminant source is computed using a contaminant fate and transport model in the backward mode. These models account for the attenuation of contaminants as they migrate from the source to the receptor point, due to advection, dispersion, chemical and biological degradation, volatilization and adsorption. Numerous models have been developed for transport in air, surface water and groundwater. Alternatively, a multimedia model such as EPAMMM[2] may be used.

Typically, analytical and semi-analytical models are used, although numerical models may be applied for complex sites. Application of these models yields an attenuation factor equal to the ratio of the receptor point concentration to the source concentration. Assuming that the receptor point concentrations are linear with respect to the source concentrations, llthe cleanup level is given by:

$$TCL = C_r/AF \qquad (4)$$

where

TCL = the cleanup level (e.g., mg/L)
AF = the attenuation factor (dimensionless)

Using the linearity assumption, the three steps used to estimate cleanup levels can be consolidated by defining the unit risk, or the risk per unit concentration at the source:

$$UR = (PEF)(AF)(PF) \qquad (5)$$

where

UR = the risk per unit source concentration (L/mg)

The cleanup level is then calculated by dividing the target risk level by the unit risk:

$$TCL = TR/UR \qquad (6)$$

The assumption of linearity requires that contamination and cleanup levels be below solubility and saturated vapor pressure levels. This assumption is usually valid for the low concentrations required for protection of human health. However, computed cleanup levels should be compared to solubility limits to verify this assumption.

APPORTIONING RISK AMONG MULTIPLE CHEMICALS

When multiple chemicals present a health hazard at a site, cleanup levels must account for the combined effects of these chemicals. Sufficient information is not available on the synergistic or antagonistic effects of chemicals; it is therefore commonly assumed that the risks from multiple chemicals are additive. Thus, at the cleanup level, the sum of the risks from all chemicals must be less than the acceptable individual excess lifetime cancer risk:

$$TR = \Sigma TR_i \qquad (7)$$

where

TR = the total target risk level
TR_i = the target risk level for chemical i

The total risk among the various chemicals can be allocated in a number of ways, considering at a minimum the type of remediation to be applied, the existing levels of contamination and the potency of each chemical. Examples of algorithms for allocating risk among multiple chemicals include:

- Allocate risk equally among all chemicals. This is the simplest alternative, but can result in prohibitively low cleanup levels for highly potent chemicals.
- Allocate risk proportional to unit risk. This alternative allocates more

risk to the more potent chemicals. If risk is allocated in linear proportion to unit risk, this alternative results in the same cleanup level for all chemicals.

- Allocate risk such that chemical concentrations are in the same proportion after remediation as before. This alternative assumes that all chemicals are remediated in the same proportion, i.e., that all chemical concentrations are reduced by the same proportion. This alternative works well when one or more chemicals occur at significantly higher levels than others, or when the chemicals respond equally to the remediation technology.

Each of the above processes has its own advantages; it often is useful to apply all three and compare the resulting cleanup levels. It also may be appropriate to allocate risk differently depending upon the remedial alternatives selected. For instance, if vapor extraction is proposed, target risks would be allocated such that volatile chemicals would have lower cleanup levels than nonvolatile chemicals.

CASE STUDY 1: CLEANUP OF A SHALLOW AQUIFER

The first case study illustrates the application of the above procedures to a contaminated shallow aquifer in the Midwest. The aquifer lies in glacial till below a former liquid incineration site and receives approximately 0.05 m/yr (2 in./yr) of vertical recharge. Chemicals of concern in the aquifer include trichlorethylene (TCE), vinyl chloride and benzene.

For this analysis, cleanup levels were developed for a hypothetical residential well exposure scenario. Ingestion of water was evaluated as the primary exposure route. To estimate the allowable concentration, realistic average exposure parameters were selected from the U.S. EPA's Exposure Factors Handbook.[3] A water intake rate of 1.4 L/day was used, based on the average total fluid intake rate minus intake of milk and other fluids not derived from tap water. Residents were assumed to stay on-site for 20 years out of an average 70-year lifetime and spend 73% of their time at home.

In this case, the aquifer was both the source of contamination and the receptor location. Thus, there was no attenuation between the source and the receptor. However, concentrations in the aquifer do reduce during the 20-year period due to flushing by natural recharge. Assuming that only the dissolved phase is leached out of the aquifer and no biological decay, concentrations will decrease exponentially over time, and the average concentration for the exposure period is:

$$C_{avg} = TCL [1 - \exp(-kt)] / [kt] \qquad (8)$$

where

C_{avg} = average concentration over the exposure period (mg/L)
TCL = the target cleanup level, i.e., the concentration at the beginning of the exposure period (mg/L)
t = the exposure period (years)
k = leaching constant (years^{-1})

The leaching constant k quantifies the rate at which chemicals are flushed out of the aquifer and is expressed as follows:

$$k = I/H(p_b K_d + n) \qquad (9)$$

where

I = the recharge rate (m/yr)
H = the aquifer thickness (m)
p_b = aquifer bulk density (g/cc)
K_d = soil-water partition coefficient (cc/g)
n = porosity (cc/cc)

The total allowable individual excess lifetime cancer risk for the exposure scenario was 10^{-6}. Table 1 shows the resulting cleanup levels for TCE, vinyl chloride and benzene. Cleanup levels are shown for all three of the risk allocation procedures discussed above and are driven by the high unit risk for vinyl chloride. Thus, the first alternative (equal risk for all chemicals) results in a very low cleanup level for vinyl chloride, and high cleanup levels for TCE and benzene. The second alternative (target risk proportional to unit risk) results in the highest cleanup level for vinyl chloride, but the lowest for TCE and benzene. The final alternative (all chemicals reduced by the same percentage)

results in perhaps the most realistic distribution of cleanup levels.

Table 1
Cleanup Levels for the Shallow Zone Aquifer,
Case Study 1

Chemical	Cleanup Level (ug/l)		
	Alternative 1	Alternative 2	Alternative 3
TCE	0.95	0.11	0.48
Vinyl Chloride	0.04	0.11	0.09
Benzene	1.70	0.11	0.39

Alternative 1: Equal Risk for all Chemicals

Alternative 2: Risk Proportional to Unit Risk for each Chemical

Alternative 3: All Chemicals Reduced in Concentration by Same Proportion

CASE STUDY 2: UNSATURATED ZONE CLEANUP

This case study illustrates the use of an unsaturated zone contaminant transport model to back-calculate soil cleanup levels. The site for this case study is a former industrial waste storage facility. As illustrated in Figure 1, the unsaturated zone consists of 15 feet of silty clay underlain by 25 feet of silty sand. The saturated zone lies at a 40-foot depth. Because the area is to be paved as part of remediation, the infiltration rate was assumed to be only 0.3 in./yr (10% of the annual rainfall excess). During the remedial investigation, soils were found to be contaminated with 1,1-DCE, 1,1,1-TCA, TCE and 1,1-DCA throughout the thickness of the unsaturated zone.
Figure 1
Generalized Cross-Section of the Site for Case Study 2

The exposure scenario for this analysis was ingestion of well water drawn from the saturated zone. Cleanup levels were derived for the unsaturated zone to meet state action levels at the water table, rather than to meet a specified target risk level. Thus, soil cleanup levels were computed as follows:

$$CL_s = (ADS)(AF\ C_{al}) \qquad (10)$$

where

CL_s = soil cleanup level (ug/kg)

AF = attenuation factor for the dissolved phase (unitless)

C_{al} = the state action level in drinking water (mg/L)

ADS = the adsorption factor, for converting dissolved concentrations to total soil concentrations (ug/kg per mg/L)
Figure 2
Attenuation of a Contaminant Migrating to the Saturated Zone

Table 2
Soil Cleanup Levels Derived from
Contaminated Transport Model Results

Source I - 5' Excavated Layer

Chemical	With Decay		Without Decay	
	Total Attenuation	Cleanup Level [ppb]	Total Attenuation	Cleanup Level [ppb]
1,1-DCE	1.7E+07	4.7E+04	450	368
1,1,1-TCA	3.1E+09	1.8E+07	500	30719
TCE	2.8E+09	2.3E+05	430	577
1,1-DCA	6.4E+05	4.8E+03	410	157

Source II - Silty Clay Layer

Chemical	With Decay		Without Decay	
	Total Attenuation	Cleanup Level [ppb]	Total Attenuation	Cleanup Level [ppb]
1,1-DCE	1.1E+06	4.7E+04	255	368
1,1,1-TCA	8.4E+07	1.8E+07	315	30719
TCE	3.5E+07	2.3E+05	260	577
1,1-DCA	9.4E+04	4.8E+03	230	157

Source III - Silty Sand Layer

Chemical	With Decay		Without Decay	
	Total Attenuation	Cleanup Level [ppb]	Total Attenuation	Cleanup Level [ppb]
1,1-DCE	1.2E+04	4.7E+04	200	368
1,1,1-TCA	5.9E+04	1.8E+07	230	30719
TCE	3.7E+04	2.3E+05	220	577
1,1-DCA	3.0E+03	4.8E+03	200	157

Based on the remediation alternatives to be evaluated, individual cleanup levels were derived for three distinct soil layers: (1) the top 5 feet of silty clay, to be excavated and treated, (2) the lower 10 feet of silty clay, and (3) the 25-foot silty sand layer. Attenuation factors for each layer and chemical were estimated by simulating the transport of the dissolved phase through the unsaturated zone to the water table. Attenuation by three processes was simulated:

- One-dimensional flow and transport through the unsaturated zone
- Lateral dispersion in the unsaturated zone
- Near-field mixing at the water table

The resulting cleanup levels for the site are shown in Table 2. Results are presented for two cases: (1) base case with decay (assuming a five-

year half-life for all chemicals) and (2) base case with no decay. Because of the slow infiltration rates (and correspondingly long travel times), the attenuation of chemicals is increased by as much as 3 to 4 orders of magnitude when chemical decay is simulated.

Figure 2 illustrates how these processes affect the transport of the chemical to the water table. One-dimensional transport was simulated using the unsaturated flow and transport component of the U.S. EPA's Multimedia Model.[2] This model simulates one-dimensional advection and dispersion, linear, reversible adsorption, source flushing by recharge and exponential chemical decay. An analytical lateral dispersion model[4] was then applied to calculate attenuation due to lateral spreading of the contaminant plume. Finally, a mass-balance mixing model was used to compute dilution of the plume as it is intercepted by the saturated zone flow. The total attenuation factor was the product of the attenuation factors for each of these three processes.

CONCLUSIONS

In the preceding sections of this paper, we have discussed procedures for computing cleanup levels using a risk assessment methodology. Two case studies were presented illustrating the allocation of risk among multiple chemicals and the use of contaminant transport models in the backward mode to estimate source cleanup levels. The following conclusions can be drawn from these case reviews:

- Cleanup levels should be set to levels protective of human health, rather than arbitrary levels such as background or analytical detection limits
- Allocation of cleanup levels among multiple chemicals should consider the type of remediation, the potency of the each chemical and the existing contamination levels
- Analytical contaminant transport models can be readily applied to estimate source cleanup levels

The National Exposure Registry: A Community's Reaction

Je Anne R. Burg
Agency for Toxic Substances and Disease Registry
Atlanta, Georgia

INTRODUCTION

The Agency for Toxic Substances and Disease Registry (ATSDR) was created by the CERCLA of 1980 to assess the health problems of persons living near waste sites and dump sites. The Superfund legislation assigned 10 mandates to the Agency, one of which was the creation of a National Exposure Registry and a National Disease Registry. The National Exposure Registry is currently being constructed and at this time contains more than 5000 registrants. The policies and procedures for the National Disease Registry are under development.

The National Exposure Registry is a listing of persons who have been exposed to selected toxic substances.[1] The purpose of the National Exposure Registry is to help assess long-term health consequences of exposure to Superfund-related hazardous substances. ATSDR is trying to determine whether any long-lasting, adverse health outcomes may be associated with low-level, long-term exposures such as those experienced by persons living near waste sites and dump sites. The National Exposure Registry is designed to facilitate epidemiologic research or health studies by creating files of data that can serve as the basis for these efforts. The Registry files also can be used to facilitate state and federal health surveillance programs and to provide information for assessing the burden of the effects of an exposure or health outcome on a population.

In keeping with the dictates of a public health agency, the registry program will benefit the public by providing current, relevant information to exposed persons on the hazardous substances to which they have been exposed. Information gained from the subregistries will also enable local, state or federal health officials to notify registrants rapidly of any adverse health effects of exposure, preventive measures or therapeutic advances that may not have been known earlier.

The National Exposure Registry is composed of chemical-specific subregistries (subregistries currently exist for trichloroethylene, dioxin and benzene) that list persons (known as registrants) exposed to the selected chemicals. The selection of each chemical for a subregistry is based on its frequency of occurrence and for potential human exposure at waste sites and on its toxicity. Chemical selection also is based on the existing data gaps identified for the chemical and an assessment of whether the data collected for the registry would fill the identified data needs.

CHEMICAL CHOSEN

Trichloroethylene (TCE), the first chemical chosen, was identified at 468 of the then 1177 NPL sites; 368 of the contaminated sites had reported contaminated groundwater; 356 of these sites reportedly depended on this groundwater for drinking water. Some sites had privately owned wells while other were municipally, county, state or federally owned wells. The dioxin subregistry was established to follow a population previously identified as exposed. A subregistry for benzene was established because of the large number of sites with relatively high levels of benzene-contaminated drinking water and the health effects noted in worker populations exposed to benzene. The paucity of data on human populations who have been exposed to benzene, particularly the long-term, low-level exposures found in populations exposed through drinking benzene-contaminated water, was also a factor.

SITE SELECTION

Specific sites for a given chemical subregistry are selected based on the existence of documented contamination of the media, the size of the potentially exposed population, the reporting of potentially chemical-related health problems by the community and the community's level of interest in participating in such a project. The cost of establishing a registry at a given location is approximately $500,000 and the cost of each annual update for that location is approximately $125,000. Given the large expenditure of resources and the potential impact on the communities involved, the sites must be chosen judiciously. One community decided, on the advice of its state health department, not to participate. ATSDR did not pursue the project further because participation in the registry is strictly a voluntary activity and the support of all parties is needed to ensure high participation rates.

EXPOSURE CRITERIA

Three criteria must be met before a potential registrant can be classified as "exposed": (1) valid analytical data must document a contaminated medium, (2) a plausible route of transmission exists from the medium to the individual and (3) evidence exists that transmission occurred from the contaminated medium to the individual. Meeting the first two criteria would make an individual "potentially exposed"; the addition of the third, "exposed." An example of a site meeting all these criteria would be: contaminated groundwater exists; the water is used for drinking; and the individual drank the water. Exposure from all media is considered.

The "potentially exposed" persons are identified at a given site through existing records such as well-water tests, air monitoring results or soil sample test results. The persons are then contacted and asked further questions to confirm their exposure; if their exposure is confirmed, they are asked to participate in the National Exposure Registry. Participation is strictly voluntary.

DATA COLLECTION

A "Core Questionnaire" is administered to each registrant, the first time in a face-to-face interview and after that by telephone. This "Core Questionnaire" consists of basic demographic questions, 25 general health questions, three general reproduction-related questions, ques-

tions related to tobacco use and background questions related to occupational exposure. The "Core Questionnaire" provides the minimum amount of information to be collected on a registrant. Additional questions may be added at some sites if more specific information is available on the health outcomes thought to be related to the chemical of interest there. The same questionnaire is administered annually from then on; all updated information is added to the existing file. The annual updates continue indefinitely until it is determined whether a health problem exists in the exposed population.

The number of persons to be enrolled on a given subregistry depends on the sample size needed to compare a given health outcome to national norms at a specified statistical level of significance. The TCE subregistry has approximately 5000 registrants; the benzene subregistry will contain approximately 7000 registrants.

DATA ANALYSIS

Using data from the National Exposure Registry, ATSDR conducts ongoing trend analyses and comparisons with national norms. These will indicate whether further health studies are needed or whether information already available, when combined with other epidemiologic and toxicologic information, is sufficient to determine that no potentially exposure-related, adverse health outcomes are present. Because of the relatively small number of eligible persons at each site, the small number of cases of any one adverse health outcome and the number of potentially confounding factors, it is almost impossible to conduct epidemiologic analysis for individual sites at an acceptable level of statistical significance. If data from multiple sites could be combined, this process would increase the sample size with the potential for reducing the level for significance testing to a point that would be meaningful for interpretation of results. ATSDR is now exploring the concept of conducting studies across multiple sites.

Although participation in a subregistry is voluntary, the current participation rate does not appear to be a matter of concern or a source of bias. At 13 of the sites where eligible persons have been asked to participate in the National Exposure Registry, the response rates have exceeded 99% (one site had 100%); at four other sites the response rate exceeds 96%. The sites now in the registry represent a broad spectrum of possible conditions—the socio-economic levels vary greatly, the level of community anger at remedial actions that have or have not occurred ranged from outrage to approval and health studies have been conducted at some sites and not at others. None of these factors, however, appears to have any impact on the response rate.

Subregistries

Nearly 5000 persons have been enrolled in the TCE subregistry and 250 in the dioxin subregistry. Data for the TCE subregistry have been collected on persons at three NPL sites in Michigan, two NPL sites in Indiana, two non-NPL sites in Indiana, five NPL sites in Illinois and one non-NPL site in Illinois. All but one of the sites have other chemicals present besides TCE. The persons on this subregistry have lived for more than 30 days in homes for which the private well serving the home was contaminated over a specified time-frame. The time-frame is determined from available information about the responsible polluter and from geographic information about the site location.

A potential registrant may or may not currently living in a home with a contaminated well. Indeed, a concerted effort is made to identify former residents, to locate them and to solicit their participation in the registry.

Registrants of the dioxin subregistry lived near one of the four NPL sites in the Times Beach, Missouri, area and previously participated in one of the health studies conducted there. The site selection process is now taking place for the benzene subregistry.

PUBLIC NOTIFICATION/PARTICIPATION

At each location, the actual data collection process is preceded by activities designed to inform each potential registrant; federal, state, county and local officials and citizen groups—everyone is to be informed! The purpose of the registry, its implementation and what the registry is and is not are discussed at conferences with officials and

meetings with citizen groups, in press releases in the local newspapers and on radio and television stations. Also, both ATSDR and a regional health official, usually the state health commissioner, send letters to each potential participant explaining the registry.

Because anger often results from unfulfilled expectations, it is imperative that the community know what to expect and, equally as important, what not to expect from the National Exposure Registry program. The registry is not an epidemiologic study with measured health variables. Nor is the registry activity a hypothesis-testing effort, although it could be viewed as a potential hypothesis-generating activity.

Community Meeting

A community meeting is held the evening before interviewing begins to discuss the registry and to introduce the interviewers to the community. This process also introduces the community to the interviewers and makes the interviewers feel involved in the project. In most cases, people living in these communities are well-informed about their exposures and the possible health-related consequences. Communities appear to accept the registry approach as not only a viable way to assess the presence of excess adverse health outcomes within their community, but also as a general tool to be applied across the nation. The exceptionally high participation rate indicates this acceptance. We have heard many individual comments that although the information provided will probably not be of benefit to them personally, it may be of benefit to their children and grandchildren.

Data Confidentiality

When the policies and procedures were presented at meetings before their adoption, a concern for confidentiality was expressed repeatedly. At many of the sites, the registrants are involved in ongoing litigation. Other persons were concerned about the potential impact on their insurance (cancellation or rate increases) should the company find out they were registrants on the National Exposure Registry. To address the concern for confidentiality, ATSDR has adopted the policy that no data containing personal identifiers will be released without the written permission of the registrant. Each registrant will be asked in writing whether ATSDR may release personal information to a specifically named researcher for a specific purpose. As an agency of the federal government, ATSDR must respond to Freedom of Information requests, but only for aggregate data with personal identifiers removed. In-house, data-handling procedures strictly limit the persons who have access to the data base with personal identifiers.

ANNUAL UPDATES

ATSDR is now initiating the first annual updates; interviews will be conducted by trained telephone interviewers. We are concerned with maintaining over time the high level of participation we experienced in the initial interviews. We are following the same procedures for disseminating information to the registrants and to all other parties involved in the initial data collection. We hope that the same factors thought to prompt initial participation—a recognition of being "exposed", a promise that ATSDR will remain in the community as long as a problem is thought to exist, the promise of being kept informed and the desire to contribute to science—will remain viable in the follow-up efforts.

CONCLUSION

ATSDR envisions that the registry data base will be used for many research-related purposes. This data base will be available to qualified researchers for their individual studies. If a specific health concern is identified in a subregistry population, ATSDR will make that knowledge public with the expectation that other researchers will conduct further studies. Researchers may access the data base, with personal identifiers, by submitting a study protocol to ATSDR; a panel will then review the protocol to assess its scientific merit and the requestor's ability to maintain confidentiality. If the request meets the established criteria for acceptance, the next step will be to obtain the registrants permission to release the requested data. These procedures will be published in the Federal Register when they are completed.

The information collected for The National Exposure Registry will help answer the question whether adverse health outcomes are associated with waste sites and dump sites. The cost of a registry program and the long-range commitment needed must be considered, however, in making long-term registry plans.

ABSTRACT

People who live near hazardous waste sites are concerned about health outcomes resulting from exposure to hazardous substances. Public health concerns are threefold: is there a possibility of exposure; are adverse health effects occurring as a result of these exposures; and are there exposure levels below which adverse health effects are not expected to occur? In an effort to answer these questions, the Agency for Toxic Substances and Disease Registry (ATSDR) prepares health assessments for each of the sites on the NPL, and where needed, conducts human exposure or health studies.

The tools available to ATSDR when it conducts health assessments or site-specific health studies are limited. One tool is biologic markers which are used in these activities to evaluate exposure to hazardous wastes and effects. Another tool is minimal risk levels (MRLs) which are environmental or external exposure levels below which adverse health effects are not expected to occur. In this paper, we explore biologic markers, MRLs and their uses in evaluating potential health concerns at NPL hazardous waste sites.

INTRODUCTION

Biologic markers are used to evaluate exposure to hazardous wastes and effects. Detecting the parent substance or its metabolites in a biologic tissue or fluid specifically indicates that exposure and absorption has occurred. The health effects that occur as a result of exposure to hazardous substances are usually less specific because many hazardous substances produce similar health effects. Furthermore, health effects may be influenced or caused by many different factors, including exposure to other substances, genetic variability, state of health and socioeconomic status. However, simultaneous detection of both biologic markers of exposure and effect provide suggestive evidence that the adverse health effect is a consequence of exposure to the hazardous substance.

It is generally believed that, for events other than cancer and genotoxicity, a threshold level exists below which adverse effects are not likely to occur. Many thresholds, however, lack precision and repeatability and are inappropriate for human health assessment. In an effort to account for this variability and to meet its mandate, the Agency for Toxic Substances and Disease Registry (ATSDR) is developing Minimal Risk Levels (MRLs). The development of MRLs begins with a determination of the threshold level and incorporates uncertainty factors to derive exposure levels for the general population below which adverse health effects are not expected to occur.

ATSDR is charged with preparing health assessments for each of the sites on the NPL. These assessments include an evaluation of human exposure and a determination of public health implications based on available medical and toxicological information. Questions generally discussed and answered include: are people being exposed to hazardous substances found at these sites? Are adverse health effects occurring as a result of these exposures? Are there exposure levels below which adverse health effects are not expected to occur? The objective of this paper is to investigate the use of biologic markers and MRLs in evaluating potential health concerns at NPL sites.

BIOLOGIC MARKERS

Biologic markers are indicators that signal events in biologic systems or samples.[1] Biologic markers do not indicate whether the event being monitored is adverse or has no known effect; they only indicate that an event has occurred. For evaluating people exposed to exogenous substances, biologic markers can be subdivided into three categories: biologic markers of exposure, effect and susceptibility.

Biologic markers of exposure have been defined by the National Research Council[1] as exogenous substances or their metabolites or the product of an interaction between a xenobiotic agent and some target molecule or cell that is measured in a compartment within an organism. Detecting a substance in a tissue or fluid such as blood, urine, hair or fat indicates that exposure and absorption have occurred. Although attempts have been made using models to correlate tissue or fluid concentrations with exposure levels, a biologic marker by itself is not an indication of the amount of substance to which a person is exposed, the total amount absorbed, the total body burden or the duration of exposure; it only indicates that the substance has been absorbed and is currently present in a tissue or fluid.

ATSDR's Toxicological Profiles contain substance-specific information on hazardous substances found at NPL sites. The profiles include information on biomarkers of exposure. Table 1 presents a survey of the detection limits and accuracy of the most sensitive bioanalytic techniques available for detection of ATSDR's 50 priority hazardous substances. The data are organized by chemical class because, with the exception of a few miscellaneous substances (e.g., dinitrotoluenes, cyanide and isophorone), exposure to each substance can be monitored using class-specific screening methods.

Despite the fact that adequate bioanalytic methods are available for clinical detection and measurement of most of the substances listed in Table 1, almost no useful biologic monitoring data have been published for populations located near waste sites contaminated with these substances. A review of the Toxicological Profiles on the first 50 priority substances indicates that information linking environmental levels with body levels exists for less than 30[4] of the subject substances. In fact, for only one of the substance classes identified in Table 1, volatile organic compounds (VOCs), is such information available for more than 20% of the class (Fig. 1). More studies involving simple, clinically available, noninvasive biomonitoring techniques are needed for populations sur-

Reported in the Toxicological Profiles

rounding waste sites. Without these data, it is difficult to interpret information obtained using biologic markers of exposure.

Many factors confound the use and interpretation of biologic markers of exposure:

- The body burden of a substance may be the result of exposures from more than one source; for example, polyaromatic hydrocarbons (PAHs) exposure can come from waste sites, but significant PAH exposure also can come from cigarette smoking and the consumption of charcoal-grilled meat
- The marker being measured may also be a metabolite of another xenobiotic substance; high urinary levels of phenol can result from exposure to several different aromatic compounds
- Depending on the properties of the substance (e.g., biologic half-life) and environmental conditions (e.g., duration and route of exposure), the substance and all of its metabolites may have left the body by the time biologic samples can be taken
- Many of the substances listed in Table 1 (particularly the essential mineral nutrients such as copper, zinc and selenium) are commonly found in the tissues and fluids of unexposed individuals; such background levels can complicate the correlation of body levels with environmental levels and health effects thereby complicate health assessments

These confounding factors and the existence of data gaps complicate the use of biologic markers of exposure and impede the performance of site-specific health studies. Exposure studies of waste site contaminants, such as the ATSDR-sponsored studies summarized in Table 2, help fill data gaps and establish background levels of these substances in biologic tissues and fluids.

Table 2
A Summary of Results from ATSDR Pilot Exposure Studies

Substance	Location	Source	Major Finding
Arsenic	Anaconda, Montana	Soil, housedust, air	Urine arsenic levels >50 ug/l in children living downwind of an inactive copper smelter
	Tacoma, Washington	Soil, housedust, air	Mean urine arsenic levels higher in children living within 1/2 mile of an inactive copper smelter than in comparison communities, but mean is less than 50 ug/L
	Park City, Utah	Soil from mine tailings	Urine arsenic levels in the normal range for children living on or near mine tailings
Lead	East Helena, Montana	Soil, housedust, air	Blood lead > 25 ug/dl in some children; related to distance from an active smelter
	Kellogg, Idaho	Soil, housedust, air	Blood lead > 25 ug/dl in some children, related to distance from a recently closed smelter
	Park City, Utah	Soil from mine tailings	Mean blood lead of children living on or near mine tailings elevated above control community but still less than 10 ug/dl
PCBs	12 NPL sites in 8 states	Soil, surface water, occupation	High prevalence of elevated serum PCBs >120 ppb in two communities; occupational importance
	Monroe County, Indiana	Soil, surface water, direct contact	High prevalence of elevated serum PCBs > 120 ppb with occupational exposure
	Newport County, Mass.	Food chain, occupation	High prevalence of elevated serum PCBs > 120 ppb with consumption of local seafood
	Fort Smith, Arkansas	Soil, dust	Serum PCBs within normal range
	Paoli, Pennsylvania	Soil, dust	Serum PCBs within normal range
Dioxin*	Missouri	Soil, occupation	Elevated adipose tissue levels in all groups of exposed persons (geometric mean 21.8 ppt compared with 6.4 ppt for controls)
	New Jersey	Occupation	Elevated serum levels in workers compared with controls
Pesticides	Memphis, Tennessee	Soil, surface water, food chain	Elevated serum levels of hexachlorobenzene (geometric mean 0.23 ppb vs 0.17 ppb for controls) and elevated adipose levels of heptachlor epoxide (0.08 ppm vs 0.06 ppm for controls) in persons living near the site, eating fish from contaminated river
	Nashville, Georgia	Soil	No evidence of elevated serum pesticides
VOCs	Doylestown, Pennsylvania	Groundwater, surface water (used for sanitation but not for drinking)	No evidence of elevated serum VOCs
	Uniontown, Ohio	Groundwater, surface water (used for sanitation but not for drinking)	Of 27 VOCs evaluated only tetrachloroethene detected in > 1.96 standard deviations above the mean (two individuals)

* 2,3,7,8-tetrachlorodibenzo-p-dioxin

Biologic markers of effect are defined as measurable biochemical, physiologic or other alterations within an organism that, depending on the magnitude, can be recognized as established or potential health impairment or disease.[1] Biologic markers of effect tend to be nonspecific for any given substance but may be relative within a given chemical class. However, similar hepatic or neurologic abnormalities can be caused by many classes of substances such as VOCs or chlorinated hydrocarbons. Organophosphorus and carbamate insecticides are a class of substances that are known to cause a decrease in red blood cell or plasma cholinesterase levels. Although these effects are specific for this class, they are not specific for any individual substance within the class.

Confounding factors such as diseases, nutritional status, genetic variability, occupation and life style can influence markers of effect. Decreased cholinesterase levels, for example, can be caused by such conditions as parenchymatous liver disease, genetic variability, malnutrition, acute infection, anemias, myocardial infarction and dermatomyositis.[3,4]

In the environmental setting, the use of meta-analysis to study the effects of exposure in a large population pool may help to better define markers of early biologic effects. The National Exposure Registry under development at ATSDR will contain information on health effects resulting from exposure to select priority hazardous substances at waste sites. Although it may not be possible to define markers of early biologic effect(s) that are truly substance-specific, the use of batteries of biologic markers of effect can provide the added information needed to verify public health concerns. A summary of some biologic effects investigated or under investigation via epidemiologic studies funded by ATSDR is presented in Table 3.

Table 3
Summary of Biological Effects Investigated
by Epidemiological Studies Funded by ATSDR

Biologic Effect Investigated	Study Location	Substance	Findings
Blood Pressure	Bristol Co, MA	PCBs	No Observed Effect
	Monroe, Co, IN	PCBs	Self-reported high blood pressure Dose response with serum PCB level
	Memphis, TN	Pesticides (pp'-DDE)	No Observed Effect
Hepatic Function	Quail Run, MO	Dioxin*	Elevated for five liver enzymes Elevated urinary uroporphyrins
	Missouri	Dioxins*	Elevated globulin and decreased albumin/globulin ratio
	Monroe, Co, IN	PCBs	No Consistent Pattern
	Memphis, TN (Hollywood)	Pesticides	No Observed Effect
Immune Function	Quail Run, MO	Dioxin*	Abnormal T4/T8 T-cell ratios - Anergy on DTH skin test in exposed group compared with nonexposed group (11.8% vs 1.1%)
	Quail Run, MO (follow-up)	Dioxin*	No Observed Effect
	Missouri	Dioxin*	No Observed Effect
Reproductive Outcomes	Missouri	Dioxin*	No Observed Effect
	Albany, NY	Multiple Substances	Under way
	Woburn, MA	Multiple Substances	Under way
	Georgia	Multiple Substances	Under way
	St. Gabriel, LA	Multiple Substances	Under way

MINIMUM RISK LEVELS

People who live near hazardous waste sites are concerned about health outcomes resulting from exposure to hazardous substances.[4] To address this issue, ATSDR is developing MRLs for substances found at NPL hazardous waste sites. The MRL provides state and local health professionals, scientists and concerned citizens with an estimate of the level of a substance below which no harmful health effects (other than cancer) are expected to occur.

This estimate is intended to provide health professionals with a basis for comparing levels that people might encounter in the environment. These data will help determine the need for further evaluation of the potential public health impacts. Although these values are not meant to support regulatory action, they may be useful to physicians, project managers and public health officials who must take appropriate actions at hazardous waste sites or chemical releases.

An MRL is based on noncarcinogenic effects and is not intended to provide any information on the carcinogenic potential of a substance. The methodology used for MRL derivation is similar to the U.S. EPA's risk assessment methodology for determining reference doses for lifetime exposures (RfDs).[5] In deriving MRLs, ATSDR emphasizes its preference for using data from humans whenever such data are reliable and otherwise appropriate. However, when sound human toxicological data are unavailable or incomplete (insufficient exposure duration, insufficient sample size, poorly documented exposure information, etc.), animal data must be used.

The most sensitive species with the highest no-observed-adverse-effect level (NOAEL), below which there are no adverse effects, is determined from an evaluation of sound toxicological data. This is the end-point from which an MRL may be derived. The lowest level at which adverse effects are observed (LOAEL) is used when all reported levels of exposure have caused adverse effects. The highest NOAEL or the lowest LOAEL are then divided by separate factors of 10 to adjust the MRL for each of the following uncertainties when appropriate:

- Human variability to protect the most sensitive population
- Interspecies variability for extrapolating animal results to humans
- The uncertainty in using a LOAEL to estimate the MRL

Thus, the uncertainty factors (UFs) used by ATSDR range from 10 to 1000.

MRLs derived for priority hazardous substances are based on an assessment of available toxicological and epidemiological data (as mentioned above). Necessary NOAELs and LOAELs are evaluated for the following organs and systems: hepatic, neurologic, developmental, reproductive, respiratory, hematologic, immunologic, dermal/ocular, renal, cardiovascular, gastrointestinal, musculoskeletal and genotoxic. MRLs are then determined for the most sensitive effect.

In a recent ATSDR effort, data from a study subset (a representative sample of 54 of the 225 priority hazardous substances listed to date) revealed that although all organs and systems are evaluated and considered in deriving MRLs, most of the MRLs have been derived from either hepatic (31%), neurologic (20%), developmental (11%) or other (15%) end-points. The "other" category mainly represents changes in body weight and rates of food intake. These four types of effects taken together account for more than three quarters of the MRLs in the sample. Other systemic effects, such as cardiovascular, gastrointestinal, musculoskeletal and genotoxic, are not represented. This pattern suggests that the majority of MRLs are derived from a minority of end-points.

ATSDR classified 225 priority hazardous substances on the basis of extractive or analytical technique.[6] Eleven categories are used: volatile organic compounds; polycyclic aromatic compounds; halogenated pesticides and related compounds; organophosphates and carbamates; phthalates; inorganic compounds, including elemental metals; phenols and phenoxy acids; nitrosamines, ethers and alcohols; benzidenes and aromatic amines; reactive intermediates; and miscellaneous compounds. Three categories contain 60% of the 225 priority substances listed: VOCs (35%), inorganic substances (12%) and halogenated pesticides and related compounds (13%).

The MRLs derived from the study subset are mainly distributed among the same substance categories: VOCs (38%), inorganic substances (15%) and halogenated pesticides and related compounds (11%). This pattern also suggests that the majority of MRLs are derived from a minority of substance categories.

ATSDR derived MRLs for the most sensitive end-point according to route and duration. Routes used to derive MRLs are inhalation and

oral. Exposure via the dermal route is discussed in the Toxicological Profiles, but dermal MRLs are not currently being derived. Duration of exposure is defined as acute (less than or equal to 14 days), intermediate (15 to 364 days) or chronic (greater than 364 days). MRLs compared on the basis of exposure route and duration were generated from the study subset. Reflected in this evaluation is the fact that MRLs from oral exposure are twice as prevalent as those from inhalation MRLs (Table 4) and acute inhalation exposures are used for 13% of the study subset MRLs, half of which were neurologically derived. Chronic exposure MRLs are underrepresented as a whole, thereby identifying a future area for research (Table 5).

tions, reference values or ranges of normal physiological values must be known. Without this knowledge, it will be difficult to evaluate information collected from people living near NPL sites.

Before biologic markers can be used to evaluate people exposed to hazardous substances, their predictive value must be assessed. Positive predictive value is the probability that people actually have the disease or organ dysfunction when the results of the biologic marker tests are positive. Negative predictive value is the probability that people do not have the disease or organ dysfunction when the results of the biologic marker tests are negative.

Predictive value depends on the sensitivity, specificity and prevalence of the end-point being measured. Sensitivity can be defined as the probability that detection of a biologic marker is not within the range of normal physiological limits. Specificity is the probability that the marker will be absent or within normal limits when exposure has not occurred or is below a level that produces observable effects. If the criteria for defining disease or organ dysfunction are broad, more people who have the disease or organ dysfunction will be detected (increased sensitivity); however, the specificity will be decreased, i.e., more people who do not have any abnormality will test positive. Abnormalities that are prevalent increase predictive value, while those with low prevalence decrease predictive value.

Many difficulties arise in trying to assess whether exposure to toxicants will result in health effects in humans. Exposure may be difficult to demonstrate because the parent substance or its metabolites may not be retained in the body long enough to be measured, or suitably sensitive or specific tests may not be available. The detection of a health effect may be delayed because the biologic capacity in such organs as the liver and kidney is so great that the effects of significant organ damage are not clinically detectable until the toxicant's effects have overcome the repair and reserve capacity of the target organ.

Genetic differences in susceptibility, prior sensitization or preexisting disease may create a situation in which one person exposed to a particular dose of a toxicant will have overt symptoms while another person with an identical dose will have no apparent effect. A toxicant sequestered in fat (e.g., DDT) or in bone (e.g., lead) may be undetectable and possibly innocuous until it is released into the circulation by stress, such as pregnancy or an appreciable loss of body fat. The long latency periods for some health end points make it difficult to correlate human exposure to toxicants at NPL sites with disease or organ-system dysfunction. The heterogeneous, usually small populations of persons affected at most NPL sites create problems for detecting subtle or rare events. Excluding confounders such as unrelated or concurrent diseases, genetic predisposition and changes in laboratory tests caused by aging, sex differences, drug use and smoking remains a challenge to researchers hoping to employ biologic markers as predictors of health outcomes. Despite these limitations, ATSDR has begun an effort to implement the use of preselected batteries of biologic markers in the hope of detecting preclinical differences in exposed vs. unexposed populations.

MRLs ultimately are derived from biologic markers. Hence, an increase in the quality and quantity of biologic markers will result in more accurate NOAELs and LOAELs which will increase the accuracy of the MRLs and, consequently, reduce the uncertainty of health assessments.

ABSTRACT

The Centers for Disease Control (CDC) has conducted nine studies of exposure to 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD or dioxin) in Missouri since 1974, when the compound was identified as the possible etiology of a 1971 poisoning episode. In an earlier report, persons who had been exposed to TCDD were observed to have had an increased frequency of anergy, relative anergy and other possible immunologic effects (increased frequencies of abnormal T-cell subsets; T4/T8 [CD4/CD8] cell ratios less than 1; and abnormalities in T-cell function). These findings were not confirmed in other studies of exposure to TCDD in Missouri. In this article, we present the historical events leading up to studies of TCDD in Missouri and selected results of the nine CDC studies.

INTRODUCTION

The Centers for Disease Control (CDC) has conducted nine studies of exposure to 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD or dioxin) in Missouri since 1974, when the compound was identified as the possible etiology of a 1971 poisoning episode. Following are the dates and titles of these nine studies.

- 1971 Toxin-Associated Illness
- 1974 2,3,7,8-TCDD Contamination of Salvage Motor Oil
- 1983 Pilot Health Effects Study[1-4]
- 1984 Quail Run Health Effects Study[5,6]
- 1986 Quail Run Followup Health Effects Study[7]
- 1986 Reproductive Outcome Study[8]
- 1986 Adipose Tissue Study[9,10]
- 1986 Adipose Tissue-Serum Correlation Study[11]
- 1987 Adipose Tissue Health Effects Study[12]

As we look back on the studies of TCDD carried out in Missouri, we are prompted to ask, What have we learned? So what? What do we know now about dioxin or hazardous substances in general that we would not have known—or might not have known—if dioxin had not been studied?

The first thing we have learned is that things are not always as they seem. As W.S. Gilbert, the poet, said, "Things are seldom what they seem, skim milk masquerades as cream." The second thing is that we do not yet know all—or even most—of what there is to know about hazardous substances, whether it be their mechanism of action or the adverse human health effects they cause. Third, even some good can come from an unfortunate event. As many of us heard in our childhood, "It is an ill wind that does not blow someone some good." First, a summary of the story of dioxin contamination in Missouri.

BACKGROUND

In August 1971, the St. Louis Division of Health, the Missouri Division of Health (DOH) and the Centers for Disease Control (CDC) investigated a toxic illness in St. Charles, Missouri (Epi-Aid 72-13-2, Atlanta, Georgia: Centers for Disease Control, Aug. 14, 1972). CDC reported that 54 of 57 horses exposed to a horse arena had died of an illness characterized by skin lesions, severe weight loss and hepatotoxicity. Birds, dogs, cats, insects and rodents also were found dead in and around the arena and one 6-year-old girl who was exposed developed hemorrhagic cystitis. Urine cultures for the girl were negative for bacterial and viral pathogens. Immediately before onset of these illnesses, the horse arena had been sprayed with salvage motor oil for dust control.

Although a phosphorus-containing compound was found in samples taken from the affected animals and the one human, results of the investigation were considered inconclusive. The authors considered PCBs, triorthocresyl phosphate, tri-butyl phosphate, zinc dithiophosphate compounds or other organophosphorus compounds as the possible etiologic agents.

The first report of dioxin contamination in the published literature was an article by Dr. Arthur A. Case, a veterinarian, from the University of Missouri.[13] In his 1972 article, Dr. Case summarizes:

> "This preliminary report of the complex and deadly sequence of events that followed the use of discarded motor oil to settle dust in a riding arena and horse stable should alert horse owners, veterinarians and physicians to a common, but potentially dangerous practice. Waste oil collected from service stations and other sources in a large midwestern city was used in June 1971 to settle the dust in a large riding arena next to a prominent stable housing valuable Quarterhorse breeding stock.
>
> As of September 1971, the loss of horses and pets and the illness of two children had already become an economic disaster with the potential of tragedy for the children's family. The girls, aged 6 and 10 years, were affected by an apparently volatile toxic agent present in the waste crankcase oil. The children played with their ponies and pet dogs and cats in the arena and collected dead sparrows as they fell from the top of the arena during the week after the application of the oil. The jury is still out on the accident, but the toll is high enough that warnings to protect others from such hazardous situations are in order."[13]

It was not until July 1974 that the possible etiology of the outbreak was determined. Until that time, there was no reason to suspect that 2,3,7,8-tetrachlorodibenzo-p-dioxin was involved. In July 1974, after the Missouri DOH was informed that the samples collected at the horse

arena had 31,800 to 33,000 ppb TCDD, Missouri invited CDC to participate in a renewed investigation (Epi Aid 75-17-2, Atlanta, Georgia: Centers for Disease Control, Mar. 31, 1975). In its Aug. 24, 1974, issue of the Morbidity and Mortality Weekly Report, CDC reported finding the TCDD.[14] The editorial for the article stated:

"TCDD is a very persistent chemical and a potent contact poison. Its acute oral LD-50 for rabbits, mice, guinea pigs and other species is in the microgram-per-kilogram range. TCDD may cause chloracne and liver damage in humans, chickedema disease in chickens and porphyria cutanea tarda in animals and perhaps man. It has been shown to be teratogenic in some mice strains and has also a general embryotoxic effect."

An investigation in August and September 1974 traced the St. Charles wastes to a chemical plant in Verona, Missouri. A tank containing 4300 gallons of wastes contaminated by TCDD concentrations of up to 343 ppb still existed at the plant. In its report, CDC acknowledged that the expected half-life of dioxin was 1 year and recommended that: (1) inaccessible contaminated soil remain undisturbed, (2) soil in residential fills be removed to a landfill, (3) the contents of the storage tank at Verona be properly incinerated, (4) the tank be marked and deep buried (5) and symptomatic persons be followed up (Epi Aid, 75-17-2, Atlanta, Georgia: Centers for Disease Control, Mar. 31, 1975).

Given the expected half-life of dioxin in soil, soil levels of dioxin were expected to approach the minimum detectable limits by 1975. The decision was made not to remove residential soil but to resample it in an effort to confirm the anticipated degradation rate of dioxin. Visits to residential sites in September 1976 confirmed that the soil was not eroding and that vegetation had been established.

From 1974 to 1977, many discussions were held about the best way to dispose of the wastes in the tank at Verona. In September 1979, a final decision was made to use a new photolysis process that could detoxify dioxin. The project was completed in August 1980. Almost immediately, the U.S. EPA received an anonymous telephone call alleging that other sites in southwest Missouri had received wastes from the Verona plant. This led to the discovery of several other sites. Cleanup of these sites was carried out between October 1979 and 1981.

Subsequently it was estimated that approximately 29 kilograms of TCDD-contaminated sludge wastes, which had originated as a byproduct of hexachlorophene production, had been mixed with other waste oils and sprayed for dust control at approximately 250 residential, recreational and commercial sites throughout Missouri.

In May and June 1982, samples were taken again from TCDD-contaminated soil. The samples were analyzed and the results were made public in Aug. 18, 1982. When TCDD was unexpectedly found in these soil samples, the issue of dioxin was raised again. This report led to further dioxin studies in Missouri.

DIOXIN STUDIES IN MISSOURI

Pilot Health Effects Study

The Pilot Health Effects Study[1-4] was carried out in 1983. It compared the health effects in 68 persons who lived, worked or played in areas with TCDD-contaminated soil with the health of 36 persons who lived, worked or played in areas without TCDD-contaminated soil. No clinical illness was associated with TCDD exposure. No cases of chloracne or porphyria cutanea tarda were seen. In-vitro lymphocyte proliferative responses, overall cell-mediated immune responses and delayed-type hypersensitivity skin testing were not statistically different between the two groups. However, one exposed person and one unexposed person were anergic (defined in the study as having less than 2 millimeters of induration to all seven skin test antigens on the Multitest CMI produced by Merieux).

The Quail Run Health Effects Study

The Quail Run Health Effects Study[5,6] was carried out in 1984.It compared health effects in 135 persons who lived in a trailer park with TCDD-contaminated soil to the health of 142 persons who lived in three trailer parks without TCDD-contaminated soil. The study showed no

consistent differences between the two groups on medical history, physical examination, serum and urinary chemistry studies and neurologic tests. However, exposed persons did have a statistically significant increased frequency of anergy and relative anergy (defined as having less than 2 mm of induration on six of the seven antigens on the Multitest CMI). Exposed persons had nonstatistically significant increases in abnormalities in T-cell subsets, T4/T8 cell ratios less than 1.0 and abnormalities in T-cell function. Although it was not possible to put a value judgment on which of these findings was most important, we were very concerned about the findings of anergy and relative anergy, which we felt could indicate a deficit in immune function that could have grave clinical consequences of infectious disease or cancer.

The Quail Run Followup Health Effects Study

The Quail Run Followup Health Effects Study[7] was carried out in 1986. It examined results of delayed-type hypersensitivity skin tests for all persons from the Quail Run Study with anergy or relative anergy who agreed to be retested. Twenty-eight exposed participants and 15 unexposed persons who had previously tested as anergic or relatively anergic agreed to participate in this followup study. Only one exposed and one unexposed person were relatively anergic and none was anergic. This finding made the results of the Quail Run Study seem questionable. This followup study was carried out 18 months after the Quail Run Health Effects Study and TCDD was thought to have a serum half-life of several years. Multiple peer reviewers believed that the differences in skin test findings from the Quail Run Study and the followup study were unlikely to be due to TCDD exposure—especially because so many unexposed persons found to be anergic or relatively anergic in the first study were not anergic in the second.

The Reproductive Outcome Study

The Reproductive Outcome Study[8] in 1986 compared birth records from 402 women who lived in areas with TCDD-contaminated soil with such records for 804 women who lived in areas without TCDD-contaminated soil. There were 17 birth defects in neonates of exposed women and 42 in neonates of the unexposed women. Fifteen of the 17 and 35 of the 42 were classified as major birth defects. No abnormalities were significantly elevated in the neonates of exposed women. Although risk ratios ranged from 1.33 to 3.00 for the categories of infant, fetal and perinatal death, low birth weight and several of the defects, the 95% confidence intervals always included a risk ratio of 1.0.

The Adipose Tissue Study and the Adipose Tissue-Serum Correlation Studies

In the Adipose Tissue Study[9-11] carried out in 1986, 51 persons who worked, lived or played in areas with TCDD-contaminated soil and 128 persons who worked, lived or played in areas without TCDD-contaminated soil donated adipose tissue samples that were assayed for TCDD. The results showed that unexposed persons' adipose tissue levels of TCDD ranged from 0 to 20.2 ppt and exposed persons' levels ranged from 3.7 to 750 ppt. Of the exposed group, 22 (43%) had adipose tissue levels of 20.2 ppt TCDD or less. Even though these 22 persons were considered exposed to TCDD using an epidemiologic definition of exposure, when a quantifiable objective laboratory measure of exposure was used, they were found to be unexposed. A following study, also performed in 1986 and designed to assess the correlation between adipose tissue and serum levels, found that the levels did correlate.

The Adipose Tissue Health Effects Study

The Adipose Tissue Health Effects Study[12] performed in 1987 examined 40 persons, classified as exposed, who had participated in the adipose tissue study in Missouri and who agreed to be retested for health effects, including delayed-type hypersensitivity skin testing. No specific patterns associated with TCDD exposure were noted in medical histories or physical examinations—for example, chloracne, abnormal vibratory sensation or abnormal reflexes. After adjustments were made for gender and age in multivariate analysis, only globulin and albumin/globulin

ratios were associated with adipose tissue levels of TCDD. No participants were anergic or relatively anergic, confirming the findings of the Quail Run Followup Health Effects Study.

Selected Serum Chemistry and Immunologic Results

The number of exposed and unexposed persons and selected results of the Pilot Health Effects Study, the Quail Run Health Effects Study, the Quail Run Followup Health Effects Study and the Adipose Tissue Health Effects Study are shown in Tables 1, 2 and 3.

- No significant difference was found in the number of reported cases of cancer between the exposed and unexposed study participants in the four studies (Table 1).
- In the two studies where serum globulin levels were measured, no clear pattern emerged of association with TCDD levels (Table 1).
- Similarly, in the same two studies, no clear pattern appeared in the albumin to globulin ratio, although the ratio was lower in exposed participants in the Adipose Tissue Health Effects Study. This finding is consistent with the increased globulin levels reported in this group (Table 1).
- The number of persons reported to be relatively anergic in the four studies is shown in Table 2. Although relative anergy was associated with TCDD exposure in the Quail Run Health Effects Study, no such association was reported in the Pilot Study, the Quail Run Followup Health Effects Study, or the Adipose Tissue Health Effects Study.
- Similarly, only the Quail Run Health Effects Study showed an association of anergy with TCDD exposure (Table 2). Twice as many exposed as unexposed persons were anergic, but the number of exposed and exposed participants was approximately the same.
- No consistent pattern was noted of association of the number of positive delayed-type hypersensitivity skin test antigens with TCDD exposure (Table 2).
- Only the Quail Run Health Effects Study shows an association of a decreased number of millimeters of induration with TCDD exposure (Table 2).
- No clear pattern was found of association with the number of T4 cells/mm³ and TCDD exposure. In none of these studies was the number of T4 cells significantly associated with TCDD exposure (Table 3).
- With T8 cells, both the Pilot Study and the Adipose Tissue Health Effects Studies showed an association with TCDD exposure. However, a review of the four studies showed a pattern of a slightly increased number of T8 cells in exposed persons compared with unexposed persons (Table 3).
- For the four studies, no overall pattern emerged of differences in T4/T8 cell ratios associated with TCDD exposure. However, a nonstatistically significant tendency was found for an association of T4/T8 ratios less than 1 in exposed persons. This association seems to be related to the slightly increased number of T8 cells in exposed persons, causing the T4/T8 ratio to decrease below the magic level of 1 in more exposed than unexposed persons (Table 3).

When the phytohemaglutinin, concanavalin A, pokeweed mitogen, tetanus toxoid and allogeneic T-cell cytotoxicity percent lysis for the four studies are reviewed, the only statistically significant finding was an increase of the pokeweed mitogen response in exposed persons.

CONCLUSION

In conclusion, we found no overall pattern to date of abnormal health effects associated with TCDD exposure in studies involving medical history, physical examination and laboratory findings including neurologic abnormalities, dermatologic abnormalities, reproductive abnormalities, routine hematology, serum chemistry, liver function and porphyrin metabolism.

The only suggested laboratory finding associated with TCDD exposure was the tendency of exposed individuals to have a few more T8 cells than unexposed individuals. Whether this finding is real and whether it will have any clinical significance, must be answered with the study of TCDD-exposed workers currently being carried out by the National Institute for Occupational Safety and Health.

What then, have we learned from these studies? As we mentioned at the beginning, things are not always what they seem. Clearly, illness occurred at the time of the original use of TCDD-contaminated wastes for dust control. But to date, we have not been able to document acute health effects even in persons known to have elevated levels of adipose tissue TCDD. Studies under way by the National Institute for Occupational Safety and Health may shed additional light on possible long-term health effects associated with TCDD exposure, including cancer.

Second, 19 years after the TCDD-contaminated wastes were used for dust control in Missouri, we still do not have all the answers on the adverse health effects caused by exposure to TCDD.

And third, the interest in dioxin has stimulated laboratories to develop expertise in measuring substances in the ppt and ppq (parts-per-quadrillion) range. The current national interest and expertise in hazardous substances has resulted in a large part from events such as those that occurred in Missouri.

Methods for Characterizing Populations Residing Near Hazardous Waste Sites

Brenda Kay Edmonds, M.S.
Allan S. Susten, Ph.D., DABT
Agency for Toxic Substances and Disease Registry
Atlanta, Georgia

ABSTRACT

In this paper, we describe the actions the Agency for Toxic Substances and Disease Registry (ATSDR) is taking to evaluate methods for obtaining demographic information about populations who reside near uncontrolled waste sites and who may be potentially impacted by releases or potential releases of hazardous substances from these sites. Door-to-door surveys represent the preferred method for obtaining such data; however, such surveys are not practical for most of the 1200 sites currently listed on the NPL. Thus, we propose to use one or more methods to obtain reliable estimates of total numbers and other demographic characteristics for populations potentially affected because of their proximity to hazardous waste sites.

Four approaches for obtaining estimates of critical demographic information about NPL sites were identified and are being evaluated. These four methods were given the following descriptive names: (1) ZIP Code Method, (2) Population Centroid Aggregate Method, (3) Block/Enumeration District Method and (4) Geographic Information System (GIS) Method.

Five NPL sites in Georgia were selected as part of a pilot project to evaluate and compare each of the methods. Total population was used as the initial demographic criterion for evaluation. Field surveys were conducted to determine base line populations for each site. Total population estimates obtained by each of the four methods are being compared against the field survey (base line) data. Data from the GIS Method were not available for this report.

Using these findings, we will apply one or more of the methods to a larger pilot of 30 NPL sites. In addition to total population, other demographic data — including information on racial and ethnic composition for populations residing near the sites — will be estimated.

INTRODUCTION

Valid demographic data are necessary to characterize populations whose health is potentially impacted because of their proximity to hazardous waste sites. Such data are critical to public health professionals and researchers who design and conduct studies to investigate possible relationships between human exposure to environmental contaminants at hazardous waste sites and adverse health effects. Human populations who live near sites that are listed on or proposed for the NPL are of particular interest.

Door-to-door surveys would provide the most accurate method for obtaining these data. However, such surveys of potentially affected residents are not practical for most of the 1200 NPL sites. Thus, we intend to use one or more methods to obtain reliable estimates of total numbers and other demographic characteristics for populations that are potentially affected because of their proximity to hazardous waste sites.

Various approaches for obtaining demographic data are being used by environmental regulators and private marketing firms.[1-6] However, these methods have limited utility for environmental health researchers because the demographic data they provide pertain to large geographic areas that are not easily linked to sources of environmental contamination at hazardous waste sites.

Four methods were identified as potential approaches for obtaining estimates of critical demographic information about NPL sites. These methods were given the following descriptive names: (1) ZIP Code Method, (2) Population Centroid Aggregate Method (also referred to as the centroid assignment technique),[6-10] (3) Block/Enumeration District Method and (4) Geographic Information System (GIS) Method.[4]

We describe an ongoing pilot project and future activities being planned by the Agency for Toxic Substances and Disease Registry (ATSDR) to evaluate and compare the utility of the above four methods for obtaining demographic data for populations near NPL sites.

METHODS

Selection of Sites

Five NPL sites located in Georgia were selected for the initial pilot project. The sites were designated as Sites 1, 2, 3, 4 and 5. Accessibility for field surveys was a criterion used to select the sites. An attempt was made to include sites that were representative of small urban and rural population areas. Sites 1 and 3 were considered to be located in rural population areas; Sites 2, 4 and 5 were considered to be located in urban population areas.

Selection of Base Line Criterion Used in Initial Evaluation

Total population was selected as the initial demographic criterion for evaluation. For these five sites, door-to-door surveys were not practical; estimates of total population for each site were determined through field surveys, which consisted of identifying and counting all houses located within one-mile radii of the sites. The estimates were made for each site by multiplying the number of residences observed by the average number of persons per household reported in the 1980 census for that county or geographic area.[11] The total population estimates were used as the population base lines against which similar estimates derived by each of the four methods were compared.

Methods for Estimating Population

ZIP Code Method

The method involved merging three computer data files: (1) the U.S. EPA NPL file, which contained addresses including ZIP Codes for all NPL sites; (2) the U.S. EPA Comprehensive Environmental Response, Compensation and Liability Information System (CERCLIS) file, which

contained similar but not identical information as the NPL file; and (3) the U.S. Bureau of the Census Master Area Reference File 3b (MARF 3b) and extract of the Summary Tape File 3b (STF 3b), which included 1980 census population data for ZIP Code areas.[12]

In merging the CERCLIS and NPL files, we noted some discrepancies between files for individual site addresses and ZIP Codes. When discrepancies were noted, the ZIP Code given in the U.S. Postal Service 1988 National Five Digit ZIP Code and Post Office Directory[13] was regarded as the actual ZIP Code. Four sites were located in one ZIP Code area and one site was located in two ZIP Code areas. Population data were retrieved from the 1980 census MARF 3b for the Zip Code areas in which the sites were located.

Population Centroid Aggregate Method

With the Population Centroid Aggregate Method, site latitude and longitude coordinates reported in the U.S. EPA CERCLIS file were used. The coordinates were used to locate sites on digitized maps for 1980 census tract, block group (BG) and enumeration district (ED) geographies. Concentric circles of one-, two- and three-mile radii were drawn around each site; the smallest concentric circle to include at least one BG or ED population center (centroid) was used to estimate the total population in 1988. Population data were derived by distributing the 1988 census tract population among the constituent BGs and EDs according to the population reported in the 1980 Census Summary Tape File 1 (STF 1) for these areas. Total population estimates were defined for each site by summing the populations for all BGs and EDs whose centroids were included within the concentric circle about the site. Total population estimates in 1988 of persons residing within one-mile radii were available for one of the five sites and within two-mile radii for four of the five sites.

Block/Enumeration District Method

The Block/Enumeration District Method involved the use of U.S. Geological Survey topographic maps to define actual site locations, which were then transferred to U.S. Census maps for 1980 census tract, block and ED geographies. One-mile radii were defined around each site and 1980 census population data were summed for all or portions of blocks and EDs that were included within the area.

Geographic Information System (GIS) Method

The GIS Method involves converting U.S. Census MARFs 1 and 3 into map coverages for each site. The coverages are generated by computing Thiessen polygons to approximate the boundaries of census blocks where the geographic centroid of each block is defined by latitude and longitude coordinates. Population densities at the corners of the Thiessen polygons and at the centroids are interpolated from the block population estimates.

U.S. Geological Survey topographic maps will be used to define actual site locations, which will then be transferred to the map coverages. One-mile radii will be defined around the sites. Total population estimates will be derived for each site by summing the population data for those blocks, BGs and EDs (and portions thereof) included within the one-mile area around the sites. The population data will be retrieved from the Census MARFs 1 and 3 and corresponding STFs 1 and 3. Areas surrounding the site that are known to be uninhabited, such as water bodies, forests and parks, will be designated as exclusion areas; population data for these areas will not be included in the total population estimates.

The GIS Method is currently being applied to the five Georgia sites. Use of this method will generate estimates for total population for geographic areas included within one-mile radii of the sites. The method can be applied to any lateral distance from the sites.

RESULTS AND DISCUSSION

The total populations for the five Georgia NPL sites that were derived using the proposed methods are shown in Table 1. Demographic data derived by the GIS Method were not available for this report. Base line estimates of total population, determined by field surveys, are included for comparison purposes.

Table 1
Total Population Estimates for Five Georgia
Sites: Results Using Three Methods[a] Compared
with Field Survey Values

Total Population

Site	Field Survey	ZIP Code	Pop Centroid	Block/ED
Site 1	980	18,512(+19)[b]	1,389(+1.4)	4,323(+4.4)
Site 2	8,087	18,512(+2.3)	1,389(-5.8)	14,377(+1.8)
Site 3	466	198(-2.3)	2,570(+5.5)	652(+1.4)
Site 4	632	54,096(+86)	40(-15.8)	2,974(+4.7)
Site 5	1,776	36,027(+20)	434(-4.1)	3,071(+1.7)

a   The three methods consisted of the ZIP Code Method (ZIP Code),
    Population Centroid Aggregate Method (Pop Centroid), and
    Block/Enumeration District Method (Block/ED).
    For the ZIP Code Method, the estimate for total population for Site 4
    includes population data for two ZIP Code areas.
    For the Population Centroid Method, the estimates for total
    population include a two-mile area for Sites 1, 2, 3, and 4, and a
    one-mile area for Site 5.
b   Numbers in parentheses indicate the difference from the field survey
    values.

ZIP Code Method

The ZIP Code Method was easy to implement and involved readily accessible computerized data files that could be cross-referenced to identify and correct inconsistencies in geographic descriptors (ZIP Codes). However, the total population estimates obtained using this method varied significantly from their respective field survey values. Estimates for four of the five sites were above the field survey levels and varied from approximately 2 to 85 times greater than these base line values. Only the estimate for Site 3 was less than the field survey value. The overestimates of the total population probably occurred because the ZIP Code areas were geographically much larger than the areas surrounding the sites and were not defined relative to site boundaries.

The population estimates generated using this method were identical for Sites 1 and 2. The two sites are reported in the CERCLIS and NPL files as being located in the same town and county; however, the sites are physically located one mile apart and Site 1 is located in a rural area and Site 2 in an urban area.

Population Centroid Aggregate Method

Total population estimates obtained using the Population Centroid Aggregate Method also varied from the field survey values, but to a lesser extent than when the ZIP Code Method was used. Three of the five estimates were less than their respective field survey values. The largest difference was a 16-fold underestimate of the population for Site 4. The population estimates for Sites 1 and 2 were identical.

The observed differences in population estimates may be attributed to several factors. First, BG geographies were large; concentric circle areas had to be extended beyond one mile in order to identify a single BG centroid. This resulted in an overestimation of total population for sites in more rural areas (Sites 1 and 3) and an underestimation of total population for sites in more urban areas (Sites 2, 4 and 5).

Second, the method relied on site latitude and longitude coordinates reported in the U.S. EPA CERCLIS file. Many of these coordinate data have not been validated and are incorrect. Last, census tract, BG and ED geographies did not conform to the one- and two-mile concentric circles defined around the sites. Rather, the concentric circles transected BG and ED boundaries and included portions of individual BGs and EDs. Population data were obtained only for those census tracts, BGs, or EDs whose centroids were included within the concentric circle; population data for the entire BG and ED area were counted in the site population estimate provided that the centroid was included within the concentric circle.

The method used population data for BGs and EDs that were derived from data reported for 1988 census tract geographies. Changes in population distributions within census tracts and constituent BGs and EDs may have occurred between 1980 and 1988. The 1988 population estimates derived using this method may not be reliable for sites whose

residential population distribution had changed during that period.

Previous work conducted by the ATSDR attempted to estimate populations residing near hazardous waste sites and at potential risk of exposure to environmental contaminants.[10] The method used to obtain demographic data was identical to the Population Centroid Aggregate Method evaluated in this pilot project. Based on population data for 725 NPL sites, an estimated 4.1 million persons were identified as living within one-mile radii of the hazardous waste sites.

Block/Enumeration District Method

The population estimates obtained using the Block/Enumeration District Method were more consistent with the field survey population values than with the estimates obtained by the other two methods. For all sites, the estimates for total population were higher than those obtained by field survey. None of the overestimates were greater than 4.7 times higher. No obvious differences between estimates for urban and rural sites were noted. The population estimates for Sites 1 and 2 were markedly different. The population for Site 2, which is located in an urban area, was 3.5 times higher than that for Site 1, which is located in a rural area.

The comparatively high level of correlation was attributed to the fact that population data for small geographic areas (blocks, EDs) defined relative to the sites were used. In addition, actual site locations were defined using topographic and census maps so that portions of census geographic areas (blocks, EDs) located within the areas surrounding the sites—and the corresponding population data for those areas—were included in the population estimates. However, manual plotting of sites on topographic and census maps and interpretation of census descriptive and geographic map codes[14] was time-consuming and resource-intensive.

GIS Method

Demographic information is currently being obtained using the GIS Method and was not available for this report. On a conceptual basis, the GIS Method combines the strengths of the Block/Enumeration District Method with those of the Population Centroid Aggregate Method. Demographic data will be obtained for small geographic areas (blocks, EDs) defined relative to the sites and will include population data for portions of blocks and EDs that are included within areas surrounding the sites. Manual plotting of sites on topographic and census maps and interpretation of census geographic and descriptive codes will not be required.

Comparison of Preliminary Data

The total population estimates varied significantly depending on the method used. In general, the largest estimates were obtained using the ZIP Code Method, and the smallest estimates were obtained using the Population Centroid Aggregate Method. This was an unexpected finding for the Population Centroid Aggregate Method, since 1988 population data were used with this method; 1980 population data were used with the other two methods. Information reported by the U.S. Bureau of the Census on population changes between 1980 and 1988 indicated that county and city population estimates increased by as much as 8.1% for four of the sites and decreased by 9.9% for one site.[15]

From the preliminary findings, demographic information obtained using the Block/Enumeration District Method correlated most closely with the field survey population estimates. For each method, the highest level of variation was observed for Site 4. The reason for this is not clear. No other patterns were obvious for the data evaluated in this pilot project.

The findings of the pilot are preliminary and should be reviewed cautiously. Only a few of sites were evaluated. A larger pilot of 30 NPL sites is planned. The larger pilot will again evaluate total population, but other variables including racial and ethnic composition will be incorporated. Field surveys similar to those for this pilot project will be conducted. After the demographic data for all 35 sites are reviewed, we will determine the preferred method or combination of methods for obtaining demographic data on total numbers and demographic characteristics for populations residing near hazardous waste sites.

The demographic information will be essential to ATSDR researchers conducting possible health investigations for these sites. The site-specific demographic information will be correlated with environmental data on contaminant concentrations and information on human exposures (e.g., biological indicators) and adverse health outcomes in order to better define possible relationships between exposure to environmental contaminants and the occurrence of adverse health outcomes.

Health Risk Assessment for Complex Mixtures of PAHs

Charles O. Shore, M.S.
Alan W. Messing, Ph.D.
ABB Environmental Services, Inc.
Washington, District of Columbia

ABSTRACT

Although most health-based risk assessments have been performed on individual toxic chemicals, hazardous waste sites contain mixtures of individual chemicals. The importance of quantitatively estimating the human health risk from exposure to such mixtures for cleanup purposes cannot be overstated. However, several less obvious benefits exist, including: (1) priority assessment of waste sites, facilitating decision-making regarding the expenditures of time, money and man-hours; (2) development of selective remediation techniques for the most hazardous component(s) of the mixture; and (3) a realistic basis for exposure assessment.

Typically, the exposure risks of only a few components in a mixture have been adequately characterized from human or lifetime animal bioassay data. Risks from mechanistically or structurally related components must be estimated using acceptable alternatives. For carcinogens, the most widely used alternative involves calculation of a relative potency or the anticipated strength of a tumor response for a poorly understood candidate chemical relative to the response from a well-studied standard. Potency ratios comparing the candidate compound to the standard typically are based on short-term bioassay end-points believed to be related to the carcinogenic response. The final product of the relative potency calculation is a risk estimate of the standard and all the candidate compounds in the mixture expressed in "toxicologically equivalent" units of the standard.

The U.S. EPA recently developed a relative potency procedure for mixtures of polycyclic aromatic hydrocarbons (PAHs) based on mouse skin painting studies. The authors of the present paper discuss the adequacy of these studies as predictors of human carcinogenic risk for six structurally similar PAHs. We also consider the appropriateness of relative potency calculations based on mechanistic experiments. Because PAH metabolism to the ultimate carcinogen depends on organismic variables, we have incorporated physiological parameters to account for interspecies variation and use default values when such data are sparse.

Our model indicates that, as a whole, the candidate compounds are considerably less potent than the standard, benzo[a]pyrene (B[a]P). Therefore, compared to an approach in which all mixture components are considered equipotent with the standard, the relative potency model can reduce cleanup costs while assuring continued compliance with health standards.

INTRODUCTION

When analyzing complex mixtures of potential environmental carcinogens, health risk assessors traditionally have used a surrogate approach to describe excess risk. According to this approach, the carcinogenic potencies of mechanistically similar but poorly studied substances are considered equivalent to the potency of a congener that has been adequately assessed for carcinogenicity in lifetime animal bioassays or epidemiological studies. Excess risk is defined as the product of the total concentration of all congeners in the environmental sample, in some standard unit, and the potency determined for the well-studied substance, or standard, minus the background risk. Because the standard is often considerably more toxic than its congeners, use of the surrogate approach can lead to serious overestimations of carcinogenic risk.

An alternative approach involves the calculation of a relative potency. Relative potency is most frequently determined as the ratio of the magnitude of an effect resulting from exposure to an empirically data-sparse substance with the magnitude of the same effect, in the same experiment, resulting from exposure to a mechanistically similar and better understood standard. Effect ratios are calculated at equal exposure (or, alternatively, equimolar) concentrations and typically are based on short-term results that, by themselves, would be insufficient to support a potency estimate. The legitimacy of the relative potency approach is strengthened if effects ratios based on different experimental conditions are approximately consistent. If such consistency is demonstrable, then the environmental concentrations of the data-sparse substances can be converted to "toxicologically equivalent" concentrations of the standard for use in the subsequent risk and exposure assessments.

For polycyclic aromatic hydrocarbons (PAHs), substances formed during incomplete combustion, the standard has been benzo[a]pyrene (B[a]P). B[a]P has been studied extensively in both oral[1] and inhalation[2] animal bioassays. Based on these studies, the U.S. EPA[3] cited unit risk estimates of 11.53 and 6.11 (mg/kg day)$^{-1}$, respectively, for oral and inhalation exposure. Although a comparable data base does not exist for mechanistically similar PAHs, results of short-term studies clearly indicate that B[a]P is considerably more potent than most of these related substances.

The fallacy of the surrogate approach can be illustrated by comparison of the cancer risks from cigarette smoking and occupational exposure to roofing materials.[4,5,6] Based on face mask residues, the amount of B[a]P inhaled daily by roofers ranged from 16.7 ug to approximately 30 ug. Daily B[a]P intake from mainstream cigarette smoke in individuals smoking two packs a day was estimated as 1.4 ug. Despite these differences, the excess lung cancer risk in smokers is considerably greater than in nonsmoking roofers. These findings indicate that a simplistic surrogate approach based on controlled animal experimentation does not always accurately reflect the cancer risks experienced by heterogenous human populations exposed to a variety of potentially interacting parameters.

The authors of the current paper will identify some of the many variables that impact on the human health risk of exposures to com-

plex mixtures, with specific reference to PAHs. Five high molecular weight PAHs, all structurally similar to B[a]P and considered by the U.S. EPA as possible or probable human carcinogens, will be considered. Using B[a]P as a standard and these five substances as comparison compounds, the robustness of the relative potency approach will be addressed. Next, some of the variables affecting the significance of the both the animal and the human B[a]P potency estimates will be considered. These variables include the appropriateness of experimental design and modeling parameters, the importance of the statistical model used to extrapolate from high, experimental exposure levels to more environmentally realistic levels, the effects of physical and chemical characteristics on risk determination and the issue of interspecies extrapolation. The ensuing sections will include an analysis of the interactive nature of other mixture components and a discussion of a recent exposure assessment for combustion sites. The paper will conclude with an analysis of the adequacy of the relative potency approach for risk characterization and a consideration of those factors that most significantly impact risk estimation.

VALIDITY OF THE RELATIVE POTENCY APPROACH FOR PAH

Common Mechanism of Action

An essential tenet of the relative potency approach is that the standard and the data-sparse substances show a common mechanism of action. For high molecular weight PAHs, the common mechanism involves metabolism to one or more short-lived, reactive ultimate carcinogens.[7] Most investigators believe that the ultimate carcinogen is a diol (or triol) epoxide that is formed adjacent to the so-called "bay-region" of the molecule. As depicted in Figure 1, all alternant PAHs (those consisting strictly of fused ring structures) have one or more true bay regions. Nonalternant PAHs, such as the cyclopentenyl-containing benzo[b]fluoranthene (B[b]F) and indeno[1,2,3-c,d]pyrene (IP), may or may not contain a true bay region. As discussed below, these latter substances contain other metabolically active sites that may influence carcinogenic potential.
Figure 1
Structures of Six High Molecular Weight PAHs[8]

Studies in newborn mice[9,10] have added support to theories about B[a]P's mechanism of action. In this paradigm, the experimental substance is intraperitoneally injected into mouse pups for 3 days, and the mice are observed for tumors for up to 40 weeks. If the substance is carcinogenic, the mice develop lung adenomas, liver tumors and/or malignant lymphomas. Using this model, Kaputilnik and his coworkers[10] determined that a specific stereoisomer, (+)7,8-diol-9,10-epoxide-2, is the putative ultimate carcinogen (Fig. 2). Rodent studies indicate that the formation of this stereoisomer is metabolically favored. Other investigators,[11,12] using the newborn mouse model, demonstrated similar metabolic reactivity for benz[a]anthracene (B[a]A) and chrysene (Ch). Although the available evidence[13] in-

dicates that bay region epoxide formation is essential for tumor expression after B[b]F or IP administration, other molecular sites may have contributory roles. Silverman and Lowe,[14] for example, discussed evidence indicating that diol epoxide formation on the phenylic ring of these nonalternant substances may impact on the carcinogenic response. To date, however, no empirical evidence for diol formation on this portion of the molecule has been found.

NOTE: Heavy arrows indicate favored metabolic pathway.
Figure 2
Metabolic Conversions in the Bay Region of Benzo(a)pyrene[18]

Dose Additivity

The relative potency approach assumes that toxicologically equivalent doses can be summed to produce an overall response. This assumption ignores the possibility of both toxicant interaction and cocarcinogenesis induced by the presence of similar congeners. Interactions (synergisms or antagonisms) could occur because other mixture components induce enzymes that either detoxify the standard or accelerate metabolism to a carcinogenic precursor. Several investigators[15,16] have found synergistic relationships between cigarette smoking (which involves exposure to high PAH levels) and other environmental hazards.

A study by Schmahl et al.[17] may provide the only data that address the issue of low PAH exposure levels and dose additivity. NMRI mice received twice weekly skin applications of PAH mixtures that were representative of concentrations in automotive exhaust. Some mice were treated with a mixture consisting of 4.0, 6.8 or 12.0 ug of B[a]P, B[a]A, B[b]F and dibenz[a,h]anthracene (DB[a,h]A). Skin carcinoma incidences at these exposure levels were adequately predicted by a relative potency approach[18] of which dose additivity was an essential component. A second group of mice received higher concentrations of a mixture containing different PAHs. In this instance, the relative potency approach overestimated risk, implying that interactions at these higher exposure levels may have reduced toxicity. Although these results support the use of the relative potency approach at low exposure concentrations, further validation in a number of test systems is needed.

Relative Potency Ratios Across Test Systems

Table 1 illustrates carcinogenic potencies, relative to B[a]P as unity, of the five high molecular weight PAHs that are the subject of this report. Although these data are from different study designs in a variety of animal models, order-of-magnitude consistency is apparent for DB[a,h]A, B[b]F and Ch. The ratios for both IP and B[a]A vary by an order of approximately 20. In general, the results indicate that a geometric mean average of the relative potencies of each compound would provide a fair to excellent estimate of tumorigenic risk in animal models. Furthermore, use of the relative potency approach may provide a more reasonable estimate of risk than the surrogate approach, which would overestimate risk in four out of five cases.

SIGNIFICANCE OF THE POTENCY ESTIMATES

Relevance of the Experimental Model

In the absence of standard lifetime bioassays for most PAHs, some researchers have calculated relative potency values on the basis of mouse skin painting studies. These studies are of two types: complete carcinogenicity assays, in which the test substance is applied repeatedly and without further stimulation from other substances, and initiation-promotion assays, in which the test substance (initiator) is applied for a limited duration, and carcinogenicity is not expressed until the repeated application of a known tumor promotor.

IARC[24] has commented on the appropriateness of mouse skin bioassays as estimates of carcinogenic risk. They noted that certain PAHs initially established as mouse skin carcinogens have subsequently been shown to produce malignancies by other routes of administration. Moreover, the skin is a functionally autonomous organ. Tumor (primarily site papillomas and carcinomas) incidence after dermal application of PAHs is dependent on the inducing activity of local enzymes, rather than the more complex induction and repair mechanisms occurring after systemic administration.

The newborn mouse model has provided considerable insight into the metabolic reactivity of various stereoisomers of alternant PAHs. Because this experimental protocol results in multiple site tumors, site relevance becomes an important factor for relative potency calculations. For example, LaVoie et al.[23] administered B[a]P and B[b]F to male and female newborn CD-1 mice on Days 1, 8 and 15 after birth. Both compounds induced hepatic tumors in male mice, but were inactive in females. Based on the hepatic tumor incidence in males, B[b]F was slightly more potent than B[a]P. However, B[b]F was much less potent than B[a]P in inducing lung adenomas. Because the liver is not a target organ for PAH activity, and the male mouse shows unusually high spontaneous hepatic activity, the pulmonary tumor response was chosen for relative potency calculations (Table 1).

Table 1
Carcinogenic Potencies of Five High Molecular Weight PAHs Relative to B[a]P

| Basis for Relative Potency | | | |
Compound	q_1*[1]	ED_{10}[2]	2-Stage Model[3]	Neonate Model
DB[a,h]A	0.69	2.26	1.11[5]	--
B[b]F	0.08	0.29	0.14[4]	0.48[6]
Ch	0.0012	0.0041	0.0044[5]	0.011[7]
IP	0.017	0.011	0.23[4]	0.035[6]
B[a]A	0.013	0.20	0.14[5]	0.30[7]

[1] Slope estimate of the carcinogenic potency. Relative potency calculated as the ratio of potencies of the data-sparse PAHs to B[a]P in mouse skin painting studies, multiplied by the oral potency of B[a]P determined by the linearized multistage model. (19)

[2] Dose associated with an excess risk in 10% of the exposed population. Relative potency calculated as the ratio of ED_{10}s of the data-sparse PAHs to B[a]P in mouse skin painting studies, multiplied by the oral potency of B[a]P determined from the linearized multistage model. (19)

[3] Relative potencies calculated from the ratio of the transition rate parameters for the data-sparse PAHs and B[a]P, calculated from a restricted 2-stage model. (18)

[4] Intrapulmonary instillation. (20)

[5] Complete carcinogenicity skin painting studies. (21, 22)

[6] Comparative incidences of tumor bearing animals with lung adenomas, adjusted for total dose administered. (23)

[7] Comparative potencies of the metabolically active stereoisomers. (7)

In general, mutagenicity assays are not adequate for the assessment of risk for complex mixtures. These assays typically require exogenous activation, which contributes variability to the test system.[7] Moreover, with the exception of the cell transformation assay, short-term in vitro studies detect only initiation activities. Rice et al.[25] have observed that the active mutagenic metabolites of B[a]P and IP in the Salmonella typhimurium assay show little tumorigenic activity.

The U.S. EPA is currently reevaluating B[a]P unit risk factors based on oral[1] and inhalation[2] exposure. Although these re-evaluations, which would probably lead to lower risk values, would not affect relative potency calculations, they would affect the human unit risk estimates for these two exposure routes.

Low-Dose Extrapolation Modeling

Regulatory agencies have traditionally used values of 10^{-4} to 10^{-7} as acceptable levels of carcinogenic risk. Animal experiments would require millions of animals per exposure group to statistically detect treatment-related effects at these arbitrarily-defined levels. To avoid this problem, experimenters typically expose smaller groups of animals to relatively large doses and then use mathematical extrapolation models to estimate low-dose risk. Because various models can predict markedly different risks at the same exposure level, the choice of a model has been a source of continuing controversy.

In the absence of a more complete understanding of the carcinogenic process at low doses, the U.S. EPA uses the multistage linearized model[26] for extrapolation purposes. This model provides a conservative, stable upper bound estimate of risk. However, the model is statistically, rather than biologically, based, and the risk estimate depends largely on experimental design rather than the actual potency of the test compound.

Researchers at ICF-Clement Associates[18] proposed an alternative extrapolation model based on a two-stage approach (Fig. 3). According to this approach, nondifferentiated stem cells may divide into daughter cells, terminally differentiate, die or undergo mutations that result in a premalignant cell. The premalignant cell may in turn undergo any of the first three processes or mutate to a cancer cell and undergo tumor formation. The numbers of premalignant and malignant cells are assumed to be random variables, while the numbers of normal cells at risk of transformation are assumed to be known. Based on experimental data,[27] researchers have concluded that a restricted form of the two-stage model was appropriate for assessment of the carcinogenic risk of B[a]P. According to this model, response probability is a function of three empirically-derived parameters: the growth rate of preneoplastic cells, the background tumor rate and interstage transition rates. Using the restricted two-stage model, a unit risk of 5.74 (mg/kg day) for oral exposure to B[a]P was calculated. Empirically-determined transition rate parameters between other carcinogenic PAHs were used to calculate potencies relative to B[a]P (Table 1). These calculations were based on intratracheal instillation[20] and complete carcinogenicity skin painting[21,22] studies.

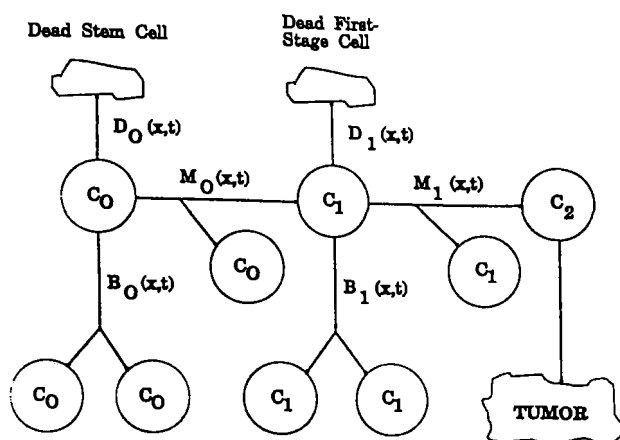
The two-stage model provides a biologically-based, maximum likelihood estimate of risk that is applicable to the study of exposure to multiple carcinogens. It apparently can be used only with genotoxic substances.

Physico-Chemical Considerations

Other factors affecting carcinogenic risk after PAH exposure include physical properties of the mixture and matrix effects. For example, Mahlum et al.[28] studied the initiating activity of three coal distillate fractions applied to mouse skin. The boiling points for two of the distillates were in the 800 to 850°F range, while the boiling point of the third was 850+°F. Each distillate was further fractionated into aliphatics and olefinics, neutral PAHs, nitrogen-containing polycyclic aromatic compounds and hydroxy-PAHs. For each distillate, the neutral PAH fraction was the most carcinogenic. Although the neutral PAH fraction of one of the 800 to 850°F distillates had the same B[a]P content as the 850+°F sample, the latter had greater biological activity. Furthermore, the presence of noncarcinogenic PAHs in the distillate fractions had a significant effect on the expression of a carcinogenic response. The results indicate that B[a]P is not the determinant factor in the carcinogenicity of these mixtures.

When adsorbed to particulate complexes, B[a]P is not subject to photo-degradation and can reach the human lung more easily than unbound B[a]P.[29] Warshawsky et al. demonstrated that the co-administration of B[a]P and crude particulate matter to the isolated perfused lung increased

the rate of dihydrodiol formation and depressed the formation of non-toxic, water-soluble conjugates.

Finally, DeCaprio et al.[30] showed that soil type was the determining factor in the toxicological activity of 2,3,7,8-tetrachlorodibenzo-p-dioxin (TCDD), a substance that is mechanistically similar to the PAHs. The soils differed markedly in TCDD binding affinity. Although each of two TCDD-containing soil samples induced cytochrome P-450 enzyme activity, only loosely-bound TCDD, after extraction, was capable of inducing toxicity in rats and guinea pigs. The differences in toxicological activity are a function of bioavailability, which can range from 0.1% in tightly bound matrices to 85% in loosely bound matrices.


C_0 is a normal, susceptible stem cell.
C_1 is a transformed, first stage cell, that can proliferate into a premalignant clone.
C_2 is a cancerous cell that will eventually develop into a detectable tumor.
$D_0(x,t)$, $B_0(x,t)$, and $M_0(x,t)$ are the exposure- and time-dependent death, birth, transition or mutation rates for the normal stem cell.
$D_1(x,t)$, $B_1(x,t)$, and $M_1(x,t)$ are the exposure- and time-dependent death, birth, and transition or mutation rates for the first-stage cell.
x is the exposure level, which is assumed to be constant over time.
t is the age of the subject.

Figure 3
Biological Schematic of the Two-Stage Carcinogenicity Process[18]

Interspecies Extrapolation

One major issue in quantitative risk assessment is the development of a general formula describing equipotent doses between species, with particular emphasis on dose extrapolation from experimental animals to man. The U.S. EPA has adopted a multiplicative conversion factor based on the 2/3 power of the ratio of the human to the animal body weight. This ratio is equivalent to extrapolation based on surface area. Mouse, rat and human data for a variety of chemicals[31] support the validity of this conversion factor.

Recently, O'Flaherty[32] has recommended a body weight ratio exponent of 3/4, based on dose equivalency at the receptor, or target organ, level (effective dose). O'Flaherty provided data indicating that this approach would be appropriate for substances, such as high molecular weight PAHs, that bind covalently to DNA and/or produce reactive metabolites. In practice, the use of the 3/4 exponent, compared to the 2/3 exponent, would not have a significant impact on risk determina-

tion. For example, based on a "standard" 30-gram mouse and a 70-kg human, conversion to the less conservative 3/4 factor would only reduce the risk estimate by a factor of 2.

More importantly, humans are exposed to genetic and environmental variables that have great influence on the expression of a carcinogenic response, and that will result in far greater variability than the controlled laboratory situation. These variables, including heterogeneity in the rate of enzyme induction, smoking and dietary habits and proximity to combustion sites, can have complex and variable effects on an initiated cell. The variability in the uncontrolled human environment is a primary reason why human carcinogenic potency is difficult to accurately determine from laboratory animal data.

INTERACTIONS WITH OTHER MIXTURE COMPONENTS

Several researchers[21,33] have studied solvent effects on the carcinogenic activity of B[a]P in skin painting studies. The data show that carcinogenicity is amplified by co-administration of C10 to C14 straight-chain alkanes, catechol, pyrogallol, pyrene, benzo(e)pyrene and fluoranthene. Carcinogenicity was increased over a thousand-fold when n-dodecane, rather than decalin, was administered with B[a]P. The results suggest cocarcinogenicity (enhancement of a carcinogenic response by simultaneous administration of a noncarcinogen), possibly through the presence of functional groups that increase hydrogen bonding and/or metal chelation. Bingham et al.[34] further demonstrated that pretreatment with n-dodecane increased 9,10-diol formation in B[a]P-treated isolated rabbit perfused lungs, compared to B[a]P treatment alone.

Although cocarcinogenicity is a putative factor for some of these compounds, other possibilities remain. The solvents may directly injure the skin, causing modifications in uptake. Dermal absorption will be also be affected by the lipophilicity of the PAH-solvent complex. For example, in the Van Duuren and Goldschmidt[33] studies, the aromatic hydrocarbons pyrene, benzo[e]pyrene and fluoranthene may have shown cocarcinogenic activity by alteration of epoxidizing enzyme activity. However, the inhibitory effect of several phenolic compounds probably involved decreased absorption efficiency.

EXPOSURE ASSESSMENT

Even after allowance for interspecies extrapolation, risk estimates based on controlled laboratory studies have little direct relevance to the "true" risks to humans resulting from environmental exposure. Although exposure assessment is one of the major components of the risk assessment process, it is often the least well characterized.

The U.S. EPA[35] conducted an environmental assessment of health risks associated with indirect exposure to combustor emissions. B[a]P was chosen as a representative carcinogenic constituent of these emissions. Indirect sources included intake from soil, the terrestrial food chain, dust resuspension, drinking water and fish. The U.S. EPA determined risk on a modeling scenario involving an individual (child, then adult) who spends 30 years within 5 kilometers of a combustion site that has been in operation for 60 years and consumes food grown within that 5-kilometer radius.

The U.S. EPA calculated risk levels for each of the exposure pathways and found that exposure through the terrestrial food chain constituted the only significant source of intake. For children and adults combined, the EPA calculated an excess risk of 5.93×10^{-5} based on the total daily B[a]P intake, a measure of absorption efficiency and the human oral cancer potency factor.[1] An uncertainty analysis for human soil ingestion and terrestrial food intakes indicated that the estimated daily B[a]P intake was probably within two orders of magnitude of the true intake.

CONCLUSIONS

Table 2 is a rating system for the various factors that impact the quantitative risk assessment for complex mixtures of PAHs. The number of check marks accompanying each factor defines the extent to which additional field, laboratory and/or literature research can refine and improve health-based risk estimates. The following descriptions accompany each rating.

Table 2
Authors' Ranking of Research Needs for Reducing Uncertainty in Quantitative Health Risk Assessment of Complex Mixtures

Research Needs	Relative Importance
Validity of the Relative Potency Approach	//
Relevance of the Experimental Model	//
Relevance of the Low-Dose Extrapolation Procedure	/
Physicochemical Factors	////
Interspecies Extrapolation	///
Effects of Other Mixture Components	/////
Exposure Assessment	////

Validity of the Relative Potency Approach

The data in Table 1 suggest that the relative potency approach is a useful tool for assessing risk of mixtures of similar hazardous substances and provides a reasonable alternative to the surrogate approach. Furthermore, preliminary evidence substantiates the possibility of dose additivity at low exposure levels. The conditions that distinguish "mechanistically similar" substances need clarification. In general, results from studies with differences in experimental design and carcinogenic end-points support the validity of the relative potency concept for PAHs. Based on these studies, a unit risk factor for groups of high molecular weight PAHs can be calculated and, after modification by the factors described below, can be incorporated into the exposure assessment.

Relevance of the Experimental Model

Both the mouse skin complete carcinogen assay and the newborn mouse models appear to be adequate predictors of the oncogenic potential of PAHs and should be used for additional comparative studies. The relevance of the oral route of exposure to human risk assessment needs to be carefully re-assessed, and, if necessary, a new unit risk factor needs to be derived.

Relevance of the Low-Dose Extrapolation Procedure

Because of uncertainties regarding the carcinogenic process, the use of a conservative extrapolation model is recommended. Although both the linearized multistage model and the restricted two-stage model provide an adequate fit of tumor incidence data in the observable dose range, the latter appears to be more consistent with the biological mechanism of action.

Physico-Chemical Factors

The physical properties and physico-chemical form of the mixture components have a great impact on quantitative risk estimation. Nevertheless, these factors are consistently overlooked in most risk characterizations. A more systematic effort to correlate these factors with toxicological findings is required. Risk estimates from similar mixtures with different physical properties can vary by several orders of magnitude.

Interspecies Extrapolation

Metabolic and physiological processes are similar across mammalian species. Nevertheless, numerous idiosyncracies in biotransformation and repair rates exist. Extensive analysis of these idiosyncracies in both experimental humans and animals is unfeasible. A general formula based on the body weight ratio has received some empirical support and is recommended for complex PAH mixtures. In addition, further study of the factors that influence base line PAH levels in humans may help reduce the uncertainty of the extrapolation procedure.

Effects of Other Mixture Components

The available data indicate that the noncarcinogenic components in the mixture have a profound effect on the expression of tumorigenicity. The interactive effects of low molecular weight PAHs can be studied through structure-activity relationships. A thorough literature review

should be conducted to assess specific solvent effects on dermal absorption. Modifying factors based on the physical composition of mixtures should be incorporated into the risk assessment.

Exposure Assessment

Exposure assessments should be customized for individual sites. Because extensive surveying of regional populations is not cost-effective, the best approximations of exposure parameters from recent data compilations (such as the FDA's NHANES reports) should be used. Whenever possible, actual data from these reports, rather than results of modeling studies,[35] are preferable.

The average human daily intake of the high molecular weight PAH fraction of the mixture should be estimated based on environmental concentrations and appropriate exposure parameters. The total intake of these PAHs can be converted to toxicologically equivalent units of B[a]P and multiplied by a unit risk factor adjusted for interspecies extrapolation, physico-chemical considerations and the interactive effects of other mixture components. The final result is an estimate of the human carcinogenic risk attributable to the high molecular weight PAH component of the mixture.

Application of the Expanded Health Assessment: The Massachusetts Experience

Suzanne K. Condon

Division of Environmental Health Assessment
Massachusetts Department of Public Health
Boston, Massachusetts

Gregory Ulirsch
Agency for Toxic Substances and Disease Registry
Atlanta, Georgia

ABSTRACT

In 1986 SARA was passed calling for a variety of environmental in-itiatives, among them health assessments at each of the NPL sites in the United States. The Agency for Toxic Substances and Disease Registry (ATSDR) developed a methodology for these health assessments (HA) and in 1987 requested proposals from state health departments wishing to enter into cooperative agreements to perform HAs.

The Commonwealth of Massachusetts responded to this request by proposing the use of a methodology Department of Public Health uses in its community health investigations. This methodology involves the evaluation of actual community health outcomes. The rationale for this approach is that if we are to suggest a variety of health outcomes which may be expected with the types of exposures a community has suffered, we should see if easily retrievable information may exist which would indicate the health outcomes that are being observed in an affected com-munity. By including such information, it would then be possible to discuss the plausibility of an association between environmental exposures and health outcomes that may be of concern to the community. This has proven to be an effective approach to community-specific health assessments in Massachusetts. ATSDR is currently developing a methodology for including health outcome data in an expanded health assessment.

Besides this additional health analysis section, considerable effort and emphasis is placed upon public education as well as cancer and environmental awareness campaigns. These types of activities aid the affected community in better understanding the work that is done, in addition to fostering communication and building trust and credibility in the health assessments. This approach has been the most effective and efficient procedure for addressing all environmental and health con-cerns posed by an NPL site. An actual case study of a Massachusetts NPL site will be presented.

INTRODUCTION

It is no secret that for a long time environmental epidemiologists and toxicologists did not have the closest working relationship. It was dif-ficult for either group to understand where the other was coming from in terms of the best methods for assessing health outcomes in relation to environmental exposures.

The toxicologists seemed to resent the "Texas sharpshooter approach" that the environmental epidemiologists took when they first identified a "cluster of disease" and then looked for a nearby environmental culprit upon which to blame the occurrence. At the same time, epidemiologists were never pleased with the fact that toxicologists often suggested that the health outcomes of interest for a particular exposure were not those that were easily measured, if measured at all.

As a result, the community often has been left in a state of confu-sion. This confusion usually has led to mistrust and/or credibility problems when environmental investigations are completed but ques-tions remain. These problems are not always easy for state environmental health officials to deal with. It is important to stress, however, that the people left with even greater problems are usually the local officials and the community. This type of situation does not occur often, but it is important to provide an example of this type of problem in order to clarify why the expanded health assessment can solve some of these problems. In order to do this, we will take an actual case study of a recent environmental health assessment in Massachusetts.

As part of a community investigation, several individuals living in close proximity to each other were diagnosed with the same primary site of cancer. Some of the exposures that might have occurred given the industry that formerly occupied this site were suggested to be associated with the cancer of interest. Naturally the community and state environmental health officials were concerned, so a more in-depth investigation began. This involved looking closely at the environmen-tal contamination present and taking into consideration environmental fate and transport of the chemicals involved. Unfortunately, the answers to all of the questions were not readily available and the local health official felt pressured to find quick answers to complex questions. He therefore began to try to find a possible explanation for each individual that had been diagnosed with cancer (e.g., smoking status) as opposed to waiting for more information regarding occupational exposures, routes of environmental exposures, etc.

As a result of these types of problems, the Massachusetts Depart-ment of Public Health established the Community Assessment Unit two years ago. This unit is housed within the Division of Environmental Health Assessment. The Division itself is set up in the form of a triage system (Fig. 1) with the community assessment unit logging in more that two dozen requests for environmental health information and assistance on a weekly basis. Questions often are answered over the telephone and do not require extensive followup. These calls warrant simple public health education regarding cancer and/or environmental awareness.

A large number of calls, however, require what we refer to as level I investigations. The level I investigation is always initiated with a com-munity meeting. The purpose of this meeting is two-fold. The first reason is to learn more about the community's concern(s). The second, and perhaps more important purpose, is to establish a working relation-ship and plan of action with both the concerned citizens and the local officials. The expanded level I investigation is what we consider the Massachusetts approach to the ATSDR health assessment.

METHODS

As can be seen, Figure 2 presents the series of steps involved in con-

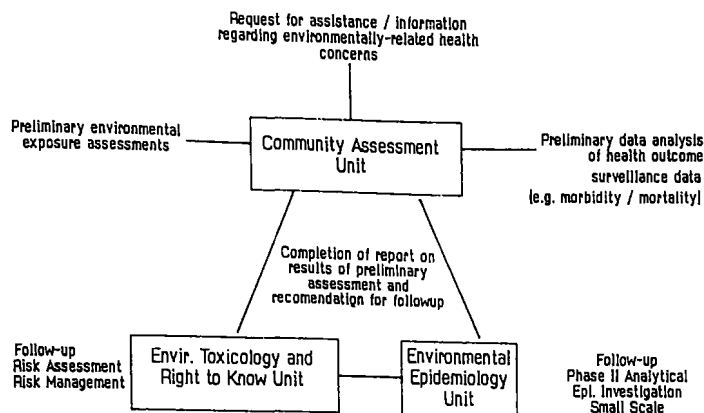
ducting the expanded health assessment. The first step in the health assessment process involves receipt of existing data from the U.S. EPA. Oftentimes, Agency for Toxic Substance and Disease Registry (ATSDR) regional staff have assisted and been extremely helpful in the transfer of these data packages.


Figure 1
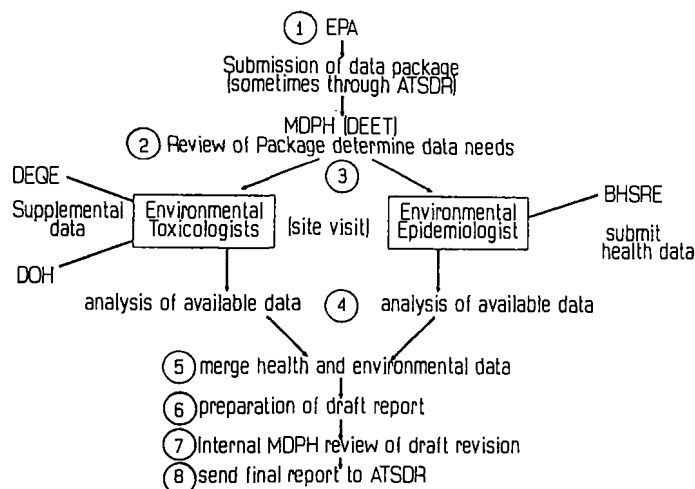
Division of Environmental Health Assessment


Figure 2
Department of Public Health Responsibilities

Step 2 involves the preliminary review of the data package to adequately determine additional data needs. At this point in the process (Step 3), the epidemiologists and toxicologists meet to determine individual supplemental data needs such as information available from the State Department of Environmental Protection and local water departments.

The toxicologists define health outcomes of interest and the epidemiologic research staff begin to collect appropriate health outcome data. As part of this step, the staff assigned to a site also perform a site visit. They are accompanied by ATSDR regional staff and the U.S. EPA Regional Project Manager (RPM) for the site as well as the local health officials and a citizen representative should there be a person so designated.

At this point, a public meeting with the community also is held to determine any special concerns that the residents may have. This is the final step in the information/data gathering process and the analysis of health and environmental data begins.

When the analyses have been completed, the staff once again meet to merge the health and environmental data and draft one report for

internal review and then submission to the ATSDR Technical Project Officer and the U.S. EPA and Massachusetts Department of Environmental Protection (DEP) officials. Soon after, a community meeting is scheduled to present an overview of the public health implications and to officially solicit comments.

We believe that this is the best possible approach we can take to provide a final document that is both scientifically sound and accepted by the affected community. The actual application of these methods at an NPL site in MA will be discussed here.

APPLICATION OF ASSESSMENT METHODS

The site of interest was the home of a chemical mixing company. The company began operating in the early 1900s and operated until 1982, during which time it produced formulations of disinfections, soap, floor wax and pesticides.

Basically, chemicals were mixed in large vats. Waste disposal consisted of direct discharge of wastewater into nearby wetlands and brooks, cesspools, sumps, and unlined lagoons. The company closed in the early 1980s when forced out of business by the local board of selectmen and was then placed on the U.S. EPA'S proposed NPL list.

Contaminant monitoring has been extensive at the site. A total of 102 chemicals have been detected on-site, including numerous pesticides (e.g., chlordane, DDT, dieldrin), the herbicides 2,4-D and 2,3,5-T, the dioxin 2,3,7,8-TCDD, arsenic, and creosote. Extensive contamination is present in the site's soils, groundwater, wetlands and sediments.

After initial review of the data was completed, a site visit was scheduled. The site visit included both an afternoon trip to the site and an evening community meeting. At the evening meeting, a great deal more was learned concerning the nature and extent of public contact with the site.

The site visit is an important phase of the expanded health assessment approach. It is here that we gain significant insight into the nature and extent of public contact with the site. What we learn about are the community concerns regarding pathways for exposure and potential health implications. In this example, the citizens were particularly concerned about drinking water quality.

We decided that it would be prudent to meet with representatives from the local water departments to learn more about several issues. Most important were where drinking water was distributed in the two affected communities and what part of the population was consuming it.

We learned that operation of a municipal wellfield resulted in the induced infiltration and capture of contaminated groundwater by the wells. The wells operated from 1958 until 1982 when closed because of contamination. As early as 1959, phenols were detected in one of the wells and strong evidence of 2,4-D also was documented. These wells were one of only three sources of drinking water for the two Massachusetts communities. A nearby river also was contaminated by the site. Water from the river was diverted to a reservoir which was used as a supplemental source of water for the towns. Several interim remedial measures have been conducted to contain the hazardous waste condition. At present, remediation is in the design and test stage.

The contaminants of interest and potential health outcomes of interest are presented in Table 1. Among the diseases caused by the contaminants that have been identified, the health outcomes of greatest interest included non-Hodgkins lymphoma (NHL) and soft tissue sarcoma (STS). It is important to stress that we have established, to the extent possible, that 2,4-D was highly likely to have been present in two particular municipal drinking water wells.

After establishing the likelihood of human exposure and the health outcomes of particular interest, the next phase of the expanded health assessment is initiated.

In this phase, we review existing health outcome data bases for information on the outcomes of interest. This is to establish if there is existing evidence for unusual occurrences of the health outcomes.

We reviewed the overall distribution and standardized incidence rates (SIR) for both diseases of concern in the two affected communities. The overall rates of NHL and STS are 22 observed and 13.4 expected with an SIR of 165 for NHL, and 3 observed and 2.7 expected with an SIR of 113 for soft-tissues sarcoma. As we look more closely at these

outcomes, NHL appears to suggest the strongest potential association.

The geographic distributions of NHL cases for the areas that were likely to have received the greatest amount of 2,4-D contaminated drinking water are presented in Figure 3. As can be seen, the majority of cases appear visually to be concentrated in census tracts 4211 and 4203. The incidence rates for NHL in these areas of greatest potential impact are 5/3.2 = 156 and 17/10.2 = 167, respectively.

What we have gathered here is some very interesting information that may suggest a potential association between historical, but fairly recent, environmental exposures and adverse health outcomes in these two communities. It is important to note that while the evidence that may link these two events is rather circumstantial, it does provide us with a more stable base for appropriate public health intervention and follow up actions.

CONCLUSION

Through the expanded health assessment approach, we believe that the communities feel the health assessments are more of a collaborative effort. We can then be responsive to community concerns that local government officials, for example, need to address on a daily basis.

It has been our experience that by using this approach we develop a document which best describes the environmental public health picture of communities affected by NPL sites. Perhaps more importantly, the document represents a document that is accepted by everyone concerned.

We feel that the expanded approach permits us to make more informed conclusions and recommendations regarding the mitigation or preven-

tion of adverse health outcomes from potential exposure to the site's contaminants.

Risk-Based Cleanup Levels For Soil

Kevin H. Reinert, Ph.D.
SMC Environmental Services Group
Valley Forge, Pennsylvania

ABSTRACT

Soils contaminated with barium, copper and lead were found as a result of a two-phased remedial investigation at a metal refinery in the southeastern United States. Contaminated soils were detected both on the site and off-site. Levels of contamination ranged from 10 - 25,000 mg/kg barium, from 10 - ~200,000 mg/kg copper and from < 10 - ~5,000 mg/kg lead. For most samples, high concentrations of both lead and barium were associated with high copper levels, although lead was detected less frequently than either of the other two metals. All three metals were found on the site primarily in their elemental, nonionic forms - relatively insoluble in water, even when acidified. EP Toxicity testing of these soils produced data containing less than 1% of the bulk concentrations of barium, copper and lead.

A background level of 100 mg/kg copper was established as an interim background goal for remediation purposes; however, cleanup to this level would have required removal of soils from the majority of the site and properties adjacent to the site and would have been extremely costly. As an alternative to cleaning up to background, a determination of a risk-based cleanup level was undertaken. This cleanup level was based on the concentration of copper that would be considered a human health problem.

A risk-based cleanup level was derived using the *Risk Assessment Guidance for Superfund*.[2] For copper, this cleanup level was found to be 1,850 mg/kg. However, since only minor amounts of this metal were considered bioavailable or absorbable (ionic), even this risk-based level was believed to be too restrictive and further refinement of the concentration was made. Using a conservative, literature-based bioavailable fraction of 0.1 (10%) for elemental copper, a risk-derived cleanup level of 18,500 mg/kg copper was developed. This level was ten times higher than the value developed using 100% bioavailability and was 200 times greater than assumed background levels, but still was considered protective of human health. With this revised risk-based cleanup level, the total volume requiring removal was reduced from 4,500 yd^3 to 1,000 yd^3 and the estimated cost of soil remediation was reduced by approximately $370,000.

Results from this study support the use of risk assessment as a mechanism for achieving a balance between the cost of remediation and the potential or actual risks present at a particular site.

INTRODUCTION

Risk assessment is a scientific tool used in many areas of environmental investigation. Risk assessment is used to characterize the probability of harm to public health, public welfare and the environment from potential or actual releases of hazardous substances. Risk assessment generally consists of four steps:

- Hazard Identification   Identification of indicator substances or chemicals
- Exposure Assessment - Identification of actual or potential routes of exposure, characterization of exposed populations including environmental populations and estimation of exposure levels or doses
- Toxicity Assessment - Determination of the nature and extent of potential effects from exposure to hazardous substances
- Risk Characterization - Determination of the probability or likelihood of adverse affects on human health, welfare and the environment

The process of completing a risk assessment involves the use of technical and scientific data applied using informed professional judgment. In many situations, a risk assessment must be completed when adequate scientific data are lacking. Appropriate, scientifically valid assumptions must then be made to evaluate a particular risk scenario. Choice of appropriate assumptions, such as the amount of soil ingested per day, weight of an individual or percent absorption of a particular substance, can lead to wide variations in the final risk ranges developed during the risk assessment.

The importance of understanding the assumptions used in risk assessment and the influence that these assumptions have on the final risk levels is supported by the following case study of a state Superfund site. The site, a metal refining facility, is located in the southeastern United States. Soils and sediments on and surrounding the site are contaminated with copper, barium and lead. Two manuals, *Superfund Exposure Assessment Guidance*[1] and *Superfund Risk Assessment Guidance for Human Health Evaluation*[2] were used to complete a risk assessment for soil primarily contaminated with copper. This risk assessment was used to develop risk-based cleanup levels which were considered site specific. These cleanup levels were then used to derive the areas of the site and calculate volumes of soil/sediment possibly requiring remediation.

METHODOLOGY

Soil Investigation

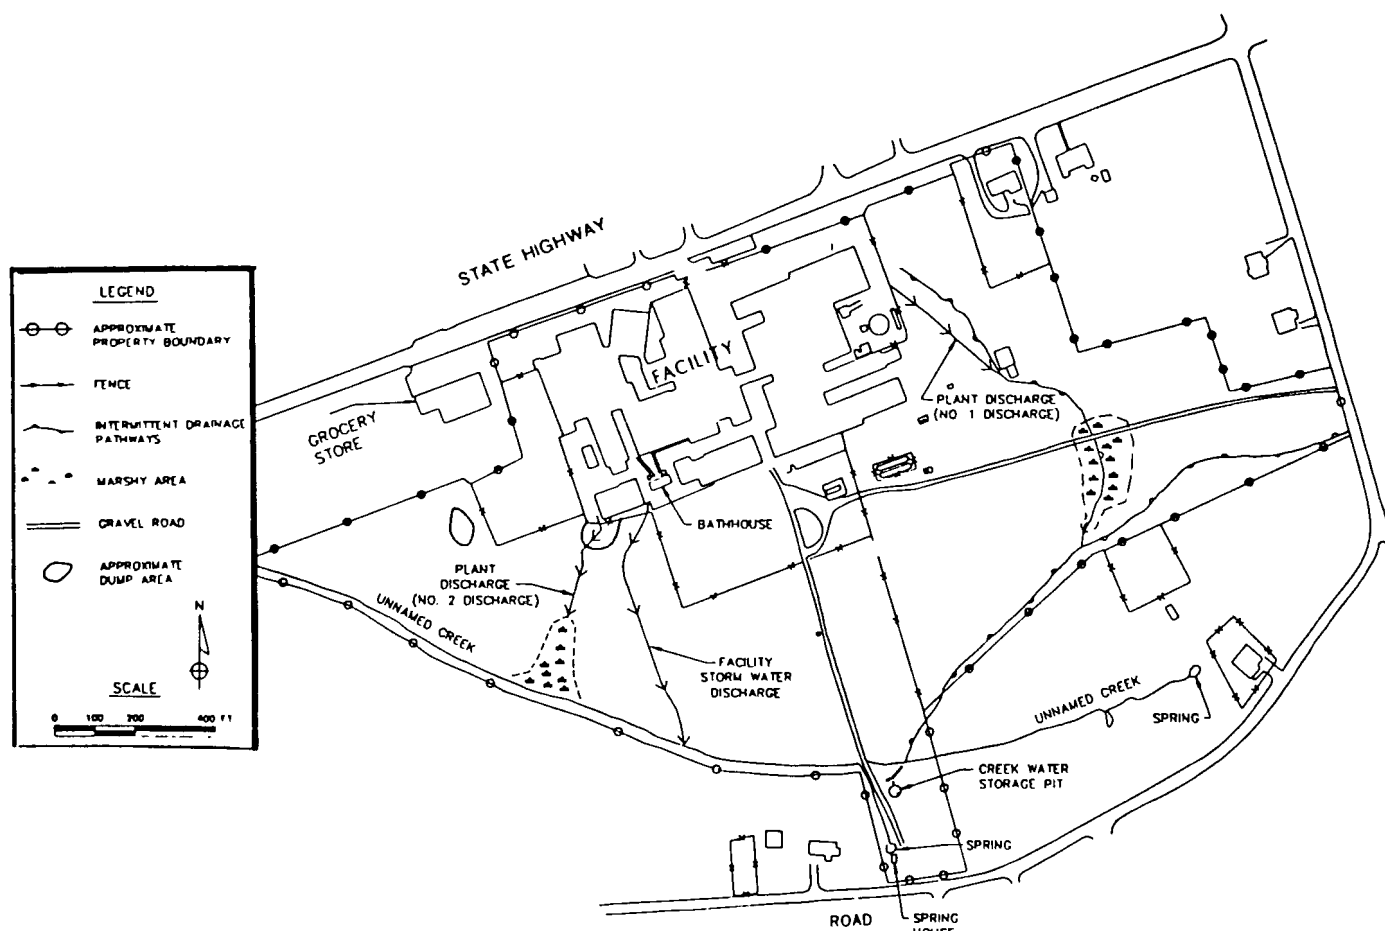
A total of 201 surface soil samples were collected at the site (Fig. 1). Additionally, 24 composite soil samples, representative of conditions 0.5 to 1.5 feet below ground surface, were collected across the site. Each soil sample was analyzed for barium, copper and lead. Two off-site locations were collected to establish background soil quality conditions. Background level for copper in the soils appeared to be approximately 100 mg/kg. Copper was used as an indicator metal because elevated barium or lead levels (above background levels) were normally associated with levels of copper which were an order of magnitude higher than either the barium or lead. Additionally, due to


Figure 1
Site Location Map Displaying
Present Plant Discharge

its widespread presence on the site, it appeared that copper would drive the remedial effort.

An isoconcentration contour map for copper in on-site soils is shown in Figure 2 and is representative of soil conditions from 0 to 0.5 feet below ground surface. Barium and lead levels across the site were found generally at concentrations at less than 100 mg/kg, similar to background levels. At the locations where barium and lead levels exceeded background, copper levels of similar or higher magnitude also were encountered. Figure 2 reveals two areas labeled Areas A and B which are defined by the 1000 mg/kg isoconcentration contour line and two other areas labeled C and D which are defined by the 100 mg/kg isoconcentration line. Within Areas A and B, copper levels generally ranged between 2000 and 3000 mg/kg and five smaller areas within Area A display copper levels greater than 10,000 mg/kg. Only one sample within Area B exhibited a copper level greater than 10,000 mg/kg. Except for five sample locations which lie outside these areas, all other on-site areas displayed copper levels below 500 mg/kg. The background level for copper, 100 mg/kg as defined by the two background samples, was exceeded at a majority of the sample locations. Within Areas C and D, however, all copper levels were equivalent to or below background.

Although a few off-site samples displayed copper levels above background, all the levels were within 100 mg/kg of background and all were within 200 feet of the facility's southern property boundary. Off-site samples collected farther from these locations were equivalent to or below background for copper. Composite soil samples collected from across the site from soils at 0.5 to 1.5 feet below ground surface all had substantially lower copper levels than the levels found in surface soil samples. Based on the composite sample results, it appeared that the elevated copper levels were restricted to a depth of no more than

0.5 feet below ground surface.

Development of Cleanup Levels

Quality criteria, target concentrations or cleanup levels have not been established by the U.S. EPA or the state in question for copper in soils. In the absence of these criteria, we developed risk assessment-based quality criteria levels for copper. These preliminary quality criteria were based on exposure scenarios obtained from the U.S. EPA *Superfund Exposure Assessment Manual*[1] and oral reference doses (RFD$_o$) from the U.S. EPA *Superfund Public Health Evaluation Manual*[3] and the *Integrated Risk Information System*[4] Only oral ingestion was addressed directly using the following assumptions and exposure scenarios:

- Soil is 100% contaminated at the analyzed levels
- The copper is in a nonelemental, water-soluble form
- 100% absorption of the metal by the gastrointestinal tract

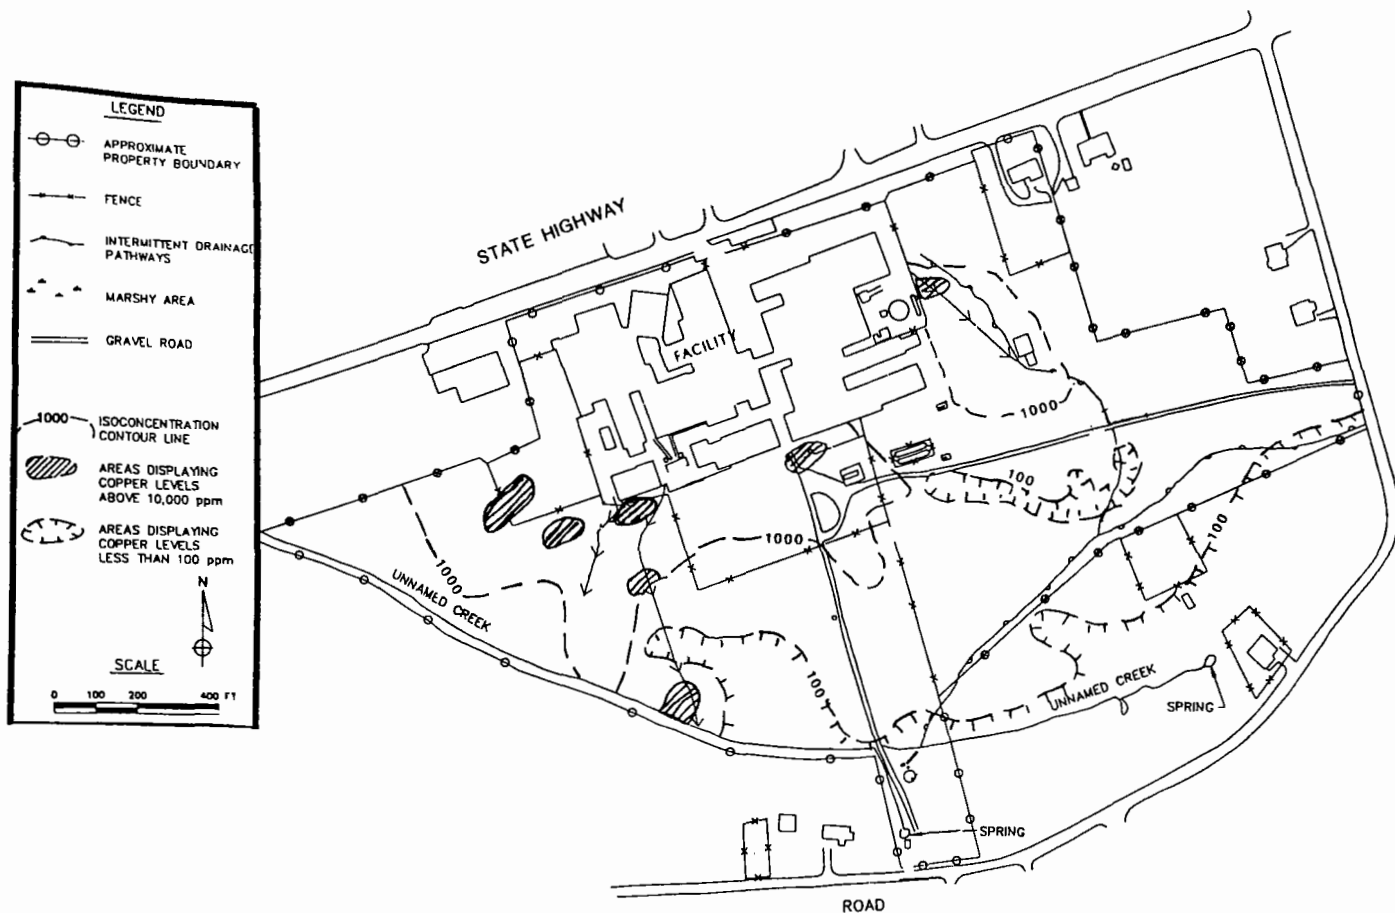
Target soil concentrations were calculated using three exposure scenarios with varying amounts of soil ingested and human weight corresponding to age and years. Target soil concentration for copper was calculated corresponding to an intake level equal to the oral RFD. Depending on a particular exposure scenario, the target soil concentration ranged from 1,850 to 259,000 mg/kg (Table 1). These initial assessment efforts assumed that copper was in an ionic form and that the human gastrointestinal tract (GI) will absorb 100 percent of the ingested copper. However, the copper found at the site was in its elemental form. An intensive literature review suggested that a significantly lower percentage (10 percent) of elemental copper would be absorbed by the GI tract as compared to the 100 percent assumed for ionic copper.[3]


Figure 2
Isoconcentration Contour Map for
Copper in On-site Soils

Table 1
Development of Soil Cleanup Levels for Copper

Exposure Scenario	Amount Soil Ingested (mg/d)	Weight (Kg)	Age (Yr)	Absorption Factor	Maximum Daily Dose (mg/kg/d [c])	Cleanup Soil Level (mg/kg)
A	200	10	1.5-3.5	1.0	2×10^{-5} [c]	1,850
B	10	17	5	1.0	5.9×10^{-7} [c]	62,900
C	10	70	18+	1.0	1.4×10^{-7} [c]	259,000
D	200	10	1.5-3.5	0.1	2×10^{-6} [c]	18,500

Maximum daily dose is the amount of contaminated soil [c] in mg/kg that may be ingested on a daily basis without exceeding the RfD (acceptable intake for chronic exposure, AIC).

Copper as an Essential Element

Copper is considered an essential trace element in plant and animal metabolism at low levels.[5] It is involved in oxidative enzyme systems, such as ascorbate oxidase, amine oxidase, tyrosinase and cytochrome C oxidase, as an integral part of an enzyme or cofactor.[5,6] Some mollusks and arthropods use a copper-protein pigment, hemocyanin, to transport oxygen to tissues in plasma.[7] Plant chloroplasts contain a blue copper-protein, plastocyanin,[6] that functions as an integral enzyme in photophosphorylation.[8] Copper deficiencies are considered rare in plants and result in chlorosis (bleaching) and reduction in

carotenoid pigments.

The recommended daily allowance (RDA) for the adult diet ranges from 2.0 to 3.0 mg/day.[9] The RDA varies from 0.5 to 2.5 mg/day for children under the age of 11 years. Despite wide differences in dietary intake of Cu, proper Cu balance is maintained in most individuals.[10]

Copper Absorption

Bioavailability or uptake potential of metals is a function of particle size and volume, membrane solubility and complexation state.[11] Copper, as well as other mineral nutrients, usually is absorbed in the

ionic form by plants and animals.[7] The biologically active form of Cu is ionic, the Cu^{2+} valence state. Copper is commonly found in human foods; the concentration of copper in food normally reflects the copper levels of the soil or water in which the copper originated.[12] The amount of Cu absorbed from the diet is a function of body needs.[12] Cu is primarily absorbed in the stomach due to low pH and in the upper portions of the small intestine via active transport.[5,13,14]

Estimated levels of ionic Cu absorption from dietary intake range from <1 percent[5] to 36 percent.[14,15] However, based upon Underwood[12] and Vanderveen,[16] 10 percent is considered the upper boundary for the absorption of elemental Cu in the diet.

Development of Cleanup Levels for Elemental Copper

Using a maximum of 10 percent absorption of elemental copper in the human GI tract, a health-based risk level of 18,500 mg Cu/kg was developed (Table 1). This level is considered protective of human health for the conditions found at the site (i.e., presence of elemental copper). The development of this level utilized oral exposure scenarios obtained from the U.S. EPA Superfund Exposure Assessment Manual[1] and Acceptable Chronic Intake Level (AIC) of 3.7×10^{-2} mg/kg/d from the U.S. EPA.[3] This AIC corresponds closely to the U.S. Department of Agriculture (USDA) recommended daily allowance (RDA) of 2.9×10^{-2} mg/kg/d and the level of 4.3×10^{-2} mg/kg/d found in several over-the-counter dietary supplements (e.g., Parke-Davis). AIC values have been replaced in current U.S. EPA guidance[1] by RFDs. IRIS[4] currently does not list an oral RFD for copper; however, at the time this work was completed, the value found in the U.S. EPA's Superfund Public Health Evaluation Manual[3] was considered valid.

DISCUSSION

The assumption used to develop risk-based cleanup levels or target levels which ultimately will be used for remedial decisions need to be reasonable and scientifically justified. Assumption of 100% absorption of elemental copper is considered unrealistic. According to Risk Assessment Guidance for Superfund,[1] exposure levels may be adjusted for differences in media since the affects levels (RFD) are based on intake through water. The intake may be adjusted accordingly based on the bioavailability or absorption of the compound or element from the environmental matrix in question. Low bioavailability of elemental copper in soils at this site is further supported by the results of the Extraction Procedure (EP) toxicity test performed during the overall site investigation where less than 1 percent of the Cu leached from the soils tested. The extraction associated with the EP toxicity test is performed with an acid that has a similar pH to the acid found in the human stomach.

Table 2 describes the areas, volumes and cost of disposal for the soil for each of the derived target levels. Using a conservative literature-based bioavailable fraction of 10% for elemental copper, a risk-derived cleanup level of 18,500 mg/kg was developed. This level was 10 times higher than the target level developed using 100% bioavailability and was approximately 200 times greater than the assumed background levels. However, this level was still considered protective of human health based on the elemental nature of copper found on the site. Using this revised risk-based cleanup level, the total volume of contaminated soil requiring removal was reduced from 4,500 yd³ to 1,000 yd³, and the estimated cost of soil remediation was reduced by $370,000.

Table 2
Cost Analysis for Soil Remediation

Approach	To Copper Level (mg/kg)	Volume (cubic yards)	Costs ($)
Excavation and Off-Site Disposal	100 or less	15,500	2,100,000
Excavation and Off-Site Disposal	2,000 or less	4,500	475,000
Excavation and Off-Site Disposal	20,000 or less	1,000	105,000

CONCLUSIONS

Results from this study support the use of risk assessment as a mechanism for achieving a balance between the cost of remediation and the potential or actual risks present at a particular site. The utilization of realistic and scientifically valid assumptions produces realistic cleanup levels which can potentially reduce remediation costs and at the same time reduce the environmental disturbance during remediation.

Bayesian Data Analysis Procedure for Contaminant Transport Studies

Kuantsai Lee, B.Sc., D.Phil., C.Eng.
Wen L. Lee, B.Sc., M.Sc., Ph.D.
Golder Associates Inc.
Atlanta, Georgia

ABSTRACT

This paper describes a Bayesian data analysis procedure for groundwater contaminant transport studies at Superfund sites. The Bayesian procedure starts with a prior probability distribution of a model parameter as determined from literature search, expert judgement or previous applications of the Bayesian procedure. Next, the procedure uses the data collected during the Remedial Investigation to boost those parts of the prior distribution that are consistent with the data and suppress those that are not. The result is a posterior probability distribution that can be used in a statistical simulation, such as the Monte Carlo method, to assess the likelihood and the magnitude of future contamination. The potential applications of the Bayesian data analysis procedure are demonstrated in four examples in this paper.

UNCERTAINTIES IN GROUNDWATER CONTAMINANT TRANSPORT STUDIES

Uncertainty permeates every aspect of groundwater contaminant transport studies for Superfund sites: (1) the transport mechanisms are poorly understood at most sites, (2) the timing, intensity and location of past spills or leakage are rarely known, (3) and a reliable inventory of the hazardous materials contained within a particular site seldom exists. Recognizing these uncertainties, the current U.S. EPA guideline for exposure assessment[1] allows the use of either site-specific measured or modelled contaminant concentration values. When using contaminant transport models, the U.S. EPA guideline encourages model calibration using monitoring well data; but there is no guideline on how close the model should be calibrated to match the data. When using measured values, the guideline further allows the risk assessor to assume that the measured concentration remains constant over the period concerned (currently 75 years for carcinogenic effects). Considering all the potential uncertainties in an exposure assessment, the methods in the U.S. EPA guideline may appear conservative, but do they always produce conservative results?

The potential discrepancy between the assessed exposure using measured data following the U.S. EPA guideline and the actual exposure may be illustrated by the two hypothetical examples shown in Figure 1. This figure shows a hypothetical site containing a series of injection wells in active use over a 15-year period from 1970 to 1985. The contaminant concentration in the groundwater was monitored by three monitoring wells adjacent to an exposure point A (Fig. 1). By assuming that the series of injection wells can be replaced by an equivalent line source and that groundwater flows in a direction perpendicular to the line defined by the injection wells, a simple two-dimensional model was adopted for the contaminant transport study.[2] The difference between the two hypothetical examples lies in the seepage velocity used in the calculation.
CASES	DETECTED CHEMICAL CONCENTRATION(PPB)					
	WELL No. 1		WELL No. 2		WELL No. 3	
	1985	1990	1985	1990	1985	1990
EXAMPLE 1	100	NA	68	NA	79	NA
EXAMPLE 2	27	NA	98	NA	82	NA
EXAMPLE 3	100	100	68	109	79	102

NA: NOT ANALYZED

CASES	HYDROGEOLOGICAL PARAMETERS		
	SEEPAGE VELOCITY (FT/DAY)	LONGITUDINAL DISPERSIVITY (FT)	SOURCE CONCENTRATION (PPB)
EXAMPLE 1	0.5	5	110
EXAMPLE 2	0.1	1	230
EXAMPLE 3	0.5	5	110

Figure 1
Hypothetical Site

The first example used a relatively fast seepage velocity of 0.5 ft/day. Using this velocity value, the calculated contaminant concentration at the exposure point is shown in the Case 1 curve in Figure 2. The area under this curve corresponds to the exposure concentration (defined as the total concentration available for intake at the exposure point) for a 75-year period from 1990. This is much less than the exposure concentration calculated by multiplying the measured concentration in the last sampling event over 75 years in accordance with the U.S. EPA guideline. In other words, the U.S. EPA guideline could overestimate the exposure concentration in this example.

This is not so, however, with the second example where a slow seepage velocity of 0.1 ft/day was used. As is also shown in Figure 2, the U.S. EPA guideline, when based on measurements made while the contaminant concentration at the monitoring wells is still rising, could underestimate the exposure concentration. Is there, then, a procedure that copes better with the uncertainties than those in the U.S. EPA guideline?
CASE 1: SEEPAGE VELOCITY 0.5 FT/DAY
CASE 2: SEEPAGE VELOCITY 0.1 FT/DAY

Figure 2
Theoretical Exposure Concentration

QUANTIFYING UNCERTAINTY

The problem discussed above is not unique to contaminant transport studies. Many other closer-to-life problems also face uncertainty and involve risk. Some examples are the seismic risk of nuclear power plants[3] and the risk of failure of large dams.[4] Whether an elaborate model is used or not, a common need among these problems is to quantify the uncertainty of the outcome—in the present case, the exposure concentration. Contrary to the traditional attitude toward risk, which aims at the rarely attainable goal of eliminating the uncertainty, the main thrust of the modern approach in risk assessment is to first recognize the uncertainty and then make an attempt to quantify it. In the examples above, a risk assessor would be making strides in recognizing that the U.S. EPA guideline does not always produce conservative results.

A common way to quantify uncertainty is to use statistical simulation techniques such as the Monte Carlo method[5,6,7] or the discrete simulation method.[8,9] Before running a statistical simulation, however, the uncertainty in the models and parameters used in the simulation must first be quantified. Quantifying the uncertainty or-in more practical terms—assigning the probability distribution of the model parameters has traditionally been achieved using one of two approaches: using prior knowledge or taking measurements. Both approaches may be used in contaminant transport studies. For example, the likelihood of a contaminant originating from a source may be assessed using records of past operations as a clue. For another example, the seepage velocity may be determined from actual measurement of water level

and permeability. These two approaches should complement each other; the question is how. The Bayesian method, to be discussed in the following sections, may provide the answer.

BAYES' THEOREM AND ITS APPLICATIONS

While widely quoted in the literature of Bayesian Statistics,[10] there does not appear to be a single, universally-accepted form of Bayes' theorem. It appeared that the English mathematician, for whom the theorem is named, never actually wrote the theorem but instead expressed in words what is now known as Bayes' rule in conditional probability. Grandy[11] pointed out that Laplace, in 1714, appeared to be the first to formulate the equation that constitutes Bayes' theorem as it is known to the statisticians today; although the equation can be derived by generalizing Bayes' rule.

In spite of its ambiguous origin, all forms of Bayes' theorem deal with the following quantities:

- A prior probability
- A measurement whose outcome relates to, but may not reveal the parameter value of interest
- A likelihood
- A posterior probability

The likelihood is the (conditional) probability of observing the outcome of the measurement given the prior probability and the posterior probability is the probability that incorporates the outcome of the measurement in the prior probability. Given these four quantities, Bayes' theorem states, in essence, that the posterior probability is proportional to the product of the prior probability and the likelihood. In effect, the theorem boosts those values that are more likely to produce the observed outcome and suppresses those values that are not.

Bayes' theorem has been used in many scientific and engineering fields. Some examples are Radio Astronomy,[12] Geotechnical Engineering,[13,14,15] Hydrology[16] and Reservoir Engineering.[17] Diverse as these applications may appear, few of them can be applied to contaminant transport studies where the measurements (such as contaminant concentration measured in the monitoring wells) do not directly reveal the value of the unknown parameters (such as the location, timing and concentration of past releases). The method described in this paper was developed for this class of problems.

THE BAYESIAN DATA ANALYSIS PROCEDURE

The details of the Bayesian data analysis procedure have been published elsewhere.[18] Appendix A in this paper presents the calculation sequence of the data analysis procedure. For simple problems, the calculation can be conducted by hand following the sequence. For complicated problems, however, a computer will be needed to cope with the amount of computation involved. The calculation sequence depicted in Appendix A had been implemented in a computer program that can run on the IBM-PC microcomputer. This program was used to calculate the four examples presented below.

EXAMPLES IN CONTAMINANT TRANSPORT STUDIES

Four examples are used in this section to illustrate the potential application of the Bayesian data analysis procedure. First, the two examples discussed at the beginning of this paper are reanalyzed to demonstrate how the proposed data analysis procedure can improve the estimates of exposure concentration. These two examples are then followed by a third, hypothetical example that demonstrates how the procedure can be used to assist in decision-making during Remedial Investigation. The fourth example used data from a Superfund site to demonstrate the feasibility of applying the Bayesian procedure to practical problems.

All the examples presented below were calculated using a simple two-dimensional contaminant transport model with a published analytical solution.[2] The contaminant concentration in the monitoring wells in the hypothetical sites was first calculated from the analytical solution. Then, to provide a touch of reality, the calculated value was tainted with a random error of up to 20%. The contaminant concentrations so obtained are shown in the tables in Figure 1; these values were used

to calibrate the input parameters in the first three examples discussed below.

Example 1

The first example corresponds to the first case in the hypothetical site shown on Figure 1. In applying the Bayesian procedure to this case, it was assumed that the location, concentration and timing of the releases are known, as is the direction of seepage flow. The two remaining parameters required for contaminant transport modelling are the seepage velocity and the longitudinal dispersivity. The prior probability distributions of these two parameters are shown in Figure 3. The prior probability distributions and the contaminant concentrations in the monitoring wells were then combined by the Bayesian procedure to produce the posterior probability distributions shown on the same figure. The values of the seepage velocity and the longitudinal dispersivity that were used to make up this hypothetical example also are indicated in Figure 3. As this figure shows, the posterior probability distributions did indeed converge to the "correct" values.
Figure 3
Prior and Posterior Probability Distributions, Example 1

Figure 4 shows the probability distribution of the exposure concentration calculated from the posterior probability distributions of the seepage velocity and the longitudinal dispersivity. For comparison, the exposure concentration calculated by the method in the U.S. EPA guideline and the theoretical concentration (given the input values) also are indicated in this figure. In this example, it is seen that while the U.S. EPA guideline grossly overestimated the exposure concentration, the most probable exposure concentration calculated by the Bayesian procedure almost coincides with the theoretical value.
Figure 4
Probability Distribution of Exposure Concentration, Example 1

Example 2

This example corresponds to the second case in the hypothetical site shown on Figure 1. Going through the same steps as in the first example, Figure 5 shows the prior and posterior probability distributions of the seepage velocity and the longitudinal dispersivity and Figure 6 shows the probability distribution of the exposure concentration calculated from the posterior probability distributions. As in Figure 4, Figure 6 also shows the exposure concentration calculated by the method in the U.S. EPA guideline and the theoretical exposure given the input values. In this case, the Bayesian procedure has largely corrected the deficiency in the U.S. EPA guideline that resulted in underestimating the exposure concentration.

In Figures 4 and 6, it is seen that the Bayesian method would, in both cases, result in a more realistic assessment of the potential exposure than the method in the U.S. EPA guideline that uses the measured concentration. This is not the only benefit that the Bayesian procedure brings, as the ability to generate the probability distribution of the exposure concentration could lead to applications that were not possible before. One such application is to assist in decision-making in Remedial Investigation, as will be demonstrated in the example below.

Example 3

This example follows on the first example with the addition of one more round of sampling. The question to be asked is whether further rounds of sampling are warranted and, if so, how does the risk assessor or the remedial project manager decide when enough samples have been collected for the Feasibility Study?

To answer this question, the prior probability distributions of the seepage velocity and the longitudinal dispersivity are duplicated from Figure 3 to Figures 7 and 8, respectively. These figures also show the posterior probability distributions of these two parameters after incorporating the results of the first and the second rounds of sampling. If this were an actual site, then the risk assessor or the remedial project manager would examine the posterior probability distributions after each round of sampling. In examining the distributions, they would look for two possible outcomes. One, the residual uncertainty (as reflected by the spread of the distribution) has been narrowed to within acceptable limits. Two, the most recent sampling results produce little change in the posterior probability distributions, indicating that the sampling activity may be approaching the point of diminishing return. Either of these outcomes may signal the end of the current sampling activity. Alternatively, the risk assessor or the remedial project manager may examine the probability distributions of the exposure concentration (Fig. 9) and continue, terminate or modify field work as this probability distribution evolves through successive rounds of sampling.
Figure 5
Prior and Posterior Probability Distributions, Example 2
Figure 6
Probability Distribution of Exposure Concentration, Example 2

Example 4

All of the first three examples presented above have been concerned with a hypothetical, over-simplified site. In practice, real sites always contain a large number of uncertainties and the samples may not always exhibit a consistent pattern. The intention of this fourth example is to demonstrate that the Bayesian data analysis procedure applies equally as well to a real site as it does to a hypothetical site.

over a period of ten years or so when the landfill was in active operation, then the major uncertain parameters required for contaminant transport study are: seepage velocity, longitudinal dispersivity and concentration at release. Note that the Bayesian procedure can also be used to evaluate the probability of the closed landfill being the source; however, such discussion is beyond the scope of the present paper and will not be further considered.
Figure 9
Probability Distributions of Exposure Concentration, Example 3

The example concerns a closed landfill (Fig. 10) that was operated in the late 1960s and early 1970s. For demonstration purposes based on a review of the site history, the site hydrogeology and a chemical fingerprinting study, it is assumed that the closed landfill contributed the barium detected in the downgradient monitoring wells. Assuming that the release of barium from the landfill, had it occurred, took place

Figure 11 shows the prior probability distributions of the release concentration, the longitudinal dispersivity and the seepage velocity. The posterior probability distributions, after incorporating the results collected in eight monitoring wells, are shown on the same figure. Figure 12 shows the probability distribution of the exposure concentration (calculated over a 75 year period from 1990 to 2065) at exposure point A (Fig. 10). For comparison, this figure also shows the exposure concentration calculated by the method in the U.S. EPA guideline based on the results of the most recent sampling event. Note that, for this real case, the application of the Bayesian procedure has produced a most probable exposure concentration that is less than one half of that estimated by the U.S. EPA guideline.

It is seen in Figure 11 that all prior probabilities were assumed to follow a uniform distribution. This assumption reflects the analyst's limited site knowledge. In practice, the risk assessor, armed with a thorough knowledge of the site, is likely to develop more realistic prior

probability distributions than the simple uniform distribution used here. This calculational process would result in more focused posterior distributions than those shown in Figure 11 and would further improve the estimate of the exposure concentration.

CONCLUSIONS

A Bayesian data analysis procedure has been developed for contaminant transport studies. This procedure offers a rational method for combining the "soft" data (personal experience, interviews and literature search) and the "hard" data (sampling and field tests). The potential applications of the Bayesian procedure are demonstrated in four examples. These examples show that the Bayesian procedure produces better estimates of exposure concentration than the existing U.S. EPA guideline. This procedure will provide probabilistic contaminant transport studies for public health assessment in Superfund sites.

APPENDIX A

Calculation Sequence for Bayesian Procedure

Consider a problem involving M parameters and an observation z. The observation z may be a single measurement or a collection of

measurements. For the type of problem considered in this paper, $z=z(\mathbf{x})$, i.e., z depends on, but does not directly reveal the values of x^m. Furthermore, the prior probability distributions of the parameters x^m have all been specified as discrete probability distribution $(p_{i_m}{}^m, x_{i_m}{}^m)$.

The first step in assigning a discrete probability distribution to a parameter x^m is to identify all possible $x_{i_m}{}^m$ values of the parameter. For certain parameters with a limited number of choices, such as the source location, identifying all possible values is a trivial task. For certain other parameters, such as the seepage velocity, where the total number of possible values is - in theory - infinite, the choice often reflects a compromise between the accuracy required and the computing resources available.

Having identified all possible values, or having selected a few representative values that cover the range of interest, the next task is to assign a probability $p_{i_m}{}^m$ to each of the values. This is the probability that the parameter x^m will have the value $x_{i_m}{}^m$, or using standard notation in probability theory, $Pr(x^m = x_{i_m}{}^m)$. Such probability may be based on actual measurements (by the frequency of occurrence) or from past experience, interviews, and professional judgement. For each parameter, the corresponding probabilities must add up to one:

$$\sum_{i_m} p_{i_m}^m = 1 \tag{1}$$

The proposed procedure considers one parameter x^m at a time. For each x^m, the calculation proceeds by first calculating the likelihood function $p(z \mid x_{i_m}{}^m)$ for each discrete value $x_{i_m}{}^m$, i.e., the conditional probability of observing z given $x^m = x_{i_m}{}^m$. Having calculated the likelihood functions for each of the discrete values of x^m, the posterior probability $\overline{p}_{i_m}{}^m$ can then be calculated using Bayes' theorem in the following form:

$$\overline{p}_{i_m}^m = \frac{p_{i_m}^m \, p(z \mid x_{i_m}^m)}{\sum_{j=1}^{n_m} p_j^m \, p(z \mid x_j^m)} \tag{2}$$

The procedure described above may be summarized in seven calculation steps:

Step 1   Select a parameter x^m.

Step 2   Select a discrete value $x_{i_m}{}^m$ from the discrete probability distribution of this parameter.

Step 3   Calculate the discrete probability distribution $(r_{i_1 \ldots i_m}, z_{i_1 \ldots i_m})$ of the observation z given $x^m = x_{i_m}{}^m$:

$$r_{i_1 \ldots i_N} = p_{i_m}^m \prod_{n=1}^{M} p_{i_n}^n \qquad n \neq m \tag{3}$$

$$z_{i_1 \ldots i_N} = z(x_{i_1}^1, \ldots, x_{i_m}^m, \ldots, x_{i_N}^M) \tag{4}$$

where $z_{i_1 \ldots i_m}$ are the collection of discrete values of z when $x^m = x_{i_m}{}^m$ and $r_{i_1 \ldots i_m}$ are the corresponding probabilities.

Step 4   Calculate the likelihood function $p(z \mid x_{i_m}{}^m)$ by summing the probabilities $r_{i_1 \ldots i_m}$ of all outcomes $z_{i_1 \ldots i_m}$ that are equal to z.

Step 5   Repeat Steps 3 and 4 for the next discrete value of x^m until all n_m discrete values of x^m have been considered.

Step 6   Calculate the posterior probability $\overline{p}_{i_m}{}^m$ by Equation (2).

Step 7   Repeat Steps 2 through 6 for the next parameter until all M parameters have been considered.

A Performance-Based Approach to Public Health Risk Evaluation and Remedy Selection at Superfund Sites

Gordon M. Elliott, Ph.D

Golder Associates Inc.
Atlanta, Georgia

ABSTRACT

The escalating cost of remedial action under Superfund is encouraging researchers and practitioners to develop alternative methodologies for evaluating cost-effective health risks that protect public health. Performance-based approaches to problem solving are not new. They have been used successfully in the mining industry and in the high-level radioactive waste field to support risk-based decision-making. However, only recently have these same concepts received consideration for addressing health impacts of exposure to hazardous substances.

The current guidelines for evaluating potential public health responses at Superfund sites follow a deterministic analysis that focuses only on the magnitude of a potential health outcome. A deterministic analysis accounts for uncertainty by choosing upper bound or conservative input parameters; this process significantly increases the cost of remediation without quantifying the degree of conservatism in the outcome.

A performance-based approach attempts to quantify the uncertainties that are discarded in a deterministic analysis and carry them through all stages of the evaluation. In this way, the result of a performance analysis is not a single value of magnitude, but is a range of magnitudes and probabilities. These probabilities describe the confidence the analyst has in the estimates of magnitude and directly relate to the uncertainties in the available knowledge of the site.

This paper describes a performance-based approach that has been successfully applied to evaluating public health responses from exposure to hazardous substances at a Superfund site. The approach has been developed in keeping with 40.CFR.300. The results of the evaluation are presented in a form that can be used to demonstrate regulatory compliance, support a formal decision analysis to identify the most cost-effective remedy and ultimately protect human health and the environment.

INTRODUCTION

The current guidelines for evaluating potential public health impacts at Superfund sites acknowledge that uncertainty exists at all stages of the public health risk evaluation and remediation selection process. For example, it is acknowledged that uncertainties may exist in the baseline data and, in the case of analyses that must be extrapolated over time, there may be uncertainties in explaining past and predicting future events. To account for these uncertainties, the procedures recommended in the public health evaluation guidance documents[1] follow a deterministic logic that considers a set of likely and unlikely-but-possible exposure scenarios using expected value and worst-case input data values. The range of values calculated using this logic is considered to represent the range of magnitude of public health risk at the site. Unfortunately, such analyses do not quantify uncertainty and rarely contain sufficient plausible information for realistic decision-making. Comparisons between the calculated magnitudes and the regulatory acceptance levels and comparisons between the effectiveness of different possible remedies, become cumbersome and invariably focus on the worst possible outcome that will rarely, if ever, occur.

This paper outlines an alternative, performance-based method for quantifying uncertainty and evaluating the true risks associated with the Superfund public health risk evaluation and remedy selection process. While a deterministic analysis provides an estimate of the potential magnitude of an adverse public health response, a performance-based analysis specifically addresses magnitude and chance. The magnitude of a noncarcinogenic response is taken to be the ratio of the dose received by the individual divided by a specific reference dose. The magnitude of a carcinogenic response is the expected recurrence of an adverse public health response. Chance is a quantitative assessment of the confidence that the magnitude, as defined, will be equal to or will exceed a nominated value. Chance is related to uncertainties in predicting the response to a given dose, uncertainties in the system used to predict what the dose may be at a given point in time and uncertainties in how the dose will vary with time. Risk is a measure of the penalties incurred when an unacceptable event occurs.

OUTLINE OF CONCEPT

Mathematically, the probability that the magnitude of a particular health response will be equal to or greater than some specific value can be represented by a cumulative density function (CDF). A CDF provides the means of progressively estimating the likelihood that the occurrence of a given phenomenon will equal or exceed a given set of values.

The principle is illustrated in Figure 1. If the CDF curve is flat, as illustrated by curve A, then the level of uncertainty is high and the outcome could be one of a wide range of values. If the curve is steep, as illustrated by Curve B, then the level of uncertainty is small and the values can be predicted to lie within a small range of values. Certainty will be represented by a vertical line (Curve C).

The CDF presents two of the components of true health risk, magnitude and chance, both of which are needed to evaluate performance. Performance must then be measured against what is acceptable before any risk can be assessed. What is acceptable is generally a reflection of the third component of true risk, exposure to loss. Exposure to loss is defined by society's preparedness to comply with whatever financial, judicial, political or social penalties that may be imposed if an unacceptable event occurs. Exposure to loss will be characterized in part by the difference between a CDF representing the expected performance and a CDF representing the acceptance limits.

Although the regulations do not explicitly specify acceptance levels in terms of CDF values, the words do allude to the fact that unlikely-
Figure 1
Illustration of Performance Curves for
Various Levels of Uncertainty

RECURRENCE OF EXCESS CANCERS

Figure 2
Base Line Performance Curve for Hypothetical Example

but-possible exposure scenarios need to be evaluated differently to most likely scenarios. The *Human Health Evaluation Manual*[1] refers to the analysis of a reasonable maximum exposure. In view of the predilection toward using 95 percentile upper bound values for calculating the reasonable maximum exposure under the promulgated guidelines, it is suggested that a calculated recurrence having a 95% chance of not being exceeded may also be acceptable for representing the reasonable maximum exposure. The regulations could, in concept therefore, be represented as a CDF.

The seriousness of a release of hazardous substances can be evaluated graphically by plotting the CDF for the expected performance of the base line case together with the CDF for risk acceptance levels. This comparison is shown for a hypothetical example in Figure 2. The bench mark scale or phenomenon is the expected frequency of an excess carcinogenic response. Curve A is the CDF representing the risk acceptance level and Curve B is the CDF representing the health impact from exposure to cigarette smoke if no effort is made to reduce the quantity of smoke in the environment. CDFs to the right of Curve A represent an acceptable chance of survival; values to the left represent an unacceptably high chance of contracting cancer. Curve B is totally to the left side of the acceptance level, indicating that the current human exposure to cigarette smoke results in an unacceptably high recurrence of fatal responses. The magnitude of the difference between the two curves reflects the seriousness of the problem.

Effectively, Figure 2 represents the end of the Remedial Investigation phase under Section 430, Subpart E - Hazard Substances Response, of the National Oil and Hazardous Substances Pollution Contingency Plan (40.CFR.300). During the Feasibility Study phase, detailed analyses of remedial alternatives that reduce the health risks should include the development of a CDF for the residual health risks after implementation using the same approach. The CDFs of different remedial alternatives can then be represented on a single graph. In this way, the effectiveness of each remedy in reducing residual health risks to acceptable levels can be directly compared with each of the other remedies with the base line case and with the acceptance levels.

Such comparisons are shown in Figure 3. Figure 3 illustrates the ultimate goal of the proposed performance-based approach to public health risk evaluation as a consequence of exposure to releases of hazardous chemicals. Presenting the results of the analysis in this way enables several important requirements of the regulations to be addresses simply and quickly in a single-sheet summary of results:

• The shape of each CDF characterizes the uncertainties in the predicted results;
• The relative positions of the base line CDF (Curve B) and the risk acceptance limit CDF (Curve A) helps establish whether a risk exists;
• The magnitude of the difference between the base line CDF and the risk acceptance limit CDF characterizes the seriousness of the risk;
• The magnitude of the differences between the residual risk CDFs (Options 1, 2, and 3) and the base line CDF measures the effectiveness of each proposed remedy in reducing health risks; and
• The magnitude of the difference between the residual risk CDFs and the risk acceptance limit CDF measures the ability of each proposed remedy to meet regulatory requirements.

RECURRENCE OF FATAL RESPONSES
Figure 3
Comparison of Performance Curves of
Different Remedial Alternatives

In addition, coupling the residual risk CDFs for each remedy with the estimated implementation costs (Options 1, 2, and 3) provides the basic input for a formal decision analysis to select the most cost-effective remedy.

METHOD

A health risk exists only if a specific series of circumstances occurs in combination:

• There is a source of substances that are hazardous to public health
• There are release mechanisms which allow the hazardous substances

to escape to the environment
- There are physical mechanisms which are capable of transporting the hazardous substances away from the source
- There is a receptor location that intercepts the transport mechanism
- There is a human intake mechanism which allows hazardous substances that have reached the receptor location to be absorbed into the body
- Hazardous substance are absorbed into the body in sufficient quantities to cause an unacceptable health response

This combination of circumstances constitutes an exposure scenario. The performance-based approach quantifies the range of values and uncertainties associated with each of these circumstances in a set of individual probability distribution functions (PDFs) for several different and representative scenarios and then this approach combines and condenses the individual PDFs into a single CDF to estimate the likelihood of an adverse health response (Curve B, Fig. 2).

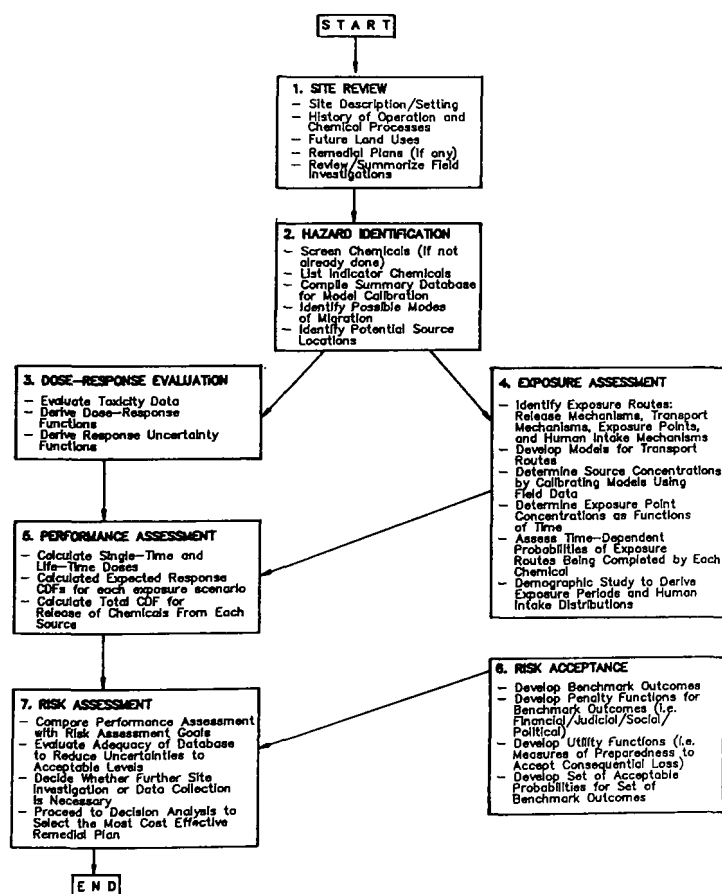
The method is illustrated in Figure 4. It comprises three main elements: a Performance Analysis (Boxes 1 to 5), a Risk Acceptance Analysis (Box 6), and a Risk Assessment (Box 7).


Figure 4
Schematic of Performance Analysis Method

The first stage of the Performance Analysis includes the Site Review and Hazard Identification (Boxes 1 and 2). This stage requires a review of all the information collected during the site investigations. It enables a data base to be set up containing PDFs for all the input parameter values as well as the information needed to calibrate the transport models used in the Exposure Assessment (Box 4). The methodology then splits into two parallel stages, the Dose-Response Evaluation (Box 3) and the Exposure Assessment (Box 4).

The purpose of the Dose-Response Evaluation is to characterize the health impacts resulting from exposure to a certain range of dosage. The evaluation establishes dose-response functions to estimate the

expected health responses and response uncertainty functions to describe the uncertainties in the predictions made by the dose-response functions. Historically, dose-response functions have been derived as a deterministic curve-fit to data for observed responses to high doses on laboratory animals. At high dose rates, the results are repeatable. However, the uncertainty in the predicted response increases as the dose decreases. Therefore, a response uncertainty function is required to provide a measure of the statistical spread of possible responses for each level of dose intake.

The primary goal of the Exposure Assessment is to compile the necessary data to establish PDFs for the expected single-time and lifetime intakes of hazardous substances which potentially may complete the exposure circuit from source to individual. The information collected during the Exposure Assessment is then combined with the Dose-Response information in the Performance Assessment stage of the analysis (Box 5) to generate a suite of PDFs describing the health response for all potential exposure routes, exposure points and exposed individuals. These PDFs may be aggregated into CDFs representing any specific health issue of concern, but eventually are aggregated into the single CDF representing the health outcome for the site in general (Curve B, Fig. 2).

The Public Health Risk Assessment (Box 7) is completed when the aggregated Performance Assessment CDF (Curve B, Fig. 2) is compared with the Risk Acceptance Limits (Curve A, Fig. 2) to assess whether the current performance of the site presents an acceptable level of risk. The risk assessment process can be reiterated to isolate the most sensitive factors, exposure routes and release mechanisms and thereby help identify the most cost-effective remedy.

The Risk Assessment can be only performed when both the Performance Assessment and the Risk Acceptance Analysis have been completed because, without either a Performance Assessment or a Risk Acceptance Analysis, there is no perceived risk, only a measure of likely or acceptable performance. The risk acceptance limits are generally provided by regulatory requirements, but where such regulations do not exist a formal Risk Acceptance Analysis (Box 6) is required to derive defensible acceptance limits.

The performance-based approach to public health risk assessments described in this paper is consistent with the broad framework and intent of 40.CFR.300, but is believed to have the following advantages over the public health risk assessment methods now being used:

- It provides a means of rationalizing and consolidating the data and information generated by a risk evaluation into a single-sheet format;
- It provides a means of estimating and graphically illustrating the range of values and uncertainties associated with each risk evaluation;
- It provides a means of combining the risks associated with different exposure scenarios into a single risk characterization of the site which can be used to estimate the likelihood that an adverse health impact will exceed a nominated value;
- It provides a graphical means of comparing the base line risks with the acceptance criteria and comparing them both with the predicted residual risks after a particular remedy has been implemented;
- It enables the use of formal decision analysis techniques when selecting the most cost-effective remedy; and
- It enables the use of formal decision analysis techniques when addressing other site related health-risk issues such as a Potentially Responsible Party's exposure to litigation from past exposure to individual people.

CASE STUDY

The performance-based approach to public health risk assessments described in this paper has been applied to a Superfund site which has already been investigated in accordance with the procedures outlined in 40.CFR.300. The purpose of the case study was to demonstrate the method on a real Superfund site and illustrate quantitatively the uncertainties in a typical Superfund public health risk assessment.

The 825-acre case study site is located in a floodplain area of low physiographic relief. It is occupied primarily by light industrial companies, trucking firms, petrochemical supply and production companies,

Read.[2] The results for carcinogenic health responses are illustrated in Figure 5. In this particular study, the relative contributions to the coefficients of variation of the results by different system components are compared in Table 1.

CONCLUSIONS

This first demonstration project has confirmed that a performance-based approach can be applied to evaluating public health risk at Superfund sites. It has also served to identify which areas of analysis require further refinement for improving the defensibility of the results. It is hoped to be able to advance this approach in the future in order to stay in the forefront of possible developments in public health risk assessment.

Conf. on Solid Wastes Management,* San Francisco, CA, October, 1990. Publ. National Solid Wastes Management Association, Washington, D.C., 1990.

small businesses and a few private residences. The land surrounding the site is mostly used for business and industrial purposes, although there is a residential development located approximately one mile from the site.

Industrial and waste disposal activities at four potential sources within the site have contaminated the local groundwater, surface water and soil. The potential sources of contamination were all redeveloped or closed before the site was added to the NPL, but included an oil refinery, a biocide manufacturing plant, a solid waste landfill and a mixed waste disposal area. Contaminants detected include volatile and semi-volatile organic compounds, biocides (pesticides, insecticides and herbicides) and heavy metals.

To focus the study on the demonstration of the method, the analysis was limited to using indicator chemicals, exposure routes and exposure points that had already been defined in the previous human health evaluation. A total of 25 indicator chemicals, four transport mechanisms, eight receptor categories and nine exposure points were used to characterize human health response for each potential source. Performance analyses were carried out for 637 exposure scenarios that could be completed. These were then aggregated into four performance curves, one for each source location. Further details on the health response calculation and derivation of the input PDFS for this study are described by Elliott and

Discussion of the U.S. EPA's Proposed Indemnification Guidelines and Risk Management for Superfund Program Response Action Contractors

ABSTRACT

This paper presents a brief overview of U.S. EPA's proposed guidelines for indemnifying response action contractors (RACs) as authorized by Section 119(c) of SARA. This paper also discusses risk management options that RACs can use to assist them in developing a formal risk management program.

Subject to certain restrictions, Section 119(c) of SARA authorizes the U.S. EPA to indemnify RACs working at Superfund sites. the U.S. EPA's authority is discretionary — the U.S. EPA is not obligated to provide indemnification. Section 119 of SARA was enacted in response to the lack of pollution liability insurance in the mid-1980s. On October 31, 1989, the U.S. EPA published proposed guidance for Superfund RAC indemnification in the *Federal Register* (54 FR 46012) with a request for public comment not usually included in guidance. The key features of the proposed guidance include: (1) the "diligent efforts" requirement, (2) the indemnification limits offered, (3) the required corresponding deductibles, (4) potentially responsible party (PRP) and other key exclusions, (5) subcontractor requirements and (6) the U.S. EPA's determination of the availability of pollution liability insurance.

The U.S. EPA's proposed indemnification guidelines are one part of a formal Superfund RAC risk management program. This paper presents a general overview of the U.S. EPA's proposed guidelines for indemnification of RACs, focusing on the "diligent efforts" requirements, limits, deductibles and key exclusions. The paper goes on to discuss the U.S. EPA's determination of the current availability of adequate pollution liability insurance and reviews the risk management process and risk management techniques already in place for RACs. Finally, the paper reviews loss financing options for RACs, such as: (1) purchasing adequate limits of insurance, (2) loss retentions and insurance deductibles, (3) self-insurance programs and (4) contractual transfers.[4]

INTRODUCTION

Congress in SARA[1] Section 119 granted the U.S. EPA and other federal agencies the discretionary authority to indemnify RACs working for the U.S. EPA, other federal agencies, states and PRPs. SARA Section 119 contains the following key provisions:

- Establishes a federal negligence standard by exempting RACs from liability under all federal laws except in cases of negligence, gross negligence or intentional misconduct. This standard does not preempt state law.
- Provides the U.S. EPA and other federal agencies with discretionary authority to indemnify RACs for claims brought because of RAC negligence. However, no agency is authorized to provide indemnification for state-enforced strict liability standards.
- Requires limits and deductibles to be incorporated into all indemnity agreements.[1]

Section 119 indemnification can be provided:

- Solely to RACs working in the Superfund program.
- Only for liability related to actual releases of hazardous substances resulting from RAC response actions under the Superfund program
- As a supplement or substitute when commercial insurance is unavailable, inadequate or unreasonably priced
- Only when the RAC has made a diligent effort to obtain insurance from nonfederal sources and has found that none is available at a fair and reasonable cost.[3] The determination of diligent efforts and fair and reasonable insurance costs rests solely with the U.S. EPA.[1]

The U.S. EPA is currently responding to public comment and is in the process of promulgating the final guidance. Promulgation of the guidelines is anticipated in the near future, probably in early 1991.

KEY FEATURES OF THE U.S. EPA'S PROPOSED GUIDELINES

Diligent Efforts Requirement

SARA Section 119 provides the U.S. EPA with the discretionary authority to offer indemnification to RACs working in the Superfund program. Because of the lack of adequate and affordable pollution liability insurance in the mid-1980s, it was the intent of Congress that Section 119 indemnification provide an interim solution to the lack of insurance until commercial liability insurers are capable of and willing to provide adequate insurance for RACs.[2] Therefore, in the proposed guidance, as directed by SARA, the U.S. EPA has imposed a diligent efforts requirement on RACs: RACs must make diligent efforts to obtain insurance coverage from nonfederal sources before entering into an indemnification agreement with the U.S. EPA and before beginning work at a new Superfund site under multisite contracts. The proposed guidance describes diligent efforts as: a RAC must submit in writing:

- "The names and addresses of at least three commercial insurers or alternative risk financiers to whom the RAC has submitted applications; and"
- "A copy of each application submitted, insurance policies offered (including the declaration page) and any rejection letters received. If pollution liability insurance was offered by a commercial insurer, but not accepted by the RAC, an explanation of the reasons why such coverage was rejected must be included."[5]

Cost reimbursement RACs may satisfy the diligent efforts requirement by procuring and maintaining pollution liability insurance in the minimum amount of $1 million, or self-insure for the same.

Indemnification Limits and Deductibles

Among the most important and controversial, features of the U.S. EPA's proposed guidelines are the indemnification limits offered and

their corresponding deductibles. As shown in Table 1, the minimum limit of $1 million offered in the proposed guidelines has a corresponding deductible of $10,000. As the limits increase, so do the deductibles. The maximum limit of $50 million has a corresponding deductible of $3.5 million. (This was done to duplicate the features of limits and deductibles often found in commercial liability insurance.)

There are several important aspects of the indemnification limits and deductibles that RACs must recognize. First, the indemnification limit as proposed is a contract aggregate limit.[5] For example, if a RAC requests, is offered and accepts a $50 million limit of indemnification on a 4-year contract, the $50 million limit is for the entire 4-year period. Therefore, if this same RAC received indemnification payments of $1 million (above the corresponding $3.5 million deductible) in the first year, only $49 million of indemnification would remain for the remaining 3 years of the contract. Second, the corresponding deductible of a U.S. EPA indemnity agreement, as proposed in the guidelines, is a per occurrence deductible. Each time a RAC incurs a loss resulting solely from its negligent actions, it must pay the full amount of the deductible before U.S. EPA indemnification would pay for the loss. Therefore, that same RAC with a $50 million limit in its indemnification agreement must incur a loss greater than the $3.5 million deductible to receive an indemnification payment from the U.S. EPA. The per-occurrence deductible mirrors those found in commercial liability insurance policies.

PRP and Other Key Exclusions

The U.S. EPA's proposed indemnification guidelines contain some key exclusions. First, the U.S. EPA will not agree to indemnify a RAC under contract to a PRP.[6] Even though Section 119 gives the U.S. EPA the discretionary authority to indemnify a RAC employed by any PRP that has entered into an agreement (such as a consent decree) with the U.S. EPA, the Agency has chosen not to exercise that authority.

Other exclusions that limit the U.S. EPA's indemnification are that the indemnification will be provided only for losses resulting from a RAC's negligence. This indemnification excludes instances where strict liability, gross negligence and willful misconduct are the cause of the loss. Furthermore, indemnification is statutorily excluded for owners or operators of facilities regulated under the Solid Waste Disposal Act, as amended and any owner or operator of a facility that receives solid or hazardous waste for disposal, treatment or storage.

Subcontractors

Another feature of the proposed guidelines is the U.S. EPA's decision that it will not directly indemnify subcontractor RACs. U.S. EPA indemnification can be extended to subcontractors only as a "pass-through" from the prime contractor. (A prime contractor RAC is the contractor that has a direct contract with the U.S. EPA.) The following scenario describes how a subcontractor RAC would receive indemnification as a pass-through from the prime contractor:

Prime contractor A has a $10 million indemnification agreement with the U.S. EPA. This agreement, accordingly, has a $250,000 per occurrence deductible (refer to Table 1 above). Prime A wants to procure well drilling services from subcontractor Z. Z has a liability exposure in drilling wells and requests $2 million of indemnification from A. If A grants Z's request, A can include any deductible. Furthermore, A's indemnification limit from the U.S. EPA would be reduced $2 million, to $8 million, until Z's agreement ends.

The U.S. EPA must approve all indemnification agreements between a prime contractor and a subcontractor. Also, because subcontractors are defined as RACs, they are subject to the same diligent efforts requirements as the prime contractors. Subcontractors must demonstrate that they made diligent efforts, as described above, to obtain pollution liability insurance and agree to continue to make such efforts as required.

U.S. EPA Determination of Pollution Liability Insurance Availability

An important determining factor that the U.S. EPA will consider before it enters into an indemnification agreement with a RAC is the

Table 1
U.S. EPA's Proposed Indemnification Limits and Deductibles

Limit	Deductible	Limit	Deductible	Limit	Deductible	Limit	Deductible	Limit	Deductible
$ 1,000,000	$ 10,000	$ 2,000,000	$ 40,000	$ 6,000,000	$ 130,000	$ 11,000,000	$ 300,000	$ 26,000,000	$ 1,100,000
		3,000,000	60,000	7,000,000	160,000	12,000,000	350,000	27,000,000	1,200,000
		4,000,000	80,000	8,000,000	190,000	13,000,000	400,000	28,000,000	1,300,000
		5,000,000	100,000	9,000,000	220,000	14,000,000	450,000	29,000,000	1,400,000
				10,000,000	250,000	15,000,000	500,000	30,000,000	1,500,000
						16,000,000	550,000	31,000,000	1,600,000
						17,000,000	600,000	32,000,000	1,700,000
						18,000,000	650,000	33,000,000	1,800,000
						19,000,000	700,000	34,000,000	1,900,000
						20,000,000	750,000	35,000,000	2,000,000
						21,000,000	800,000	36,000,000	2,100,000
						22,000,000	850,000	37,000,000	2,200,000
						23,000,000	900,000	38,000,000	2,300,000
						24,000,000	950,000	39,000,000	2,400,000
						25,000,000	1,000,000	40,000,000	2,500,000
								41,000,000	2,600,000
								42,000,000	2,700,000
								43,000,000	2,800,000
								44,000,000	2,900,000
								45,000,000	3,000,000
								46,000,000	3,100,000
								47,000,000	3,200,000
								48,000,000	3,300,000
								49,000,000	3,400,000
								50,000,000	3,500,000

availability of commercial pollution liability insurance. The proposed guidance states that the U.S. EPA will determine on a case-by-case basis whether adequate insurance is available at a "fair and reasonable price" at the time the indemnification request is submitted by the RAC. Although the proposed guidance does not specify what the U.S. EPA will consider a "fair and reasonable price," it is likely that the U.S. EPA will base the determination on a percentage of the contract value. In other words, it is unlikely that the U.S. EPA will consider an insurance premium of $100,000 "fair and reasonable" for a contract that has a value, or estimated RAC revenue, of $100,000.

U.S. EPA guidelines, when promulgated, will govern the U.S. EPA's indemnification of RACs for work initiated after October 17, 1986 and will supersede OSWER Directive #9835.5, "the U.S. EPA Interim Guidance on Indemnification of Superfund Response Action Contractors Under Section 119 of SARA." The guidelines will also govern all RAC indemnification by the U.S. EPA for future response action contracts.

DISCUSSION OF RISK MANAGEMENT TECHNIQUES FOR SUPERFUND RACs

Risk Management

Risk management is traditionally defined as the practice of analyzing all noncompetitive and nonproductive exposure to risk or loss (loss by fortuitous or accidental means) and taking steps to reduce those potential or real losses to levels acceptable to the organization. To undertake this practice, RACs must develop a risk management process to control pure risk (risk that can only result in a loss). This risk management process typically includes a four-step process: (1) identifying and analyzing the loss exposures, (2) selecting the appropriate risk management technique(s) (which typically include risk retention, contractual or noninsurance transfer, loss control, risk avoidance, and insurance transfer) to handle exposures, (3) implementing the chosen technique(s) and (4) monitoring the results to verify and improve the process.[7] RACs must practice sound risk management techniques to identify and control their loss exposures. Figure 1 provides an overview of the risk management process.

Exposure Identification/Analysis

Numerous tools exist to assist RACs in identifying and analyzing losses. These tools include (1) base line risk assessments, (2) remedial investigations (RIs) and feasibility studies (FSs) and (3) records of decision (RODs). Furthermore, because NCP laws, regulations and guidance assist RACs by directing actions at remedial action sites, RACs have a distinct advantage over many other industries when it comes to risk management.

One primary liability exposure that should concern RACs and is the focus of this paper, is the liability a RAC would face if there is a release, or threatened release, of contaminants at a site during the remedial activities performed by the RAC.

One task that is done during the early stages of a Superfund site cleanup that assists RACs in risk identification is a base line risk assessment. Base line risk assessments are done to help determine what risk the site poses to human health and the environment. These risk assessments provide RACs with valuable information to help them identify the liability loss exposures they may face during remedial activities. Risk assessments will identify the surrounding population that could be affected by the contamination at the site, as well as the environmental impacts of the site. Therefore, RACs can use this information in the risk management process to help identify and analyze the liability loss exposures that may exist in the event of a release during remedial activities. This information will assist RACs in developing proper loss control programs and choosing adequate risk financing levels.

Another RAC activity that assists RACs in risk identification involves performing very detailed Ris and Fss at a site. Ris are designed to help identify where contamination exists, what contaminants are there and how the contamination is affecting the surrounding population and the environment. Fss are developed to determine what technologies can be applied to clean up the site. The RI and FS provide the U.S. EPA

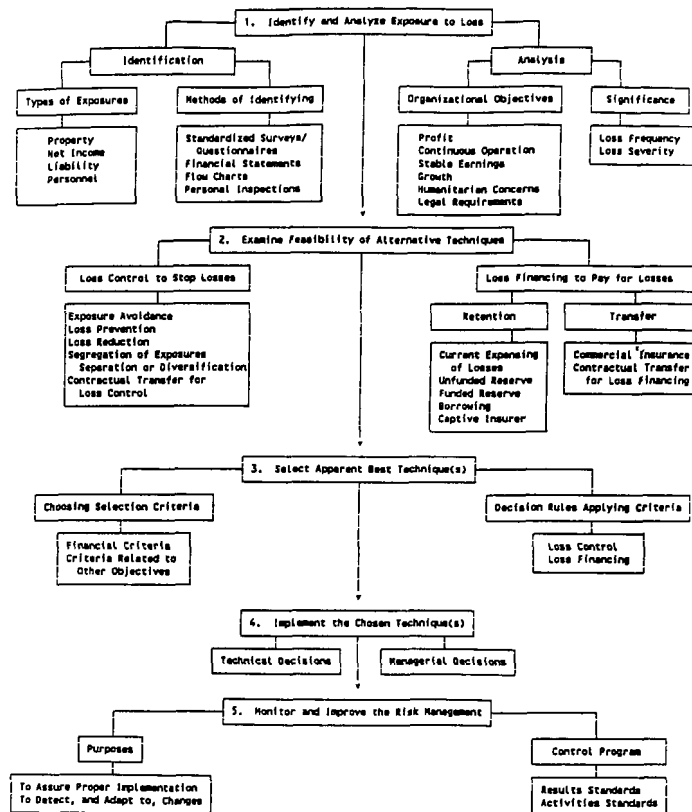
and RACs with extensive information regarding the site that can be used in the risk management process to help determine what release exposure may exist when remedial actions take place at the site. For example, if a remedial action calls for the excavation and removal of buried drums at a site, the RI/FS will help the RAC determine where the drums are. This information would help to avoid, or at least control, the liability exposure that would result if the drums were accidentally pierced during excavation, causing a release of their contents.


Figure 1
The Risk Management Process

Loss Control

One of the first things that Superfund RACs are required to do before going on-site is to develop a health and safety plan. These plans are a risk management tool that help RACs limit the liability exposures to their personnel and limit the exposure of the surrounding community by allowing only certified and properly equipped personnel onto the site. A properly implemented health and safety plan, along with physical barriers that are constructed to restrict access to the site (for example, fences and gates), help to manage one of the primary pathways from which RAC liability may arise: on-site exposure.

The experience of the RAC's personnel and the ability to draw on the expertise of the U.S. EPA's On-Scene Coordinators (OSCs) and Remedial Project Managers (RPMs), provide RACs with valuable risk management expertise and information. Although some RACs may be new to the industry, most have well-educated and well-trained personnel in the field who are responsible for implementing the remedial activities. Furthermore, RACs can rely on the expertise of the U.S. EPA's OSCs and RPMs to provide further guidance and direction during remediation of a Superfund site.

Should a release occur at a site during a remedial action, the RAC's own expertise should be used to help contain and control the amount of damage caused by the release, providing another loss control advantage. As part of an overall loss control program, RACs also should ensure that proper control devices and equipment are in place at the site in case of a release. Furthermore, RAC personnel should be properly trained in the implementation of containment procedures.

The U.S. EPA's Environmental Response Team (ERT) would probably be involved if a serious release were to occur during remedial activities, another asset to a RAC's risk management program. ERT brings necessary expertise to assist in the control and containment of contaminants, thereby helping to minimize the incurred losses resulting from a release.

A U.S. EPA-directed device that assists RACs in loss control is the site-specific ROD. The ROD is the product of the RI/FS. The ROD provides RACs with a very important loss control mechanism by specifying the remedial action(s) that will be implemented at the site based on the RI/FS. Since RACs do not choose the remedial action that is implemented at the site (the U.S. EPA does), this process controls a RAC's loss exposures because the RAC is only doing what it was told. RACs' professional liability may be limited because they implement remedial actions based on remedial designs approved by the U.S. EPA. Recent case law shows that this defense has not been consistently successful, however.

Another loss control method that RACs have available is the remedial design. As part of the ROD, remedial designs are based on extensive study during the RI/FS. Therefore, the extensive study that is done before a ROD is signed helps to limit the RAC's liability exposure by limiting the possibility that the RAC will implement the wrong remedial action.

RACs have many other loss control devices and actions that they can implement in their risk management programs. Briefly, these loss control steps include the following:

- Developing a formal risk management and control manual for field personnel
- Avoiding remediation work that calls for expertise not available within the RAC's organization
- Developing detailed, site-specific contingency plans
- Dedicating a full-time staff for a formal risk management program responsible for implementing all steps in the risk management process

After a RAC has identified, analyzed and controlled loss exposures, it is necessary to develop a risk financing program to pay for any resulting losses that were either unidentified or uncontrolled. The next section discusses how a RAC can develop a risk financing program.

RISK MANAGEMENT FOR SUPERFUND RACs—RISK FINANCING

RAC risk financing is part of the risk management program that anticipates losses and arranges to pay for them with a mix of loss reserves, self-insurance, contractual transfer, insurance, and U.S. EPA indemnification. The indemnification program the U.S. EPA has proposed provides RACs with an alternative risk financing mechanism when commercial pollution liability insurance is inadequate or too expensive. U.S. EPA indemnification, when offered, is one mechanism that RACs can use to help pay liability losses resulting from negligence associated with Superfund remediation work. The options RACs can use to help finance such losses and the steps that they should undertake before reaching a risk-financing decision are shown in Figure 2. Some risk identification and control techniques that RACs use were explained above. This section describes the three ways RACs can finance losses: retention, transfer and insurance (Fig. 2).

In choosing an adequate risk-financing mix, a RAC should consider the following questions:

- In the event of a loss, what financial position do we want to be in: survival, continuity of operations, profitable, stable earnings or growth?
- What loss amount can our business expect?
- What is the current availability of funds to pay for losses as they occur?
- If regulatory requirements are established for various insurance coverages and other risk-financing techniques, how does this affect our decision?
- What alternative uses of funds (opportunity costs) affect our risk-financing decision?

This section briefly explores the role the U.S. EPA indemnification can play in a RAC's overall risk financing plan.

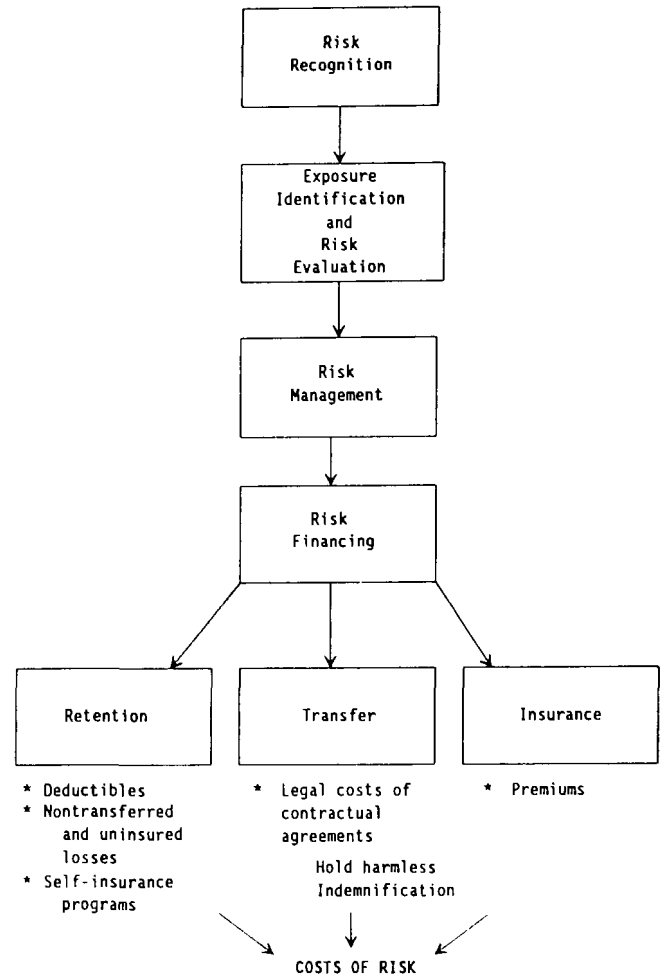
To help define its intended financial condition should a loss occur, the RAC should identify its post-loss goal. Typically, post-loss goals range from the basic objective of survival to the ambitious and often unattainable, goal of continued growth. As described below, a RAC's post-loss goals are affected by its expected losses. Once a RAC chooses its post-loss goal, it can proceed to analyze various risk-financing mechanisms.


Figure 2
Steps Toward Risk Financing

After a RAC establishes its post-loss goals, the first crucial step, as described in the previous section, is the identification and analysis of loss exposures. The two factors that affect potential losses are severity and frequency. RACs are believed to be in a high-severity, low-frequency expected loss industry.

Insurance is the typical risk-financing mechanism used to limit the adverse impact of a high-severity, low-frequency loss. RACs would seek contractor's pollution liability (CPL) insurance and environmental engineer's errors and omissions pollution liability, otherwise known as professional pollution liability, insurance. Available limits of commercial insurance for project-specific CPL are $10 million per occurrence and $10 million annual aggregate. Available limits of commercial insurance for blanket CPL are $5 million per occurrence and $5 million annual aggregate. Available limits of commercial insurance for blanket and project-specific environmental engineer's errors and omissions pollution liability are $5 million per occurrence and $5 million annual aggregate. Factors that will affect a RAC's decision to insure are the availability and cost of insurance.[8]

RACs also should explore retention and transfer as risk-financing mechanisms. As Figure 2 indicates, retention consists of insurance deductibles, nontransferred and uninsured (or unreserved) losses and

self-insurance programs. Retention can be most effective when a RAC properly reserves funds to pay for future losses. Transfer typically involves contractual hold harmless and indemnification agreements that relieve the RAC from the costs of risks. Self-insurance is a viable risk financing method that the U.S. EPA recognizes as meeting the diligent effort requirement of the proposed indemnification guidelines. By working with qualified insurance brokers, a RAC can develop a self-insurance program that would help pay for losses in the event of a release of contaminants during a remedial action.

RACs must be aware that indemnification and insurance are only two ways to finance risks. A mix of retention, contractual clauses, insurance and U.S. EPA indemnification should be used to offset the potential liability costs of doing remedial work at Superfund sites.

CONCLUSION

U.S. EPA indemnification is one part of a RAC risk management program. RACs should examine all the information that they receive through base line risk assessments, RI/FS and RODs to help identify their potential liability exposures and to determine necessary risk-financing and loss control actions. A formal risk management program will help RACs to better understand and deal with the pollution liability risks that are inherent in their profession, so that if a release occurs during remedial actions, the RAC is better prepared to control the extent of the damage to human health and the environment and the financial implications to the RAC organization.

Assessing Uncertainty in the RI/FS Process

Steven M. Keith
CH2M HILL
Milwaukee, Wisconsin

ABSTRACT

Though pervasive throughout the process, uncertainties in the CERCLA RI/FS process generally are not recognized as a priority issue. RI reports typically address uncertainty in a qualitative fashion and generally only in the risk assessment; and FSs often only address uncertainty in volumes of contaminated media and remediation costs using sensitivity analyses. These analyses can provide useful information, but do not provide a comprehensive analysis of uncertainty. Qualitative analyses of uncertainty can be assumed to hold less importance and are more difficult to incorporate into the decision-making process than quantitative results.

As more techniques are developed to evaluate uncertainties quantitatively, decision-makers may place increased reliance on quantitative descriptors of uncertainties to assist in comparing options and planning for contingencies resulting from deviations in the proposed remedial action plan. A number of methods have been and currently are being developed to evaluate uncertainty more quantitatively.

This paper identifies several factors believed to contribute to uncertainty in remedial investigations and feasibility studies and evaluates their relative importance in the interpretation of data in defining the nature and extent of contamination and in the selection of a remedy. Methods and strategies that can be used to describe and reduce uncertainties are presented.

THE IMPORTANCE OF UNCERTAINTY ANALYSIS

Few solutions to problems addressed in science and engineering are free from uncertainty, and the RI/FS process is no exception. Because uncertainties predominate over clear-cut facts in many RI/FS studies, the need for uncertainty analysis in the RI/FS process appears well-deserved. The recognition of the scientific limitations of data acquisition and methods of analysis can benefit the development of reasonable and defensible remedial action strategies. A recognition of the uncertainties can help to emphasize the need for contingencies in any remedial action plan.

To gain an understanding of the relative importance of the different factors that contribute to uncertainty, it is necessary to first consider the basic goals of the RI/FS process, and then consider what factors are critical to the decision-making process. The basic purpose of the RI/FS process is to determine: (1) if there is an unacceptable endangerment posed by the site to human health and the environment, and if so then (2) determine the nature and extent of the contamination and (3) determine a cost-effective means of achieving a suitable remedy. The following sections identify factors that are considered critical to determining if there is an unacceptable risk, determining the nature and extent of contamination and evaluating the cost of a potential remedy. This paper does not attempt to qualify all possible factors that could influence uncertainty. Instead, quantitative approaches to analyzing uncertainty for several key parameters are addressed.

UNCERTAINTIES IN DEFINING THE NATURE AND EXTENT OF CONTAMINATION

Many of the major uncertainties in the RI/FS process result from an incomplete understanding of the nature and extent of contamination. How well the nature and extent of contamination is defined (e.g., what contaminants are present, where are they now and how might they migrate to human and animal receptors) can affect the assessment of the risk posed by the site to human health and the environment and will impact the development and selection of a remedial action plan. A poor assessment of the nature and extent of contamination can result in the selection of a less cost-effective remedy or an inappropriate level of protection to the community and the environment.

The definition of nature and extent is a product of planning, field sampling, analytical work and interpretation of data. Errors that occur in any of these stages can introduce uncertainty in the conclusions of the remedial investigation. Sampling error is the improper use of the prescribed methods for sample collection and storage. Sampling bias, such as sampling only areas of suspected or observed contamination, could skew results of a risk assessment or proposed remedy if the bias is not accounted for in the interpretation of results. Although sampling error and sampling bias can significantly affect the results of an RI, they are difficult to assess and characterize. Several approaches have been developed, however, to quantitatively evaluate analytical error.

The difference between the reported concentration and the actual concentration of a contaminant in a sample is the analytical error. Analytical error can be described quantitatively via measurement of accuracy and precision. Accuracy of a test often is measured by the percent recovery of a surrogate compound from a laboratory spike. While low surrogate recoveries may indicate significant analytical error, correction for the bias is not standard practice. Surrogate recoveries as low as 25% can be used to validate reported concentrations for a host of other compounds that exhibit different recovery rates than the surrogates.

For initial investigative work, the relative impact of analytical error is likely to be less significant than error introduced in the sampling planning stage (i.e., conceptual error). Should the reported values play a major role in the decision-making process and have concentrations that approach action levels, then the

consequences of this error could be considerable. Uncertainty in reported values due to analytical error could be addressed by: (1) accounting for the uncertainty in the results and deriving "probable" range of actual values, (2) resampling or (3) selecting more sensitive methods of analysis. Defining probable ranges for a reported value can be performed when the bias associated with analytical accuracy is known and when the precision of an analytical test is known. Replicate samples are commonly used to define the precision of an analysis in terms of relative percent difference or relative standard deviation. A range of probable concentrations can then be derived by adding and subtracting percent bias and relative standard deviations (having a corresponding probability) to the reported concentration.

Some variation in reported results can contribute to differences in analytical reliability between laboratories. This variability is likely to be small relative to spatial variability of contaminants within a sample or about the site, particularly for solid matrices. If the variability in results between laboratories is a concern, this concern can be addressed by having split samples or laboratory performance audit samples (i.e., a sample spiked to known quality) analyzed by different laboratories. Uncertainty due to laboratory variability can be reduced by maintaining the same laboratory over the course of a project.

The spatial variability of contaminant concentrations and physical properties of contaminated media on-site can impart significant uncertainty on the interpretation of data. Replicate samples can provide valuable information regarding the spatial variability within the media sampled throughout the site and provide an indicator as to how well a single sample reflects "representative" conditions for a given location. Reported concentrations for replicate samples taken from soil or sediment could easily differ by as much as a factor of two (relative differences greater than 66%). Such variability could be contributed by both the variability inherent to the sample collection and analysis used and the difficulties in homogenizing the sample.

The collection of samples that are representative for an area typically requires that replicate, co-located or composite samples be taken from the area in question. Replicate and co-located samples can provide a means of estimating the variability at a given point and, therefore, may prove more useful than composites unless the areas to be remediated are well-defined and concentrations are well above detection limits. The use of screening methods and correlations can help reduce cost, but may have limited use as input data to risk assessments.

The uncertainty in values estimated for unsampled locations can be equally as important as, if not greater than, the uncertainty in sampled locations (i.e., reported values). Analysis of uncertainty in unsampled locations generally requires some consideration for spatial statistics. Spatial statistical analyses can be used to estimate probabilities of locating or classifying areas as above or below action levels and can assign probabilities to estimates of volumes of contaminated media.

Several examples of how spatial statistical methods can be used to quantify probabilities of grid sampling networks to locate "hot spots" are found in the literature. The application of these methods requires some prescription of permissible conditions, e.g., the definition of maximum allowable probability of a false positive or false negative for the maximum hot spot area to go undetected or be misclassified. The sampling grid that provides the desired level of confidence can be determined using readily available nomographs.

While interpolation can be used to estimate values at unsampled locations, simple interpolation does not provide measures of the uncertainty associated with the estimate. Kriging and probability kriging, also known as geostatistical methods, have been applied to estimate concentrations at unsampled locations and to estimate uncertainty associated with the estimates. Kriging uses a generalized least squares approach to model and predict spatial correlation of a given parameter. The model uses weighted averages of known values to estimate values for locations having undefined values. The method attempts to account for spatial dependence, i.e., that the magnitude of the difference in observations increases as the distance between sample locations increases, using a statistic similar to a covariance. The method also estimates (quantitatively) the uncertainty associated with the estimated values. This information has been used to assign confidence limits to estimated values, which has implications for estimates of average concentrations for risk assessments or volumes of contaminated media in feasibility studies.

The application of these methods, however, requires some understanding of the algorithms and their limitations, can increase the number of assumptions input to the data analysis and may not produce results more accurate than would be produced by applying best practical judgment given the available information. The utility of the method is that it can provide an approach to deriving confidence intervals for estimated values.

UNCERTAINTIES IN DEFINING THE LEVEL OF RISK

Considered by many to be the cornerstone of the RI/FS, the risk assessment must fashion a quantitative description of the risk a site poses to human health and the environment based on theoretical and empirical equations that incorporate an admittedly high level of uncertainty. Although it has undergone some recent revisions, the approach used to perform risk assessments is somewhat standardized through the direction of U.S. EPA guidance documents. The U.S. EPA guidance on preparing risk assessments has devoted a section exclusively to uncertainty analysis. While U.S. EPA guidance calls for risk assessments to discuss uncertainty in the risk assessment in some detail (e.g., the weight-of-evidence analysis), quantitative analysis is not recommended. U.S. EPA guidance, although acknowledging that the risk measures are "not fully probabilistic estimates of risk," suggests that highly quantitative statistical uncertainty analysis usually is not practical or necessary. Many of the factors used in the risk calculations, however, do have probabilities associated with them, and the approach is based upon a number of assumptions that have limited scientific supporting evidence.

Estimated risks for carcinogenic chemicals, for example, are calculated based upon an assumed dose, an estimated potency of the carcinogen and an assumed exposure period, each of which has an associated probability of occurrence. Exposure concentrations typically used are the 95% upper confidence limit on the arithmetic average (or geometric mean) of measured concentrations in the media of concern. Carcinogenic risk is a product of the concentration value and the dose, which incorporates the slope factor. The slope factor, which estimates the risk per unit dose, typically represents an upper 95th percentile confidence limit on the probability of a response per unit intake of a chemical over a lifetime. Clearly then, the risk assessment does incorporate some confidence intervals in the calculation of risk. Risk assessments, however, typically do not address this confidence analysis in a quantitative manner.

Alternative approaches to risk assessments that incorporate some quantitative methods for addressing uncertainties have recently been proposed. Burmaster[2] suggested the use of Monte Carlo techniques to develop probability distributions for risk, where the input parameters are permitted to be random independent variables. This approach clarifies the fact that a significant number of assumptions are used to derive the estimated risk and also provides an alternative means of estimation.

The technique, and other methods like it, requires that the probability distributions of each random variable, e.g., the amount of soil or water ingested per day, be defined. In all likelihood, these distributions would have to be assumed. The U.S. EPA guidance argues that, for this reason, the value of this technique is greatly diminished and review becomes too cumbersome to handle. Instead, the guidance suggests presenting quantitative

uncertainty analysis graphically for individual parameters to illustrate the relative sensitivity of each parameter.

Alternative approaches to evaluation of uncertainty would be to calculate risks from a variety of input combinations of estimated probability for individual parameters. For example, risks could be calculated for any combination of the possible exposure periods (with associated probability), exposure concentrations (with associated probability) and possible exposure weights (e.g., child vs. adult). The combinations could be assembled to illustrate the range of possible risks.

UNCERTAINTIES IN THE SELECTION OF REMEDY (THE FEASIBILITY STUDY)

The purpose of the FS is to define an appropriate remedial action, assuming one is warranted. More often than not, the selection of a remedy will be influenced most strongly by the perceived capabilities of the alternatives' technologies to achieve the remedial action goals, and the comparative cost of the alternatives. The performance of a technology can be assessed best through bench- and pilot-scale testing. Testing should be performed not only on "representative samples," but also the range of input conditions likely to be encountered by the technology. This process requires that the variability in characteristics be defined. The quantity of media considered contaminated (i.e., the volume) will greatly influence the estimated costs of the alternatives. An assessment of the uncertainty in the estimated volume of contaminated media will require not only an estimated distribution of contaminants about the site, but also an estimate of their spatial variability.

One of the simpler approaches to evaluating uncertainty in the extent or volume of a contaminated soil is to use best judgment (e.g., based on historical use patterns and physical barriers to contaminant transport) in conjunction with some linear interpolation to contour around observed values to estimate the volume of contaminated soil. While such an approach may be supported by the available information, it may incorporate some bias in the interpretation and does not generate information that can be used to estimate the confidence in the values outlined. Alternative approaches include the use of statistical methods such as kriging. The U.S. EPA has proposed the use of geostatistical methods such as kriging for the development of sampling plans.[13]

An advanced method of kriging, e.g., probability kriging, has been used to derive probability-contour maps, i.e., concentration contours having associated confidence limits.[5] This method is significantly more complex than ordinary kriging, however, and is not as readily available for application as ordinary kriging. An alternative approach is to use the estimation variance, derived in ordinary kriging, to derive volumes with associated confidence intervals. This approach assumes that the kriging variance (estimation variance) is normally distributed, and the use of this approach has been cautioned by some researchers due to the sensitivity of the calculated kriging variance.[13]

Volume typically is not as significant an issue of uncertainty in groundwater remediation as it is for soil. Groundwater remedies, by and large, can be designed to be robust, implemented in phases or modified without substantial loss in work performed to date or increase in overall capital cost. Nevertheless, the evaluation of uncertainties can become worthwhile when capture zones for wellhead protection and tradeoffs of maximizing cleanup times while minimizing capital costs are to be evaluated. A variety of work has been done to date in the evaluation of uncertainty in the effectiveness of groundwater pumping schemes. Many of the quantitative approaches to evaluating this uncertainty address aquifer parameters such as transmissivity or porosity as a random variate. The WHPA model, for example, incorporates a subroutine for quantitatively characterizing uncertainty in the effectiveness of an extraction well to contain a groundwater plume by use of Monte Carlo simulation with parameters such as transmissivity and porosity as random variables.[15] The model, however, ignores the correlations that exist between parameters and is limited to the application of a single extraction well in a homogeneous aquifer. More elaborate analyses, where the aquifer is treated as nonhomogeneous, have been investigated by a number of researchers. Because uncertainties in aquifer parameters and extraction system performance generally are resolved through pump tests, an "observational approach"[1] to investigations may prove to be more cost-effective than detailed uncertainty analyses.

CONCLUSION

Methods of quantifying uncertainty in the RI/FS process have been developed, and more methods are likely to be developed in the near future. Although they may introduce greater complexity to the decision-making process, the need to address uncertainties will become more important to devise defensible sampling strategies and remedial actions, given the scientific limitations in the data and in the methods of analysis used. Uncertainty analyses should be a principal focus of the RI/FS and should be used to develop appropriate contingency plans to the selected remedial action plan. The consequences of not addressing uncertainty will depend on the extent to which PRPs, the public and the agency overseeing the RI/FS consider uncertainties to be an issue.

Indirect Assessment of Risk to Groundwater from Hydrocarbon Contamination in Overlying Soils

Jeanne S. Wallberg
Brown and Caldwell Consultants
Sacramento, California

ABSTRACT

A leak in a petroleum pipeline in California's Central Valley contaminated the adjacent soil with hydrocarbons. The initial investigation established that high levels of total petroleum hydrocarbons (TPH) contaminated the area's clayey jointed soils to a depth of 30 feet. The unsaturated zone was known to be at least 40 feet deep, but depth to groundwater was uncertain. The TPH contamination appears to follow a 90 degree joint set and has a sharp, well-defined base. Benzene, ethylbenzene, toluene and xylene (BETX) constituents also were determined to be present.

Brown and Caldwell Consultants (BCC) proposed assessing the risk to groundwater indirectly by applying, in the field, the Leaking Underground Fuel Tank Field Manual (LUFT Manual) risk assessment procedures of the California State Water Resources Control Board. The advantage in using this method was the avoidance of drilling to possibly great depths through a clean soil column. The procedures assess the risk of groundwater contamination on the basis of cumulative BETX concentrations in the soil column. If the cumulative concentrations indicated no risk, drilling would cease. If risk were indicated, drilling would continue to groundwater and a groundwater sample would be collected for analysis.

The California Regional Water Quality Control Board, Central Valley Region (Regional Board), the agency charged with protection of water quality in the Central Valley, insisted on a direct groundwater sample. BCC installed a monitoring well in May of 1990 and collected groundwater samples for analysis. BCC also later characterized BETX contamination of the soil column according to the LUFT Manual method. Application of the LUFT Manual method in the field would have resulted in drilling to 75 feet, terminating the borehole in the unsaturated zone and concluding that groundwater at a greater depth would not be contaminated. After installing a groundwater monitoring well and collecting a direct sample, BCC found that groundwater, occurring at 106 feet below ground surface under confined conditions, had not been contaminated with hydrocarbons leaching from the soil contamination.

INTRODUCTION

A leak in a pipeline carrying petroleum products contaminated approximately 33,000 yd³ of soil with hydrocarbons. The products carried in the pipeline include a gas-oil mixture, crude oil and petroleum distillate with carbon chain lengths ranging from C-6 to C-32. Figure 1 shows the site, borehole locations, the monitoring well location installed during the investigation and two cross-section lines.

The pipeline is located in the California Central valley adjacent to the California Aqueduct (Aqueduct). The pipeline leak occurred at a bend in the pipeline where the pipeline crosses the Aqueduct. The Aqueduct is a concrete-lined canal carrying water from the Sacramento-

San Joaquin Delta to southern California.

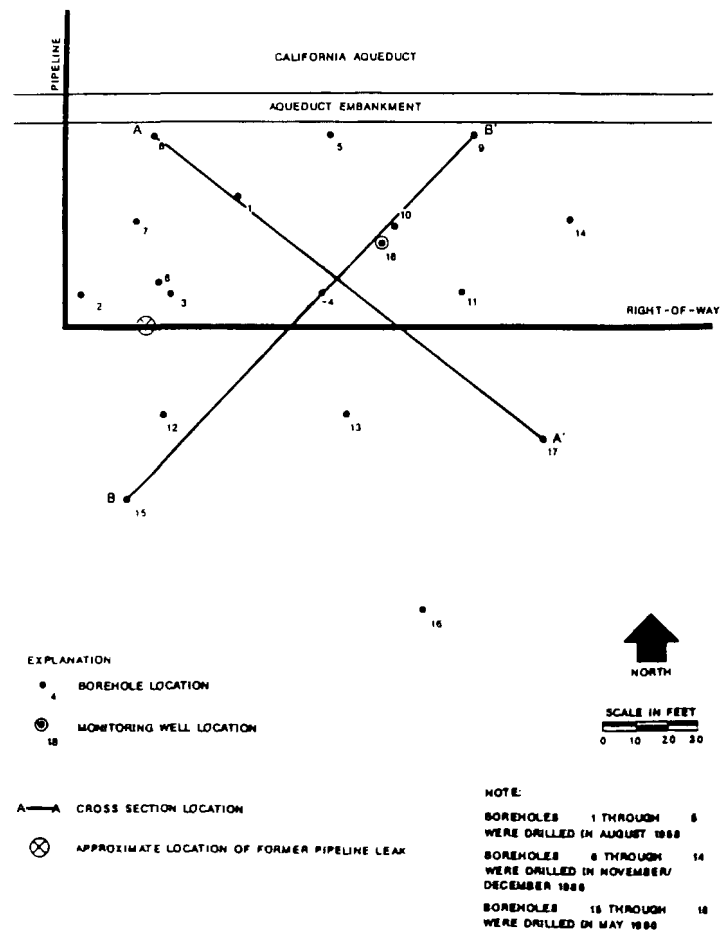
The two major concerns were that hydrocarbons might have contaminated the underlying groundwater and that hydrocarbons might enter the water carried in the adjacent Aqueduct. The leak site was approximately 8 feet below ground surface and 60 feet from the Aqueduct embankment. Approximately 50 yd² of contaminated soil are in contact with the Aqueduct embankment (at the location of Borehole 5; Fig. 1). The concern was that any bank storage water contaminated with hydrocarbons might leak into the Aqueduct. After discussions, BCC


Figure 1
Site Map

and the California Department of Water Resources (DWR), which operates the Aqueduct, agreed that during normal operation of the Aqueduct, the pressure of water in the canal against the sides of the Aqueduct should prevent any significant amount of Aqueduct water in bank storage from entering the canal.

The initial investigation, which took place in the summer and fall of 1988, succeeded in defining the extent of soil contamination at the leak site. Fourteen continuously cored boreholes (Boreholes 1 through 14) were drilled to 30- to 40-foot depths. Borehole core samples were almost entirely dry clay with evidence of joints. Contour maps of the TPH analytical results of the soil samples at 5-foot intervals were used to estimate the volume of contaminated soil and to depict the occurrence of the contamination. These contour maps indicated that most of the contamination had migrated from the leak site in two directions: to the southeast and to the northeast. These apparent migration routes, along with the joints identified in the core samples, indicated the presence of two joint sets, one set parallel and one set perpendicular to the regional northwest strike. Figure 2 shows two cross sections drawn parallel and perpendicular to the regional strike, with the TPH contamination shown in profile. The bulk of the contaminated soil was found to occur between 10 and 25 feet below ground surface. The highest TPH concentration at 20 feet below ground surface was 40,500 mg/Kg. The deepest TPH contamination was found at 30 feet below ground surface. Groundwater was not encountered in any borehole.

ASSESSING THE RISK TO GROUNDWATER

The Regional Board was concerned that the hydrocarbons in the soil, particularly the more mobile BETX constituents, might have migrated downward and contaminated groundwater beneath the site. The Regional Board requested that groundwater monitoring wells be installed and groundwater samples be collected.

Little information was available on depth to groundwater beneath the leak site. The site lies at the western edge of the Great Valley Geomorphic Province of California. It is south of the San Francisco Bay area near the boundary between the Central Valley and the Coast Ranges. Unconsolidated and semi-consolidated sedimentary deposits of Tertiary- and Quaternary-age (including the Plio-Pleistocene-age Tulare Formation) overlie the Coast Range rocks. The Coast Range in this area is a folded and faulted sequence of metasedimentary rocks of marine origin and basement rocks of Jurassic-, Cretaceous- and Tertiary-age. The Tulare Formation, which crops out at the site, is a regionally extensive unit made up of beds, lenses and tongues of clay, sand and gravel. Thick layers of clays accumulated in intermittent shallow lakes during deposition of the Tulare Formation. This formation is the major fresh water-bearing formation in this part of the Central Valley and contains water under a variety of pressure conditions, including unconfined, semiconfined and confined.

A record search of existing well logs yielded little useful information on depth to groundwater. A field survey was conducted of wells at the nearest residences and businesses. On the basis of these data, static water level was estimated to be approximately 70 feet below ground surface at the project site. However, no direct measurements or well logs were available from the field survey. In addition, the information gathered was from wells on both sides of the Coast Range-Central Valley boundary. Uncertainty over whether the information obtained from the field survey was accurate and applied to the same aquifer made a reliable estimate of depth to groundwater difficult.

BCC was concerned about avoiding drilling through a thick column of uncontaminated soil to collect a groundwater sample. BCC and the Regional Board discussed what criteria to use in making field decisions about how far to drill before deciding that a direct sample was not necessary and they could conclude that groundwater had not been contaminated. BCC proposed applying the *Leaking Underground Fuel Tank Field Manual's* risk assessment procedures to make field decisions. The *LUFT Manual* risk assessment procedures include a method for determining if a column of soil with known BETX concentrations represent a risk to underlying groundwater. The method is intended to aid in establishing soil cleanup levels at a site where depth to groundwater is known. BETX concentrations from soil samples collected from the borehole column at 5-foot intervals are individually summed. The resulting cumulative concentrations are compared with distance to groundwater and mean annual precipitation to arrive at acceptable levels of soil contamination protective of groundwater quality. The acceptable levels have been determined from modeling of environmental fate and chemical data for BETX. The suitability of this risk assessment procedure for a particular site is determined by a check list that includes geomorphology; surface recharge; extent of soil contamination; maximum BETX concentrations; subsurface conduits; the presence of structures such as fractures, joints or faults; a minimum distance between soil contamination and groundwater; and the presence of sand or gravel layers. This particular site met all check list requirements, with the exceptions of the extent of soil contamination and the presence of joints in the soil.

To use this method as a field tool, BCC proposed having soil samples collected at 5-foot intervals with analysis on 24-hour turnaround for BETX. When the cumulative concentrations were known and acceptable depth to groundwater for those concentrations determined, BCC would drill to that depth. If the soil column beneath a cumulative concentration level was free of contamination and groundwater was not encountered, BCC would not install a monitoring well, but rather would grout the borehole back to ground surface. If groundwater was encountered, a monitoring well would be installed. If additional contamination was encountered, the cumulative concentrations would be redetermined and the process would continue until either the required column of clean soil was encountered or groundwater was encountered.

Because the Regional Board knew of several cases where little or no TPH or BETX were found in the soil column yet groundwater was contaminated and because of the volume of contaminated soil at this site, the Regional Board did not allow this use of the *LUFT Manual*

method. Instead, it required the installation of a monitoring well and the collection of a groundwater sample.

INSTALLATION OF THE GROUNDWATER MONITORING WELL

In May 1990, a 115-foot deep monitoring well was installed at the site in Borehole 18. Three additional boreholes (Boreholes 15, 16 and 17) also were drilled at this time to confirm the earlier estimate of soil contamination. During drilling of Borehole 18, a continuous core was collected for lithology and samples were collected for analysis for BETX and TPH at 5-foot intervals. Dry, fractured clay extended to 40 feet below ground surface. A 15-foot-thick clayey silt was encountered beneath the near-surface clay. Massive, unfractured clay was found beneath the clayey silt to a depth of 106 feet below ground surface, at which depth groundwater was encountered under confined conditions in a silty sand. Groundwater rose in the borehole to 47.5 feet below ground surface.

During initial installation of the monitoring well, the bentonite seal placed on top of the well sand pack could not withstand the 58.5 feet of pressure head in the annular space. The bentonite collapsed when grout was added. Groundwater rose to the surface in both the annular space and the well casing. The grout entered the sand-packed annular space, the screened interval of the well and possibly the aquifer. The casing string was pulled out of the borehole and cleaned. The borehole was reamed and the well was successfully reinstalled with a much thicker bentonite seal. The lithology of Borehole 18 and the construction of
Figure 3
Geology of Borehole 18

the well are shown on Figure 3.

Trace BETX concentrations extended 15 feet below any detectable TPH. There were approximately 15 feet of clayey silt underlain by approximately 50 feet of massive clay between the BETX in the soil

and the groundwater. TPH and BETX concentrations in the soil column are shown in Figure 4.

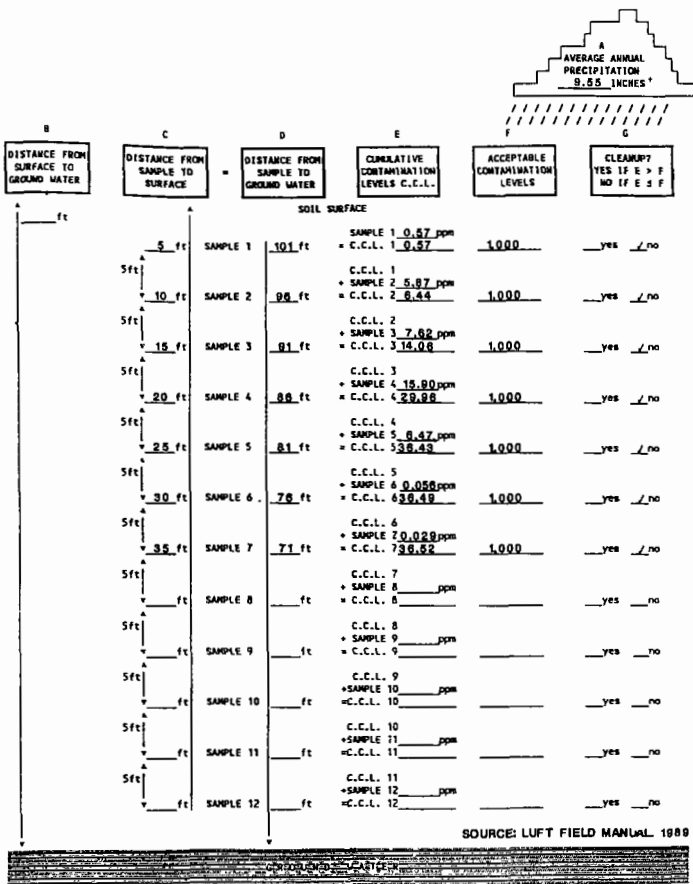
Cumulative gallons purged	440	770	1,520

[a]Field measurement.

A total of 1,520 gallons of water was purged from the well over the course of three sample collection events. Electrical conductivity and pH were monitored during all purging events. The BETX concentrations in the three groundwater samples collected are shown in Table 1. The field-measured pH and cumulative total gallons purged at the time of the sample's collection are also shown. A definite correlation between declining BETX concentrations and pH with increasing volumes of groundwater purged from the well can be seen. The high pH is attributed to the effects of grout entering the groundwater during the initial construction of the well. The initial BETX concentrations in groundwater samples are attributed to contact with the near-surface soils during the time the borehole was drilled and remained open during the construction of the well. The borehole was completely filled with a groundwater, grout and sand mixture during initial construction of the well.

The occurrence of TPH only in the jointed clays suggests that vertical contaminant transport, like the lateral transport along suspected joint sets, is joint controlled. BETX constituents have migrated slightly deeper


than detectable TPH. The massive clay layer beneath the deepest BETX occurrence appears to have effectively retarded any further vertical migration.

Considerable purging of the well has almost removed the contamination introduced in the immediate vicinity of the well during drilling/installation. BCC believes the aquifer has not been contaminated by leaching processes. The pressure head exhibited by groundwater in the confined aquifer indicates the massive clay aquitard is probably laterally extensive and can be expected to continue to act as an effective barrier to downward contaminant migration.

APPLICATION OF THE *LUFT MANUAL* RISK ASSESSMENT PROCEDURES

The *LUFT Manual*'s risk assessment procedures were applied to the BETX concentration results in the soil column of the 115-foot-deep monitoring well following the completion of the fieldwork. This was done by BCC at their expense to satisfy curiosity about whether, in hindsight, the field application of the *LUFT Manual* method at this site would have been a good procedure.

Of the four BETX constituents, the benzene cumulative concentrations were found to be the driving force in how deep the borehole would have been drilled if the method had been used in the field as BCC proposed. The environmental fate worksheet for benzene at this site and the table for acceptable cumulative soil contamination levels for benzene are shown in Figures 5 and 6, respectively.

The benzene cumulative concentrations would have indicated that groundwater at a depth of 75 feet below ground surface would not have been at risk of benzene contamination. Upon drilling to 75 feet below ground surface and finding no detectable benzene between 35 feet and 75 feet, BCC would have terminated the borehole at that depth and grouted. It would then have been presumed that groundwater beneath the site (deeper than 75 feet below ground surface, although the actual depth would remain unknown) was not contaminated with hydrocarbons.

CONCLUSIONS

The application of the *LUFT Manual* risk assessment procedures as a field decision tool at this site would have resulted in terminating the borehole at 75 feet below ground surface. It would have been established

Note: Individual concentrations for any soil sample cannot exceed 100 ppm. The numbers in this table do not represent soil concentrations; they reflect the accumulation of pollutant mass in contaminated soil. These numbers can be derived from the LUFT manual worksheet (Table 2-3).

SOURCE: LUFT FIELD MANUAL, 1989

Figure 6
Acceptable Cumulative Benzene Contamination Levels

that 45 feet of massive, low permeability, uncontaminated clay existed between the contaminated soil and a depth of 75 feet. The decision to terminate the borehole at 75 feet would have been reasonable.

This case history application of the indirect *LUFT Manual* method of assessing the risk of groundwater contamination from hydrocarbon contamination in the overlying soil, supported by direct evidence collected at this site, suggests that the *LUFT Manual* method could be used in lieu of direct groundwater samples at similar sites. It points out the need to move away from adhering rigidly to the idea that direct samples are always necessary. More flexibility in designing fieldwork (and changing fieldwork in progress as additional geologic information is collected) should be allowed.

Monte Carlo Techniques for Quantitative Uncertainty Analysis in Public Health Risk Assessments

ABSTRACT

Most public health risk assessments combine a series of average, conservative and worst-case assumptions to derive a conservative point estimate of risk. However, this procedure has major limitations. This paper demonstrates a methodology for extended uncertainty analyses in public health risk assessments using Monte Carlo techniques. The extended method begins as some conventional methods—with the preparation of a spreadsheet to estimate exposure and risk. This method, however, continues by modeling key inputs as random variables described by probability density functions. Overall, the technique provides a quantitative way to estimate the probability distributions for exposure and health risks within the validity of the models used. As an example, this paper presents a simplified case study for children playing in soils contaminated with benzene and benzo(a)pyrene.

INTRODUCTION

Following guidance published by the U.S. Environmental Protection Agency (EPA), most public health risk assessments combine a series of average, conservative and worst-case assumptions to derive a point estimate of risk that is conservative, i.e., protective of public health.[1,2] The *Interim Final Human Health Evaluation Manual*,[3] the most recent guidance document from the EPA headquarters, states:

"...Each intake variable in the equation has a range of values. *For Superfund exposure assessments, intake variable values for a given pathway should be selected so that the combination of all intake variables results in an estimate of the reasonable maximum exposure for that pathway.* As defined previously, the reasonable maximum exposure (RME) is the maximum exposure that is reasonably expected to occur at a site. Under this approach, some intake variables may not be at their individual maximum values but when in combination with other variables will result in estimates of RME..." (page 6-19, emphasis in the original).

Unfortunately, the Agency offers no further definition—either qualitative or quantitative—for the key concept of reasonable maximum exposure. The guidance does not address the amount of conservatism which should be used in risk assessment.

Current risk assessment procedures have three major limitations. First, by selecting a combination of average, conservative and worst-case assumptions, risk assessors and risk managers have no way of knowing the degree of conservatism in an assessment. Second, by setting the bias high enough to swamp the uncertainty for each of many variables—but not necessarily all the variables—the risk assessment considers scenarios that will rarely, if ever, happen. Third, it is fundamentally meaningless to run traditional sensitivity analyses (e.g., to make calculations at $\pm$ 10 or $\pm$ 25 percent from each input value) to determine the uncertainties in the final point estimates because many of the

input variables are at or near their maxima. Thus, the current procedures offer comfort if the estimated risk falls below a de minimis value, but they offer no interpretation if the estimated risk exceeds a de minimis value.

Developed long ago, Monte Carlo simulation addresses the weaknesses of the current risk assessment methods identified above.[4] In extending the regular methods for public health risk assessments, Monte Carlo techniques add several steps to estimate both point values and full distributions for the exposures and risks.

First, the analyst determines (continuous or discrete) probability density functions to describe each of the variables to be included in the uncertainty analysis. In this step, the analyst must also determine if any correlations exist among the input variables and take appropriate actions if they do.

Second, the analyst uses suitable software to make a large number of realizations of the random variables in the model. For each realization, the computer draws one random value from the appropriate distribution for each of the random variables in the model and computes and stores a single result. This computation is repeated a large number of times.

Third, with computer assistance, the analyst retrieves the results and establishes: (1) the shapes of the distributions for intermediate and final results and (2) various statistical summaries of the results. In this framework, a complete risk distribution is derived from distributions for the antecedent variables.[5-7] These extended techniques make the analyses more informative to risk managers and members of the public.[8]

In Monte Carlo simulation, each of many input variables can become a random variable (rv) with known or estimated PDF. [Equivalently, an input variable can be specified by a cumulative distribution function (CDF)]. Within this framework, a variable takes on a range of values with a known probability.

The PDFs for the final estimates are often highly non-Gaussian in shape for two reasons. First, some or all of the input variables may not have normal or even symmetric distributions. Second, the input variables enter the formulae by multiplication and division (and subsequent summation), so that even if all inputs have Gaussian distributions, the results will not.

To illustrate the application of Monte Carlo simulation to human health risk assessment, we consider a simplified case for a hypothetical site. We estimate the PDFs and summary statistics for the Incremental Lifetime Cancer Risk (ILCR) for one scenario involving exposures to two chemicals (benzene and benzo(a)pyrene) found in soil for two exposure pathways: (1) inadvertent ingestion of soils and (2) dermal contact with soils. We choose PDFs for the key input variables. By assumption, each of these distributions is statistically independent of

the others. (This assumption of independence limits the analysis as discussed below.) Each of these assumptions is reasonable (or not unreasonable) in view of the current knowledge and belief. The resulting simplified risk assessment illustrates the strengths and weaknesses of the Monte Carlo method.

While the Monte Carlo approach has many strengths and while it provides quantitative estimates of the distributions of the exposures and risks to people in certain situations, the results from this simplified analysis (and any simulation) are limited by many explicit and implicit assumptions. We present this simplified analysis to explore and demonstrate the approach as an extension to methods currently recommended by the U.S. EPA, not to claim that it represents an exhaustive treatment of the technique. We seek to illustrate the Monte Carlo method as applied to a simplified public health risk assessment and we seek to extend probabilistic analyses and interpretations in such assessments.

HYPOTHETICAL SITE AND EXPOSED POPULATION

For this report, we create a hypothetical site and an exposed population for analysis. Acme, a private company, owns the 500-ft by 600-ft site which is located at the edge of Central City. Beginning its operations in the early 1850s, Acme used and maintained 27 coke ovens and 2 gas holders and produced blue gas at the site until 1945 when the buildings and equipment were demolished. From 1952 to 1988, Baker Company leased the southern third of the property from Acme for use as a fuel storage and tank truck depot.

Central City created a 20-acre City Park to the north of the site in 1933. In 1989, Central City asked Acme to donate or sell the whole property to them to enlarge the City Park. At first, thinking that they might develop the site, Acme cleared the site and removed the visually stained surface soils. However, in further talks with the city last year, Acme agreed in principle to sell the property for inclusion in the park. Depending on the outcome of a site risk assessment for the surface soils on the site, Acme retains the right to limit the use of the site to activities with little or no soil contact, e.g., a parking lot with concession stands or a swimming pool with large concrete pavilions.

Since our purpose is to illustrate the use of Monte Carlo simulation, we consider only one of the many scenarios which could be considered for this site. The scenario considers children who play in the park extension contemplated for the old Acme/Baker property. We assume that the children will spend 3 hours per day playing at the park on the site and that they visit the park one day per week, 20 weeks per year for 10 years (from ages 8 to 18 years). We make the conservative and simplifying assumption that the children contact the soil enough with their hands and lower arms to have a rate of soil deposition on their skin of ~1 mg/cm² per day and they ingest ~50 mg per day of soil from the site.

Given the uncertainties inherent in an exposure assessment, this scenario is constructed in accordance with current U.S. EPA guidelines and using conservative (or health-protective) assumptions in the spirit of analyzing the RME case, not the absolutely worst case.

EXPOSURE MODELS

To estimate health effects for compounds with carcinogenic potencies, we first estimate the average daily dose that a person receives in units of milligram of bioavailable chemical per kilogram of body weight per day [(mg/(kg-day)], averaged over a 70-year life [abbreviated as the ADD(life)]. The scenario requires two exposure models: (1) incidental ingestion of soil and (2) dermal contact with soil.

Ingestion of Soil

In this simplified case, we consider exposures from the incidental and inadvertent ingestion of contaminated soil (i.e., we include only children who do not exhibit pica). We use the equation shown in Figure 1a to estimate the ADD(life), the average daily dose (bioavailable daily dose, averaged over a life in which exposure occurs), for inadvertent ingestion of contaminated soil.

Dermal Contact with Soils

Risk assessments often evaluate exposures from dermal contact with

contaminated soils. McKone (TM) recently completed a new model which estimates the uptake of chemicals from a soil matrix deposited onto the skin surface.[9] In the model, the stratum corneum is the barrier to uptake and the amount of chemical which passes through the stratum corneum represents the bioavailable dose. The model depends on scenario specific inputs, soil properties, skin properties and chemical properties of the soil contaminants. Although both continuous and one-time deposition versions of the model are available, we use the one-time or unit-deposition model in this simplified analysis.

$$ADD(life) = \frac{(Cs \cdot SIngR \cdot RBA \cdot DpW \cdot WpY \cdot YpL \cdot CF)}{(BW \cdot DinY \cdot YinL)}$$

where:

ADD(life)		average daily (bioavailable) dose, averaged over a lifetime (mg/(kg·d)),
Cs		soil exposure concentration (mg/kg),
SIngR		soil ingestion per day on a day of exposure (mg/d),
RBA		relative bioavailability (frac),
DpW	=	exposure days per week (d/wk),
WpY		exposure weeks per year (wk/yr),
YpL	=	exposure years per lifetime (yr/life),
BW	=	average body weight of the person (kg),
CF	=	conversion factor of 1 / 1,000,000 (kg/mg),
DinY	=	total number of days per year 7 (d/wk) · 52 (wk/yr), and
YinL	=	total number of years per lifetime (70 yr/life).

Figure 1a
Exposure Model for Soil Ingestion

McKone derives a Personal Exposure Factor (PEF) which, when multiplied by the concentration of the chemical in the soil, estimates the average daily dose on a day of exposure. This PEF is averaged over a day of exposure and is a function of 17 variables: average body weight, time the soil stays on the skin, average body surface area, skin area exposed, skin soil loading, soil bulk density, soil porosity, soil water content, organic carbon fraction of the soil, skin thickness, skin fat content, skin water content, boundary layer size, octanol-water partition coefficient of the chemical, Henry's Law coefficient of the chemical, diffusion coefficient for the chemical in air and diffusion coefficient for the chemical in water. To estimate the ADD(life) for dermal exposures, we use the PEF in the equation shown in Figure 1b.

$$ADD(life) = \frac{(Cs \cdot PEF \cdot DpW \cdot WpY \cdot YpL)}{(DinY \cdot YinL)}$$

where:

ADD(life)	=	average daily (bioavailable) dose, averaged over a lifetime (mg/(kg·d)),
Cs	=	soil exposure concentration (mg/kg),
PEF	=	personal exposure factor, averaged over a day of exposure (kg/(kg·d))
DpW	=	exposure days per week (d/wk),
WpY	=	exposure weeks per year (wk/yr),
YpL	=	exposure years per lifetime (yr/life),
DinY	=	total number of days per year 7 (d/wk) · 52 (wk/yr), and
YinL	=	total number of years per lifetime (70 yr/life)

Figure 1b
Exposure Model for Dermal Contact with Soils

Since McKone's model requires 17 inputs (and creating or finding 17 different parameterized distributions is an arduous task), we per-

formed a standard sensitivity analysis to identify the most sensitive inputs. By varying each input variable ± 10 percent from its nominal value while holding all the other inputs constant, we found those variables which have the greatest effect on the output when changed.

After defining our exposure models, we need to: (1) identify point estimates for all of the model inputs, (2) find in the literature or formulate distributions for the inputs we want to vary and (3) put all of the information into an appropriate simulation program. For use in both exposure models, we formulate distributions for the concentrations (mass fractions) of benzene and benzo(a)pyrene (BaP) in the site soils and the cancer potency factors (CPFs). Considering the results of the sensitivity analysis, we formulate distributions for 6 of the 17 input variables of McKone's model: body weight, the time soil stays on skin, skin area exposed, soil loading, bulk density of soil and skin water content. In addition, for the soil ingestion model, we formulate distributions for soil ingestion rates and body weight of the children. This gives a total of 11 parameterized distributions.

POINT ESTIMATES AND PARAMETERIZED DISTRIBUTIONS

In this paper, we use three well-known distributions to describe the key model inputs: the normal or Gaussian distribution, the lognormal distribution and the uniform distribution. We assume the reader is familiar with each of these distributions.

We denote random variable X with a normal distribution as X ~ Normal (μ, σ), where μ and σ represent the arithmetic mean and standard deviation, respectively. Similarly, the lognormal distribution is denoted as X ~ Lognormal (m, s) where m and s represent the arithmetic mean and standard deviation of the underlying normal distribution, respectively. (The underlying normal distribution is generated by taking the logarithms of the values in the distribution). Finally, we use the notation X ~ Uniform (x1, x2) to show that the random variable X is distributed uniformly between fixed minimum (x1) and maximum (x2) values.

Chemical Concentrations in the Soils

For this hypothetical site, we synthesize a data set consistent with the site history. We estimate the exposure point concentration for each chemical in the soils as the 95th percentile of the arithmetic mean of the soil data, i.e., 3.39 mg/kg for benzene and 29.49 mg/kg for BaP. Next, following the Monte Carlo framework, we fit lognormal distributions to the synthetic data for each chemical to estimate PDFs for the exposure point concentrations (where Cs represents the concentration of the chemical in the soils on the site in mg/kg): $Cs_{benzene}$ ~ Lognormal (0.84, 0.77) and Cs_{BaP} ~ Lognormal (2.81, 0.68).

Cancer Potency Factors

Because of the assumptions made and the methodology used in their derivation, CPF values estimated from human or animal data are inherently uncertain values. Extending the ideas in earlier publications,[15-17] Crouch evaluated the U.S. EPA CPFs for benzene and BaP and estimated the degree to which the U.S. EPA values are overly conservative. Based on this information, we parameterize the CPFs for benzene and BaP, for use in quantitative uncertainty analyses, as lognormal distributions conditional on certain modeling assumptions. The CPFs for benzene and BaP have these distributions and each in units of (mg/(kg-day))$^{-1}$]: $CPF_{benzene}$ ~ Lognormal (−4.33, 0.67) and CPF_{BaP} ~ Lognormal (−0.79, 2.39).

We choose the published U.S. EPA CPFs as the point estimates of the CPFs for benzene and BaP, 2.9E-02 and 11.5 (mg/(kg-day))$^{-1}$), respectively.[18-20] These values occur at approximately the 88th and 91st percentiles of their respective distributions.

Point Estimates and Distributions for the Variables in the Exposure Models

Table 1 shows the 27 variables and constants in the two exposure models and the two CPFs. The first two columns of the Table show the name, symbol and units of the variable or constant. The third column indicates whether the parameter applies to the dermal contact model, the soil ingestion model or both. The fourth column gives the

point estimates for the inputs and the fifth column shows the parameterized distribution we used for those inputs we chose to vary. The sixth column specifies the sources of each of the point estimates and distributions and the seventh column gives the location of the point estimate in the distribution. All of the point values are reasonable in the sense that the U.S. EPA has endorsed or could readily endorse the values for a particular site.

RISK ASSESSMENT

In keeping with the methods recommended by the U.S. EPA,[3,11] we use the equation shown in Figure 1c for estimating Incremental Lifetime Cancer Risk from low-dose exposure to carcinogens by compound and by pathway. In the absence of specific information on possible synergisms or antagonisms among carcinogenic compounds, the total ILCR is estimated by summing the values for each compound over all pathways.

$$\text{ILCR} = \text{ADD(life)} \cdot \text{CPF}$$

where:

ILCR	Incremental Lifetime Cancer Risk, the additional probability that a person will develop cancer during lifetime (dimensionless probability)
ADD(life)	Average Daily Dose of a compound, averaged over life during which exposure occurs, (mg/(kg·d))
CPF	Cancer Potency Factor for a compound, using ingestion ((mg/(kg·d))$^{-1}$)

Figure 1c
Equation to Estimate Incremental
Lifetime Cancer Risk

Computation of the Point Estimates of Risks

We have now described all of the components of the spreadsheet. For steady conditions, the algebra in the spreadsheet describe the governing equations for source strength, transport of the contaminants, exposures and toxicities. We calculate the point estimate of risk in the usual fashion by combining the point estimates for the inputs. These point estimates of risk represent the stopping point for most risk assessments.

Computation of the Distributions of Risks

We now estimate distributions of health risks using the spreadsheet and Crystal Ball^{TM}(Market Engineering Corporation, Denver, CO). In the last column of Table 1, the random variables are grouped according to their anticipated effects on the output. The Group I variables have symmetric distributions and the point estimates fall at the average or median value. The Group II variables also have symmetric distributions, but the point estimates fall between the 75th and 95th percentiles. The Group III variables have nonsymmetric distributions and the point estimates fall near or above the mean. The Group IV variables are the CPFs. Each of these different groups has a different qualitative effect on the distribution for exposure dose.

When only point estimates are used in the simulation, the histograms for the results appear as lines because there is no variability in the outputs and the point estimates for the outputs match those estimated in the spreadsheet. In this example, most of the total risk comes from the dermal contact with BaP. Figures 2(a-g) and 3(a-g) show the histograms for the ILCRs from dermal contact with BaP in soils and from soil ingestion of benzene, respectively, using: (1) the point estimates, (2) the Group I random variables, (3) the Group II random variables, (4) the Group III random variables, (5) the combination of Groups I, II and III random variables, (6) the Group IV random variables and (7) the combination of the Group I, II, III and IV random variables. The right-hand black triangle under the risk axis shows the location of the

point estimate, and the gray area of the distribution represents the portion of the distribution which exceeds the point estimate.

The Group I random variables (body weight, surface area, soil loading, soil bulk density and skin water content) have symmetric (normal or uniform) distributions and the point estimates fall at the center of the distributions. Consequently, we expect the Group I variables to cause lightly-skewed spread around the point estimate for the outputs, with little or no lateral shift. As expected, the Group I variables acting jointly cause almost symmetric variation about the point estimates for the outputs (Figs. 2b and 3b).

Table 1
Variables and Constants in Exposure Models

Name, Symbol	Units	Model	Point Estimate	Distribution *	Source	Point Estimate Location	Group
Scenario Specific Data:							
average body weight, BW	kg	both	47	Normal (47,8.3)	10 (11)	mean	I
time soil stays on skin, T	hr	dermal	8	Normal (6,1)	10	95th percentile	III

The Group II random variables include the concentrations of benzene and BaP in soils. Because the concentrations are modeled as lognormal distributions with the arithmetic means close to the point estimates, we expect these distributions will cause the results to have lognormally-shaped distributions. As expected, the distributions for the Group II random inputs cause moderately-skewed spread in the output distributions, with a general shift of the measures of central tendency for the output distributions to the left of the point estimates (Figs. 2c and 3c).

The Group III random variables include the soil ingestion rate, the time the soil stays on the skin and the fraction of the body exposed. For these random variables, the point estimates exceed the 70th percentile of the respective distributions, and we expect to see shifts in the distributions. As expected, the distributions in Figures 2d and 3d show dramatic shifts in the distributions toward values lower than the point estimates.

Figures 2e and 3e show the distributions with all Group I, II and III random variables in the simulation. As expected, these output

distributions have long right tails, high variance and average values much lower than the point estimates.

The CPFs for benzene and BaP with the distributions given earlier are the Group IV random variables. Figures 2f and 3f show the distributions for the five measures of risk. As expected, we see dramatic shifts in the distributions toward values lower than the point estimates. For each of the two pathways, the point estimates fall at the 88th percentile for benzene and the 91st percentile for BaP.

Finally, Figures 2g and 3g show the distributions with all Group I, II, III and IV random variables in the simulation. As expected, the output distributions in these figures have long right tails, high variances and average values much lower than the point estimates. The point estimates of risk fall between the 90th and 96th percentiles of the respective distributions. Comparing the results in the last three distributions of these figures, we see how combinations of conservative assumptions in the exposure scenarios (Figs. 2e and 3e) and in the Dose-Response Assessment (Figs. 2f and 3f) can shift the modes, medians and even

the 95th percentiles of the risk distributions far below the point estimates (Figs. 2g and 3g).

Simulation Tools, Run Times and Convergence

A variety of companies now sell software for running Monte Carlo simulations on microcomputers.[21-23] We prefer Crystal Ball^{TM}, which runs in conjunction with Excel^{TM} on Apple Macintosh^{TM} computers.

Crystal Ball^{TM} v2 running on a 25-MHz Apple Macintosh^{TM} IIci computer performed all the simulations in this report. A simulation with 10,000 iterations takes ~16 minutes. We compare the results from independent simulations as a way to test the convergence and stability of the results for the highly skewed distributions shown in Figures 5e and 6e. First, for two independent runs of 10,000 iterations each, the estimated means, standard deviations, variances and the 90th and 95th percentiles agree within one percent. Second, for two independent runs of 10,000 and 20,000 iterations, all of the summary statistics—except the sensitive 95th percentile and maximum—agreed within one percent. From this, we conclude that 10,000 iterations are sufficient to ensure convergence and stability of the output distributions. In a comprehensive Monte Carlo simulation, the analyst may spend a significant portion of time determining an appropriate number of iterations to support the final statements (unless the software does so automatically).

DISCUSSION

Advanced spreadsheets running on powerful personal computers now provide an easy and fast way to estimate full probability distributions for human health risks in assessments conducted for sites with chemical contamination. While the methods are straightforward and can easily be extended to linked spreadsheets and while the arrival of new software such as Crystal Ball^{TM} speeds the computations, more research is needed to determine and justify the specification of input distributions for exposure-related variables, and new methods are needed to quantify the distributions appropriate for Cancer Potency Factors.

As mentioned previously, the conclusions reached in this report rest on many assumptions which simplify the analysis but which also limit the results. While it is not possible to list all the simplifications — hence limitations — it is important to discuss some of the main types and to give illustrations. First and foremost, the report uses greatly simplified equations to estimate exposure to chemicals. While in the spirit of current federal guidance for public health risk assessments, these equations are dramatic simplifications of reality. This example demonstrates the point: the equation used to estimate children's exposure to soil ignores changes in body weight and in behavior as a function of age. The equation rests on the further assumption that all children are identical in size and behavior—surely an oversimplification.

Second, the report ignores obvious correlations among variables. As a prominent example, body weight and skin area are certainly correlated and the joint distribution of these variables is again a function of the age and sex of the child. As a less visible example, the thickness of the skin and the water content of it are surely correlated, if not related directly.

Third, even in the Monte Carlo simulations, the report treats many variables known to be stochastic as deterministic. For example, the simulations consider that children visit the site: (1) on a fixed number of days per week, (2) for a fixed number of weeks per year and (3) for a fixed number of years in their lives. Surely these simplifying assumptions limit the interpretation and application of the results. While it is relatively easy to overcome the third class of oversimplifications and limitations within current knowledge and computational resources, much more research is needed to address and resolve the serious limitations imposed by the first two classes of simplifying assumptions.

A Classification System for Hazardous Chemical Wastes

Michael Crutcher
Frank L. Parker, Ph.D., P.E.
Vanderbilt University
Nashville, Tennessee

INTRODUCTION

Man has always lived with some degree of exposure to toxic materials in both the forms of natural toxins and natural background radiation. With the industrialization of society, the amount and type of toxic materials entering the environment has changed dramatically. Many of these compounds are manmade and their effects are, as yet, uncertain. The growth of industry and the country's population have increased the potential for exposure to the public and concern over the effects have risen.

Recent estimates are that industry in the United States alone generates approximately 2,500 pounds of hazardous wastes per capita each year.[1] As waste products are an inevitable consequence of production and consumption in today's society, the elimination of vast and increasing quantities of waste is an important issue facing us in the future. Despite the land ban provisions of RCRA and its amendments,[7] the ultimate fate of many hazardous waste materials is through land disposal. Landfills are simultaneously objectionable, undesirable and necessary.[2] They remain a requirement to assist in the protection of public health and safety through the prevention of uncontrolled disposal.

Presently all hazardous chemical wastes are subject to the same land disposal requirements, although many chemicals behave quite differently in the natural environment. The fate of hazardous chemical wastes in the environment is dependent upon both the characteristics of the site and the physical and chemical properties of the waste. Although characteristics of the site are quite variable from location to location, many of the physical and chemical properties of the wastes remain relatively constant. Since properties of chemical compounds will remain relatively constant at different sites, it may be possible to develop a ranking system based on these properties.

A simple, quick method of ranking hazardous substances can be used to assist managing the disposal of these materials. The use of chemical and physical parameter values, without applying weighted numbers, allows the ranking to be done objectively. As part of the decision-making process, the disposal method may be incorporated as a function of the potential hazard of the substance. One possibility is to consider those compounds with low potential hazards as candidates for municipal or sanitary landfills, while the higher potential hazard compounds should be immobilized, incinerated or placed in hazardous waste landfills with different degrees of retention.

The three chemical properties used to rank hazardous compounds are: toxicity, degradation potential and adsorption potential. The toxicity of a substance essentially describes the degree to which adverse effects may result from that substance. The more toxic a substance, the less of the substance is required to cause adverse effects. Degradation is the breakdown or change of a chemical in the environment. Many compounds are known to decay to less toxic substances quite readily, others

may remain in their original form for extended periods of time, and some hazardous compounds degrade to compounds of equal or greater toxicity. Adsorption is the ability of chemical substances to attach or bind to solid surfaces such as soil or aquifer materials. Many chemicals have a strong adsorption potential and may become relatively immobile in the environment.

RANKING ALGORITHM

Several ranking and classifications of hazardous substances have been promulgated. Many chemicals are classified into groups such as the persistent pesticide classification of Rao and Davidson:[3] pesticides are grouped as either nonpersistent, moderately persistent, or persistent. Others[4-6] have used the classification of degradable and nondegradable for other groups of compounds such as solvents and aromatic hydrocarbons.

Under RCRA,[7] hazardous wastes are classified as hazardous by their ignitability, corrosiveness, reactivity and toxicity. This method, however, gives no indication as to their potential environmental hazards once placed in a landfill. A bench mark ranking comparison was conducted by Conway[8] for pesticides. This comparison used the contaminants' physical constants to determine a leaching index, volatilization index and an exposure index. It ranks pesticides in the near surface application area.

Often ranking models rely on establishing a set of criteria such as chemical constants, hydrogeologic conditions, site designs and various other factors. Each criterion is then given a weighted index value which is then used to determine the environmental risk. The weighted values is often determined quite subjectively and may incorporate political and sociological factors that have little scientific basis.

The three characteristic parameters used in ranking substances are the chemical's toxicity, its adsorption potential and its potential for degradation. Adsorption and degradation are used because they are the two most important chemical characteristics that determine the ultimate fate of hazardous substances in the environment. The toxicity of a hazardous substance determines what concentration of the substance is necessary to have an adverse affect upon humans and/or the environment.

The toxicity level and the adsorption potential are used to determine a Hazard Potential Number (HPN) which can be defined by the equation:

$$HPN = 10^6/(K \text{ Tox}) \qquad (1)$$

where
HPN = Hazard Potential Number (unitless)
Tox = maximum concentration level (mg/L)
K = adsorption or distribution coefficient (mL/g)

and 10^6 is the constant used to convert units.

The HPN is inversely proportional to the toxic concentration of the compound. When comparing hazardous substances, the smaller the concentration required to create adverse conditions (10^{-6} cancer risk, death, etc.), the greater risk or potential for risk exists. The HPN is also inversely proportional to adsorption. Adsorption can be defined by a chemical's adsorption or partitioning constant. Again, a substance with a small adsorption constant indicates that it will not be readily adsorbed to soil and aquifer particles. Compounds that are not strongly adsorbed will tend to leach and migrate from their original source location and become a greater risk of possible contamination.

After determining the HPN for each chemical, the degradation process is considered. The degradation process for hazardous substances is often modeled using a first order reaction. The hazard potential can be viewed as reducing with time by the same first order reaction, so the equation will appear as:

$$HPN = HPN_o \exp[(k_b + k_H)t] \qquad (2)$$

where:

HPN = Hazard Potential Number (dimensionless)
HPN_o = Hazard Potential Number at time, t_o (dimensionless)
k_b = biological degradation rate constant $(time)^{-1}$
k_H = hydrolysis degradation rate constant $(time)^{-1}$
t = time

Since the amount of a chemical at a site will degrade and reduce exponentially with time, the HPN can be viewed as decreasing with time in a similar manner.

The hazard potential of a substance, with respect to time, can be characterized graphically, as in Figure 1, and several hazardous substances can be compared simultaneously.
Figure 1
HPN vs. Time
Organics and Lead—Aerobic/Hydrolysis

The Hazard Potential Ranking depends upon several assumptions. The first assumption is that adsorption can be described by a linear isotherm and that an infinite number of adsorption sites exist, i.e., adsorption of the compound will always occur. The second assumption is that conditions exist for degradation to occur at the described rate. This essentially means that microorganisms are present for degradation, the necessary aerobic or anaerobic conditions are present and environmental conditions such as pH and temperature are met. Additionally, it is assumed that the products of degradation are less hazardous than the original substance or they are not hazardous. This means that their adsorption will not decrease and that they are either not toxic or less toxic. The final assumption is that equal amounts or concentrations of each hazardous substance exist. For any individual site, a weighted average hazard potential ranking could easily be calculated. However, at that time, all the site characteristics should be taken into account to determine the true hazard rather than the hazard potential.

TOXICITY

The toxicity of a hazardous substance is the concentration level at which adverse affects will occur to humans and/or their environment. The effects may be either acute or chronic. Exposure concentrations are established by government agencies such as the U.S. EPA or OSHA. To establish concentration levels, both exposure and health outcome data must be analyzed. Generally, extrapolations must be made from animal and/or human studies at high dose rates. This extrapolation is performed using either the threshold model for noncarcinogens or the linear no-threshold model for carcinogens (Figure 2). The threshold theory (Curve A) states that there exists a dose, at low levels, where no adverse effects might occur. The most common extrapolation for carcinogens is the linear no-threshold model, (curve B), which assumes that no dose level exists at which no biological effect occurs and that the degree of effect is directly proportional to the dose.[9] The no-threshold model is considered to be a conservative model that does not account for any type of biologic repair mechanisms.
Figure 2
HPN vs. Time

Organics and Lead—Anaerobic/Hydrolysis

Correlation of chronic exposure is typically done on a population basis. Rates of illness in exposed populations are compared with reference populations. This effect is expressed as an exposure level that will cause a 10^{-5}, 10^{-6} and 10^{-7} increase in the effect. A maximum lifetime risk of 10^{-6} is considered to be an acceptable individual risk standard for exposure to carcinogens.[10] The U.S. EPA has established, in a series of publications,[11-18] the ambient water quality drinking levels at which effects may occur for many hazardous substances. The toxicity values used in this ranking model were all obtained from these publications and used the 10^{-6} risk values.

ADSORPTION

The adsorption process is the second key parameter in determining the HPN of each chemical. Adsorption is the accumulation or concentration of chemical contaminants on the soil or sediment surfaces.[18] The fate of a chemical in the environment is highly dependent upon its adsorptive behavior. Adsorption of chemicals onto soils and aquifer materials causes a reduction or retardation in the rate of movement of a contaminant through the soil or aquifer. Extremely strong adsorption may render a contaminant essentially immobile, although eventually all the adsorption sites could be occupied and breakthrough would occur. It is believed to assist directly and indirectly in the pollutant degradation process.[4]

Adsorption is generally described by the Langmuir and the Freundlich adsorption isotherms. The Freundlich isotherm can be further simplified to a linear isotherm. When adsorption can be defined as a linear relationship, the slope to the line is defined as the distribution or adsorption coefficient, Kd. The distribution or partitioning coefficient, Kd,

can vary widely between chemicals as some are more readily adsorbed than others. Additionally, for the same chemical, the degree to which it is adsorbed has been found to vary widely from soil to soil. Many researchers[19,20] have found that the adsorption of many organic compounds is dependent upon the organic content of the soil or aquifer particles. Karichoff[19] has shown a linear relationship between adsorption and organic carbon content which can be written as:

$$Kd = K_oc \times oc \qquad (3)$$

where

Kd = distribution of partitioning coefficient
K_oc = organic carbon partitioning coefficient
oc = fraction organic carbon.

Adsorption of organic compounds with respect to organic carbon, (K_{oc}), remains relatively constant for a given chemical and is nearly independent of soil type. The organic carbon partition coefficient generally assumes a linear isotherm exists for the determination of the distribution coefficient (Kd). The organic carbon partition coefficient does begin to lose consistency as soil organic carbon becomes extremely low or extremely high. Organic carbon partition coefficients are listed in several publications and also may be obtained from equations relating octanol-water partition coefficients with organic carbon coefficients.[36] The organic carbon partition coefficient was used for ranking organic chemicals.

DEGRADATION

The degradation or transformation process is the final parameter used in ranking the hazard potential of chemicals. Degradation of contaminants is a major process that determines the fate of many organic chemicals in the environment. Degradation can be described as the breakdown or transformation of a chemical substance into another substance. A fast degradation rate means the chemical may reach a safer concentration level quickly. As organic chemicals degrade, they may be transformed into less complex, more degradable and possibly less toxic substances. Degradation of chemical substances can occur by chemical and biological routes.

The rate of degradation by biological and chemical methods of many organic chemicals is dependent upon many conditions. The rate constant is often viewed as a pseudo-first order constant. Under actual environmental conditions, the rate constants for various chemicals can range over 14 orders of magnitude with corresponding half-lives of a few seconds to more than 100,000 years. Rate constants determined under laboratory conditions must be used with caution when applied to actual environmental conditions. Factors such as pH, temperature, catalysts and soil/sediment conditions may effect the rate constants.

Hydrolysis is a chemical transformation process in which an organic compound reacts with water forming a new carbon oxygen bond and cleaving an original carbon bond in the original organic molecule. A simple reaction can be defined by:

$$R-X \rightarrow R-OH + X^- + H^+ D \qquad (4)$$

The resulting product can then be more readily degraded or metabolized and may be less toxic than the initial substance.

Biological degradation is the transformation of chemical compounds by living organisms, generally bacteria and other microflora. Microorganisms can play a major role in the fate of organic chemicals because of their abundance, diversity, high metabolic activity and adaptability to varying environmental conditions. Microorganisms within the subsurface environment that breakdown or transform naturally occurring organic compounds have always existed and it has been shown that many of these same microorganisms are able to degrade synthetic or man-made organic chemicals.

The biodegradation process can occur under both aerobic and anaerobic conditions. Generally, the structure of the compound will determine under what condition and at what rate it will degrade. Some substances may degrade in both environments, possibly at different rates, while other substances may readily degrade only in the aerobic or

anaerobic environment. The biodegradation of many aromatic compounds requires molecular oxygen and therefore aerobic conditions. Many chlorinated hydrocarbons, such as pesticides, have been shown to degrade more readily under anaerobic conditions.[4]

Biological degradation is difficult to study in the natural environment, therefore laboratory studies such as microcosm studies are conducted. In general, a soil or aquifer sample is collected and the desired chemical substance is added to the sample. Under controlled conditions the loss of substances is measured at specific time intervals.

Mathematical modeling of both degradation processes can be described using first order kinetics. The use of first order kinetics also allows the easier application of the analytical transport model for evaluation. The first order model means that the rate of degradation is dependent upon the amount of substance and can be expressed by the equation:

$$d[C]/dt = -kx [C] D \qquad (5)$$

where

C = concentration of contaminant
t = time
k = first order rate constant

This can be integrated over time to obtain the equation:

$$C = C_o \exp[-k \times t] \qquad (6)$$

where

C_o = concentration at t_o

CHEMICAL INFORMATION

Seven different chemical compounds were used in this ranking model. The chemicals ranged from an elemental heavy metal to aromatic hydrocarbons to chlorinated hydrocarbons. The parameter values were obtained from various literature sources and are listed in Table 1. Degradation rate constants are reported in aerobic, anaerobic and field conditions when possible. Additionally, hydrolysis rate constants are reported for some compounds when available.

Table 1
Parameter Values

Chemical Compound	Toxicity (day-1)	Log Koc (ml/gm)	Aerobic Biodegradation (day-1)	Anaerobic Biodegradation (day-1)	Hydrolysis (day-1)	Field Degradation (day-1)	Ref
Benzene	4 6 E-04	2 03	0.042	0.004	---	--	11,19,21-24

DDT = Dichloro-diphenyl-trichloroethane
DCM = Dichloromethane
TCE = Trichloroethylene

DISCUSSION

Comparison of Organic Chemicals

Despite a thorough computer search of the relevant literature and discussions with experts in the field, it quickly became obvious that there were insufficient data of adequate quality to develop a ranking system with enough compounds to make it generally applicable. Therefore, only six compounds for which sufficient information was available have been analyzed. These six chemical compounds were compared with respect to each other under three environmental degradation processes: anaerobic biodegradation, aerobic biodegradation and hydrolysis. The six hazardous compounds used are benzene, chloroform, DDT, dichloromethane, heptachlor and trichloroethylene. These were the six compounds with the best available degradation rate constants under all three conditions. Of the six compounds, four (DDT,

chloroform, DCM and heptachlor) have essentially equivalent initial HPNs followed by benzene with trichloroethylene having the lowest value. (Table 2)

Table 2
Hazard Potential Numbers (HPN) for Lead and Organics

Chemical Compound	Log HPI Koc (dimensionless)	Kaolinite		Montmorillinite	
		Log Kd (ml/gm)	Log HPN (dimensionless)	Log Kd (ml/gm)	Log HPN (dimensionless)
Benzene	7.15	-0.26	9.44	-0.006	9.19
Chloroform	8.19	-0.76	10.56	-0.51	10.29
DDT	8.27	3.06	10.05	3.31	10.31
DCM	8.28	-0.85	10.57	-0.60	10.32
Heptachlor	8.17	2.09	10.46	2.94	10.28
Lead @ pH 5.5	---	1.63	5.67	1.85	5.43
TCE	6.57	-0.29	8.86	-0.04	8.60

Comparison of Heavy Metal Lead & Organic Compounds

Metal ion adsorption cannot be directly correlated to the fraction organic carbon or to the organic carbon partition coefficient as with many organic compounds. To make a comparison between organic compounds and the heavy metal lead, the distribution coefficient, Kd, must be determined for the desired organic compound. For the two clay soils, kaolinite and montmorillinite, used in the lead adsorption analysis (USEPA 1978),[36] the percent organic carbon was 0.51% for kaolinite and 0.92% for montmorillinite. The Hazard Potential Number of lead (Figures 1 and 2) was compared with the organic chemicals benzene, dichlorobenzene, heptachlor and trichloroethylene at pH 5.5 for both soil types.

The Hazard Potential Number is a changing value. With time, the potential hazard of compounds can begin to decrease often at different rates. This process allows some substances with initially higher potential hazards to become less hazardous. This is the case with heptachlor and TCE under aerobic conditions. Initially, heptachlor is a much higher potential hazard than TCE, but it degrades more rapidly and its potential hazard drops below TCE. Comparing the changing HPN values under anaerobic and aerobic conditions shows how important the environmental conditions become in evaluating hazardous substances. Not only are the majority of the evaluated compounds degraded more readily under anaerobic conditions, but their relative risks are also changed after sufficient time has passed. DCM, which is less toxic than DDT, has essentially the same initial potential hazard because of its mobility in the subsurface. Degradation changes their relative potential hazard depending upon the environmental conditions. Because DCM has not been shown to degrade under aerobic conditions, its risk of exposure will depend upon a low hydrolysis rate constant while DDT is biodegradable at a faster rate and its overall hazard potential will decrease more significantly with time. Under anaerobic conditions, however, DCM's potential risk will decrease much more rapidly and become less than that of DDT's, given sufficient time.

When evaluated as a function of time, the respective ranking orders change in both aerobic and anaerobic environments. The initial ranking at time zero under both environments is DCM > DDT > chloroform > Heptachlor > benzene > TCE. Under anaerobic conditions (Figure 1) TCE degrades more slowly than the other evaluated compounds. After 100 days, its relative position has moved up dramatically to just below dichloromethane, which is essentially nonbiodegradable under anaerobic conditions. The new order becomes DCM > TCE > DDT > chloroform > benzene > heptachlor. The time for the HPN to decrease under anaerobic conditions is much less for several of the compounds as shown in Figure 2. Again, the ranking order changes significantly after 100 days to benzene > TCE > chloroform > DDT > DCM > heptachlor. This is essentially a complete reversal in the ranking order.

CONCLUSIONS

Most classification systems result in an invariant system. Sometimes this is based on conditions at a generic site with a specified transport time to the point of ingestion. Neither of these methodologies is satisfactory since degradation reduces the amount of a substance and decreases its potential exposure risk. Degradation has the ability to alter any ranking order with time. When degradation is incorporated into a ranking scheme as shown, hazardous substances can be compared at different time periods after disposal. This system shows how the properties of hazardous substances can be used in an objective ranking method and that the rankings can change with time.

Probabilistic Risk Assessment Applications to the Safety Evaluation of Technological Systems

Daniel Kofi Asante-Duah, Ph.D.
International Technology (IT) Corporation
Irvine, California

ABSTRACT

Risk assessment techniques provide a structured and systematic framework for evaluating the safety of technological systems. Information developed in the assessment aids in making decisions about the allocation of resources for safety improvements and hazard prevention by directing attention and efforts to the features and scenarios that dominate the risks.

Concepts and techniques for the application of risk assessment in relation to decisions on the safety evaluation of technological systems are provided. In particular, the basic concepts involved in the development and analysis of event trees, as applied to strategizing safety assessment tasks, are presented. The approach will provide an effective way to build the comprehensive and technically defensible information base necessary for tackling potential societal hazards. The emphasis is on identifying a systematic approach for assessing risk costs and other safety parameters associated with the failure of technological systems operating under several variable scenarios. By using the proposed methodology, those sequences of potential causative events and exposure scenarios contributing most significantly to risks can be identified and addressed.

INTRODUCTION

There is always some element of risk in every technological development/system. Faced with the bewildering array of risks in modern society, man is motivated more than ever before to develop systematic tools that will help bring the unpleasant but inevitable situation under control less expensively. This challenge is destined to remain alive. Systematic tools can be used to assess potential risks and courses of action to minimize the consequences attributed to such risks.

In recent years, great interest has evolved in the use of risk assessment tools for the evaluation of engineered facilities and other potentially hazardous activities. Risk assessment techniques provide a structured, systematic framework for evaluating the safety of such systems. In this manner, the risk associated with a decision alternative can be delineated and, if desired or necessary, measures can be taken to control or minimize the corresponding potential consequences.

Risk assessment generally embodies the heuristic approach of empirical learning, with large uncertainties in event probabilities and public consequences. Nonetheless, the central values of the final estimates do provide a "best knowledge" estimate of the relative importance of a risk. Through probabilistic modeling and analysis, uncertainties can be modeled and assessed properly, and their effects on a given decision can be accounted for systematically.

The process of quantifying risk does, by its very nature, deepen our understanding of the strengths and weaknesses of the system being examined. It shows where a given effort can do the most good in modifying a system to improve safety and efficiency. To arrive at more meaningful management decisions, however, results from the risk evaluation must also be supplemented, or complemented, with information relating to a number of external events.

PROBABILISTIC RISK ASSESSMENT (PRA) CONCEPTS

In a generic sense, risk assessment may be considered as a systematic tool for making estimates of all the significant risk factors that may prevail over an entire range of failure modes and/or exposure scenarios. The overall purpose of risk assessment is to provide a complete information set to risk managers, so that the best possible decision can be made concerning a potentially hazardous problem. A major goal in a risk assessment process is to identify failure modes and scenarios that will help work out methods to reduce the probability of failure and the attending human, economic and environmental losses of a failure event. Some major attributes of risk assessment include the following:

- It explicitly considers all failure modes and/or exposure scenarios
- It quantifies risks associated with the full range of loading conditions, system responses and exposure scenarios, not just extreme events
- It identifies factors and exposure routes contributing most to total risk of failure and/or exposure
- It facilitates determination of cost-effective risk reduction through remedial alternatives and/or risk management and prevention programs.

Tasks performed during a risk evaluation are intended to help answer the question "How safe is safe enough?" The type and degree of detail of a risk assessment performed will depend on the intended use of the process. Its purpose will shape the data needs, the protocol, the rigor and related efforts. Current regulatory requirements at the federal, state, and local levels are particularly important considerations in establishing acceptable safety levels.

Probabilistic Risk Assessment (PRA) is a method used to quantify the frequency of occurrence, the degree of system response and the magnitude of consequences of accident events or system failures at industrial facilities and other technological systems. Though its most extensive use has been in the nuclear industry, PRA has also been successfully used to estimate safety for a number of industrial facilities as well as for such undertakings such as the transport of hazardous materials. A PRA may use fault tree or event tree analysis. With the PRA method, risk is defined in terms of frequency and magnitude of consequences, or the failure probability. Subsequently, the product of frequency and magnitude, or the failure probability are summed over all incident sequences (Figure 1).

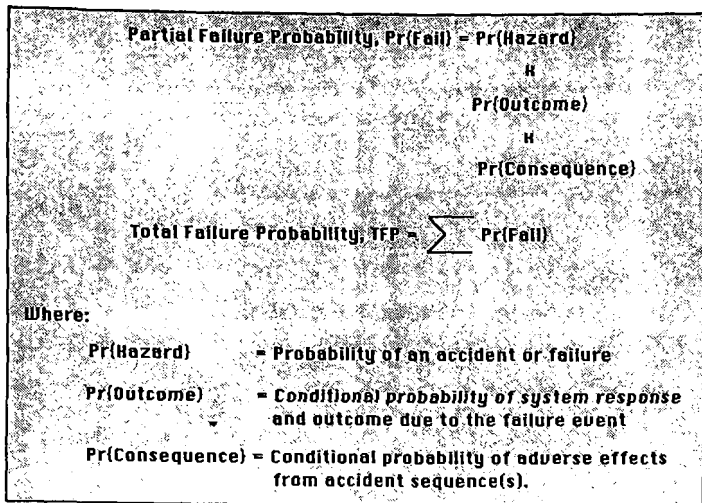
The concept of probability of failure required in the risk evaluation usually is defined by using the likelihood of structural breach and/or


Figure 1
Risk Definition in a Probabilistic Assessment

an accident event. Estimation of the applicable probability values is achieved by the use of reliability theory and/or expert judgments or by the use of stochastic simulations and historical information. A Bayesian approach may always be employed to update estimates on the basis of additional information acquired in time.

Through probabilistic modeling and analyses, uncertainties can be assessed properly and their effects on a given decision accounted for systematically. In this manner, the risk associated with given decision alternatives can be delineated and then appropriate corrective measures can be taken accordingly.

EVENT TREE MODELING AS A TECHNIQUE IN THE APPLICATION OF PRA TO TECHNOLOGICAL SYSTEMS

Two types of decision trees can be used to identify sets of events leading to system failure—event trees and fault trees. Event and fault trees are useful techniques for identification and quantification of accidents and failures of technological systems. In this paper, the author discusses event tree concepts only. The event tree model displays, in a rather explicit way, paths of the events that relate to the safety or potential for failure of a technological system and also the anticipated consequences for the various pathways. In many situations, fault tree analysis is used to supplement event tree modeling by using the former to establish the appropriate probabilities of the event tree branches.

The event tree is a diagram that illustrates the chronological ordering of event scenarios in a problem calling for decision analytical protocol. Each event is shown by a branch of the event tree. Event trees provide tools that can be used to analyze conditions that could potentially lead to adverse consequences. An event tree uses deductive logic, starting with an initiating event and then uses forward logic to enumerate all possible sequences of subsequent events that will help determine all possible outcomes and consequences. The event tree structure requires that each event level be defined by its probability, which is conditional on preceding events in the tree structure.

Events identified as part of a failure scenario can be displayed in a tree structure that represents a sequence of events in progression, displaying branching points where several possibilities can be anticipated that can lead to an event at the top. This technique basically is an algorithm in which it is possible to assign probabilities to each of the events. Then, by simply multiplying or adding probabilities, the overall chance of failure can be calculated for a given period of time. This technique can indeed help designers anticipate risk in order to correct problems at the design stage rather than through retrofit technologies.

The methodology presented models risk as a chain of interconnected events through the use of event tree analysis. The approach allows for a systematic consideration of all potential loading conditions that may be brought to bear on a system, the potential exposure scenarios fol-

lowing system breach and the consequences of all potential exposures to any population/receptors at risk. In general, the potential risk is modeled as a chain of interconnected events according to the following pathway concept:

HAZARD -> SYSTEM RESPONSE -> OUTCOME -> EXPOSURE -> CONSEQUENCE

This is systematically developed using an event tree.

A typical event tree scenario for an accident event can be developed according to the hypothetical illustration in Figure 2, displaying the logic used in constructing the event tree. This structure provides a systematic approach for decisions on potential hazards. It also provides a mechanism for tackling hazardous problems in a logical and comprehensive manner.

Some Basic Concepts in Probability Theory

A summary of the notations and theorems pertaining to some probability definitions and concepts used in this elaboration are given below. A more detailed review may be found in several standard textbooks of statistics and probability theory.

- *Conditional Probability*, $Pr\{A/B\}$ => the probability of occurrence of event A, given that event B has already occurred. This is the proportion/fraction of items resulting in event A amongst the total set of items that give rise to event B.
- *Unconditional Probability*, $Pr\{A\}$ => is the fraction of items resulting in event A, among the complete set of all items.
- *Joint Probability*, $Pr\{A \& B\}$ => the fraction of items giving rise to the simultaneous occurrence of events A and B, among the complete set of all items. Thus, $Pr\{A \cap B\} = Pr\{B\} \times Pr\{A/B\}$.
- *Independence* => Event A is said to be independent of event B if, and only if $Pr\{A/B\} = Pr\{A\}$. This means, the probability of event A is unaffected by the occurrence of event B and vice versa, so that, $Pr\{A \cap B\} = Pr\{A \cap B\} = Pr\{A\} \times Pr\{B\}$.

The Pathway Probability Concept

Where appropriate, in a probabilistic risk evaluation, the probability of a consequence due to the occurrence of a hazardous situation is defined by a so-called pathway probability (PWP), which is the product of an initiating probability value and the conditional probabilities of subsequent events. The consequence probability, defined by the PWP, is given by the following relationship:

$$
\begin{aligned}
PWP &= Pr\{H \cap R \cap 0 \cap E \cap C\} = Pr\{H \cdot R \cdot 0 \cdot E \cdot C\} \\
&= Pr\{H\} \times Pr\{R/H\} \times Pr\{0/H \cap R\} \times Pr\{E/H \cap R \cap 0\} \\
&\quad \times Pr\{C/H \cap R \cap 0 \cap E\}
\end{aligned} \tag{1}
$$

where:

$Pr\{H\}$ is the probability of a specific Hazard (H) of an initiating event occurring;

$Pr\{R/H\}$ is the conditional probability of System Response (R), given H;

$Pr\{0/H \cap R\}$ is the conditional probability of an Outcome (0), given H and R;

$Pr\{E/H \cap R \cap 0\}$ is the conditional probability of Exposure (E), given H, R and 0;

$Pr\{C/H \cap R \cap 0 \cap E\}$ is the conditional probability of specific Consequence (C), given H, R, 0 and E.

Risk Cost (RC) Computations

The cost associated with the probability of failure (i.e., risk cost) is based on anticipated consequences. This parameter may be computed according to the following relationship:

$$
\text{Partial RC, } Ci = PWP_i \times \text{Consequences, for i-th pathway} \tag{2}
$$

$$
\text{Total RC, } C = \Sigma C_i, \text{ for all existing N pathways} \tag{3}
$$

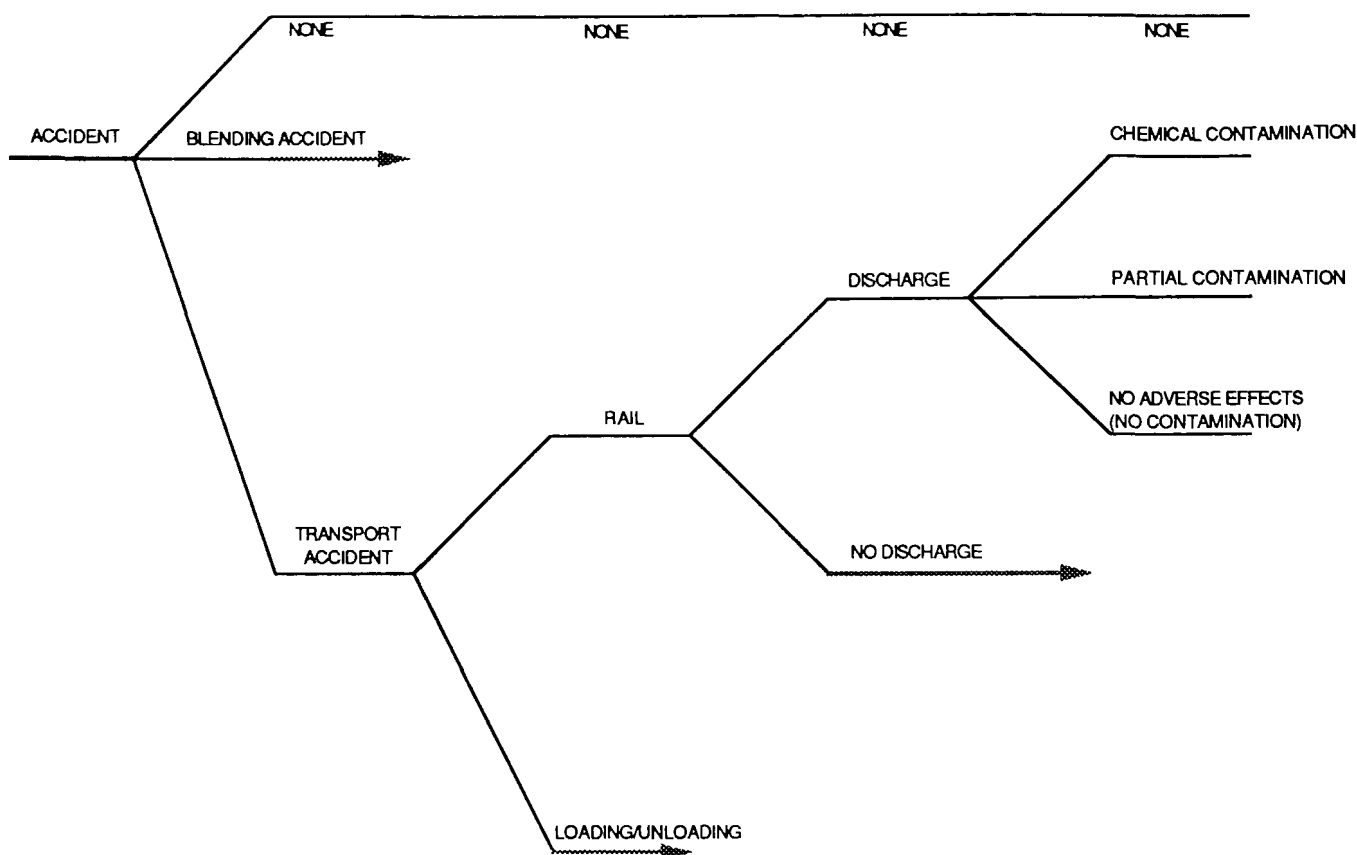
Level 1	Level 2	Level 3	Level 4	Level 5


Figure 2
Using the Event Tree Concept in the Probabilistic
Risk Evaluation Process

Assessment of Potential Life Loss, LL

The potential life loss depends on the exposed population (i.e., population at risk, PAR), and is computed as follows:

$$\text{Life Loss/Event} = \text{PAR}_i \times \text{Exposure Probability (EPi)} \tag{4}$$

$$\text{LL}_i = \text{PAR}_i \times \text{EP}_i \times \text{PWP}_i \tag{5}$$

$$\text{Total LL, LL} = \Sigma \, \text{LL}_i \tag{6}$$

Results from the event tree model can be put into a spreadsheet format for better comprehension. Such a formulation also allows for easy comparison of alternative remedial actions. The effect of each remedial alternative in reducing the risks associated with corrective actions for the technological system can be evaluated and compared.

POTENTIAL APPLICATIONS OF PRA IN THE SAFETY EVALUATION OF TECHNOLOGICAL SYSTEMS

The potential for failures of technological systems, the potential for human errors and the inherent uncertainties associated with technological systems, all pose some degree of hazard. Safety and/or risk analyses are techniques used to identify possible hazards and potential consequences. Such analyses will allow for a better design and/or operation that minimizes risks and/or that improves safety. In general, the safety analysis of technological systems incorporates several steps (Figure 3). The event tree concept aids in the identification and evaluation of possible failure cases which fully represent the spectrum of possible failure paths.

The event tree concept offers an efficient way to perform a probabilistic risk evaluation when necessary. This evaluation will aid in the development of a structured risk assessment framework that will facilitate systematic decision-making associated with failure of technological systems. Failures may range from design flaws and deficiencies or faults, to operational and traffic accidents, to natural and man-made disasters. The PRA method aids in estimating the probabilities of events with adverse consequences or the potential to cause adverse consequences. The technique presented may find several applications amongst those uses discussed below.

Hazardous Materials Storage Facility Design

Safety aspects of the design of a hazardous waste facility or a hazardous materials storage facility can be evaluated using the PRA methods. In this case, the risk evaluation will address the consequences associated with the probability of failure. Incremental risks due to failure, as a result of modifications in design criteria, also can be assessed. For instance, the probability of failure using only one liner versus the probability of failure using multiple liners in a hazardous waste facility design can be evaluated and compared using PRA techniques.

Hazardous Materials Containment and Facility Failure

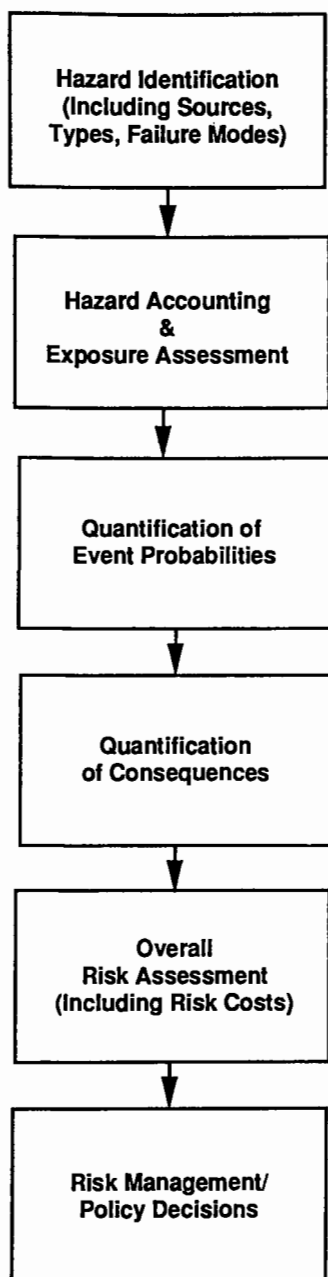
Risks associated with the failure of hazardous materials containments and other facilities can be evaluated using probabilistic risk assessment concepts. Failure is the result of containment breach followed by migration of the released contaminants through the environment. The risks associated with the failure of a hazardous materials facility can be evalu-


Figure 3
Steps in the Safety Evaluation of Technological Systems

ated using the event tree model. Probabilities of failure and conditional probabilities of system responses, outcomes and consequences are estimated and used for assessing potential economic losses as well as health impacts from a failure or an accident event involving hazardous materials containments.

Transportation Risks

Transportation risks can be analyzed for a system by examining several variables, including the road network, loading/unloading accidents and traffic density. In the transport of hazardous materials, an accident during transport will not necessarily cause a release. Therefore, transportation risks would be estimated as the product of the probability of an accident and the conditional probability of release from a given accident. The approach presented may find great use in assessing risks from transportation of hazardous materials.

Safety Evaluation of Engineering Structures

PRA techniques utilizing the event tree model can be used in the safety evaluation of dams and other engineered structures that will allow for evaluation of appropriate remedial alternatives by comparing potential life losses and economic damages that could result from breach of the structural integrity.

General Risk Management and Risk Prevention Programs

Risk management and prevention programs (RMPPs) are instituted to ensure reasonable safety of industrial equipment and facilities. Equipment failures will occur if and only if one or a combination of several initiating events occur that will lead to system responses that create adverse consequences. The event tree model, used in the context of PRA, facilitates the development of good RMPPs. Individual component failure rates for a given system can be used to estimate the potential for adverse situations for a given technological system.

CONCLUSIONS

The main objectives of this presentation have been to:

- Present concepts and techniques in risk assessment that may be applied to the safety evaluation of technological systems
- Provide a guidance framework for the formulation of risk assessment tasks for technological systems
- Define steps for carrying out specific safety and/or risk assessment tasks in the safety evaluation of technological systems

Major attributes of the methodology discussed here include the following inherent capabilities and features:

- It will explicitly consider all failure modes and/or exposure scenarios
- It will quantify risks associated with the full range of loading conditions, system responses and exposure scenarios, not just extreme events
- It will identify exposure factors and exposure routes contributing most to total risk of failure and/or exposure
- It will facilitate the determination of cost, effective risk reduction policies, or risk management and prevention programs

It is apparent that risk communication may dictate public perception and, therefore, public acceptance of risk mitigation alternatives. Thus, it may be important to give as much consideration to risk communication as is given to risk quantification. A systematic evaluation using structured decision methods, such as the event tree approach elaborated here, can greatly help in this direction. The event tree model can aid risk communicators in improving the quality and effectiveness of their performance.

Estimated Versus Final Costs on Hazardous and Toxic Waste Remediation Projects

ABSTRACT

An accurate cost estimate is an essential element for both budget planning and contract administration on hazardous and toxic waste Remedial Action projects. Typically, these estimates are prepared at the Record of Decision (ROD) stage by consultants responsible for the Remedial Investigation/Feasibility Study (RI/FS). This estimate is used primarily for budgeting purposes. At the Final Remedial Design (RD) stage, the estimate is more likely to be prepared by professional cost estimating engineers. This estimate is used as a confirmation of the budget and as a tool for evaluating contractors' bids prior to a contract award. A proper estimate is essential at both levels. However, our short history in remedial action projects indicates the potential inaccuracy of these estimates.

This paper presents a comparison of estimated versus actual remedial action cost. Factors affecting cost growth are identified and discussed with recommendations for an improved process.

INTRODUCTION

This paper reviews the factors affecting potential cost growth on remedial action projects. Cost growth is defined as estimates to the final Remedial Action cost, including all change orders and modifications. This potential cost growth represents a risk to agencies or other parties paying for the site cleanup. Thus, the potential cost growth also is referred to as a cost risk.

This paper first reviews the overall remedial action cost estimating process to provide a basis for additional discussion. A limited data base of Superfund remedial action projects is provided and discussed. Finally, key conclusions and recommendations for improvement in the process are presented.

CURRENT STATUS OF THE COST ESTIMATING PROCESS

Typically, cost estimates for a remediation project are undertaken during two distinct phases of the project's evolution. The first estimate generally is done during the remedial investigation/feasibility study phase. At this point, once the nature and extent of the contamination and the appropriated remediation technology have been identified, a cost estimate is prepared. It should be recognized that this estimate at best is of a conceptual nature. The RI/FS engineer prepares the cost estimate based on the feasibility study, relying on his or her general knowledge of the remediation process to develop a likely assessment of the cost. As no definitive design has been addressed yet, the cost is developed using unit prices for major work items typical for that type of technology and that type of project. Because of the very preliminary nature of the information available, a significant contingency normally is applied. The cost developed during this phase becomes a part of the ROD and becomes part of the initial project budget.

During the following phase, the Remedial Design/Remedial Action (RD/RA) phase, cost estimates often are undertaken at the 30%, 60% and final design submittals as they are typically done on conventional construction projects. The purpose of these estimates is to track the cost of the design with respect to the budget as the design evolves. Once in the actual design phase, it is possible for the estimator to begin to generate line item detail in the labor, material, equipment, overhead and profit classifications. As the design becomes more complete in the later submittals, the confidence level in the costing increases allowing a corresponding reduction in the design contingency. The final estimate provides a basis for the government's independent estimate of cost. Selected quantities contained in the estimate can be used to provide the basis for the government's tabulation of quantities for unit price items.

SUPERFUND PROJECT EXAMPLES

Table 1 shows a list of 44 Superfund projects which have been totally or almost completed. Thirty of the projects were taken from the General Accounting Office (GAO) Report "Superfund, Cost Growth on Remedial Construction Projects."[8] The remainder of the projects were the result of direct research by the authors, primarily telephone discussions with either EPA Remedial Project Managers or Corps of Engineers Project Managers. The majority of the projects are Superfund-led projects.

Following the example of the GAO report, the projects shown in Table 1 are divided into Routine and Nonroutine categories. Routine projects typically involve containment or provision of an alternate water supply. Nonroutine projects typically involve excavation of contaminated soil or of drums and barrels. The GAO report indicated an average cost growth (original to total construction) on routine projects of 5%, while nonroutine projects averaged 19% cost growth. Both were considered to be within the industry range for routine projects (2 to 12%) and nonroutine projects (up to 25%).

All of the additional projects researched by the authors were placed in the nonroutine construction category. As may be seen, there was significant cost growth associated with several Table 1 projects: Metamora Landfill (147.1%), ChemDyne (61.1%) and Highland Acid Pits (156.7%). Seven of the projects retained from the GAO report also experienced significant cost growth above the 25% industry standard. These ranged from the Bridgeport project (27.6%) to the Jibboom Junkyard (98.9%). The inclusion of the additional projects increased the average cost growth to 39.4%.

Figure 1 graphically indicates cost growth by remedial action type. Most of the projects which experienced large cost growth involved the excavation of soil or drums and barrels, with transport to off-site landfills or burial in on-site landfills. In all cases, the project managers reported that the cost growth resulted because the excavation revealed more contamination than was reported in the Remedial Investigation report.

Figure 1
Cost Growth By Remedial Action Type from the
Original Construction Estimate to
Total Construction Cost

Many of the other projects from the GAO report and our research experienced relatively little cost growth. Once project in Table 1 (Del Norte Pesticide in California) experienced a contract which was awarded based on approximately 4-year old groundwater analytical data. After the contractor began mobilization, the monitoring wells were resampled, and constituent levels were below action levels, apparently as the result of natural attenuation. Thus, the contractor's mobilization costs ($137,000) were needlessly expended.

Table 1 also indicates the cost estimate prepared as part of the Record of Decision (ROD) for selected projects.[1] Cost growth from the ROD estimate to total construction cost is shown on Figure 2. As can be seen, this ROD cost growth is generally greater than the cost growth from the original construction price. This result is not unexpected based on the lesser project definition at the ROD stage. However, examination of individual projects indicates no consistent trend in decreased cost growth from ROD to RD stages. This trend apparently results from the significant assumptions implicit at both estimating stages, and particularly the estimate of a contamination volume which may remain consistent in both stages.

CONCLUSIONS AND RECOMMENDATIONS

The following conclusions are based on the projects presented previously and the combined experience of the three authors.

Excavation-Based Remedial Actions
Pose a Greater Cost Risk Potential

The remedial action projects presented in the previous section demonstrate that projects involving excavation present the greatest risk of cost growth. The cause for this cost growth potential is clear. A typical site assessment, even a well-performed assessment, still represents only an approximation of Figure 2 the volume of contaminated material. Excavation, on the other hand, allows a direct examination of the subsurface and a revelation of previously undiscovered contamination. "Plume

chasing" in these cases leads to significantly higher excavation volumes and disposal/treatment costs, while confirmation testing to meet strict cleanup guidelines assures that the chase will not be prematurely ended. This reason for cost growth should not surprise anyone associated with normal construction excavation or underground construction activities. "Changed conditions" on these projects are the normal course of business. The erratic and elusive nature of contamination only tends to worsen this situation.
Figure 2
Cost Growth From ROD Estimate to Total Construction Cost

In contrast to projects involving excavation, most other remedial actions assume that the contamination volume has been correctly evaluated as shown conceptually in Figure 3. These types of projects may include pump-and-treat methods, in situ methods (such as biological treatment, vacuum extraction, in-place solidification, etc.) or containment (such as capping or slurry walls). Cost growth on these types of remedial actions is limited to the more typical change orders, etc. However, while in situ projects may not experience significant cost growth during construction, they may exhibit a greater cost risk during the O&M phase. In part, this cost increase occurs because the length of time associated with these projects usually is a rough estimate at best.

The Remedial Investigation

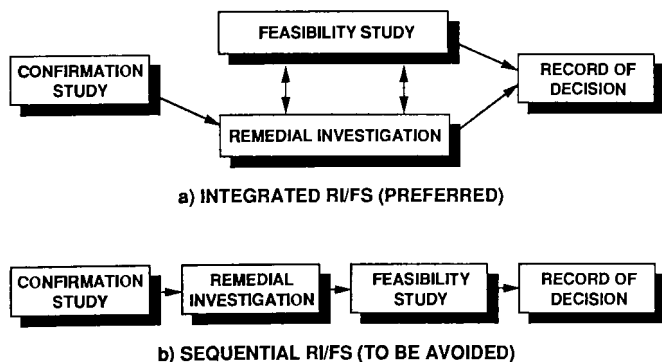
The previous discussion highlights the critical role the Remedial Investigation plays in the potential for cost growth. Remedial Investigations typically are expensive undertakings. Often, it is assumed that a reasonably complete RI will serve all purposes. This often may be the case. However, the previous data indicate that some RIs do not provide sufficient information to accurately estimate costs. We recommend that the RI be tailored to the anticipated remedial action. This tailoring is suggested in the U.S. EPA guidance for RI/FS studies[5] with an integration of the RI and FS activities (Figure 4a). The anticipated remedial action should be identified as early as possible in the FS, with the remaining RI activities geared toward a specific objective. Strictly sequential RI and FS activities should be avoided (Figure 4b).
Figure 3
Effect of Contamination Volume on
Excavation vs. In Situ Treatment


Figure 4
The RI/FS Process and Its Effects on Cost Growth

The question of "How much investigation is enough?" is highly relevant to the potential for cost growth. The hope is that increased investigation will reduce the potential for cost growth, while the fear is that mounting investigation costs will not be recouped during remedial action. A fundamental decision must be made early in the RI/FS process if an excavation-based technology will be used. If so, increased investigation is recommended to adequately estimate the excavation volume for budgeting purposes. However, the goal of this investigation should clearly be understood. The goal is not to precisely define the extent

of contamination, utilizing highly accurate methods with extensive QA/QC methods. These data are unnecessary because the volume of the contaminated soil will be clearly revealed during remedial excavation. Sampling and laboratory- analysis can be performed more accurately and economically while the excavation occurs and provides the community and regulators the requisite information to assure the site is "clean." Rather, the RI goal for an excavation-based technology is to roughly assess the volume of contaminated material for budgeting purposes only. These activities can be conducted using economical field screening and other less precise analytical methods. Using cheaper methods, a greater number of samples can be analyzed for the same or reduced cost as a detailed RI study. More accurate analyses can be conducted after the risk assessment, cleanup goals and appropriate remedial technology are developed. Also, it should be realized that for some projects no reasonable amount of investigation can adequately define the volume of contaminated material. For these projects, the construction contingency should be appropriately increased.

This emphasis on excavation-based versus nonexcavation-based RIs should not obscure the other potential effects of the RI/FS process on cost risk or absolute cost. As discussed previously, in situ remedial methods are typically straight-forward to implement (i.e., little immediate cost risk). However, significant cost growth may occur later if the system is ineffective or takes much longer to achieve cleanup goals than anticipated. Thus, the RI activities must adequately define the volume of contaminated materials (to the satisfaction of the regulators) and provide sufficient information about the complex physical and biological factors needed for an effective remedial design.

Finally, absolute cost, while not the subject of this paper, is an important and closely related subject. The RI/FS process plays a central role in absolute cost determination. Trained and experienced professionals in both the RI and FS areas are necessary to make informed and innovative decisions.

Effect of Quantity Overruns on Contracting Process

Federal policy with regard to construction type contracts has generally recognized that certain risks are potential costs to the government. In developing its contract documents, the federal government has in effect directed the contractor not to include costs to cover certain risks such as: (1) significant changes to the scope of requirements of the contract as a result of the direction of the government; and (2) significant differences in the character or condition of the work site between that which is represented by the contract documents or within the contractor's reasonable ability to determine and the actual condition when the work area is exposed. The reason for this governmental decision is that rather than incur the cost of the successful contractor's assessment of these risks on every contract, the government prefers to incur the cost of the risk only on those projects when the risk is realized. The two contract mechanisms by which this is accomplished are the "changes clause" and the "differing site condition clause" which are a part of almost all federal construction and remediation contracts.

In a typical fixed price remediation project, the contract documents might represent a quantity of contaminated earth to be removed and treated. This quantity has been calculated based on the site investigation data. The contractor relies on the government's representation of the quantity of contaminated earth in preparing his bid. After award of the contract and notice to proceed, it might be discovered that the contamination had been dispersed more widely than the site investigation data suggested. The government's only real choice at this time is to issue a change order to the contractor to remove and treat the additional quantity.

Typically, the contractor would respond to the change order with a price for the additional work, negotiate that price with the government and undertake the work. Generally the government has the right to direct the contractor to continue work on the additional work while the pricing and negotiations take place. If the negotiations are not successful, the government would likely issue a unilateral change order. Often the price for the change is negotiated covering the direct cost of labor, material and equipment only, the contractor reserving the right to claim for ex-

tended overhead and related costs on the completion of the project.

By their nature, remediation projects have high public visibility and are vulnerable to media coverage. As a result, the government often is under pressure to complete the remediation effort without delay. If, in dealing with the contractor, the government is burdened by inadequate contract documents resulting from the inclusion of incorrect quantities, it is quite possible that the completed projects costs will be higher than those originally bid when the final costs of change orders, extended overhead claims and litigation are tallied.

Most remediation projects are bid on the basis of a contract which includes a combination of lump sum and unit price items. Often the Government Contracting Officers, in order to "Tighten up the Contract," place some items whose actual quantities are unknown in the lump sum portion of the contract to reduce the number of unit price items. If during the remediation process, some of those items overrun, the costs of the affected items can be subject to renegotiation under the "changes" or "differing site conditions clauses." If the same items had been contracted as unit price items, they could be handled more simply and at reduced cost to the government.

Because of a desire to achieve "certainty" in the project cost, the government often does not desire to include an appropriate contingency in the final estimate. While this decision is understandable when dealing with Congress and budget agencies, the fact remains that on projects involving excavation, certainty of estimating the final cost is not likely. On projects requiring excavation of soil drums, the contingency factor should be higher than that used on a more standard remedial action project.

Other Factors Affecting Cost Risk

Inaccurate quantities cannot bear the responsibility for all the increases from budgeted costs to actual costs on remediation projects. Realistic costing while the design is taking form requires a quality estimating effort. The estimator needs access to an up-to-date data base which contains line items appropriate to remediation work. The data base needs to include remediation health and safety line items, remediation general conditions line items and the ability to factor conventional line items which occur on remediation projects for loss of productivity due to the presence of contaminants. One such data base is currently under development by the U.S. Army Corps of Engineers.

The Corps of Engineers' Walla Walla, Washington District office has been tasked with developing the data base to supplement the current data bases used on the Corps' Micro Computer Aided Cost Engineering System (MCACES), formerly called the Micro Computer Aided Cost Estimating System. MCACES is a PC based estimating system containing a data base of approximately 20,000 line items which are sensitive to crew size and composition, labor rates, equipment rates and productivity.

Another factor affecting the accuracy of final cost estimates for remediation projects is that the cost estimator rarely has access to the Final bid documents, including special contract provisions, bid item schedule and the time allotted for completion of the project, at the time the final estimate is prepared. These documents usually have not been prepared when the final cost estimate is made. This information, while available to the remediation contractor at the time of bid preparation, can greatly impact the independent government estimate.

Several other factors may play a significant role in the determination of cost risk and absolute cost. Schroeder and Shangraw[3] have prepared a data base with 40 private and public sector remedial action projects. Their conclusions, based on an analysis of this data base, are summarized in Table 2. Note that the table includes both conclusions supported by their analysis and those for which only a general suspicion exists. Also note that the authors cite this as a preliminary study to be modified by future analysis of projects.

Our experience allows us to suggest slight revisions to the preliminary conclusions drawn by Schroeder and Shangraw:[3]

- Clearly the stage of project definition is a factor in cost risk as recognized by the U.S. EPA guidelines of +50/-30 percent for FS studies, compared to higher standards Table 2 for RD level estimates. More

detailed design and more refined cost estimates should be available as the project progresses. However, if the site investigation does not provide a proper foundation for the cost estimate, cost estimating at any stage of project definition presents a significant cost risk. Prior action at a site should also reduce cost risk, as it allows a greater "window on the contamination" than available from typical RI studies.

Table 2
Summary of Schroeder and Shangraw[3] Preliminary
Conclusions on Factors Affecting Cost Risk

FACTOR	EFFECT	COMMENT
Stage of Project Definition (ROD, RD, etc.)	Major	Cost risk decreases with increased definition
Prior Action at Site	Major	Cost risk decreases when prior action has taken place
Types of Contamination	Mostly None	Major cost increase risk when tanks or drums are present
Treatment Technological	None	Slight decrease in risk when containment is employed
Regulatory Events	--	Suspect significant effect
Project Management	--	Suspect major impact
Public versus Private Cleanups	--	Suspect that private sector cleanups have less cost risk

- It appears that this type of contamination should significantly affect cost risk. For example, VOC is very amenable to in situ remediation techniques, whereas inorganic contamination is more likely to require and excavation-based technology. Thus, inorganic contamination should be prone to the greater cost risk related to excavation. This matter directly relates to the next category (technological complexity), as a back-hoe is not complex but represent a large potential for cost risk. Technological complexity as it relates to in situ methods may have more effect on increased O&M costs.

- Regulatory events could have a significant effect on cost risk. The Land Disposal Restrictions and interstate agreements on landfill disposal are of particular concern. Assumptions about transportation and disposal costs could shift significantly from FS or Remedial Design stage to actual implementation.

- The effects of project management and public versus private sector cleanup appear to be significant and interrelated. Many excellent professionals work in the public sector. However, the private sector is more likely to retain experienced project managers and provide them with more resources to allow them to make more consistent and informed choices.

CONCLUSIONS

The most significant factor affecting cost risk is the decision to use an excavation-based remediation technique. Excavation will reveal the full extent of the contamination, previously only estimated by the RI. Thus, greater investigation will be required to provide more confidence in the cost estimate. However, in some cases, no amount of investigation will be enough. Thus, contracting procedures must provide suffi-

cient flexibility to handle the increased cost risk on these projects. This recommendation means the cost estimate should include more unit price items (rather than lump sum) and provide a greater contingency than on other projects. Other factors may also influence cost risk, most notably the state of project definition, the type of contamination, regulatory events, and the skill and resources of the remedial action project manager.

Cost Inaccuracies in Superfund Projects: Strategies for Building Better Estimates

Brett R. Schroeder
Independent Project Analysis
Reston, Virginia

ABSTRACT

Estimates of cleanup costs during the 1980s failed to provide reasonably accurate projections of actual costs. This statement is especially true for federally-led Superfund projects. Two primary approaches have been used to tackle the problem of building better estimates. One approach is the development of computerized cost estimating systems for generating base estimates. The other approach is to build methods to better understand the cost risks for remediation projects. Currently, five major computerized systems are in existence for generating base estimates and two are actively under development. The majority of these systems provide early order-of-magnitude estimates of remedial construction costs. Unfortunately, little effort has been directed at understanding the cost risks of remediation. However, new methods such as Monte Carlo analysis and historically based models are now available that take into account project and site characteristics for assigning contingencies. The cost-estimating lessons learned from the experience of the 1980s demonstrate the need for adjusting estimates by taking into account the unique risks of each site. In addition, there is an ongoing need to collect better cost data and to improve other historically based statistical methods employed for building estimates.

INTRODUCTION

Estimates of the cost of remediating the nation's hazardous waste sites have been characterized by a high degree of uncertainty. Cost estimates for nationwide cleanups have ranged from $8 billion in 1984 to more than $500 billion in 1989.[1] Receiving less attention, but just as notable, has been the poor record of these estimates in predicting the actual costs at the individual project (OU or SWMU) level. Traditional engineering and construction methodologies have failed to provide reasonably accurate estimates for this class of projects.

Through joint funding by a consortium of major chemical and oil companies and the U.S. Department of Energy (DOE), the HAZRISK data base containing detailed information on completed Remedial Investigation/Feasibility Studies and Remedial Design/Remedial Actions (RD/RA) has been compiled. The objective of this paper is to use the HAZRISK data base to describe the cost estimating record of the 1980s, to outline the tools and strategies available and under development for building better estimates and to summarize the lessons learned from the past decade as they relate to building cost estimates for hazardous waste projects.

COST ESTIMATING EXPERIENCE OF THE 1980s

While many remedial actions are just underway, there is enough collective experience across the country to assess the accuracy of cost estimates for this class of projects. Figure 1 graphically depicts the accuracy of cost estimates for more than 50 remedial actions completed over the past decade. The vertical axis measures the percent deviation between actual project cost and estimated cost for the construction stage of a cleanup project. The horizontal axis indicates the stage at which the estimate was made. In theory, the ratio of the actual cost to the estimated cost should average zero with a narrowing band of variability around this ratio towards the completion of the project (shaded region of figure). In reality, however, there is a problem with both estimate accuracy and variability. The figure shows a consistent problem with underestimation, especially at early project stages. In addition, there is a wide variance in the accuracy of the estimates. At early project stages, costs can be underestimated by as much as 53% and overestimated by more than 250%.
Figure 1
Estimation Accuracy For Remedial Actions

Figure 2 shows the mean and range of cost growth for 51 completed remedial actions by project lead. The figure shows that federally-led Superfund cleanups historically have experienced the largest cost growth on average. At project authorization cost growth averaged 75% for federal-led Superfund cleanups; 41% for cleanups at DOE facilities conducted by the DOE; 25% for state-led Superfund projects; and 15% for a sample of industry-led cleanups. Project authorization is the ROD (Record of Decision) for Superfund projects. For other projects, this is the point at which the project was authorized to proceed with design and construction. It should be noted that both the industry and DOE samples of cleanups were not conducted under CERCLA/SARA. The sample these numbers are based on is large enough to give an indication of the comparative magnitude of the problem facing both the government agencies and the private sector.

Figure 2
Comparison of Cost Growth By Project Lead
An even more intractable problem than the average cost growth, especially for federally-led and DOE-led cleanups, is the wide range in deviations of actual costs from estimates. While high cost growth can be accounted for with the use of an adjustment factor, the large variability in cost growth is much more difficult to resolve. This result suggests that uncertainties present in cleanups are greater than commonly perceived.

This wide variation also suggests that there is a fundamental problem with current estimating methods for cleanups and a continuing reliance on conventional "bottoms-up" approaches or ad hoc techniques that do not take into account the unique risks and uncertainty associated with this class of projects.

We can conclude that regardless of project leader, estimates of cleanup costs have been largely inaccurate and that costs have not been controlled effectively during project implementation. We can speculate that the far superior estimating performance exhibited by industry-led cleanups is due to a combination of factors. These reasons might include: (1) better project management; (2) more effective contractor selection; and (3) greater control over the choice of the remedy. Perhaps an even more fundamental reason for the difference in project outcomes between the industry and government sample is due to industry's greater motivation to bring cost within budget. In contrast to the government, the private sector is interested in maximizing profits. Thus, cost-effectiveness means that cost-minimization is the number one priority. While achieving a permanent remedy and complying with regulations is important, selection of a remedy is made under the framework of minimizing costs, not vice versa. An analysis of RODs by the U.S. EPA showed that when PRPs lead the remedial action, less innovative and lower cost technologies are chosen.[2] Research has shown that the employment of more complex and innovative remedial technologies are associated with higher cost growth.[3] Moreover, the penalties for a wrong estimate are far greater in industry to both the individual and company than they are in government.

Figure 3 shows that two approaches have been used to tackle the problem of generating better cleanup cost estimates. One approach has been the development of computerized cost estimating systems for generating base estimates targeted exclusively at environmental restoration projects. The other is the development of methods to better understand the cost risks of individual cleanups and thereby assign more appropriate contingencies. Although more attention has been focused on the former approach, the unusually high cost risks associated with cleanup projects have generated increasing interest in the latter.

TOOLS FOR GENERATING BETTER BASE ESTIMATES

The large number of cleanup sites resulted in the development of several computerized cost estimating systems for environmental restoration projects in the latter half of the 1980s. The focus of these systems was primarily on generating better base estimates early in the project cycle for the remedial construction phase of a cleanup. Figure 4 traces the time of introduction of these systems. (It should be noted that this

survey excludes noncomputerized methodologies for estimating environmental restoration costs. We also exclude discussions of generic cost estimating systems such as COSTPRO, G2 and Primavera even though some estimators are using these tools for cleanup projects.) Although there are several other computerized systems in existence that deal with the issue of cost, these are the primary tools for generating base estimates that are currently available or actively under development. The following section contains a brief description of each system.
Figure 3
Approaches for Building Better Estimates
Figure 4
Overview of the Development
in Computerized Cost Estimating Systems

CORA (Cost of Remedial Action)

CORA was developed by CH_2M Hill for the U.S. EPA to estimate the remedial action costs associated with Superfund sites. The U.S. EPA routinely uses CORA to build budget estimates of remedial action costs at Superfund sites. CORA is probably the most widely used cleanup

cost estimating tool and effectively serves as the industry bench mark against which other cost estimating tools are judged.

RACES (Remedial Action Cost Estimating System)

RACES (formerly known as PRACES) was developed by PEI, Inc. for the U.S. EPA Risk Reduction Engineering Laboratory (RREL). A "quasi-design" system, the program allows the user to estimate costs at a component level. The system is structured to cost out remedial technologies and actions at a site on a line-item approach and relies upon a unit cost, cost estimating relationship (CER) and operations and maintenance item data base.

SCEES (Superfund Cost Estimating Expert System)

SCEES was developed by CDM Federal Programs Corporation for the U.S. EPA to estimate the cost of the RI/FS at Superfund sites. SCEES is a menu-driven system that walks the user through the steps of conducting an RI/FS.

HAZRISK

The HAZRISK models were developed by Independent Project Analysis for a consortium of private sector companies and the DOE to estimate the cost, cost risk and schedules for both the RI/FS and RA stages of environmental restoration projects. The models are based on a data base of completed projects and involve the systematic linking of cost and schedule outcomes with project and site characteristics.

TRAC-ER (Project Tracking for Environmental Restoration)

This system, developed by Los Alamos National Laboratories, currently is used to produce definitive base line costs and schedules of RI/FSs. It relies on a unit cost data base that can be augmented with historical unit costs. Currently, this system is in the working prototype stage and is installed at four DOE sites under the Albuquerque Operations Office.

M-CACES (Micro-Computer Aided Cost Engineering Support System)

M-CACES was developed by the Army Corps of Engineers as a detailed "bottoms-up" construction cost estimating tool typically applied to heavy civil projects, new building construction, process plants and rehabilitation projects. CACES is oriented towards lump-sum contracts. The Corps is in the process of building an environmental restoration unit cost library so that both the mainframe and micro-version of CACES can be used for hazardous waste projects.

RAAS (Remedial Action Assessment System)

RAAS currently is under development for DOE's EM-50 (Office of Research and Development) by Pacific Northwest Laboratory. RAAS is designed to be used during the RI/FS stage as a computer based advisory tool to screen and evaluate remedial action alternatives. RAAS will work in tandem with the Multimedia Environmental Pollutant Assessment System (MEPAS) in order to "focus on and prioritize the environmental issues at a waste unit."[4] It will be a total screening advisory tool as it will have the capacity to identify health risks and environmental damage as well as recommend remedial alternatives and estimate the remediation costs associated with a site.

Use of Computerized Cost Estimating Systems

Figure 5 summarizes the tools by the project stage at which they are most appropriately applied, the underlying methodology used by each tool and the applications of the tools. Four of the seven tools listed are used to generate order-of-magnitude estimates. Order-of-magnitude estimates are approximate estimates made without detailed engineering data. Actual costs should be accurate within plus 50% or minus 30% of the estimates. Budget (intermediate) estimates are made at the beginning of the design stage and actual costs should be accurate within a range of plus 30% or minus 15% of the estimate. Definitive estimates are defined as estimates made when engineering may be up to 40% completed. The actual cost should be accurate within plus 15% to minus 5% of the estimate.[5]

Tool	Estimate Generated			Underlying Approach		ER Application			
	Order-of-Magnitude	Budget	Definitive	Unit Cost	Historical	RI & FS	Remedial Construction	O&M Costs	Contingency
CORA	•			•			•	•	
HAZRISK	•				•	•	•		•
M-CACES (Environmental)			•	•			•		
RACES		•		•			•	•	
RAAS	•			•			•		
SCEES	•			•		•			
TRAC-ER		•		•		•			

Figure 5
Summary of Computerized Cost Estimating Systems
for Environmental Restoration Projects

The higher level of effort focused on systems for generating order-of-magnitude estimates probably is a reflection of the fact that this is the area where there is the greatest need for cost estimating tools due to the difficulty in producing reasonably accurate estimates during early stages of a cleanup project. The relative lack of effort devoted to developing tools for the latter stage of a remediation project can be attributed to several factors. First, we are in the middle of the evolution of environmental restoration cost estimating tools. Tools that currently are used for order-of-magnitude estimates may, with later versions, be used to generate intermediate and definitive cost estimates. Second, it is easier to use generic cost estimating tools to estimate cost in the latter stages of a project since a more detailed "bottoms-up" approach is required. These tools provide a framework for generating the estimates and require a unit cost data base for environmental restoration items.

TOOLS AND APPROACHES FOR UNDERSTANDING COST RISK

The only tool in our survey currently available for assessing cost risks and assigning contingencies for environmental restoration projects is the HAZRISK model. Contingency in cost estimates represents an allowance for elements within the project scope that are not included in the detailed estimate. More formally, "it is a cost element of an estimate to cover a statistical probability of the occurrence of unforeseeable elements of cost within the defined project scope due to a combination of uncertainties, intangibles and unforseen/highly unlikely occurrences of future events, based on management decision to assume certain risks for the occurrence of those events."[5] Traditionally, three approaches have been used to assign contingency to cleanup projects. Each is discussed below:

Fixed Percentage

The most commonly used method for assigning a contingency is some fixed percentage of the base estimate. Typically these contingencies are the same as those required for other classes of projects and are in the range of 10 to 15%. With average cost growth across all cleanup projects at 41%, this is generally insufficient to cover the uncertainty associated with these projects. In addition, the use of a fixed percentage can be appropriate for the average project, but for all others it will be inaccurate.

Estimator's Judgement

Unlike the fixed percentage approach, this is defined as a varying percentage or allowance based on the judgement of the estimator. While this method can be fairly accurate if the estimator is familiar with cleanup projects, it also can be inaccurate if the reverse is true. It is also difficult to justify.

Monte Carlo

The Monte Carlo estimating technique is a statistical method that uses sampling theory to calculate a contingency. This method is being

used increasingly for assigning contingencies to all classes of projects. Although it is relatively easy to justify, the results can be highly variable. In addition, assigning the appropriate parameters requires detailed knowledge of cleanup costs and cost drivers.

HAZRISK Models

The HAZRISK models differ from these approaches in that they take into account project and site characteristics. Logically, there are only a few potential causes of cost and schedule estimating problems:

- The cost estimates were developed poorly - not in accord with best practice
- The project changed (project definition) from that envisioned in the cost estimate
- Project implementation was faulty
- The "state-of-the-world" assumed in the estimates changed[6]

Although the causal factors can be sorted this way in theory, in practice the challenge is to identify what contribution, if any, a given factor is contributing to a given result. Obviously, however, the estimator cannot be held accountable for all things that may go wrong in a project. Some events and situations that can have a substantial effect on project costs are not, in fact, predictable by estimators. For example, external factors such as unusually bad weather, labor strikes, shortages of labor, new regulations, equipment and inflation are risks that can only be assessed in a rudimentary way by estimators. The estimator also has little control over the implementation of the project, including planning and definition; design and engineering; and construction.

The HAZRISK model for estimating remedial action contingency concentrates on the controllable aspects of misestimation; estimate error and project definition. Figure 6 graphically shows that three of the primary sources of cost growth in cleanup projects: (1) project definition, (2) technological complexity and (3) media complexity of the site, are controllable by the estimator and accounted for by the HAZRISK model. Conversely, the influence of external factors on cost growth is not assessed by the model. However, Figure 7 shows that external factors only account for at most 29% of the variance in cost growth. By contrast, 71% of the variance in cost growth can be accounted for by the estimator with the model. In other words, the factors which drive cost growth are identifiable before major expenditures are made and can be accounted for in the estimate. Cost growth is largely a result of three systematic and controllable sources: low levels of project definition: poor understanding of the influence of site characteristics on costs; and neglecting the impact of the selected remedial technology on costs. While regulatory and other external factors certainly influence cost growth, they are not the sole or even primary causes of cost growth.
Figure 6
Sources of Cost Growth
Figure 7
Cleanup Cost Growth Drivers

LESSONS LEARNED: STRATEGIES FOR MORE ACCURATE ESTIMATES

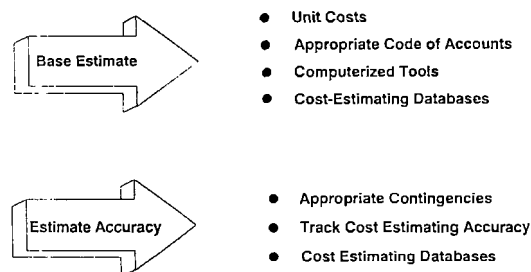
The experience of the 1980s showed that cleanup cost estimation errors are a persistent and serious problem. Data are now becoming available to help improve methods for generating estimates as well as for understanding the unique cost risks of cleanup projects. Figure 8 summarizes the strategies available for generating better base estimates and improving estimate accuracy. The challenge now facing the environmental restoration community is how to translate the experience of the past decade into building more accurate estimates. A few of the primary lessons learned are discussed below.


Figure 8
Current Strategies for More Accurate Estimates

Adjust for Uncertainties by Assigning an Appropriate Contingency

Most of the cleanup estimates in our analysis included contingencies intended to cover the costs of unforseen problems. These contingencies rarely exceeded 20% and generally are in the range of 10 to 15%. These contingencies tend to be based on contingencies required for more conventional projects and do not begin to cover the cost risks associated with cleanup projects.

Collect Better Cost Data

Because many estimates will continue to rely on unit cost data, the collection of new data and the routine update and maintenance of a cost estimating library is essential. Gathering data is also critical for building historical based models. Currently, only DOE, of the government agencies, has moved in the direction of developing a historical data base that tracks historical cost estimates as well as actual costs for cleanups and assessments. Without a historical track record documenting the cost and schedule performance of past projects, it is difficult to evaluate the potential of future projects in meeting their performance objectives. The U.S. EPA's CERCLIS data base, for example, does not currently track cost estimates.

The Key Cost and Cost Growth Drivers of Cleanup Projects Can Be Identified Before the Start of a Cleanup

This statement contradicts a prevailing view among NPL site mangers and environmental cost engineers that every site is so different that

attempts at classification are futile. The implication of this view is that we cannot use past experience to assist us in estimating new sites. The HAZRISK models, however, have demonstrated the utility of a historically based approach in checking the reasonableness of base estimates and in assigning appropriate contingencies.

CONCLUSION

Increasingly, tools and methods are becoming available to help improve the accuracy of cleanup cost estimates. By incorporating the lessons learned from completed projects, the cost estimating record of the next decade can be greatly improved.

ABSTRACT

This paper summarizes the efforts of the U.S. Department of Energy (DOE) to better understand the cost and cost risks of environmental restoration (ER) projects. DOE is in the early stages of assessing and remediating their sites and therefore has the opportunity to put new systems into place to better manage cleanup projects. Understanding the factors that drive the cost and schedule of environmental restoration projects has been a particularly challenging problem for most of the responsible parties involved in cleanups. DOE recently completed the first phase of a program that included:

- **Developing a cost estimating handbook for DOE personnel.** This handbook provides guidelines for estimating both the assessment and cleanup stages of environmental restoration projects.
- **Organizing the Cost Assessment Team (CAT).** The CAT is composed of representatives from the major operating sites in the DOE complex and includes a mix of cost engineers and environmental professionals. This group serves as a forum for discussing cost issues and for recommending cost and schedule estimating procedures.
- **Initiating a research program in environmental restoration costs.** The research program included a detailed study of the factors that drive the cost and schedule of hazardous waste cleanup projects. The research program also resulted in the development of several cost and schedule assessment tools.

This paper provides insights on the utility of this approach and discusses the results of this program. In addition, future activities to improve cost estimates are identified.

INTRODUCTION

This paper provides an overview of the U.S. Department of Energy's (DOE) activities in developing more consistent and accurate environmental restoration (ER) cost estimates. The program was started in 1985 and recently was transferred from the Division of Planning and Project Management (DP-521) under DOE's Assistant Secretary for Defense Programs to the newly created Division of Program Support (EM-43) under the Office of Environmental Restoration and Waste Management.

DOE has taken a three-part approach to improving ER cost estimates. First, a group was formed to address ER cost estimating issues in the DOE complex (the Cost Assessment Team [CAT]). Second, a handbook was developed to strengthen DOE's ER cost estimates (the *Cost Estimating Handbook for Environmental Restoration*). Third, a research program was inaugurated to study the factors driving ER costs and schedules and to develop tools to assist DOE personnel in developing more accurate cost and schedule estimates (the HAZRISK Study). Each facet of this program is discussed in more detail below.

DOE'S COST ASSESSMENT TEAM

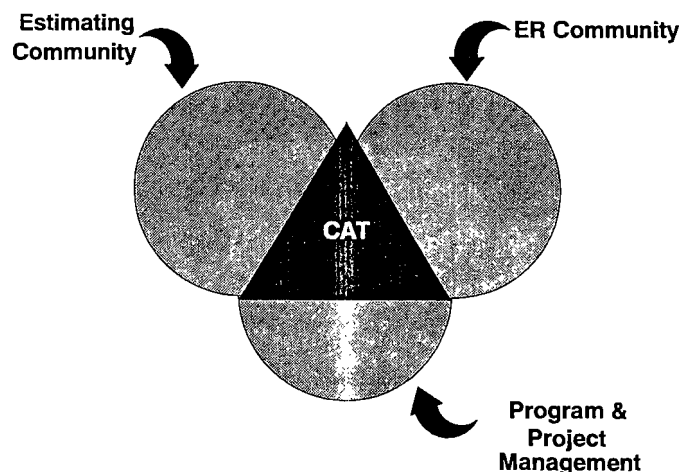
In 1988, DOE initiated a program to assemble a team of both cost estimators and environmental professionals to develop and review cost guidance in the ER area (Fig. 1). This group, known as the Cost Assessment Team (CAT), was designed to serve as a resource for the development and promulgation of tasks, techniques, procedures, data bases and project management activities related to environmental restoration cost estimating. The group first met on March 29, 1989, and the group's first product, the Cost Estimating Handbook for Environmental Restoration, was finalized in September, 1990.


Figure 1
Where Does the CAT Fit?

The CAT was split into seven subtask groups to address cost estimating concerns. These groups were asked to:

- Develop recommendations regarding guidelines for RI/FS, Program/Project Management, Remediation Activities and ED&I
- Develop recommendations regarding guidelines for contingency applications
- Develop recommendations regarding cost estimating formats reflecting reporting and review requirements
- Develop a catalog of ER data bases
- Develop a dictionary of terms
- Develop recommendations regarding guidelines for escalation application

• Develop a catalog of cost estimating techniques and methods relevant to ER

The reports from these seven working groups formed the basis for the *Cost Estimating Handbook* and resulted in a set of issues papers that were forwarded to DOE-EM management.

Over the next several years, the CAT will be a source of cost estimating expertise for ER projects. Individuals on the CAT already serve a gatekeeping role in their home organizations with regard to new approaches and tools for ER cost estimating. Undoubtedly, the CAT can play an important role in improving DOE's learning curve in the cost estimating arena.

COST ESTIMATING HANDBOOK FOR ENVIRONMENTAL RESTORATION

The purpose of the *Handbook* is to assist cost estimators in the preparation of estimates for Environmental Restoration and Waste Management (EM) projects undertaken by DOE. The DOE has, in recent years, seen a significant increase in the number, size and frequency of environmental restoration projects that must be estimated by the various DOE offices. Current projections indicate that the EM program will be the largest nonweapons program undertaken by DOE. These projects create new and unique estimating requirements since historical cost and estimating precedents are meager at best.
Figure 2
Process for Developing Cost Estimating Handbook

The principal thrust in producing the *Environmental Restoration and Waste Management Cost Estimating Handbook* was to produce a document which could be widely used in the field. This goal meant that the end users would have to be a principal source of the information in the *Handbook*. Therefore, it was prepared by cost engineers with extensive field experience in the DOE process. Further, it was intended to capture, as much as possible, the environmental restoration experience to date within the Department and throughout other government agencies

and the private sector. Figure 2 graphically depicts the process by which the *Handbook* was developed.

The *Handbook* is drawn from existing Department of Energy cost guidelines and orders and from U.S. EPA and Army Corps of Engineers documents, where appropriate. However, much of the *Handbook* was created by the participants based on their expertise, their research and the character of the environmental restoration process. Table 1 summarizes the contents of the *Handbook*.

Table 1
Chapter Summaries of U.S. DOE's Cost Estimating
Handbook for Environmental Restoration

Chapter	Title	Description
Chapter 1	Introduction	This chapter provides an overview of the *Handbook* and describes how the *Handbook* can be used by different audiences.
Chapter 2	Types of Estimates	This chapter describes several different types of cost estimates likely to be developed during the course of an environmental restoration project. Throughout this Chapter, the regulatory terminology for the CERCLA/SARA and RCRA programs is used to provide a baseline for discussing estimate types.
Chapter 3	Basis of the Estimate	A basis of the estimate should be written for each task explaining how the estimate was developed. This chapter outlines the items that constitute the basis of the estimate.
Chapter 4	Guidelines for Developing Cost Estimates	This chapter provides guidelines for estimating costs in each of four categories: Assessment, Cleanup Design, Cleanup Action, and Project and Program Management. These categories correspond to major classes of work within a typical environmental restoration project.
Chapter 5	Work Breakdown Structure	This chapter summarizes the Work Breakdown Structure (WBS) for ER work. The Environmental Restoration Program Work Breakdown Structure provides a framework for all program management functions for a project. The WBS will integrate budget, scope, and schedule through a program oriented hierarchy that begins at the highest level with the DOE Environmental Restoration program and progressively subdivides the work into smaller increments down to the subcategory level (Task Phase).
Chapter 6	Contingency	Environmental Restoration (ER) projects pose unique difficulties and challenges for the estimator. They are characterized by greater uncertainty than typical construction projects since contaminant types, amount of contamination, and the remedial technology are often not known until a detailed assessment has been completed. As a result, traditional engineering and construction estimating methodologies have failed to provide reasonably accurate estimates for ER projects. The purpose of this section is to provide guidance and a standard approach to the DOE community regarding contingency estimating practices for ER projects.
Chapter 7	Escalation	This chapter provides guidance in the application of anticipated economic escalation rates to ER cost estimates.
Chapter 8	Estimator's Checklist	Checklists have been prepared to assist the estimator in evaluating the proposed scope of work for completeness, complexity and accuracy. The checklists are organized to agree with the activities and program phases identified in the WBS and are not intended to be all inclusive, but merely a guide.
Chapter 9	Catalog of ER Databases	The objective of this chapter is to present a catalog of data sources and databases available for the preparation of cost estimates and undertaken as part of the DOE Environmental Restoration and Waste Management (EM) Program. The catalog of data and databases should facilitate the exchange of cost information between DOE estimators that would be unavailable or scarce to some groups and to keep data a current as possible to the actual cost experience.
Chapter 10	Catalog of Computerized ER Cost Estimating Tools	The first section of this chapter describes the cost estimating framework for categorizing the various tools. The second section provides a brief overview of each tool organized by the estimating stage at which it is best applied. The third section looks at other generic cost estimating tools that may be applied to environmental restoration projects. Finally, the conclusion offers recommendations on improvements and changes that are needed for the next generation of tools. A summary sheet on each tool also is included.
Appendices		Acronyms and Abbreviations, Glossary, Background on the Environmental and Waste Management Cost Assessment Team (EM-CAT), Illustrations and Examples, Bibliography

It is anticipated that this *Handbook* will enhance the quality of cost data within DOE in several ways by providing:

• The basis for accurate, consistent and traceable base lines

- Sound methodologies, guidelines and estimating formats
- Sources of cost data and data bases and estimating tools and techniques available to DOE cost professionals

The result will be greater comparability between estimates, reduced risk to projects from under/over estimating, expanded communication of cost drivers and improved capability to successfully meet budget validation requirements.

The *Handbook* was published in September 1990. Given the nature of the environmental restoration field, the *Handbook* will need frequent updates. It is expected that later versions of the *Handbook* will be expanded to include discussions of ER-specific escalation rates and factors, a code of accounts, contracting guidance and indirect cost calculation guidance.

DOE'S COST RESEARCH PROGRAM

Estimating the cost and time required for hazardous waste cleanup projects is a new art with little directly applicable experience. Existing cost and schedule data tend to be thinly scattered among a number of companies and federal agencies, and reliable cost estimating tools are just now emerging on the market. There are well-documented discussions of the ER estimate accuracy problem, including Schroeder's paper in these Proceedings; therefore, this issue will not be revisited in this paper.[1]

A research program was initiated in 1985 to better understand environmental cleanup cost drivers and to build a family of tools aimed at improving the accuracy of ER cost estimates. The early research, conducted by Hackney, concluded that a set of factors known early in the ER project cycle was related to cost overruns in projects.[2] However, in the 1985-1986 time period, there were insufficient data from completed remediation projects to fully test this hypothesis.

In 1988, the DOE along with seven firms in the oil and chemical industries provided support for the HAZRISK Project. Independent Project Analysis, Inc. (IPA) pooled their sponsors' experience and that of many others in order to develop realistic cost estimating, contingency setting and scheduling algorithms to be used for hazardous waste cleanup projects.

IPA's approach involves the systematic linking of cost and schedule outcomes with project characteristics. A HAZRISK project worksheet was developed to capture project information and was reviewed by the corporate sponsors, the DOE and the U.S. EPA. The worksheet organizes project information into the following areas:

- Site characteristics
- Nature and Type Contamination
- Site cleanup history
- Cleanup Funding History
- Cleanup technology
- Project management
- Estimated and actual costs
- Estimated and actual schedules
- Regulatory and external events

The tools are built using parametric statistical techniques such as correlation and multiple regression and have been described in detail in earlier publications.[3,4] These techniques are powerful extensions of the plots and cost-capacity curves familiar to all cost engineers. These methods have been used by DOE and IPA with considerable success to gauge the cost growth, schedule slippage and performance difficulties to be expected in first-of-a-kind process plants, megaprojects and other complex, innovative projects.[5,6]

Two classes of tools were developed during the first phase of the HAZRISK project. These tools:

- Identify and quantify the causes of cost and schedule overruns in environmental assessment projects (RI/FS projects under CERCLA/SARA or RFI/CMS projects under RCRA)
- Identify and quantify the causes of cost growth and schedule slip in environmental cleanup projects (RD/RA projects under CERCLA/SARA or CMI projects under RCRA)

The HAZRISK tools can be used early in the project cycle to evaluate

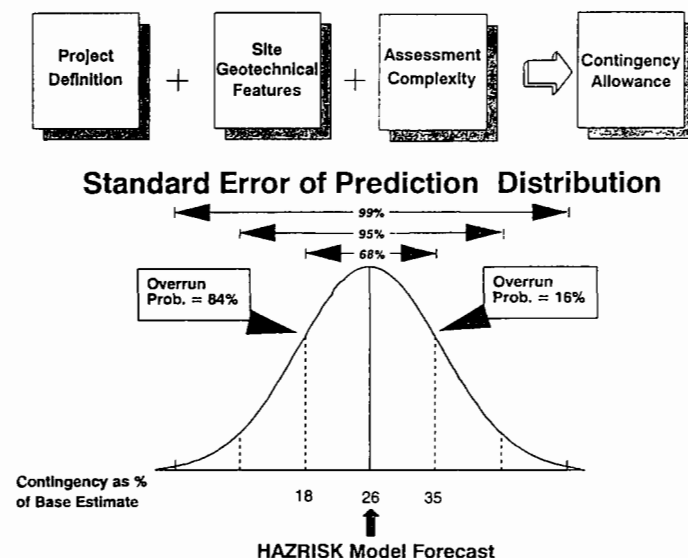
the riskiness of a project. A sample output from the assessment cost risk model is shown in Figure 3. Project managers can use the tools to build better estimates and to more effectively manage project risk. The HAZRISK project evaluation system also provides DOE with an easily applied set of techniques for checking the reasonableness of estimates generated by other organizations.


Figure 3
Output from the Assessment Contingency Allowance Model

The primary benefits to DOE of the HAZRISK research are:

- Knowledge of the factors driving cost growth in environmental remediation projects
- Set of models for evaluating and quantifying cost and schedule risks for assessment and cleanup projects
- Method for estimating the percent contingency needed to minimize cost overrun/underrun risks
- Ability to compare project costs and schedules with other cleanup projects around the country
- Capability to independently validate cost and schedule estimates generated by others
- User-friendly software package for evaluating the cost risks of assessment and cleanup projects

The second phase of the HAZRISK Project is underway. Funding has been provided to maintain the models, to validate the tools and to collect additional DOE data as they becomes available.

CONCLUSIONS

It is unfortunate, in some respects, that the activities discussed in this paper were not initiated even earlier. DOE is under a great deal of pressure from Congress and others to document and justify their multibillion dollar estimates of cost to remediate the complex. DOE's recent doubling of cost projections from the previous year simply exacerbates the problem. A well researched, systematic approach to generating cost estimates is likely to pay high dividends in the current cost conscious environment. It is hoped that the three activities described above will play a significant role in initiating improvements in DOE's ability to produce consistent and accurate cost estimates.

Selection of a Commercial Hazardous Waste Facility with Minimum Generator Liability

Ravindra Pendurthi, M.S.

University of Oklahoma
Norman, Oklahoma

ABSTRACT

Potential liabilities associated with hazardous waste disposal are related to the waste properties, disposal practices and the threat to people and the environment in case of a potential or existing pollutant release. Based on the regulations, the liabilities are enforceable and long standing.

This paper summarizes a methodology developed to aid hazardous waste generators in selecting a commercial disposal facility with a relatively low risk of potential liability. In this methodology, 35 factors grouped into 9 categories were used. The methodology has two parts. The first part covers factors common to all facilities and the second part deals with the waste and treatment or disposal technology factors. The first part is highlighted in this paper. This two-part evaluation feature enables the user to adapt the methodology, to any type of waste disposal. In determining the scores for the factors used in the evaluation, an unranked paired comparison technique with slight modifications was used to weight the relative importance of the factors. In the methodology it is possible for the user to redefine the factors and change the scoring system.

To make the methodology usage more efficient, a computer program is used. The computer program is user-friendly and is written such that any changes in the methodology can be readily adapted. In addition to the basic evaluation, the computer program also has the capability for record-keeping related to waste disposal information.

INTRODUCTION

The current problem in hazardous waste management is that companies or agencies that generate hazardous waste, either as an ultimate product of a handling method or an intermediate process, must find the best disposal alternative.[7] Alternative handling methods for hazardous wastes include reuse, recycling, exchange, minimization and/or disposal. The waste disposal category includes treatment and/or direct land disposal.

Waste disposal in an environmentally sound manner could occur on-site or off-site. On-site disposal involves sizable environmental risks and liabilities and it has numerous regulatory compliance requirements.[2] Off-site disposal requires the selection of facilities that show full regulatory compliance, in addition to necessary investments in facilities, equipment and personnel to protect the generator from liability.

This study involved the development of a methodology which could be used to assess the potential liability associated with an off-site commercial hazardous waste treatment, storage and disposal facility (TSDF). The methodology is based on a thorough literature review of treatment and disposal considerations for hazardous waste and on existing methodologies (manual and computerized) that can be used to assess potential risks associated with hazardous waste handling and disposal. In the evaluation of potential liabilities, considerations related to a facility's financial strength (in terms of the company which owns the facility), regulatory compliance, business handling methods, management methods and technical ability are evaluated.

DESCRIPTION OF METHODOLOGY

The methodology we have developed has nine categories and 35 factors to evaluate the TSDF (Table 1). The categories are divided into two parts; the first part contains eight categories with 30 factors, while the second contains one category with five factors. The emphasis in this paper is on the facility evaluation in Part I.

According to their perceived relative importance, the categories and factors were assigned weights using an unranked paired-comparison technique.[4] Then each factor was assigned possible occurrence or

Table 1
Categories and Factors in the TSDF Evaluation Methodology

Part I: Eight Categories with 30 Factors Common to All Facilities

Category 1: Company's Financial Strength

 (F1) Financial Size
 (F2) Growth Pattern
 (F3) Average Annual Growth
 (F4) Ratio of Assets to Net Worth
 (F5) Revenue from Hazardous Waste
 (F6) Years in Hazardous Waste Business

Category 2: Facility's Legal Status

 (F7) Permit Status
 (F8) Insurance Coverage
 (F9) Closure and Post Closure Costs
 (F10) Provisions for Closure Costs and Post Closure Costs

Category 3: Facility's Business Status

 (F11) Number of Generators Using a Facility
 (F12) Types of Waste Handled

Category 4: Facility's Waste Handling Methods

 (F13) Waste Identification
 (F14) Record Keeping
 (F15) Waste Shipment

Category 5: Facility's Management Attitude

 (F16) Personnel Technical Training
 (F17) Process Technical Control
 (F18) Management Location

Category 6: Facility's Site Characteristics

 (F19) Population Pattern
 (F20) Flood Vulnerability
 (F21) Depth to Ground Water
 (F22) Vadose Zone Permeability

evaluation scores which represent varying degrees of potential risk (and, in turn, potential liabilities). A relative liability score can be obtained for each facility being evaluated by multiplying the importance weights by the scores and aggregating the products. The facility with the highest overall numerical score is considered to offer the least potential liability.

To aid in using the methodology, a user-friendly computer program was developed by the Environmental and Ground Water Institute (EGWI).[3] The basic structure of the methodology and the program are parallel. The program has a built-in flexibility to accommodate changes in the factor scoring. In addition, the program can retrieve facility information in the data base in different formats and it can be used to keep records of waste disposal information.

Category 1: Company's Financial Strength

The financial strength of a company is one indicator of an ability to adapt to changing regulations and advancing technologies. More importantly, it may be the best indicator of a firm's ability to finance facility repair or maintenance and to correct any facility deficiencies or releases. The rationale used in reaching this conclusion assumes that a company with greater financial strength offers lower liability to the firm using it for the wastes disposed of through its facility(ies). It is assumed that the financial strength of a facility is represented by the financial strength of its parent company, since a company could have more than one facility. A company here represents the company which exists today. It is assumed that present financial strength is more important than the financial history of the company.

Financial strength in the methodology is assessed in terms of six factors: (1) financial size in terms of a company's total assets and the profits in the latest fiscal year; (2) growth pattern over the last five years; (3) average annual growth over the last five years; (4) ratio of company's total fixed assets to the company's net worth during the latest fiscal year; (5) number of years in the hazardous waste disposal business; and (6) percentage of revenues obtained from hazardous waste management during the latest fiscal year.

Category 2: Facility's Legal Status

In terms of potential liability, a facility's legal status is very important. Legal status can be determined by the evaluation of four indicator factors: (1) permit status and the ratio of number of citations to the number of visits for site inspections; (2) insurance coverage; (3) closure costs; and (4) provisions for meeting closure costs. A facility with the maximum legal status category score is assumed to offer the least liability.

According to Section 3006(c) of the RCRA, state regulations must be equivalent to, or more stringent than, the federal regulations. State programs must be consistent with the federal programs and must ensure adequate enforcement. Therefore, while evaluating a facility for legal status, both federal and state regulations must be considered.

Category 3: Facility's Business Status

Under business status, the potential liability associated with a commercial hazardous waste facility is analyzed by considering possible causes of a release event and the possibility of reducing the impact of the liability in case of such events. The business status is determined by two indicator factors: (1) the number of hazardous waste generators using a facility; and (2) the types and quantities of wastes handled at a facility. Considering the fact that there is always some degree of uncertainty associated with hazardous waste handling (fear of "something going wrong somewhere"), it is to the generator's advantage to send the wastes to a facility: (1) where there is a relatively lower possibility of a release event occurrence; and (2) in case of an event, where there is a responsibility for equitable apportionment of the liability between the contributors.

Category 4: Facility's Waste Handling Methods

Liability based on waste handling at a facility is determined by three factors: (1) waste identification; (2) record-keeping; and (3) waste location. By regulation, a waste must be analyzed prior to treatment, storage and disposal in order to obtain sufficient information on the

waste being handled.[7] Waste analyses include both detailed physical and chemical analyses using U.S. EPA-approved methods. For an unknown waste, an analysis can be performed following a set of steps specified in the regulations.

Once a waste is analyzed, it is assigned for a proper treatment, storage, or disposal method either on-site or off-site. In case of an off-site disposal (i.e., when the appropriate method for handling is not available at a facility), the waste may be sent to another facility operated by the same owner/operator or to a different facility. According to regulations,[7] there must be proper waste manifesting and record-keeping of all the waste analysis results and the ultimate treatment and/or disposal. The ease with which the details of a disposal of waste can be traced at a facility is also an important measure of the potential liability.

Category 5: Facility's Management Attitude

Good management practices at a facility are assumed to be indicative of lower risks and less associated liability. Management practices in terms of potential liability can be determined by three factors: (1) technical training imparted to the personnel; (2) technical quality control implemented in the treatment process; and (3) ease with which the top management can be reached (management location) in case of an emergency.

Some of the good management practices identified in different methodologies include:[4] (1) employment of personnel with proper training to accomplish a quality job; (2) the presence of a special advisory committee for waste management; (3) use of special facility environmental auditing; (4) provisions for tight facility security; (5) proper worker protection equipment and insistence on proper use of the equipment; (6) medical surveillance programs; (7) presence of a well-trained on-site emergency rescue team; (8) periodic drills for fire and other kinds of emergency situations; and (9) good public and customer relations. A facility with all or most of these good management practices is assumed to exhibit minimum liability.

Category 6: Facility's Site Characteristics

In addition to the management/operational practices (covered under management attitude) at a facility, site physiographic demographic, hydrogeologic and water use characteristics are important in terms of risks to the environment or human health resulting from the potential release of a pollutant. This potential impairment could be through any one of four possible pathways (air, water, soil and direct contact). Direct contact could occur due to poor operational practices at a facility, lack of proper security measures to warn and advise the nearby public to keep away from facility operations or emergencies such as fires or accidental spills. Evaluation of the management attitude category has taken into account possible liability associated with direct contact.

In terms of site characteristics at a TSDF, impairment through direct contact and water pollution (both surface and groundwater) are the most important and often lead to large potential liabilities. Therefore, factors such as (1) population pattern, (2) flood vulnerability, (3) depth to groundwater, (4) vadose zone permeability, (5) class of the aquifer underlying a facility and (6) surface waste use at a facility are considered for indirectly evaluating potential liability. A site with a nearby dense population pattern will offer a greater potential liability than a facility surrounded by less dense population patterns. Water pollution is evaluated based on the following factors: (1) flood vulnerability of a facility; (2) depth to shallow groundwater table; (3) permeability of the vadose zone; (4) class of the major aquifer underlying the site; and (5) surface and groundwater use near the site.

Category 7: Facility's Monitoring Program

Monitoring of facility operations based on several parameters is required under regulations. Some of these monitoring parameters include: (1) regular personnel health examinations; (2) training on performing various facility operations (including security); (3) impact of biota; (4) air emissions; (5) surface water discharges; and (6) contamination of groundwater and the vadose zone. Monitoring requirements under each of these parameters are different; but, in a generic sense, each of these monitoring programs must have a well-documented monitoring plan.

According to the plan, a monitoring system to obtain information/samples is required. Also, a detection system is needed. Proper management (record-keeping, maintenance and operation) of the monitoring and detection systems is a must.

Potential liabilities associated with the monitoring programs related to personnel health, facility operations and impact of biota are covered under other factors (such as management attitude). Therefore, in this evaluation, it is assumed that only the programs related to monitoring of pollution pathways such as air emissions, surface water discharges and groundwater contamination need to be considered. It is assumed that poor monitoring of any one or more of these pathways will result in potential liabilities. The monitoring programs can be evaluated based on three factors: (1) detection system; (2) monitoring system; and (3) management of monitoring system.

Category 8: Facility's Deficiencies

According to regulations, facility deficiencies are inadequacies in a facility's design, operations and/or management. Deficiencies have the possibility of causing damage to human health or the environment. The damage could be due to a sudden or accidental (acute) release or a slow (chronic) release of a pollutant. Once a pollutant is released, the impact of damage varies according to the magnitude and type of the pollutant. Facility deficiencies are determined by evaluating three factors: (1) nature and type of a release; (2) impact of a release; and (3) the response of a facility to a release. These considerations cover both existing and past deficiencies. However, in considering past deficiencies, only those that have long-term impacts are considered.

Description of Factor Evaluation for Four Selected Factors

Detailed information on the evaluation of the 35 factors in the methodology is contained elsewhere.[4] Four examples will be included herein for illustration purposes: (1) insurance coverage; (2) personnel technical training; (3) surface water use; and (4) monitoring system management.

Insurance Coverage

The liability to a hazardous waste generator is, to some extent, reduced by liability insurance coverage for injury and property damage. This insurance is required under Subpart H of RCRA (40 CFR 264.147 and 265.147) for the owners and operators of TSDFs. The owner or operator must demonstrate financial assurance for liability coverage of third-party damage for as long as the facility remains in operation.[5] The U.S. EPA[7] specifies the actual amount of coverage required for each occurrence. For sudden accidental occurrences, a TSDF has to have liability coverage of at least $1 million per occurrence with an annual aggregate of at least $2 million, exclusive of legal defense costs. For non-sudden accidental occurrences, a land treatment, storage and disposal facility must have at least $3 million per occurrence with an annual aggregate of at least $6 million, exclusive of legal defense costs. The coverage can be through Comprehensive General Liability-CGL (covering sudden accidental occurrences) insurance or through Environmental Impairment Liability-EIL (covering both sudden and non-sudden accidental occurrences) insurance. Insurance coverage bought by a company can cover more than one facility owned by the company.

Considering the limited availability of insurance, according to Tenusak and Bailey[5], the U.S. EPA is studying alternative insurance mechanisms that could provide adequate protection. These alternatives can be: (1) pure captive, that is, owned and controlled by one company; or (2) group captive, that is, owned and controlled by a number of companies. A risk retention group is a kind of group captive that can only offer coverage to companies or professionals with similar exposure. Even though a TSDF with secure management practices offers low liability, liability coverage is considered here to reinforce the concept of the need for management. This point is emphasized by the fact that insurance coverage is difficult to obtain unless the management practices are sound and offer very low potential risk for the insurer.

The section dealing with financial instruments under the Hazardous Waste Data Management System (HWDMS) of the U.S. EPA lists all the financial instruments implemented at different RCRA facilities. The information on the financial instruments also can be obtained from facility documents, annual and other reports and state and federal regulatory offices. The selected scoring for the insurance coverage factor is as follows:

Insurance Coverage	Grade
Covers more than required using CGL/EIL	A
Covers adequate amount using CGL/EIL	B
Covers more than required using financial instruments other than CGL/EIL	C
Covers adequate amount using financial instruments other than CGL/EIL	D
There is no adequate coverage	E

Personnel Technical Training

With the increasingly sophisticated technologies and equipment being employed in hazardous waste management, it is important to employ highly qualified, well-trained and skilled technical personnel in order to obtain acceptable results. Required technical skills can be imparted to properly qualified employees by periodic training. Training is especially crucial when one considers the evolving nature of hazardous waste regulations and technologies. SARA regulations (OSHA-promulgated rules) clearly define the specific requirements of personnel in terms of qualifications and training in hazardous waste handling. Therefore, facility management which promotes good personnel training practices is assumed to offer minimum liability.

This factor is evaluated based on regulator site inspection findings on personnel training (in accordance with 40 CFR 264.16). The selected scoring for this factor is shown below.

Technical Training	Grade
Approved training plan and positive findings for the requirements under 40 CFR 264.16 or the state equivalent	A
Approved training plan and positive findings for most of the requirements (except for a few minor requirements) under 40 CFR 264.16 or the state equivalent	B
Approved training plan and negative findings for most of the requirements under 40 CFR 264.16 or the state equivalent	C
No approved training plan	D

Surface Water Use

Potential liability associated with a release to surface water is anticipated because of the relative risks to the people, resources and environment surrounding a facility. According to the revised Hazard Ranking System (HRS), a release to the environment can threaten drinking water, the human food chain, recreation and the environment.[8] The surface water source near a facility could be a stream, river, pond or lake.

The potential liability threat from surface water is determined by considering the distance to the nearest surface water source and the actual use of the surface water. The boundaries of the factor alternatives are fixed by applying the divisions used in the revised HRS's distance to surface water factor. In the revised HRS, the factor value is calculated to determine the potential of release by overland flow. In calculating the distance to the nearest surface water body, the high water level of the water body is used. The selected scoring for the surface water use factor is shown below:

Surface Water Use	Grade
Present at a distance > 2 miles but not used for human consumption or recreational purposes	A
Present at a distance > 2 miles but used for human consumption or recreational purposes	B
Present at a distance from 1 to 2 miles but not used for

Monitoring System Management

Monitoring system management refers to the periodic and/or daily maintenance of equipment, stations, wells and laboratories. The monitoring system management factor also addresses the use of the best available field and/or laboratory sampling, analytical and statistical techniques.

The performance of monitoring system management is indicated by: (1) effective record-keeping; (2) adequate monitoring data; (3) high quality laboratory analysis based on an approved QA/QC program; and (4) proper maintenance of monitoring equipment. In addition, efforts at a facility to improve the monitoring system are considered to be good management practice. These efforts might include: (1) improving personnel skills through participation in a round-robin conference and periodic training (in-house, through a university or U.S. EPA workshops); and (2) improving the process through the use of state-of-the-art equipment. Information on monitoring system management practices can be obtained by a site inspection. The selected scoring for the management performance factor is as follows:

Monitoring System Management	Grade
No construction or maintenance deficiencies in equipment/stations/wells; full compliance with data/information record-keeping; full compliance with the U.S. EPA's or state monitoring QA/QC program; periodic training related to laboratory analysis.	A
No construction or maintenance deficiencies in equipment/stations/wells; full compliance with data/information record-keeping; full compliance in providing sufficient monitoring data; full compliance with U.S. EPA's or state's monitoring QA/QC program; lack of periodic training related to laboratory analysis.	B
No construction or maintenance deficiencies in equipment/stations/wells; minor/major non-compliance with data/information record-keeping and/or minor/major non-compliance or compliance in providing sufficient monitoring data; full compliance with the U.S. EPA's or state monitoring QA/QC program; lack of periodic training related to laboratory analysis/presence of periodic training.	C
No construction or maintenance deficiencies in equipment/stations/wells; compliance or minor/major noncompliance or compliance in providing sufficient monitoring data; non-compliance with the U.S. EPA's or state's monitoring QA/QC program; lack of periodic training related to laboratory analysis/presence of periodic training.	D
There are construction or maintenance deficiencies in equipment/stations/wells; compliance or minor/major non-compliance with data/information record-keeping and/or minor/major non-compliance or compliance in providing sufficient monitoring data; compliance or non-compliance with U.S. EPA's or state's monitoring QA/QC program; lack of periodic training related to laboratory analysis/presence of periodic training.	E

HYPOTHETICAL EXAMPLE

A hypothetical example of the use of Part I of the relative potential liability evaluation methodology described earlier is summarized herein, while detailed information is contained elsewhere.[4] Four cases are used in the example: three are fictitious and one is real. The three fictitious cases were framed such that they represent best, worst and moder-

ately better facilities in terms of potential liability. Computer input data for four selected cases are tabulated in Table 2. The data were evaluated using the computer program developed for this methodology.[3] The modified unranked paired comparison technique was used in the evaluation and the relative ranking category weights and factor scores used in the computer program are presented elsewhere.[4]

The results of the Part I scores indicate that there is a possibility of obtaining maximum and minimum scores of 5000 and 980. The breakdown of the category scores (for these four cases) into factor scores is presented in Table 3. The breakdown of the total scores (for these four cases) into category scores is presented in Table 4. The real facility had a score of 4590 in Part I. Incidently, this case was ranked as the best of eight large United States hazardous waste facilities by the Council on Economic Priorities (Council on Economic Priorities, 1986).

Total Scores for Part I

CONCLUSIONS

The methodology described in this paper can be used to evaluate a selected TSDF or several TSDFs for which information is available,

based on factors covering financial, regulatory, business, management, location, legal and technical aspects. If several facilities are evaluated, whichever facility scores the highest can be assumed to offer the minimum potential liability.

When an individual facility is evaluated, the relative potential liability offered by a facility can only be estimated based on the experience of the user with the methodology. The methodology uses only such factors for which identified/identifiable sources of information exist. It is assumed that information gathering would not require facility inspection, although this could be done as part of the selection process.

Existing methodologies (parallel to the one described herein) on risk or liability assessment mostly cover only limited aspects of a hazardous waste facility. Here, the methodology covers a broad spectrum of important aspects of a facility. For better usage of the methodology, the following observations and comments are in order.

- Even though it is possible to relatively compare and evaluate different facilities with insufficient information, a user should give priority to those factors which have a relatively high weighting in the evaluation (e.g., in fixing the scores for the methodology, it is realized that site characteristics are the most important category of factors).
- More elaborate methodologies (similar to the present) can be developed covering individual categories of factors, which can be assembled to fit a particular user's needs. This gives a user more flexibility in the evaluation.
- The present methodology does not cover liability in terms of risks associated with hazardous waste transport; this deserves an exclusive and exhaustive evaluation. Therefore, similar methodologies can be developed to cover related aspects of the transport of hazardous waste.
- The methodology could be updated based on information obtained from a thorough review of previous liability law suits in the hazardous waste business.
- In the future, attempts could be made to connect existing state, federal and other data bases to evaluate the facilities, thus reducing the present need for special data collection requirements.

Reduce Liability with Quality Data:
A Risk Management Approach

Tracey L. Vandermark
S-CUBED, A Division of Maxwell Laboratories
Alexandria, Virginia

ABSTRACT

In recent years, litigation has too often been the means of resolving incidents involving inappropriate measurements based upon inaccurate laboratory data. Remediation activities begun unnecessarily or false positive results of athletes' drug tests may both incur considerable costs, not solely financial, for the responsible party.

Since environmental monitoring data are being used on a more frequent basis as proof in legal actions, it is no longer sufficient that the data be accurate, precise, representative and complete. In addition, analytical results must be obtained by appropriate procedures (or methods) and must be carried through an unbroken chain-of-custody to eliminate the possibility of intentional contamination of or tampering with the samples. In certain cases, the analytical results may be completely invalid depending upon the amount of time by which the holding time for sample preparation or analysis has been exceeded.

Clients unwilling to pay for the analysis of recommended (and often required) QC samples, which can be both extensive in scope and expensive in price, bear the risk of receiving unreliable data. When key decisions are based upon such data, those making the decisions expose themselves and their organizations to potential losses of any of the following key elements:

- Net income
- Personnel
- Property
- Freedom from liability

By taking appropriate risk control measures before exposure to loss of one or more of these elements occurs, both the frequency and the severity of potential losses may be reduced.

INTRODUCTION

All too often everyday, activities have legal actions which revolve about them. Occurrences that twenty years ago would have been resolved equitably between the parties involved are now being protracted into years of court battles, with each successive ruling being appealed by the party against whom the decision was made.

Not only has this litigious trend created a significant increase in available work for lawyers, it also has necessitated more careful and specific contract negotiations between parties before any services are performed or products are delivered. The focus of this paper is to discuss methods which environmental laboratories and users of these analytical laboratories may use to reduce the potential for incurring liability. By its nature, this paper is intended to highlight the general topics to be considered in reducing liability; it is not meant as a specific examination to be applied exclusively to any organization.

Although the concept of Risk Management has been in existence for several decades, it traditionally has been associated with underwriters and the insurance profession. Now, however, the basic premise of risk management is being applied to almost every kind of business, particularly chemical analytical services, where site investigation and remediation decisions hinge primarily on the results of sample analyses from the laboratories. As the responsibilities and, in turn, costs of being named a potentially responsible party increase, so do the stakes involved in the event of litigation.

The Risk and Insurance Management Society defines risk management in its glossary as "a management discipline whose goal is to protect the assets and profits of an organization by reducing the potential for loss before it occurs... and financing the remaining exposures so that in the event of a major loss, the organization can continue to function without severe hardship to its financial stability."[1] Risk management can be subdivided into three categories: (1) risk assessment, (2) risk control, and (3) risk financing. (This paper is only concerned with the first two categories, the third being a world unto itself, usually addressed by the curriculum of a business school).

DISCUSSION

Risk assessment, the first area of risk management, involves identifying exposures to loss, examining feasible alternative procedures to be implemented for the identified losses and then selecting the apparently best risk management technique or combination of techniques to be used.

Identifying the exposures to loss inherent in any organization means examining every aspect of the business from material holdings and real estate to intangible images of the company, such as public relations and long-term employment potential for the employees. In general, there are four areas into which potential losses may be grouped:

- Net income
- Property
- Liability (legal action)
- Personnel

For example, a poor or sudden downturn in the image of the company as perceived by the general public could result in a loss of net income due to a decrease in patronage and, therefore, sales. This is what happened to Exxon following the Valdez oil spill. On the other hand, a company may own a piece of real estate which is found to be the source of groundwater contamination in a suburban area. This problem would decrease the value of that property as well as incur considerable cost to the company if it is found responsible for cleanup. Regardless of whether or not he or she is an employee, if an individual is injured on the company's property, or because of an oversight on the part of the company, a lawsuit may be filed against the organization, incurring significant costs, not just in the settlement of the claim but in legal fees as well.

Feasible Risk Management Procedures

Examining feasible alternative risk management procedures to those already in existence can be accomplished in one of two ways. A risk manager, or some internal management-level person with an appropriate background, may review the options. This method is usually most effective when only a few elements are lacking or need updating in an organization's risk management structure. For instance, if risk management has been an established aspect of a corporation's structure, and some real estate is being considered for acquisition by the company, the prudent risk manager might have a background check done on the history of the site. A few soil and water samples could be taken for analysis if contamination is suspected. Based on the findings of a preliminary investigation of this sort, a recommendation could be made regarding purchase of the property. If the property had merits in spite of a likelihood of some minimal degree of contamination, the property could be purchased by a subsidiary of the parent company. With the benefit of specific legal conditions written into the contract, in the event of a lawsuit, only the subsidiary and its assets would be subject to legal action, rather than the whole organization.

The second means of examining feasible alternative risk management techniques is to have a full evaluation done on the corporation by an independent consultant, who would also assist in implementing a corporate-wide risk management program. This option is most appropriate for a business without an existing risk management structure or with one in need of major revision or updating.

Selecting Risk Management Techniques

Once a comprehensive examination has exhausted the possible alternative risk management techniques available to the organization for each of the four major categories of potential loss, selection of the best technique or combination of techniques is the obvious next step. This phase of the process is individually tailored to meet the specific needs of each corporation; therefore, in each instance, the technique or techniques chosen will be different. However, the decision-making process should be conducted on the corporate level involving upper level management if it is to be far-reaching in scope and is to affect the entire organization (or a large part of it). If, on the other hand, only one department, division or single process in the whole corporate structure is likely to be affected, these decisions should include the input of that department or section manager.

Risk control, the second area of risk management, involves implementing the risk management measures which have been selected as the best possible alternative measures in order to avoid exposure to loss, prevent exposure to loss or reduce exposure to loss. In reality, it is often neither practical nor possible to avoid any exposure to potential losses since this would necessitate doing no business at all. Therefore, the most that can be done is to either prevent or reduce exposure to loss. Preventing exposure entails reducing the probability, or frequency, of the occurrence of a particular loss, but does not eliminate it entirely. Reducing exposure is accomplished by implementing any measures which diminish the severity of any losses which do occur.

Environmental Data

One of the best ways to ensure that environmental data are of adequate quality to meet the stated objectives for which the samples were originally collected is to practice risk control measures which will reduce exposure to loss. This process entails employing the necessary quality control components associated with the analytical method appropriate for evaluation of the samples, as well as some more general quality control practices which need to be followed regardless of the analytical testing procedure used.

Precision, accuracy, completeness and representativeness are the usual quality control elements that an analytical method is expected to provide in order to be considered appropriate for a given purpose. Three additional elements, method detection limit, comparability and data usability, are equally important considerations which determine a method's suitability.

Method Detection Limit

The analytical method needs to be chosen based upon the quantitative objective for detection of the analytes specified by the data collection activity, not vice versa. More simply stated, the objectives should be written first and the analytical methods then chosen in order to meet those objectives. The objectives should not be written based upon the capabilities of a particular method. For instance, it should first be determined that groundwater samples are to be analyzed to the part per billion level for trace metals; then a method may be selected that is capable of detecting trace metals in water to that level.

Comparability

Comparability is a qualitative measure which expresses the measure of confidence with which data are found to be equivalent to data generated at other times and places by different scientists using the same procedures. Evaluating the comparability of data sets indicates the degree of equivalence the data set has to others in terms of the measurement of a specific parameter or group of parameters. This requirement is particularly important when data sets for a specific parameter are interpreted in regard to action levels, permit limits or regulatory standards.[2]

Data Usability

Whether or not a data set is sufficiently complete and meets the quality criteria defined in terms of the specific objectives of the data collection activity determines its usability. The specific objectives, defined in quantitative and qualitative terms, are the criteria for evaluating the usability of the data. There are additional quality control measures which can be practiced to control the risk inherent in analytical work and which can and should be followed regardless of the analytical method employed. An experienced sampling team should always collect the samples according to the procedures and at the specific locations and depths prescribed in the work plan. Obviously, the data will be meaningless if the sample is collected at a depth of two feet at a location where waste is suspected to exist below eight feet.

Chain-of-Custody

From the moment the samples are collected, an unbroken chain-of-custody needs to be maintained. This requirement means that when not in direct sight of the responsible individual, the samples must be secured such that access to them cannot be gained by unauthorized personnel. These limited access measures prevent tampering with the samples and ensure that the analytical results are from the samples collected at the actual site location designated. Each time the samples are transferred from one person to another, both the individual relinquishing the samples and the individual receiving them are to sign the chain-of-custody form. A properly maintained chain-of-custody form provides a record of every person who has come into contact with the samples, including shipping agencies.

Analysis

Once the samples arrive at the sample receiving area of the laboratory, holding time becomes important. The time period between sample receipt and completion of the sample preparation process is critical to the viability of the sample. While it may be argued that a sample found to contain benzene at 200 parts per million even though the holding time has expired would have shown even more benzene had it been prepared and analyzed within the holding time, problems arise when the reported concentration approaches the detection limit or an action limit. Also, the possibility is strong that target compounds which were present in low concentrations in the sample may be reported as nondetectable if the holding time is exceeded.

Finally, it is critical that appropriate methods be used for preparation and analysis of the sample, depending upon the matrix, the analyte(s) of concern and the method detection limit. Equally important in obtaining meaningful analytical results are the instrumentation used for detection and, therefore, the analytical method chosen.

Once these various risk control techniques, in the form of specific and general quality control measures, have been implemented, the results need to be monitored. Both project specific measures and overall program implementations of these practices need to be evaluated and modified as necessary. No quality control measure or program is able to sustain itself once initiated without any attention or adjustment to make the system work. Quality control is a living system, not a perpetual motion machine.

CONCLUSIONS

Quality control should not be thought of as extraneous or as an "add on" at the end of a project or procedure. The purpose of quality control measures can be thought of as "insurance," not against things going wrong, which is sometimes inevitable, but against the data being worthless or meaningless when problems do occur. Blanks help locate possible sources of contamination, for example; however, they do not eliminate the contamination. The blank results may change the way in which the data are interpreted in light of contamination that is known.

The same results might be interpreted in a completely different manner, possibly incurring needless exorbitant costs to the party involved, if the blank results were not available because blanks had not been prepared and analyzed. Quality control is therefore a worthwhile expenditure as a form of insurance policy against some of the considerably more costly risks that are reducible or preventable.

Structuring Environmental Cleanups

ABSTRACT

The U.S. EPA in its recent report, *A Management Review of the Superfund Program*[1] — the "90-day review" — pledged to rely on an "enforcement first" strategy that seeks cleanup funding from responsible parties at hazardous waste sites and turns to the Superfund only as a last resort. This strategy already shows promise: recent EPA reports indicate that responsible parties now bear the cost of more than half the studies and cleanups underway nationally. But even as potentially responsible parties (PRPs) come to accept Superfund liability, they face a renewed assault on corporate finances as the average cost of cleanup grows.

Because of increasing costs, realistic and innovative mechanisms for PRPs to finance cleanups have become more important than ever. Recognizing this need, the U.S. EPA recently agreed for the first time to accept a PRP's use of a structured settlement — payments over time in lieu of a lump-sum settlement, usually funded by an annuity — to pay for portions of cleanup at a Superfund site.

The structured settlement offers a proven means of covering large, long-term payments, combining an initial, cash payment with periodic payments in the future, usually funded through an annuity or similar financial instrument purchased from a qualified life insurer. Such an arrangement takes advantage of the "time value" of money — in other words, earns interest through investments — so that the initial expense for PRPs is less than a traditional lump-sum payment, providing an added inducement to settlement. The U.S. EPA itself in a 1988 study[2] cited structured settlements as the most promising alternative means of achieving settlement between the Agency and PRPs.

The structured settlement is used routinely by private industry in settling wrongful death and bodily injury cases and recently has been applied in at least four hazardous waste cleanup settlements where remediation costs ranged as high as $6 million.[3] The first use of the structured settlement in a federal Superfund cleanup was in some respects unconventional — rather than the common steady stream of payments stretching over a number of years, the structured settlement in this case will return a one-time payment 17 years in the future. But the U.S. EPA's decision to accept this financing alternative marks an important first step in more routine use of the structured settlement in hazardous waste cleanups and other environmental areas.

This paper briefly reviews alternative methods of cleanup funding, describes the structured settlement and examines the U.S. EPA's first use of the structured settlement. The paper concludes by summarizing the views of responsible parties, the life insurance industry and structured settlement specialists on applying the concept to Superfund sites and reviews possible next steps.

ALTERNATIVES FOR FUNDING CLEANUP

As the number of potential hazardous waste sites grows and the average

cost of cleaning up a single site climbs past $25 million, the U.S. EPA, PRPs and insurers alike will turn to alternative financing mechanisms. Traditional methods such as lump-sum cash payments or trust funds could be complemented by alternative means such as annuities, surety bonds, letters of credit, financial tests or corporate guarantees.

The traditional arrangement in Superfund settlements has been the lump-sum cash payment, usually to compensate for past, present and future cleanup costs. But lump-sum payments have at times proven difficult to negotiate because of the complexity of issues involved and the high cost associated with Superfund cleanups. In addition, the U.S. EPA cannot directly receive cost reimbursement; instead, recovered funds revert to the Superfund at the U.S. Treasury, so the U.S. EPA cannot guarantee that recovered funds will be returned to assist in continuing cleanup at the site where they were spent.[4]

TRADITIONAL USE OF THE STRUCTURED SETTLEMENT

The search for innovative cleanup financing methods has until recently overlooked a tried and proven approach that, while not a universal cure, could benefit both the regulated community and the government.

In a structured settlement, the plaintiff agrees to accept payments for damages over time in lieu of a single lump-sum payment from the defendant. The payments can be funded in several ways, but the most common method is an annuity issued by a life insurance company. The structured settlement offers a method of financing that lowers the PRP's initial cost, offers other benefits to the PRP, its insurers and U.S. EPA and provides a "coalescing" factor leading to successful negotiations for past, present and future cleanup costs.

First applied to settle thalidomide cases involving bodily injury during the 1960s, the structured settlement came into greater use during the early 1970s. Structured settlements initially were limited to serious bodily injury cases, although they have been used increasingly in other liability settlements involving both catastrophic and less serious liability claims and have moved from exclusively private sector to include government settlements. The most recent (1988) U.S. Department of Justice estimate indicates that the federal government has used the structured settlement to resolve approximately 500 claims.[5] In addition, at least 16 states now permit — or even require — their use in settling liability claims that meet certain criteria.

STRUCTURED SETTLEMENTS AND ENVIRONMENTAL CLEANUPS

The structured settlement is increasingly moving into the environmental arena. Representatives of the life insurance and structured settlement industries report that cleanup costs for at least four private hazardous waste sites will be financed by structured settlements.[6] The cleanup sums involved have ranged from $1 million to $6 million. In addition, the U.S. EPA recently accepted what appears to be the first-

ever structured settlement to fund portions of cleanup at an NPL site. This settlement is more fully discussed later in this paper.

Briefly, the structured settlement can reduce the initial cost to PRPs by taking advantage of the time value of money and yet still ensures the U.S. EPA of full recovery of the agreed-upon sum. A 1988 U.S. EPA study[7] of existing and alternative financing mechanisms found that structured settlements showed great promise for promoting Superfund settlements.[8] Of the mechanisms studied — lump-sum payments, traditional trust funds, liens on PRP assets and alternative means including surety bonds, letters of credit, financial tests and corporate guarantees — structured settlements alone showed promise in lowering the settlement cost to PRPs without interrupting planned response activities.

The study found that structured settlements may promote CERCLA settlements because they can: (1) reduce PRPs' settlement cost compared to a lump-sum payment, (2) provide a secure source of funds for cleanup, (3) help ensure the timely completion of the U.S. EPA or PRP response actions, (4) provide payments in excess of the estimated response costs, perhaps providing incentive for the U.S. EPA or PRPs to settle, (5) serve as a no-cost coalescing factor between PRPs and the U.S. EPA and (6) contain special features to encourage PRPs to settle. A test case in the U.S. EPA study showed that the structured settlement could have reduced PRPs' initial expense by 34 percent at one Superfund site.

The concept may be seen initially as applying predominantly to long-range actions involving as future costs, including operations and maintenance — its application in the case is discussed later in this paper. The structured settlement may be best suited to the remedial action (cleanup) phase because the remedy is well defined and the PRPs' extent of liability and ability to pay are more clearly understood.[9,10]

CASE STUDY

The process for negotiating a structured settlement generally proceeds as follows. The plaintiff, as recipient of the annuity payment, agrees to accept a stream of periodic payments instead of a lump sum from the defendant.[11] (The Superfund structured settlement will differ here because the U.S. EPA as plaintiff agrees only that PRPs may fund cleanup through a stream of periodic payments instead of a lump sum. The U.S. EPA is not the "recipient" of the payments.) Annuities[12] issued by life insurance companies provide the funding mechanisms because of their security, flexibility and ability to lower initial costs.

The settling parties confer with a structured settlement specialist to design a schedule of payments tailored to meet the needs of a specific case. The specialist is an annuity broker, financial consultant and third-party negotiator. Specialists generally are not compensated directly for time spent in negotiations; instead they receive a commission from the life insurer selected to issue the annuity.

A life insurance company the U.S. EPA deems qualified issues the annuity used to fund the structured settlement. The defendant — in a Superfund settlement, the PRP — buys the annuity for a single premium. The life insurer or its affiliate then makes payments to the party the settlement designates and is legally bound to deliver the payments to the specified party according to the terms of the annuity policy.

The U.S. EPA recently accepted a proposal by a group of PRPs to provide for a Superfund cleanup partially funded by a structured settlement. The agreement involves the Liquid Disposal, Inc. site in Shelby Township, Michigan.[13] The original consent decree for Liquid Disposal was signed in May 1989 and entered in December 1989; parties first broached the concept of a structured settlement to fund cleanup in January 1990 and agreement was reached in March 1990.

It is important to note that this application of the structured settlement differed from the traditional method in that, rather than supplying the conventional stream of payments over time, the annuity purchased will provide a one-time payment for operations and maintenance in 2007. In addition, this case is simple but illustrates the advantages of the structured settlement.

The 6.8-acre Liquid Disposal facility was used mostly to incinerate combustible liquid organic wastes. Since the site's inclusion in September 1983 on the NPL, the U.S. EPA has completed four removal actions

at the Liquid Disposal site. The ROD for the site calls for solidification and fixation of soils, installation of a slurry wall and groundwater extraction and treatment with long-term operations and maintenance. Operations and maintenance, to begin about 17 years from the date of the agreement, are projected to cost about $6.1 million.

Parties to the $24.5-million settlement include about 500 de minimis settlers not included in the structured settlement[14] and 27 major parties that will perform the Liquid Disposal site cleanup. The site consent decree required establishment of a separate operations and maintenance trust fund; this fund will be financed through an annuity or structured settlement payment.

The U.S. EPA agreed to the 17-year annuity term as coming 16 years after groundwater treatment began. But the U.S. EPA retained power to review and change the structured settlement. In addition, the U.S. EPA wanted to avoid assuming responsibility for the selection of the company that issued the annuity. Therefore, the U.S. EPA would only "not disapprove" of the selected annuity fund.

Although the Liquid Disposal case represents a simple application of the structured settlement, it illustrates the concept's advantages. Significantly for the PRPs, the annuity premium — the total cost to PRPs for operations and maintenance — represented less than 25 percent ($1.5 million) of the $6.1-million total fund that will be required for operations and maintenance over the life of the cleanup. Under a traditional lump-sum agreement, the entire $6.1 million. Such cost savings provide a powerful economic incentive for PRPs and their insurers to settle with the U.S. EPA. Yet the U.S. EPA is assured that full funding will be available when needed to complete operations and maintenance activities. Furthermore, the Liquid Disposal case demonstrates the flexibility of the structured settlement. Rather than the traditional stream of payments, the structured settlement in this case was tailored to the needs of the U.S. EPA by providing a one-time payment many years in the future. If needed, the structured settlement also could have been tailored to accommodate uncertainties such as cost overruns or remedy failure.

PRIVATE INTEREST AND USE GROW

Over the past several years, PRPs, their representatives, structured settlement specialists and life insurers have shown growing interest in applying the structured settlement to Superfund cleanups. To date, at least four private cases, with a total annuity value exceeding $10 million, have been resolved by structured settlements.

Since its 1987 study, the U.S. EPA has investigated the possible application of structured settlements to Superfund cleanups; the private sector also has taken steps toward their more routine application. In informal conversations held over the past year, specialists, life insurers and representatives of private parties said they regarded the structured settlement as a useful tool in Superfund settlements and predicted continued rapid growth in its use. The following general points emerged from these conversations:

- Although the structured settlement usually has been applied to high-cost settlements, the concept may be useful for long-term cleanups involving small, less financially stable PRPs. The PRP may declare bankruptcy, go out of business or in some other way become inaccessible as a source of funding when cleanup is under way. The structured settlement, however, ensures that cleanup funding is available when needed. In addition, the structured settlement provides a sort of double guarantee to the U.S. EPA that funding will be available when needed; unless the PRP is released from further liability, it stands as guarantor to the annuity.
- The structured settlement as applied to Superfund has certain unusual features such as the potentially large number of parties. In addition, apportionment of liability may complicate the settlement process, as it does with all variants of Superfund settlements.
- The structured settlement may be useful in other environmental areas as well, although many members of the industry concede they have yet to explore these options in much depth. For example, some have suggested that structured settlements may be equally suited to corrective actions under the RCRA and to commercial real estate transactions that involve a high degree of environmental exposure.

- Generally, the advantages offered by structured settlements increase with the size of the cleanup and the time involved. Some facets of hazardous waste cleanup are more predictable than others and these areas are probably better suited to this approach. Where the process is less predictable, the structured settlement still may be suitable as a partial settlement to reduce the overall cost of the work.

- Some barriers remain to the widespread use of structured settlements in environmental cleanups. First, parties to a settlement need to understand the potential financial, substantive and security advantages of this type of settlement. Second, some public resistance to structured settlements could be encountered. Citizens, believing that the parties who created the pollution should pay a penalty, may object on the basis that the structured settlement allows the responsible parties to lower their cost.

- Even among PRPs, the largest contributors may balk at a structured settlement. They may want to retain the "time value" of money for themselves. In addition, as the number of PRPs grows, such issues as accounting for interest income, costs associated with the separate vehicle and even simple bookkeeping become obstacles.

- Finally, federal and state governments could play a role in promoting the concept simply by endorsing it and encouraging its early consideration among PRP groups without necessarily making a policy statement for that particular site.

- The structured settlement can be applied to any situation where periodic payments satisfy the requirements, both cost and payout, of the settling parties. Current United States tax codes are, however, favorable only in cases involving physical injury or illness.

NEXT STEPS

The first step in successfully applying structured settlements to hazardous waste site cleanups that involve the U.S. EPA as a party is building consensus within the structured settlement community. In addition, structured settlement specialists who decide to enter the environmental field must operate on common ground, underscoring the importance of consensus within the industry. The concept also would benefit from the early design of products that can be tailored to site-specific circumstances and easily understood by private parties already facing myriad complex technical and legal issues. The structured settlement industry should attempt to anticipate the many contingencies that must be accommodated in hazardous waste cleanups, such as the possible need for changes in cleanup plans or the potential for remedy failure. The expertise that already exists in the industry should, however, enable structured settlement specialists to overcome such obstacles.

If the structured settlement is to come into routine use, the hazardous waste defense bar and especially outside counsel to PRPs, should continue its process of self-education on the financial aspects of hazardous waste cleanups. For PRPs and their attorneys, liability as an issue typically takes precedence over the method of financing that will best meet the needs of private parties and the government. In addition, as structured settlements initially are applied in a sporadic manner, transaction costs may be high and PRPs may only reluctantly embrace the structured settlement. Therefore, real gains in this area will come only when PRPs and their representatives are convinced that the structured settlement is a viable and workable option for financing cleanup.

The technical and legal intricacies native to the traditional uses of structured settlements may be dwarfed by the complexities in the environmental area. The structured settlement industry will find that federal and state governments (and their environmental agencies) will become more receptive to this and other innovative concepts as the industry becomes versed in environmental cleanup issues, programs, regulations and requirements.

DISCLAIMER

The opinions and conclusions in this paper are the authors' alone and do not necessarily reflect those of the U.S. EPA. Mention of company, trade, or product names is not intended as an endorsement.

CONCLUSION

The structured settlement could become an important element in the nation's effort to clean up an unanticipated and still growing array of environmental problems. Issues such as tax ramifications and institutional reluctance both in the public and private sectors continue to hinder its widespread use. But as government and industry begin to realize the advantages this concept can provide in the environmental field, quicker, more financially secure cleanups at lower cost will occur.

4. The U.S. EPA is developing guidance on management of "special accounts" for cashouts that will enable the Agency to receive money directly for response work to be performed by the U.S. EPA or PRPs. A cashout to the U.S. EPA will generally result from one of the following circumstances:
   - *De minimis* PRPs settle for a cash payment to the U.S. EPA
   - Marginally viable prps make payments commensurate with their ability to pay
   - Major settlers agree to fund a U.S. EPA response in lieu of conducting the response themselves.
5. Correspondence from Jeffery Axelrad, Director of the Torts Branch, Civil Division of the U.S. Department of Justice, revised July 19, 1988. Cited in Hindert, Dehner, Hindert, *Structured Settlements and Periodic Payment Judgements*, p. 1-16.

9. It also has been suggested, but not demonstrated, that the structured settlement could be considered for short-term actions such as remedial investigations/feasibility studies.
10. Despite its advantages, the structured settlement generally may not be useful when the sum involved is small or the repayment period is brief. Structured settlement specialists cite four additional potential drawbacks, although these primarily relate to structured settlements in cases involving personal bodily injury:
    - A minor but real level of financial risk in accepting payments over time
    - Limited lack of the amount of the award
    - Potential misperception of the amount of the award
    - A new level of complexity in settlement
11. The U.S. EPA, for example would continue to require past costs as a lump sum.
12. The annuity is an investment that yields a level or varied stream of cash flows for a defined period in exchange for payment of a premium.
13. The following was based on conversations with parties to the settlement.
14. Liquid Disposal also represents the first de minimis settlement for U.S. EPA Region 5.

Development of a Real-Time Air Monitoring Technique for Dimethyl Mercury

ABSTRACT

Many forms of organic and inorganic mercury are pervasive in the environment, and both natural and industrial sources contribute to the total environmental mercury burden. Mercury can be biologically metabolized to form various organo-mercurials such as dimethyl mercury (DMM). Dimethyl mercury is approximately ten times more toxic and 10,000 times more volatile than elemental mercury. In biologically active areas where an organic or inorganic source of mercury is present, DMM represents a potential health risk via the air route of exposure because of its high volatility and toxicity.

Mercury-contaminated soils and sediments are frequently biologically active and have been demonstrated to contain DMM. If left undisturbed, emissions of DMM will be related to the biological generation rate of DMM as well as the emission rate through the soil or sediments as regulated by porosity, temperature, pressure and other physical-chemical factors. However, when the soils are disturbed, as in a remedial action at a waste site, the potential for elevated emissions of DMM increases. This increased potential for emissions raises numerous concerns from an industrial hygiene point of view.

Due to DMM's high volatility and toxicity, real-time monitoring, in conjunction with confirmatory sampling, is the preferred method of quantifying any health threat. Recent research conducted by the U.S. EPA's Environmental Response Team (ERT), with the support of the Response, Engineering and Analytical Contract (REAC) Roy F. Weston Inc., has resulted in a potential real-time monitoring technique.

Concerns over the potential health threat represented by the excavation of mercury-contaminated soils prompted the ERT/REAC team to examine both real-time monitoring techniques and time, weighted average sampling methods for DMM. This paper will address the real-time methods examined, while focusing on the technique which appears to have the most potential.

INTRODUCTION

The U.S. Army Corps of Engineers had been conducting a cleanup of mercury-contaminated soils at the Nyanza Chemical Site in Ashland, Massachusetts. However, site remediation was suspended due to the potential for dimethyl mercury (DMM) emissions and the lack of a real-time air monitoring method. The suspension of remediation activities was costing the government an estimated $10,000 per day.

In response to a request for assistance from the Army Corps and U.S. EPA Region I, ERT and Weston/REAC conducted a preliminary investigation. This investigation involved a site examination and literature review. The site examination provided information regarding topography and contaminant distribution. The literature review indicated that DMM could conceivably be present in the soils, especially in swampy areas where anaerobic activity is prevalent.

BIOLOGICAL TRANSFORMATION OF ENVIRONMENTAL MERCURY

Mercury in the environment is primarily inorganic in form. Inorganic mercury may be methylated through the action of bacteria; methyl mercury compounds have a high affinity for living tissue and are readily taken up by organisms. Methylation via aerobic pathways is a common means of methylation; however, anaerobic methylation is not uncommon.

One widely accepted metabolic pathway for transferring methyl groups to mercury involves the transfer of a methyl group from a methyl corrinoid, for example, methyl cobalamin. Methyl cobalamin (Vitamin B_{12}) is a common constituent of microorganisms. The following reaction is one possible route:

$$\begin{array}{ccccc} CH_3 & & & & H_2O \\ | & & & & | \\ Co^{+3} & + \; Hg^{+2} & ----> & CH_3Hg^+ & + \; Co^{+3} \\ | & & & & | \\ R & & & & R \end{array}$$
REVIEW OF REAL-TIME PORTABLE INSTRUMENTS FOR DETECTING DMM

The criteria established in this study for selecting a real time instrument for monitoring DMM were quite restrictive. First, the instrument had to be portable and permit operation by non-technical personnel. Second, it had to provide real time or semi-real-time monitoring capabilities. The third and final requirement was that it had to be specific to organo-mercurials.

Several instruments met the first two criteria. However, upon preliminary examination, none appeared to meet the final criterion. Previous experience with elemental mercury sampling indicated that silver-coated Chromosorb was an excellent sorbent for elemental mercury. This finding suggested that the silver-coated Chromosorb might be employed as a pre, scrubber to remove elemental mercury while allowing DMM to pass unimpeded to the monitoring instrument. Some experiments indicating the effectiveness of this process will be discussed later in this report. In summary, these experiments indicated that the silver-coated Chromosorb effectively removed the elemental mercury while allowing the DMM to pass through.

A literature review indicated that the primary methods for detecting elemental mercury were atomic adsorption/UV detection and gold film technology. The UV detectors appeared to have a number of interferences such as H_2O, O_3, SO_2 and a variety of organic compounds.

Gold film detectors are also cross-sensitive to sulfide compounds. However, the use of an internal sulfide trapping pre-filter negates this cross, sensitivity. The gold film technology thus appeared to have the greatest potential for the required application and so a gold film mercury vapor analyzer was selected for detailed review.

GOLD FILM TECHNOLOGY

The Arizona Instruments (formerly Jerome Instruments) Model 411, Gold Film Mercury Vapor Analyzer was selected as the instrument of choice. The Model 411, originally developed for monitoring elemental mercury in air, operates on the principle that mercury will form an amalgam when it contacts a gold film. The formation of the amalgam causes a change in the resistance of the film which can be quantified by the instrument.

The Model 411 detects the presence of mercury by passing a stream of air across a thin gold film. As the mercury in the air contacts the film, an amalgam is formed; this amalgam is simply a mixture of gold and mercury. The amalgamation causes an increase in the electrical resistance of the film proportional to the mass of mercury in the sample—that is, the higher the concentration of mercury, the greater the increase in resistance of the gold film. The change in resistance is then compared to a reference gold film across a Wheatstone bridge circuit. The instrument then integrates the increase in resistance with a precise volume of air contacting the gold film. The difference in resistance is magnified by an amplifier and processed by a microprocessor to provide a digital read-out of mercury concentration in mg/m^3.

The adsorption or amalgamation of mercury with the gold film is a surface phenomenon and it is not within the scope of this paper to enucleate surface chemistry. However, it should be noted that the reaction is reversible. Heating the film to approximately 250°C and subsequently passing a stream of mercury-free air across the film desorbs the mercury and restores the film to its baseline resistance. In order to eliminate the necessity of thermally desorbing the gold film after each use, the Model 411 employs a microprocessor which allows the instrument to operate over a wide range of resistances while remaining balanced with the reference film. Therefore, thermal desorption of the gold film is required only after it becomes so saturated with mercury that the microprocessor can no longer compensate for the difference in resistance between the sample and the reference film.

EXPERIMENTS WITH SILVER-COATED CHROMOSORB

Since DMM may be metabolized from elemental mercury, the assumption was made that both DMM and elemental mercury might be present during air monitoring. Elemental mercury would interfere with the detection of DMM in monitoring air, therefore, a means to remove the elemental mercury from the sample without affecting the DMM concentration was required. Silver-coated Chromosorb was subsequently tested as a prescrubber.

First, the silver-coated Chromosorb was tested to determine if it could adequately remove elemental mercury from the Model 411 monitoring stream. This experiment involved monitoring for elemental mercury with the Model 411 using a silver-coated Chromosorb tube prescrubber within a test vessel containing elemental mercury in which the vapor pressure had reached equilibrium. Thirty samples of the mercury-saturated air were collected without breakthrough occurring from the silver, coated Chromosorb tube. The breakthrough study was terminated at this point because ambient air mercury levels approaching the saturated concentrations present in the test chamber were not likely to be encountered.

The next test of the silver-coated Chromosorb prescrubber required that it allow DMM to pass through it. This was accomplished by preparing a DMM standard and measuring the concentration with and without the silver-coated Chromosorb pre-scrubber. As Table 1 indicates, the test results for the analysis with and without the pre-scrubber are essentially the same.

Since the air volume sampled by the Model 411 is required for the conversion of the change in resistance of the gold film to mg/m^3, it was necessary to determine if the flow rates of different silver-coated Chromosorb tubes were consistent. This evaluation was accomplished by randomly selecting silver-coated Chromosorb tubes from a single lot of tubes and measuring the flow rates of each. The Model 411 was utilized as the air moving device and a primary air flow measuring standard (bubble meter) was employed to determine the tube flow rates.

Table 1
Comparison of Arizona Instruments Model 411 Response With and Without a Silver-Coated Chromosorb Pre-Scrubber to 4.8 ppb-v and 24.6 ppb-v Standards of DMM

First, the flow rate was set to approximately 850 cm^3/min on the Model 411. Next, six individual tubes were randomly selected from the same manufacturer's lot. Then, five flow measurements were recorded for each tube. The flow rate population standard deviation was then determined for each tube. The flow rate population standard deviation never exceeded 1.2 for the six tubes tested. Subsequently, five additional tubes from the same manufacturer's lot were tested for flow variation among different tubes. A population standard deviation of 6.9 was obtained when five flow rate measurements were compared between five separate tubes.

PREPARATION OF DMM STANDARDS

A significant problem encountered while conducting research for this study was that of obtaining certified DMM in air standards. None of the specialty gas manufacturers routinely produces DMM. In fact, a vendor could not be located to custom mix and certify a DMM standard in the time-frame available. Therefore, it was necessary to prepare DMM standards in-house.

DMM standards were prepared in Summa passivated canisters by injecting a measured volume of DMM and methanol solution into the canister. This process was accomplished by injecting the DMM solution into a heated (60°C) stainless steel "Tee" which connected the Summa canister to a cylinder of Ultra-High Purity Nitrogen. The nitrogen simultaneously flowed through a heated stainless steel transfer line into the Summa canister at a flow rate of 200 cm³/min so as to pressurize the Summa. The Summa canisters were then pressurized to between 30 and 40 psig. Knowledge of the initial concentration of the DMM solution, the volume of liquid injected and the final pressure of the Summa canister in psig, allowed the DMM concentration to then be calculated. This calculation is represented by the following formula:

$$\frac{DMM\ (g)}{Total\ vol\ (L)} * \frac{1\ mole\ DMM}{M.W.\ DMM\ (g)} * \frac{molar\ volume\ (L)}{1\ mole\ DMM} * 10^9\ ppbv\ (l)$$

This formula assumes that temperature and pressure are corrected for, the total air volume is exact and that all of the DMM is transferred from the syringe to the Summa canister. Due to uncertainties in this procedure, DMM standards were subsequently confirmed by select ion gas chromatography and mass spectra analysis.

USE OF THE MODEL 411 FOR DETECTION OF DMM

Once the Model 411 was selected, the manufacturer was contacted for additional information on its applicability for detecting DMM. The manufacturer, Arizona Instruments, indicated that the Model 411 was indeed capable of detecting DMM. However, they also stated that very little was known regarding the instrument's response factor and linear range for DMM.

Initial experiments conducted with the Model 411 (configured as per manufacturer's specifications) provided erratic results and an inadequate detection limit for DMM. The manufacturer was again consulted, this time for methods to increase the instrument's sensitivity as well as for a means to quantitatively detect DMM. The modifications suggested included increasing the sampling period and air sample flow rate as well as adjusting the gold film detector sensitivity potentiometer. After these modifications, the instrument could be reliably calibrated to DMM by adjusting the display potentiometer until the meter display yielded the correct reading.

The Arizona Instrument's Model 411 was modified as follows:

- The detector resistance was increased from approximately 60 ohms to approximately 98 ohms
- The instrument's sample flow rate was increased from 720 cm³/min to 866 cm³/min
- The sampling duration was doubled from 10 to 20 seconds
- A silver-coated Chromosorb tube was utilized as a pre, scrubber to remove elemental mercury
- The calibration switches were adjusted to calibrate the instrument to a known concentration of DMM

SENSOR STATUS DRIFT IN THE MODEL 411

One phenomenon observed while developing this monitoring method was that the Model 411's sensor status would first increase after the instrument detected DMM, then decrease after a period of time. The sensor status is an indication of the percent gold film saturation. The increase and subsequent downward drift in sensor status was not encountered with elemental mercury. This finding suggests that the DMM/gold amalgamation process is somehow different. It appears that DMM forms a transient amalgam with the gold film.

The authors propose that the methyl groups preclude the formation of a true amalgam. The sensor status drift, which was encountered, affected the instrument readings by disrupting the balance between the sample gold film and the reference film. This phenomenon resulted in the instrument indicating readings lower than actual concentrations. The sensor status drift was corrected for by allowing the instrument to balance the Wheatstone bridge between the sample gold film and the reference film prior to monitoring another sample. It is postulated that the transient amalgam dissipates during this period. This process was accomplished by drawing four, 20-second samples into the instru-

ment through an iodized charcoal filter. The filter effectively adsorbs organic and inorganic mercury resulting in mercury free sweep air. The number of mercury free air sweeps required to permit the instrument to reestablish base line was determined empirically to be four.

LINEAR RANGE OF THE MODEL 411 FOR THE DETECTION OF DMM

The linear range of the Model 411 for the detection of DMM was determined by diluting a 13.70 ppb-v DMM standard down to approximately one half the Threshold Limit Value (TLV) of mercury of 0.01 mg/m³. Dilutions were made to 0, 0.64, 6.40 and 13.70 ppb-V. The DMM concentrations were validated by GC/MS analysis. The DMM standards were tested by the Model 411 by:

- Filling a 1-L Tedlar bag with a standard air sample
- Sampling from the bag with the Model 411 with the silver-coated Chromosorb pre-scrubber in-line and the instrument configured as previously indicated (98 ohms, 866 cm³/min...)
- Recording the meter response
- Purging the instrument four times with a zero air (iodized carbon) filter in-line
- Repeating steps 1-4 three times for each concentration
- Determining the average meter response at each concentration (Table 2)

Table 2
Arithmetic Mean and Linear Regression Values
for the Model 411 as Related to Dimethyl Mercury Concentration

DMM CONC. (ppb-V)	METER RESPONSE
0	0
0.64	0.008
6.40	0.043
13.70	0.126

Linear regression values:

R^2 = 0.98
y intercept = 0.00220
Standard error of y = 0.010048
Slope = 0.008959
Standard error of x = 0.000911

These data were then utilized to generate a calibration curve (Fig. 1). The calibration curve was found to be linear, with a critical correlation coefficient (R^2) of 0.98. This accuracy was deemed to be an acceptable linear range for this work effort.
Figure 1
Plot of Model 411 Response Versus
Dimethyl Mercury Concentration (PPB-V)

CONCLUSIONS

This study indicates that gold film mercury vapor detectors have definite potential in determining air concentrations of DMM. The Arizona Instruments Model 411 analyzer appears promising because of its simplicity, stability and ease of use. Initial testing indicates that the Model 411 is an effective screening tool. However, as with any screening device, it should not be relied upon exclusively. Rather, it should be incorporated into a multi-tiered sampling and monitoring program. The multi-tiered sampling and monitoring program should include: screening work areas with the Model 411 as well as a time weighted average sampling method utilizing an appropriate sorbent tube with subsequent analysis.

A reliable source for DMM air standards remains to be located and the stability of these standards determined. The method for producing DMM standards must be described in this study is inappropriate for an in-depth research project because the volume of standard produced per batch is insufficient to carry out multiple experiments.

Further experimentation is required to confirm the results of this study. This monitoring method relies heavily on the selective removal of elemental mercury by silver-coated Chromosorb This selective exclusion technique has been found by others[1,2,3] to be of dubious reliability when applied to field conditions. That is, the silver amalgamation of elemental mercury may be negatively impacted under field conditions by the presence of chlorine and sulfur dioxide because of the following reactions:

$$Cl_2 + 2AgCl = 2AgCl$$
$$SO_2 + 6Ag_2S + Ag_2O$$
These reactions reduce the collection efficiency of the silver proportionally. As yet, no adequate means of selectively isolating DMM from other organo-mercury species has been tested for application in this monitoring technique. Therefore, other organo mercury compounds such as phenylmercuric acetate would be reported as DMM. This monitoring method requires further field testing and the determination of a correlation between Model 411 readings and sorbent tube analysis.

The results obtained in this study should be scrutinized further and confirmed or refuted. The sensitivity of the gold film detector may be further increased through the use of advanced electronics and a means to obtain direct readings should be developed. It was not within the scope of this study to specifically develop a complete air monitoring method for DMM. Rather, this study attempted to bring forth a method which others might bring to fruition.

Field Analytical Support Project (FASP) Use in a Site Characterization for Removal: On-Site Laboratory Support to Optimize Use of Analytical Results for Subsurface Sampling and Monitoring Well Placement

Tracy Yerian, Ph.D.
Ecology and Environment
Seattle, Washington

Robert Mandel
United States Environmental Protection Agency
San Francisco, California

ABSTRACT

Brown and Bryant, Inc., an inactive pesticide formulating facility in Arvin, California, was listed on the NPL in June 1989. Due to concerns about the groundwater contamination potential of the site, a 90-day study was initiated under the Technical Assistance Team (TAT) contract to determine what short term removal actions were necessary under the NCP.

Existing site data showed $\mu g/kg$ to percent levels of halogenated volatile fumigants and the herbicide dinoseb. To provide cost-effective analytical support with rapid turnaround, an on-site laboratory was used to support the drilling operation. The laboratory analyzed both surface and borehole soil samples for six fumigants of concern and provided results to the project manager within 12 hours of sample collection. The on-site laboratory analyzed 536 soil samples; 15% of the samples were sent to an off-site laboratory for confirmatory analysis. The on-site analytical data were instrumental in an early site characterization; field analytical results agreed with off-site confirmatory analyses. As a direct result of the field analytical support, drilling costs were more than 40% under U.S. EPA's budget, monitoring well placement was optimized in a single field effort and the site assessment was completed within 90 days.

INTRODUCTION

Brown and Bryant, Inc. (B&B) is located at 600 South Derby Road, Arvin, Kern County, California. Beginning in 1960, the 5-acre site was used for the formulation of agricultural chemicals, including various pesticides and fertilizers. Due to the improper waste management practices used in spill management, equipment and container washdown and on-site liquid waste disposal, the operator came under State enforcement scrutiny in 1985. The operator was required to bring waste management practices into compliance and to conduct environmental assessments of surface and subsurface contamination. The operator went out of business in 1988, before fully investigating the extent of contamination in the soil and groundwater. However, the preliminary data revealed serious and widespread contamination in on-site subsurface soils and groundwater. Based on the release of dinoseb into the regional aquifer below the site, B&B was added to the NPL.

In April 1989, the Agency for Toxic Substances and Disease Registry of the United States Public Health Service (ATSDR) conducted a preliminary health assessment at the site and concluded that B&B was a potential health concern because of possible human exposure to hazardous substances at concentrations that may result in adverse health effects (the major public supply well is 1,700 feet downgradient of the site). ATSDR recommended further site characterization and downgradient drinking water well monitoring.

In July 1989, a preliminary assessment by the U.S. EPA and the Region 9 Ecology and Environment, Inc. (E & E) Technical Assistance Team (TAT) determined that the existing groundwater monitoring system was inadequate to monitor contaminants and it could not be determined if the NCP criteria for a removal action had been satisfied. A comprehensive site assessment was required, including soil borings for geotechnical and chemical analyses, the installation of an effective groundwater monitoring system both on- and off-site, aquifer testing and treatability studies. The goal of the site assessment was to determine if a removal should be conducted and what type of on-site treatment would be feasible.

SCOPE OF WORK

For the B&B site assessment, chemical contaminant concentrations and locations and physical characteristics such as horizontal and vertical permeability were necessary to provide information concerning groundwater quality and soil characteristics at the site. Existing site data were available from two 50-foot borings in areas suspected to be the most highly contaminated, based on past site practices (Table 1). Thirty boreholes were scheduled to be drilled on the 5-acre site to determine the design and placement of on-site and off-site monitoring and extraction wells, to retrieve representative samples of subsurface soils for lithological descriptions and geotechnical parameters bearing on contaminant migration through the vadose zone and to characterize the extent of fumigant and dinoseb contamination. Samples were to be collected at regular intervals for laboratory analysis of contaminants of concern. The high levels of the dinoseb (percent levels) and the fumigant ethylene dibromide (EDB) detected established the need to perform all on-site activities in Level B protective clothing.

Although the project was allocated more funds for subcontracting than a typical removal assessment ($500,000), it was estimated that the drilling costs for 30 boreholes and the laboratory analysis for geophysical parameters would require all the budgeted funds. Off-site laboratory support for analysis of the volatile contaminants and dinoseb was projected to be very costly; these costs would either cause the project to go over budget or compromise the drilling effort. Additionally, the shortest possible turnaround time for the analytical results was critical in optimizing the drilling location depths and borehole sampling plans which would aid in controlling project cost. Data available within 24 hours also would be used to support site safety decisions. However, quick turnaround analyses would drive the analytical cost up as much as 100%. To provide cost-effective analytical support for the site assessment with rapid turnaround, an on-site laboratory was employed. The mobile laboratory was provided by the Region 10 Field Analytical Support Project (FASP).

FASP

FASP was developed and implemented by E & E in 1983 under the U.S. EPA Field Investigation Team (FIT) contract. E & E has developed a series of analytical options—documented as Standard Operating Guidelines (SOGs)—that form the basis for matching FASP analytical support capability with project Data Quality Objectives (DQOs). SOGs for many analyte groups (VOCs, chlorinated pesticides, nitrogen/phosphorus pesticides, phenoxy herbicides, PCBs, polycyclic aromatic hydrocarbons, phenols and selected metals) in various matrices (soil, water, air, soil gas and oil) have been developed in response to specific needs within the Superfund program.

The Region 10 FASP laboratory had the expertise and instrumentation available to support the Region 9 site assessment; therefore, the loan of Region 10 FIT FASP to Region 9 TAT was effected for on-site laboratory support.

DATA QUALITY OBJECTIVES

To generate data that would meet the project needs, it was imperative that the DQOs at B&B be established clearly. The site DQOs were established through coordination of FASP, TAT and U.S. EPA personnel. The project DQOs at B&B were required to determine the level of analytical support necessary to provide decision-makers with sufficient confidence to support a removal action. In general, choices of specific analytical options for a project may be determined by:

- Health-based concerns
- Sample analysis costs
- Statutory compliance needs
- Analytes of concern or target/indicator analytes
- Regulatory action levels that dictate method detection limits
- Sample matrices
- Sample collection, handling and storage requirements
- Statistical uncertainty in the qualitative identification of analytes and the errors associated with the quantitation.

All of the above considerations must be weighed to determine the appropriate analytical level for the project data. Rarely, if ever, will a single level of information provide the best technical information and the most cost-effective solution to address all concerns at a site.[1]

At the B&B site, initial DQOs were based on the following considerations:

- The need to minimize sample analysis cost
- The need to analyze 30-60 samples per day and to generate contaminant information at 6-inch intervals down each borehole

- The need for the fastest possible turnaround to guide placement of boreholes

Based on the need for cost control and the initial DQOs listed above, it was determined that field analytical laboratory support for the site assessment at B&B would be appropriate.

FASP IMPLEMENTATION

The Region 10 FIT FASP group was approached with the project DQOs and the "wish list" of analytes shown in Table 2 in February 1990. After discussion about the information required to guide on-site decisions, the target analyte list was modified to the parameters shown in Table 3. On-site analytical data generation was restricted to the fumigants—halogenated VOCs that could be determined with a single analytical system and with rapid turnaround. Based on studies of the existing data, project managers determined that information about fumigant contaminations would be sufficient to determine the extent of off-site contamination and the degree to which contaminants had migrated towards the shallow and the deeper aquifers. It was expected that these compounds would migrate the furthest distance from spill locations. Although the dinoseb contaminant distribution was considered to be critical to the site assessment, turnaround in the on-site laboratory would not be fast enough to guide borehole placement. Additionally, the FASP effort would have increased significantly, reducing the cost-effectiveness of the on-site analysis. Dinoseb analysis was performed by a commercial laboratory on the samples chosen for confirmatory volatile analysis.

1,3-Dichloropropane	20
1,2-Dibromoethane	20
1,2,3-Trichloropropane	50
1,2-Dibromo-3-chloropropane	20

FASP methodology for the volatile fumigants was developed prior to mobilization. Existing methodology for chlorinated VOC analysis was modified to meet site DQOs (i.e., positive quantitative identification was compromised for very short analytical run times to accommodate the need for quick turnaround of reported results [2 hours] and the potentially large sample load). These data were to be used only to screen to select samples to be sent to an off-site laboratory for analysis.

After further evaluation of the dynamics of the drilling operation, it became apparent that 12-hour sample data turnaround (rather than 2-hour) would be sufficient to guide borehole placement. The project manager determined that samples collected at 5-foot intervals rather than 6-inch intervals would generate enough data to meet the project DQOs; the sample load on-site would be reduced to 15 to 20 samples per day. The reduced sampling effort in each borehole would allow more field effort to be directed towards drilling, as sampling in Level B was slow and labor-intensive. Rather than using FASP data as a screening tool, it would be used to aid in site characterization, which eliminated the need for off-site laboratory fumigant analysis with 12-hour turnaround. Confirmatory data with standard turnaround were easily available commercially and much less expensive. Consequently, the FASP method was revised prior to the fieldwork to provide more qualitatively accurate results. The field analytical results would be used directly to guide drilling. The on-site phase of the site assessment was initiated in the first week of March 1990.

FASP METHODOLOGY

Sample Preparation

Soil samples were collected in the field in preweighed 22-Ml glass vials. Approximately 0.5-gram samples were collected in each vial; four vials were collected for each field sample.

In the laboratory, the 22-Ml vial was connected directly to the sparging apparatus of the Tekmar system. Internal standard solution was added to the soil volume immediately prior to analysis. Samples with target analyte concentrations greater than 2,000 μg/kg were extracted with methanol prior to analysis.

Instrumentation

Two gas chromatograph (GC) systems were employed on-site: (1) a Tekmar LSC-2000 Liquid Sample Concentrator, coupled to a Varian 3400 GC with a Tracor Photoionization detector (PID) connected in series to a Tracor Electrolytic Conductivity (Hall) detector; and (2) a Tekmar LSC-1 Liquid Sample Concentrator coupled to a Shimadzu GC Mini-3 with an O.I. Corporation Hall detector. Data processing and storage was accomplished using Nelson Analytical PC Integrators. Specific parameters are listed in Table 4.

Table 4

Instrument Parameters	
Extraction	
Instruments:	Tekmar LSC-2000 Liquid Sample Concentrator and Tekmar LSC-1 Liquid Sample Concentrator
Sample Trap Columns:	Silica Gel/Tenax and 34% Silica Gel/65% Tenax/1% SP1000
Purge Gas:	Ultrapure helium – flow 40 mL/min
Trap Column Temperature:	Purge at ambient temperature: preheat trap to 60°C. Desorb 4 minutes at 225°C; bake 5 minutes at 225°C
Analysis	
Instruments:	Varian 3400 gas chromatograph (GC) with a Tracor Photoionization Detector (PID) connnected in series to a Tracor Electrolytic Conductivity (Hall) detector and a Shimadzu GC Mini-3 with an O.I. Corporation Electrolytic Conductivity (Hall) detector
Integrators:	Nelson Analytical PC Integrators with dual channel interfaces and 30MB hard disk drives for data storage
Columns:	J&W 30 meter x 0.53mm fused silica capillary with DB-624 phase
Carrier Gas:	Ultrapure helium – flow approximately 10 mL/min
Makeup Gas:	Ultrapure helium – flow approximately 40 mL/min

Oven:	Initial temperature – 50°C
	Initial time – 5 minutes
	Ramp rate 1 – 10°C/minute
	Final temperature 1 – 100°C
	Ramp rate 2 – 20°C/minute
	Final temperature 2 – 150°C
	Final time – 5 minutes
Detector/Injector:	150°C

Instrumentation and all auxiliary equipment were stored and operated in the Region 10 mobile laboratory.

Analysis

Qualitative identification and quantitation of target analytes were based on both detector selectivity and relative retention time as compared to known standards, using the internal standard method. An initial five-point calibration curve was generated using serial dilutions of a standard mix prepared from NBS traceable individual standards. Standard analyte concentrations ranging from 40 μg/kg to 800 μg/kg (Shimadzu system) or 2,000 μg/kg (Varian system) were used to establish detector linearity (Fig. 1). Daily calibrations and method blanks were performed and required to meet established QC protocols. Matrix spike and duplicate analyses were performed on 10% of the samples to evaluate system performance on the specific site matrix. Representative results for matrix spike and duplicate analyses at the B&B site are presented in Tables 5 and 6.

ANALYTICAL PERFORMANCE

The FASP laboratory analyzed 536 samples, including quality control samples. Approximately 15% of the samples were sent to an outside laboratory for confirmatory analysis. An initial data set was sent for quick turnaround analysis by a commercial laboratory to provide confirmation data at the start of the field project; a summary of detected volatile analytical results is presented in Table 7. All subsequent volatile analyses were performed by the U.S. EPA Region 9 laboratory; the first set of results is presented in Table 8. Approximately 70 additional samples were analyzed by the U.S. EPA laboratory. A summary of the comparison of FASP results and U.S. EPA results for the 70 samples is presented in Table 9.

1,2,3-Trichloropropane	70.4 F	93.1 F	16.5
1,2-Dibromo-3-chloropropane	25.0 UF	23.8 UF	0

U - The material was analyzed for but was not detected. The associated numerical value is a contractual quantitation limit, adjusted for sample weight/sample volume, extraction volume, percent solids, and sample dilution.

F - Data have been generated using Field Analytical Support Project methodologies. Analytes are tentatively identified and concentrations are quantitative estimates.

Field analytical results for all analytes agree on a presence/absence basis in greater than 85% of the samples. Of the 15% of the results out of agreement, approximately half of the analyte concentrations reported are below the quantitation limits of the laboratory reporting nondetected results.

Labor Hours and Project Costs

As of September 1, 1990, a total of 9,247 E & E (FIT and TAT) labor hours were charged to the B&B site assessment. Of this time, 1,871 resulted from field laboratory support—project planning and management, method development, mobilization/demobilization activities, on-site analyses and preparation of the FASP deliverables. The hours invested in on-site analyses can be partially offset by the 85% reduction in on-site labor hours dedicated to the documentation and shipping of samples sent for off-site laboratory analysis.

U   The material was analyzed for, but was not detected. The associated numerical value is a contractual quantitation limit, adjusted for sample weight/sample volume, extraction volume, percent solids, and sample dilution.

F   Data have been generated using Field Analytical Support Project methodologies. Analytes are tentatively identified and concentrations are quantitative estimates.

Expendables purchased for the B&B laboratory support totaled approximately $8,500; no instrumentation purchases were required. The cumulative dollars charged to the site assessment by TAT, FIT and subcontracts to date total approximately $808,000. Of this total, 30% ($242,800) represents "drilling dollars." Clearly, drilling costs drove the project, primarily due to the complications of working in Level B.

It was estimated that it cost $60,000 to set up/breakdown the drilling operations. This cost consideration greatly influenced the decision to not follow the traditional approach of:

Mobilize → Drill some boreholes; Demobilize ↑ → Commercial laboratory analysis → Review results; Make decisions ↓

————————————— Remobilize
Table 9
Comparison Summary of Results from
FASP and U.S. EPA Laboratories

Percent of non-detects in FASP results with positive detect results from EPA	9	8	6	9	5	11

* Based on results from 73 co-located samples

[1] Linear regression correlation coefficient for positive results

The field laboratory's quick turnaround results allowed continuous review of the borehole placement, optimizing drilling time, with only one setup/demobilization throughout the assessment. The U.S. EPA's original project estimate was $500,000 for drilling and geophysical analysis subcontracts. Actual costs total approximately $300,000. The $200,000 cost savings were attributed to field analytical support at the project.

CONCLUSIONS

The B&B site assessment was allocated 90 days to determine appropriate short-term removal actions. The TAT and FIT (FASP) teams were on-site approximately 30 days after the project was initiated; on-site activities continued for 55 days. At the end of that time, enough information had been gathered to describe the site geology and map on-site contaminants. Field analytical data were instrumental .in generating on-site data to support the accelerated time-table of an emergency removal.

It was anticipated that 30 boreholes would be drilled on-site; 37 boreholes actually were drilled based on decisions made from the results provided by the on-site laboratory. The boreholes ranged from 30 feet to 130 feet in depth.

On-site analytical results demonstrated that fumigant migration was much deeper than anticipated. The field analytical data allowed the project manager to revise the drilling plan to trace the fumigant migration pathway deeper, without a remobilization of the drillers at a later date. Off-site contamination was more extensive than anticipated; this off-site migration also effected a change in the original sampling scheme, preventing the need for remobilization to determine the extent of off-site migration.

The B&B site assessment demonstrated how field analytical support can be implemented to guide a site assessment—drilling costs were minimized and borehole placement yielded enough information to support the removal decision.

Determination of Hexavalent Chromium in Soil Samples

Gregory D. DeYong
Brian K. Bowden
Rodney S. Harl
Robert J. Anglin
Hach Company
Ames, Iowa

ABSTRACT

A field screening method for hexavalent chromium [Cr(VI)] in soils was developed and evaluated. The method uses soil extraction and colorimetric Cr(VI) determination with 1,5—Diphenylcarbohydrazide.[1] Determination of Cr(VI) in soils at concentrations down to 0.5 ppm is accomplished within 30 minutes. A simple, inexpensive test kit was assembled, this kit includes convenient, prepackaged reagents and a hand-held color comparator which does not require electrical power. This lightweight kit is easily transported to and used in the field. For laboratory analysis, the system can utilize various equipment to increase efficiency.

In performance testing against TCLP and other extractants, this method demonstrated significantly higher recovery of Cr(VI) in a wide variety of samples. Because of the wide variety of reactions possible between Cr(VI) and soils, no method was capable of recovering 100% of the Cr(VI) in all of the soil samples. However, the Hach method delivered superior results in a short time, which makes it ideal for field screening and site mapping purposes.

INTRODUCTION

Hexavalent chromium is an especially hazardous oxidation state of chromium, because of both its toxicity and its mobility. Cr(VI) is a known carcinogen and irritant,[2] as well as a powerful oxidizing agent. Cr(VI) has been reported to reduce plant growth at soil concentrations as low as 5 ppm.[3] It can be very mobile due to the solubility of some forms in water. These properties make the detection and monitoring of Cr(VI) contamination a very important task.

Unfortunately, determination of Cr(VI) generally is not a simple undertaking. Most current instrumental methods, such as atomic absorption, X-ray fluorescence and mass spectrometry, are not suitable for use in screening for Cr(VI). Some of these methods are unable to separate Cr(VI) from other Cr species, while others are not useful as field methods because they are not very rugged, require stable power sources or must be operated by highly skilled personnel. All of these methods are much more costly than the method proposed here.

The extraction of Cr(VI) from soil samples is also a difficult process. While some forms of Cr(VI) are highly mobile in aqueous solution, other Cr(VI) compounds are insoluble and therefore are not recovered by extraction with water. In addition, Cr(VI) can be adsorbed by soils under some conditions.[3,4] Adsorbed Cr(VI) is removed best by basic solutions,[3] but many forms of Cr(VI) are insoluble in basic solutions. Acidic extractants can recover substantial amounts of Cr(VI), including some forms which usually are insoluble in basic solutions, but acidic solutions also can cause the loss of Cr(VI) because of the tendency of Cr(VI) to be reduced by organic matter under acidic conditions.[3,4] This problem was noted with some extractions during the comparative study conducted for this paper. The extractant developed for the method discussed in this paper overcomes these problems and consistently recovers more Cr(VI) than any of the other methods tested.

EXPERIMENTAL WORK

Soil samples for this comparison are listed in Table 1. Samples included both contaminated site soils and uncontaminated soils with Cr(VI) added. The contaminated soil samples (SS) are listed as SS 1 and SS 2. The origin of SS 1 was unavailable due to confidentiality agreements; SS 2 was obtained from a contaminated site near an engraving company.

The spiked soils were chosen to cover a large range of soil types and compositions. They include samples from Ohio (pH = 6.95, 3.71% organic matter), Oklahoma (pH = 8.15, 0.2% organic matter), Iowa (pH = 6.47, 6.32% organic matter) and Arizona (pH = 8.10, 0.1% organic matter). The spiked samples simulate different degrees of Cr(VI) contamination and extraction difficulty. Samples 1002 and 1004 provide good conditions for extraction, the soils are alkaline and there is little organic matter present. This leaves little chance of Cr(VI) reduction. Samples 0051, 1001, 2001 and 4001 present somewhat more difficult conditions. There is organic matter present, but not in large quantities. This, along with the nearly neutral pH, results in a better chance of Cr(VI) loss through reaction with the organic matter. The final spiked soil, sample 1003, has high organic matter content and a slightly acidic pH. When compared with the other soils tested, this soil provides the best conditions for the reduction of Cr(VI).

The soils which were spiked had been dried and sieved to pass a 20 mesh screen. $PbCrO_4$ and Na_2CrO_4 were added to simulate insoluble and soluble Cr(VI) species. The amounts of the two compounds added were calculated to provide 20% of the Cr(VI) as easily soluble Na_2CrO_4 and 80% as insoluble $PbCrO_4$. After the addition of Cr(VI), each of the spiked soils was mixed with a kitchen mixer for several hours. The low standard deviations obtained in the analyses suggest that the spiked soils were well mixed during the preparation. All of the soil samples used to prepare the spiked soils were analyzed to determine the Cr(VI) blank value, but none contained significant amounts of Cr(VI).

Hach Method

The extractant solution is prepared by dissolving one Cr(VI) Extractant Powder Pillow in 40 mL of deionized water. This solution is then added to a soil sample in a disposable sample cup. The cup is covered and placed on a mechanical shaker for 15 minutes. The soil/extractant mixture is then filtered and an aliquot of the filtrate is analyzed colorimetrically for Cr(VI) using the ChromaVer 3 reagent. The Cr(VI) concentration of the filtrate is used to calculate the amount of Cr(VI)

Table 1
Soil Characteristics

Sample	Origin	% Organic Matter	pH	Cr(VI) Source
0051	Ohio	3.7	6.95	Spiked Soil
1001	Ohio	3.7	6.95	Spiked Soil
2001	Ohio	3.7	6.95	Spiked Soil
3001	Ohio	3.7	6.95	Spiked Soil
4001	Ohio	3.7	6.95	Spiked Soil
1002	Okla.	0.2	8.15	Spiked Soil
1003	Iowa	6.3	6.47	Spiked Soil
1004	Ariz.	0.1	8.10	Spiked Soil

SS 2	Engraving Company	0.7	9.39	Contaminated Site

in the original soil sample.

During the laboratory testing of the methods, a Hach DR/3000 spectrophotometer was used to determine Cr(VI) in the extractant solutions. The kit designed for field use utilizes a color comparator to determine the concentration of Cr(VI). This conclusion device measures Cr(VI) in the soil extract by a visual comparison of the sample with ChromaVer 3 added against a calibrated color wheel. A direct evaluation of the color comparator with the DR/3000 shows that the two measurement methods produce similar results. This is demonstrated by the following comparison of results obtained using Cr(VI) standard solutions (Fig. 1). Each standard was analyzed once using the DR/3000 and once using the color comparator. The agreement between the two methods is excellent over the entire range of the ChromaVer 3 reagent.
Figure 1
Color Comparator vs. DR/3000 Comparison

The results also are very similar when evaluating soil samples by both the mechanical and manual methods. In Figure 2, each soil sample was evaluated twice, once using a mechanical shaker and DR/3000 and once using hand shaking and a color comparator. The results are expressed as recovery percentage of the spiked soils.

Extractions

A sample of soil (1-10 g) is placed in a disposable sample cup with 40 mL of extracting solution. The cup is covered and placed on a mechanical shaker for 15 minutes. The solution is then filtered through filter paper and the filtrate is analyzed colorimetrically for Cr(VI) using the ChromaVer 3 reagent and DR/3000 spectrophotometer. The concentration of Cr(VI) in the soil is then calculated.

TCLP

The Toxicity Characteristic Leaching Procedure (TCLP) was performed as detailed in U.S. EPA Method 1311(5), with the exception that

SS 2	TCLP	------	124 ppm	------	

the extractions were performed at onehalf volume and sample size (1 L extractant and 50 g soil rather than 2 L extractant and 100 g soil). The solution was rotated in a plastic bottle at 30 RPM for 18 hours using a Lightning Rotary Blender, the solution was then filtered and the filtrate was analyzed colorimetrically using the ChromaVer 3 reagent. Using the Cr(VI) concentration of the filtrate, the apparent amount of Cr(VI) in the soil was calculated.

Each soil sample was analyzed once using the TCLP procedure and in triplicate using each of the other three extracting methods. The average and standard deviation of the recovery percentages [Cr(VI) concentrations for TCLP data] was calculated and is listed with the data in Table 2.

REAGENTS AND APPARATUS

Reagents used for the determinations:

Cr(VI) Extractant
ChromaVer 3 Reagent
TCLP Extractant, prepared from:
  Glacial Acetic Acid
  1.0 N NaOH
HCl
Deionized water
Apparatus and instruments used in the experimentation:
Balance
Color Comparator
  Chromate Color Disk
  Long Path Viewing Adaptor
DR/3000 Spectrophotometer
pH Meter
Mixer
Rotary Blender
Shaker Table

Graphing the average recovery percentage of the four extracting procedures for the spiked soil samples shows that the Hach extractant delivers superior recovery and consistency (Fig 3).
Figure 3
Extractant Comparison: Spiked Soils

In Figure 3, our extractant is shown to extract from 74.4% to 102.2% of the Cr(VI) which was added to the soils. This variation probably is due to the oxidation and reduction of Cr(VI) under the varying soil conditions. It does not appear that oxidation occurred during these trials. Although recoveries of greater than 100% were noted, these excesses are small and the values all are within one standard deviation of 100%. The exception is sample 1001, which was close to 100%, but had an extremely small standard deviation. However, oxidation of Cr(III) to Cr(VI) is a possibility under certain conditions. This oxidation can occur by several mechanisms, including oxidation by atmospheric O_2,[6] or by Mn present in the soil.[6,7]

The low recoveries in some samples can be explained by the reduction of Cr(VI). Reduction can occur through the action of organic matter on some ions, including S^2 and Fe^{2+}.[7] This is the most likely explanation for the low recoveries in two of the samples, 0051 and 1003. Sample 1003 contains a large amount of organic matter, which probably caused the reduction of some Cr(VI). In sample 0051, there is a loss of approximately 7 ppm Cr(VI), which is a significant portion of the

50 ppm originally present. This result would appear to be an indication of a problem with this extraction, since other spiked samples prepared from this same soil (1001, 2001 and 4001) did not show any significant Cr(VI) loss. However, it is more likely that each of these samples was subject to a small amount of Cr(VI) loss, but that the only sample in which this loss was noticeable was sample 0051, due to its low Cr(VI) content. In this case, the actual amount of Cr(VI) reduced is small, but quite often the loss of Cr(VI) by reduction appears to be the main source of error in determining Cr(VI). Therefore, it is most important to minimize the loss of Cr(VI) by avoiding conditions which are conducive to this process.

Figures 4 and 5 present a comparison of several extracting methods which were used to evaluate the contaminated site soils, SS 1 and SS 2. Again, our extractant outperformed the other methods tested.
Figure 4
Extractant Comparison: SS 1
Figure 5
Extractant Comparison: SS 2

When using the TCLP extraction procedure, 18 hours is required to complete the extraction. With our method, the extraction of Cr(VI) is mostly completed within a short time and so longer extraction times are not necessary to obtain useful results. In a comparison of HCl, water and our extractant over an 8 hour extraction, the results obtained are shown in Figure 6.

Our extractant quickly removes the Cr(VI) while consistently outperforming the other extractants, even after long extraction times.

DISCUSSION

Determination of Cr(VI) in soils is a difficult task under the best of situations. The accepted techniques involve lengthy extraction periods prior to analysis. These methods are also designed to determine
Figure 6
8 Hour Extraction: SS 1

leachability and often ignore a large portion of the Cr(VI) which is present. This problem is demonstrated in the extraction method comparison, Figure 3. TCLP analysis generally recovered only the easily soluble portion of the Cr(VI) which was added to the soils. This may be acceptable if applied to containment of waste, but TCLP provides very little information about the actual amount of Cr(VI) in a soil sample. The TCLP also uses an acidic extractant leading to reduction of Cr(VI) and is less efficient at removing adsorbed Cr(VI). In addition, the TCLP cannot be considered a field-portable method because of problems with time and equipment.

The other extractants tested all have the potential to be applied to a field method. They have a short extraction time and do not require any bulky equipment for analysis. The differences among these solutions are found in their ability to consistently extract different forms of Cr(VI).

Deionized water will extract the easily soluble Cr(VI) species, but is unable to extract insoluble forms. From the comparison data, it appears that deionized water achieves approximately the same results as the TCLP procedure.

HCl is sometimes able to extract a large portion of the Cr(VI), but it also can cause the reduction of Cr(VI) to Cr(III) when there is organic matter present. This appears to be the cause of the varying recovery percentages for HCl shown in Figure 1. The samples which resulted in low Cr(VI) recoveries were those with considerable organic matter present. HCl also failed to recover most of the Cr(VI) in sample SS 2. Again, reduction of Cr(VI) is the most probable cause.

Our extractant was developed with this possible reduction of Cr(VI) in mind and therefore utilizes a buffering system to prevent the development of acidic conditions during the extraction. The use of a basic extracting solution, however, does not generally allow the recovery of insoluble, sparingly soluble or adsorbed Cr(VI) species. This required the addition of several components to solubilize the Cr(VI) in basic solution, which has resulted in an extractant which has been shown to recover more Cr(VI) than the other methods examined.

The extractant is packaged as a dry powder for easy transportation. When extractant solution is needed, the powder is dissolved in 40 mL of deionized water to produce the correct amount of extractant for one soil sample. With its specialized extractant and portability, this analytical method delivers accurate estimates of Cr(VI) contamination on-site without the use of bulky equipment or the expenditure of valuable time. In addition, with prepackaged reagents and simple procedures, there is no need for the highly skilled operators which are necessary with more complicated instrumental methods. All of these factors, limited equipment, simple procedures, accurate results and on-site analysis, combine to deliver useful results in a short time at a cost which is much lower than any other available method.

Another area of interest when testing for Cr(VI) is groundwater, which can be analyzed by the 1,5—Diphenylcarbohydrazide method. This test kit can also be used to determine Cr(VI) in groundwater at levels as low as 20 ppb.

This flexibility makes our Cr(VI) test kit a valuable tool for Cr(VI) site mapping and contaminant estimation. The use of a field method has been shown to greatly reduce the expenditure of time and funds when evaluating possibly contaminated sites.[9] Currently, the field method of choice is X-Ray Fluorescence, but this method is not able to determine Cr(VI). Our proposed analytical method fills this need for a Cr(VI) field screening and site mapping test.

Site-Wide, Real-Time Air Monitoring During Remediation

Bruce S. Yare

Applied Meteorology, Inc.
St. Louis, Missouri

ABSTRACT

The Brio Refining Superfund site is an abandoned refinery and petrochemical recovery operation located immediately adjacent to a 300-home subdivision. From October 1989 to December 1989, refinery structures, tanks, buildings and process equipment were dismantled and removed from the site. To ensure that any air emissions escaping the work zone were immediately detected, five air monitoring stations (AMSs) were installed upwind and downwind of the dismantlement area. Each transportable AMS consisted of a Byron 301 total hydrocarbon analyzer, two sample intake ports (five feet and fifteen feet above grade) and a one-liter, stainless steel grab sample bottle.

Methane and nonmethane hydrocarbon (NMHC) concentrations were transmitted from each analyzer to a system controller where the upwind and downwind nonmethane hydrocarbon concentrations were compared. An alert sounded when the downwind NMHC concentration was 0.5 ppm greater than the upwind reading and an alarm sounded when the downwind NMHC concentration was 1.0 ppm greater than the upwind concentration. Under alarm conditions, an air sample was collected automatically.

During dismantlement, operations were modified to reduce or eliminate emissions when NMHCs were greater than 1 ppm above background at the downwind fence line. Currently, the system is collecting ambient air quality data in preparation for the planned excavation and treatment of 80,000 yd^3 of organic-containing soil, sludge and liquids.

INTRODUCTION

The Brio Refining Superfund site, ranked 183 on the NPL, is a 58-acre abandoned oil refinery and petrochemical recovery plant located approximately 15 miles south of downtown Houston, Texas. From 1957 to 1978, the plant recycled petrochemical process residues to recover ethylbenzene and other salable products. Raw materials, primarily styrene production byproducts, were stored in a series of earthen impoundments which were closed under state order between 1976 and 1979. During closure, pumpable liquids were removed, nonpumpable liquids were stabilized with sand, clay or calcined clay and the remaining pit was filled with clay soil. Refinery dismantlement and excavation and treatment of 80,000 yd^3 of organic-chemical-contaminated soil, sludge and liquid were selected in the ROD as the primary remedial measures for the site.

Fence-line monitoring was required by the U.S. EPA during the RI/FS to insure that emissions resulting from test trenching, soil boring and other investigatory activities did not have an off-site impact. If downwind fence-line organic concentrations, as measured by a photoionization detector (PID), were more than one ppm above background, invasive investigatory procedures were discontinued. PID concentrations

at the downwind fence line were remeasured every 10 minutes after that until concentrations returned to less than 1 ppm above background. Work then resumed and fence-line monitoring continued. If another exceedance occurred, all work at that location was discontinued and the hole or trench was backfilled immediately to prevent further emissions.

Dismantlement at the Brio Refining site and the adjacent Dixie Oil Processors site, carried out between October and November 1989 under an administrative order issued by the U.S. EPA, created a large potential for emissions as process vessels, tanks, piping, etc., which might contain organic liquids or sludges, were decontaminated and salvaged or cut up for scrap. Prior to the start of work, a real-time air monitoring system (AMS) was installed to measure fence-line air quality during refinery dismantlement. The purpose of this system was to insure that work-zone emissions did not leave the site. This goal was accomplished by cessation or modification of work activities when downwind fence-line nonmethane hydrocarbon (NMHC) concentrations were 1 ppm greater than upwind fence-line NMHC concentrations.

AIR MONITORING SYSTEM

Station Locations

Five air monitoring stations were installed at the site during September 1989: (1) AMS-1 at the southern property line, (2) AMS-2 adjacent to the southern side of Dixie Farm Road (a heavily travelled commuter road), (3) AMS-3 adjacent to the northern side of Dixie Farm Road, (4) AMS-4 in the northwestern quadrant of the site and (5) AMS-5 in the northeastern quadrant of the site (Fig. 1). Station locations were selected on the basis of the prevalent north/south winds, the proximity of potential receptors and the area of the site to be dismantled. Generally, winds in the Houston area come from the south off of the Gulf of Mexico. The next most prevalent wind direction is from the north.

AMS-1 was the upwind, background concentration station when the wind was from the south (Table 1). When the wind was from the north, AMS-1 monitored the impact of site activities both north and south of Dixie Farm Road. Located between the southern fence line of the site and the area to be dismantled, a distance of twenty feet or less, this station was impacted by the site even when the wind was from the south. For that reason, the sample intake port was extended 60 feet to the south and terminated at the property line.

AMS-2 and AMS-3 were placed on opposite sides of Dixie Farm Road to determine the impact of vehicular emissions on ambient air quality. For southerly winds, AMS-2 was the upwind station and AMS-3 was the downwind station. With northerly winds, AMS-3 became the upwind station and AMS-2 was the downwind station.

AMS-4 was the upwind monitor when the wind was from the north

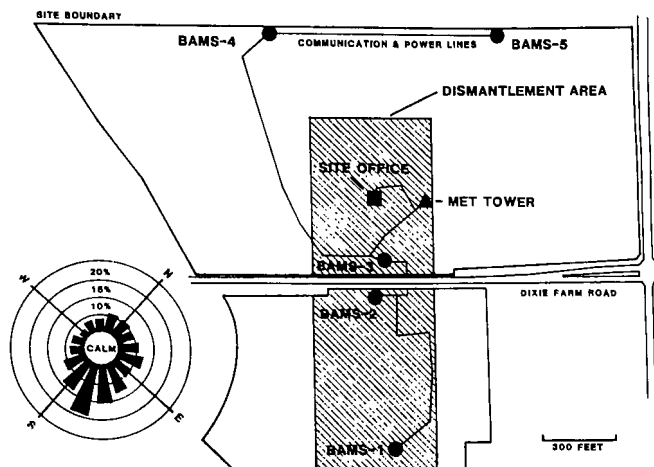
through northwest and the downwind monitor when the wind blew from the south through southwest (Table 1). AMS-5 became the upwind station for winds from the north through northeast quadrant and the downwind station for winds from the south through southwest quadrant. The upwind/downwind stations for southerly and northerly wind conditions are shown on Figure 1.


Figure 1
Air Monitoring Station Locations

Table 1
Upwind/Downwind Air Monitoring Station Selection

Wind Direction (Quadrant)	Wind Direction (Degrees)	Upwind Station	Downwind Station
Northerly	54 to 312	BAMS-5	BAMS-1
Easterly	54 to 132	BAMS-1	BAMS-4
Southerly	132 to 222	BAMS-1	BAMS-5
Westerly	222 to 312	BAMS-4	BAMS-1

Note: Wind direction is the direction the wind is from.

Each air monitoring station was mobile. Mounted on steel skids, the location of any station could be readily changed to any point along the power and signal cable network.

Station Configuration

Each station consisted of two sample intake ports, a total hydrocarbon analyzer, a grab sampler and a particulate sampler (Fig. 2). Air samples were drawn from two intake ports: (1) a low-level intake at five feet above grade and (2) a high-level port fifteen feet above grade. Samples were taken from the five-foot intake on a routine basis to monitor breathing-zone air quality. The fifteen-foot level port was sampled for 15 minutes every two hours to insure that any air deflected upwards by fences or other obstructions, such as buildings, tanks, etc., was monitored.

Air was drawn into the total hydrocarbon analyzer through a heated, stainless steel intake line by a diaphragm pump. Heating the intake line was necessary to prevent condensation from forming when moist outside air entered the climate-controlled instrument enclosure. Capillary tubing was used to route a small amount of air to the hydrocarbon analyzer.

Byron 301 Hydrocarbon Analyzers were installed in air-conditioned, weatherproof equipment enclosures at each station. Cylinders for fuel gas, span gas and calibration gas were mounted outside the enclosures;

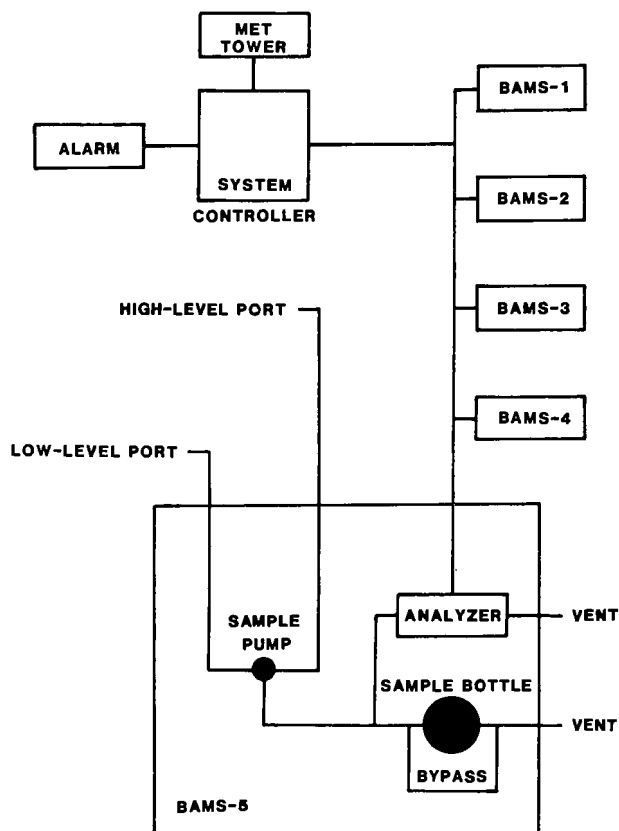
however, the gas regulators were located inside the enclosure. The analyzer was a laboratory-grade instrument which used a short GC column and a flame ionization detector to analyze methane and nonmethane hydrocarbons. Instrument cycle time was three minutes, so the analyzer was capable of up to 20 analyses/hr providing continual but not continuous analyses of ambient air concentrations. Instrument ranges were 0 to 2, 0 to 5, 0 to 10, 0 to 20, 0 to 50 and 0 to 100 ppm. Analyzer accuracy was 1% of full-scale. Since on-site nonmethane hydrocarbon concentrations were not known in advance of system installation and regional total hydrocarbon concentrations of 20 ppm or more were known to occur, the analyzers were operated on the 0 to 100 ppm scale. A mix of 80 to 90 ppm methane and 80 to 90 ppm propane was used as calibration gas.


Figure 2
Air Monitoring System Schematic Diagram

At each station, a stainless steel sampling cylinder was mounted as a flow-through portion of the sample intake line. By closing solenoid-operated valves at each end of the sampling cylinder, a sample of ambient air was trapped until removed for VOC analysis. When these valves were closed, air flow was diverted to a bypass line and routed around the sampling cylinder. This sampling system allowed collection of ambient air samples whenever a threshold concentration above background was reached. Initially, the sampling threshold was set at one ppm above background, but it was later changed to five ppm above background.

A General Metal Works GMWS-2310 high-volume particulate sampler was also installed on the same transportable platform as the hydrocarbon analyzer. Total Suspended Particulate samples were taken every day during equipment dismantlement.

System Controller

Communication cable was used to transmit methane and nonmethane hydrocarbon concentrations, hi-vol sampler flowrate and meteorological

parameters from each of the air monitoring stations and the meteorological tower to the system controller. The system controller, an XT-compatible computer equipped with a 20 megabyte hard disk, acquired the data from the individual air monitoring stations and meteorological tower (wind speed, wind direction, etc.), calibrated the hydrocarbon analyzers, controlled the operation of the hi-vol samplers and displayed real-time data in the site office. Instantaneous and one minute, 15 minute and hourly average values of methane and nonmethane hydrocarbons, wind speed and wind direction were displayed on the monitor. These data were stored on the hard disk for later processing and analysis and also printed every 15 minutes to provide hard copy on-site.

SYSTEM OPERATION

During dismantlement, the system controller constantly polled the meteorological tower to determine wind direction, selected the upwind and downwind air monitoring stations based on the direction the wind was blowing from (Table 1) and determined the difference between downwind and upwind nonmethane hydrocarbon concentrations. Alert conditions existed when the NMHC concentration downwind of the site was 0.5 ppm higher than the base line NMHC concentration detected by the upwind air monitoring station. An alert level of notification was provided to give advance warning of an increase in NMHC concentrations. Alarm conditions existed when the NMHC concentration downwind of the site was 1.0 ppm higher than the base line NMHC concentration detected by the upwind air monitoring station. Different audible and visual alarms were used to distinguish between the alert and alarm conditions in the site office. The dismantlement contractor was notified of these conditions and activities were modified to reduce or eliminate any hydrocarbon emissions resulting from this work.

A number of problems were encountered during system startup, most of them associated with transmission of commands from the system controller to the air monitoring stations and data from the remote air monitoring stations to the system controller. First, varying soil resistivity between the stations and the system controller produced large differences in ground potential. During thunderstorms, a frequent occurrence in the Houston area, these potential differences were so large that the short-haul modems used to transmit data from each AMS to the system controller would burn out even with surge protection. Changing the method of connecting the communication cables to the earth solved part of the problem in the early stages of dismantlement. However, modem burnout was not solved until after dismantlement was completed when more sophisticated, transformer-isolated modems were substituted for the short-haul modems.

Second, a Houston-area radio station induced enough radio frequency interference (RFI) in the communication system to cause errors in data transmission and random activation of the analyzer's zero and span calibration controls. RFI was controlled by installation of line filters and modification of system programming to provide more rigorous error checking. This problem was not be eliminated entirely because there were periods of the day when the station operated at high power levels and the potential for data transmission errors increased. Intelligent data loggers, capable of two-way error checking, will be installed to eliminate the problem with RFI. Random activation of zero and span calibration cycles was controlled by switching from automatic, system-controlled calibration to manual activation of analyzer calibration. When the transformer-isolated modems and intelligent data loggers are installed, the system will be returned to automatic daily calibration.

Another problem with system operation was selecting the analyzer operating range. The manufacturer's recommended start-up calibration gas concentration was 80 to 90 ppm methane and 80 to 90 ppm propane which required analyzer operation on the 0 to 100 ppm scale. Regional air monitoring indicated total hydrocarbon concentrations of 20 ppm or more could occur in the area of the site. Since the range of emissions potentially resulting from dismantlement was unknown and calibration gas concentrations were 80 ppm, the operating range of the analyzers was kept on the maximum scale of 0 to 100 ppm after start up. As mentioned above, alerts were sounded when downwind NMHC concentrations were more than 1.0 ppm above background. With an accuracy of 1 ppm when the analyzers were operated on the 0 to 100 ppm scale (1% of full-scale), instrument drift alone caused alarms to be sounded even during evening and early morning hours when no work was being done at the site. Alarms were always responded to during working hours. However, to avoid constant sample bottle replacement, the ambient air sampling algorithm was changed so that a bottle sample was collected when any NMHC concentration was five ppm higher than the upwind NMHC concentration instead of the 1 ppm difference originally programmed into the system. In the future, this problem will be eliminated by changing the calibration gas concentration and operating the system on the 0 to 20 ppm scale.

CONCLUSIONS

The Brio Air Monitoring System provided a real-time method of determining whether or not dismantlement activities were adversely affecting air-quality at the boundaries of the site. When combined with work zone monitoring, this system provided the assurance that any emissions leaving the work zone were detected at the site fence-line in time to stop or modify the activities causing the releases.

Accurate, On-Site Analysis Of PCBs In Soil
A Low Cost Approach

Deborah Lavigne
Dexsil Corporation
Hamden, Connecticut

ABSTRACT

Polychlorinated Biphenyls (PCBs) are very stable materials of low flammability used as insulating materials in electrical capacitors and transformers, as plasticizers in waxes, in paper manufacturing and for a variety of other industrial purposes.

There are many PCB transformers and capacitors still in service throughout the United States today. The Environmental Protection Agency estimates that there are 121,000 (askarel) PCB transformers, 20 million PCB-contaminated mineral oil transformers and 2.8 million large PCB capacitors currently in use. A certain percentage of this equipment will leak, fail or rupture and spill PCB into the environment each year.[1]

Because of equipment leakage and widespread industrial dumping, PCBs have appeared as ubiquitous contaminants of soil and water. Chemical analysis for PCBs has been almost exclusively performed by gas chromatography. Other analytical techniques such as nuclear magnetic resonance (NMR) and liquid chromatography with UV detection are alternative methods for PCB analysis but can only be successfully applied where the suspected concentration level of PCBs is greater than 1000 ppm.[2]

A new instrumental method has been developed to analyze for PCB content using electrochemical methodology and a chloride-specific electrode to measure quantitatively the amount of chloride. The instrument converts the chloride concentration into a PCB equivalent amount of PCBs in an oil or soil sample and gives a direct readout in parts per million of PCBs. The preparation steps involve extracting the PCBs from the soil (not necessary for oil samples) and reacting the sample with a sodium reagent to transform the PCBs into chloride which subsequently can be quantified by the instrument. Oil samples take approximately 5 minutes to prepare and soils approximately 10 minutes. One operator can complete approximately 150 oil tests or 100 soil tests in an 8-hour day.

Although this paper will concentrate on the results of soil samples obtained from a Superfund site analyzed both electrochemically and by gas chromatography, it demonstrates the accuracy and economic advantage of employing the electrochemical procedure in analyzing both oil and soil samples.

INTRODUCTION

PCBs were first formulated in 1881. Although they were known to exist in the late 1800s, manufacturing on a commercial scale did not start until 1929. All U.S. production of PCBs was halted in 1977.

In the late 1960s, PCBs were recognized as a potential environmental problem, which was probably due to the unregulated maintenance and handling of PCB-containing equipment. Several studies have been done to identify and quantify the distribution of PCBs in the United States. The overall distribution is shown in Figure 1.

Presently in use	750 million pounds	60%
In landfills and dumps	290 million pounds	23%
Released to environment	150 million pounds	12%
Destroyed	55 million pounds	5%
Total production	1,245 million pounds	100%

Figure 1
U.S. Distribution of PCBs[4]

The wide use of PCBs was due to their nonflammable characteristics as well as their chemical inertness, heat resistance, chemical stability, low vapor pressures at atmospheric temperature and high dielectric constant. Although the use of PCBs in some applications has been banned, they still are being used in vacuum pumps and gas-transmission turbines. PCBs previously were used as plasticizers in synthetic resins, in hydraulic fluids, in adhesives, in heat transformer systems, in lubricants, in cutting oils and in many other applications.

The U.S. EPA currently recommends two PCB-specific methods of analysis: (1) the GC/MS Method 680 for quantitating PCB isomer class totals and (2) the GC/ECD Method 8080 for quantitating Aroclors. Over the past decade, the use of these instrumental methods has increased dramatically. It is the purpose of this paper to provide an example of one type of nonspecific analysis of PCBs where simple inexpensive chemical procedures can, in fact, under certain circumstances be a preferable alternative to chromatographic methods.

The two examples chosen in this paper are the analyses of PCBs in transformer oil and soil. The tests involve measurements of PCB concentrations down to a few parts per million where, as a result of extensive legislation, inaccurate results would likely evoke expensive litigation and heavy fines. The different methodology and apparatus will be described, the accuracy and precision of each method discussed and the costs of each analysis reported.

METHOD FOR THE ELECTROCHEMICAL DETERMINATION OF PCB IN OILS AND SOIL

This procedure utilizes sodium metal to remove chlorine from any PCBs present in the sample. Using a chloride-specific electrode, the concentration of chloride contained in the final aqueous extract can then be determined electrometrically. By immersing a chloride-specific electrode in the aqueous extract and measuring the EMF produced, the chloride concentration and, thus, the PCB content can be estimated. The chloride concentration is exponentially related to the electrode EMF and thus with a suitable electronic circuit design the results can be presented digitally on an appropriate meter in ppm of the selected PCBs.

This is a nonspecific method, testing for the presence of chlorine in the sample being examined. As a result, other chlorinated compounds will cause a false positive result because the analysis method reads all chlorinated compounds as PCBs. False negative results should not occur, however, because if no chlorine is present, PCBs cannot be present.

SAMPLE PREPARATION

Oil Samples

A 0.2-mL aliquot of a solution of naphthalene in diglyme is added to 5 mL of oil sample. To this mixture is added 0.4 ml of a dispersion of metallic sodium in mineral oil, and the mixture is shaken for 1 minute. A 5 mL quantity of buffer is then added to neutralize the excess sodium and to adjust the pH to 2.0 to ensure the pH of the mixture is within the operating range of the electrode. A 5-mL aliquot of the aqueous layer is then carefully decanted into a suitable vessel.

Soil Samples

A 10-g sample of soil is extracted by shaking for 1 minute with 12 mL of solvent containing 2 mL of distilled water in 10 mL of an immiscible hydrocarbon. The soil is then allowed to settle and the supernatant liquid is filtered through a column containing Florisil to remove any moisture and inorganic chloride. A 5-mL aliquot of the dry filtrate is then treated with 0.2 mL of a solution containing naphthalene in diglyme, followed by 0.4 mL of a dispersion of metallic sodium in mineral oil and shaken for 1 minute. A 5-mL aliquot of buffer solution is then added and the aqueous layer is allowed to separate. Finally, 5 mL of the aqueous layer are then decanted into a suitable vessel.

ANALYTICAL METHOD

The measuring instrument (Dexsil L2000™, Hamden, Connecticut) is fitted with temperature compensation as the output of the chloride-specific electrode varies with temperature. Initially, the temperature compensation adjustment is set to the sample/electrode temperature. The electronic measuring device is then calibrated employing a solution containing chloride equivalent to 50 ppm. The electrode is immersed in 5 mL of the calibration solution and appropriate adjustments are made to the calibration control to provide an output on the digital meter of 50 ppm of chloride.

After rinsing and drying, the chloride-specific electrode is immersed into the 5 mL sample, gently stirred for 5 seconds and allowed to stand for 30 seconds. The concentration of PCB in ppm is then read directly from the digital output meter. The dynamic range of this analytical procedure is from 5 to 2000 ppm. The precision varies with the concentration. At concentrations between 50 and 2000 ppm, the precision is +/- 10%. Between 5 and 50 ppm, the precision is approximately +/- 2 ppm.

ANALYTICAL TESTS, RESULTS AND DISCUSSION

Oil Samples

In general, PCB-specific methods are more accurate than nonspecific methods, but they also are more expensive, more lengthy to run

and less portable. The L2000™ PCB analyzer provides accurate analysis of PCB concentrations in oil by testing for the total amount of chlorine that is present in the sample.

The PCB concentration is calculated from the chloride concentration using a conversion factor based on the Aroclor present in the sample. If the specific Aroclor is not known, then the most conservative estimate results from assuming that the PCB present is Aroclor 1242. Aroclor 1242 contains the lowest percentage of chlorine of the commercially produced PCB mixtures.

The 1260 setting is used when a sample contains Aroclor 1260 but not the associated trichlorobenzene.

The Askarel setting is used for samples that contain Aroclor 1260 and associated trichlorobenzene. Askarel accounts for the majority of contaminated transformer oil samples and, therefore, this setting will usually supply the most accurate results. However, if a 1242-contaminated sample is tested on the Askarel setting, a false negative will result if the sample contains between 50 and 120 ppm.

Tables 1 and 2 show comparison results of transformer oils contaminated with 1242 and 1260 (as Askarel), respectively, analyzed by the PCB-specific GC method versus the L2000™. The GC method used to analyze the transformer oils in this study is U.S. EPA Method 600/4-81-045.

Accurate and precise results are obtained over a wide concentration range of PCBs and although false positives can cause unnecessary secondary testing, this method can be very economical when used on transformer oil, which contains few sources of chlorine other than PCBs. Used crankcase and cutting oils, however, always contain some chlorinated paraffins and almost always give false positive results with nonspecific testing. More expensive gas chromatographic analysis is required when testing for regulated levels of PCBs in these matrices.

Soil Samples

The U.S. EPA Spill Cleanup Policy stipulates that a PCB spill, once detected, must be cleaned up within 48 hours.[3] The U.S. EPA mandates that cleanup actions are taken in this short time-frame in order to minimize the risk of human and environmental exposure to the spilled PCBs. In addition to the many PCB Superfund sites, there are many other PCB spill sites that have not made the National Priorities List that still must be cleaned up.

One of the most time-consuming steps in laboratory soil analysis is the drying time. When a soil sample is received for GC analysis by ASTM D3304, the sample is dried for 24 hours. The sample is then weighed and placed in an extractor and allowed to cycle for 8 hours. The sample must be completely dry, since the extraction solvent (usually hexane or isooctane) is immiscible with water. Extraction of a wet sample would yield a low result since the solvent cannot fully interact with the soil to extract the PCBs. Typically, 90% of soil samples received for laboratory analysis by GC require drying prior to extraction. With a 48-hour cleanup policy, 24 hours of drying time could be a substantial setback. Ideally, the content of the spilled material must be determined at once and the cleanup procedures begun immediately. The L2000™ allows the operator to respond immediately and to make a quick evaluation of the PCB concentrations at the site. At an excavation site where soil analysis is being performed, the decision can be made immediately if more soil needs to be removed or if the excavation has been carried far enough.

The results of soils obtained from a Superfund site and analyzed by GC and the L2000™ are compared in Table 3. Since gas chromatography can quantitate each Aroclor present, the GC results are presented for each Aroclor actually detected in the soil samples. The corresponding L2000™ results for that particular sample are seen on the same line. These results are listed according to each setting available to the analyst. The L2000™ does not have the capability to quantitate each Aroclor; instead, all the chloride present is interpreted according to the Aroclor setting being used. For samples contaminated with an unknown Aroclor, the prudent analyst would use the 1242 conversion to provide the most conservative estimate.

Using the L2000™ as a screening method, the samples are

evaluated according to column 4 interpreting chloride as 1242. For the ten samples analyzed, Samples 2, 3, 4 and 6 would be considered as below the Code of Federal Regulations limit of 10 ppm set by the U.S. EPA. Since this is a site remediation, the results would indicate that these areas can be considered clean and would not need further treatment. If active cleanup were underway, these samples would indicate that the excavation has gone far enough in that area.

The remaining samples indicate that there is still possible contamination above the 10 pm level. This would result in further excavation being required to reach safe levels. If active excavation is not underway, the samples can be further analyzed to determine the specific Aroclor content. Whether the samples are further analyzed, or excavation is continued based on the 1242 estimate, will depend on the cost consideration of waiting for laboratory results while paying for an idle excavation team and remediation equipment, or excavating excess material while the crew and equipment are still on-site.

From the GC analysis, it was determined that only two of the six "positives" were "false positives" in that the total chlorine makeup indicated an equivalent of PCBs above the regulatory 10 ppm limit, whereas GC analysis of those samples showed an actual level below 10 ppm.

The problem of contamination with chlorinated solvents is exemplified by Sample 1, where the L2000™ result is considerably higher than the GC results. This high reading again is an overestimation of the PCBs present, and would result in a conservative action being taken such as retesting using GC or further excavation.

To make a systematic comparison of the GC results which quantify each Aroclor separately, to the L2000™ results, an equivalent amount of a single Aroclor must be calculated from the sum of all Aroclors detected. For the results given in this paper, Aroclor 1242 was chosen as the basis for equating the L2000™ results with the GC results. The equivalent L2000™ reading, which converts the chloride concentration to PCBs using a single Aroclor conversion factor, can then be calculated. The direct conversion of ppm 1260 by GC to its equivalent in ppm 1242 is based on the percent chlorine difference of 1242, 42%, versus 1260, 60%, according to the equation:

$$\text{L2000 equivalent ppm } 1242 = (X)(60/42)$$

where

X = ppm 1260 by GC
60/42 = ratio of percentage chlorine

For example, the GC results for the first soil sample shown in Table 3 of 11.59 ppm 1242 and 2.24 ppm 1260 should theoretically read 14.79 on the L2000's 1242 setting. The value of 14.79 is attained by converting the GC 1260 value to 1242 according to the equation above, and adding it to the GC value for 1242. The actual reading on the L2000 1242 setting was 25.0 ppm, which is significantly higher than the theoretical prediction. The false high reading can probably be attributed to other chlorinated compounds being present in the soil that the GC does not detect. Nevertheless, from a regulatory point of view, a false positive is preferable. A more realistic and expected result is seen from the results for the seventh soil analysis shown in Table 3 and, once again, a theoretical concentration of 1242 can be predicted from the conversion equation. The GC result for that sample was 92.66 ppm 1242 and 15.08 ppm 1260. 15.08 ppm 1260 converts to 21.54 ppm 1242 which, when added to 92.66 ppm 1242, gives a theoretical projection of 114.2 ppm 1242 as the L2000 result. The actual 1242 result given by the L2000 was 122.7, which is within the +/- 10% accuracy level accepted for GC analysis.

Like the oil samples, soil sample concentration of PCBs are also based on the detection of chlorine; however, it is only chlorine present from an organic source that would cause a false positive, as seen in the first example above, rather than an inorganic source such as road salt or sea salt. Some possible sources of chlorine contamination are pesticides and solvents.

Table 3
Comparison of Superfund Site Soil Analyses:
Gas Chromatography vs. L2000 Readings

GC RESULTS			L2000 RESULTS (read as)		
1242	1254	1260	1242	1260	ASKAREL
11.59 ppm		2.24 ppm	25.0 ppm	17.5 ppm	10.6 ppm
... ppm		0.25 ppm	0.9 ppm	0.6 ppm	0.4 ppm
	2.64 ppm	1.78 ppm	7.9 ppm	5.5 ppm	3.3 ppm

0.77 ppm	0.80 ppm	0.35 ppm	7.5 ppm	5.3 ppm	3.2 ppm
92.66 ppm		15.08 ppm	122.7 ppm	85.8 ppm	51.7 ppm
7.18 ppm	1.54 ppm	0.08 ppm	11.5 ppm	8.1 ppm	4.9 ppm
7.87 ppm	3.25 ppm	0.30 ppm	13.0 ppm	9.2 ppm	5.6 ppm
		9.43 ppm	16.2 ppm	11.4 ppm	6.9 ppm

Table 4 shows a comparison of results from soil samples obtained from a PCB spill site.

Table 4
Comparison of PCB Spill Site Soil Analyses:
Gas Chromatography vs. L2000

GC RESULTS			L2000 RESULTS (read as)		
1242	1254	1260	1242	1260	ASKAREL
.30 ppm		6.09 ppm	10.8 ppm	7.5 ppm	4.5 ppm
.10 ppm		41.59 ppm	62.5 ppm	43.8 ppm	26.4 ppm
.97 ppm		0.40 ppm	5.7 ppm	4.0 ppm	2.4 ppm
.38 ppm		0.05 ppm	6.1 ppm	4.3 ppm	2.6 ppm
.68 ppm		6.67 ppm	14.8 ppm	10.3 ppm	6.2 ppm
		4.42 ppm	7.3 ppm	5.1 ppm	3.1 ppm
		206.0 ppm	404.0 ppm	281.0 ppm	167.5 ppm
		1699.0 ppm	>2000 ppm	1642.0 ppm	996.0 ppm

One benefit to the laboratory personnel analyzing soils is to use the L2000™ first to screen PCB content, thus allowing the GC chemist to make an accurate dilution immediately. The appropriate dilution is to 1 ppm, and one chromatographic analysis is approximately 40 minutes long. The analysis time can certainly add up with trial-and-error dilutions being made, especially if there are many samples waiting to be analyzed. Knowing the right dilution also prevents overloading the column with PCB contamination.

The L2000™ system can analyze to fewer than 5 ppm in oil and soil, can be used in the field by non-technical personnel and requires less than 10 minutes to run an analysis. These attributes make the instrument an excellent alternative to gas chromatographic analysis, especially for soil samples.

Although this new technique does not replace gas chromatography, it can significantly reduce the number of samples requiring GC analysis, and thus allow a greater amount of samples to be run at a lower cost.

Source Identification and Characterization Using Areal and Vertical Soil Gas Sampling Techniques

Kurt O. Thomsen, Ph.D., P.G.
Sarah Joyner
PRC Environmental Management, Inc.
Chicago, Illinois

ABSTRACT

Areal and vertical soil gas sampling techniques were used to locate and characterize a 200-foot diameter carbon tetrachloride (CCl_4) release area within a 370-acre site. In 1985, a municipal well was found to be contaminated with CCl_4. A detailed site history profile was developed to help identify the source of the groundwater contamination. This profile identified several potential sources within the site boundary, but subsequent sampling yielded no conclusive data.

A shallow areal soil gas survey was conducted, which consisted of 100 samples collected at 86 sampling locations within the site. Soil gas samples were taken from a depth of 2 to 3 feet and analyzed on-site for CCl_4 by a close support laboratory. The results identified three areas for further study.

As a result, PRC devised a technique to determine vertical CCl_4 concentration in soil gas profiles. This technique consisted of driving a soil gas collection probe ahead of a hollow-stem auger and taking a gas sample. Soil gas samples were collected from eight boreholes at regular intervals throughout the unsaturated soil zone (approximately 120 feet).

The borehole soil gas data identified the presence of CCl_4 above the water table in one borehole next to a former grain storage facility. To identify the source of this contamination, PRC collected shallow to mid-level soil gas samples from three depths between 8 and 22 feet at 34 locations around the facility. The results identified a CCl_4 release area and its areal extent. Subsurface soil gas sampling in additional boreholes in the source area confirmed the location and described the vertical configuration of the soil gas plume and its relation to the water table. Sufficient in situ groundwater samples were taken from each borehole within the saturated zone to describe the CCl_4 source and to select remediation alternatives. The approach used to locate and characterize the CCl_4 source area was very efficient and cost-effective.

INTRODUCTION

To remediate contamination at Superfund sites, it is often difficult, yet critical, to pinpoint the exact location of the contaminant source. Our firm, PRC Environmental Management, has developed an approach that was efficient and cost-effective in locating and characterizing the source of contamination at a subsite of a Superfund site in Hastings, Nebraska.

As part of an extensive Superfund investigation initiated in 1984, the U.S. EPA identified six subsites that may be contributing to groundwater contamination in the city of Hastings, Nebraska. The sites found included the M-3 subsite, which is the focus of this paper. The subsite covers approximately 370 acres in the west central part of town. It contains the release area responsible for the CCl_4 contamination of a nearby municipal well (M-3) in Hastings, Nebraska, and is partially respon-

sible for the contamination of the drinking water supply for the entire town.

The State of Nebraska discovered in 1984 that well M-3 was contaminated with CCl_4; it was decommissioned in 1985. The source of contamination was not identified until intensive investigations were initiated in late 1987. The field work for the remedial investigation activities for the M-3 subsite was conducted between the fall of 1987 and the spring of 1989.

METHODOLOGY

The approach used to locate and characterize the source of contamination consisted of the following five steps:

Source Location Steps

- Conducting a historical search of property use
- Conducting a surface soil gas survey
- Drilling boreholes using multiple-phase data collection techniques
- Conducting a followup shallow to mid-level soil gas survey in the source area

Source Characterization Steps

- Drilling additional boreholes in the source area using multiple-phase data collection techniques

The ability to have immediate access to data throughout the investigation was essential. Therefore, a close support laboratory (CSL) was used on-site to keep the investigation progressing in a timely manner. Use of the CSL allowed ongoing data interpretation, which was necessary to make the decisions and implement the steps outlined above. The CSL located in the PRC field office, was equipped with a gas chromatograph. The CSL was used to analyze samples collected during the M-3 subsite remedial investigation. The U.S. EPA's Contract Laboratory Program (CLP) laboratories were used to analyze replicate portions of the samples collected as quality control checks on the CSL and to provide litigation-quality data.

The following sections discuss each of the remedial investigation steps.

Historical Records Search

U.S. EPA Region VII conducted an historical search uses of the site, which consisted of a title search and interviews with area residents. The results revealed the locations of former grain storage areas and other operations that may have been responsible for the well M-3 contamination. CCl_4 had been used extensively as a grain fumigant in the area.

Surface Soil Gas Survey

A surface soil gas survey was conducted in the areas of former grain

storage activities in an attempt to locate the source of contamination at the subsite. Since the locations of the former grain storage areas were so widespread, 100 surface soil gas samples had to be collected. The samples included duplicates and were collected from 86 locations within the subsite.

To collect the surface soil gas samples, a hand-held probe was hammered into the ground to reach the sampling interval at a depth of 1 to 3 feet below the ground surface. At the top of the probe, a sampling air line was connected to a quick-disconnect fitting. The sampling line ran from the top of the probe to a small vacuum pump. Prior to sampling at each location, the probe and line assembly were purged with the pump until the pump exhaust reached equilibrium. To determine the point of equilibrium, the exhaust from the pump was monitored with an HNu organic vapor analyzer. The purge times were approximately 12 minutes. When the purge was completed, soil gas samples were collected in Tedlar bags and sent to the CSL.

The results of the surface soil gas sampling effort were generally inconclusive. However, trace amounts of CCl_4 were detected in an area where a railroad company had once operated a solvent-generating maintenance facility. CCl_4 also was found in the vicinity of a few former grain storage areas.

Borehole Drilling

Exploratory boreholes were drilled using the "multiple-phase" approach, so named because it determines the distribution of volatile organic compound (VOC) contaminants in three phases—soil, gas and water. The borehole data were used to establish vertical profiles of the chemical and physical characteristics for each phase. In the unsaturated zone of each borehole, vertical profile data were collected for specific parameters—relative density, visual classification, unsaturated permeability, moisture and the chemicals of interest for soil and soil gas. The CSL analyzed all soil and soil gas samples for CCl_4 and other selected VOCs.

Boreholes were drilled using hollow-stem augers. Soil samples were collected with a 3-inch-diameter split spoon sampler at 5-foot intervals beginning at the surface and continuing to a depth of 120 feet (depth of the water table). Soil samples were monitored in the field with an HNu organic vapor analyzer, followed by visual classification. Portions of the samples were sent to the chemical and physical CLP laboratories for analysis. In situ soil gas samples were collected at 10-foot intervals between soil samples. A soil gas probe was driven into the undisturbed formation ahead of the auger flights. Samples were collected in the same manner as described above in the surface soil gas survey section.

Based on the results of the historical survey and the surface soil gas survey, eight locations were designated for drilling exploratory boreholes. Six of the eight boreholes failed to yield more than background levels of CCl_4. Soil gas results from the seventh borehole indicated that a nearby gas tank was leaking or had leaked in the past. CCl_4 concentrations in the range of 15 ppmv were found in samples above the water table at the eighth borehole (C-2), located in the western portion of the subsite. As a result, this portion of the subsite was chosen for more detailed study, which included a shallow to mid-level soil gas survey.

Shallow to Mid-level Soil Gas Survey

Shallow to mid-level soil gas samples were collected throughout the source area. A grid was surveyed over the entire source area and, where possible, sampling locations were evenly spaced along the grid. Thirty-four soil gas samples were collected along the surveyed grid.

The shallow to mid-level soil gas samples were collected by using a hydraulic soil gas sampling device called a Geoprobe. The Geoprobe is a van-mounted sampling unit consisting of a hydraulic press capable of pushing a 1-inch outer diameter rod, with a slotted rod, used as a screen, as deep as 40 feet below the ground surface. Samples generally were collected at intervals of between 8 to 10 feet, 14 to 16 feet and 20 to 22 feet below the ground surface. The exact sampling depths varied slightly between locations, depending on the types of soils encountered. Some soil types were too resistant for the Geoprobe, in which case samples could not be collected.

At the top of the Geoprobe rod was a sample port with an attached gas sample line. The soil gas samples were collected in basically the same manner as the surface soil gas samples and were analyzed by the CSL.

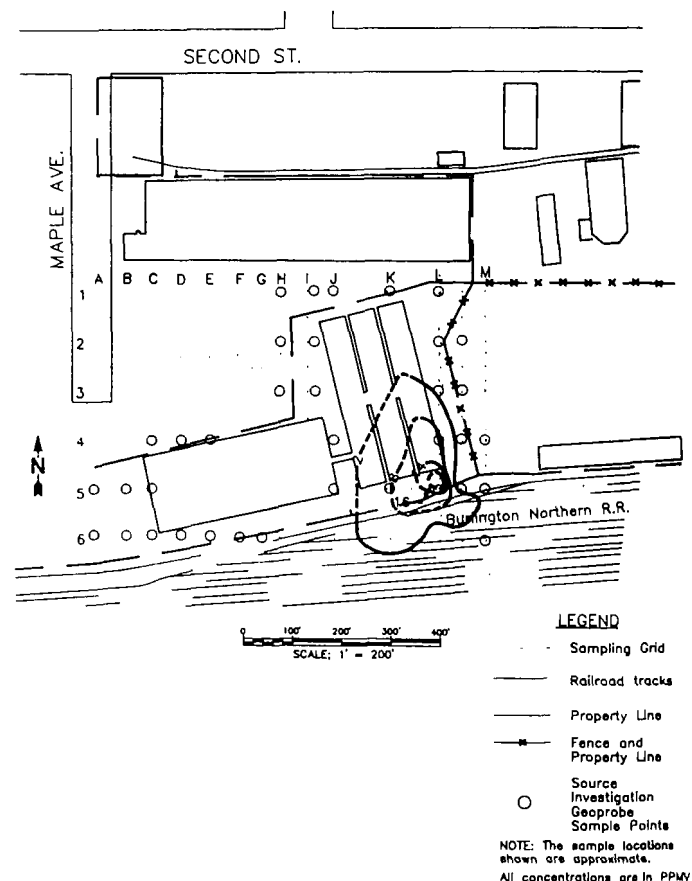
The shallow to mid-level soil gas survey identified the exact location of the suspected CCl_4 release area within the M-3 source area. Figure 1 is a plan view of the approximate boundaries of the CCl_4 soil gas plume. The highest concentrations were detected in a sample from the southeast corner of a warehouse. Generally, CCl_4 concentrations increased with depth. However, the Geoprobe soil-gas survey was intended as a screening tool to help locate the next borehole locations. The Geoprobe survey was actually used to locate the source of contamination, while the multiple-phase borehole drilling activities characterized the soil gas contamination plume.


Figure 1
Carbon Tetrachloride Concentrations at
8-10' on Geoprobe Results at M-3 Subsite

Additional Borehole Drilling

Once the source of contamination was identified, three additional boreholes were drilled to characterize the source. The multiple-phase approach was used again for drilling the boreholes. These boreholes were different from the boreholes previously drilled in that they were advanced into the saturated zone. In the unsaturated zone, soil and soil gas samples were collected in the same manner previously described using the hollow-stem auger technique. In the saturated zone of each borehole, vertical profile data were collected for specific parameters—relative density, visual classification, porosity, specific yield, horizontal hydraulic conductivity and the chemicals of interest for soil and groundwater. The CSL analyzed all soil and groundwater samples for CCl_4 and other selected VOCs. In situ groundwater samples were collected at 10-foot intervals between soil samples. Groundwater samples were collected using a groundwater sampling probe that was driven into

the undisturbed formation ahead of the auger flights. A pneumatic slug test method was used to test hydraulic conductivity in the same intervals from which groundwater samples were collected.

Figure 2 depicts the CCl_4 concentrations soil gas plume in the unsaturated zone. CCl_4 soil gas concentrations ranged from 0 to greater than 1,200 ppmv. The greatest concentrations were recorded directly above the water table. Groundwater samples collected from 5 to 10 feet below the water table contained CCl_4 concentrations ranging from 33 to 49 ug/L in borehole C-9.

The dimensionless Henry's Law constant for the partitioning of CCl_4 from the gas phase to the water phase is 0.97 or, for practical purposes, unity. This finding means that a one-to-one relationship probably exists between the CCl_4 concentrations in the soil gas and the ground water in the capillary fringe and directly below the water table. The gradient of CCl_4 concentrations between the water table and the groundwater sampling zone located 5 to 10 feet below the water table is apparently very steep, as evidenced by relatively low CCl_4 concentrations in groundwater samples collected from this lower zone. Also, the data clearly indicate that soil gas contamination is responsible for groundwater contamination in the subsite area.

CONCLUSIONS

Using the above approach, PRC successfully located a source area, with an approximate diameter of 200 feet, within a 370-acre subsite. The source was located and sufficiently characterized to begin remediation activities. Based on this study, soil vapor extraction will be used to remediate the unsaturated zone. Not only will soil vapor extraction remove the contaminated soil gas, but it also will favor limited partitioning of the CCl_4 from the surface of the ground water into the gas phase above the ground water. The source area should be remediated using this approach in a relatively short period of time. More study will be needed, however, before the ground water can be remediated.

Economic Analysis of the New Toxicity Characteristic Leaching Procedure

Jay Boyd Best
Metcalf and Eddy
Division of Hazardous Waste
Wakefield, Massachusetts

ABSTRACT

On Mar. 29, 1990, the U.S. EPA published in the Federal Register the final Rule of the Toxicity Characteristic Leaching Procedure (TCLP). The Implementation of this rule will bring an estimated 730 million metric tons of waste each year under the provisions of Subtitle C of RCRA. This figure is roughly 300% increase in the volume of regulated hazardous waste. The goals and merits of this ruling are examined from a neoclassical economics perspective. Does this regulation succeed as government policy to maximize the social welfare?

The history of the Extraction Procedure Toxicity Characteristic (EPTC) which proceeded the TCLP is considered. Each procedure uses a similar logic to determine the regulatory concentration.

The U.S. EPA, although required by Congress to change the EPTC, had considerable leeway in creating the new regulation. The intent of the TCLP is to reduce human health risks and environmental damage. Given these criteria, the TCLP rule should be very successful. When the costs of the rule to industry are considered, however, the rule may be too expensive. Higher allowable regulatory concentrations provide very nearly the same benefits but at substantially reduced costs. In economic terms, the marginal cost of the rule exceeds its marginal benefits.

As with any economic analysis, this one suffers from a lack of sound data. Measurements of economic costs are relatively easy to compute, but measurements of benefits are notoriously difficult.

INTRODUCTION

In 1976 Congress passed the Resource Conservation and Recovery Act.[2] RCRA contains provisions which affect the disposal of nearly all municipal and industrial material waste produced in this country. This act created two broad categories of waste: hazardous and nonhazardous waste. The disposal requirements of hazardous waste are governed by Subtitle C of RCRA. As might be expected, the disposal requirements for hazardous waste are more stringent and more expensive than those for nonhazardous wastes.

RCRA uses two methods for classifying waste. One method is based on the industrial process which created the waste. The U.S. EPA has performed numerous studies of different industries and of different industrial processes. These studies have identified wastes that are considered to be hazardous. The U.S. EPA then promulgates a regulation which brings all of the waste produced by a particular industrial process under the realm of Subtitle C. This process works well for industry which prefers easy determinations of regulatory applicability. A process either is or is not regulated and the waste either is or is not hazardous.

The time and expense of these industrial process studies combined with the sheer number of industrial processes necessitated a second method of classifying waste. This method is based on four characteristics: ignitability, corrosivity, reactivity and toxicity. Each of these characteristics is determined by a laboratory test and compared to a regulatory criteror. The Mar. 29, 1990 Federal Register[1] changes the protocol of the laboratory test and the criteria used for determining the toxicity characteristic. This new rule becomes effective Sept. 25, 1990 for large facilities and Mar. 29, 1991 for small facilities. (A small quantity generator is defined as one producing less then 1000 kg/mo.)

Mismanagement Scenario

TCLP will replace the old toxicity characteristic Extraction Procedure Toxicity Characteristic.[6] Before elaborating on the critical differences between the these procedures, it is important to understand the logic behind the toxicity characteristic. A specific mismanagement scenario which assumes the disposal of wastes in an unlined municipal landfill creates a mechanism for human exposure via groundwater contamination.[1,5,6] As water migrates downward through the landfill, it contacts the waste. Some constituents of the waste become mobile, traveling downward with the water until they reach groundwater, then traveling laterally in the subsurface aquifer. Once in the aquifer the waste may become a contaminant in a downgradient drinking water well. Human exposure occurs and the potential for toxic response exists.

The U.S. EPA set out to model the toxic risk resulting from improperly disposed waste. The model assumes a toxicity threshold for human exposure. The toxicity threshold is the concentration of a contaminant below which humans show no toxic response. This may be considered the maximum safe exposure level over the lifetime of a human, referred to as chronic toxicity reference level (CTRL).[1,5,6] The CTRLs are based on the maximum concentration limits (MCLs) promulgated as part of the National Interim Primary Drinking Water Standards (NIPDWS) when available. When these do not exist for specific compounds in question, oral reference doses (RfDs) and risk-specific doses (RSDs) for carcinogenic and noncarcinogenic compounds, respectively, are used. These are based on published and generally accepted standards.

From the landfill to human exposure dilution of the contaminant is assumed to occur.[1,5] A dilution and attenuation factor (DAF) can be determined by modeling the groundwater flow through the hydraulic media. To determine the maximum contaminant level safe for disposal in an unlined landfill, the CTRL is multiplied by the DAF. This product determines the regulatory levels:

$$DAF \times CTRL = Regulatory\ Concentration \qquad (1)$$

Both the TCLP and the EPTC are extraction procedures designed to mimic the possible conditions resulting in the leaching of toxic compounds into the groundwater. The waste extract is then analyzed and compared to the regulatory levels.

EPTC vs. TCLP

The original EPTC contains criteria for 14 compounds; eight metals and six organic compounds.[5] Only 14 compounds were regulated due to the lack of widely accepted data for determining the CTRLs for other compounds. A DAF of 100 was applied as a "best guess" for the time. Accurate groundwater modeling data were unavailable.

From its first use in the early 1980s, it was felt that the EPTC underestimated the leaching of organic compounds due to technical inadequacies in the procedure[1]. Critics of the EPTC also pointed out that testing should be conducted for a larger list of compounds.

In 1984 as part of the HSWA Congress mandated that The U.S. EPA make changes to address these concerns(Sections 3001 g-h,2). In the June 13, 1986 *Federal Register*, The U.S. EPA proposed the TCLP with 38 new compounds to be regulated.[5] The TCLP overcomes the technical shortcomings of the older extraction procedure and regulates a variety of new organic compounds.

Before a proposed regulation is put into effect, however, it goes through a period of comment and study. When the regulatory agency is satisfied that the rule has been studied, explained and commented on to the extent that is productive, it is published in its final form in the *Federal Register*.

In March of 1989, nearly 3 yrs. after the rule had first been proposed and nearly 5 yrs. after Congress had mandated that the U.S. EPA make changes, the TCLP rule had not been finalized. On Mar. 8, 1989, the Environmental Defense Fund(EDF) brought a citizens action suit against the U.S. EPA for failing to meet a number of mandates including the TCLP that had been set forth in the HSWA.[7] On Feb. 21, 1990, a federal judge ruled in favor of the EDF and ordered the U.S. EPA to release the new rule.[8]

The Mar. 29, 1990 TCLP will regulate 25 additional organic compounds. Thirteen compounds originally proposed in 1986 will not be regulated. The 14 compounds regulated under the EPTC will continue to be regulated at the same maximum concentrations. Some of the CTRLs for the 25 new compounds have been changed from the 1986 proposal based on changes in accepted toxicity threshold.[1] A DAF of 100 is used to calculate the maximum concentration levels of all of the regulated compounds.

REGULATORY OPTIONS

All major rule makings require the U.S. EPA to prepare a Regulatory Impact Analysis (RIA).[6] The RIA considers five regulatory options: the baseline (i.e., no TCLP rule) and DAF options of 500, 250, 100 and 33. These options are listed in order of increasing regulation. The base line represents the situation before the implementation of the TCLP. The regulatory concentrations are proportional to the DAF. Lower DAFs result in lower maximum concentrations or increased levels of regulation. The RIA provides estimated data for each of these options, and it is from this document that many of the cost/benefit figures come.

GOALS/BENEFITS

The benefits to be achieved from this rule are both reduced financial cost and reduced human health risk.[6] The financial benefits can be divided into two separate categories; reduced resource damage and reduced future cleanup costs. Resource damage is defined as the cost to replace or provide an alternate supply of a resource that has been lost due to pollution. In this case the resource is the groundwater, and if it becomes polluted an alternate supply will need to be provided.

Under CERCLA, out-of-control hazardous waste contamination must be cleaned up.[9] The funds for clean up come largely from taxpayer dollars. Clean up cost is a measure in dollar value of the expenditures required to clean up groundwater to meet cleanup targets. The TCLP rule will reduce the likelihood of the formation of future Superfund sites requiring cleanup under CERCLA.

Human health risk is calculated in 2 ways: for the most exposed individual(MEI) and for the population. The risk for the MEI is the health risk for that person who receives water from the closest downgradient well from the contamination source.[1,10] If no downgradient well exists, then no MEI risk is computed. Population risk is also calculated for landfills with down gradient wells. Population risk is based on the number of people affected by the contamination plume. Both the MEI risk and the population risk are calculated for carcinogenic and noncarcinogenic compounds.

Table 1 summarizes both the financial and health benefits. It is a compilation of all the major affected industries and all of the waste that they produce. Note that all of the noncarcinogenic exposure above the threshold reference dose is eliminated for all of the regulatory options. In a similar manner, all of the resource cleanup costs are eliminated for all options. Resource damage and the number of cancer cases both decrease with increasing levels of regulation, but DAF 500 removes more than half of the risk or damage.

Table 1
Summary of Regulatory Benefits[1]

Benefit Measure (units)	Base-line Risk	Benefit For Regulatory Option[2]			
		DAF33	DAF100	DAF250	DAF 500
Cancer cases over 70 years (number of cases)	5.6	5.6	5.5	5.5	5.2
Facilities with cancer risk >10E-5 (number of facilities)	790	790	780	730	460
People exposed to non-carcinogenic compound>RfD (number of people)	320	320	320	320	320
Resource Damage (billions of dollars)	3.8	3.8	3.8	3.6	2.4
Cleanup Costs (billions of dollars)	15	15	15	15	15

1   Table adapted from TC RIA exibit 5-6

2.   All regulatory options are reported as reduction from baseline risk (i.e. Benefit)

COSTS

The TCLP, because it represents an increase in the level of industrial regulation, will force more sophisticated and expensive waste management practices. The RIA makes two types of cost predictions: social costs and costs to industry or compliance costs. Social costs are a measure of the goods and services lost to society due to the increase in regulation. Industry, however is more concerned with the compliance costs. What are the additional revenue requirements to maintain the same profitability? Industry uses compliance costs to make economic decisions. The RIA defines social cost as the total cost minus transfer payments. The RIA gives the example of a Subtitle C landfill owner/operator who charges $200 per unit of waste for disposal. If it only costs the owner/operator $105 to dispose of the waste, then $200 is the total or compliance cost, $105 is the social cost and $95 is a transfer payment from the generator of the waste to the landfill owner/operator.

The RIA makes cost predictions by examining each industry. First base line management practices are identified along with waste streams that are likely to be affected by the TCLP. Alternative practices for the disposal of these wastes are considered along with the costs of these options. Industry is assumed to choose the most cost-effective solution. Based on the cheapest alternative for industry, social costs and

Table 2
Summary of Total Annual Costs[1]

	Regulatory Options			
	33	100	250	500
Large Facilities				
Annual Cost (millions)	320	220	89	68
Facilities Incurring Cost	1900-2600	1100-1800	870-1300	700-1100
Small Facilities				
Annual Cost (millions)	35	28	25	13
Facilities Incurring Cost	15,000-16,000	14,000-16,000	13,000-15,000	13,000-15,000
Total Cost to Industry (millions)	350	250	110	82
Total Social Cost (millions)	270	190	67	52

1.   Table adapted from TC RIA exibit 3-3 and 3-4

compliance costs are estimated. Table 2 summarizes these costs. From DAF=250 to DAF=100, social costs nearly triple and compliance costs more than double.

IMPACTS

The effect of this rule on industry is varied. There is a disproportionate burden placed on different industries and waste stream types.

A vast majority of the affected waste (over 99%) by volume for all of the regulatory options considered is wastewater managed in surface impoundments.[4,6] Based on the least expensive alternative, most of this wastewater will be managed in tanks which are exempt from Subtitle C requirements. This conversion from impoundments to tanks is relatively inexpensive. By comparison nonwastewater costs account for more than 95% of the total compliance cost. Table 3 provides wastewater and nonwastewater costs for 12 different industries.

CONCLUSIONS

When government policy is considered from a neoclassical economics perspective, the test of effective policy comes from a comparison of the marginal benefits of the general social welfare to the marginal costs that are a result of the policy.[11] If the marginal costs exceed the marginal benefits, then our economic system is existing in a state of over regulation. If the marginal costs are less then the marginal benefits, then society would benefit from a greater degree of regulation. The question of whether this type of standard is the most efficient regulatory framework economically is a topic to itself, although I will conclude with a few remarks on this issue.

This kind of analysis can be used for regulation designed to control and minimize pollution. Large amounts of uncontrolled hazardous waste entering the environment cause; exposure of people to dangerous chemicals, increased cancer risk and destruction of vital resources which may need to be replaced or cleaned up at great expense. The RIA estimates that the average Superfund cleanup costs $15 million. All of which implies a reduction in the social welfare.

If, however, regulations are made too restrictive, then industry in this country will be paying a disproportionately large share of the costs for hazardous waste disposal.[11] People may lose their jobs, needed products may become unavailable or more expensive and people's standard of living may decrease. Once again, the social welfare is not maximized.

The test of effectiveness of the new TCLP is simply a matter of measuring the benefits to society resulting from more protective waste classification compared to the costs that society will bear resulting from greater expenses for waste disposal. The RIA prepared by the U.S. EPA provides a great deal of information regarding the expected costs and benefits to society. From this I have extracted what information I could about the marginal costs and benefits of this rule. The Methods section which follows describes how the marginal cost and benefit data were derived. Following the methods section is an Analysis and Discussion of the data generated.

Methods

Marginal benefit and marginal cost are nowhere presented for the TCLP rule. The RIA does, however, provide four increments in regulation. Average marginal cost or benefit between each of the regulatory options is calculated. For example, the total annual social costs of the rule at DAFs of 100 and 250 are $190 million and $67 million dollars respectively.[6] The difference is $123 million annually. The average marginal social cost (MSC) is the quotient of $123 million and the change in DAF of 150.

$$\text{Average Marginal Cost} = \frac{\text{change in cost}}{\text{change in DAF}} = \frac{190-67}{250-100} \quad (2)$$

$$= .82 \ (\$million/unit \ DAF)$$

When making a comparison of the MSC and the average marginal resource damage benefit (MRB),(the value of resources that would have been destroyed if the regulation were not implemented), present value terms are used because the resource damage benefit presented in the RIA and in Table 1 presents the data as total resource damage avoided, not in terms of an annual figure. Table 4 computes the present value of all of the future costs of the rule discounted at 3% and at 10%. The

Table 3
Costs to Industry Split by Wastewaters and Non-wastewaters[1,2]

Industry	DAF 33			DAF 100			DAF 250			DAF 500

WW - Wastewaters   NWW - Non-Wastewaters   T Total
1 Table adapted from TC RIA exhibit 3-5 through 3-8.
2 All costs are listed in thousands of dollars.

discount rate used by the U.S. EPA in the RIA is 3% and the 10% value is given for comparison.

Table 4
Present Values of Costs

	33	100	250	500
Present Value of All Social Costs to Infinity Discounted at 3%	9.0	6.3	2.2	1.7
Present Value of All Social Costs to Infinity Discounted at 10%	2.7	1.9	.67	.52
Present Value of All Social Costs to 20 years[1]	5.2	3.7	1.6	1.2

1   These figures are taken from the RIA Exhibit ES-5

If C is the annual cost and r is the discount rate, then the discounted value of all of the future cost is given by the formula:[11]

$$\text{Discounted Value} = \frac{C}{r} \qquad (3)$$

Table 5 presents the marginal cost and benefits as calculated. Marginal human health risk reductions are calculated in a manner similar to the MSC and the MRB, except that it must be done in annual risk reduction rather than total present day value since I know of no accepted way to discount future human lives. The marginal cleanup cost reduction is not even considered because, as calculated by the U.S. EPA, the cleanup cost benefit is nearly constant across all of the options.

Table 5
Marginal Costs and Benefits

	33 to 100	100 to 250	250 to 500	500 to Baseline
Average Marginal Social Cost (Summed to Infinity, Present Value)[1]	39.8	27.5	2.0	3.4
Average Marginal Social Cost (Summed to 20 years, Present Value, $billions)	22.4	14	1.6	2.4
Average Marginal Resource Benifit ($billions)	0	1.3	4.8	4.8
Average Marginal Cancer Risk Reduction	.1	0	.3	5.2
Average Marginal Social Cost (Annual, $millions)	1.19	.82	.06	.11

All marginal units are (units of benifit/Change DAF)

Using the marginal values generated in Table 5, curves can be generated as shown in Figures 1 and 2. Based on the "Mean Value Theorem," all that we can really say about the relevance of the average marginal values calculated is that they are equal to the actual marginal cost/benefit value at least one point. The mean value theorem says that the average rate of change along a curve whose slope is continuous along the interval, equals the slope of the curve at least one point.[12] Throughout the rest of the discussion the average marginal cost/benefit will be used synonymously with the marginal cost/benefit, although mathematically the two are quite different.

Analysis and Discussion

If all of the costs and benefits are represented accurately, then neoclassical economics tells us that the ideal level of regulation, that which maximizes the social welfare, should be where the marginal costs to society equal the marginal benefits.[11] At this point, if the level of regulation were increased, then the costs to society of the regulation would be greater than the benefits of greater protection from hazardous wastes. Conversely, if the level of regulation were reduced, then the increased damages caused by the less protective disposal requirements would be greater than the money saved from less regulation. This point of equal marginal cost and benefit is an ideal point; the best compromise between pollution and environment.
Figure 1
Marginal Cost vs. DAF
Figure 2
Marginal Cancer Reduction and Marginal Annual Cost

Table 6
Cost Effectiveness of Regulatory Options Based on Present Values[1]

	33	100	250	500

Reduction in Resource Damage per Million Dollars (Reduction in Present Value Resource Damage Divided by Present Value Compliance Cost, Millions of Dollars)	.73	1.0	2.3	2.0

1   Table adapted from the RIA Exhibit ES-5

From the curves generated and shown in Figures 1 and 2. It would seem that a DAF of approximately 300-400 would be ideal. The DAF used in the actual regulation is 100. The RIA makes some attempt to show what the most cost effective levels of regulation are. These are shown in Table 6. The results shown here indicate that DAF 250 is the most efficient for two out of three benefit criteria and DAF 500 is the most cost effective for the third criteria listed.

Before coming to the firm conclusion that the TCLP rule as it stands represents over regulation a number of considerations need to be made. First we must consider the validity of the data that EPA has presented. By their own admission the data often represents a worse case scenario when presenting costs.[6] There are still many questions about what

wastes will need to be handled as hazardous. Many waste streams have not been tested by this new protocol.

Given the uncertainty and the drastic cost of environmental cleanups it may make sense to regulate in an apparently sub-optimal way. If the RIA has not anticipated some of the benefits to society then our comparison may no longer be valid. Only ground water damage is considered in this RIA. Hazardous waste discharge to surface waters and other land areas cause large amounts of environmental damage that is not accounted for. Economic analysis often place a low monetary value on land that is undeveloped because value is based on market value. Some intrinsic value of the land may not be accurately represented in the analysis.

There are other sources of environmental damage like volatile organic compound release into the air from such things as wastewater impoundments are a form of air pollution. Quantitative data is unavailable for this pollution source. Lastly, in the past several years, most notable since the Love Canal site became infamous for the effects of hazardous waste, public sentiment has been very much in favor of tighter restrictions of the production and disposal of hazardous waste. This has been the great impetus for much of the legislation that has gone through Congress during the last 10 yrs. and seems to indicate that people are willing to pay for a cleaner environment. Preservation value is a more important concern then it has been in the past.

One of the interesting conclusions to come out of this type of analysis is that there is an ideal level of pollution. No pollution is not an option if we wish to live in a modern society. Conversely, a completely laissez faire system allows too much pollution. At the beginning of this paper, I spoke of compliance costs versus social costs. In a completely unregulated system there are no compliance costs. Waste may be disposed of at no cost to industry although perhaps at great cost to society. The task of regulators is to attach a cost to the disposal of waste (i.e., compliance cost) that balances the damage caused to society while allowing market forces to distribute the burden in the most equitable manner. One of the important conclusions to come from neoclassical economic analysis is that the free market will create the most efficient and beneficial distribution of resources provided that there are not significant externalities. An externality is a cost to society that is not reflected in the compliance costs of industry. Many types of pollution are externalities. Regulators should be trying to internalize the cost of pollution. When pollution costs industry money, then steps are taken to reduce the amount of pollution. This may mean, however, that some businesses or industries will no longer be profitable or competitive,

particularly if regulated businesses are forced to compete with unregulated businesses. This is often the case when United States manufacturers compete with those from less developed and less regulated nations.

The TCLP rule described in this paper is part of the regulatory framework established by RCRA under subtitle C. [2,13] Until now, I have considered this change as compared to the EPTC rule being phased out. Let me point out several interesting features of the subtitle C regulations. No facility or plant is prohibited from producing hazardous waste. Disposal costs are not directly regulated, they are market driven. Thus, market forces will allow firms to set their marginal costs of waste disposal equal to their marginal benefits from producing the waste. The most efficient outcome should result provided the costs of producing the wastes have been adequately internalized.

Long-Term Environmental Monitoring at Hanford, Washington

Robert H. Gray, Ph.D.
Office of Hanford Environment
Pacific Northwest Laboratory
Richland, Washinton

ABSTRACT

Environmental monitoring has been an ongoing activity on the U.S. Department of Energy's Hanford Site in southeastern Washington for over 45 years. The objectives of this monitoring program are to detect and assess potential impacts of site operations (nuclear and nonnuclear) on air, surface and groundwater, foodstuffs, fish, wildlife, soils and vegetation. Data from monitoring efforts are used to calculate the overall radiological dose to humans working on-site or residing in nearby communities.

In 1988, measured Hanford Site perimeter concentrations of airborne radionuclides were below applicable guidelines. Tritium and nitrate continued to be the most widespread constituents in on-site groundwater. Concentrations of radionuclides and nonradiological water quality in the Columbia River were in compliance with applicable standards. Foodstuffs irrigated with river water downstream of the Site showed levels of radionuclides that were similar to those found in foodstuffs from control areas. Low levels of ^{137}Cs and ^{90}Sr in some on-site wildlife samples and concentrations of radionuclides found in soils and vegetation from on-site and off-site locations were typical of those attributable to worldwide fallout. The calculated dose potentially received by a maximally exposed individual (i.e., based on hypothetical, worst-case assumptions for all routes of exposure) in 1988 (0.08 mrem/yr) was similar to those calculated for the years 1985-1987.

In addition to monitoring radioactivity in fish and wildlife, population numbers of key species are determined. Chinook salmon (*Oncorhynchus tshawytscha*) spawning in the Columbia River at Hanford have increased in recent years with a concomitant increase in winter roosting activity of bald eagles (*Haliaeetus leucocephalus*). An elk (*Cervus elaphus*) herd, established by immigration in 1972, is increasing. The Hanford site also serves as a refuge for Canada geese (*Branta canadensis*), great blue heron (*Ardea herodias*), and various plants and other animals, e.g., mule deer (*Odocoileus hemionus*) and coyote (*Canis latrans*).

INTRODUCTION

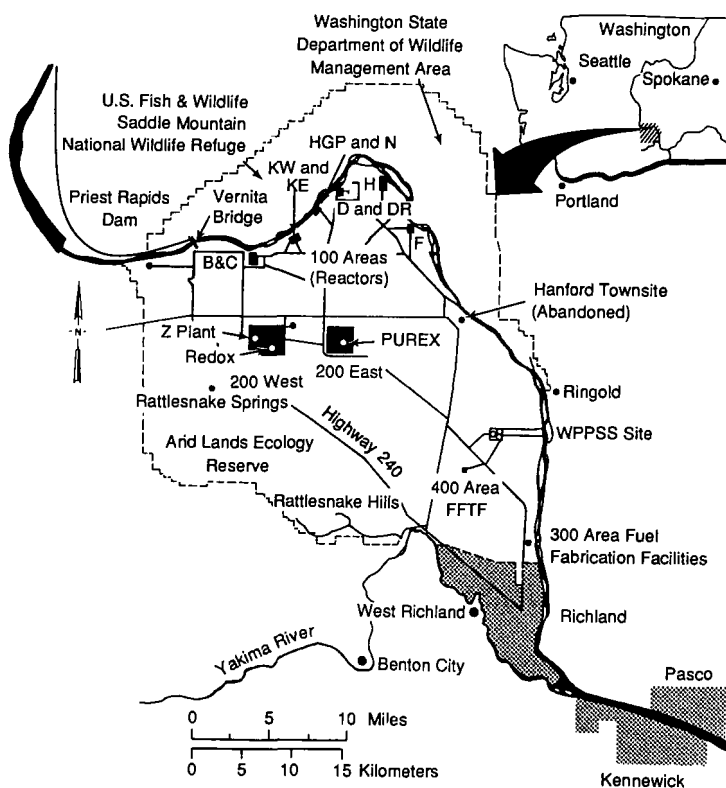
The U.S. Department of Energy's (DOE) Hanford Site occupies a land area of approximately 1,450 km² (560 mi²) in semi-arid southeastern Washington (Figure 1). The Columbia River flows through the site and forms part of its eastern boundary. Flow of the Columbia River is regulated daily according to electric power demands. Although the river was once closed to public access, public use for recreational and barge traffic is again practical. The southwestern portion of the site includes the southern terminus of the Rattlesnake Hills with elevations exceeding 1000 m. Both unconfined and confined aquifers lie beneath the site.


Figure 1
The Hanford Site

Nuclear and nonnuclear industrial and research activities have been conducted at Hanford since 1943. The most environmentally significant activities have involved the production of nuclear materials and the chemical processing and waste management associated with the major product, plutonium. By-product wastes have included gamma-, beta-, and alpha-emitting radionuclides and various nonradioactive chemicals in gaseous, liquid and solid forms.

There are currently four major DOE operations areas on the Hanford Site (Fig. 1). The 100 Areas located along the Columbia River include the dual-purpose N Reactor that produced plutonium for national defense and steam for the Hanford Generating Project (HGP), operated by the Washington Public Power Supply System (WPPSS) and eight, now

deactivated single-purpose, plutonium production reactors. The plutonium uranium extraction (PUREX) plant (reactor fuel reprocessing), plutonium finishing plant (Z Plant) and waste-disposal facilities are located in the 200 Areas on a plateau (elevation 229 m) approximately 11.3 km west of the Columbia River. The 300 Area, located just north of Richland, Washington, contains the uranium fuel manufacturing facilities in support of N Reactor and research and development laboratories. The Fast Flux Test Facility (FFTF) which has operated intermittently since 1981 to test new fuels and materials for future breeder reactor technology is located in the 400 Area. Nongovernment facilities within Hanford Site boundaries include HGP, the WPPSS nuclear plant (WNP) sites, WNP-1, WNP-2 and WNP-4, including one commercial reactor (WNP-2) that achieved full operation status in the fall of 1984 and a commercial low-level radioactive-waste burial site near the 200 Areas, operated by U.S. Ecology. The Advanced Nuclear Fuels Corp. (formerly Exxon) fuel fabrication facility is immediately adjacent to, but not located on, Hanford Site property.

Environmental monitoring at Hanford has been ongoing for 45 years. The program is conducted to assess potential impacts to individuals and populations that may be exposed to radionuclides, ionizing radiation and hazardous chemicals. Environmental monitoring currently includes air, surface and groundwater, fish, wildlife, soil, vegetation and foodstuffs (fruits, vegetables and milk). Fish and wildlife are monitored for radioactivity and to determine the population status of key species.

RADIOLOGICAL MONITORING

Air

Potential airborne transport of stack releases containing radionuclides from Hanford facilities offers a direct pathway for human exposure. Thus, air is sampled continuously for airborne particulates and analyzed for radionuclides at 50 locations on-site, at the site perimeter and in nearby and distant communities.[1] At selected locations, gases and vapors are also collected and analyzed. Many of the longer-lived radionuclides released at Hanford are also present in atmospheric fallout that resulted from nuclear weapons testing in the 1950s and 1960s or from nuclear accidents that occurred elsewhere.

In May and June of 1986, air samples collected on-site as well as those from distant locations showed increases in several long- and short-lived radionuclides (e.g., ^{137}Cs, ^{131}I, ^{103}Ru) that resulted from the April 1986 reactor accident at Chernobyl in western Russia. However, even then, no sample exceeded 0.17% of the applicable DOE derived concentration guide (DCG) for areas permanently occupied by the public.[2]

Groundwater

The shallow unconfined (water-table) aquifer has been affected by wastewater disposal practices at Hanford more than the deeper, confined aquifers. Discharge of water from various industrial processes has created ground-water mounds near each of the major wastewater disposal facilities in the 200, 100 and 300 Areas (Fig. 1). Discharge to groundwater in the 200 Areas may contribute ten times more water annually to the unconfined aquifer than natural input from precipitation and irrigation.[3] These groundwater mounds have altered local flow patterns in the aquifer, which are generally from west to east.

Groundwater, primarily from the unconfined aquifer, is currently sampled from 551 wells and analyzed for radionuclides.[1] Tritium (^{3}H) occurs at relatively high levels in the unconfined aquifer, is one of the most mobile radionuclides and thus reflects the extent of groundwater contamination from on-site operations. Many liquid wastes discharged to the ground at Hanford have contained^{3}H. The PUREX facility is currently the main source for ^{3}H-containing wastes.[4] Tritium from releases prior to 1983 that passed downward through the vadose (unsaturated) zone to the unconfined aquifer continues to move with groundwater flow toward the Columbia River. Tritium concentrations in Hanford groundwater range from less than 300 pCi/L to over 2,000,000 pCi/L near or within the 200 Areas.[1,2,5]

Groundwater from the unconfined aquifer enters the river through subsurface flow and springs that emanate from the riverbank.

McCormack and Carlile[6] identified 115 springs along a 41-mile stretch of river. Tritium concentrations in wells near the springs ranged from 19,000 to 250,000 pCi/L and averaged 176,000 pCi/L in 1985.[7] Although the distribution of ^{3}H and other radionuclide concentrations in springs generally reflected those in nearby groundwater wells, the magnitude was generally less in springs due to mixing of surface and groundwater. Tritium concentrations in the river were generally less than those in springs. Tritium concentrations in springs were less than 4% of the DOE DCG (2,000,000 pCi/L). Tritium concentrations in the river were less than 0.5% of the DCG and less than half the regulatory limit for drinking water (20,000 pCi/L).[8] From 1983 to 1988, annual average ^{3}H concentrations in the river (<200 pCi/L) were at least a factor of 100 below the drinking water limit.[1] It is noteworthy that ^{3}H also occurs naturally in the Columbia River upstream from Hanford. From 1983 to 1988, annual average ^{3}H concentrations in the river, upstream at Priest Rapid Dams, ranged from 70 to 100 pCi/L.

Surface Water

Columbia River water is used for drinking at downstream cities, for crop irrigation and for recreational activities (fishing, hunting, boating, waterskiing and swimming). Thus, it constitutes the primary environmental pathway to people for radioactivity in liquid effluents. Radionuclides can be delivered to human foodstuffs through crops irrigated with river water and cow's milk through irrigated alfalfa and other cattle forage. Although radionuclides associated with Hanford operations, worldwide fallout and natural phenomena continue to be found in small but measurable quantities in the Columbia River, concentrations are below Washington State and U.S. EPA drinking water standards.

Deep sediments in downstream reservoirs still contain low concentrations of some long-lived radionuclides.[9-13] Trace amounts of ^{239}Pu, ^{60}Co, ^{137}Cs and ^{152}Eu persist in sediments accumulated above the first downstream dam (McNary). In 1977, approximately 20 to 25% of the total plutonium inventory ($^{239, 240, 241}$Pu) in Lake Wallula sediments, 100 km downstream, was believed to originate from the 1944 through 1971 releases at Hanford.[13] However, only ^{239} Pu was believed to actually reflect earlier reactor operations. Further, this ^{239}Pu was derived from ^{239}Np (produced by neutron capture in natural uranium followed by decay to ^{239}Np), an abundant isotope in Columbia River water. Thus, plutonium may not have been released to the river from reactor operations.

Fish and Wildlife

Fish are collected at various locations along the Columbia River, and boneless fillets are analyzed for ^{60}Co, ^{90}Sr and ^{137}Cs. Carcasses are analyzed to estimate ^{90}Sr in bone. Following shutdown of the last single-purpose, once-through cooling reactor and installation of improved liquid effluent control systems at N Reactor, short-lived radionuclides, including the biologically important ^{32}P and ^{65}Zn, essentially disappeared from the river[14] through radioactive decay. Radionuclide concentrations in fish collected from the Hanford Reach of the Columbia River are similar to those in fish from upstream locations.

Deer (*Odocoileus* sp.), ring-necked pheasants (*Phasianus colchicus*), mallard ducks (*Anas platyrhynchus*), Nuttall cottontail rabbits (*Sylvilagus nuttallii*) and black-tailed jack rabbits (*Lepus californicus*) are collected and tissues are analyzed for ^{60}Co and ^{137}Cs (muscle), $^{239, 240}$Pu (liver) and ^{90}Sr (bone). The doses that could be received by consuming wildlife at the maximum radionuclide concentrations measured between 1985 and 1988 were below applicable DOE standards.[1,2,5,7]

Soil and Vegetation

Airborne radionuclides are eventually deposited on vegetation or soil. Samples of surface soil and rangeland vegetation (sagebrush) are currently collected at 15 on-site and 23 site perimeter and off-site locations.[1] Samples are collected from nonagricultural, undisturbed sites so that natural deposition and buildup processes are represented. Sampling and analyses in 1985 through 1988 showed no radionuclide buildup off-site that could be attributed to Hanford operations.[1,2,5,7]

Foodstuffs

The most direct way for deposited radionuclides to enter the food-chain is through consumption of leafy vegetables. Samples of alfalfa and several foodstuffs, including milk, vegetables, fruit, beef, chickens, eggs and wheat, are collected from several locations, primarily down-wind (i.e., south and east) of the site.[1] Samples are also collected from upwind and somewhat distant locations to provide information on radiation levels attributable to worldwide fallout. Foodstuffs from the River-view Area (across the river and southeast) are irrigated with Columbia River water withdrawn downstream of the site. Although low levels of ³H, ⁹⁰Sr, ¹²⁹I and ¹³⁷Cs have been found in some foodstuffs, concentrations in samples collected near Hanford are similar to those in samples collected away from the site.

Penetrating Radiation

Penetrating radiation (primarily gamma-rays) is measured in the Hanford environs with thermoluminescent dosimeters to estimate dose rates from external radiation sources. Radiation surveys are routinely conducted at numerous on-site locations including roads, railroads and retired waste-disposal sites located outside of operating areas. On-site and off-site measurements and survey results from 1985 to 1988 were similar and comparable to past years. Dose rates near some operating facilities were only slightly higher than natural background rates.

Overall Impact from Hanford Operations

Beginning in 1974, the evaluation of radiation doses has included assessment of the maximum external dose rate at a location accessible to the general public, doses to a hypothetical maximally exposed individual and doses to the population within 80 km of the site. The calculated 50-year whole-body cumulative dose received by the maximally exposed individual ranged from 0.5 to 3 mrem during the years 1981 through 1986.[2] The maximally exposed individual is a hypothetical person who receives the maximum calculated radiation dose when worst case assumptions are used concerning location, inhalation of radioactive emissions, consumption of contaminated food and water and direct exposure to contaminants. Expressed as effective dose equivalents, the calculated dose received by a hypothetical maximally exposed individual was 0.05 to 0.1 mrem annually from 1985 through 1988. The average per capita effective dose for 1985 through 1988, based on the human population of 340,000 living within 80 km of the site, was 0.01 to 0.03 mrem annually.[1,2,5,7] Based on these assessments, potential radiation doses to the public from Hanford operations have been consistently below applicable standards and substantially less than doses from other routinely encountered sources of radiation, such as natural terrestrial and cosmic background radiation, medical treatment and x-rays, natural internal body radioactivity, worldwide fallout and consumer products (Fig. 2).

	Dose (mrem/yr)
U.S. Average Radon Dose	200
Natural External Background, Denver CO	140
Average Washington State External Background	88
Measured (TLD) Hanford Area External Background	78
U.S. Average Natural External Background	60
Average Per Capita U.S. Medical Dose	53
Average U.S. Internal Dose from Natural Radioactivity	40
Consumer Product Radiation (TV, Smoke Detector, etc.)	10
Global Weapons Fallout	<1
Average Per Capita Dose (Internal and External) from 1988 Hanford Operations	0.01

Figure 2
Annual Radiation Doses from Various Sources

CHEMICAL MONITORING

Air Quality

Nitrogen oxides (NO_x) are routinely released on-site from fossil-fueled steam and chemical processing facilities, most notably the PUREX plant. Nitrogen dioxide is currently sampled at seven on-site locations by the Hanford Environmental Health Foundation (HEHF). Nitrogen dioxide concentrations measured between 1984 and 1988 were well below federal (U.S. EPA) and local (Washington State) ambient air quality standards.[1,2,5,7]

Groundwater

In 1988, samples from 328 groundwater wells were collected and analyzed for chemical constituents. In addition, on-site drinking water sources (not public) were sampled and analyzed by HEHF for water quality. Detected constituents included several metals, anions, coliform bacteria, radionuclides and total organic carbon. Many of these constituents are expected in natural groundwater. Chromium, cyanide, fluoride and carbon tetrachloride were found in wells not used for drinking water near operating areas.

Columbia River

Nonradioactive waste water is discharged at seven locations along the Hanford reach of the Columbia River. Discharges consist of backwash from water intake screens, cooling water, water storage tank overflow, a building drain and fish laboratory wastewater. Effluents from each outfall are monitored by the operating contractors. The Columbia River also is monitored by the United States Geological Survey, upstream and downstream of the site, to verify compliance with Class A[18] water quality requirements.

Numerous studies have evaluated and resolved the potential environmental issues associated with water intake and thermal discharge structures on the Columbia River at Hanford. For example, retrofitting of the HGP water intake and a newer design for the intake used at WNP-2 have ensured safe downstream migration of juvenile chinook salmon.[19-22] Other studies have concluded that thermal discharges from N reactor and HGP to the Columbia River were biologically insignificant.[23,24]

HANFORD FLORA AND FAUNA

Most of the Hanford Site consists of undeveloped land that supports stands of native vegetation and a few exotic species (e.g., cheatgrass, *Bromus tectorum*; Russian thistle, *Salsola kali*; and tumble mustard, *Sisymbrium altissimum*) is free from agricultural practices and has been essentially free from livestock grazing and hunting for 45 years. Thus, the site serves as a refuge for migratory waterfowl, elk (*Cervus elaphus*), mule deer (*Odocoileus hemionus*), coyote (*Canis latrans*) and other plants and animals.[25] Restricted land use has favored native wildlife species that frequent riverine habitats, for example, mule deer, great basin Canada goose (*Branta canadensis*) and great blue heron (*Ardea herodias*).

The Columbia River at Hanford supports up to 48 species of fish[26] and serves as a migration route for upriver runs of chinook (*Oncorhynchus tshawytscha*), coho (*O. kisutch*) and sockeye (*O. nerka*) salmon and steelhead trout (*O. mykiss*, formerly *Salmo gairdneri*). The Hanford Reach supports the last remaining mainstem spawning habitat for fall chinook salmon. Steelhead trout also spawn in the Hanford Reach. The salmon population is maintained by a combination of natural spawning, artificial propagation and regulated commercial and sport harvest of returning adults.

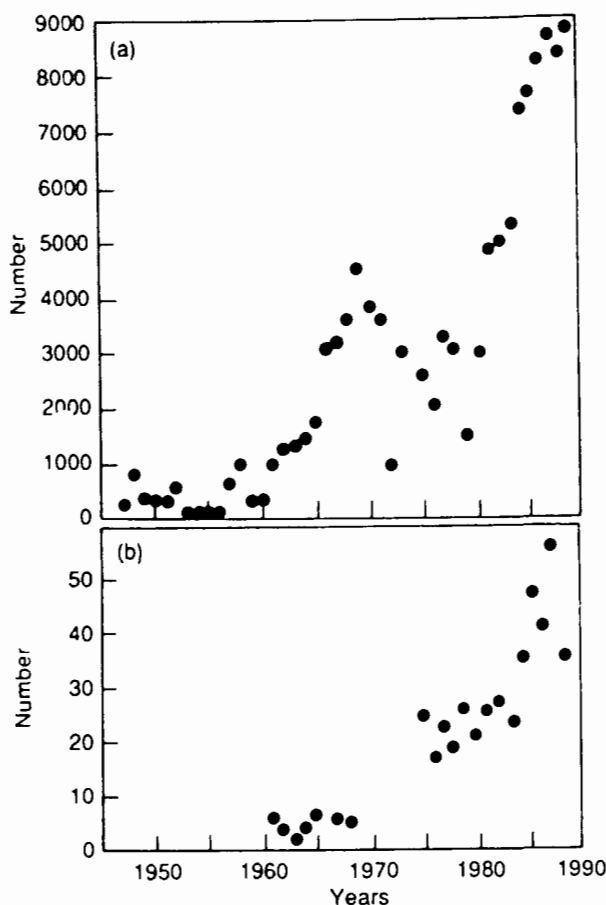
Based on redd (nest) counts from the air, fall chinook salmon spawning in the Hanford Reach of the mainstem Columbia River has increased dramatically since 1980 (Fig. 3). Recent observations by divers[28] showed salmon redds at depths below those visible by boat or aircraft and suggests that salmon spawning in the Hanford Reach may be even greater than previously estimated.) The increase in salmon spawning has attracted increasing numbers of wintering bald eagles (*Haliaeetus leucocephalus*).


Figure 3
Numbers of (a) salmon redds (nests) and
(b) wintering bald eagles at Hanford

tions on the local environs, on-site workers and the off-site public. Monitoring for radiological emissions at Hanford has been ongoing for 45 years and includes air, surface and groundwater, fish, wildlife, soil, vegetation and foodstuffs. Measured and calculated radiation doses to the public have been consistently below applicable regulatory limits. The Hanford Site now serves as a refuge for key fish and wildlife species.
Figure 4
Numbers of Elk at Hanford After Calving
in Spring and Off-site Hunting in Fall

The sparsely vegetated islands in the Columbia River have historically been used as nesting habitat for great basin Canada goose.[29,30] From the mid-1950s to the mid-1970s the number of goose nests declined from a high of 250-300 to approximately 100 annually. From the late 1970s to the present, the number of nests has increased and appears to have stabilized at approximately 150-200. Initially, closure of the Hanford Reach was beneficial to the geese by providing freedom from human intrusion. However, the coyote, a natural goose predator, also benefitted and is believed to be the major cause of the decline in numbers of goose nests into the mid-1970s.

Initially there were no nesting great blue heron on the Hanford Site. However, there are now four active colonies consisting of approximately 35-40 or more birds each and herons are present year-round.[25] Elk first arrived on the Hanford Site in 1972.[31] From a small founding population, the herd size grew to approximately 80 animals in 1987 (Figure 4). The rapid increase in elk is attributed to the lack of predation or human disturbance during calving, absence of on-site hunting and the lack of competition from sheep and cattle for available forage. For the last four years, off-site hunting has limited further population increases by removing approximately 15 to 20 animals annually from the herd.

The mule deer population at Hanford is estimated at several hundred animals and appears stable even in the absence of on-site hunting. Coyote predation on fawns is believed to be an important factor that maintains the stable deer population.[32]

CONCLUSIONS

The Pacific Northwest Laboratory (PNL) conducts an environmental monitoring program to assess potential effects of Hanford Opera-

ABSTRACT

Soil gas sampling, ambient air sampling and emission isolation flux chamber sampling are techniques used to evaluate organic vapor distributions at hazardous waste sites. This paper presents comparative results of tests on all three sampling methods used during characterization of a hazardous waste site. The site at which the monitoring took place is a residential housing tract constructed on abandoned pits and trenches containing heavy hydrocarbon and sulfuric acid sludge wastes. The waste material periodically seeps to the surface, posing a potential acute dermal, ingestion and inhalation threat. Various air sampling tasks were implemented to evaluate the acute and chronic health threats posed by airborne vapors and provide data to support a risk assessment.

Soil gas sampling was used to delineate the horizontal extent of the buried waste. Ambient air sampling using Tedlar bags and Tenax tubes was performed to determine if a release to the breathing zone was occurring. Results were not conclusive, but indicated that soil vapor concentrations were below Permissible Exposure Limits; ambient sampling results were ambiguous due to the detection of relatively high background concentrations of contaminants of concern.

A sampling strategy was employed during the remedial investigation, combining ambient sampling at the breathing zone with Tedlar bags and soil-air interface sampling with a co-located emission isolation flux chamber. Sampling stations were on and adjacent to emergent waste seeps. Indoor ambient sampling was conducted at the same time for comparative analyses. Data obtained were more conclusive; consistent detections were obtained from co-located bag and flux chamber samples, allowing for calculation of vapor flux rates. Benzene, toluene and xylene isomers were detected above California Department of Health Services Applied Action Levels. Relative contributions of contaminants from waste seeps compared with the soil column were defined, demonstrating the emergent seeps to be the source of potentially harmful concentrations. Taken together, the data indicate that vapor emissions from emergent waste seeps pose the greatest potential health threat.

Results obtained are critical for a risk assessment, which is essential for completing a feasibility study and remedial action plan for the site. Field activities, advantages and disadvantages of the sampling methods and applications to future remedial planning are discussed.

INTRODUCTION

This report describes analytical data obtained by various techniques for collecting soil gas and air samples. Samples were collected during a series of site evaluation projects conducted at a hazardous waste site in southern California. Four sampling techniques were employed:

- Soil gas sampling with subsurface probes
- Ambient air sampling with sorbent tubes
- Ambient air sampling with Tedlar bags

- Soil gas sampling at the soil-air interface with an emission isolation flux chamber (flux chamber).

Comparative results and applications to risk assessment are discussed. The experience gained from these studies is useful for developing sampling/analytical strategies for remedial investigations and risk assessment projects.

Site Description

Westminster Tract No. 2633 is located in the city of Westminster in northern Orange County, approximately 35 miles south of downtown Los Angeles, CA (Fig. 1). The site is in a residential neighborhood surrounded by industrial and commercial areas. The surface of the tract is either paved, vegetated or occupied by buildings (Fig. 2). Isolated areas of vegetation appear to be stressed or neglected.

Prior to development, portions of the site were used for disposal of refinery wastes and drilling muds. The waste material is primarily polycyclic aromatic hydrocarbons (PAHs) and sulfuric acid sludge. The waste has a distinct odor, attributable to sulfur compounds and mercaptans. Waste is less dense than surrounding soil matrix and becomes plastic and mobile at ambient temperatures greater than 80 °F. During warm weather, waste migrates upward in tabular veins and necks, emerging and spreading at the surface. These surface seeps present a potential acute health threat due to organic vapors generated and direct contact with the acidic waste. The buried waste also presents a potential chronic health threat due to emissions of organic vapors through the soil column.

In the late 1950s, the site was purchased by a real estate company for residential development. During the construction of Tract No. 2633 in the late 1950s and early 1960s, tar pits were discovered. The Regional Water Pollution Control Board (now the Regional Water Quality Control Board) stipulated that waste could be left on-site if it were isolated from groundwater, but warned that problems might result if the waste remained in place. Waste was to be redisposed in trenches and covered with concrete. No evidence of a concrete cap has ever been found in the course of field investigations; the waste may have reacted with and dissolved any concrete, or the cap was never placed.

Homeowners have reported problems with differential settling of foundations and fences, difficulty growing gardens, odors and waste seeps in yards, swimming pools and, in one case, under the living room carpet (the waste had migrated through the concrete foundation). Homes at the site do not have basements or extensive crawl spaces.

The original disposal areas were identified through analysis of historical aerial photographs. Five separate areas were identified, with a total surface area of approximately 68,972 ft² (1.58 acres). The present extent of waste has been determined through an intensive drilling investigation; sample locations are depicted in Figure 2. Both the original

Figure 1
Regional Site Map; Westminster Tract No. 2633
Westminster, California
pits and the redisposal trenches are potential sources of organic vapors.

Figure 2 shows the locations of the streets, parcels and approximate locations of the trenches. No other waste disposal areas are known to exist, based on site investigation work, historical reports and historical aerial photographs. Waste material may be present beneath some houses in the tract, but investigations to date have not evaluated the subsurface beneath homes.

Site Investigations

Several investigations of potential environmental and health problems at the site were performed by local, state and federal agencies, as well as independent parties. The key investigations and their principal objectives discussed in this report are:

- The preliminary site investigation conducted by E & E under contract to DOHS in 1987, was designed to evaluate the need for further investigation and possible remedial action[1]
- The Listing Site Inspection (LSI) performed by the U.S. EPA Region IX field investigation team (FIT) in 1988 was designed to develop a Hazard Ranking System score for potential inclusion on the NPL[2]
- The Phase I remedial investigation (RI) conducted by E & E under contract to DOHS in 1989 was designed to determine the extent of contamination and provide data for a feasibility study and risk assessment[3]

Project tasks have included:

- Review of historical data from regulatory agencies
- Aerial photographic analyses
- Geophysical surveys
- Surface soil, water and waste sampling
- Subsurface soil and groundwater sampling
- Real-time air monitoring during drilling and sampling activities with Hnu, OVA, H₂S monitors, SO₂ monitors, dust meters)
- Soil gas sampling
- Ambient air sampling with Tedlar bags and Tenax tubes
- Flux chamber sampling

Since 1987, DOHS has also implemented annual excavation and removal of waste seeps to prevent exposure to residents. This annual removal project has served as an interim remedial measure until the RI/FS is completed and full-scale remediation proceeds. The California Department of Health Services (DOHS) currently is preparing a risk assessment for purposes of completing the FS. The site eventually may be proposed for NPL listing.

AIR INVESTIGATIONS

E & E/DOHS—1987

The DOHS tasked E & E to conduct a site investigation to describe the source and extent of contamination at the site and identify any potential migration pathways.[1]

Soil gas sampling was conducted at 20 sample locations (Fig. 2) to identify the types of volatile contaminants present and the extent of their possible release. Samples were collected by driving perforated pipe to a depth of 5 feet, then retracting the pipe a few inches; samples were then collected in Tedlar bags.

Four groups of compounds were analyzed: halogenated organics, aromatics, aliphatics and hydrogen sulfide (H₂S). Analytical results are presented in Table 1. H₂S was tentatively identified in four of the Tedlar bag samples. Independent real-time monitoring with H₂S-specific devices during soil sampling suggested no H₂S was present in the free atmosphere. Therefore, additional samples were collected with zinc acetate impingers to confirm the H₂S detections. H₂S was not detected in the impinger samples, leading to the conclusion that previous H₂S detections were false positives caused by a reaction with the Tedlar bag material.

The survey was unsuccessful in defining the boundaries of the redisposal trenches because soil gas was detected in all locations sampled. Real-time air monitoring in two residential homes revealed OVA readings slightly above the background level, but the concentrations were not considered significant. Sulfur dioxide and hydrogen sulfide were not detected in the survey.

Table 1
Summary of SCR Soil Gas Results, Westminster Tract #2633, 1987

Compound	Maximum Concentration (ppm)	ACGIH TLV (1) (ppm)	10% of ACGIH TLV
Halogenated Organics:

* TLV for Butane. Other C1-C4 compounds to be simple asphyxiants without a TLV.
** TLV for n-Pentane.
* TLV of 50 ppm for n-Hexane; TLV of 500 for other isomers.
+ TLV for n-Heptane.
++ TLV for n-Octane. (1) Limits for Benzene changed in 1989 from 10.0 to 1.0

U.S. EPA-FIT—1988

During March and April 1988, the U.S. EPA Field Investigation Team (FIT) collected air, surface water, groundwater, soil and soil/waste and sediment samples. The purpose of this investigation was to collect data necessary to support a Hazard Ranking System (HRS) score for poten-

tial NPL listing.[2] Target compounds for the air samples were essentially the same as for the soil gas survey.

Air samples were collected from the breathing zone (4-6 ft above ground surface). Two rounds of sampling were conducted, using sorbent tubes and Tedlar bags in Round 1 and sorbent tubes only in Round 2. Because of the previous false detections of H_2S with Tedlar bags, sorbent tubes were utilized to provide analytical redundancy. Bag samples were collected by using a negative pressure/passive inflation technique, similar to that described in *Air Resources Board Procedure for Atmospheric Tedlar Bag Sampling, Appendix A, Method 201*. Tube samples were collected by drawing air through a Tenax tube connected with Tygon tubing to a personal air sampling pump.

Air sampling locations are shown in Figure 2. The sample locations were selected to discriminate between air contamination arising from the on-site waste and that coming from an industrial area south of the site.

Analytical results for the tube samples are presented in Table 2. The Tedlar bag samples were judged to be inconclusive due to contamination of field blank samples; the cause of this problem has not been diagnosed. Although valid analytical results were obtained from the Tenax tube samples, the results still did not conclusively demonstrate the release of vapors into the atmosphere from the wastes. Background and upwind samples detected levels of contaminants comparable to those detected at on-site sample stations.

Analysis by: Paul H. Johnson, FIT E & E May 3, 1988 (Source: EPA-Field Investigation Team, 1988)

E & E/DOHS RI—1989

The original RI/FS workplan proposed ambient air sampling utilizing absorbent tubes (Tenax or charcoal) and impingers. Based on inconclusive results from U.S. EPA-FIT air sampling, DOHS requested consideration of other alternatives to this approach be considered.[3]

DOHS proposed an air sampling program different from that proposed in the RI/FS workplan. The revised program comprised indoor air sampling, ambient air sampling (breathing zone), flux chamber sampling, real-time air monitoring (following protocols established in the Health and Safety plan), review of historical meteorological conditions and collection of meteorological data with an on-site meteorological monitoring and data collection station (the "met station").

Sampling with Tedlar bags and air sampling at the soil surface using a flux chamber were the preferred alternatives for obtaining data to be applied to a quantitative risk assessment. Bag samples were collected by negative pressure/passive inflation (California Air Resources Board, Method 201). The flux chamber device is designed to collect air at the soil/air interface and hold the sample in a Tedlar bag until analyzed; the procedure is discussed in more detail below. A diagram of the flux chamber device is shown in Figure 3.
Figure 3
A Cutaway Diagram of the Emission Isolation Flux Chamber

A review of 1987 and 1988 sampling data resulted in a revised list of target compounds. The contaminants of concern are mainly volatile organic compounds: benzene, toluene, xylene isomers (ortho/meta/para), ethylbenzene, cyclopentane, cyclohexane, methylcyclohexane and tetrahydrothiophene. All air samples (indoor, flux chamber and ambient air; described below) were analyzed for these compounds.

Thirty samples were collected during two rounds of sampling, which included ambient indoor and outdoor air samples (Tedlar bag) and outdoor flux chamber sampling. The on-site sampling stations (indoors and backyards at 14662 and 14682 Kathy Street) were specified due to the past or current presence of waste seeps at these homes. Seeps had recently been removed from the 14662 Kathy Street yard; two seeps were present in the 14682 Kathy Street yard. An additional sampling station on Santee Avenue was used as a control (background) for the flux chamber measurements. The upwind and downwind locations were selected based on historical prevailing wind conditions (generally from the southwest). Air sampling stations (indoor, flux chamber and ambient air) are shown in Figure 2.

Air sampling results obtained in the RI are presented in Table 3. Calculated emission rates from the flux chamber sampling are presented in Table 4.

Indoor Air Monitoring and Sampling

Indoor real-time air monitoring and ambient air sampling were conducted at the two homes to determine if VOCs were present at hazardous levels and to compare these results with flux chamber and ambient air samples collected in the backyards. Two types of in-home monitoring were performed at the residences: real-time monitoring with portable field screening instruments (OVA, Hnu and SO₂ monitor) and ambient air sampling with Tedlar bags, using the same procedure as for outdoor ambient air sampling.

Prior to monitoring and sampling, a preliminary survey was initiated to document the floorplan of the house and to evaluate the potential emission sources for volatile organic compounds. The survey identified the following sources in each home that could contribute to in-home air contaminants: gas wall heaters, gas stoves and gas hot water heaters; solvents and miscellaneous chemicals in garages; and cleaning fluids below baths and kitchen sinks. The floorplans of the two homes were nearly identical.

The results suggest that the presence of these compounds may be due to in-home sources mentioned above or may be the result of outdoor air which has filtered into the houses. The BTEX compounds in indoor air samples could come from automobile exhaust emissions on nearby roads and freeways and from other industrial sources.

Flux Chamber Sampling

A flux chamber was used to determine the rates of emission for several volatile compounds from the backyards of three homes at the site (the Kathy Street residences and a background residence on Santee Avenue on the northern side of the site). The flux chamber offers several advantages over other ambient air monitoring methods for detecting and measuring emissions. Operating procedures are described in *Measurement of Gaseous Emission Rates from Land Surfaces Using an Emission Isolation Flux Chamber User's Guide* which has been used by the U.S. EPA⁶. The flux chamber allows direct measurement of emissions from the ground surface or waste material. It was determined that flux chamber would provide the most reliable source of data to be used in a risk assessment.

Samples were collected from five separate stations: the designated background location on Santee Avenue, one lawn area where no seeps were present (14662 Kathy Street), one location where seeps had been removed earlier (14662 Kathy Street), one location on bare ground adjacent to a seep (14682 Kathy Street) and one location on top of a

seep (14682 Kathy Street). A duplicate sample was collected from over the large seep at 14682 Kathy Street. The duplicate was obtained by splicing a "tee" fitting onto the sample line inside the chamber containing a pair of Tedlar bags, allowing the simultaneous collection of duplicate samples.

Samples were collected by connecting a Tedlar bag to the sampling line from the flux chamber and filling the bag by the negative pressure/passive inflation method. Prior to sample collection, the flux chamber was purged using ultra high purity nitrogen. System blanks were collected after purging by placing a glass plate between the flux chamber and bare ground and following the normal collection procedure. The purge and sampling cycle was then repeated with the glass plate removed. Ambient temperatures (inside and outside the flux chamber) were monitored during sample collection. Exit gas concentrations were measured using a Hnu; use of the Hnu was discontinued due to a battery problem. Background and system blank samples provided QA/QC checks.

The flowrate into the flux chamber was set at 4 L/min. The residence time in the chamber was 7.5 minutes. Sampling started after purging the flux chamber for a minimum of four residence times (30 minutes or greater). The flowrate into the Tedlar bag from the flux chamber was 1.2 L/min with a sampling period of 8 minutes. Multiple point calibration on the flux chamber sampling train was performed prior to field sampling. Single point calibration was performed in the field prior to and following daily sampling events.

Flux Chamber Sampling Results

The analytical results for the flux chamber samples are presented in Table 3. Table 4 summarizes the emission rates for each chemical of interest for flux chamber Samples 6 and 7, which were calculated using Equation 2-1 from the *User's Guide:*

$$E_i = Y_i Q/A \tag{1}$$

where: E_i = emission rate of component i (mass/area-time)
Y_i = concentration of component i in the N₂ flowing from the chamber (mass/volume)
Q = flow rate of N₂ into the chamber (volume/time)
A = surface area enclosed by the chamber (0.130 m²)

The laboratory results reported concentrations for each chemical species of interest in ppb by volume. In order to perform the necessary emission rate calculation, ppb by volume must be converted into μg/L using the following equation:

$$\mu g/L = [ppb] (4.09 \times 10^{-2} (\mu g \; mol)/(g \; m^3)) (Mwt) (m3/1000 \; L) \tag{2}$$

No emission rates for tetrahydrothiophene were calculated since it was not found above detection limits in any of the samples. The two duplicate samples (6 and 7) collected over the waste seep at 14682 Kathy Street were the only samples with emissions of the high concentration. Toluene was detected in four of the samples, while o-xylene and cyclohexane were each found in one sample. The detection of toluene in two of the three system blanks (flux Samples 1 and 4) and o-xylene in Sample 4 are anomalous. These findings could possibly be from laboratory contamination or incomplete purging of the flux chamber system. The system blank collected at 7151 Santee Avenue did not contain any contaminant above detection limits, nor did flux Sample 2 which was collected over grass immediately after the system blank at 14622 Kathy Street.

The results of this sampling effort indicate that small amounts of certain volatile compounds may be released through lawn or dirt areas into the backyard atmosphere. But these releases are negligible compared with the amount of volatile compounds released from waste material which has seeped to the surface.

Ambient Air (Outdoor) Sampling with Tedlar Bags

Ambient air samples were collected from the breathing zone at locations near the flux chamber sample stations in the backyard at 14682 Kathy Street and in upwind and downwind locations chosen in accor-

dance with the prevailing wind direction (Fig. 2). Flux chamber samples were collected from the backyard at 14662 Kathy Street, as discussed above; no waste seeps were emergent in this yard during the July 1989 sampling and therefore no ambient air samples were collected at that location.

Two rounds of ambient air sampling with bags were conducted: Round 1 in July 1989 (concurrent with flux chamber sampling) and Round 2 in August 1989. A malfunction with the met station had occurred during Round 1 sampling; therefore, an additional round of samples was collected concurrent with operation of a new met station.

The same ambient air sampling procedures were used, but Round 2 samples were collected using lower flow rates and at different on-site locations. (Seeps at the 14682 Kathy Street residence had been removed; fresh seeps had appeared in a vacant lot at the southwest corner of the site). Therefore, field and duplicate samples also were collected during Round 2.

In Round 2, a laboratory blank and daily trip blanks were analyzed for QA/QC purposes. The laboratory blanks were prepared using new Tedlar bags. Trip blanks were prepared by the laboratory on a daily basis and carried to and from the field to determine if cross-contamination occurred during transport. No contaminants of concern were detected in any of the blank samples above the method detection limits. The analytical results are presented in Table 3.

Round 1 Results

The results obtained from the outdoor ambient samples are consistent with those of the flux chamber samples for BTEX compounds, but are lower in concentration. Cyclopentane, cyclohexane, methylcyclohexane and tetrahydrothiophene were not measured above the method detection limits in the Round I ambient air samples.

At the 14682 Kathy Street location, BTEX compounds were detected in both field and duplicate samples, as well as the upwind station. (The sampling pump at the downwind station was stolen approximately 20 minutes after initiation of sampling; therefore no results were obtained).

The analytical results from the flux chamber and outdoor ambient air samples suggest that the observed airborne contamination originates primarily from seeps. This conclusion is supported by comparison of the results of the indoor sampling versus the flux chamber samples collected over the waste seeps. Indoor and off-site sources, such as gas heaters and automobile exhaust, are other possible contributors. The variations in concentrations detected probably are due in part to the differing nature of the sampling devices: the flux chamber captures vapors at the soil/air interface, while the ambient samples are subject to dilution by mixing, diffusion or dispersion during transport from the seep to the sample intake.

Round 2 Results

The analytical results of the Round 2 samples were less definitive than Round 1. In general, concentrations at field stations were comparable to upwind and downwind locations.

Quantified concentrations were lower than for Round 1 sampling. This finding may be an artifact of the lower flow rates used for sample collection. A lower flow rate allows for longer sample collection time, but also allows for dispersion and diffusion to take place at a faster rate relative to the sample collection rate. Other factors could have contributed to lower concentrations, notably the smaller size of seeps over which samples were collected. Also, the seep locations on the southwest side of the site (vacant lot) were exposed to the wind to a greater degree than those seeps investigated in Round 1 (located in walled back yards).

Round 2 samples did confirm the prior detections of benzene, toluene, ethylbenzene, cyclopentane and cyclohexane. Cyclopentane was not confirmed by the duplicate field station. Cyclohexane was detected in only the downwind sample at 9 ppb on the final day of sampling. While cyclohexane was detected in flux chamber samples collected over seeps in Round I, it is possible that the Round 2 detection could have originated from an off-site source. Methylcyclohexane was detected only in one sample at 14 ppb, at the upwind station. This compound was also detected in flux chamber samples collected over seeps in Round 1;

however, the Round 2 detection suggests an additional off-site source.

Results from the Round 2 sampling are not as definitive as Round 1. Round 2 sample results suggest that off-site sources are contributing to the observed airborne contamination. The generally lower concentrations detected suggest that source concentrations were lower, or that more dilution in the free atmosphere was taking place. The seeps at 14682 Kathy Street had been removed between Rounds 1 and 2 and the seeps in the vacant lot were much smaller than those at 14682 Kathy Street. Also, the seep stations in the vacant lot were not shielded from the wind as much as samples in Round 1, allowing for greater dilution in the atmosphere between the seep surface and the intake line.

A summary of all soil gas and air sampling data is presented in Table 5. This table compares the common compounds detected in the investigations with established DOHS Applied Action Levels.

Table 5
Comparison of Detections by Different Methods (ppb)

Compound	Flux Chamber	Tedlar Bag	Tenax Tube	Soil Gas	DOHS Applied Action Level
Benzene	4000	37	40	340	1.0
Ethylbenzene	330	79	5	300	32.3
Toluene	8700	50	nd	1800	53.3
Xylene (M/P)	3700	410	15	680	23.1

Notes:
(1) Flux Chamber detections are all from seep at 14682 Kathy Street
(2) Tedlar bag samples -- cyclopentane not confirmed by duplicate; cyclohexane detected at downwind station only; methylcyclohexane detected at upwind station
(3) Tenax Tubes -- ethylbenzene and xylene detections at station just upwind of known Waste area
(4) Soil Gas originally reported in ppm; aliphatic C5 and C6 shown for qualitative comparison with cyclopentane and cyclohexane
(5) Maximum detections recorded in various surveys
(6) na = not analyzed
(7) nd   not detected

APPLICATIONS TO RISK ASSESSMENT

Three different categories of risk evaluation may be used during hazardous waste site investigation and remedial planning. Qualitative risk assessment answers the question of whether a site is sufficiently contaminated to warrant further investigation (e.g., do preliminary data indicate potential health/environmental threats). Semiquantitative risk assessment compares relative risk of a site as determined by a standardized model (e.g., the Hazard Ranking System/HRS). Quantitative risk assessment is a more intensive evaluation for establishing site-specific cleanup standards; a variety of approaches may be used. For the Westminster site evaluation, all three levels of assessment were applied.

Qualitative Assessment

During the 1987 investigation, soil gas data were compared to ACGIH Threshold Limit values (TLV) for preliminary evaluation. To be conservative, 10% of the TLV value was established as the level of concern. Contaminants detected by the soil gas survey during the SI were all well below this action level at that time.

Preliminary data indicated that residents were not endangered due to soil vapors. However, the recommended TLV for benzene was revised downward in 1989 to 10% of the prior value. Therefore, under the current permissible exposure limit (PEL) criteria, potential exposure to benzene is a concern warranting further evaluation in the risk assessment. In retrospect, the soil gas data were acceptable for a preliminary qualitative assessment. However, these data are deceptive because at the time of the 1987 site investigation the potential health threat posed by soil vapors could not be conclusively determined. The preliminary conclusion was that the soil vapor was not a major cause for concern.

For qualitative assessment, any of the air sampling and monitoring methods discussed herein could be applied.

Semi-Quantitative Assessment

The HRS utilized in the Superfund program is a commonly used method of semiquantitative risk assessment. The original HRS requires that exposure to receptors via the air pathway be verified by sampling data which demonstrate that an airborne release is occurring or has occurred. The revised draft HRS allows potential air releases to be a component of the total score. (The revised draft HRS has not been implemented yet for NPL listings).

The LSI (U.S. EPA-FIT) was conducted to determine if the Westminster site could be eligible for inclusion on the NPL. The low HRS score (less than the 28.5 required to propose for inclusion on the NPL) was due to the lack of a demonstrated release of hazardous materials to the atmosphere or drinking water aquifers beneath the site.[2] Tenax tube sampling data obtained by U.S. EPA-FIT did not pass the rigorous QA/QC criteria for NPL listing.

Ambient air sampling data obtained during the RI could be applied to either version of HRS. Rescoring the Westminster site could be performed using these more recent air sampling data.

Under the original HRS, soil gas data were unacceptable for air pathway scoring, but could be applied to the revised HRS to show potential air releases. Ambient sampling data of the breathing zone with sorbent tubes or Tedlar bags are applicable to either version of the HRS. Flux chamber sampling would not be acceptable under the original HRS as it does not sample the breathing zone, but it is applicable to revised HRS as it shows release to the free atmosphere.

Quantitative Risk Assessment

Quantitative risk assessments are necessary to establish cleanup standards and select remedial action alternatives. A complete risk assessment includes an exposure assessment, which requires analytical or numerical modeling based on field sampling data.

The combined flux chamber and ambient sampling with Tedlar bags provided the critical quantitative data necessary to proceed with the risk assessment. The flux chamber samples provided the data to calculate emission rates at the soil-air interface which, in turn, are used for downwind exposure modeling. Results from ambient air sampling at co-located stations provide the information to evaluate the effects of diffusion and dispersion during airborne transport.

The risk assessment for the Westminster site currently is being conducted by DOHS.

CONCLUSIONS

Soil gas sampling is acceptable for preliminary site investigations, but in this case was inconclusive and did not provide usable data for risk assessment. Concentrations detected suggested that there was no cause for concern with the exception of benzene because of the recent change in TLV.

Ambient air sampling with Tenax tubes was inconclusive in this case, due to high background concentrations detected. Tenax analyses are inherently more difficult to interpret due to more complicated analytical methods (e.g., desorption, runs with standards, etc). If only one or two target compounds are to be monitored, Tenax may be a preferred method. Also, theoretical detection limits are lower with adsorbent tubes since the detection limit is proportional to the volume of air passing through the tube.

Ambient air sampling with Tedlar bags is probably more reliable due to simpler analytical procedures (vapor in the bag is essentially run directly to GC). The method may be prone to false detections; hydrogen sulfide in particular was deemed to result in erroneous measurements on the soil gas program.

Flux chamber sampling is an elegant combination of the soil gas and ambient air methods; bags or sorbent tubes can be used for sample collection and retention. Flux chamber data allow one to calculate actual emission rates at the soil-air interface. If only one method can be used, this technique should be strongly considered.

The combination of flux chamber and co-located ambient sampling with Tedlar bags proved to be the most conclusive approach. Emission rates were calculated for flux chamber data; ambient sampling data confirmed that key compounds of concern were migrating into the breathing zone. This combined method approach provided critical data for the risk assessment necessary to continue with regulatory action on the site.

ABSTRACT

Modern penetrometers typically employed in foundation investigations provide the basis for a rapid, economical system for investigating hazardous waste sites. The major changes needed to produce a useful tool for waste site work include: development of hardware that can be easily decontaminated, development of a grouting system that can seal the holes that are produced by the penetrometer, production of sensor and sampler systems for detecting the presence of contaminants of interest and integration of the components into a site characterization system. This paper discusses the progress that has been made in developing such a penetrometer system.

INTRODUCTION

Cone penetrometers were originally designed to assess soil strength properties for railroad grades and unpaved roadways. Typical penetrometer equipment consists of a standard instrumented rod (35 mm in diameter) tipped with a 60° cone. The rod is driven into the soil using hydraulic rams at a standard rate of 2 cm/sec. The reaction force for the rams usually is provided by earth anchors or a large mass (such as a 20-ton truck). The penetrometer equipment generally is mounted on skids if earth anchors are used or on a heavy-duty truck equipped with all-wheel drive if a reaction mass is used (Fig. 1).

Soil strength is determined by measuring the resistance developed on the cone tip and on a fixed area of the rod behind the tip (referred to as the sleeve). The tip resistance and sleeve friction vary with the grain size of the soil and the degree of compaction or cementation. The cone resistance and sleeve friction measurements when combined can be used to determine the type of soil penetrated as the rod is advanced.[1,5]

In addition to its role in determining the strength properties and character of the soil under a site, the penetrometer is now being recognized as a simple, rapid method of introducing a variety of sensors and samplers into the soil. The penetrometer generally can be used to push to a depth of up to 50m in normally compacted soil. Penetrometers are becoming increasingly popular for use in hazardous waste site (HWS) investigations because they combine speed and versatility with a degree of safety that is not available in conventional drill-and-sample operations.[3] The purpose of this paper is to show how the basic penetrometer can be combined with sensors to produce a site characterization system for use in investigating toxic and hazardous waste sites.

SOIL CHARACTERIZATION

Penetrometers have become very popular as a method of investigating soil conditions, and the basis for a soil contamination investigation system is present in a modern penetrometer unit. The soil strength measurement systems have been linked to a computer and to real-time data displays so that soil characteristics can be displayed for the operator as the penetrometer rod advances. For example, in a typical foundation investigation, the operator can watch the real-time display of the tip resistance and sleeve friction as the penetrometer moves through the soil. Computer programs have been developed that work out the type of soil encountered from the strength properties measured by the rod and cone and display the probable soil type directly.

Figure 1

A penetrometer unit in operation in the field. The expanded cupola on top of the enclosure allows the rods to extend through the roof. During a push, the unit is supported on jacks as shown to use the entire weight of the truck for reaction.

HAZARDOUS WASTE SITE INVESTIGATIONS

HWS investigations can build on the basic soil investigation capabilities of the penetrometer equipment. In conventional foundation work there typically was no requirement for sealing the penetrometer holes produced during operation. On an HWS, a grouting system must be used to seal the holes as a guarantee that the penetrometer holes will not prolvide conduits for the movement of toxic material on the investigation site. Conventional grouting systems used for servicing well drilling operations

can be adapted for use with penetrometers. Some penetrometers are now equipped with grouting systems that pump grout through the push rod to seal the hole as the rod is withdrawn.

The penetrometer operations usually are run from inside a heated and air-conditioned, truck-mounted enclosure. The truck body makes a useful shelter for the computer equipment needed to make a fully-integrated HWS characterization system. The enclosure can be divided into separate areas equipped with controlled and filtered ventilation systems to house the "clean" computer area and the "dirty" rod-handling area. A decontamination system can be provided for cleaning the rods and the "dirty" part of the enclosure containing the hydraulic rams and rod handling and sampling equipment (Fig. 2).

The major adaptation to a penetrometer system involved in HWS work relate to sensors and samplers furnished with the penetrometer. The sensors and samplers must be suited to the type and level of contaminant being considered.

Figure 2
Interior of the rod-handling compartment in a truck equipped for HWS investigations. Note the walls and floor are surfaced with stainless steel. The unit is equipped with floor drains and a waste-containment tank so that the area can be decontaminated.

PENETROMETER SENSORS/SAMPLERS

Penetrometers developed for foundation investigations have instrumentation designed to measure soil strength and soil pore pressure. Sensors are now available for measurement of electrical conductivity of soil, natural radioactivity and soil optical properties (fluorescence and reflectance).

The electrical conductivity sensor usually takes the form of a series of metal bands separated by ceramic or epoxy insulators mounted on the penetrometer rod. The unit is analogous to an electric logging sonde, but with close contact to the soil and short electrode array, conductivity changes in the soil can be located to within a few centimeters. Conductivity sensors have been successfully used in locating closed evaporation ponds and in delineating the plume of contaminated (high conductivity) water associated with abandoned landfills.[3,4]

The cone developed for detecting radioactivity is analogous to the well logging tools used for measuring natural gamma activity. A miniaturized downhole scintillation counter can locate both natural radioactivity (such as that associated with weathered organic shales) and manmade radioactivity from mine tailings or other radioactive wastes.

The optical sensor for the cone penetrometer is a new device that uses a visible or ultraviolet light source (lamp or laser) shining through a sapphire window in the penetrometer tube wall. The return signal from the soil is collected by a fiber optic element that passes the signal to analytical equipment at the surface. The optical cone has been used primarily in the fluorescence mode to locate and track fluorescent tracer dyes and waste oil and fuel in natural soils and hydraulic fill materials. The unit has potential applications as a colorimeter for locating geologic units or contaminated soils with distinctive spectral characteristics. The optical cone uses an 8-mm diameter window and can technically locate the position of a soil color or fluorescence interface within 1 cm.

Soil and water samplers suitable for use in HWS investigations are available for incorporation into a penetrometer-based system. The samplers typically are of all-stainless steel construction and are designed to be disassembled for thorough cleaning between uses.

INTEGRATING DEVELOPMENTS TO FORM A SYSTEM

Pulling together a coherent picture of the conditions in the subsurface at a HWS requires simultaneous data acquisition and data evaluation. The sensors provide unprocessed responses that require refinement and interpretation before they can be displayed in a meaningful way. For example, the operator must know the depth of the rod reading when all of the sensors are positioned at different places on the penetrometer rod. The soil strength is measured on the bottom 50 cm of rod, the optical and electrical sensors are positioned 25 cm above this point. The operator must see all of the information produced for a common depth with all of the various calibration and standardization factors applied to the data.

Figure 3 shows the level of complexity involved in the data transfer for a penetrometer unit that is measuring the optical response and the soil strength properties (soil type) simultaneously. The system shown uses two 386-level personal computers (386 PCs) and a separate optical multichannel analyzer computer (OMA computer) to handle data acquisition and display. The three computers are linked with a token ring network inside the truck so that each machine can communicate with the other two. This system can measure optical properties and strength properties of the soil and maintain a record of the exact depth of the rod tip (through the string pot amp) and the geographic position of the truck on-site (survey equipment). The truck-mounted computers also can pass data to a large graphics computer for presentation level displays.

CONCLUSIONS

The existing penetrometer systems used in foundation investigations provide the platform for a new and sophisticated HWS characterization system that combines the speed and versatility of the penetrometer for data collection and sampling, with the ability of modern computer equipment to log data and produce a

synthesis of the data for operator interpretation. This approach allows the penetrometer crew to obtain immediate information in the field on the soil type being penetrated and an index of the level of contaminant present in the soil unit. Site investigations can now become interactive exercises where the direction of the characterization effort can be altered to take advantage of the information collected in each penetration. Soil and groundwater samples can now be obtained as a confirmation of the information obtained from sensors.

Monitoring wells can be placed late in the HWS investigation program in positions that penetrometer sensor and sampler data indicate are critical for long-term monitoring. It also is possible to consider using the penetrometer to implant well points to serve as monitoring wells where a full well installation cannot be justified.

Slug Testing in Highly Permeable Aquifers Using a Pneumatic Method

Gerald A. McLane
Deborah A. Harrity
Kurt O. Thomsen, Ph.D., P.G.
PRC Environmental Management, Inc.
Chicago, Illinois

ABSTRACT

Highly permeable, unconsolidated deposits with horizontal hydraulic conductivities in the 10^{-3} to 10^{-1} cm/sec range often are encountered during environmental site characterization studies. Standard slug tests are ineffective in such formations, since a large and nearly instantaneous decrease in the well water level is required for a rising head test and an instantaneous increase in the water level is required for a falling head test. PRC Environmental Management, Inc. developed a quick and cost-effective pneumatic slug test method to lower or raise the static water level in such wells. Viable data can then be recorded when the water level is allowed to return to equilibrium. The method is very flexible and has been successfully used in 2-inch wells with a shallow (10-foot) water table and in 4-inch wells with a deep (125-foot) water table. Unlike other methods, it has the added advantage that both rising and falling head tests can be performed with a single, four component equipment setup.

The pneumatic slug test method requires four components: (1) a pneumatic well head assembly capable of providing an air-tight seal with a pressure/vacuum port, a quick release pressure valve and the capacity to accommodate a transducer cable and water level indicator tapes; (2) an oil-less air compressor capable of supplying positive and negative pressure; (3) a high-speed data logger interfaced with a pressure transducer; and (4) two electronic water level indicators. Statistical analysis of replicate rising and falling head tests in the same well showed that a high level of precision is attained using the pneumatic slug test method in highly permeable formations that were previously unsuited to slug test methods.

INTRODUCTION

Recent advances in slug testing, using a pneumatic technique, have increased the range and application of measuring hydraulic conductivity. Hydraulic conductivity has long been successfully determined in single wells by introducing or removing water or solid slugs.[1-4,7] These methods, coupled with water level measurement devices such as electrical water level indicators or percussion sounding instruments, can accurately determine hydraulic conductivities in the range of 8×10^{-4} cm/sec to 1×10^{-3} cm/sec.

The advent of data logging devices used in conjunction with pressure transducers allows successful slug testing in aquifers with hydraulic conductivities in the range of 1×10^{-2} cm/sec. However, these methods typically cannot be applied in aquifers with hydraulic conductivities greater than 1×10^{-2} cm/sec. In these instances, water levels rapidly reach equilibrium before the entire slug is added or removed. The initial change in water level is neither instantaneous nor of great enough magnitude to adequately monitor the recovery period. The use of solid slugs also makes it difficult to measure water levels, since the slug can

jar and offset the pressure transducer suspended inside the well. This problem particularly occurs in small diameter wells. At sites where wells are to be sampled for environmental parameters, traditional slug test methods have on additional limitation because the addition of potentially contaminated solid slugs or clean water can bias subsequent sampling results.

The pneumatic method for conducting slug tests overcomes all of these limitations. This method involves either injecting air into a sealed well to lower the water level[5] or applying a partial vacuum to a sealed well to raise the water level.[6] PRC has developed a pneumatic slug test method capable of conducting both rising and falling head tests with essentially the same equipment setup. This method is very versatile and has been used at sites with distinctly different geology and well construction. It has been used successfully in 2-inch I.D. wells, where depth to water was only 10 feet, and in 4-inch I.D. wells, where depth to water was 125 feet.

EQUIPMENT

The equipment needed to conduct pneumatic slug tests includes the well head assembly, two electronic water level indicators, a pressure transducer coupled with a high speed data logger, an oil-less air compressor capable of supplying both positive and negative pressure and a stop watch.

The principal component of this system is the well head assembly. This assembly, shown in Figure 1, consists of three major parts: (1) a rubber sleeve connector, (2) a quick release pressure valve, (3) and the pneumatic well cap assembly. The entire assembly is connected to the well head by means of the rubber sleeve connector. The sleeve is fitted around the riser pipe and a short section of pipe (of the same diameter) and sealed with hose clamps. A T-type pipe connector is attached to the top of the short pipe section.

The quick release pressure valve assembly and the pneumatic well cap assembly are in turn attached to the T-connector, as shown in Figure 1. The quick release pressure valve assembly consists of a ball-type valve attached to a short section of pipe. The pipe and valve must be equal to or greater in diameter than the well riser pipe. The pneumatic well cap assembly is shown in greater detail in Figure 2. This assembly fits into and rests on top of a short section of pipe. The assembly is constructed of two steel plates, separated by a 1- or 2-inch thick disk of foam rubber. The lower plate must be slightly smaller in diameter than the connector pipe it fits into. A quick release hose fitting is attached to the upper plate and passes through the foam rubber gasket and lower plate. The pressure or vacuum hose attaches to this fitting. The upper and lower plates are slotted to accommodate the transducer and water level indicator lines. An airtight seal is created by tightening the three bolts. This raises the lower plate, which in turn compresses the foam rubber gasket to make the seal.

Pneumatic Well Head Assembly
Figure 2
Pneumatic Well Cap Assembly

METHODOLOGY

Specific site information, such as the depth to water and well construction details, must be known before conducting pneumatic slug tests. As in all slug test procedures, the top of the well screen must lie well below static water level. Before the rising head test can be conducted, the height of the water column above the top of the well screen must be determined to ensure that air is not injected into the aquifer in the course of lowering the water level in the well.

A pretest should be conducted prior to performing rising or falling head tests. The pretest is conducted in much the same manner as the actual test, except that the transducer and data logger are not activated. The equipment setup for conducting a falling head pretest and actual test is shown in Figure 3. The two water level indicators and the pressure transducer are lowered into the well through the pneumatic well cap assembly and set at the proper depths. The pressure transducer is typically set in the well screen. One water level indicator probe is set 1 inch above static water level; the other is set 10 feet above static water level.

With both water level indicators turned on and the quick release pressure valve closed, the vacuum line is attached to the quick release hose fitting on the pneumatic well cap assembly, causing the water level in the well to rise. At the instant the upper water level indicator sounds, the quick release pressure valve is opened. A stop watch records the time required for the water level to return to equilibrium (shown by the lower water level indicator). This time interval should be at least three seconds, which is the minimum elapsed time necessary to collect accurate data for the standard hydraulic conductivity calculations. If the initial 10-foot water level rise recovers to equilibrium before three seconds, the upper water level indicator should be raised in increments of 5 feet until the 3-second limit is reached. Experience with this equipment has shown that water levels can be raised or lowered 25 feet in 4-inch I.D. wells with little effort.

To conduct pretests for rising head tests, the water level indicators are set approximately 1 inch and 10 feet below static water level (Fig. 4). The quick release pressure valve is closed and the pressure line is attached to the quick release hose fitting on the pneumatic well cap assembly, causing the water level in the well to fall. The quick release pressure valve is opened and the stop watch is activated simultaneously when the lower water level indicator stops sounding. The time required for the water level to return to equilibrium (shown by the upper water level indicator) is recorded. The lower water level indicator is lowered in five foot increments until the three second recovery limit is reached.

The water level recovery times noted during the pretests are also useful for estimating the test duration. This pretest process prevents the unnecessary monitoring of the water level recovery after well conditions have returned to equilibrium.

For the actual falling head and rising head tests, the initial depression or elevation of the water level in the well is performed as in the pretests. When the water levels reach the predetermined elevation, the quick release pressure valve is slightly opened and closed to maintain the water level in the well (as indicated by the water level indicator) at that elevation. This is done for 5 to 10 seconds so that the aquifer can return to equilibrium (an assumption for hydraulic conductivity calculations) before the recovery phase. The actual test is then initiated by simultaneously opening the quick release pressure valve and starting the data logger. The rate of recovery, as well as the initial head displacement, will be recorded automatically by the data logger.

It is important to stress that the quick release pressure valve opening must be equal to or greater in diameter than the riser pipe. This relative sizing is required if air pressure inside the well is to return to atmospheric pressure instantly. Smaller diameter openings prohibit the instantaneous return to atmospheric pressure. In the case of a rising

head test, an inordinately small pressure release opening causes the well to recover under pressures greater than 1 atm, thereby leading to erroneously slow recovery rates. The same result is true in the case of the falling head test, where a partial vacuum above the water column will decrease the rate at which the water column falls back to static water level. Both conditions will lead to erroneously low estimates of hydraulic conductivity.

Figure 5 demonstrates the importance of the valve diameter. In the figure, replicate rising head tests are plotted with the Hvorslev method.[4] The log of the head ratio is plotted on the vertical axis and the recovery time is plotted on the horizontal axis.

Test A is the plot for a test using the quick release pressure value assembly shown in Figure 1. When the air pressure inside the well returns instantly to atmospheric conditions, as in the case of Test A, the plot is a straight line. If an apparatus that restricts the flow of air into or out of the well is used, as shown in Test B, water levels in the well fluctuate radically until air pressures reach atmospheric conditions (at point R). After this point, water levels recover at the same rate observed in Test A, as indicated by the parallel slopes. However, the basic time lag T_o, defined by Hvorslev as the time at which the log of the head ratio = -0.43, is erroneously high in Test B. If this high T_o value is used in the Hvorslev equation for partially penetrating wells, the resulting hydraulic conductivity will be too low. The Hvorslev equation is shown below:

$$K_h = \frac{d^2 \ln (2 \, mL/D)}{8 \, LT_o} \qquad (1)$$

where:

K_h = horizontal hydraulic conductivity
d = diameter of riser pipe

m = transformation ratio
L = length of well screen
D = diameter of well screen
T_o = basic time lag

The error described above will be accentuated as the depth to static water level increases, since greater volumes of air must escape or enter the well before equilibrium is reached.

ANALYSIS

The pneumatic slug test method has been successfully tested at two Superfund sites with very different hydrogeology and monitoring well types. At the first site, in northern Michigan, monitoring wells are constructed of 2-inch I.D. PVC riser and screen. The aquifer consists of very clean, well-sorted, fine to medium-grained quartz sand. The static water level in this aquifer is approximately 10 feet below ground surface. At the second site, in central Nebraska, monitoring wells are constructed of 4-inch I.D. stainless steel riser and screen. This aquifer is composed primarily of poorly sorted sands and gravels with some silt. The static water level in this aquifer is approximately 125 feet below ground surface.

PRC conducted six replicate rising and six replicate falling head tests on a single well at each site using the pneumatic method. The precision of the method was measured by: (1) the reproducibility of the results within each set of six tests and (2) the reproducibility of the results between the rising and falling head tests conducted at each well. The data for each test were plotted using the Hvorslev method. The slopes of the linear portion of the curves were determined using linear regression analysis. The average slope and the upper and lower 95 percent confidence limits were determined for each of the four sets of replicates. This information is summarized in Table 1.
Figure 3
Equipment Setup for Conducting the
Falling Head Set
Figure 4
Equipment Setup for Conducting
the Rising Head Test
Figure 5
Replicate Rising Head Tests Showing Effect
of Inadequate Pressure Release Valve Diameter

Table 1
Statistical Comparison of Test Results

		Mean	95% LCL	95% UCL
Nebraska Site				
Rising Head	Slope	-7.857	-8.185	-7.530
	K_h	7.68×10^{-3} cm/sec	7.32×10^{-3} cm/sec	7.98×10^{-3} cm/sec
Falling Head	Slope	-8.962	-9.169	-8.751
	K_h	8.74×10^{-3} cm/sec	8.53×10^{-3} cm/sec	8.94×10^{-3} cm/sec
Michigan Site				
Rising Head	Slope	-7.753	-8.412	-7.058
	K_h	1.06×10^{-2} cm/sec	9.60×10^{-3} cm/sec	1.15×10^{-2} cm/sec
Falling Head	Slope	-7.906	-8.545	-7.267
	K_h	1.08×10^{-2} cm/sec	9.90×10^{-3} cm/sec	1.16×10^{-2} cm/sec

Hvorslev's equation was rearranged to use the slope of the plot, rather than a single point, to calculate hydraulic conductivity:

$$K_h = \frac{d_2 \ln (2 \; mL/D)}{8 \; L} \quad x \;_l n \quad \frac{(H/Ho)_1}{(H/Ho)_2} \qquad (2)$$
$$\frac{}{T_2 - T_1}$$

The far right side of the equation is the slope of the linear portion of the plotted data. The absolute value of the slope, as determined by linear regression analysis, replaces the T_o (basic time lag) portion of Hvorslev's equation.

Replicate testing has shown the pneumatic method to be very precise. In Michigan, hydraulic conductivity as measured by the rising head test in the test well fell between 9.60×10^{-3} and 1.15×10^{-2} cm/sec 95

percent of the time. The falling head test results fell between 9.90×10^{-3} to 1.16×10^{-2} cm/sec 95 percent of the time.

In Nebraska, hydraulic conductivity was measured in rising head tests at between 7.32×10^{-3} and 7.98×10^{-3} cm/sec 95 percent of the time. The falling head test results fell between 8.53×10^{-3} and 8.94×10^{-3} cm/sec 95 percent of the time.

The Michigan testing showed that hydraulic conductivities calculated using the rising and falling head tests were statistically equal based upon replicate testing results. In the Nebraska testing, however, the hydraulic conductivities were statistically different for the two tests.

One possible explanation for this difference is the precision of new technology in the form of high-speed data loggers and an easy-to-use, convenient method for conducting the testing. Although the average hydraulic conductivity resulting from the rising head test (7.68×10^{-3} cm/sec) during the Nebraska testing is statistically different from the falling head test (8.74×10^{-3} cm/sec), the use of one value over the other would not significantly affect the outcomes of relationships in which hydraulic conductivity values are commonly used. More testing will be done to study the difference in results.

The Michigan and Nebraska testing were conducted in formations with medium conductivities—in the range of the upper 10^{-3} cm/sec to the lower 10^{-2} cm/sec. This range is toward the upper limit of the other slug testing methods. The authors feel that the pneumatic slug test method could easily measure hydraulic conductivity in formations where the hydraulic conductivity is several orders of magnitude higher.

CONCLUSION

The pneumatic slug method for conducting rising and falling head tests is a cost-effective and versatile procedure for determining hydraulic conductivities in highly permeable formations with hydraulic conductivities greater than 10^{-2} cm/sec. Replicate testing indicates that a high level of precision can be achieved with the pneumatic slug test method. Unlike other pneumatic methods, its flexibility allows both rising and falling head tests to be performed with the same equipment setup. Unlike traditional methods, it allows a maximum initial change in water levels, so that well recovery rates can be adequately monitored. Similarly, it allows the recovery period to begin instantaneously, a procedure that is very difficult to achieve with the traditional methods. The pneumatic method also avoids the introduction into the well of potentially contaminated solid slugs or clean water slugs, which may bias subsequent sampling results.

Using Hydraulic Probe Sampling in Shallow Aquifers for Groundwater Contaminant Plume and Source Location

Ray M. Mastrolonardo
Kurt O. Thomsen, Ph.D., P.G.
PRC Environmental Management, Inc.
Chicago, Illinois

ABSTRACT

PRC Environmental Management, Inc., developed a technique to conduct preliminary groundwater contaminant plume and source location surveys using a hydraulic probe sampler in shallow aquifers (water table less than 30 feet). The technique was used to conduct an areal site survey at a Michigan Superfund site to define a contaminant plume and identify the sources of that contamination.

Periodic sampling of residential wells had detected gasoline-derived contaminants in groundwater from many of those wells. Rather than relying on the usual approach of drilling boreholes and installing monitoring wells, PRC used a hydraulic probe sampler and a close support laboratory (CSL) to determine the areal extent of the groundwater contaminant plume and identify the contaminant sources. The collected data were used to design a borehole drilling program to define the vertical extent of contamination and install monitoring wells in the optimum locations.

Soil gas sampling techniques were modified to accommodate the collection of groundwater. The hydraulic probe sampler was used to collect in situ groundwater samples at depths ranging from 9 to 20 feet at 69 locations. The 1-inch outer diameter hollow probe was hydraulically driven to 2 feet below the water table, as determined using an electronic water level indicator. Groundwater samples were then taken, using a peristaltic pump and transported directly to the on-site CSL for analysis. Groundwater levels were recorded and locations were surveyed. All the field work was completed in 5 days. Data analysis required another 5 days.

Using these data, PRC was able to develop a preliminary potentiometric surface map, determine the groundwater flow direction, determine the areal configuration of the groundwater contaminant plume and identify two contaminant sources. A cost-effective borehole drilling program then was designed to establish the vertical extent of contamination and to install a groundwater monitoring system. By using the preliminary survey technique, PRC reduced data collection time from as long as 12 weeks to only 2 weeks, which resulted in significantly lower costs for the remedial investigation.

INTRODUCTION

During the summer of 1989, a remedial investigation (RI) was conducted at a Michigan Superfund site. The site was centered in the commercial portion of a small residential town in northeast Michigan. Previous investigations and site background information suggested that possible sources of chlorinated solvents and petroleum hydrocarbons existed at the site. The goals of the RI were to define the areal extent of groundwater contamination and to identify contaminant sources.

Rather than use the conventional approach of strictly drilling boreholes, a technique was used to conduct a preliminary groundwater plume and source location survey. This technique consisted of using a hydraulic probe sampler to collect groundwater samples in a fast and, therefore, cost-effective manner. It was essential to have a close support laboratory (CSL) on-site during this groundwater survey to provide short turn around time for the sample results.

INVESTIGATION METHOD

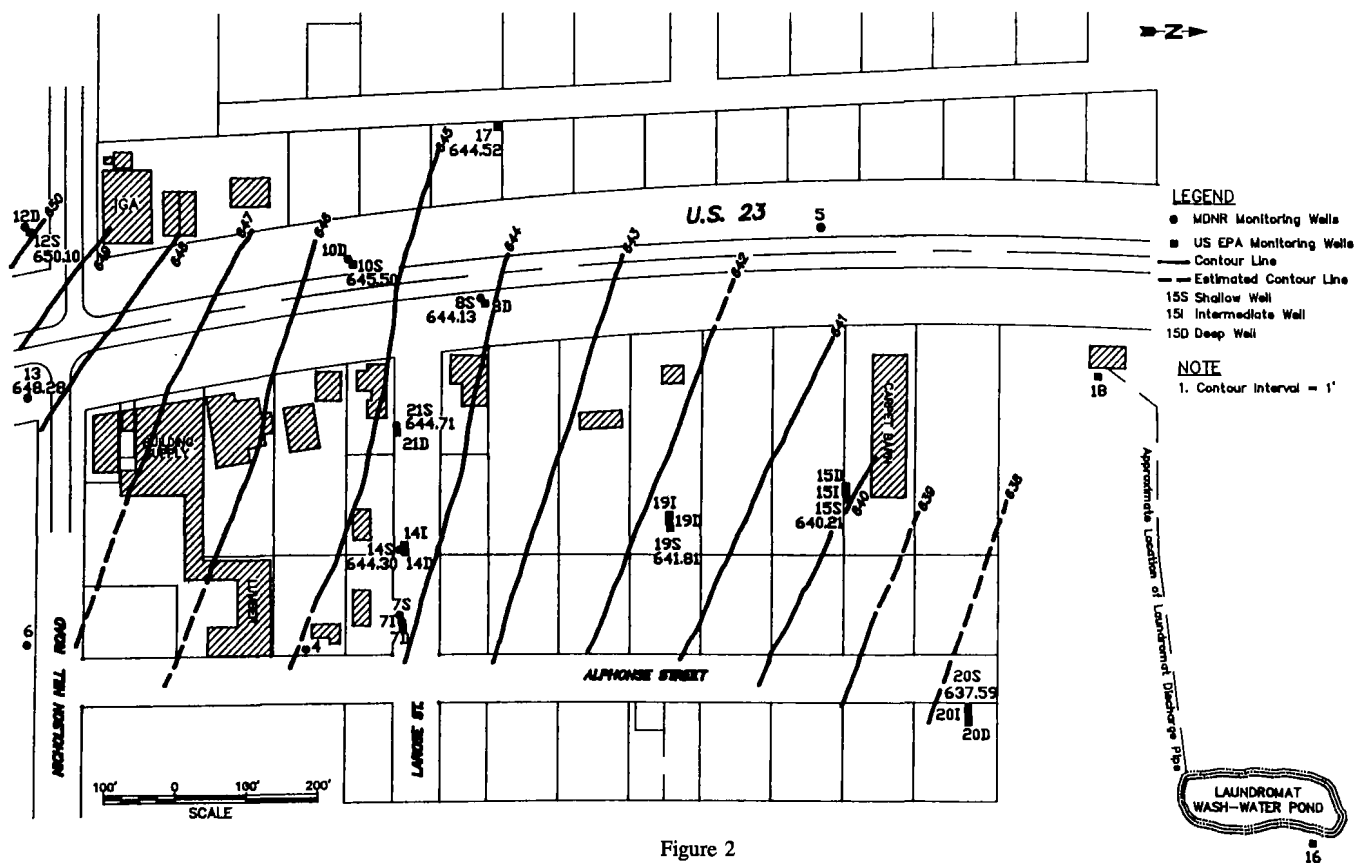
The groundwater plume and source location survey was conducted by first establishing a grid system for sampling. A local licensed surveyor laid out a 200-foot grid within the preliminarily designated site boundaries. As samples were collected from grid locations and analyzed by the CSL for target compounds of concern, the generated data dictated in which direction to stray from the grid and in which area to concentrate sampling efforts. Figure 1 shows the locations where the in situ groundwater samples were collected.

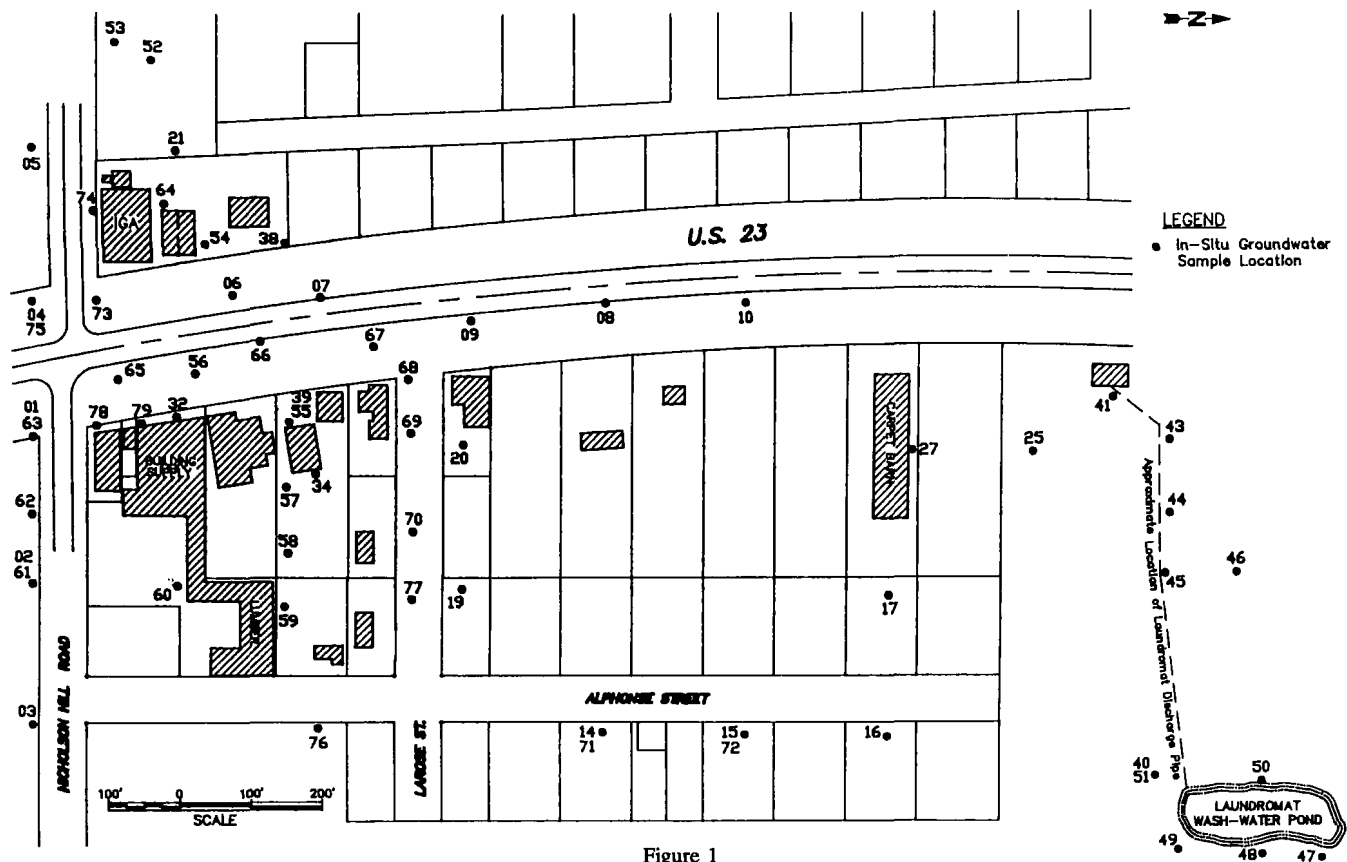
The sampling procedures used were tailored to the conditions at this particular site. The local geology consists of approximately 30 feet of consolidated sand overlying a silty clay aquitard unit. The water table was encountered at depths ranging from approximately 15 feet to the southwest to only a few feet to the northeast (Fig. 2). The sampling equipment included a van with the capability to hydraulically push the sampling probes, 3-foot sections of threaded 1-inch outer diameter (OD) stainless steel rod, rigid 0.375-inch PVC tubing, a peristaltic pump and sample containers.

Sampling was conducted by pushing the probes to the desired depth of 2 feet below the water table. The depth to the water table was established by using an electronic water level indicator. The water level sensor was lowered inside the probe after the probe was pushed to the expected depth of the water table. When the water table was located, the depth of the probe tip was adjusted so that the tip was 2 feet below the water table before sampling was initiated. The probe tip was retractable so that when the rod was pulled back, the tip remained in place and a void space was created for groundwater to enter the rod. Rigid 0.375-inch PVC tubing was inserted into the rod to the bottom of the hole and cut above grade. The tubing was connected to a peristaltic pump. The system was purged and a sample was collected and promptly transported to the CSL. PVC tubing was discarded after sampling and the stainless steel rods were steam cleaned prior to reuse. The peristaltic pump was flushed with clean water between each sample. When field monitoring detected the presence of organic vapors, the tubing in the peristaltic pump was replaced as well.

The total time required to drive the rod, collect the sample and remove the rod usually was no more than 30 minutes. The limiting factor for this procedure was the rate at which the CSL could analyze the groundwater samples. More samples could be collected during a given day than could be analyzed the same day.

Figure 1
Hydraulic Probe Sampling Locations

Figure 2
Groundwater Contour Map




In addition to obtaining in situ groundwater samples, this method also can be used to collect preliminary groundwater elevation data. In loose soils or sands, a water-level indicator can be inserted inside the stainless steel rod to obtain a water-level measurement, as described above. This technique is best suited for loose soils where collapse of the hole is likely. In a more cohesive soil environment, the rod can be removed and a 1-inch PVC temporary piezometer can be inserted into the void space. Either one of these techniques can be used to measure groundwater levels to get an indication of the flow direction. Each temporary piezometer (probe or PVC) location is surveyed to establish the horizontal coordinates as well as the surface elevation. The piezometer stickup is measured at the same time as the water levels. After all locations are surveyed, the elevations of the groundwater levels are determined.

In less than 2 weeks, 69 locations were sampled at depths ranging from approximately 9 to 20 feet. Quality control samples were collected as part of the survey. Duplicate samples were collected at the frequency of one duplicate for every 10 samples. Equipment blanks were collected at the same frequency to verify the effectiveness of the decontamination procedures.

RESULTS

Groundwater samples usually were analyzed by the CSL usually within 24-hours. The samples were analyzed for target volatile organic compounds. These target compounds included benzene, toluene, ethylbenzene, m,p and o-xylenes, tetrachloroethene and 1-2-dichloroethane. Analytical results for the groundwater samples are presented in Table 1.

Historical records indicated that several underground gasoline tanks were in operation in the area at one time. The three other areas containing elevated BETX concentrations correlate with former locations of underground gasoline tanks. The two areas near the intersection of U.S. Highway 23 and Nicholson Hill Road match two separate former tank locations and represent residual contamination from inactive sources. The third area southwest of the intersection of LaRose and Alphonse Streets is at a location where tanks had been removed and replaced with new operating tanks. The BETX detected here seems to be due to residual contamination rather than from an active source. It is much more localized than either of the active source pumps.

Trace levels of BETX contaminants were detected farther downgradient near the laundromat. The primary constituent detected was benzene, the most mobile of these compounds.

Target compounds such as 1,2-dichloroethane and tetrachloroethene were analyzed to determine the extent of contamination from chlorinated solvents. Tetrachloroethene was detected at only five locations and 1,2-dichloroethane was detected at only four locations. The highest concentration of tetrachloroethene was detected at sample location 54 (7.7 μg/L), while the highest concentration of 1,2-dichloroethane was detected at sample location 57 (41 μg/L). All other locations where these compounds were detected contain only trace levels (less than 3 μg/L).

DISCUSSION

A groundwater survey using the hydraulic probe sampling technique can be compared with other more common groundwater sampling techniques such as borehole drilling and monitoring well installation when used in shallow aquifers. Although the hydraulic probe survey most likely will not completely replace all drilling activities in a groundwater investigation, it can significantly reduce the amount of drilling and, ultimately, reduce the cost.

The information obtained from the groundwater survey served as the basis for the borehole drilling program. Boreholes were drilled at sample locations 39, 54, 55, 57 and 65 to define the vertical extent of contamination. As expected, locations 39, 54, 55 contained the highest levels of contaminants.

A monitoring well system was established to verify preliminary data and to provide permanent sampling locations for long-term monitoring (Fig. 4). Only 5-foot screen lengths were used, so many of the well locations were nested. Upgradient well locations south of Nicholson Hill Road provided background groundwater data. Monitoring wells 21, 19 and 15 were placed downgradient of one active source and wells 8 and 10 were located downgradient of the other active source. Wells 4, 7, 14 and 20 were located to monitor the eastern fringe, and wells 5 and 17 were located to monitor the western fringe. Monitoring wells 16 and 18 were located to monitor groundwater near the laundromat and its washwater pond where chlorinated solvents were suspected.

CONCLUSION

The hydraulic probe groundwater sampling technique can be an effective part of a site investigation in areas having shallow aquifers. This technique, combined with the use of a close support laboratory, provides preliminary groundwater data with short turn-around time. The quick return of sample results enables the sampling team to make decisions and draw conclusions at an expedited pace. Nearly 70 locations were sampled along with QA/QC samples and the resulting sampling data were analyzed in less than 2 weeks. The hydraulic probe van is much smaller than a drill rig, making it easier to maneuver into areas where a drill rig might not be practical. It also requires less overhead clearance from trees and utilities.

A clear picture of the areal extent of contamination was obtained by using the survey. Boreholes were drilled to define the vertical extent of contamination and monitoring wells were installed to provide a long-term monitoring system. All drilling activities were based on information generated by the groundwater survey. Because this method is relatively inexpensive compared with borehole drilling and well installation, it provides a cost-effective way to decrease the amount of drilling time and, ultimately, reduce the cost of the investigation.

Notes

Only locations with target compounds detected are presented in this table

M,p xylenes were analyzed but not detected in in situ ground-water samples

The detection limit for in situ ground water analyses is 0.5 ppb

ppb = parts per billion

ND = Not Detected

Sample locations containing levels of petroleum hydrocarbons were detected in five areas (Fig. 3). The concentrations are presented as a sum of benzene, ethylbenzene, toluene and m, p and o-xylenes (BETX) in μg/L. The two areas with the highest BETX concentrations were traced to operating underground gasoline tanks. One plume is originating from underground tanks west of U.S. Highway 23. Another plume is originating from underground tanks east of U.S. Highway 23. Sample locations along U.S. Highway 23 contain only trace levels of contaminants between the two plumes.

ABSTRACT

Bentonite consists of mainly the clay mineral montmorillonite and is found worldwide, mostly in the deposits of the Cretaceous age. Nearly all the commercial bentonite deposits were produced by the devitrification of tuff or volcanic ash. Bentonite is known for its physico-chemical properties that include shrink-swell, cation exchange capacities, thixotropy and fluid-loss reducing properties.

Bentonite clays have been traditionally used in the oil well drilling industry since the early 1930s. The oil industry has used chemical additives with drilling mud despite concern about possible chemical reactions with aquifer waters. As recently as the 1970s, bentonite clays have also been used in the groundwater monitoring industry. Unlike the oil industry, however, the material used in well construction or borehole completion is closely scrutinized and chemically analyzed for purity. Material used in groundwater monitoring must be chemically inert and not alter the ambient quality of monitored groundwaters.

There is much confusion about historic oil field terminologies of bentonites and their applications to the groundwater monitoring industry. Recent advances in the production of bentonite-based materials have further convoluted the problem. This paper describes various properties that must be considered in evaluating when to use a drilling mud, slurry, bentonite seal, cement-bentonite grout and high-solid bentonite grout. It also provides environmental definitions for these categories.

INTRODUCTION

In the 1880s, William Taylor identified an unusual high-swelling clayey material in the vicinity of Rock Creek, Wyoming, and he called this material "taylorite." In 1898, W.C. Knight renamed this clay-like, sticky material with soapy properties "bentonite" because of its occurrence in the Fort Benton shale unit of Cretaceous age.[1] Various unique physical properties of bentonite made it commercially valuable. The bentonite-producing industry rapidly developed in Wyoming and additional bentonite deposits were soon discovered in Arizona, California, Mississippi and Texas and in England, Germany, Japan and the Soviet Union. The first serious effort at bentonite production occurred in the United States in Wyoming in about 1920. Production outside the United States developed in the late 1920s.[2]

The *Glossary of Geology*[3] describes bentonite as a soft, plastic, porous, light-colored rock composed essentially of clay minerals from the montmorillonite (smectite) group and colloidal silica. It is produced by devitrification and accompanying chemical alteration of a glassy igneous material, usually a tuff or volcanic ash. It often contains accessory crystal grains that were originally phenocrysts in the parent rock. Its color ranges from white to light green and light blue when fresh and becomes light cream with exposure, gradually changing to yellow, red or brown. The rock is greasy and soaplike to the touch

(without a gritty feeling) and absorbs large quantities of water, which increases its volume about eight times.

Bentonite is used in ceramics, foundry molding sands, engineering projects, the petroleum industry and in the manufacturing of a variety of miscellaneous products ranging from adhesives to soaps. Which physico-chemical property of bentonite is utilized depends on the purpose of the job. The use of bentonite in the groundwater industry is relatively new and has basically evolved from the petroleum industry. In the first part of this paper, the geology, mineralogy and the origin of bentonite are described. In the second part, monitoring well construction, the use of bentonite, its physico-chemical properties and its transition from the oil industry to environmental usage are discussed.

GENERAL GEOLOGICAL FEATURES OF BENTONITES

According to Grim and Guven,[2] bentonites are most commonly associated with beds that are marine in origin. The associated beds may also be nonmarine in origin, such as freshwater limestones, carbonaceous shale or beds of coal.[2] A few bentonites are reported to be fossiliferous.

Most bentonites are grey, bluish grey, light yellow or green in color. Individual beds of bentonite may be laminated or massive. Because of its expansion when wet and contraction while drying, bentonite outcrops frequently have a "popcorn" appearance. Weathering of an outcrop tends to increase the colloidal properties. Bentonite layers vary in thickness from less than 1 inch to more than 20 feet. Often, the thicker beds seem to be composites of several layers.

Bentonite deposits range in age from Upper Paleozoic to Recent. World-wide, most bentonites occur in the formations of the Cretaceous age. Bentonites are found on every continent. A list of countries and regions where bentonite deposits are known to occur is presented in Table 1. (The reader can refer to Grim and Guven for further details).[2]

Table 1
Countries/Regions Where Bentonite Deposits Occur

1	The United States of America	
	Black Hills Region	Rocky Mountain and California areas
	Gulf Coast Area	Other areas (Illinois, Missouri, Delaware, Georgia, and Alaska)
2	Western Hemisphere (excluding those in the United States)	
	Argentina	Brazil
	Canada	Colombia
	Cuba	Equador
	Jamaica	Mexico
	Peru	Puerto Rico
	Uruguay	
3	Africa	
	Algeria and Morocco	Namibia

Egypt	Sudan Republic
Kenya and Tanganyika	Union of South Africa
Mozambique	

4. European and eastern Mediterranean countries

Austria	Bulgaria

5. Soviet Union, Asia, and the Southwest Pacific

Australia	Burma
China	India
Indonesia	Iran
Iraq	Japan
Korea	New Zealand
Pakistan	Phillipines
U.S.S.R.	

The so-called metabentonites are reported in many formations of Paleozoic age. In general, these materials are composed of illite-smectite mixed-layer minerals, so that the material does not have the physical properties of a bentonite. These have been looked upon essentially as altered volcanic ash to which potassium has been added later, giving rise to the illite component with the loss of bentonite properties.

In terms of physicochemistry, there are two types of bentonites: sodium and calcium, the most commonly occurring exchangeable cations. The amount of interlayer water absorbed varies according to the type of bentonite, the nature of interlayer cations and the physical conditions. Calcium bentonites usually take up two layers of water molecules in each space, while the amount taken up by sodium compounds is variable and shows a greater swelling capacity.[6,8]

In the United States, the northern (Black Hills-Wyoming area) and the southern (Mississippi-Texas area) bentonites are marked by sodium and calcium varieties, respectively. The former shows a greater degree of swelling and is more desireable for drilling fluids, grouts and sealants. This bimodal compositional pattern is not well-defined in the literature. Three possible explanations exist: (1) the seawaters in which the ash/tuff was deposited and later yielded bentonite were enriched in sodium and calcium that are now reflected in their respective bentonite compositions; (2) the chemical composition of the original ash/tuff was different, which influenced the sodium/calcium contents of the resulting bentonites; and (3) groundwater that percolated downwards carried dissolved calcium. The leaching replacement of some exchangeable sodium by calcium rapidly re-equilibrated under low-grade burial metamorphic conditions, thereby giving rise to the calcium-rich bentonites. A combination of all three of these conditions could also have been operative in bringing about this regional variation in bentonite chemistry.

MINERALOGICAL FEATURES OF BENTONITE

The smectite group of clay minerals forms the major component in bentonite, which has exceptionally high water-absorbing and cation exchange capabilities. This group includes montmorillonite, beidellite, notronite, hectorite, saponite and sauconite. Commonly, bentonite is a mixture of the montmorillonite-beidellite series. The general chemical formula for this group is $(\frac{1}{2} Ca, Na)_{0.7} (Al, Mg, Fe)_4 [(Si, Al)_8 O_{20}]$ $(OH)_4 \cdot nH_2O$ where the composition of montmorillonite is $(Na)_{0.7}$ $(Al_{3.3} Mg_{0.7}) Si_8 O_{20} (OH)_4 \cdot nH_2O$ and that of beidellite is Al_4 $(Si_{7.34} Al_{0.66}) O_{20} (OH)_4 \cdot nH_2O$. They are all "swelling" clays in that they can contain water or organic liquids between their structural layers and all show marked cation exchange properties.[4,5]

The crystal structure of smectites consists of superimposed layers, each of which contains a plane of Al ions sandwiched between two inward-pointing sheets of linked SiO_4 tetrahedra.[6] Therefore, the two silica sheets and one alumina sheet are also called a 2:1 mineral (Fig. 1). The octahedral sheet is between the two inward-pointing sheets of silica tetrahedron sheets, with the tips of the tetrahedrons combining with the hydroxyls of the octahedral sheet to form a single layer (Fig. 2).

The thickness of each 2:1 layer is approximately 0.96 nm. Because the bonding by van der Waal's forces between the tops of the silica sheet is weak and there is a net negative charge deficiency in the octahedral sheet, water and exchangeable ions can enter and separate the layers.[7]
Figure 1
Schematic diagram of the structure of montmorillonite[9]
Figure 2
Atomic structure of montmorillonite[10]

As seen under the microscope, smectites occur in fine-grained aggregates that may be dendritic, lamellar or spherulitic. Refractive indices increase with loss of interlayer water. In general, optical methods alone are not reliable for the identification of smectites, and it is usually necessary to observe other properties, such as differential thermal analysis curves, dehydration curves, x-ray powder patterns, electron microscopy and atomic absorption spectroscopy. Free silica minerals, such as cristobalite and tridymite, are important components of some bentonites. Quartz, feldspars, kaolinite, mica, illite, gypsum, calcite and accessories (heavy minerals) are the minor components in bentonites. Zeolites are rare. Zircon, magnetite, apatite, magnesite and pyroxenes also have been reported.[2]

GEOLOGIC ORIGIN OF BENTONITES

The origins of all documented bentonites fall into four categories: (1) hydrothermal alteration, in which hot aqueous solutions of magmatic origin generate a zonal distribution of alteration products, including clay minerals; (2) deuteric alteration in which changes take place in an igneous rock through the reaction of the vapors and gases included within the igneous mass; (3) miscellaneous origins that include weathering and groundwater reaction; and (4) in situ alteration of volcanic ash/tuff. This last category is the most common origin of commercial bentonite deposits and is described in more detail in the next section.

In the in situ process, devitrification of ash is the basic alteration process accompanied by hydration and crystallization of smectite around multiple nuclei. Also, some beds underlying bentonite horizons have been found silicified, indicating a downward migration of silica. With a few exceptions, the devitrification process is generally believed to have taken place underwater and not by superficial weathering. The ash/tuff-to-smectite alteration process probably occurred at the same time as the accumulation of the igneous material and after the formation of smectite, very little further alteration took place. Oxygen-isotope work carried out by Henderson et al.[11] has shown that smectite was formed at approximately 25° C.

The geologic process is established by the presence of microscopic shards and other relict volcanic structures, the character of nonclay minerals and, less commonly, the transitions to associated units of ash or tuff. This transitional contact, in conjunction with high concentrations of clay minerals and the absence of detrital minerals, shows that the alteration took place in situ. The wide range of associated sedimentary rocks indicates that the environments in which the alteration took place also varied widely. These environments range from shallow marine and fresh water to desert conditions. Most bentonites have formed from volcanic ash of dacitic to rhyolitic composition.

USE OF BENTONITE IN THE PETROLEUM INDUSTRY

Bentonite clay is the primary material used in mud rotary drilling, which is a preferred oil well drilling method due to its ability to complete the most feet of hole per hour in a wide range of geologic formations. The goal of oil well drilling is to complete an oil producing well as cost-effectively as possible. A comparison of the efficiency of drilling methods (cable tool, mud-rotary and air hammer) for different geologic formations is given in Figure 3. In the past, little concern was given to the environmental effects of drilling fluids and other materials used during well completion. Much of the current drilling technology and terminology used in today's environmental investigations was developed in the oil industry.

A typical mud rotary system is shown in Figure 4. Bentonite clay and water are used as the primary drilling fluid in the system.

Bentonite clays have been widely used in the oil well industry as a drilling mud since the early 1900s. The unique chemical composition and physical properties inherent to bentonite make it an ideal natural drilling fluid. When mixed properly with fresh water, a bentonite slurry will maintain borehole integrity, reduce fluid loss, reduce bit wear and suspend and lift cuttings from the borehole. Additives can be mixed with the slurry to enhance drilling fluid performance. A list of typical oil well drilling additives is given in Table 2. However, some of these additives can cause an impact on groundwater quality and are known to have adverse toxicological effects.

TERMINOLOGY

The American Petroleum Institute developed specifications and terminology for the methods and materials (including bentonite drilling fluids) used for oil well drilling. Much of this technology has been applied to the environmental industry. However, the terminology has not been updated or modified to reflect changes in applications. The following terms pertain to bentonite and are defined for accurate understanding.

- **Slurry** - A generic term that describes any suspension of bentonite clay and water.
- **Drilling Fluid** - A circulating fluid used in rotary drilling to perform various functions required in the drilling operation. The dry material (typically sodium bentonite) must be free of additives or ingredients that will adversely impact groundwater quality.
- **High Solids Clay Grout** - A mixture of sodium and calcium bentonite clays that, when mixed with fresh water, will form a slurry with a minimum 20 percent solids and a minimum mud weight of 9.5 lbs/gal. The material will remain pumpable during placement and, when set, will have a minimum permeability value of 1 x 10^{-7} cm/sec.

Table 3
Physical Properties Versus Applications of Bentonite

	High solids clay grout		Drilling fluid	
Montmorillonite Content	X	85% - 90%	X	85% - 90%
Fluid Loss Control	O		X	<15 ml. maximum
Barrel Yield	O		X	90 - 200 bbl yield
Gel Strength	O		X	PV/YP maximum of 3
Permeability	X	1 x 10^{-7} to 1 x 10^{-8} cm/sec	O	
Solids Content	X	20% - 30% solids	O	2% - 6% solids
Mud Weight	X	9.5 - 10.0 lbs./gal.	X	8.7 - 9.2 lbs./gal.
Viscosity	O		X	> 30 cps. @ 600 rpm Fann

To fully understand the difference between a bentonite drilling fluid and a bentonite high solids grout, the properties that are specific to each mixture must be understood. The properties and values significant to drilling fluids and high solids clay grout are presented in Table 3. Definitions for properties specific to the different applications of bentonite are provided below.

- **Montmorillonite Content** - Refers to the chemical purity or the percent of active ingredients in the clay. This property is presented in percent of montmorillonite. The remaining portion of materials present is usually comprised of feldspar or silica sand.
- **Fluid Loss** - Refers to the relative amount of fluid lost (filtrate) through permeable formations or membranes when the drilling fluid is subjected to a pressure differential. This property is very important to a drilling fluid and is of less importance to a grout. Drilling fluids are designed to maintain borehole integrity by maintaining a wall cake of bentonite on the borehole so that hydrostatic pressure can be maintained.
- **Barrel Yield** - A term used to define the quality of a clay by describing the number of barrels of a given viscosity (centipoise) slurry that can be made from one ton of the clay. Bentonite clays are classified as high yield (200 bbl) or low yield (90 bbl) clays. Yield is an important factor when choosing a drilling fluid.
- **Gel Strength** - The ability or the measure of the ability of a colloid to form gels. Gel strength is a pressure unit usually reported in lb/100 ft^2. It is a measure of the same inter-particle forces of a fluid as determined by the yield point, but gel strength is measured under static conditions, yield point under dynamic conditions.
- **Thixotropy** - The ability of fluid to develop gel strength with time. It is a property that causes a build up of a rigid or semirigid gel structure if allowed to stand at rest and can be returned to a fluid state by mechanical agitation. This change is reversible.
- **Plastic Viscosity (PV)** - A measure of the internal resistance to fluid flow attributable to the amount, type and size of solids present in a given fluid. It is expressed as the number of dynes/cm^2 of tangential shearing force in excess of the Bingham yield value that will induce a unit rate of shear. This value, expressed in centipoises, is proportional to the slope of the consistency curve determined in the region of laminar flow for materials obeying Bingham's Law of Plastic Flow. When using the direct-indicating viscometer, the plastic viscosity is found by subtracting the 300-rpm reading from the 600-rpm reading.
- **Yield Point (YP)** - The yield point (also called yield value) is the resistance to initial flow, or the stress required to start fluid movement. This resistance is due to electrical charges located on or near the surfaces of the particles. The values of the yield point and thixotropy are measurements of the same fluid properties under dynamic and static states, respectively. The Bingham yield value, reported in lb/100 ft^2, is determined by the direct-indicating viscometer by subtracting the plastic viscosity from the 300-rpm reading.
- **Permeability (Hydraulic Conductivity)** - A coefficient of proportionality describing the rate at which water can move through a permeable medium.[14] The density and kinematic viscosity of the water must be considered in determining the hydraulic conductivity. Typically it is expressed in cm/sec, ft/day or gal/day/ft^2.
- **Solids Content** - The total amount of solids in a drilling fluid as determined by an evaporation process that includes determination of both the dissolved and the suspended or undissolved solids. The suspended-solids content may be a combination of high and low specific gravity solids and native or commercial solids. Examples of dissolved solids are the soluble salts or sodium, calcium and magnesium. Suspended solids make up the wall cake; dissolved solids remain in the filtrate. The total suspended and dissolved solids contents are commonly expressed as percent by volume.

Percent solids in a mixture can be calculated using the following formula:

$$\frac{\text{Weight of material (lb)}}{\text{Weight of material (lb)} + \text{weight of water (lb)}} \times 100 = \% \text{ solids} \qquad (1)$$

Application	Composition	Trade Name
Alkalinity or pH Control	Calcium Chloride Potassium hydrate Sodium hydroxide Hydrated lime Organic-silicate comp.	Caustic Potash Caustic Soda Lime Synergic
Bactericides	Biocide Biocide Paraformaldehyde	Aldecide Surflo-B19, 33 Various

USE OF BENTONITE IN MONITORING WELL CONSTRUCTION

A monitoring well measures the physical and chemical properties of ambient groundwater without adversely affecting its quality. The cleanliness of well construction and the collection of meaningful data are the goal of a properly installed monitoring well.

Among various available drilling methods, hollow stem augers are preferred for well installation. The advantages of hollow stem augers include drilling without fluids, installing wells within a temporary casing and obtaining accurate soil samples. The disadvantages of using hollow stem augers are that they are limited in depth capabilities and cannot be used in consolidated formations. A diagram of a typical hollow stem auger system is shown in Figure 5.

Bentonite clays are used extensively in the construction of monitoring wells. A typical well construction diagram showing the different applications of bentonite in a monitoring well is found in Figure 6.

Bentonites currently have two distinct purposes in the role of monitoring well construction: (1) to provide a low permeable seal (permeability values will range from 1×10^{-7} to 1×10^{-9} cm/sec for a bentonite grout) that will not adversely affect ambient groundwater quality and prevent the mixing and migration of interaquifer and surface fluids;[14] and (2) to create a drilling fluid that will not adversely impact ground-water quality, lubricate the bit, provide borehole stability, lift cuttings, reduce fluid loss and provide a filter cake during mud rotary drilling.[15-17]

Bentonite clays in a dry tablet form are placed on top of the filter pack to provide a seal so that water samples can be extracted from a discrete zone in the formation and to control the migration of overlying grouts into the filter pack.

Bentonite in powdered form is mixed with fresh water to form a high solids clay grout. This mixture can be used to fill boreholes for abandonment or seal the annular space overlying the filter pack between the casing and formation in a monitoring well. When augers cannot be used, monitoring wells are often drilled using the mud rotary method. Powdered bentonite (without any polymers or additives) is added to fresh water to form a natural drilling mud. Powdered bentonite can also

be added to cement to form a cement bentonite grout. This mixture is also used to fill boreholes and the annular space of wells. Although this method is widely used, it has recently been questioned because of the following disadvantages:[16,17]

- Excessive heat of hydration during curing
- High pH values and questionable levels of trace heavy metals
- Excessive loss to formation
- Permeability values greater than the formation
- Cracking and shrinking
- Incompatibility of the cement and bentonite

In the past, bentonite has been misused due to a lack of accurate terminology, education about its use, competitive pricing and product variety. Slurries of bentonite and water that resemble drilling fluids have been misused to abandon boreholes and seal casings. Due to the low solids content of these mixtures, the bentonite could separate and settle out, leaving an inadequate borehole seal.
Figure 5
A hollow-stem continuous flight auger bores into soft soils carrying the cuttings upward along the flights. When the desired depth is reached, the plug is removed from the bit and withdrawn from inside the hollow stem. A well point (1/4 inch or 2 inches) can then be inserted to the bottom of the hollow stem and the auger pulled out leaving the small diameter monitoring well in place

- **Mud Weight** - Refers to the density of the slurry. This measurement is normally expressed in either lb/gal or lb/ft^3.

Mud weight of a slurry can be calculated using the following formula:

$$\frac{\text{Weight of Bentonite (lb)} + \text{Weight of Water (lb)}}{\text{yield (gal)}} = \text{mud weight lb/gal} \qquad (2)$$

- **Viscosity** - The internal resistance offered by a fluid to flow. This phenomenon is attributable to the attractions between molecules of a liquid and is a measure of the combined effects of adhesion and cohesion to the effects of suspended particles and the liquid environment. The greater this resistance, the greater the viscosity. Viscosity can be reported in centipoise when measured on a viscometer or in seconds when measured on a marsh funnel.

High Solids Clay Grouts

High solids clay grouts were first used in the mid-1980s as a substitute for cement in the annular space of monitoring wells. The ease of mixing the clay grouts, pumpability, low permeability values, no heat of hydration during curing, neutral pH and plasticity make them highly desirable. Properties that are important for distinguishing a grout from a drilling fluid are:

- **Permeability** — Values should range between 1×10^{-7} to 1×10^{-9} cm/sec and should be lower than those of the surrounding formation.
- **Solids Content** — Values should range between 20 to 30% solids by weight of water.
- **Mud Weight** — Values should range between 9.5 to 10.0 lb/gal and are directly proportional to the solids content. As solids increase, so does the mud weight.
- **Chemical Purity** — The mix should be free of polymers or additives that will adversely affect groundwater quality.

CONCLUSIONS

Bentonite occurs on all continents in the deposits of Cretaceous to Recent age. It is made up chiefly of the clay mineral montmorillonite, which gives it many useful physico-chemical properties. The chemical purity of this naturally occurring mineral with high swell capacity and plasticity, adsorptive and absorption properties and low permeability, allows for many uses in the environmental industry. This paper explored the use of bentonite as a drilling fluid, a high solids grout and as a sealant.

Sodium bentonite also can be used as an admixture with native soils to construct low-permeability liners, cutoff walls and caps for waste impoundments, landfills and contaminated sites. The latest development in containment is the thin geotextile-bentonite mat, which has seepage control characteristics equivalent to several feet of low-permeability soils.

To differentiate the application and type of bentonite needed, one must be familiar with its properties, relevant terminologies and product use. We hope the supplied definitions will help minimize the misuse of bentonite and allow the installation of monitoring wells that yield meaningful data.

Identification of Previously Unrecognized Waste Pits Using Ground Penetrating Radar and Historical Aerial Photography

Ira S. Merin, CPG
Radian Corporation
Herndon, Virginia

ABSTRACT

To investigate whether wastes were buried in a portion of the property of a manufacturing facility located in the Mid-Continent, an investigation was conducted using ground penetrating radar (GPR) and historical aerial photographs. Analysis of historical aerial photographs provided information on previous patterns of land use and on changes in topography over time. Acquisition and analysis of GPR data confirmed the presence of subsurface disturbances and thus permitted identification of no longer existing or only partially existing topographic depressions, indicative of pits that are believed to have been used for waste disposal.

Four anomalous topographic depressions, clearly visible on aerial photographs acquired in 1966, 1967 and 1972, are only partly apparent on 1980 and 1985 aerial photographs. This finding indicates that these depressions were partially or completely filled and wastes may have been buried on the property. The aerial photographs do not have sufficient resolution to reveal whether debris was contained within the topographical depressions. However, the photographs did reveal that the depressions were devoid of vegetation and had irregular topography that varied for each photo acquisition date, typical of waste pits being filled over time.

Because some of the historical depressions are not apparent now on the land surface, GPR data were obtained along traverses crossing the entire project area. Zones of subsurface disturbance or signal loss, typical of buried waste, were apparent in GPR data obtained at the same locations as those where depressions were apparent on the historical aerial photographs. Thus GPR data provided information, prior to drilling, which confirmed the existence of zones of subsurface disturbance that are believed to mark buried waste. These data delineate partially buried waste pits and also provide a method to identify the optimum drilling locations for investigating potential impacts of buried waste on groundwater.

INTRODUCTION

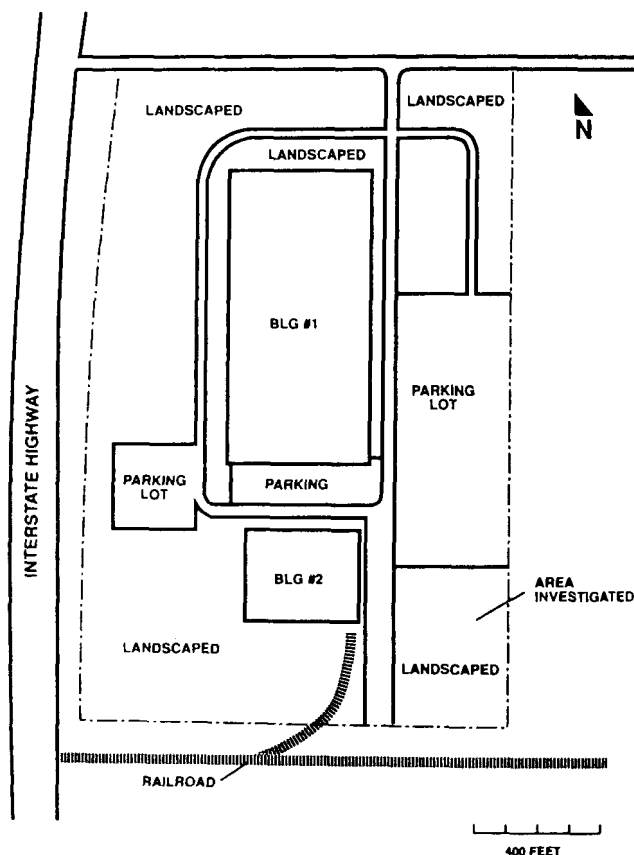
The purpose of this investigation was to discover whether waste was buried in trenches or pits in a portion of the property of a manufacturing facility. The portion of the property investigated is approximately 62,500 square feet in area and is bounded by a chain link fence delineating the southern and eastern property boundaries (Fig. 1). The investigation consisted of four elements: (1) analysis of historical aerial photographs, (2) acquisition and analysis of ground penetrating radar data; (3) field observations; and (4) installation of monitoring wells and collection and analysis of samples of soil and groundwater. Only the first three elements of the investigation are discussed in this paper.


Figure 1
General Layout of Facility Property Showing
the Specific Area Investigated

ANALYSIS OF AERIAL PHOTOGRAPHS

Stereoscopic pairs of black and white aerial photographs obtained from the State Department of Transportation were analyzed to identify previous patterns of land use and to characterize changes in topography over time. The dates of the aerial photographs used are April 1950, November 1955, May 1961, March 1966, April 1967, April 1972, May 1981 and September 1985. The scales of the photographs range from 1 inch equals 2,000 feet to 1 inch equals 400 feet. Photographs from different dates were compared to establish a chronology of land use

and topographic patterns in the area investigated. This chronology is summarized below.

The portion of the property investigated is clearly visible in the aerial photographs as relatively flat, largely grass-covered undeveloped land. The 1966, 1967 and 1972 photographs reveal several small topographic depressions that are slightly different in appearance, shape and size on each of these photographs, indicating that the morphology of these features changed between 1966 and 1972 (Figs. 2c and 2d). These depressions are light-colored, irregularly shaped with sharply defined edges and devoid of vegetation. Some depressions have angular boundaries and appear similar to excavated pits that are dry. Others have slightly rounded boundaries, similar in appearance to partially liquid-filled pits. The topographic depressions range in size from approximately 20 by 30 feet to 30 by 100+ feet. These depressions appear in the 1981 photographs (Fig. 2b) as water-filled ponds and in the 1985 photographs (Fig. 2a) as a flat-lying, partially grass covered area, with a few large deciduous trees.

Dirt roads are visible on the 1966, 1967 and 1972 photographs (Figs. 2c and 2d). One road passes to the south from the parking lot and splits into two roads, with each road terminating at a specific depression. Another dirt road circles the entire area. The presence of these roads indicates that vehicular access to these depressions was maintained.

Although the aerial photographs were not of sufficient resolution to reveal whether debris was within the depressions, the photos did reveal that the depressions had features typical of waste pits. The areas identified in earlier photographs as depressions are clearly visible in earlier photographs as flat lying land, indicating that the former depressions were subsequently filled in. Additionally, the depressions were devoid of vegetation, their internal topography and shape were different in each the aerial photograph and they were connected by dirt roads to each other and to the main facility.

FIELD OBSERVATIONS

Field reconnaissance was performed to help characterize nature of
Figure 2
Land Use Patterns Interpreted from
Historical Aerial Photographs

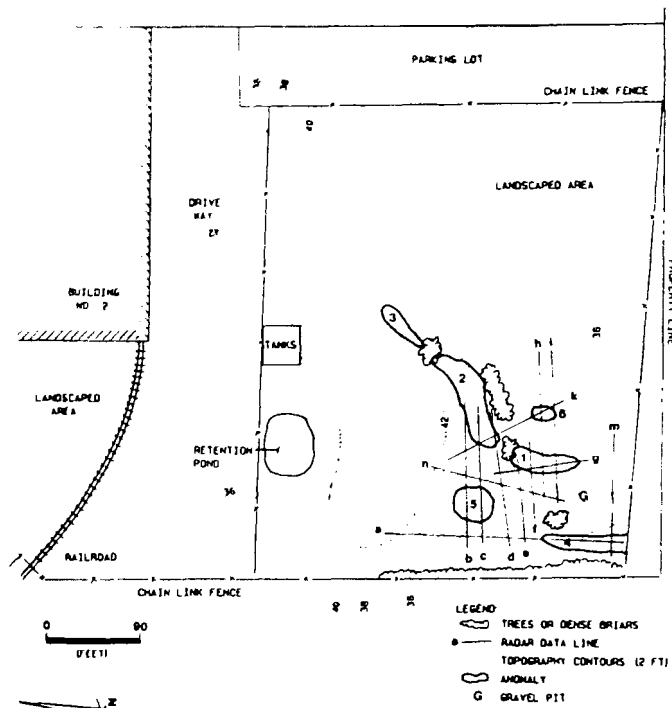
the features observed on the aerial photographs. Portions of three of the topographic depressions identified on the 1966, 1967 and 1972 aerial photographs were located by field observations. These features are labeled "1, 2 and 3" on Figure 3. Portions of one feature identified on the 1972 aerial photographs also were located by field observations and are labeled "4" on Figure 3.


Figure 3
Area Investigated Showing Topography,
Radar Data Lines, and Anomalies

Features 1, 2 and 3 are curvi-linear topographic depressions with less than 2 feet of relief. These depressions range between 0.5 and 2 feet deep, have relatively flat bottoms covered with mud and leaves and act to collect surface water run-off. Feature 1 and the southeastern portion of Feature 2 are devoid of the grass that grows in the adjacent flat terrain. Most of the large deciduous trees in the portion of the property investigated are located along the edges of these depressions. A gravel pile covers the southeastern portion of Feature 1. The northern portion of Feature 2 and most of Feature 3 are covered by debris consisting of broken blocks of concrete, pieces of metal pipes and bricks.

Feature 4 is located in the southeast corner of the area investigated. This feature is as flat as the surrounding terrain; however, it has only sparse grass cover and is partially marked by a rust colored, hard, cinder-like, gravel-size material covering the ground surface. A dense growth of briars covers the northern and southern portions of Feature 4 and a gravel pile covers part of the northern portion, obscuring the locations of the northern and southern edges.

GROUND PENETRATING RADAR

Background

Ground penetrating radar (GPR) is a geophysical investigation technique that provides data which are used to characterize the subsurface without disturbing the ground. This GPR investigation was performed to help assess the nature of the depressions observed on the historical aerial photographs. Because some of the depressions observed on these photographs were partially apparent or not apparent at present-day land surface, the GPR data was obtained in a grid pattern that traversed the entire project area.

GPR is a device that transmits a pulse of radio frequency electromagnetic energy into the ground, records the radio frequency

response of the subsurface and displays this response on paper as a graphic record. The propagation of radio wave energy into the subsurface is governed by the electrical properties of the subsurface. When the radio frequency energy encounters a variation in the electrical properties of the subsurface, a portion of the energy is reflected back up toward the ground surface while the remaining energy continues to propagate downward. The radar response printed on the graphic record is a function of the amount of time required for the radio energy to propagate from the radar antenna into the ground, to reflect off of an interface between two subsurface layers of different electrical properties and to propagate back up toward the radar antenna.[1]

The pulse of radar energy transmitted by the radar antenna interacts with subsurface interfaces and is recorded several nanoseconds (ns: 10^{-9} seconds) later by either the same antenna (in a monostatic radar system) or by a different antenna (in a bistatic system). The intensity of the radar signal recorded by the antenna and displayed on the graphic record increases as the difference in electrical conductivity between adjacent layers increases. Any pulse of energy detected by the antenna in excess of a threshold value is displayed by the graphic recorder as a shaded spot on the graphic record. Interfaces between subsurface layers detected by the radar signal are represented on the radar graphic record by two to four black lines (Fig. 4).[1] Therefore, GPR can be used to produce an approximation of a subsurface cross-section showing layers that have different electrical conductivity.
Figure 4
Example of a Single Radar Waveform 'and
Resulting Graphic Record
(from Geophysical Survey System, Inc.)

The horizontal scale of the radar graphic record is governed by the rate the antenna moves across the ground surface and by the rate at which paper feeds through the graphic recorder. Typical rates for moving the antenna across the ground surface range between 1/2 and 2 miles per hour.[2] Vertical lines (markers) placed on the graphic record that correspond to survey flags located at regular intervals along the line of traverse can be used to indicate the distance traversed.

The vertical scale of the graphic record is a function of the amount of time required for the radar signal to propagate from the antenna through the subsurface and then back to the antenna. This is known as "two-way travel time" and is a function of the velocity that radar

energy propagates through a medium; the travel time is governed by the electrical conductivity of that medium.[1] The velocity (V) of radar energy through a medium is related to the velocity of light (C) by a constant termed the dielectric permittivity (Er) through the following:

$$Er = \frac{C^2}{V^2} \qquad (1)$$

because C = 1 ft/ns

$$Er = \frac{1}{V^2} \qquad (2)$$

where V is ft/ns

Radar energy velocity (V) is related to two-way travel time (t) and the distance (D) traveled by:

$$V = \frac{2D}{t} \qquad (3)$$

Therefore, when the dielectric permittivity is known, the effective propagation velocity is:

$$V = \frac{C}{(Er)^{-2}} \qquad (4)$$

where C = 1 ft/ns

and the depth (in feet) to any radar interface is:

$$D = \frac{Vt}{2} \qquad (5)$$

The radar data are displayed on the graphic record in nanoseconds (ns) of two-way travel time. The maximum two-way travel time recorded is established manually on the radar unit by setting the range dial to a specific range. Ten equally spaced horizontal lines are printed on the graphic record and can be used as a vertical scale in nanoseconds of two-way travel time. Thus, the depth to any radar interface displayed on the graphic record can be calculated by picking the travel time where the radar event occurs and substituting this value for t in the above equation.

The value for radar velocity (V) used will depend on the dielectric permittivity (Er) of the material that the radar propagated through. Values of dielectric permittivity (dielectric constant) tabulated from Morey[1] and radar velocity calculated using the above formula are shown in Table 1.

Table 1
Approximate Conductivities, Dielectric Constants and Radar Velocities for Various Earth Materials

Material	Approximate Conductivity (mho/m)	Approximate Dielectric Constant	Two-Way Interval Time (ns/ft)	Velocity (ft/ns)
Air	0	1	2	1
Fresh Water	10^{-4} to 3×10^{-2}	81	18	0.11
Fresh Water Ice	10^{-4} to 10^{-2}	4	4	0.50
Permafrost	10^{-5} to 10^{-2}	4 to 11	4-5	0.50-0.45
Granite	10^{-6} to 10^{-3}	5.6 to 8	5-6	0.42-0.35
Dry Sand	10^{-7} to 10^{-3}	4 to 6	4-5	0.50-0.41
Sand, Saturated (Fresh Water)	10^{-4} to 10^{-2}	30	11	0.18
Silt, Saturated (Fresh Water)	10^{-3} to 10^{-2}	10	6	0.32
Clay, Saturated (Fresh Water)	10^{-1} to 1	8 to 25	6-10	0.35-0.20
Average "Dirt"	10^{-4} to 10^{-2}	16	8-10	0.25-0.20

Approximate values for conductivity and dielectric constant are tabulated from Morey (1974) and two way interval time from Benson et al (1982). The values for velocity are calculated from the formula V = 1/(Er)$^{-2}$ as discussed in the text. Two way interval time is defined in ns/ft as twice the reciprocal of radar velocity. It is used for convenient calculations of depth to a radar interface: divide the travel time of a radar interface picked from the graphic recorder by the medium's two-way interval time.

For convenience of field calculations, some workers[2] use a parameter called two-way interval time (Table 1), which is defined in ns/ft as two times the reciprocal of velocity. Hence the depth (in feet) of a radar interface is calculated by dividing the two-way travel time picked from the graphic record by the two-way interval time of a given material. However, if the mineral composition or the moisture content of the subsurface changes with depth, then the velocity is not constant with depth and the vertical depth scale is not uniform.

The depth of penetration of the radar signal is inversely related to the radar frequency and to the conductivity of the ground surface. Conductivity is directly related to groundwater salinity and to the amount of clay minerals present in the subsurface. Penetration depths typically range between a few feet and tens of feet, unless the subsurface is nearly devoid of clay minerals. However, examples of penetration depths of more than 75 feet have been reported in areas where the subsurface consists exclusively of sand and gravel.[3,4]

Methods

A Geophysical Survey Systems, Inc. SIR System 3 Ground Penetrating Radar (GPR) unit was used with a single 80 megahertz antenna. The antenna was connected to the radar unit by 100 feet of electric cable and the unit was powered by a standard car battery. The radar unit was operated with print polarity set to +/−; paper take-up set to off; paper speed set to 200 lines per inch; radar antenna scans set to 16 scans per second; surface gain set to 3.3; mid-depth gain set to 2.2; deep gain set to 3.5; and range set to either 100 or 50 ns

Before obtaining radar data, the position of each line along which data were to be obtained was accurately identified in the field and its position placed on the field map. Additionally, survey flags were placed every ten feet along each line. Figure 3 shows the locations of the data lines. Because of the rough terrain and the debris in Feature 3 and in the northern end of Feature 2, radar data could not be obtained in these areas.

Radar data were acquired by rolling the radar antenna at a constant rate along the ground following the predetermined lines. Registration marks were placed on the graphic record (vertical dashed lines on Figures 5 and 6) to denote the location of the antenna as it was rolled past each of the flags along the data lines. These registration marks provide a horizontal scale on the graphic record of the radar data.

Based on examination of the published geological map[5] of the area and on observations made in the field, we concluded that the subsurface is predominately composed of clay with minor amounts of silt and sand. Such material typically has a radar velocity of approximately 0.20 ft/ns[1] or a two-way interval time of approximately 10 ns/ft.[2] If we assume that the subsurface has relatively uniform electrical properties to the depth of radar penetration for the radar range used, then the vertical scale for the radar graphic records obtained for data acquired with range set to 100 ns is approximately 1 foot per each horizontal calibration line and the vertical scale for the data acquired with the range set to 50 ns is approximately 0.5 feet per each calibration line. Thus, the radar data acquired when the range was set to 100 ns were from a maximum depth of approximately 10 feet, and data for the 50 ns range was from a maximum depth of approximately five feet.

A preliminary interpretation of the radar graphic record was made in the field immediately after acquisition of radar data from each line. Annotations were made directly on the graphic record. This preliminary interpretation permitted making initial judgments on data quality and on where additional data might be needed to better define features detected by the radar.

Interpretation

The radar data were interpreted for the presence of zones of subsurface disturbance and zones of signal loss (Figs. 5 and 6). Zones of subsurface disturbance are recognized by the sudden irregular disruption of the uniformly horizontal bedding pattern present in undisturbed layers. These zones may mark areas that have been disrupted by man-induced processes such as digging. Zones of signal loss are recognized by large white areas on the graphic record. Signal loss can appear in a radar

graphic record if two laterally adjacent subsurface areas have very different electrical conductivities, which causes the radar velocity to be very different in each of the adjacent areas of the subsurface. Man-induced processes (e.g., digging followed by filling) that result in placing materials of substantially different conductivities adjacent to one another in the subsurface may result in signal loss.
Figure 5
Radar Graphic Record Crossing Feature #1. The Distance Traveled Along the Traverse is Posted in Intervals of 10 Feet. Data was Collected Using an 80 Megahertz Antenna with the Range Set at 100 ns. Note the Loss of the Signal Between Approximately 26 and 50 Feet Along the Traverse.

Three Features (Features 1, 2 and 4 in Figure 3) identified on the 1966, 1967 and 1972 aerial photographs and during the field reconnaissance as areas of concern each show evidence of subsurface disturbance and signal loss on the radar graphic records. Two additional areas (Features 5 and 6 in Figure 3) show evidence of subsurface disturbance on the radar graphic records. Features 5 and 6 lack any obvious surface indications.

Features 1 and 2 are visible on the 1966, 1967 and 1972 aerial photographs as depressions and are partially marked on current ground surface by a lack of grass. Feature 1 appears in radar data lines E, F, G, H and I as a zone of signal loss occurring at the same location where the ground surface is devoid of grass cover. Figure 5 is a portion of radar data line F showing such a signal loss. Assuming a radar velocity of 0.20 ft/ns for the subsurface material at this location, the zone of

signal loss extends to approximately between 3 and 5 feet below the ground surface.
Figure 6
Radar Graphic Record Crossing Feature #4. The Distance Traveled Along the Traverse is Posted in Intervals of 10 Feet. Data was Collected Using an 80 Megahertz Antenna with the Range Set at 100 ns. A Subsurface Disturbance Occurs Between Approximately 40 and 85 Feet Along the Data Line. The Subsurface is Apparently Evenly Bedded Between Approximately 85 and 180 Feet. The Gentle Upward Slope of the Ground Surface Toward the West Creates a Dip in the Radar Data from Approximately 130 Feet West Continuing Toward 180 Feet Along the Traverse.

Feature 4 is visible in the 1972 aerial photographs as a depression and is partially marked at the present-day ground surface by the presence of a rust-colored material. This feature appears clearly in radar data line A (Fig. 6) as a subsurface disturbed zone extending approximately 85 feet west from the chain link fence near the eastern property boundary. The rust-colored material at the land surface extends approximately 70 feet west of the chain link fence. Thus, based on the radar data, Feature 4 extends approximately 15 feet further to the west in the subsurface than is apparent by surficial observations. Assuming a radar velocity of 0.20 ft/ns for the subsurface material at this location, the zone of subsurface disturbance extends to at least 4 feet in depth.

Features 5 and 6 are marked by a slight subsurface disturbance on data lines B and C, and K and H. These features are not visible on the historical aerial photographs and they have no distinguishing surface characteristics. This slight subsurface disturbance is of concern because it has the same character as the subsurface disturbance apparent on the radar data lines that cross historical topographic depressions (e.g., Features 1 and 4).

CONCLUSIONS

Six features were identified on historical aerial photographs as topographic depressions, similar in character to dug pits. Four of these historical depressions are partially marked on the current surface by slight topographic depressions and/or a partial lack of grass cover. The remaining two features lack any evidence on the current land surface that historical depressions may have been existed. Five of the six historical depressions were located within the area investigated using ground penetrating radar. All of those five features show evidence of subsurface disturbance or signal loss visible on the radar graphic records. Furthermore, the only locations with the area investigated using GPR that show subsurface disturbances or signal loss are the areas where these five historical depressions were located.

Thus, using both historical aerial photographs and ground penetrating radar provided complementary information that permitted identifying pits that may have been used to bury wastes in a portion of this property. The historical aerial photography permitted initial identification of areas of concern as possible waste pits. Acquisition and analysis of GPR data provided confirmation of the presence of subsurface disturbances and thus permitted identification of no longer existing or partially existing topographic depressions that are believed to have been used for waste disposal. These data provided information, prior to drilling, to allow us to delineate (partially) buried pits and provided us a method to identify the optimum (and safe) drilling locations for investigating potential impacts the waste may have on groundwater.

ABSTRACT

The strategy for developing and obtaining U.S. EPA acceptance of a verification sampling program for the identification of the lateral extent of a source area is discussed, along with the problems encountered with the execution of the program at the project site. The sampling program features the use of discrete and composite sampling of excavation faces, along with the development of a grid system for tracking and registering of sample collection grids.

The project site is an active aluminum reduction facility in the western United States. Historical waste management and handling practices resulted in the contamination of surficial sediments and the shallow groundwater horizon. U.S. EPA requirements for the remediation of the site identified soil cleanup criteria and required a sampling and analytical program be established to verify that the remediation criteria were attained. The boundaries of the waste management and handling areas were defined by the location of existing plant structures, surface drainage features and plant boundaries (the historic limits of waste placement). Other factors interacting in the verification sampling program were the rocky fill materials encountered within the sampling areas and the impact of the active plant structures.

The verification sampling program was implemented successfully and identified the need for additional soil removal in selected areas. The verification sampling program successfully identified the horizontal and vertical distribution of contaminants in the shallow soil horizon and provided assurance to the U.S. EPA that the soil remediation activities addressed the lateral extent of waste placement at the site.

INTRODUCTION

A strategy for verification of the historic limits of waste management and handling areas was required such that impacted areas at the site would be isolated and removed for long-term management, in accordance with the recommended alternative presented in the Record of Decision (ROD). In response to the need for verifying the removal of surficial soils impacted by previous waste management and handling practices, a verification sampling program (VSP) was developed, accepted by the U.S. EPA and implemented as an element of the CERCLA Remedial Actions.

The selection and application of verification sampling techniques at the site was facilitated by the identification of several sampling constraints. The location of active plant operating units (structures or capital facilities), the historic location of plant structures defining the limits of waste management and handling, and the confines of the actual plant area were all used to define the scope of the overall approach to implementing the verification sampling program.

BACKGROUND

Geologic Setting

The project site is located adjacent to the Columbia River in northern Oregon and was constructed in the river floodplain. Due to the impoundment of the Columbia in this reach, flooding is no longer a concern in the area. The surface stratigraphy of the site is dominated by deposits of volcanic basalt described as the Columbia River Basalt Group (CRBG). The CRBG, formed from approximately 300 basalt flows that erupted from linear fissures in the Columbia Plateau, and was deposited between approximately 6 and 17 million years ago. The surficial basalt formations in the area of the project site are characterized by undulating and often jagged and angular surface profiles created by environmental conditions during the spreading and cooling of the lava flows and by the process of weathering of the exposed materials. Portions of the basalt rock are present at elevations above the general ground-surface elevation, which is established by the wind-blown sands and sediments which occupy the pockets and crevices of the basalt surface. Based on the results of regional geologic investigations and site-specific hydrogeologic assessments, the upper basalt formations serve as a confining unit, separating surface and subsurface waters from deeper and more transmissive units below. The surficial basalt tended to dip in the direction of the river, and some generalized surface drainage features are present in the area.

Plant Activities

The project site is the location of an operating aluminum reduction facility. The waste byproducts of the aluminum reduction process include spent potlining materials (also referred to as cathode waste), which are the protective lining materials placed between the reduction vessels and molten aluminum. The management of these materials was accomplished by commercial recycling from 1961 to 1971. Potlining waste materials were managed on-site within designated areas between 1971 and 1984.

The aluminum reduction facility uses the Herroult process for the reduction of aluminum oxide to elemental aluminum, which utilizes an anodic/cathodic cell to separate the elemental aluminum and oxygen ions. The magnetic field is established and maintained in the reduction cells with the use of electrical current. The elemental aluminum in the reduction vessels exists in a molten state and is separated from the vessel by lining materials consisting of carbon blocks, refractive bricks and carbon paste, collectively referred to as the potlining. At the end of the useful life of a reduction vessel (when skin temperatures on the vessel indicate that the breakdown of the protective lining is imminent), the vessel is removed from service and dismantled once the spent lining materials have cooled.

Spent potlining materials were managed at the site and contained within designated waste handling and storage areas. The characteristics of the spent potlining materials made them useful as a general fill material. Therefore, as the need for additional work area increased, work areas occasionally were expanded using spent potlining materials.

In 1983, the State of Oregon Department of Environmental Quality listed spent potlining material as a hazardous substance. A waste storage facility was constructed in 1984, and the spent potlining materials previously stockpiled at the site were relocated to this interim status storage facility.

RI/FS Summary

In 1983, the U.S. EPA performed a hazardous ranking of the site after cyanide concentrations above detection limits were detected in one of the plant production wells located adjacent to the spent potlining storage area. In 1985, the principal responsible party entered into a consent order to conduct an Remedial Investigation and Feasibility Study (RI/FS).

A total of 23 individual study areas of the site were included in the scope of the Remedial Investigation (RI) which included the sampling of soil, groundwater, stream sediments and surface waters. In addition, perched water (water trapped on the surface of the basalt rock) was identified beneath four potlining handling and management areas. The perched water was an accumulation of leachate that had been generated from the open storage of spent potlining materials in direct contact with the ground and/or general fill. An electromagnetic survey of the spent potlining handling and storage areas was performed to estimate the volume of perched water estimated that between 0.5 and 2.0 million gallons of perched water were present.

The primary constituents associated with spent potlining materials were polynuclear aromatic hydrocarbons (PAHs), cyanide and fluoride. The sources of the PAHs are the raw carbon materials in the carbon block and pastes used to assemble the cell and reaction of the materials in the reduction environment, while cyanide is created as an undesired product of the reduction of atmospheric nitrogen with carbon dioxide and the carbon blocks. Fluoride is a residual waste from the catalytic agents used in the reduction process.

Applicable or Relevant and Appropriate Requirements (ARARs) were identified during the RI/FS process for fluoride, cyanide and PAHs to determine which study areas were impacted by spent potlining materials handling and management and to provide cleanup criteria. The Risk Assessment (RA) evaluated the three constituents of concern. Cyanide concentrations present within the soil matrix were below the risk threshold value and were not applied as a soil ARAR. There were no discernible risks associated with fluoride in the soil matrix. However, the ARAR for fluoride in the soil matrix was derived utilizing a conservative approach for the protection of groundwater. Urban background concentrations for PAHs were determined to be acceptable soil ARARs. ARARs for cyanide concentrations in surface water were statutory and, based on an EPA health advisory for adults for groundwater, the ARARs for fluoride were statutory for both surface and groundwaters. PAHs were not detected in the surface or groundwaters.

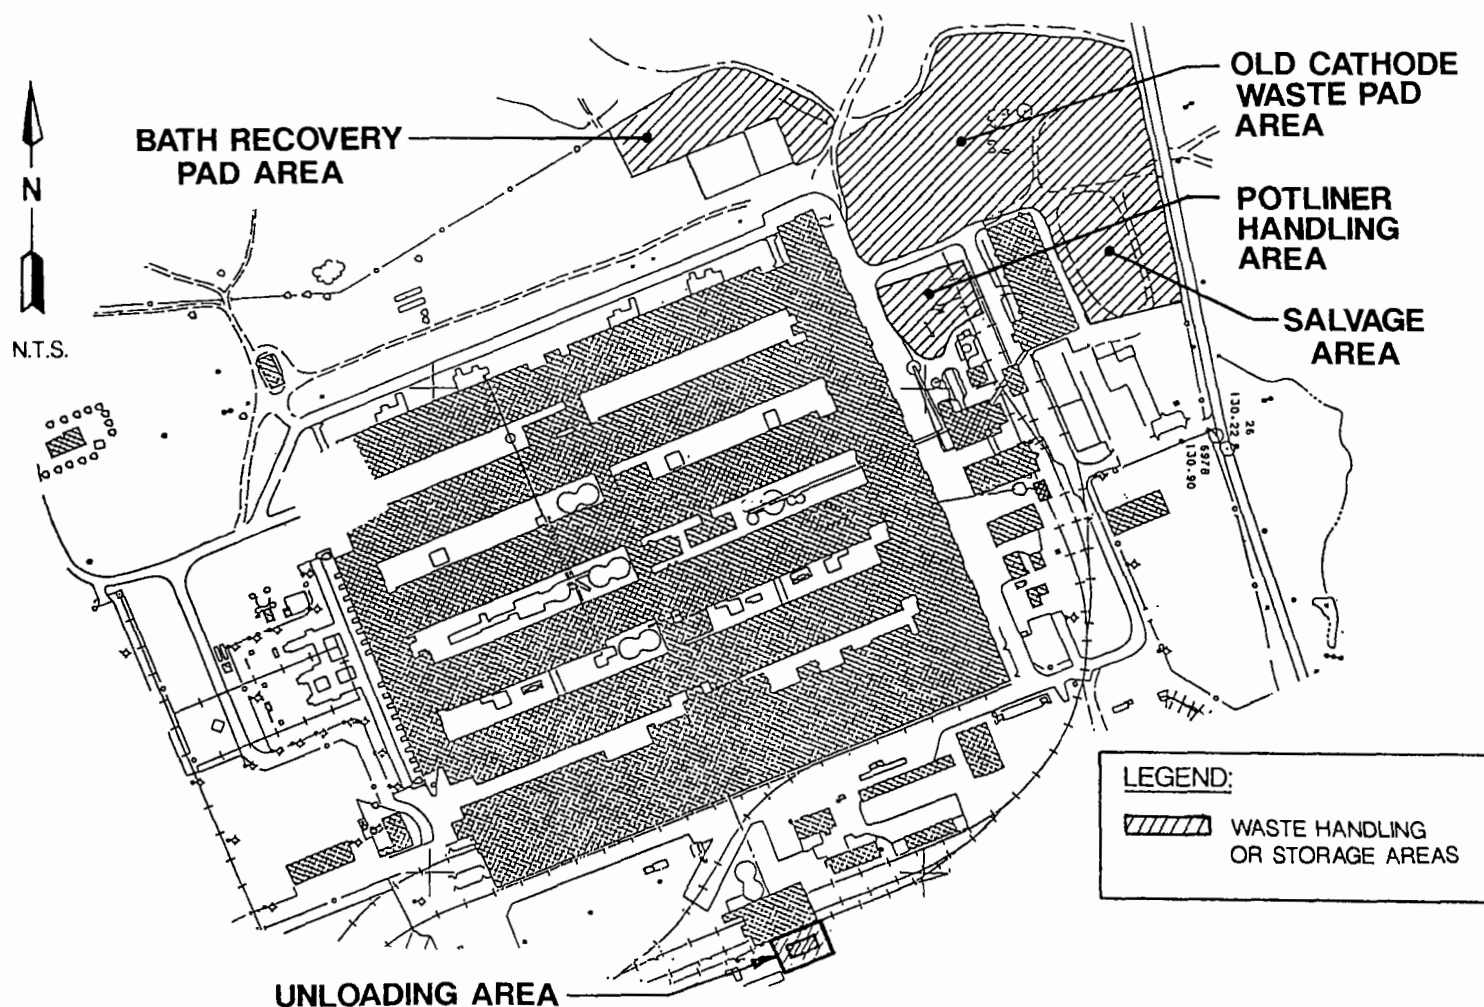
Soil samples taken from the former spent potlining handling and management areas revealed only one study area which exceeded ARARs


Figure 1
Location of Waste Handling and Storage Areas

based on known waste characteristics of spent potlining materials. The perched water exceeded ARARs for cyanide and fluoride when compared to surface and groundwater standards. Since spent potlining materials had been used as general fill in areas where perched water was present, an important strategy was developed to treat the perched water as a source, rather than as a shallow groundwater system. This strategy required the removal of the fill materials and a one time collection and treatment of the perched water. The strategy involved the collection and treatment of a concentrated and potentially mobile source and was determined to be the preferred alternative when compared to other options requiring containment (capping and other source controls) with long-term groundwater management.

DEVELOPMENT OF THE VERIFICATION SAMPLING PROGRAM

The verification sampling program (VSP) was developed based on the analysis of site-specific conditions and the previously-established needs for assurance that the limits of waste placement were determined. The purpose for the VSP was to: (1) establish and document the physical extent of soil and perched water contamination at the site; (2) establish an appropriate methodology for detecting the presence of contaminated materials; and (3) implement the plan, including the contingent measures to be taken in the event that an exceedance of the sampling criteria occurred. The process utilized in the development of the VSP required that the following site data be collected and interpreted in the approximate order as presented in the following items:

- Definition of the historic areas of spent potlining materials placement at the site
- Establishment of verification sampling constituents and the respective concentration limits
- Identification of the vertical and lateral constraints to verification sampling
- Selection of areas for verification sampling
- Detailed analysis of the verification sampling areas
- Selection of an sampling strategy, based on implementability and effectiveness
- Development of sampling procedures and establishment of field procedures
- Establishment of quality assurance protocol

Definition of Historic Areas of Spent Potlining Materials Placement

The areas of the project site in which spent potlining materials handling and storage activities occurred are presented in Figure 1. The principal waste handling and storage area is bounded by plant buildings and access roads, a surface drainage ditch and a county road. The identified Salvage and Bath Recovery Pad Areas both possessed a boundary which could not be accurately defined based on historic data. The Unloading Area is a site area in which waste materials were used as general backfill during the development of a parking and storage area. The intent of the VSP was to provide assurance that these boundaries represented the lateral limits of contamination.

Definition of Sampling Constituents and Sampling Criteria

Two spent potlining material constituents were identified as a primary concern in the verification of soil remediation at the site: fluoride and PAHs. Research into the types of PAHs which were present in the spent potlining materials identified seven individual PAH compounds which were known or believed to exhibit the characteristics of carcinogens in the human body at reference doses and identified periods of exposure. These individual PAH compounds were referred to as carcinogenic PAHs (cPAHs). The verification sampling concentration criteria for these two classes of constituents were developed as Applicable or Relevant and Appropriate Requirements (ARARs) for the site remediation. The verification sampling criteria were:

Fluoride ≤ 2200 mg/kg

cPAHs ≤ 175 mg/kg (cumulative)

Identification of Sampling Constraints

The identification of constraints used to guide the development of

the VSP occurred as a result of the determination of active, operating units of the facility and the evaluation of historic and institutional land uses on the site. Historic waste placement at the project site was defined by the limits of the areas used for spent potliner materials storage. As presented previously in Figure 1, the spent potlining placement areas were bounded substantially by the locations of plant buildings and facilities. The delineation of areas in which perched water contamination was expected (due to perched water travel in the general direction of the Columbia River) identified that the active plant structures were located in areas hydraulically upgradient of the expected direction of travel. The active plant structures and facilities represent significant capital assets of the reduction facility and were a consideration in the definition of excavation and verification sampling limits. Based on these data, the active operating structures were not considered for demolition or for verification sampling.

Figure 1 shows that an eastern boundary of the facility is a county roadway. The historic alignment of the roadway was useful in defining the limits of waste placement at the site. As areas east of the county road were not used for spent potliner materials handling or storage, samples collected and analyzed during the RI verified these areas were not impacted by spent potlining materials or residuals. Selected areas east of the roadway were excavated to determine what, if any, perched water transport may have occurred. The roadway alignment was considered a limit of waste placement for the purposes of waste excavation and verification sampling.

Physical constraints encountered during VSP development included compliance with OSHA excavation requirements and the presence of site utilities in the verification sampling areas. OSHA requirements were observed during the establishment of stable trench-face configurations for the areas. Railroad, electric and potable water utilities were accommodated or relocated during design and implementation of the VSP.

Verification Sampling Areas

In consideration of the identified boundaries established by data generated during the RI and the historic land uses at the site, three verification sampling areas were established. Figure 2 presents the locations of the verification sampling areas proposed to the U.S. EPA for inclusion in the program.

Two separate areal configurations were required to address the needs for verification sampling. The verification sampling areas identified in Figure 2 as the Salvage and Bath Recovery Pad Areas represent a lateral boundary defined by the historic limits of spent potlining materials handling and management. The third verification sampling area, referred to as the Unloading Area, received spent potlining material as general site backfill during expansion of the plant. In order to fully verify the limits of the spent potlining materials placed as general backfill, a boundary completely surrounding the Unloading Area was required.

Sampling Strategy and Quality Control

In developing a program which would achieve the goals of the verification sampling at the site (to provide assurance that any spent potlining materials or residuals would be excavated), be implementable at the site and be practical from a standpoint of providing useful and determinative data, a system of discrete sampling units with supporting quality assurance protocol was established. The process of proposal to and acceptance by the U.S. EPA of strategies for the sampling evaluation involved the combination of several sampling objectives into one cohesive and rational approach. The considerations included in the development of the strategy are identified as follows:

- Definition of sampling cells or units (intended to detect "hot spots" or spikes along the sampling line)
- Selection of sample cell size
- Development of the methodology for collecting and combining samples, based on the results of literature evaluation on the sampling of soil matrices
- Provisions established for the further remedial actions required in response to an identified exceedance

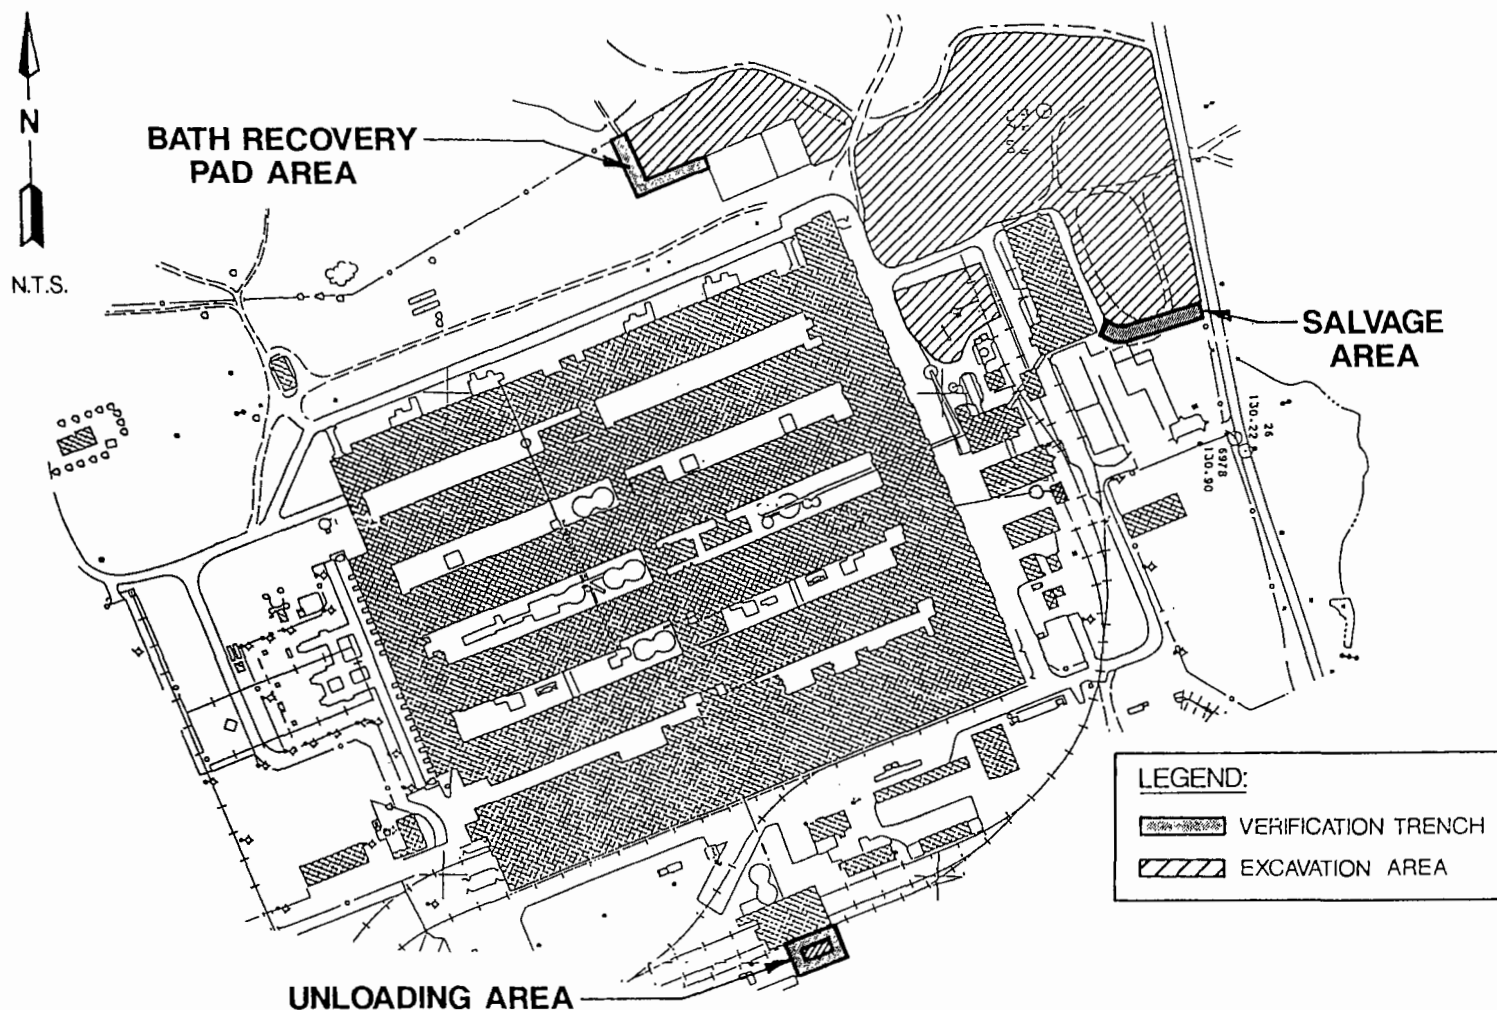
The strategy proposed to the U.S. EPA for the sampling of the soil


Figure 2
Location of Verification Trenches

column left by the removal of material within the excavation areas involved the division of the exposed face into 500-square foot areas. The individual sampling cells were constructed by measuring the distance along the excavation slope from the ground surface to the competent basalt rock and the calculation of the length of the cell by dividing this length by the 500-square foot area.

One of the primary difficulties encountered in the application of basic sampling principles to the soil matrix (consisting of basalt rock, wind-blown sediment and general backfill components such as spent potlining materials and residuals) was understanding the behavior of the contaminants in the soil matrix. Unlike a liquid matrix in which contaminants are customarily diluted by osmosis into an approximately homogenous mixture, contaminants in a soil matrix are customarily bound or associated with discrete soil particles. The importance of this characteristic to the development of the sampling program is that a soil sample may be composited without a substantial dilution effect—a contaminated soil grain selected for analysis in the laboratory will display a high level of contamination regardless of the effects of compositing. Therefore, the use of limited compositing of the collected samples prior to laboratory analysis was accepted by the U.S. EPA.

The identification of an objective and acceptable method for sample collection from an individual cell resulted in a methodology which utilized the discrete sampling of an arbitrary grid system with the use of a random number table. The sampling cell would be divided into 10 equal-sized areas, and four of these areas would be selected with the use of a random number table for sample collection. Once the four samples were obtained, the samples would be mixed completely and quartered in a sampling bowl, with the sample bottle filled from equal

and sequential aliquots from the four quarters.

The acceptance of the sampling strategy was obtained from the U.S. EPA after several modifications were made to the plan. The U.S. EPA required that the sample cell size be reduced from the original 500-square foot to the 200-square foot size, which resulted in a doubling of the number of samples collected. The strategy for sample collection was modified to reflect the U.S. EPA's concern that all four random samples could be located in one area or quadrant of the sampling cell. This concern was resolved by establishing four rectangular sub-cells within each sampling cell and then sampling each sub-cell, with the sub-samples composited to form the sample. This quartering of the sample cell assured that at least one sample would be collected from each quadrant of the cell. The U.S. EPA requested that an individual exceedance of the sampling criteria in any sampling cell would require that the cell be excavated further and resampled. These requests were incorporated into the sampling program.

Selection of Sampling Grids

The sampling grids were completed in accordance with the previously discussed procedures. Each 200-square-foot area was marked by stringing colored tape from the top of the trench to the toe of the slope. The four 50-square-foot areas were then marked using a different color of tape. The locations of each grid were presented previously in the profile figures. The individual sampling locations were selected with the use of a random number table, and each 50-square-foot area was divided vertically in half and subdivided into the 10 equal-sized grids. The length of the trench face at the sampling location was divided into five segments which determined the height of each grid. The individual

grid locations were not physically marked and a tape measure was employed to accurately identify the sampling locations.

VERIFICATION SAMPLING PROGRAM IMPLEMENTATION

The VSP was implemented at the project site over a 6-day period in 1989. Consistent with the health and safety requirements established for the remedial activities at the site, the verification samplers donned Level D protection garments, which provided a fugitive dust mask, exterior coveralls and gloves, in addition to the standard work ensemble of hardhat, steel-toed boots and safety glasses.

Certain constraints were introduced into the sampling program by the operation of the reduction facility and the ongoing remedial activities. The need for minimizing the open-trench time between excavation and sampling was anticipated; the ambient emissions from the reduction facility and the potential for fugitive dust generation from adjacent excavation activities were identified as concerns which could possibly bias sampling results. Modifications made to the program due to site conditions included scraping material from the sampling face prior to collecting the sample and covering sampling equipment until use.

Table 1
Sampling Procedures and Equipment Checklist
Verification Sampling Program

Procedures

1. Excavate verification sampling trenches at a 3:1 side slope unless otherwise directed by Corps of Engineers Construction Representative.

2. Measure depth from top of ground to basalt surface every 10 linear feet along trench length.

3. Starting at one end of the trench and using the data identified in item No. 2, determine the trench length required to obtain 200 square foot areas along the entire trench.

4. Drive stakes (tied with orange tape) at limits of the 200 square foot areas.

5. Divide each 200 square foot area into four 50 square foot areas. Mark these limits with a stake tied with blue tape.

6. Use a tape measure to locate the previously identified, randomly selected, 5 square foot sampling locations within each 50 square foot area.

7. Collect samples from each 50 square foot area.

8. Mix, quarter, and composite sample. Provide label with all pertinent information.

9. Prepare all samples for shipment to pre-selected analytical laboratory.

Equipment

1. Cargo type mini-van for transportation of supplies

2. 400' of plastic sheet (5' wide) in a roll or individual sheets

3. 5 stainless steel (S.S.) spoons
   5 small (1L) S.S. bowls
   5 large (5L) S.S. mixing bowls or pans

4. 100 glass bottles (1L) wide-mouth, with lids as contained in sample packs or coolers provided by the analytical laboratory.

5. Extension ladder (rented)

6. Wooden stakes (600)

7. Flagging tape (orange and blue), or spray paint

8. 100 bottle labels

9. Coolers for shipment

10. Sample boxes (25 minimum)

11. Detergent (Alquinox, Liquinox, or equivalent)

12. Isopropanol (2 gallons)

13. Fed-Ex labels (pre-typed)

Field observations recorded during the excavation and sampling process consist of: (1) field conditions at the time and date of sampling; (2) the status of work activities and other external factors which could affect the sampling results; and (3) the general depth and composition of earth materials encountered in the sampling areas which are described in this section. A sampling equipment and procedures checklist is presented in Table 1.

Salvage Area

Figure 3 presents the location and alignment of the verification sampling trench excavated in the Salvage Area. Figure 4 presents the verification sampling profile view for the Salvage Area. The outside face was excavated to an approximate 1:1 (H:V) side slope, and the interior face was excavated to an approximate 2:1 side slope. Both faces were stable for sampling operations. The average trench depth was 15 feet resulting in an average trench face length of 13 feet. The greatest depth was at Station 1+10 with a trench face length exceeding 18 feet. The excavated material consisted of silt mixed with rock (up to 0.5 cubic yard in size). Excavation of the Salvage Area continued during sampling activities because dust generation was minimal.

Unloading Area

The limits of excavation at the Unloading Area were visually determined due to the lack of precise historical data on the limits of waste placement. The general location is shown on Figure 5, while Figure 6 is the corresponding profile view of the Unloading Area. The presence of spent potlining materials was identified by its grey-black color and the presence of refractory bricks and other potlining debris. Excavation continued until the excavation faces displayed none of these characteristics. The depth to the basalt surface varied from 5.5 to 8 feet and was excavated at an approximate 1:1 slope adjacent to the railroad tracks. An active power pole present in the northwest area of the excavation prevented the complete removal of waste materials in the Unloading Area until it could be relocated.

Bath Recovery Pad Area

The alignment of the trench excavated in the Bath Recovery Pad (BRP) Area is presented in Figure 7 and the profile is presented in Figure 8. The BRP Area trench was shallow, with trench depths ranging from 1 to 6 feet. The material excavated consisted of large rock (over 1 cubic yard in size) mixed with silt and small rock fragments. No remedial activities were occurring in the vicinity of the BRP Area; however, other construction activities conducted by the plant were ongoing approximately 200 feet west of the BRP Area.

RESULTS OF THE VERIFICATION SAMPLING PROGRAM

Table 2 summarizes the analytical results from the verification sampling program. The results listed for the cPAHs are total combined concentrations of the seven identified constituents.

Evaluation of the data reported in Table 2 identified that three of the sample cells in the program had analytical results which exceeded the concentration limits for cPAHs established in the ROD. The exceedance areas include: (1) the western face of the Bath Recovery Pad Area, sample locations BRP-4 and BRP-5; and (2) the western end of the Salvage Area, sample location SA-12. Appropriate actions were taken, as approved by the U.S. EPA, in further material removal and resampling of the exceedance areas.

The results obtained from the implementation of the program indicate that the objectives of the program were met. Through implementation of the VSP, lateral limits of soil contamination were defined and the effectiveness of the CERCLA Remedial Actions at identifying and removing spent potlining materials and residuals was verified.

The application of verification sampling at hazardous waste sites for the purpose of defining the lateral and/or vertical extent of contamination is a determinative demonstration of the effects of site cleanup. The conduct and results of a verification sampling program are also useful as a public relations tool, demonstrating to the public that the site cleanup has been effective and that verification has been obtained.

Field Test Kit for Quantifying Organic Halogens In Water and Soil

Deborah Lavigne
Dexsil Corporation
Hamden, Connecticut

ABSTRACT

In a continuing data-gathering program, the U.S. EPA monitors organic chemicals in the waters of the United States. The list of monitored chemicals includes aliphatic and aromatic hydrocarbons, pesticides, industrial chemicals, plasticizers and solvents. Many of these materials are halogenated, produced by chlorination of water during purification processes, through industrial and municipal run-off, natural sources and sewage purification practices.

Chlorine is a contaminant often found in oils, soils, sludges and organic liquids found at hazardous waste sites. Controlling wastewater discharges and landfilling of chlorinated compounds have become priority issues for the U.S. EPA since the passage of the Hazardous and Solid Waste Amendments in 1984.

In response to toxicological and environmental concerns of trihalomethanes and other halogenated compounds present in water and soil, a quick, accurate, easy to use, portable field test kit has been developed for quantifying organic halogens. The analytical procedure requires an extraction with a suitable solvent, followed by colorimetric chemistry to quantify the organic halogens present.

This paper discusses detail field and laboratory results, limits of detection, matrix effect and cost analysis.

INTRODUCTION

U.S. EPA regulation 40 CFR 261 establishes that any used or waste oil containing greater than 1000 ppm organic chloride may have to be classified as a hazardous waste. Chlorinated solvents are the primary contaminants found in waste oils and oily wastes.

Currently available instrumental methods of chlorine analysis (microcoulometric titration, X-ray fluorescence spectometry, oxygen bomb combustion and gas chromatography) are time-consuming and must be performed in a laboratory by trained technicians. Foreseeing the additional testing that would be required under the new regulations, the U.S. EPA Region II contracted Dexsil Corporation to develop a field-portable test kit that could be used by untrained personnel. The result was two small, disposable test kits that require less than five minutes to determine chloride contamination in waste oil. The first method is a go/no-go test, indicating over or under 1000 ppm chloride. The second method is a quantitative analysis giving an amount of contamination between 200 and 4000 ppm.

These test kits were evaluated by Research Triangle Institute in Raleigh, North Carolina) for U.S. EPA and were found to be acceptable methodology for chlorine detection. As a result, the kits were assigned U.S. EPA method 9077, to be published in the forthcoming SW-846 manual.

Interest has since increased in a test kit that would work on oil containing large quantities of water (oily waste) and, in light of the current regulations pertaining to leaking underground storage tanks, it would be useful to have a kit that would detect total organic halogens in soil. Two field-portable test procedures have been developed which address these issues of halogens in wastewater, oily waste and soils. The different methodology and apparatus will be described, the accuracy and precision of each method discussed and the costs of each method reported.

USED OIL CONTAMINATION

How do chlorinated solvents contaminate used oil? Chlorinated solvents are not ingredients of crankcase oil, but are indirectly introduced through careless management practices, such as pouring used degreasing and cleaning solvents into used oil storage drums. The most common solvents found in waste oils are dichlorodifluoromethane, trichlorotrifluoroethane, 1,1,1-trichloroethane, trichloroethylene and tetrachloroethylene.[1] Levels of contamination range from 100 ppm to thousands of ppm. The presence of chlorinated solvents can be determined by checking total chlorine, an indicator of the potentially hazardous chlorinated substances present.

The U.S. EPA estimates that more than 350 million gallons (approximately 30% of all used oil) are landfilled or dumped annually. Approximately 160 million gallons come from "do-it-yourself" oil changers, who typically dispose of their oil by dumping it on the ground, into sewers, or into waterways, or by placing it with the household trash destined for a landfill that has not been lined to protect against soil and groundwater contamination. The remaining 190 million gallons are dumped or landfilled by automotive shops and industrial facilities.[2]

OILY WASTE SOURCES

Sources of oily waste include bilge and ballast, rain run-off, washings from cleaning vehicles and tanks and cutting oils. All of these materials are predominantly water, containing from 0.1 to 10% oil.

Bilge oil is a mixture of fuel oil, lubricating oil and hydraulic oil dispersed in sea water along with dirt, rust and bacterial sludge. Ballast oil composition depends on what is carried in the ballast tanks when the ship is not in ballast, usually fuel oil, crude oil, or petroleum products. The oil usually will exist as free oil droplets in the seawater, or as a sheen on the water surface.

Rain run-off that carries oil from contaminated areas often cannot be legally discharged to storm sewers. Trucks and fuel storage tanks are cleaned with water containing detergents. This process produces oily water containing solids, emulsions, free oil, dissolved oil and detergents. Metalworking fluids are used for both lubrication and cooling in various machinery processes such as cutting and grinding.

Oily waste resulting from used oil mismanagement causes damage to streams, groundwater, lakes and oceans. For instance, the U.S. Coast Guard estimates that sewage treatment plants discharge twice as much

oil into coastal waters as do tanker accidents - 15 million gallons per year versus 7.5 million gallons from accidents. A major source of this pollution is dumping of oil by do-it-yourselfers into storm drains and sewers. A startling example of this dumping has occurred in the Seattle area, where more than 40% of the water quality trouble calls received are related to used oil and other wastes dumped down storm drains, thus contaminating water bodies.[3]

ENVIRONMENTAL IMPACT

Many contaminated sites containing oily wastes and oily waste sludges are now being cleaned up under authority of Superfund. The Superfund regulations govern the handling of oil wastes in the areas of spills and accidental releases, leaky storage tanks and abandoned storage facilities. Oils from abandoned storage facilities fall into one of three categories: (1) abandoned tank pumpings, (2) abandoned drummed oils or (3) sludge pit residues.[4]

The composition of the oils in each of these categories can vary significantly from site to site. Over time, the oils in tanks and drums absorb material from the walls of the container. This process is exacerbated by corrosion due to seasonal temperature variations, rain, mechanical abrasion. The oils are usually significantly diluted by water infiltration. In order to fall under Superfund jurisdiction, must present a danger to the public or the environment. Thus the emphasis is on quick and inexpensive analysis and disposal of the materials, rather than on recycling and reuse.[5] Ideally, hazardous waste determinations, whenever possible, should be carried out in the field to quickly identify the extent and magnitude of the contamination. The advantages of alternative simple chemical tests have been foreseen by the U.S. EPA and some procedures have, in the face of alternative instrumental methods, been examined and subsequently have been approved by the U.S. EPA.

METHOD FOR THE DETERMINATION OF ORGANIC HALOGENS IN WASTEWATER, OILY WASTES AND SOILS

This procedure requires an extraction with a suitable hydrocarbon solvent. Covalently bonded halogens present in the hydrocarbon solvent are then stripped from their solvent backbones by sodium metal according to the Wurtz reaction:

$$2Na + 2R\text{-}X \rightarrow 2NaX + R\text{-}RD \qquad (1)$$

Any halogens that are present (now in ionic form) are extracted into

an aqueous buffer, to which is added a color reagent to measure the concentration of the resulting chloride. A solution of mercuric nitrate is added dropwise until a color change from yellow to purple is realized and the concentration (in ppm) is read directly off the dropper.

ANALYTICAL METHOD

Method for Samples Containing Water

Ten mL of the liquid sample are extracted by shaking for one minute with 10 g of an immiscible hydrocarbon and 0.5 g of a (granular) emulsion breaking material. The sample is allowed to settle until it has separated into distinct phases (approximately three minutes).

Approximately one-third of the top layer is dispensed into a vial containing a drying agent which will remove any moisture and inorganic chloride. The vial is shaken and the drying agent is allowed to settle. A 0.34-g aliquot of the dried solvent is then treated with 1.5 mL of a solution of naphthalene in ethyl diglyme followed by 0.4 mL of organic dispersion and metallic sodium and shaken for 1 minute. Buffer solution (7 mL) is then added and the aqueous layer is separated and combined with 0.5 mL of a solution of s-diphenyl carbazone in alcohol.

A solution of mercuric nitrate is added dropwise from a 1-mL microburette. When a true purple color is realized, the test is stopped and the chloride concentration of the original oil/water or wastewater sample is read directly off the microburette.

Method for Soil Samples

Ten grams of the soil sample are extracted by shaking for one minute

with 12 mL of a mixture that contains 2 mL of distilled water and 10 mL of an immiscible hydrocarbon. The soil is then allowed to settle and the supernatant liquid is filtered through a column containing florisil to remove any moisture and inorganic chloride. A 0.34-g aliquot of the dry filtrate is then treated with 1.5 mL of a solution of naphthalene in ethyl diglyme followed by 0.4 mL of organic dispersion and metallic sodium and shaken for 1 minute. Buffer solution (7 mL) is then added and the aqueous layer is separated and combined with 0.5 mL of a solution of s-diphenyl carbazone in alcohol.

A solution of mercuric nitrate is added dropwise from a 1-mL microburette. When a true purple color is realized, the test is stopped and the chloride concentration of the original soil sample is read directly off the microburette.

ANALYTICAL TESTS, RESULTS AND DISCUSSION

The samples chosen were both laboratory mixtures and Superfund samples containing a range of 125 ppm to 6500 ppm chloride. The procedures employed were the same as those described above, except a packed kit was used (HydroClor™, Dexsil, Hamden, Connecticut). All reactions with this kit are carried out in sealed plastic tubes and all reagents are contained in crushable glass tubes to obviate any need to handle the reagents. This procedure is advisable, as some of the reagents are hazardous to handle in the normal manner. The results obtained from the laboratory samples are shown in Table 1 and Table 2 and the results from the Superfund samples are shown in Table 3. All three tables include results from the microcoulometric titration (U.S. EPA method 9076) of the same samples. The results from both the test kit and the microcoulometric titration of the samples agree very well. It is also clearly demonstrated that no interference occurs in the presence of inorganic chloride.

Laboratory soil samples were also tested in the same manner using an analytical kit (TerraClor™, Dexsil, Hamden Connecticut). This kit is a similar to the one used for liquids, but also provides a simple balance

for weighing out the soil. The procedures previously described were used. The results obtained for wet and dry soils are shown in Table 4 and the results for wet and dry sands are shown in Table 5. Microcoulometric titration results of the same samples are shown in each table, agreement is good between the two methods.

The cost of each kit is $10-15 and no capital investment in instruments is needed. The kits can easily be used in the field and little skill is needed. The test takes approximately ten minutes. With increasing testing requirements, laboratory fees and laboratory turn-around times, the field-portable chemical test with colorimetric end-point would be the first choice for a suspect site or container, prior to laboratory analysis.

Analytical Field Screening of Soil and Water
By Thin Layer Chromatography

J. Scott Newborn
Jerry S. Preston
Law Environmental, Inc.
Kennesaw, Georgia

INTRODUCTION

Thin Layer Chromatography (TLC) has been in use for decades in the chemical industry where it has been used to identify many compounds. Law Environmental, Inc., has employed TLC as a screening tool for on-site environmental analyses. The technique is both qualitative and quantitative for a variety of semivolatile organic compounds, including petroleum distillates, polynuclear aromatic hydrocarbons (PNA), chlorinated pesticides, PCBs, phenols and explosives in soil and water. Low parts per million detection limits can be achieved for most of these compounds through the use of concentration techniques and compound-specific development sprays. TLC is fast, inexpensive, simple to implement and versatile when used as a screening tool.

Currently most screening analyses are accomplished through Gas Chromatography (GC) or colormetric tests. TLC cannot match the detection limits of the more expensive GC for many compounds; however, the sensitivity of a GC may not be required by all projects. TLC is comparable in cost, speed and simplicity to colormetric tests, but is not as susceptible to false positives that often plague the colormetric tests. This paper provides a discussion of the TLC methodology we have employed, a presentation of results and a summary discussion of the advantages and disadvantages of TLC as a field screening tool.

METHODS

This section contains a brief description of sample preparation, procedures and analyses. The methods are mainly based on a modification of the method described by Friedman and Bruya.[1]

Groundwater Sample Preparation—Petroleum Hydrocarbons

Groundwater samples suspected of containing JP-4 and No.2 fuel oil were prepared for analysis by using a modified California Department of Health Services preparation for the semivolatile compound portion of the Total Petroleum Hydrocarbons.[2] A 250 mL sample of groundwater was extracted with two 20 mL aliquots of pesticide-grade methylene chloride. The two extracts were combined and concentrated to 5 mL with a Kuderna-Danish apparatus to yield a 50 to 1 concentration factor.

Soil Sample Preparation

Soils suspected of being contaminated with petroleum products were prepared using the following procedures. A 10 gram soil sample was mixed with 1 to 2 grams of silica gel and then mixed with a 10 mL portion of methylene chloride in a 40 mL vial. The mixture was agitated for 90 seconds. Polynuclear aromatic and pesticide compounds also were extracted by this method.

Soils suspected of containing PCBs were extracted with a mixture of deionized water, methanol and hexane (1:4:5) according to the method

of Spittler.[3] This mixture and soil were shaken for 90 seconds and the solids were allowed to settle out. The hexane layer was then collected.

The concentration method involved decanting the hexane or methylene chloride extract and evaporating the solvent with a hot air blow dryer. Concentration factors were 5:1 or 10:1 depending on the analyte. This concentrate was applied to the silica gel TLC plate. The TLC plate was then eluted in a glass developing chamber containing hexane as the eluting solvent. Methylene chloride was used as the eluting solvent for more polar compounds, such as phthalate, cresol and nitroaromatic compounds.

Analysis

Once the TLC plate was eluted, it was air-dried and developed for compound-specific analysis. The development consisted of exposing the plate to iodine vapor and ultraviolet light. The dried plate was placed in a second glass iodine-charged development chamber. This iodine-charged chamber contained a purplish-red iodine vapor. After 5 minutes, the plate was observed using a 254 nm UV light source, which was placed directly above the glass development chamber. Dark spots appeared against a fluorescent green background if detectable contamination was present.

The detection of all categories of tested compounds was enhanced by using a 7,8-benzoflavone based development spray. Approximately 30 seconds after the removal from the iodine chamber, a mixture containing 1.5 grams of 7,8-benzoflavone in 95 mL of ethanol and 5 mL of 30% sulfuric acid was lightly sprayed onto the TLC plate. This quantity of spray was adequate for observation of several plates and lasted at least eight hours.[4]

Contamination was evaluated by measuring standards (Rfs) and comparing the intensity of the spots to multiple known concentrations of standards. Rfs were measured according to the classical methods.[6,7,8] The origin of the material was assigned a value of 0.0 and the solvent front was assigned a value of 1.0. The center of a developed spot was measured with a ruler for its distance from the origin. This value was divided by the distance of the solvent front from the origin to produce an Rf value for that compound. Intensities of ovals were judged against those produced by standards that were analyzed on the same plate. For example, a sample spot might have appeared to be more intense than the 200 mg/L standard, but less than the 300 mg/L standard oval. This sample was assigned a concentration value of 250 mg/L. Figure 1 depicts the eluted compounds of interest with associated Rf values. An example of the calculation for the Rf of Aroclor 1242 is also included on the figure.

RESULTS

This section briefly describes the results of the TLC experiments

which stem from a groundwater contaminant survey a soil contaminant survey and laboratory investigations.
Figure 1
TLC Representation Showing Aroclor and
Petroleum Products Patterns. A Rf Calculation
is Made for Aroclor

Groundwater Samples

The results of the analysis of groundwater samples for fuels were compared to GC-FID results for samples from the same locations. High concentration (percent level) standards of diesel, JP-4 and No.2 fuel oil yielded identical TLC Rf values; however, the appearance of the developed TLC chromatogram pattern was dissimilar. The heavier the fuel, the more intense and streaked the chromatogram appeared at the Rf 0.5 value. The lighter the fuel, the more intense the spot appeared at the Rf 0.9 value. As the concentration of the standards approached environmental concentrations (e.g., 1,000 mg/L), only the 0.9 Rf spot was visible.

Contamination by JP-4 and No.2 fuel oil was not detected at the test site by GC. In order to test the effectiveness of TLC vs. GC on the these fuels, 100 mg/L spiked samples of No.2 fuel oil and JP-4 were prepared and analyzed by TLC and GC-FID. The TLC analysis yielded spiked sample results of 40 mg/L and 60 mg/L on two samples for No.2 fuel oil and 20 mg/L and 40 mg/L for JP-4. These values were confirmed by the GC-FID.

Soil Samples

A screening program was undertaken where 100 soil samples from a second site were screened by TLC for petroleum lubricants and heavy fuels. The objective of this screening program was to aid in the selection of soil boring placement. The soil boring samples were later sent to the laboratory for analysis. Field samples, quality control samples and samples known to be contaminated with petroleum products were analyzed.

A positive result was defined as any sample that exhibited an oval-shaped iodine-stainable material in the 0.8 to 0.9 Rf value region. Standards analyzed for the petroleum products suspected of being present showed chromatographic patterns indistinguishable from each other at detection limits of 100 mg/L. Positive results were obtained for 19 field samples; 7 samples were judged to be in the 100 mg/L range, 10 samples in the 200 mg/L to 400 mg/L range and 2 samples were greater than 1,000 mg/L. Soil samples known to contain used motor oil were com-

parable to high concentration standards of motor oil, except that the 0.5 Rf constituents were clearly more elongated or "stretched."

Quality control samples were analyzed in addition to the standards. These samples included matrix spikes, duplicates and soil blanks. Duplicate samples were analyzed for 10 of the positive samples, with all 10 reconfirmed as positive. Blank samples, consisting of commercial grade sand, were negative for all fuel analyses. Four soil matrix spiked samples were tested for motor oil. All four TLC analyses indicated an approximate recovery of 70% of the motor oil.

A comparison of TLC results for PCBs to a commercially available colormetric test was completed with soil samples from the two sites. The colormetric test yielded a purple color if a sample contained PCBs at concentrations less than 50 mg/L. A pale yellow color was observed if the soil contained PCBs at levels greater than 50 mg/L. One drawback to the colormetric test is that it is subject to interferences from chlorinated compounds found in fuels.[5]

The TLC standards were analyzed with Aroclor 1242, which yielded a detection limit in soil of approximately 35 mg/L. The TLC chromatogram for Aroclor 1242 produces a purplish "dual oval" at an Rf of 0.5. Samples were spiked with a 50 mg/L mixture of Aroclor 1242 and 1,000 mg/L motor oil. The PCB were recovered well and were clearly distinguishable from the motor oil. Analysis times using the PCB test kit and TLC were similar. Thus, simultaneous analysis of fuel and PCB was achieved using the TLC within the same time frame as the PCB test kit. A lower detection limit was also achieved using the TLC method versus the PCB colormetric test.

Soil samples from a site that previously had been characterized by contract laboratory analysis for semivolatiles were tested by TLC. Soils from this site were heavily contaminated with a wide range of polynuclear aromatic compounds. Soils for the TLC analysis were selected from the "hot spots" identified by the contract laboratory analysis results. Benzopyrene was common to many of the analysis results and for this reason this compound was chosen as the primary standard. Standard analysis of benzopyrene established a 1.0 mg/L detection limit with an Rf value of 0.15. Benzopyrene produces dark blue spots when treated with 7,8-benzoflavone spray. Standard mixtures of polynuclear aromatic compounds varied considerably in Rf values due to the differing polarities of each compound.

Two samples were selected for TLC analysis. One laboratory-analyzed sample contained fourteen different PNAs with a total concentration of 0.4%. The other laboratory-analyzed sample contained eight PNAs for a total concentration of 30 mg/L. The 0.4 PNA concentrated level soil sample saturated the TLC plate. That is, the sample chromatogram appeared as a large "slurr" that extended from the 0.0 Rf point to the 1.0 Rf or solvent front end point. The 30-ppm sample showed a column of five oval spots, one of which had an Rf value identical to that of benzopyrene. Benzopyrene was indicated in the results from the laboratory analysis of soil from this area. The TLC chromatogram was judged to be between 30 mg/L and 50 mg/L total PNA content. A sample that was free of PNA compounds was spiked with 200 mg/L of benzopyrene and indicated no detectable loss of this compound when chromatographed.

The pesticide 1,1,1-trichloro-2,2-bis(p-chlorophenyl) ethane (DDT) was analyzed from soil samples obtained from two different sites. A 100-ppm sample was easily detected. DDT appears as a purple oval with an Rf value of 0.25. The detection limit for DDT was determined from the lowest visible standard as 3 mg/L. DDT produces white spots on a light blue background when treated with the 7,8-benzoflavone spray.

The spiked samples included a laboratory-analyzed sample (SS-1) and a previously TLC screened sample (I2) that had not been tested for pesticides. Each sample was analyzed with its corresponding spike sample. Both the SS-1 sample and the spike saturated the plate such that a determination of DDT for each was not possible. The I2 sample did not show DDT; however, the I2 spiked sample showed complete recovery of DDT for the 100-ppm spike.

DISCUSSION

Our study of TLC shows that this method is superior to a soil colormetric test for PCBs, is effective in the analysis of other semivolatile

compounds in soil and is comparable to gas chromatographic analysis of petroleum products in soil. TLC's clearest advantage over GC is cost. Table 1 compares the cost of a typical on-site analysis of 100 soil samples using GC and TLC. GC is approximately twice as expensive as TLC. In addition, much of the TLC's cost are one time purchases (i.e., development chambers, UV lamps, etc.). TLC becomes more cost effective the more it is used. Other factors directly affecting cost are speed and reliability. Since TLC is faster, support personnel should have less time in the field, therefore, reducing the cost associated with personnel time. TLC does not require field maintenance and does not suffer the down time that can be associated with field instrumentation. A timely and inexpensive analysis is very important for site remediation activities.

Table 1
Comparison of GC vs. TLC:
Field Summary of One Hundred Soil Samples

* Labor cost are based on $60 per hour billing rate for one person; 80 hours GC (12 samples per day), 36 hours TLC (40 samples per day).

** Rental cost are based on one month rental.

TLC can, in the analysis of some semivolatile compounds, compare favorably with laboratory analysis. The method is very practical for PNA compounds, as indicated by our results from TLC vs. soil samples analyzed by a contract laboratory. Again, cost is a consideration. TLC analysis for semivolatile organic compounds in the soil was accomplished at approximately 1/30 the cost of a laboratory analysis. This is based on $50 per sample analyzed on-site (including labor) vs. $1500 for an average 24 hour turnaround time from laboratory analysis for semivolatile compounds.

TLC was shown to be superior as a screening tool when compared with the soil colormetric test. The cost is similar, but, TLC has the advantages of yielding qualitative and quantitative information. TLC offers simultaneous analysis of multiple components and, most importantly, is not as susceptible to interferences from nonspecific compounds. The colormetric test does offer convenience and ease of use.

In summary, the TLC method is a cost-effective tool for the field screening of samples. It should be considered for use, especially for soils, when low detection limits are not required. The TLC method will have its greatest utility if low cost, fast screening techniques are of premium importance and slightly higher detection limits will meet the need of the data quality objectives of a particular project.

Monitoring Mercury-Contaminated Soils For Monomethylmercury

B. Chris Weathington
Stanley D. Furdyna
Jennifer A. Isett
RMC Environmental Services
Tri-County Business Campus
Pottstown, Pennsylvania

ABSTRACT

Hazardous waste sites that are found to be contaminated with mercury should be further characterized by determining the presence or absence of monomethylmercury. The health risks are greater for the methylmercury than inorganic mercury, and it has been shown that inorganic mercury can be converted to monomethyl and dimethylmercury under anaerobic conditions. A procedure was developed in our laboratory using Gas Chromatography with an electron capture detector to determine monomethylmercury in soils. Hydrochloric acid is used to hydrolyze dimethyl and monomethylmercury to the monomethylmercury chloride. The acidic solution is extracted with benzene and concentrated prior to analysis. The gas chromatography requires conditioning of the GC column with mercury chloride to ensure reliable peak resolution. A method detection limit of 14 ppb (14 ug/kg) was determined. The accuracy ranges from 82 to 117%. The procedure is described.

Using this analytical procedure, nine hazardous waste samples known to be contaminated with mercury were evaluated to determine the presence of organic mercury contamination. Total mercury versus methylmercury concentrations for these samples was nine randomly selected samples, a probability of finding methylmercury appears to be greater than 75%. Risk assessments should include mercury speciation.

INTRODUCTION

The purpose of this paper is to describe a procedure to test for dimethyl and monomethylmercury in soil/solid matrices and the application of this test procedure on six randomly selected mercury-contaminated soil/solid matrices. The Superfund Program, RCRA and NPDES require testing for mercury. A site investigation will usually include the determination of mercury as part of the assessment. Rarely is speciation of mercury into its various organic compounds required. However, determining the mercury species present can help evaluate the potential means of transport from the site via air or water, further delineate the toxicology and/or provide evidence of the source of contamination. Dimethyl and monomethylmercury have been analyzed for frequently in biological species, particularly fish.

Mercury and its compounds are frequently occurring contaminants in the enviroment whose toxicity is well known and characterized. Since 1900, it has been estimated that more than 170,000,000 pounds of mercury have been used in the United States. Major uses of mercury and its compounds include the electrical industry (switches, lamps and rectifiers), producers of chlorine and caustic soda, paint manufacturers (fungal retardants), agriculture (fungicides), paper and pulp (slimicides), catalytic uses pharmaceutical and cosmetic industries.

A U.S. EPA validated procedure does not exist for determining methylmercury in soils. The Food and Drug Administration has been testing for methylmercury for a number of years in fish with a method described in *Official Methods of Analysis of the Association of Offical Analytical Chemists.*[1] The method described is a modification of the AOAC procedure.

ANALYTICAL METHODOLOGY

Solid samples are extracted with benzene and the extract containing any dimethyl and monomethylmercury is transferred to a second test tube and mixed with a warm solution of 70:30 hydrochloric acid: ASTM Type II water. The acid/benzene mixture is heated at 60°C for 2 hours. During the 2 hour span, the mixture should be shaken vigorously. The dimethyl and monomethylmercury chloride in the presence of hydrochloric acid.

The benzene layer containing the methylmercury chloride derivative is concentrated to 10 mL or less by Kuderna Danish or nitrogen evaporation. From 3 to 5 μL of the concentrated extract are analyzed on a gas chromatograph equipped with an electron capture detector. The gas chromatographic column must be conditioned and equilibrated prior to analysis with multiple injections of mercury chloride. The extraction procedure is outlined in Figure 1. A cleanup procedure using an LC-18 solid phase extraction was developed to cleanup sample extracts which may contain interfering compounds.

Solvents/Reagents

Pesticide grade benzene is used for extraction. Toluene probably is an acceptable solvent, but the lower boiling benzene results in faster concentrations. Hydrochloric acid should be ultrapure reagent grade. Ultrex grade from J.T. Baker has a trace amount of mercury that will result in an artifact at the retention time of methylmercury chloride. This trace amount of mercury must be removed prior to use of the acid as a derivatization reagent.

Prepare a 70:30 mixture of hydrochloric acid and distilled deionized water. Extract this mixture five times with a 25% volume of benzene. The acid should always be extracted immediately prior to use. The final volume of benzene wash is concentrated to 10 mL and analyzed by GC-EC to determine the presence of artifacts in the area that methylmercury chloride elutes. A noncontaminated hydrochloric acid mix will result in a nondetectable GC response. Any acid left over from a series of extractions can be stored for later use. However, the acid should be extracted again prior to use because, on standing, an artifact is generated in a lesser yet still detectable amount.

Calibration

For best performance of this procedure, calibration is performed by derivatization of dimethylmercury to the methylmercury instead of the use of purchased methylmercury chloride. Dimethylmercury for for-

tification and calibration may be purchased from Aldrich. A calibration mix from 0.05 mg/L to 1 mg/L of dimethylmercury is prepared in benzene. Each calibration standard is derivatized in the same manner and at the same time as the samples. Experiments were performed which indicate that a derivatization efficiency of approximately 50% to 60% results after acidification at 60 °C for 2 hours. Experiments to improve the efficiency of approximately 100% were not performed. It is assumed more rigorous conditions of temperature, pressure and greater mixing would increase the derivatization efficiency.

Figure 1
Soil Extraction and Analysis for Methylmercury

Extraction/Derivatization/Concentration

Ten gram soil/solid samples are weighed into a Teflon-lined screw cap test tube. Ten milliliters of the hydrochloric acid derivatization reagent are trasferred to another screw cap test tube, and the acid solution is placed in a 60 °C water bath. The test tubes used should be large enough to hold sample and extracts. When the acid reaches 60 °C, begin extraction of the sample using three 10 mL aliquots of benzene. Shake or vortex the sample vigorously for 3 to 5 minutes. Extraction with benzene may produce emulsions. Centrifugation for 2 minutes at 2000 rpm will reduce the emulsion. Transfer each aliquot of benzene directly to the acid and begin shaking vigorously. Continue to shake the benzene/acid mixture every 10 to 15 minutes for at least 2 hours. Transfer the benzene layer to Kuderna Danish concentrator or another test tube for nitrogen evaporation. The results reported here are based upon a 10-mL final volume. A final volume of 1 mL is easily attained and can result in a 10-fold reduction in the detection limit. Approximately 20 samples can be extracted in eight hours.

Gas Chromatography

Analysis is performed on a gas chromatograph with an electron capture detector. The packing of the separation column should be diethyleneglycol succinate (DEGS) 5% on 100/120 Supelcoport (Supelco, Inc., Catalog Number 1-1870M). The column should be six foot glass with a 2-mm ID and 6.4-mm OD. The instrument conditions use a flowrate of 60 mL/min of argon-methane (95*5), inlet temperature of 235 °C, detector temperature of 325 °C and isothermal runs of 155 °C. By increasing the temperature to 165 °C after 5 minutes, the column can be quickly cleaned of any extraneous compounds prior to the next sample analysis. To prevent carryover, the run times were set at 20 minutes.

The conditioning of the column prior to analysis is critical. Failure to perform the conditioning steps described here will result in poor or no resolution/detection of the monomethylmercury chloride derivative. Various experiments were performed on a number of columns, and the chromatographic conditioning procedure of the AOAC produced the best results. The AOAC procedure recommends first conditioning a new column with a 0.5 hour flush of carrier gas at 30 mL/minute at room temperature, heating to 100 °C for 1 hour, then heating the column at 4 °C/minute until 200 °C and holding overnight. The column is then ready for mercuric chloride treatment.

A mercuric chloride solution (1000 mg/L) is prepared and five 20-uL injections are made onto the column at 10 minute intervals. The oven temperature should be 160 °C. Large, broad peaks will elute and approximately 1.5 to 2 hours after the last injection a large peak will elute. A methylmercury chloride standard at 0.1 mg/L should be injected until the retention time and peak height are stable. The temperature should be adjusted to 155 °C and analysis can begin.

The column should be treated periodically during use to ensure that peak resolution and retention times do not degrade. After the initial treatment, an end of work day single injection of 20 uL of mercuric chloride at a temperature of 115 °C will prepare the column for analysis the following day. A large peak will elute 11 to 15 hours after the injection.

Use of these AOAC-derived chromatographic conditioning procedures resulted in very stable retention times of 2.0 to 2.2 minutes. The peak heights for calibration standards on a day-to-day basis resulted in the variabilities recorded in Table 1. Over the 10-day span there was less than 12% variability in peak heights.

Quality Control

Analyses performed using these procedures must include a method blank that consists of hydrochloric acid extracted in the same manner as the samples. The method blank is absolutely necessary to avoid reporting false positives. Early experiments with improperly prepared hydrochloric acid resulted in an artifact at the same retention time as the methylmercury chloride.

In addition, it is recommended that the calibration standards be prepared by derivatization of dimethylmercury and not from purchased

methylmercury chloride. At least one sample matrix in 10 should be spiked in duplicate with dimethylmercury to determine the precision and accuracy of the extraction. A calibration standard should be run after every 10th sample to ensure peak height and retention time stability.

Table 1
Stability of Day-to-Day Calibration

10	0.500	20363
Relative Standard Deviation		**11.7%**

Health and Safety

Mercury and its compounds are toxic. Methylmercury and its various salts are especially toxic because they are completely absorbed via breathing or ingestion and not eliminated from the body. All mercury compounds have neurotoxic effects and can cause kidney and liver damage.[2,3,4]

Anyone using this procedure should use extreme care in preparation of standards and handling extracts. The chromatographic column should be vented directly into a carbon trap. A glovebox should be used whenever possible and an efficient fume hood at a minimum. Under the new OSHA requirements for laboratories, technicians should inform their colleagues that methylmercury is in use and establish an area that only authorized personnel may enter.

Extract Cleanup

Extracts of heavily contaminated environmental samples may require some type of cleanup to ensure that there are no organic interferences during analysis. The electron capture detector is prone to fouling if excessive concentrations of compounds other than the target compound are present in the extract. For a quick cleanup procedure, pass the benzene extract through a solid phase extraction column. Several sample extracts analyzed for this paper were highly colored, and passage through a Supelclean LC-18 column (Supelco, Inc., catalog number 5-8298M) resulted in a dramatic reduction in color. Recovery from the Supelclean LC-18 column was validated by quadruplicate analysis of four soils that were fortified with 1 ppm dimethylmercury, extracted and derivatized as described. Table 2 indicates a recovery average of 101% with a standard deviation of 18%.

Table 2
Recovery of Dimethylmercury After LC-18 Cleanup

Sample Designation	Spike Concentration mg/Kg	Found Concentration mg/Kg	Percent Recovery
MDL 1	1.000	0.962	96.2%
MDL 2	1.000	0.763	76.3%
MDL 3	1.000	1.270	127.0%
MDL 4	1.000	1.058	105.8%

Method Validation and Detection Limit

The method was validated by fortification of a silty/clay soil with dimethylmercury. The soil was approximately 40% silt and 60% clay. A batch of seven fortifications was prepared by weighing 10 g of sample aliquotes into test tubes and spiking each with 1 ml of 1 ppm dimethylmercury solution which results in a 0.1 ppm final concentration in the soil. The soil was shaken to mix well and the solvent was allowed to evaporate. Extraction and analysis of these samples resulted in an average recovery of 97.3% with a standard deviation of 9.9%. Table 3 lists the found versus true concentrations. Figure 2 is a representative calibration curve.

The same data were used to derive a method detection limit.[5] The method detection limit for these data is 14 ppb. Since a 10-mL final extract volume was used, it can be assumed that concentration to a final volume of 1 mL should produce a 1.4 ppb method detection limit. Because 14 ppb was an acceptable detection limit for this project, further validation and procedure development to achieve a lower limit was not done.

Table 3
Total Mercury and Methylmercury Results of Selected Environmental Samples

Example Calibration Methylmercury

DISCUSSION

Our laboratory performed 3250 total mercury analyses over an 18-month period from July 1988 to February 1990. Of these tests, 1375 were digested samples and 1080 were RCRA EP Toxicity Leachates.

Of these, 24% had mercury concentrations >0.0002 mg/L. Only one mercury leachate failed to pass the RCRA regulatory limit of 0.2 mg/L. Only 6% of the samples had mercury concentration >0.5 mg/L.

For the purposes of this paper, nine samples with positive mercury concentrations were selected for methylmercury analysis. At the time of analysis, no information about the sample or site the sample was collected from was known. The tests were performed, results were tabulated and then the clients who provided the samples were contacted to inquire about the samples' history.

The results of the methylmercury analyses are reported in Table 4 with the total mercury concentration for camparison. The sample histories are:

- Sewage Plant Debris - During an expansion of local sewage plant, soil and debris were removed from old sludge digester pits. The debris was tested for RCRA parameters for disposal.
- Utility Fly Ash - Fly ash collected during coal burning operations at a local utility was tested to meet RCRA disposal regulations.
- Cement Kiln Dust - This sample was supplied as a solidification medium for an engineering treatability study. Total mercury was tested to characterize the sample prior to solidification tests.
- Soil and Debris (Tool and Die) - The samples were part of a site investigation for a real estate transfer. The soil samples were contaminated with a heavy oil like substance. Originally the site was a tool and die manufacturing facility.
- Soil from Army Arsenal - The sample was provided for RCRA analyses. History of the sample site is unknown.
- Soil from Munition/PVC Plant - The sample was provided for RCRA analyses. The sample site was a munition plant from 1915 to 1950. From 1950 to the present, the site has been a manufacturer of polyvinyl chloride products.

Table 4
Total Mercury and Methylmercury Results of Selected Environmental Samples

Sample Type	Total Mercury (mg/Kg)	Methyl-Mercury (mg/Kg)
Sewage Plant Debris	1.8	0.899
Utility Fly Ash	0.33	<0.015
Utility Fly Ash	0.30	<0.015
Cement Kiln Dust	0.87	0.018
Soil & Debris (Tool & Die) 1	0.5	1.612
Soil & Debris (Tool & Die) 2	4.3	0.706
Soil & Debris (Tool & Die) 3	4.3	0.542
Soil from Army Arsenal	0.77	0.594
Soil from Munition/PVC Plant	1.4	1.584

The expected concentration of methylmercury should be less than equal to the total mercury concentrations. A soil and debris sample from the tool and die site and the soil from the munition/PVC plant did not meet this criterion. The soil and debris tool and die sample concentration of 1.612 mg/kg methylmercury versus 0.5 mg/lg total mercury may be the result of two factors. The first is nonhomogeneity of the sample and the second is the large difference in sample size used for the total mercury analysis (0.2 g) versus the methylmercury analysis (10 g). A 10 g sample would be much more representative than 0.2 g. On the other hand, the soil from the munition plant had a total mercury result of 1.4 mg/kg versus 1.584 mg/kg of methylmercury. This is well within the error limitations of the two analyses.

That seven of nine randomly selected samples with total mercury present also had concentrations of methylmercury was unexpected. However, each sample had a history that would indicate the potential for organomercurials. The sewage plant debris methylmercury concentration may have been the result of all the incidental uses of mercury-containing products that are disposed of by individuals and businesses. Metallic or inorganic mercury in sewage sludge can be converted to methylmercury via anaerobic methylation[6] and, therefore, could be the source of the methylmercury-contamination.

The two samples with a munition background may have mercury present as a result of the manufacture of mercury fulminate. In addition, the site where polyvinyl chloride is manufactured has a high probability of methylmercury since the source of methylmercury-contamination that resulted in Minamata disease in Japan was the catalytic use of mercury in preparing vinyl chloride and acetaldehyde.[7] The tool and die samples may have been contaminated by mercury leaking from electrical units or cleaning/fumigation which occurred at the site, as well as metabolic methylation of inorganic mercury.

As might be expected, the presence of mercury in fly ash from a coal burning utility is not surprising since trace amounts of mercury are present in coal. That these samples had no methylmercury was also reassuring because of the thermal processes involved in producing the fly ash.

The presence of methylmercury in the cement kiln dust was surprising since cement kiln dust is a byproduct of cement manufacturing where high temperatures are to be expected. A finding of 0.018 mg/kg of methylmercury is at the detection limit of the method and may in fact be a false positive. The result for the cement kiln dust is not discounted, however, because the concentration of total mercury of 0.87 mg/kg is high enough to warrant the presence of methylmercury. The process which may have produced this methylmercury is not known.

Although a sample population of nine is small, it is significant that seven of nine sample tested positive for methylmercury. The collection and handling of samples which contain mercury should be considered potentially more hazardous than expected since methylmercury is much more readily absorbed than mercury and apparently has a great potential for being present in any mercury-contaminated sample. Testing for methylmercury should be considered when mercury has been identified as a site contaminant and a risk evaluation should be made based upon the presence of both inorganic mercury and methylmercury.

CONCLUSION

The test procedure for methymercury described here can produce valid results for the detection and quantification of methylmercury in soil. Results of this test performed on randomly selected soil samples resulted in the detection of methylmercury in seven of nine samples that had total mercury concentrations. As a result of the greater biological risks associated with methylmercury, site investigations should include a test for this mercury species.

Use of High Resolution Passive Soil Gas Analyses to Characterize Sites Contaminated with Unknowns, Complex Mixtures, and Semi-Volatile Organic Compounds

James H. Viellenave
James C. Hickey
PETREX Division of Northeast Research Institute, Inc.
Lakewood, Colorado

ABSTRACT

Soil gas methods are recognized to be useful tools for reconnaissance testing of underground storage tanks and shallow groundwater contamination by volatile organics. Advanced, high resolution soil gas techniques, exhibiting multiple vapor collection and analytical methods, can dramatically expand the applicability of soil vapor surveys into more difficult chemical and lithologic environments. Where photoionization detectors and even probe/GC methods fail to yield reliable results, a combination of passive sampling with mass spectrometry and GC/MS, and multivariate statistical chemometric tools can identify and differentiate a broad range of volatile and semivolatile organic compounds, fingerprint multiple sources and assist in pinpointing industrial activities and waste disposal practices.

Applications that are of greatest importance include landfills and other waste disposal sites, property conveyance studies where detection of unknowns is vital and assessment of sites with a historical use of industrial products containing semivolatiles or characterized by non-priority organic pollutants.

An overview of different vapor collection techniques is presented along with the use of multiple analytical methods illustrating how such compounds and mixtures can be detected in a reconnaissance mode using soil gas. Two case histories are outlined illustrating the application of these principals: (1) property conveyance showing the existence of both on- and off-site sources of contamination; and (2) fingerprinting of hydrocarbon mixtures to differentiate between diesel and creosote contamination. In addition, several examples of semivolatile compounds detected in soil gas will be presented.

INTRODUCTION

Evolutionary changes in the methods of environmental site investigations have been gaining momentum nationwide over the last decade. Both the environmental manager and consultant are utilizing a variety of lower cost, reconnaissance techniques that provide upfront insight into potential problem areas that exist at a site. These methods afford the investigator a data base from which he can develop effective Phase II subsurface investigations and proceed efficiently to remediation.

One method that has gained an increasing acceptance is soil gas surveying. Soil gas sampling and analysis was first developed as a petroleum exploration tool dating back to the early 1900s.[1] A number of different sampling and analytical methods emerged during the ensuing years. These analytical techniques include free soil gas sampling, desorption of sorbed and occluded gases from soils and the use of adsorbent materials for passive collection.

Early analytical methods were based on simple combustion and manometry techniques, becoming more sophisticated with the development of the gas chromatograph in the 1950s.[1] Ultimately, the applica-

tion of two state-of-the-art, high technology analytical methods, (such as mass spectrometry and gas chromatography/mass spectrometry) were introduced as geochemical problem solving tools in the late 1970s to early 1980s.[1] Subsequently, several environmental researchers applied the basic soil gas systems to volatile organic compound (VOC) contaminant plume tracking, underground storage tank (UST) assessments and source delineation problems.[2-5]

Now the next generation of methods has emerged: rapid, high resolution soil gas techniques that are additionally capable of detecting many semivolatile organic compounds (SVOC) and utilizing a variety of sophisticated computerized data processing techniques.[6]

STANDARD SOIL GAS METHODOLOGIES

All soil gas methods involve varying sampling and analytical techniques. Two primary types of sampling methods are utilized by environmental soil gas practitioners: active and passive. Active sampling systems withdraw an aliquot of gas from a sampling location at a given instance of time, while passive systems incorporate a sample collection medium to sample the migrating gases as they propogate towards the atmosphere. Several company specific variations to each of the primary sampling method types are currently being practiced.[4,5] A summary of the different sampling types, advantages and limitations as compiled by Eklund[4] for the American Petroleum Institute is provided in Table 1.

Table 1
Comparison of Soil Gas Sampling Techniques
(Modified from Ekland[4])

Technique	Disturbance Of Soil Gas Equilibrium Small	Large	Suitable For Rocky Soil Yes	No	Sampling Time Hour(s)	Days	On-Site Analysis Pratical Yes	No
1) Grab Sampling of Soil Cores								
- Auger		X	X		*X		X	
- Driven Sleeve	X	X		X	X		X	
2) Surface Flux Chamber	X		X		X		X	
3) Subsurface Flux Chamber								
- Auger/Enclosure		X	X		X		X	
- Groundprobe type	X			X	X		X	
4) Accumulator Device								
- Curie Point Wire	X		X		X	X		X
- Absorbant/Pump		X		X	X			
5) Groundprobe								
- Passively Emplaced		X	X		X			
- Driven	X			X	X			
- Driven, small Volume	X			X	X			X

In addition to the two primary types of sampling methods that are commonly utilized, a multitude of analytical methods also is employed.[4,5] Analytical methods include total volatile screening, analysis of pathfinder analytes by using field or laboratory gas chromatographs with varying detectors, mass spectrometry and standard gas chromatography/mass spectrometry techniques. Table 2 is a compilation of the various types of analytical methods commonly employed, their uses, advantages and limitations.[4,5]

HIGH RESOLUTION SOIL GAS SURVEYING

During the last four years, Northeast Research Institute, Inc. (NERI),

has adapted a soil gas surveying system (PETREX Technique) developed at the Colorado School of Mines for application at sites with complex contamination histories.[1-3] The basic system utilizes a passive soil gas sampler that continuously collects VOCs and SVOCs over a few hours to several days. During this sampling period, VOCs and SVOCs are sorbed onto a specially treated substrate, thereby decreasing the lower limit of detection for many compounds. The integrative nature of the passive sampler tends to smooth temporal variations that can plague most "instantaneous" sampling methods.[1]

The standard analytical system uses a Curie-point desportion inlet interfaced to a quadruple mass spectrometer (CpD-MS) for fast, adequately reproducible analyses. During each analysis, all VOCs and SVOCs collected in a mass range of 30 to 240 (C2-C16) are desorbed, analyzed and stored on a computer as a composite of the VOC/SVOC compounds collected at each sampling location. These data are then downloaded onto a graphics workstation where data processing and interpretation are conducted.

Analytical flexibility is another advantage afforded by such a high resolution soil gas system. An enhanced version of the PETREX sampling system often is combined with other analytical techniques such as specific detector—gas chromatography, gas chromatography/mass spectrometry and gas chromatography/mass spectrometry/mass spectrometry for enhanced individual compound sensitivity or complex mixture resolution. This advanced sampler incorporates multiple adsorption wires in the same collection device. One adsorption wire is analyzed by Cpd-MS, while the others are available for another analytical method depending on the results of MS analysis and the objectives of the survey.

The ability to readily adjust the analytical program during the interpretative stages of a survey offers tremendous advantages over stan-

Table 2
Comparison of Analytical Techniques

Method	Uses	Advantages	Limitations
VOA/HNU	Total Volatile Screening	Minimum Operator Training; Inexpensive	Poor Sensitivity No Compound Discrimination

Examples of SVOCs Detected in Soil Gas

dard sampling and analytical techniques. For example, landfills frequently exhibit a large number of unanticipated compounds whose identification can be essential in differentiating PRP responsibility. Figure 1 is an example of a PETREX MS soil gas sample from a landfill site where several unanticipated SVOCs were identified. Followup GC/MS analyses confirmed the SVOC compounds tentatively identified by straight mass spectrometry. Review of a survey where the application of combining the enhanced PETREX sampling system with gas chromatography/mass spectrometry is outlined in the second case history described later in this paper.

DATA INTERPRETATION

Two different interpretation strategies are used when evaluating high resolution soil gas data. All soil gas practitioners report the relative relationships between soil gas response or concentrations for a given compound or compound class in the form of a contoured map.[2-5] These maps usually represent the soil gas distribution of a predetermined target chemical or chemical class.[4,5] However, unlike those techniques relying on gas chromatographic analysis, composite mass spectrometry does not limit the types of compounds that are detectable to predetermined or standard compounds. When analyzing by mass spectrometry, it is not necessary to select a detector to optimize sensitivity for a specific class of chemicals as with a gas chromatograph. This advantage is very important when dealing with real estate conveyance surveys where site history is often sketchy and past chemical use uncertain. In addition, the extensive library of mass spectral signatures permits reasonable identification of many unknown or unanticipated compounds.

The second type of interpretative tool focuses on treating the composite VOC/SVOC response at each sampling location as a discrete soil gas Fingerprint. Once characteristic Fingerprints are identified (e.g., diesel or gasoline), the data set is modeled using computerized pattern recognition techniques to classify the balance of the survey set relative to the likelihood of being associated with that type of contaminant occurrence. One example demonstrating the use of Principal Component Analysis (PCA) in discrimination of different hydrocarbon soil gas Fingerprints is provided in the second case history described below.

CASE STUDIES

Two case histories illustrate the value of adding a high resolution soil gas method to site investigation. The information developed in both cases either: (1) is essential data that otherwise would be unrevealed or (2) could only have been supplied at a large multiple of the costs actually incurred.

OFFICE BUILDING PROPERTY CONVEYANCE

The first case involves a property acquisition. It is now common for buyers to carry out a Phase I investigation prior to purchasing property. Phase I surveys can include a variety of activities, but too frequently only include limited evaluation of three elements essential when the property is in urban areas; namely:

- Long-term land use history for the property under investigation
- Surrounding land use, both present and historical, and its potential impact on the site
- Non-invasive sampling, including off-site sampling

This case involves NERI's conduct of a Phase I study related to the acquisition of a 15 year old office building in Denver, Colorado. After discussion with the client, the scope of work was expanded by adding more extensive off-site and on-site land use evaluation, plus a phased approach for soil gas sampling. Soil gas surveying was to be deferred to a rapidly deployed Phase "IA" depending on the preliminary results of other researches.

The office building, with underground parking garage, was constructed in the mid 1970s and sold twice thereafter without any environmental assessments. Public record searches showed no on-site or off-site environmental problems within 1/2 mile or so of the site. Even though heavy commercial and some industrial activities (including industrial dry cleaners) had been located within that distance upgradient, there were no recorded CERCLA, UST, or RCRA actions in
Figure 2
Denver Office Building
PETREX Sampler Locations

evidence. Neither the State of Colorado nor the U.S. EPA data bases indicated any contamination problems nearby or on the site.

Detailed historical land use research, using newspaper and other public records at the historical society and similar agencies, revealed that during the 1940s and 1950s the site had been used extensively for the manufacture of electronic and avionic components. Combined with the off-site usage history, there was sufficient circumstantial evidence to warrant the application of a rapid and broad-based soil gas survey.

Twenty-three PETREX Samplers were installed on the site and in public rights-of-way over the entire city block following acquisition of requisite permits (Fig. 2). Samplers remained in the ground for 48 hours to obtain equilibration with soil vapors. Analysis was conducted by CpD-MS.

Two principal VOCs were identified: trichloroethylene (TCE) and tetrachloroethylene (PCE). These compounds exhibited two very different distributions. Figure 3 shows that the TCE is confined to the site and does not appear to have migrated off-site. The PCE (Fig. 4) appears to be in a broad unconfined plume extending from upgradient off-site northeasterly to downgradient off-site areas.

The soil gas results confirmed some of the suspicions raised by the historical land use search within 72 hours of learning of the potential problem.

Two monitoring wells were installed to establish whether the TCE contamination had reached groundwater and to confirm that the PCE had an off-site source. MW 1 and MW 2 soils (silts and silty sands) were sampled at 5 ft intervals from the surface to the water table (20 ft BGS). Subsequently, monitoring wells were completed and developed in each of the borings and the groundwater sampled and analyzed in NERI's laboratory.

The results are shown in Figure 5, which combines the soil gas data with the soil and groundwater results. The data indicate that the site was the source of the TCS, which apparently resulted in trace amounts of TCE reaching groundwater. The PCE however, was determined to be present only in groundwater, not in near surface soils. PCE was thus confirmed to come from an off-site source only.

This study indicates the dangers of limiting Phase I property conveyance studies, particularly in urban areas. Routine record searches failed to show actual contaminant conditions. Most environmental

regulatory agency records are useful only for the past 10-20 years, depending on the location. Both older conditions and undiscovered problems hide in extensive gaps in the records.

Only direct measurements can give reliable indicators of contamination. A high resolution soil gas method effectively fulfills this need

for sites involving a wide range of organic contaminants. Use of VOA analyzers or an HNU would not have differentiated between on-site and off-site sourced contamination.

RAILROAD YARD ASSESSMENT

The second case involved the assessment of a former railroad yard. the assessment was difficult because of the size of the property and the nature of the potential contamination. Encompassing nearly 100 acres, the site was reportedly used in the early part of the century for railroad tie treatment, storage and disposal. In addition, engine fueling and maintenance apparently were conducted on the site. The exact locations of these activities and their areal extent were less than certain.

Assessment by traditional drilling and sampling, without advance screening, were expected to be extremely expensive. However, most soil gas practitioners report difficulty in detecting such semivolatiles as creosotes and heavy fuels.[7] Following a review of reconnaissance methods, the client selected the PETREX 2-wire sampler to screen the site prior to drilling.

Seventy PETREX samplers were placed in a two-tiered reconnaissance grid across the site (Fig. 6). Spacing was approximately 100 feet in the areas suspected to be near historical sources; it expanded to approximately 200 feet in outlying areas of the site. Samplers were allowed to equilibrate with the air in the ground for approximately one week.

A review of the MS data showed two primary hydrocarbon mixtures. Each mixture exhibited a relatively consistent composition derived from upwards of 40 different hydrocarbon constituents in the range of C_5 to C_{15}. Representative mass spectra are shown in Figure 7. Figure 7A is typical of the mixtures that generally correspond to cresote. Creosote is a generic term which includes a range of hydrocarbon coal tar compounds, but in general, the more volatile of the components are aromatic hydrocarbons, naphthalene and biphenyl and the alkyl substituted derivations of both.

Principal Compounds—Diesel/fuel Sample
Derived from GC/MS Analysis of PETREX Sampler

Figure 10
Factor Spectrum Creosote vs. Diesel

Figure 7B reflects a fuel type mixture, in this case dominated by diesel fuel, but including fuel oil components as well. The mixture is largely aliphatic and alicyclic, although there are quantities of alkyl aromatic hydrocarbons. The naphthalenes and biphenyls that were found in the creosote mixture are present only at trace levels.

These general chemical characterizations were made on examination of the CpD-MS results. A number of duplicate wires were selected for CpD-GC/MS analysis to confirm these identifications. The results of each analysis were given in Figures 8 and 9, listing the primary compounds identified by GC/MS.

The Analytical results were used in conjunction with Principal Component Analysis to develop a geochemical model of each mixture. The chemistry of each "model" is illustrated in Figure 10. Mass peaks extending upwards are characteristic of the creosote. Those peaks reaching down reflect the principal discriminating components of the fuel (diesel). These correspond closely to the compounds identified in the GC/MS analysis.

It should be recognized that both mixtures contain some common compounds. This is to be expected with numerous hydrocarbon mixtures. However, PCA permits identification of those compounds which either by presence or relative abundance discriminate between mixtures.

Each individual grid sample in the data set was then compared with the model using discriminant analysis and a Similarity Value (Discriminate Function) was calculated and mapped. Geostatistics were used to determine the cutoff point. The mapped results are given in Figures 11 and 12.

Figure 11 shows an E-W zone of intense fuel (diesel) contamination lying between the two primary trackages known to have entered the site. Investigation revealed a former underground diesel storage tank at the center of the zone. Drilling and sampling near PETREX sample 69 showed 1.5 feet of free product fuel on groundwater some 8 feet below surface.

Creosote contamination is found scattered across the site, reflecting the more diffuse nature of treatment, storage and disposal of RR ties. Two areas are indicative. The first contaminated area is along both sides of the fueling area where trackage was known to run prior to site clearing. The second area was near sample 54, where soil analyses revealed low ppm levels of creosote components.

CONCLUSIONS

Rapid, high resolution soil gas surveys can effectively yield reconnaissance data regarding the presence of VOCs and many SVOCs and can then direct subsequent investigations at a fraction of the cost of traditional drilling and sampling. Soil gas surveys are extremely sensitive to low levels of such volatiles as TCE, PCE and light petroleum hydrocarbons (BTEX). The sensitivity is not projected to be as good for semivolatile compounds. Depth to sources, lithology and contaminant concentration are all limiting factors to consider.

Insufficient research data makes it impossible to firmly define the

lower limits of SVOC detection at this time. As a result, more experimentation and trial studies are required before we can confidently delineate the limits of such applications. Despite these limitations, investigators should be encouraged to carefully apply high resolution soil gas methods to such problems, being cautious to integrate sampling, analytical and statistical methods into the overall investigative programs for optimum interpretation reliability.

Geochemical Techniques for Site Characterization and Monitoring

Jeffrey B. Cange
Andrew J. Lonergan
Ebasco Environmental
Arlington, Virginia

ABSTRACT

Groundwater geochemistry data (major anions and cations) are widely used as an interpretive tool for groundwater quality and water resources studies on the regional scale. Applications in the field of contaminant hydrogeology, however, have been largely overlooked even though the analyses are inexpensive and do not require extensive validation. Ionic data were collected during hydrogeologic characterization and contaminant assessments at two hazardous waste sites (including one on the NPL) to determine the feasibility of applying these techniques on a smaller scale. The data provided useful information at each site, including delineation of variation in groundwater quality related to the introduction and migration of contaminants that were undetected through "full scale" analyses and better definition of circulation patterns in fractured rock. Hydrochemical facies were used to correlate monitored intervals in on-site wells and nearby residential wells and document variations in background groundwater quality controlled by off-site sources of contamination. The results of this study indicate that geochemical techniques should be given full consideration for the majority of site characterization/monitoring studies.

INTRODUCTION

The use of groundwater geochemistry data as an interpretive tool for characterization of groundwater quality and circulation patterns is a widely accepted practice for water resources evaluation and regional aquifer studies.[8] These techniques are not often used for contaminant-related studies that typically involve relatively small study areas, in most cases because the sampling and analysis that occurs is heavily biased toward constituents recognized by the U.S. EPA as priority pollutants or listed on its target compound list; the emphasis is nearly always on contamination rather than natural groundwater quality. This natural water quality is broadly defined on the basis of the ionic composition of the water, typically expressed as the distribution of the major anions and cations. Although standard metals analyses quantify the major cations, anionic analyses are rarely employed even though the analyses themselves are relatively inexpensive and do not require extensive validation procedures.

Interpretations of groundwater quality on the basis of ionic concentrations are usually accomplished using graphical methods. These methods require that the concentrations of the ions be converted from mg/L to milliequivalents per liter (meq/L), based on the gram formula weight of the compound and its valence. The meq/L data can be graphically plotted in several ways, following the methods of Piper,[7] Stiff,[8] or Collins.[3] The graphical representations can then be compared and used to detect and identify mixing of waters of different chemical composition and to identify some of the chemical processes that occur as natural waters circulate.[4,6] The concept of hydrochemical facies as

developed by Back[1] is a means of grouping water compositions into identifiable groups or categories. The hydrochemical facies are distinct zones that are characterized by particular compositions of anions and cations. The facies are commonly based on subdivisions of the trilinear diagram.[2] Evaluation of the different types of facies and their areal and vertical distribution in the vicinity of the sites support interpretations regarding the mixing of groundwaters.

The objective of this study was to determine the feasibility of applying these techniques on a smaller (i.e., site-level) scale. To this end, samples were collected from monitoring and/or residential wells at two sites and analyzed for major anions and cations. The resulting data were plotted graphically on trilinear diagrams and used to construct Stiff diagrams.

Monitoring well samples were collected with stainless steel bailers following purging of 3-5 well volumes and stabilization of temperature, pH and specific conductance parameters measured in the purge waters. Residential well samples were collected from taps closest to the well, in most cases at the base of the pressure tank. The residential wells were purged 10-15 minutes to remove stagnant water from the plumbing and well.

Monitoring well samples were filtered in the field with 0.45 μm filters and placed into polyethylene sample bottles. Residential well samples were not filtered. The filtered and nonfiltered samples selected for cation analyses were acidified with concentrated HNO_3 at the rate of 0.5 mL/100 mL of sample. All samples were stored in sealed ice chests and shipped to the laboratory for ion analyses. At four of the five sites, bicarbonate analyses were performed in the field using standard alkalinity titration methods.

Samples were analyzed in the laboratory for major cations and anions (except bicarbonate) in accordance with standard procedures. For the cations, atomic absorption methods were used; for the anions, ion chromatography was used. Major cations quantified included calcium (Ca^{+2}), magnesium (Mg^{+2}), sodium (Na^+) and potassium (K^+); major anions included chloride (Cl^-), bicarbonate (HCO_3^-) and sulfate (SO_4^{-2}). Nitrate (NO_3^-) was also measured at both sites and phosphate (as PO_4^-) was identified at the two Hohenfels landfills.

SITE BACKGROUND

The two sites utilized in this study are the Greenwood Chemical Company site in Virginia and the Hohenfels Training Area in the Bavarian State of West Germany.

Greenwood Chemical Company

The Greenwood Chemical site is an abandoned chemical manufacturing facility located in Albemarle County, Virginia, between the cities of Waynesboro and Charlottesville, approximately four miles east of

Rockfish Gap at the foot of Bear Den Mountain and the Blue Ridge Mountain Range (Fig. 1). The site is located on the southeastern edge of the Blue Ridge physiographic province and just west of the Piedmont province.
Figure 1
Site Location
Greenwood Chemical Company

Site History

The Greenwood Chemical Company site was investigated as part of the U.S. EPA's Superfund Program. The work discussed herein was part of the Remedial Investigation conducted at the site from 1988-1990.

The Greenwood site has extensive soil, groundwater, surface water and sediment contamination. The source of this contamination has been attributed to improper waste handling and disposal activities during the operational life of the facility, which extended from approximately 1947 until 1985. Waste handling and disposal activities centered around the five shallow lagoons (Fig. 2) used for wastewater disposal and various areas around the site used for burial of containerized waste.

Releases of hazardous chemicals to the environment have been documented over a period of at least 15 years. A direct consequence of these releases has been extensive soil and groundwater contamination over an area of approximately 7 acres. Continued release of this contamination to groundwater is occurring in response to downward percolation of precipitation waters through these contaminated soils.

Geohydrology

The bedrock at the Greenwood site consists of coarse-grain granodiorite with gneissic texture.[5] The bedrock is moderately to highly fractured at shallow depths, with decreasing fracture intensity with increasing depth. Overlying the bedrock is an unconsolidated overburden horizon comprised of colluvial soils and saprolite; its thickness ranges from zero (at an outcrop on the southern portion of the site) to nearly 100 feet in the central portion of the site.

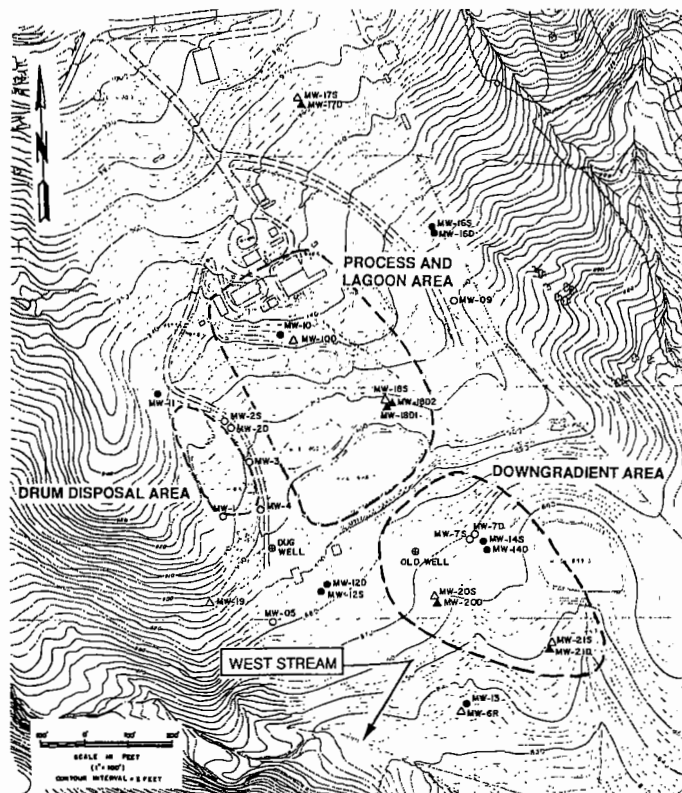
Groundwater at the Greenwood site is present in both the bedrock and overburden horizons, with the water table occurring in the overburden at depths between 5 and 35 feet below ground surface. Aquifer


Figure 2
Site Layout
Greenwood Chemical Company

test results from monitoring wells on the site indicate that these two units exhibit a high degree of hydraulic connection; however, potentiometric data indicate that the overburden is acting as a confining layer over much of the site. Groundwater flow directions in the overburden and bedrock are to the southeast, reflecting the topographic slope of the site. The vertical direction of flow is downward in the central part of the site but upward elsewhere. Discharge of groundwater from the bedrock into the overburden is followed by surface discharge of overburden groundwater near a small stream along the southern border of the Greenwood property. Flow velocities in the overburden and bedrock are estimated to average 0.04 and 0.21 feet per day, respectively.

Hohenfels

The Hohenfels Training Area is a U.S. Army installation located in central Bavaria, approximately 60 kilometers southeast of Nurnberg and 115 kilometers north of Munich (Fig. 3). The 17,800 hectare Training Area is located in the Franconian Alps geographic region, which is characterized by high limestone plains, deeply incised valleys and relatively few perennial streams or rivers.

Site History

The Training Area contains two solid waste landfills; one is active (the Operating Landfill), and the other was closed in 1965 (the Old Landfill). Both landfills are located near the main field camp, which contains the administrative, residential, logistical and maintenance facilities for the installation. Investigation of groundwater quality at the Operating and Old Landfills was undertaken in response to a request from the Bavarian State Water Authorities after volatile organic contamination was detected in a water supply well for a nearby village.

The Operating Landfill consists of approximately 4.8 hectares. The landfill has no liner, leachate collection system, or other engineered structures for the containment or diversion of leachate or run-off. There is some evidence that waste may have been placed directly on the exposed bedrock at the site. Landfilling operations at the Operating

Figure 3
Site Location
Hohenfels Landfill

Landfill began in 1965. Wastes reportedly included municipal solid waste generated by the Hohenfels military community (approximately 4,500 soldiers and their families), construction/demolition debris and wastes from vehicle maintenance activities.

The Old Landfill is approximately 1.5 kilometers north of the Operating Landfill. The landfill area comprises approximately 0.7 hectares and, similar to the operating landfill, does not have a liner, leachate collection system or other diversion systems for leachate or run-off. Landfilling operations at the Old Landfill began in the early 1940s and continued until 1965. The majority of the wastes placed in the unit were domestic refuse and construction debris. Given the period of operation for the Old Landfill, other waste types, including explosives, petroleum products and chemical wastes such as solvents also may have been placed in the landfill.

Geohydrology

The Malm Formation is the uppermost bedrock unit and principal aquifer in the Hohenfels area. It consists of thinly bedded to massive limestone which has been dolomitized to varying degrees and karstified. The Malm aquifer is confined, with groundwater occurring generally in the fractures, joints and solution cavities associated with the karst. The top of the aquifer beneath the Operating and Old Landfill occurs at a depth between 40 and 60 meters below ground surface. Groundwater flow is to the northeast with an average gradient of 0.021 (2.1%). Transmissivity values for the Malm range from 0.44 to 380 m^3/m/day. Seepage velocities ranged from 0.001 to 6.3 m/day. Groundwater geochemistry was found to be largely controlled by the limestone and dolomite of the aquifer.

DISCUSSION OF RESULTS

Results from ionic analyses of samples from Greenwood and Hohenfels were reported in concentration units of mg/L and converted to meq/L for graphical plotting and analysis. Because of space limitations, the actual concentration data are not presented here.

Greenwood Chemical

A trilinear diagram presenting ionic data from the Greenwood site is shown in Figure 4; separate trilinear diagrams for overburden and bedrock were developed. The trilinear plots show that the groundwater geochemistry is quite variable at the site. The bedrock monitoring and residential wells were classified as either calcium bicarbonate type waters (i.e., calcium and bicarbonate are the dominant cations and anions, respectively) or as calcium chloride water (due to replacement of bicarbonate by chloride as the predominant anion).

All of the bedrock monitoring wells plotted in the calcium chloride field on the trilinear diagram are contaminated with a variety of organic contaminants including trichloroethene, toluene, carbon tetrachloride and chloroform. Bedrock monitoring wells in the calcium bicarbonate field are either free of contamination or contain significantly lower levels of contaminants than do those in the calcium chloride field. The bedrock monitoring wells plotted in the calcium chloride field are directly downgradient of the principal source areas of the site.

The overburden groundwater plotted across a much wider spectrum of chemical facies, with samples falling into the calcium bicarbonate, calcium chloride and sodium chloride fields on the diagram. All of the samples classified as calcium bicarbonate-type water were from wells on the western portion of the site near the drum disposal area. The majority of the remaining overburden wells had chloride as the dominant anion and either calcium or sodium as the major cation. Three monitoring wells and an old hand-dug well on-site had sulfate as the dominant anion.

The separation of hydrochemical facies between the eastern and western portion of the site is not readily explained. The boundary between these two areas is more or less defined by a major lineament identified in a fracture-trace study completed by the U.S. EPA's Environmental Photography Interpretation Center in 1987. The presence of chloride as the dominant anion in overburden groundwater to the east of the lineament probably is due to its introduction into the environment through waste disposal activities in the process area and lagoons. The absence of chloride in wells to the west of the lineament would not be expected, given the potential for groundwater flow toward the buried drum area in response to topographic variations as well as mounding of the water table beneath the lagoons.

Evidently, the feature identified as a lineament is acting as a hydraulic barrier (in this case a drain) which is preventing groundwater on either side of the fracture-trace from mixing. The contrasting hydrochemical facies caused by the absence of chloride in the groundwater to the west of the lineament is a strong argument in support of this interpretation.

Another trend obvious from the trilinear plots is the divergent nature of bedrock and overburden water chemistry, particularly with regard to anionic constituents. The majority of these differences can probably be attributed to site-related, inorganic contaminants. Given the apparent degree of hydraulic interconnection that exists between overburden and bedrock based on pump test data, the groundwaters from these units should be more homogeneous due to the mixing that should be occurring in response to this connection. The geochemical data suggest that the mixing is not as significant as the pump test alone would suggest. The differences in chemistry are further illustrated in Figure 5, which utilizes another method of graphical interpretation[8] to present the contrast between overburden and bedrock groundwater chemistry.

A final interpretation regarding groundwater geochemistry concerns on-site bedrock monitoring wells and off-site bedrock residential wells. Groundwater at the Greenwood Chemical site is contaminated with both volatile and semivolatile TICs (Tentatively Identified Compounds), including many compounds classified as unknown constituents. Residential well data collected in 1988 and 1989 included several unknown TICs. Initially thought to be evidence of site-related contamination, these results were subsequently discounted on the basis of ionic data from the same residential wells.

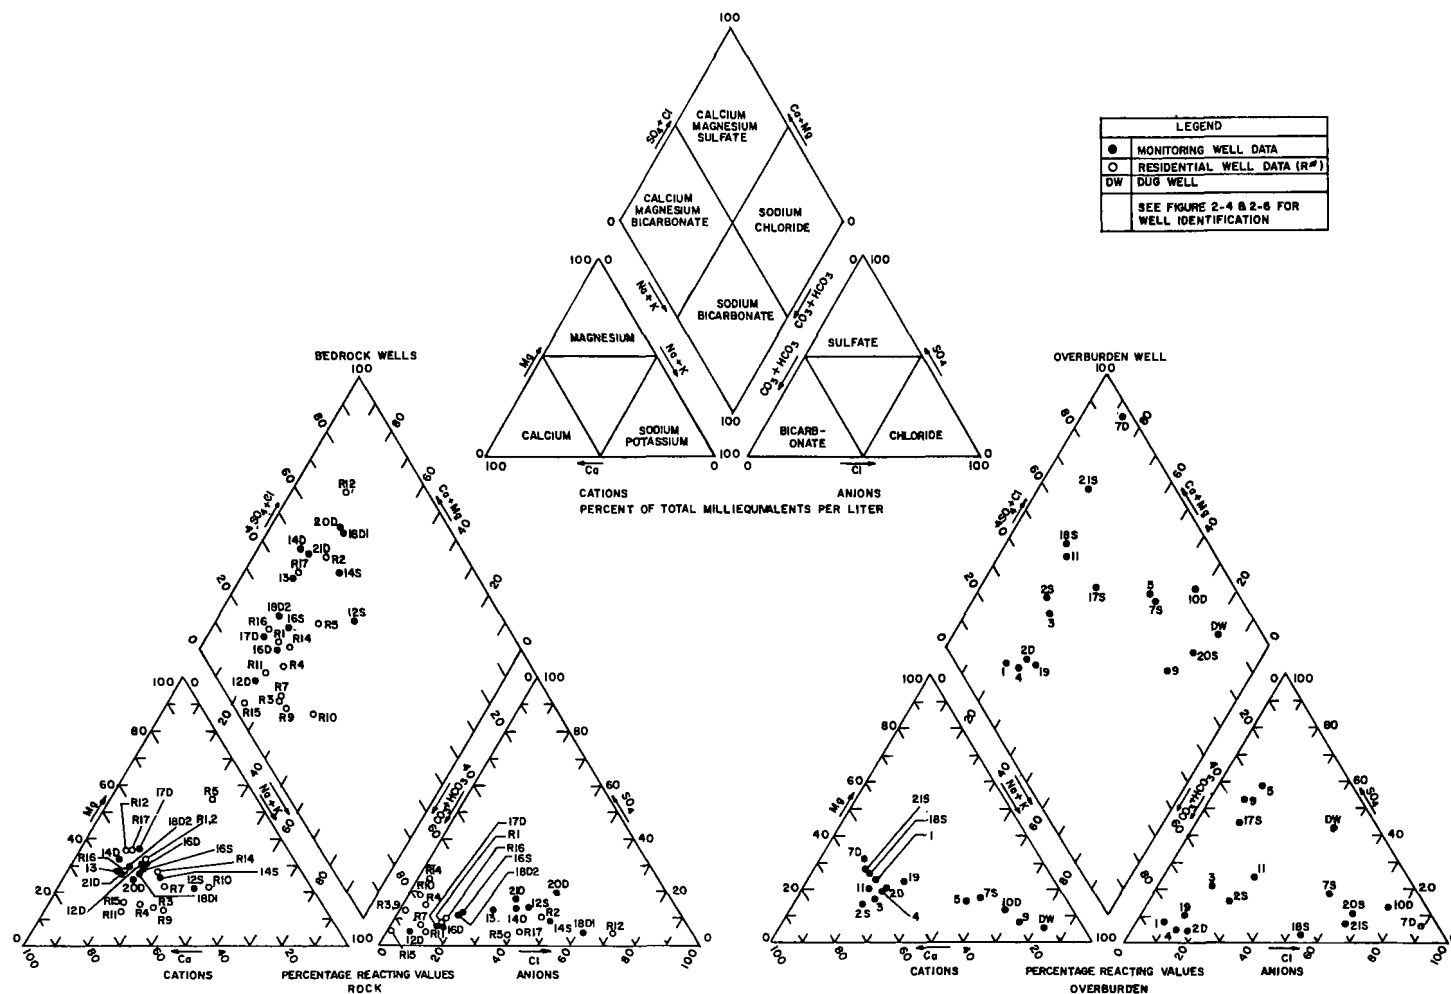
The conclusion that site-related contamination has not impacted nearby residential wells was supported by examining individual ionic concentrations in samples from the wells with TIC contamination. Certain anionic constituents are considered to be nonreactive and


Figure 4
Hydrochemical Facies
Greenwood Chemical Site

therefore capable of rapid transport by groundwater. These nonreactive constituents, specifically chloride and sulfate, are thus able to migrate faster than the organic components of the contaminant plume at the site and would likely mark the leading edge of any such plume emanating from the Greenwood site.

Most of the residential wells containing TICs were downgradient of the primary source area at the site and also downgradient of the monitoring wells with elevated chloride concentrations. The fact that the nonreactive constituents have not been detected above background levels in any of the residential wells (Fig. 6) containing unknown TICs is evidence that these compounds are not site-related and that in general site-related contamination has not affected these wells.

Hohenfels

The investigation conducted at the Hohenfels Sanitary Landfills included the analysis of organic, inorganic and water quality parameters. Water samples were collected from the six on-site monitoring wells and from two water supply wells located off-site (5 and 8 km away). The two off-site water supply wells were considered to be representative of background groundwater quality. The interpretation of these analytical results concluded that neither the Operating Landfill nor Old Landfill were contributing contamination to the groundwater of the Malm aquifer. Water quality data were instrumental in this determination, as they strongly suggested that the contamination detected in the groundwater was not site related.

At both of the landfills, low levels of organic contamination were detected in the groundwater. However, no trends were apparent in

distribution of the organics data, i.e., upgradient and downgradient wells contained similar contaminants present at similar concentrations. The two off-site water supply wells also contained similar types and concentrations of organic contaminants. These results suggested that the source of the organic contamination was not the landfills.

In contrast to the organics data, inorganic data suggested that the landfills were contributing slight amounts of heavy metal contamination to the groundwater. Results for several metals (iron, chromium, manganese, lead and nickel at the Operating Landfill) displayed a trend of increasing concentration between upgradient (B1) and downgradient monitoring wells (B2 and B3) at the Operating Landfill, suggesting that the landfill was the source of the metals. At the Old Landfill, similar concentrations of metals (chromium, lead and nickel) were present in both the upgradient (B4) and downgradient monitoring wells (B5 and B6). In all 3 wells, the concentrations were elevated relative to the concentrations detected in the two water supply wells (i.e., background). Given the uncertainty regarding groundwater flow direction at the Old Landfill (a function of the limited number of monitoring points and complex hydrogeology), the presence of contamination in an upgradient well was not wholly unexpected.

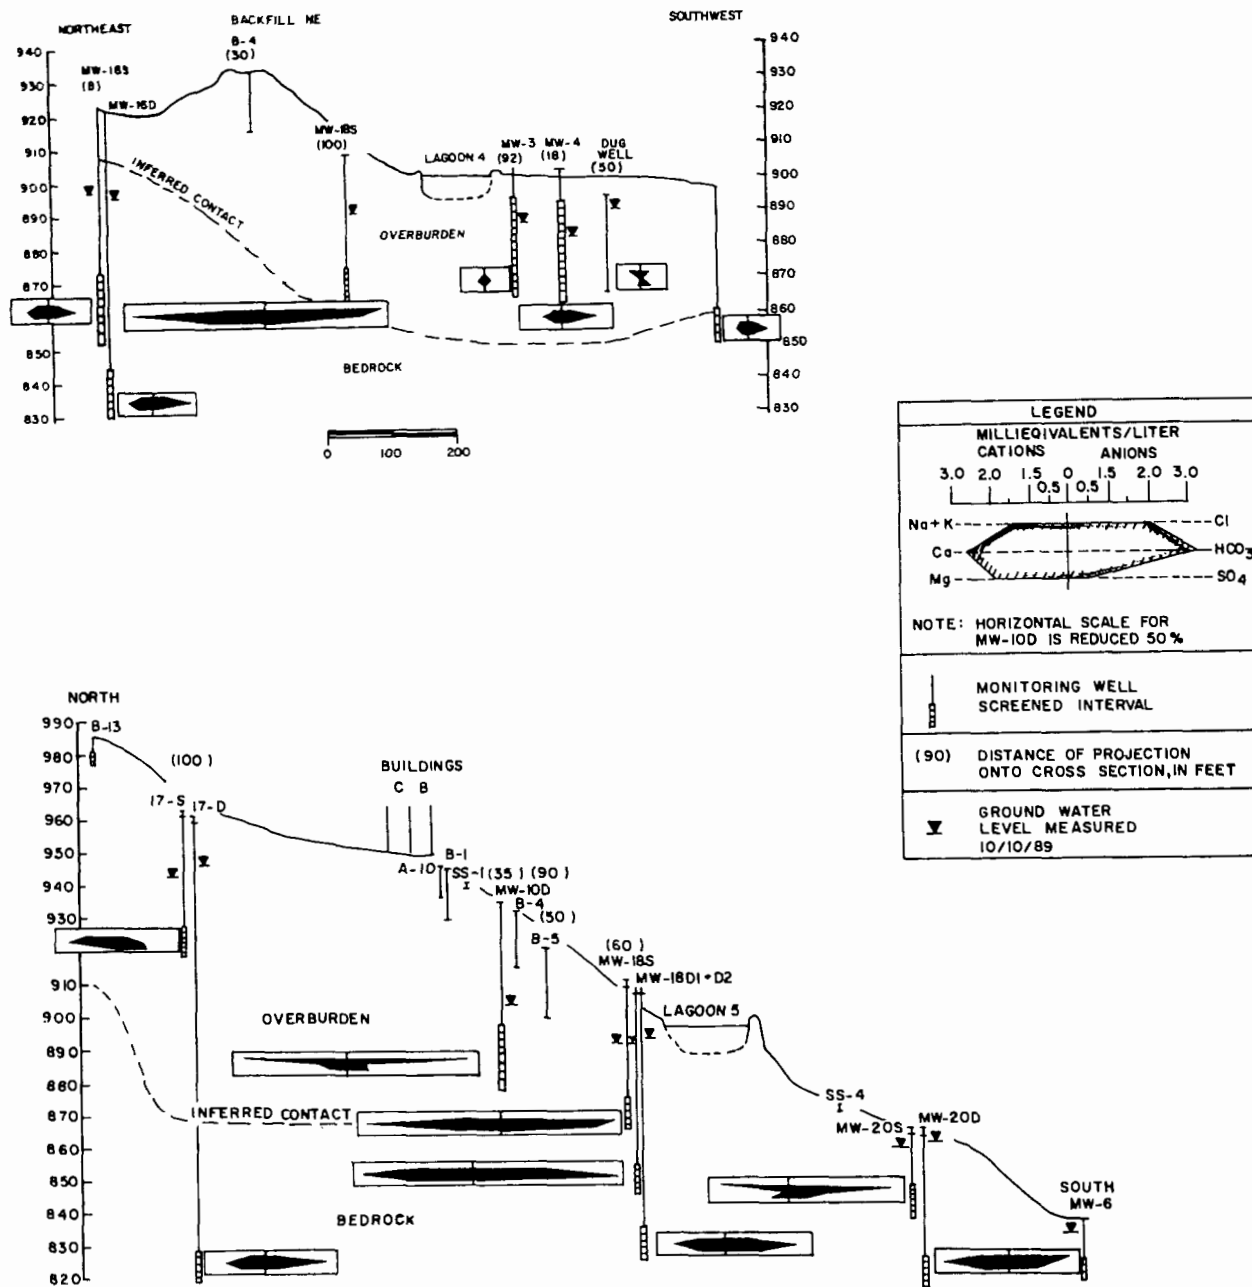
This apparent contradiction between organic and inorganic data was resolved with the use of water quality data. Figures 7 and 8 show Piper and Stiff diagrams, respectively, for the Operating Landfill and the Old Landfill. Data from the two water supply wells, considered to represent background conditions in the area, also are presented. All of the monitoring well samples collected at the site were found to have little variation with regard to geochemical composition, as indicated by the


Figure 5
Vertical Profile of Groundwater Quality
Greenwood Chemical Site

tight grouping of the samples shown on Figure 7 and the similarity of Stiff polygons shown in Figure 8. Comparison of site groundwater geochemical composition with that of the two water supply wells also indicates that the waters are very similar.

Typical landfill leachate is enriched in chloride, nitrate, phosphate and ammonium. Although there are limited data available concerning the exact types of wastes buried at the two landfills, the bulk of the material is known to be ordinary domestic waste generated by the family housing and the troop billeting facilities at the Training Area. Therefore, the composition of leachate generated by the landfills should approach that described as typical. The samples collected from two landfills and the two water supply well show virtually no difference with respect to the water quality parameters of chloride and nitrate.

The source of the metals contamination was not resolved. It is unlikely that a leachate dominated by dissolved heavy metals constituents alone would be generated at either of the landfills. Equally improbable is that an ordinary leachate is being generated, but that only the heavy metals are reaching the water table. This second scenario would require significant attenuation capacity in the vadose zone. Heavy metals are much more likely to be attenuated (e.g., through ion exchange, complexation and adsorption) than are constituents such as nitrate, chloride and sulfate. If heavy metals can migrate to the water table, so should many of the other leachate constituents. The absence of these constituents suggests that neither the Operating nor the Old Landfill are the source of the heavy metal contamination.

The organic contamination, which is present in the water supply wells

Figure 7
Piper Diagrams for Samples from Hohenfels Landfill Study
(January 1990 Data)

and both upgradient and downgradient monitoring wells from the two landfills, suggests that there has been an area-wide degradation of groundwater quality. This conclusion is supported by the water quality data which show no effects from the two landfills.

CONCLUSIONS

The application of geochemical techniques during investigation at the sites described in this paper resulted in a more accurate characterization of the hydrogeology and a better understanding of the factors controlling contaminant transport at each site. These results support the conclusion that geochemical methods should be considered for the majority of site characterization studies and contaminant assessments. The techniques may be applied best at sites where little data are available,

where residential well data have a significant impact on the overall findings and in complex hydrogeologic settings where circulation and/or migration trends are not readily apparent. The design of monitoring programs for the evaluation of remedial actions or detection of releases from hazardous or solid waste management units are additional scenarios where geochemical data can provide highly useful (and relatively inexpensive) information concerning groundwater flow and groundwater quality on the site level.

Investigations of Contract Laboratories: U.S. EPA Superfund Program Actions

Joan K. Barnes
U.S. Environmental Protection Agency
Office of Emergency and Remedial Response
Washington, D.C.

ABSTRACT

Recently, a number of laboratories under contract to the U.S. EPA's Superfund program have come under investigation for allegations of fraud. The U.S. EPA is taking action on the individual investigations, on policies and procedures related to the investigations and on further the prevention and detection of contract laboratory fraud.

INTRODUCTION

Currently, the U.S. EPA sends more than 100,000 samples a year from Superfund sites to commercial testing laboratories for analysis under Superfund's Contract Laboratory Program (CLP) contracts. The U.S. EPA's contracts with the laboratories contain extensive quality control provisions with strict limits and documentation requirements. While the CLP is not a laboratory accreditation or certification program, nor is it intended to be, other parties such as the U.S. EPA's prime contractors, states, other federal agencies and PRPs may contract independently with laboratories in the CLP for Superfund analyses they submit to the U.S. EPA. The data from these commercial laboratories are used by the U.S. EPA and these other parties in all aspects of Superfund site actions - site assessment, removal and remedial actions, enforcement and cost recovery.

Recently, some 10-17 of the approximately 100 laboratories in the CLP have become the subject of preliminary inquiries, investigations or civil or criminal actions by the U.S. EPA's Office of the Inspector General (OIG) and the Department of Justice (DOJ). These laboratories are alleged to have misrepresented the data they have submitted under their current or prior CLP contracts. Specifically, they allegedly have reported their data as having met the requirements of their contract provisions when in fact they have not. The primary examples relate to backdating and altering data to disguise time limits for analyzing the samples that were exceeded, instrument calibration requirements that were not met and results of quality control standards that were outside specification limits.

To assess the impact of this, we must first know whether or not any falsification of the testing process has in fact occurred - in most instances we only have allegations. Second we must know the nature and extent of the falsification. The falsifications may have variable or no impact on the final test result, depending on the nature and extent of the falsification in each specific instance. Finally, the impact on site decisions and actions will depend on the specific use of the data, whether results are available from other laboratories and whether independent data and information are available. The Agency is proceeding to make these determinations as the information with which to make them is made available. Only a very small percentage of the samples analyzed under the CLP is potentially affected by the allegations. Further, in the majority of cases, samples from a site were sent to a number of laboratories. The

Agency will take the actions necessary to protect public health and the environment while this matter proceeds to final resolution.

U.S. EPA SUPERFUND PROGRAM ACTIONS

The U.S. EPA's Superfund program is taking action in three major areas. It is pursuing the individual investigations of the laboratories, developing policies, procedures and guidelines related to the investigations of CLP laboratories and is implementing a data authenticity program to further prevention and detection of fraud in the CLP.

Individual Laboratory Investigations

The Superfund program has referred the allegations of fraud or laboratory self-disclosures that it has received to the Inspector General and is providing technical support to the OIG investigations and DOJ actions. We are working with other U.S. EPA offices and the OIG and DOJ to pursue criminal, civil and administrative actions. As a result, CLP samples have stopped being shipped to any laboratory that the OIG has notified us they have under investigation, five laboratories and nearly a dozen individuals have been suspended from receiving future contracts, a civil settlement with one laboratory has been reached, one individual has pleaded guilty and several indictments, pleas and settlements are pending.

Proposed Office of Solid Waste and Emergency Response (OSWER) Interim Final Policy for CLP Investigations

The proposed interim final policy outlines the actions OSWER will take to protect the integrity of data generated for OSWER's programs when a laboratory in the CLP is placed under investigation by the OIG. The provisions of the interim final policy are intended to provide the protection of OSWER's programs allowable under law and regulation, within the constraints of the criminal and civil investigative and judicial processes, while preserving the constitutional due process rights of the laboratories and the individuals. The provisions of the interim final policy, which are subject to change, are as follows:

- REPORTING
  - Report fraud allegations to the OIG
- COOPERATION
  - Cooperate with OIG investigations
- OSWER ACTION
  - Refer actions for suspension/debarment for future contracts
    Refer actions to stop CLP samples
    Refer actions to terminate CLP contracts
    Do not recommend/direct state, prime contractor,other federal agency or PRP action on their contracts
    Consider available investigation information in quality assurance project plan review/approvals

Exclude data from decisions until determine not misrepresented, unless can defend and document use
Consider referring/concurring on action to lift sample stop, suspension, etc. only when OIG/DOJ complete action

- NOTIFICATION

  Notify U.S. EPA offices of actions and information authorized by OIG/DOJ for release

  States, prime contractors, federal agencies and PRPs not notified of investigation or sample stop are notified of suspension, debarment, termination; notify states, prime contractors and other federal agencies of information authorized by OIG/DOJ for release

  Provide sample stop, suspension and other public documents upon request; will not provide Investigation Notice

  Notify states, prime contractors, federal agencies and PRPs that U.S. EPA will exclude data unless they can defend and document use

  Refer investigation inquiries from outside U.S. EPA to OIG/laboratory; give only information in public documents

  Notify all parties of completed investigation and U.S. EPA/DOJ action

The interim final policy is to be effective upon its issuance. When OSWER makes this interim final policy a final policy, it intends to issue it as a *Federal Register* Notice so that all parties involved with the CLP will be aware of the actions OSWER will take.

Other Related Policies and Guidelines

The Superfund program is also working with other Agency offices to develop guidelines that address press releases and other communications related actions. In addition, we are drafting a policy regarding the use of data from laboratories under investigation. Additional procedures and guidance will be developed as necessary.

Data Authenticity Program

To further prevent and detect fraud in the CLP, the U.S. EPA is working jointly with the Departments of Defense and Energy to identify and implement several types of measures. These measures include contract provisions related to business integrity and automated data management; oversight procedures such as tailored audits and performance indicators; and communicating the importance of data integrity, individual's responsibilities and the consequences of fraud to the laboratory community.

CONCLUSIONS

Based on the actions we have taken and the consequences to the laboratories and the individuals involved, few if any laboratories should consider misrepresenting data in the future. The Superfund program welcomes any suggestions regarding this matter.

DISCLAIMER

The proposed policies outlined in this paper are currently under Agency review and may be revised. The content of this paper is not a statement of final Agency policy and no action should be taken on the basis of it.

New Horizontal Wellbore System for Monitor and Remedial Wells

Haraldur Karlsson
Ronald Bitto
Eastman Christensen
a Baker Hughes company
Houston, Texas

ABSTRACT

This paper describes the development and field testing of an innovative drilling system for installing horizontal wells for groundwater monitoring and remediation. Detailed technical specifications and planning and operating considerations are presented. In addition, the paper suggests specific applications for the system.

INTRODUCTION

Over the last decade, horizontal drilling technology has been developed and applied in the petroleum industry for oil and gas production and in civil engineering projects for utility and pipeline installation. The oil industry has drilled more than 2000 horizontal wellbores since 1980. This experience has helped service companies develop new drilling technology and has helped oil companies gain a better understanding of how to use horizontal wells for petroleum production.[1]

In 1989, the authors initiated a research project to identify potential applications for horizontal drilling in the environmental industry. This study determined the industry's preferences for well construction, the geologic strata to be drilled, as well as requirements for well depth, overall length and borehole directional accuracy. Other considerations such as availability of suitable drilling rigs, site space limitations and acceptable operating schedules also were investigated. These efforts resulted in the general systems specifications listed in Table 1.

MAJOR DESIGN CONSIDERATIONS

Major considerations in designing the drilling system included:

Table 1
System Specifications

Depth of Horizontal Section: 18 ft to 300+ft below surface

Horizontal length: more than 500 ft

Screen size in the horizontal section: 6-inch nominal (6 5/8 in OD)

Casing size in the curve section: 10-inch nominal (10-3/4 inch OD)

Casing and screen material: High density polyethylene pipe

Horizontal Placement accuracy: True vertical depth +/- 5 ft

Azimuth: +/- 2 degrees

Pumping specifications: submersible pump ahead of screen

Seal specifications: sand pack or other filter

- Placement of horizontal sections at depths ranging from 20 ft to more than 300 ft.
- Installation of horizontal lengths of more than 500 ft
- Drilling in very unconsolidated formations
- Effective completions of the wells with a minimum 4-in. OD screen
- Operation with a minimum rig crew
- Use of noncontaminating drilling fluids (as close to fresh water as possible)
- The industry requirement to drill wells economically
- Personnel safety and protection of surface environment from contamination

CUSTOM DRILLING SYSTEM

After reviewing the available contract drilling service and hardware, the project team concluded that technology is not available within the water well and monitoring well industry to conduct horizontal drilling operations. In addition, mining and civil engineering technology do not meet the specific requirements of horizontal drilling in environmental applications. Because of these factors, an entirely new drilling system, including downhole technology and a custom slant drilling rig, would have to be designed and built for horizontal drilling in the environmental industry. The project team developed the concept by adapting advanced oilfield technology. The rig and downhole tools were designed to work as a system to drill to horizontal on a 100-ft radius (Figs. 1 and 2).

Important features of the drilling rig that resulted from this effort include:

- Capability to slant the rig mast from vertical to 60 degrees in 15-degree increments. Figure 3 shows how this capability enables the drilling system to place the horizontal section at any depth in this range.
Figure 1
Horizontal Wellbore System Schematic
VIEW AT REAR OF TRAILERS
Figure 2
Horizontal Wellbore System Drilling Rig

- The rig is hydraulically operated for precise, automated control from a single driller's console. Rated at 2000 ft for vertical drilling, the unit has a hoisting capacity of 70,000 lb and 30,000 lb of push down capability. This gives the rig ample power for handling the system's dual drill string which may encounter significant torque and drag during horizontal drilling.
- Pipe handling is accomplished with a hydraulic pipe-handling arm and two hydraulic top drives: one for the casing and one for the drill pipe. In addition, a power tong makeup and break-out unit is incorporated for making/breaking connections. Casing tongs are provided to hold the well casing when required.
- The drilling unit's fluid system—with mud pumps, fluid tanks, solid control equipment and a grouting machine—is included in a single trailer. The circulation takes place in a closed loop and requires no earthen mud pits. At the conclusion of the job, drilling fluids and cuttings can be placed in drums for disposal.
- Rig operation requires only a three-man crew per shift, with a project engineer supervising the job.
- Pipe storage, rig-site office and electrical generator are housed in a third trailer. The site office has a computer; the office area can also be used as a laboratory as needed. The generator provides power for lights used for nighttime drilling. A small crane, mounted on the trailer, is used to move drill pipe and casing.
- All three trailers that comprise the drilling unit can be transported without special permits on highways in the contiguous 48 states.

DOWNHOLE DRILLING EQUIPMENT

Like the drilling rig, the downhole system also had to be specifically engineered to solve the unique problems associated with horizontal drilling in shallow, unconsolidated formations. The downhole drilling assembly is comprised of a dual drill string; a hydraulic downhole motor; an expanding drill bit; and a toolface indicator/inclination measurement device. (Fig. 4).

The unique drilling assembly was designed to address the problems of drilling horizontally through unconsolidated and heterogeneous formations found near the surface. Such strata make it difficult to maintain hole integrity, even in vertical drilling. In horizontal drilling, there is an even greater risk of hole collapse. This is especially true in environmental drilling applications where most drilling fluid additives are avoided. In such conditions, the horizontal hole could be lost when the drilling assembly is changed or during installation of completion hardware
Figure 3
Layout and Depth Capability
Figure 4
Horizontal Drilling Downhole Equipment

A new casing/drilling method was developed to solve this problem. An inner string of 2.875-in. drill pipe pushes the high density polyethylene (HDPE) casing/well screen into place. This casing protects the hole from cave-in during drilling and installs the well casing at the same time. (HDPE was chosen because of its unique physical properties including strength, flexibility and resistance to damage from a broad range of chemical contaminants.) The casing is centralized in the hole to permit cementing and effective well completion. Once the well is drilled to total depth, the inner drilling assembly is withdrawn from the hole and the casing is left in place.

Downhole power and the ability to guide the hole are provided by a steerable downhole hydraulic motor. The motor is based on the oilfield positive displacement moineau motor concept which converts the hydraulic energy of the pumped drilling fluid into mechanical energy (speed and torque) that rotates the bit. However, it is an especially-designed multilobed motor that is approximately one fifth the length of oilfield tools. Flowrates range from 150 to 300 gpm, generating 35 to 75 hp at the bit.

Directional drilling is accomplished by placing the motor in an eccentric position in relation to the hole axis by installing stabilizer rings at two points on the motor housing. (Fig. 5). These eccentric stabilizers are positionally matched with the concentric stabilizers in the lowest
Figure 5

$$Radius\ (R) = \frac{L_1 + L_2}{2\,Sin\,(\emptyset)}$$

$$Build\text{-}up\ Rate\ (BUR) = \frac{2\emptyset}{L_1 + L_2}$$
Figure 6
Calculation of Buildup Rates

joint of outer casing. By orienting the direction of the bit offset (also called "toolface"), the hole can be steered. The configuration of the drilling assembly is designed to turn the borehole at a constant rate which can be precisely calculated (Fig. 6). The two stabilizers and the bit gauge serve as tangency points that define a constant radius arc along which the assembly will be drilled. Build rate can be controlled by varying the eccentricity of the inner stabilizers. The system can be used to drill a straight course by regularly adjusting the toolface from side to side.[2]

The downhole drilling system features an expanding drill bit which drills a hole that is large enough to permit the casing to be installed during drilling. The bit used in the curved section drills a 12.25-in. hole for installation of 10.75-in. OD casing, and the bit used in the horizontal section drills an 8.625-in. hole to permit running a 6.625-in. OD casing/ well screen and providing space for gravel packing around the screen. The initial bits used with the system were drag-type bits with hydraulically-spread wings and tungsten carbide cutting surfaces. Other drill bits, in development, will include roller-cone bit technology for drilling harder formations and glacial till.

The toolface indicator system is a mud-pulse telemetry system which measures inclination from vertical and toolface orientation and transmits the measurements to the surface via pressure pulses in the drilling fluid. These pulses are detected at the surface by a pressure transducer, whose readings are interpreted by a surface control computer. The toolface indicator sensors are located just 8 ft above the drill bit, giving system operators the ability to monitor the drill bit's position and wellbore trajectory every 15 sec. The TFI therefore saves a significant amount of time that would be required for single shot surveys, while eliminating the complication and risk associated with electric wireline steering tool devices commonly used in petroleum drilling and river-crossing applications.

DRILLING PROCESS

Before drilling begins, wells are carefully engineered to meet the specific objectives of the project. Site characterization studies, including monitor well data, are reviewed to determine the size and three-dimensional position of the contaminant plume. Groundwater flow and contaminant migration characteristics are analyzed to assure proper well placement. Next, surface location and operational factors are considered. Then, the depth and direction of the horizontal wellbore, screen length, development and pumping methods are determined.

The rig is moved onto location and aligned to drill the horizontal wellbore in the desired direction. The angle of the rig's mast is adjusted to drill the horizontal section at the proper depth.

A 14-in. hole is augered 5 to 10 ft into the soil and a 12.75-in. conductor is set and cemented in place to provide a controlled conduit for the drilling fluid.

A straight drilling assembly is lowered in the hole to drill to the required depth so that the 100-ft radius curve will reach horizontal at the desired vertical depth. Once this depth is reached, the assembly is withdrawn and the curve drilling assembly is picked up and run into the hole.

The curve is drilled in a 12.125-in. hole and case at the same time with 10.75-in. casing. The assembly is oriented in the proper direction using the toolface indicator and by holding orientation at the surface. The same survey tool is used to track the progress of the assembly. After the 20 ft lengths of dual drill string are drilled into the hole, both components of the dual drill string are added simultaneously with the articulated pipe handling system in the rig mast. Once the curve reaches horizontal, the inner assembly is withdrawn leaving the 10.75-in. HDPE in place.

A cementing plug is then run into the hole to seal the end of the casing and to allow the cement grout to be circulated through the drill string to fill the annular space between the casing and the hole wall. Once the desired amount of cement is in place, the drill pipe is withdrawn from the well and the grout is allowed to set. The grout will provide structural support to the casing as well as prevent the migration of contaminants from one zone to another along the outside of the casing.

The plug is drilled out with a special mill on a downhole motor until the formation is encountered. This assembly is then retrieved, and the horizontal drilling assembly is run into the hole.

As mentioned above, the system uses an 8.625-in. bit to drill the horizontal section. A 6.625-in. OD HDPE screen is pulled into the lateral wellbore by the drilling assembly as the well is drilled. The system is steerable for course corrections and fine tuning of the horizontal section. Steering capability is provided by the hydraulic downhole motor, by stabilizers on the casing and by survey instrumentation.

Formation evaluation is accomplished at desired intervals using a core, soil or gas sampler. Drilling is stopped and the inner assembly consisting of the bit, motor and drill pipe is retrieved from inside the slotted liner. The bit and motor are replaced by the sampling tool and run into the hole. The sampling tool is then drilled into the formation the required depth and samples are retrieved. Shelby-tube and soil gas sampling devices also are in a testing phase.

Drilling continues with the horizontal drilling assembly until the desired displacement is achieved. The inner drilling assembly is then retrieved leaving the 6-in. screen in place.

A combination plug running tool, wash sub is run into the ID of the 6.625-in. casing, and a plug is placed at the bottom of the screen. The screen is then washed by circulating fluid through the inner string and out through the nozzles of the wash sub. These nozzles are aimed radially outward to clean the screen to remove any drill cuttings plugging the screen slots or remaining in the wellbore. Once the hole is clean, the wash sub is removed and the string is run back into the hole for the filter packing procedure, should a filter be required between the screen and the wellbore.
Figure 7
Typical Well Construction

Filter packing is performed using low density materials and a special gravel directing device to assure a uniform layer around the screen. The material is put in place by circulating the packing material suspended in water down through the annulus. As the water passes through the screen to enter the inner string, the filter packing material is screened out, filling the volume between the screen and the wellbore.

Once the filter packing is complete, a submersible pump can be lowered into the well to complete the development. Typical well construction is shown in Figure 7.

An alternative completion method involves using well screen in the horizontal section which has an additional layer of fine mesh well screen to provide sand control, in lieu of the gravel packing. In the right formations, this completion method can cut a day off the well installation process.

A variety of other completion methods are being investigated. In cases where the horizontal section is placed in bedrock, the well can be drilled without the outer casing string, and the desired production hardware, for example stainless steel or wire-wrapped screens, can then be run.

FIELD TEST OBJECTIVES

The prototype horizontal wellbore system underwent its first field trials in the summer of 1990, southeast of Houston, Texas. The objectives of the field test were to:

- Test the functionality of the surface equipment, including rig system components and circulating system.
- Drill a 45-ft vertical hole to demonstrate casing while drilling; to test the functionality of the expanding drill bit; and to gain experience making a hole in the target formation.
- Drill a horizontal hole with approximately 400 ft of departure from the wellhead. This included drilling from a 45-degree slanted rig position and building the hole's inclination along a 100-ft radius. This curved section would be drilled in 12.125-in. hole and cased in 10.75-in HDPE casing, which would then be cemented in place. Then the smaller drilling assembly would be used to drill the horizontal section and install the 6.625-in. liner simultaneously.
- Complete the horizontal section by pumping HDPE gravel packing material into the annulus between the casing and the hole wall.
- During test well drilling, project engineers would monitor the performance of system components, noting areas for improvement.

FIELD TEST PREPARATION

To prepare for the test, a vertical surface hole 12-ft deep was augered and the 12.75-in. conductor was set and cemented in place. A slanted conductor was installed at 45 degrees, close to the vertical hole and positioned so the rig would not have to be moved to drill through it. Once this slanted conductor was cemented in place, an unstabilized rotary assembly with a roller cone bit was used to drill the cement plug and approximately 4 ft of the formation.

VERTICAL HOLE

The vertical hole was drilled with a bottomhole assembly comprised of the 8.625-in expanding bit, a 4.75-in. drilling motor placed con-

centrically in the casing and a 6.625-in. well casing. The hole was drilled to 60 ft in 1 hr, at a flowrate of 150 gpm. The casing easily ran into the hole, demonstrating that the motor/expanding bit concept could successfully be applied.

The formation was a fine, unconsolidated sand, interspersed with clay stringers. Pockets of gravel also were encountered.

When the drilling assembly was pulled out of the hole, the HDPE casing string came with it. Sand had been drawn into the casing causing the motor to jam. Some simple modifications, such as beveling the edges of the eccentric stabilizer rings, were made to facilitate releasing the motor from the lower casing joint.

DIRECTIONAL WELL

The first borehole drilled from a slanted conductor demonstrated the directional drilling capabilities of the downhole system. Drilling parameters and operating procedures were varied to test directional results.

After the vertical hole was drilled, the rig mast was tilted to 45 degrees in preparation for drilling the horizontal hole. Then the 6.75-in. motor assembly was made up and inserted in the plastic casing, and together they were lowered into the conductor.

After orienting toolface to high side (for maximum angle build), drilling circulation was begun at 200 gpm. However, the motor stalled almost immediately. It was surmised that this problem was caused by the condition of the conductor pipe, which still contained some cement which had not been cleaned out. The assembly was retrieved from the hole along with the casing and a stiff assembly, including a 12.125-in. bit and two stabilizers, was used to drill from the conductor (12 ft MD) to 16 ft MD, providing a straight pathway for the curve-drilling assembly to enter the formation.

The curve drilling assembly with casing was run into the hole. The motor was started with a flow rate of 150 gpm, and the assembly was worked up and down until it ran smoothly into the hole. Drilling commenced at 4 ft/min. Because there was no identifiable torque created by the motor, it is likely that the formation was being jetted away ahead of the bit. The formation was an unconsolidated, very fine sand.
Figure 8
Plot of Directional Test Well

The assembly drilled to 42 ft, but dropped angle at the rate of 0.58 degrees/ft.

Below 42 ft MD, the penetration rate increased to 3.5 ft/min, but the hole continued to drop angle at 0.27 degrees/ft over the next joint to 62 ft MD.

On the next joint, the flow rate was reduced to 150 gpm and the penetration rate dropped to 2.5 ft/min. Over this hole section, the assembly began to build angle at the rate of 0.43 degrees/ft. Some clay was seen for the first time in the return flow of drilling fluid.

Because the reduced flowrate appeared to help regain control over the angle build, it was concluded that the fluid was washing the hole diameter. To reduce these effects, the inner string was tripped out of the hole. The outer-facing bit nozzles (which had been 0.438-in.) were plugged and the forward facing nozzles (previously 0.576-in.) were replaced with 0.625-in. nozzles.

The drilling assembly was placed back inside, and drilling was commenced with 150 gpm of circulation. ROP of 3 to 4 ft/min was achieved. The assembly built angle at 0.36 degrees/ft (159 ft radius).

On the next joint (102 to 122 ft MD), the flowrate was increased to 200 gpm to improve hole cleaning. The penetration rate increased to 4 ft/minute, and the build rate increased to 0.54 degrees/ft. (106-ft radius). At a measured depth of 136 ft (96 ft True Vertical depth TVD), the hole had achieved 52.2 degrees of inclination. (Fig. 8).

Changing the bit nozzles had significantly improved the directional performance of the bottomhole assembly. Armed with this knowledge, the project team decided to start a new well with a newly-installed slanted conductor. Casing from the slanted well would be pulled from the hole for reuse on the second attempt, after installing new threaded HDPE connections using fusion welding techniques.

HORIZONTAL WELLBORE

A second slanted conductor was augered into place approximately 8 ft north of the first one and cemented into place. After moving the rig, the stabilized rotary drilling assembly was used to drill out the cement plug and establish contact with the formation.

The curve-drilling BHA used on this borehole varied from that used on the directional well in that: (1) the outside bit nozzles were plugged and two 0.625-in. nozzles were used at the nose of the bit, resulting in no hydraulic horsepower at the bit and less hole enlargement; and (2) an increased bit deflection (caused by greater eccentricity of the stabilizers on the motor body) was used, resulting in an assembly with a theoretical 90-ft turning radius (compared to the 100-ft radius used on the directional well).

As in the slant well, it was difficult to build angle in the soft formation immediately below the conductor. The well dropped angle slightly as the first joint was drilled, then held angle to approximately 63 ft MD. Then the assembly began building angle steadily, reaching 80 degrees of inclination at 150 ft MD (87 ft TVD), the end of the 10.75-in. casing section.

Due to the low flowrate, pulse heights from the TFI tool had been adjusted to improve the strength of the signal. This system performed impeccably while drilling the curved section.

Some hole drag and compressive buckling of the casing were experienced during the drilling of the curve, possibly due to clay and gravel stringers or to some spiralling of the hole. The drilling assembly was pulled easily from the casing string, and the casing did not move.

The curved casing was cemented into place through the drill pipe by setting a cement plug, dropping a dart and then pumping cement until it came out the annulus. Once the cement had cured, a downhole motor-driven milling assembly was used to mill out the plug and retrieve it. A ring left in the hole was retrieved in one try with a specially-built fishing tool. After a cleanup trip, the project team was ready to drill the horizontal section.

The downhole system comprised of an 8.625-in. expandable bit, 4.75-in. drilling motor, TFI measuring device and 2.875-in. drill pipe was run into the hole along with the 6.625-in. HDPE slotted screen.

Once on the bottom, the drilling assembly began to drill immediately with no stalling or sticking. At a flowrate of 150 gpm, the system drilled at 2 to 3 ft/min. It was found that pump rates have a significant affect

on hole inclination. When flow rate was increased to 250 gpm to improve hole cleaning, inclination dropped by 8 degrees while drilling one 20-ft joint.

By orienting the toolface upwards and holding pump rate steady at 150 to 175 gpm, angle was built to horizontal and maintained until 400 ft of total departure was achieved. (Fig. 9). Some hole sticking was experienced, but these problems were overcome by picking up approximately 6 ft off bottom to ream and circulate. The project team believed they could drill further, but drilling was stopped because all test objectives had been met.
Figure 9
Plot of Horizontal Test Well

Once total depth was reached, the drilling assembly was withdrawn from the hole. Sand drawn into the hole through the open end caused some sticking on this outward trip, but after working the pipe up and down and circulating a little, all tools were successfully pulled from the hole.

COMPLETION

One technical objective of the field test was to prove that a slotted casing could be drilled in—place using the dual string drilling technique. This operation was successfully performed with slotted casing used from surface to total depth.

Several days after drilling was completed, a gravel packing procedure was attempted on the well. First a plug was set in the bottom of the well, and a wash sub, run on the drill pipe, was used to clean the well slots (which were 0.020-in. wide) only in the horizontal section. Pumps and seals were configured to reverse-circulate 0.125-in. HDPE pellets into the annulus between the well screen and the formation. When pumping commenced, it was found that the hole wall had bridged into the casing somewhere in the curve above the horizontal section, preventing gravel packing material from reaching the bottom of the hole. Work continues toward perfecting this gravel packing techniue. Future gravel packing operations, for example, probably will use slotted screen only in the zones of interest.

The project team also has investigated completion techniques that are less complicated than the gravel-packing method. Specifically, a new completion string, incorporating a screen outside the HDPE slotted casing, has been designed and introduced since the initial field test. This system should provide adequate sand control in most situations.

APPLICATIONS

This recently demonstrated horizontal drilling technology has many potential applications in the environmental industry. For example, there are numerous "common sense" applications for horizontal drilling, including recovery of contaminated groundwater or leachate from beneath lagoons, landfills, buildings, storage tanks, refineries and chemical plants. (Fig. 10) In these cases. it is difficult to place vertical wells to perform sampling or remediation.

In other situations, where vertical wells now are used to extract polluted groundwater for treatment, horizontal wells can offer significant advantages. By placing a long horizontal section through the contaminant plume, a single horizontal well may replace many vertical wells, while also reducing clean-up time.[3]
Figure 10
Horizontal Well Used To Sample
and Remediate Beneath Obstacles
Figure 11
Horizontal Well Used for Soil Gas Extraction

Soil gas extraction is another important potential application for horizontal wells. Figure 11 shows how pairs of horizontal wells can be drilled at different depths. The lower well could be used to inject air, while the upper well could be used to extract the air stream along with VOCs that have been stripped from the soil.[4]

In situ remediation also may benefit from horizontal drilling technology. For example, horizontal wells might be used to convey microbes and/or nutrients for bioremediation of underground contaminants. Likewise, horizontal wells might make it possible to chemically treat heavy metals in-place without incurring the expense and hazards of digging up contaminated soils. Horizontal wells also could be used for in situ vitrification of nuclear waste. In this application, the drilling system would bore a pathway for electrical conductors to turn hazardous waste into glass.

Horizontal wells also could be applied at landfills and other areas where a barrier must be installed to keep pollutants from migrating into the groundwater. A series of horizontal wells beneath a landfill or a lagoon, for example, could be used to place a pressure curtain of pumped air or water, or a floor of grout, epoxy or cement to contain the potentially harmful leachate.

During our technical review, many potential users requested the capability to take samples of soil gas, soil and bedrock from beneath landfills, lagoons, tanks and buildings. In these situations, vertical methods are either impossible, inconvenient or pose a threat to the environment by providing contaminants a pathway into the aquifer. Horizontal drilling systems can be applied to handle the majority of these sampling needs.

In the future, other technologies are likely to be added to the horizontal wellbore system. These innovations could include methods for obtaining undisturbed formation samples and containerized gas samples beneath landfills and buildings; geophysical logging services adapted for horizontal data acquisition; and completion technology to isolate zones along the horizontal well for selective sampling and completion.

CONCLUSION

In conclusion, a new horizontal drilling and sampling system has been designed and built to meet the special requirements of the environmental industry. A prototype system has been successfully field tested and has been refined and introduced for commercial use. We believe there will be many applications for the new system as the environmental industry begins to remediate contaminated groundwater.

New Technique For Landfill Leachate Well Installation

Robert G. Hornsby, PE
AWD Technologies, Inc.
Houston, Texas

Michael S. Miller, MS
CECOS International, Inc.
Livingston, Louisiana

INTRODUCTION

Landfilling of industrial wastes has been used extensively as a means of disposal throughout the United States. Prior to RCRA, many landfills were little more than excavated trenches. Although some attention may have been given to engineering concepts and long-term environmental/operational aspects, often they were not fully developed during the construction and filling of such trenches. With the passing of time, one aspect of land management that has been given major emphasis is the concept of water (leachate) management within a landfill. Indeed, leachate treatment has risen to such importance that waste management facilities succeed or fail based on the quality of their leachate management efforts, as judged by groundwater quality around the landfill.

The CECOS International Inc. facility near Livingston, Louisiana, has three pre-RCRA disposal units (landfills) that were designed, constructed and closed by a previous owner. These disposal units were constructed without any type of leachate removal system.

During 1984 and 1985, samples from two nearby monitor wells revealed evidence of groundwater contamination in the area, principally in the shallow (30 foot) zone. A one-year, state-approved groundwater assessment revealed the nature and extent of groundwater contamination. Later, the Louisiana Department of Environmental Quality (LDEQ) approved a remedial action plan (RAP) for this area that included:

- Installation of an engineered slurry wall surrounding the disposal units to isolate the shallow groundwater regime
- Placement of an engineered cap over the units to prevent rainwater infiltration
- Installation of several recovery wells inside the units to facilitate removal of leachate

While efforts are now underway to provide for removal of impacted groundwater in the vicinity of these old wells, the long-term solution is to reduce or, to the greatest extent possible, eliminate the liquid volume inside the cells.

This paper deals with the installation of 16 leachate recovery wells inside the pre-RCRA disposal units.

CONSIDERATIONS

The well installation method selected was required to meet the following criteria:

- Reduced Health and Safety problems: Waste inventories for the pre-RCRA disposal units were given in general terms. Because of the nature of these records, the contents of the disposal units were largely unknown. Costs for personnel protection, if significant amounts of waste material were exhumed, were estimated at $1,000/day.
- Minimized waste generation: Conventional drilling techniques could potentially bring up to the surface substantial volumes of wastes.

Disposal costs were estimated at $1,000 per drum of waste exhumed.
- Reduced risk to the environment during installation: Exhumed wastes could pose a threat to human health and the immediate environment and contaminate the newly placed composite cap.
- Assured uniform sandpack: An effective recovery system required installation of a uniform sandpack in the loosely compacted fill material, which could have collapsed into an open hole. Since it was known that a substantial portion of the inventory was drummed, placement of a conventional sandpack might have been very difficult.

Drillers proposed several approaches for achieving the requirements stated above:

- Conventional hollow stem auger as the sole means
- Hollow stem auger as the primary technique, with a driving technique as a secondary means
- A driving technique to be used as the sole means.

Bids from prospective drillers ranged from $100,000 to $125,000 for the entire job, exclusive of additional personnel protection or monitoring.

AWD Technologies, Inc., a wholly owned subsidiary of The Dow Chemical Company, proposed to install the entire system using an innovative method of driving pipe. CECOS was led to this technique through a conversation about the project with the Louisiana Department of Environmental Quality. The Dow Chemical Company plant in Plaquemine, Louisiana, had used the method to install 236 recovery wells in contaminated soils.

SELECTION

The "driving" technique for well installation was chosen for the following reasons:

- Time: This method was estimated to take 16 days (conservatively) in contrast to a minimum of 30 days using conventional drilling techniques.
- Waste reduction: AWD's previous experience had shown the method capable of substantial reductions in volumes of waste generated.
- Health/Safety: Due to minimal waste production, the method greatly reduces the need for extensive Health and Safety equipment and monitoring.
- Obstructions: The method works even where obstacles, such as drums, are encountered.
- Sandpack: The method would allow the installation of a prepacked well screen, thus providing some assurance of a functional pack.
- Cost: All of the above factors have the potential to keep the cost of installation to an acceptable level.

SAFETY

The entire area immediately around the landfills was secured and

designated as a restricted work area. Further, a 40-foot diameter "exclusion" area was established around each borehole. Anyone working in this area had to wear all personal protective equipment (PPE) recommended by the Health and Safety Officer. Areas were designated for decontaminating PPE as well as for rest breaks.

A preconstruction meeting was held to fully brief all crew members on the project objective, Health and Safety requirements, management structure and communications procedures.

The work was started in modified level C protection; i.e., Sanarex suits, steel-toed rubber boots, rubber gloves taped to the suits and full-face cartridge respirators. A large portable fan placed approximately 20 feet from the borehole provided air movement across the work area.

When the first casing was set in clay at the bottom of the landfill, the Health and Safety officer removed the push cap, sampled the air, detected no appreciable volatile organic carbons (VOCs), and approved the use of level D protection for the remaining wells. Careful monitoring was continued to detect any need to upgrade the personal protection.

The entire project was coordinated by CECOS.

EQUIPMENT AND MATERIALS

Three pieces of equipment were required during the installation process: a back-hoe (CAT 245 or equivalent), a 50-ton crane and a manlift.

Several specialized tools were developed by Ray Frankson and Charles Oliver of The Dow Chemical Company to implement this procedure. The key components were a thread-jointed casing that allows installation to various depths and an internal thread-jointed driving tool that could be removed once the casing reaches the desired depth. Shackling facilitates extracting the casing and driving tool from the ground and moving the apparatus to a new location (Fig. 1).

Figure 1
Well Installation Tool

INSTALLATION

Prior to beginning work, all equipment was positioned to maximize use of time and effort.

Well installation began with assembling the outer casing pipe. The inner "insert" with the driving point was assembled next. The back-hoe held the casing in a vertical position while the driving insert was slowly lowered into the casing using the crane. Once this was accomplished, a flat, threaded pressure plate was attached to the outer pipe and the back-hoe then pushed both pipes into the ground at the same time (Fig. 2). When the desired depth was reached, the insert with the point was removed and replaced by another insert which had a hollow sampling tube at the bottom (Fig. 3). When this sample tube was positioned inside the casing pipe, both pipes were again pushed approximately one foot to obtain a sample to verify that the well was seated in clay at the bottom of the landfill. The sampling tube was

Figure 2
Back-Hoe Pushes Pipes Into Ground

removed from the insert and transported in a 55-gallon drum to an extruder in order to push the sample out, monitor organic vapors and perform visual classification of the material.

At this point, only the outer drive pipe remained in the ground (Fig. 4). The fiberglass reinforced epoxy (FRE) well casing with a presanded screen was then assembled and lowered in sections using a detachable grommet at the top of each section (Fig. 5). Once the complete well was installed, the outer pipe was slowly pulled out of the ground. As this casing was removed, crew members scraped residual materials from the outside surface using special tools. These scrapings (waste material and clay) generally amounted to no more than 1 gallon of material per well. Scrapings and coring samples were containerized as the work progressed.

Since the outer pipe was somewhat larger than the presanded well casing, the annular space was filled with sand. Because the entire depths of waste (20 to 25 feet) were screened, the bentonite seal was placed on the lower level of the engineered cap. Water was added to the pellets, and the bentonite was allowed to hydrate at least overnight. The grout plug was completed the next day (Fig. 6).

Leachate was pumped from each well. An average of one well volume of liquid was removed per well. All wells produced water. As expected, recovery rates varied because of the heterogeneity of landfill materials.

To complete the installation and comply with state regulations, a 12-inch diameter steel protective pipe was driven into the ground, and later the final well shroud and concrete slab were placed around it.

Completed, Grouted Well

CONTAMINATED GROUNDWATER CONTROL & WELL TYPES 365

DECONTAMINATION

During breaks and at the close of each day, all working personnel removed soiled personal protective equipment (PPE) prior to leaving the work area. Their boots were washed and stored for reuse. All PPE waste, including decontamination water, was containerized and stored on-site awaiting disposal.

After well installations were completed, the drive pipe and tools were cleaned using a pressure steam cleaner in a secure containment area on-site. All the water generated in this manner was containerized.

CONCLUSIONS

Overall, the installation method fulfilled our expectations. The entire well installation took 8 working days to complete, for an average of two wells per day. It met our Health and Safety, waste volume, environmental risk and uniform sandpack expectations.

- Health and Safety concerns were minimal. We found that, with few exceptions, virtually all work could be completed using Level D protection.
- The volume of waste produced by the well installation was extremely low. The core samples and casing scrapings were the only well installation wastes directly produced. The waste containers which required sampling prior to disposal were:

Decontaminated water	330 gallons
Personnel protective equipment & water	715 gallons
Soil cores	25 gallons
Leachate	440 gallons

Each waste type was sampled and submitted to a laboratory for analyses of full Appendix 3 plus EP-tox parameters. The results verified that all of the wastes generated could be disposed of on-site.

- The environmental risk was very low. Since the only drilling waste was the clay core samples and the very small amount of material adhering to the casing, contamination of the new clay cap did not occur.
- A uniform sandpack was guaranteed through the use of a presanded well screen. The loose sand added when the casing was removed served only to fill any voids.

All the leachate wells have water in them, and it appears that they will function adequately. We are in the process of constructing a treatment and storage facility to manage the liquids to be extracted for off-site disposal. Once this system is in service, the long-term effectiveness of the wells can be quantified.

This well installation method should be considered in situations requiring the following:

- Expedited installation
- Greatly reduced Health and Safety concerns
- Reduced disposal costs
- Reduced potential for adverse environmental impact
- Comparable installation costs.

The choice of this method must also include considerations of the subsurface geology and the nature of any man-made materials which could be encountered.

Use of Modified Hydropunch For Cost-Effective Groundwater Sampling

Brian Swarthout
Judy Papesh
PRC Environmental Management, Inc.
San Francisco, California

ABSTRACT

During field investigations at the Naval Supply Center (NSC) Oakland, in Oakland, California, PRC Environmental Management, Inc., (PRC) used a modified Hydropunch to obtain groundwater samples. This sampling method was chosen to maximize the amount of data collected while minimizing costs associated with traditional groundwater sampling methods. The modified Hydropunch allows the collection of a discrete, chemically-representative groundwater sample without incurring the costs associated with the installation, maintenance and sampling of groundwater monitoring wells.

The purpose of field investigations at the NSC Oakland site was to determine the presence of contamination at two sites. By providing a rapid, cost-effective means for collecting groundwater samples, the modified Hydropunch effectively achieved this goal. For each site under investigation, little specific information existed concerning storage and disposal of hazardous materials. Therefore, sufficient information did not exist to determine efficient placement of monitoring wells. By using the modified Hydropunch, PRC was able to effectively assess the areas of concern without the need to install monitoring wells. This sampling device allowed a sufficient number of representative samples to be obtained at costs significantly less than those associated with traditional sampling methods.

During field investigations at NSC Oakland, 20 shallow soil borings were performed, each drilled to the top of the water table approximately 10 feet below land surface. By placing the modified Hydropunch inside the hollow stem augers and pushing it into the aquifer, 18 representative groundwater samples were collected from the 20 soil borings performed. Water samples were extracted from the modified Hydropunch using a standard bottom filling bailer. In all cases where water samples were not collected, the limiting factor was the availability of water in the aquifer, not the sampling tool. Because the modified Hydropunch places a 3-foot section of Teflon screen within the aquifer, the volume of water extracted is sufficient to perform a full suite of chemical analyses.

INTRODUCTION

PRC Environmental Management, Inc. (PRC) performed a site inspection (SI) at the Naval Supply Center (NSC) Oakland, in Oakland, California. As part of the SI, groundwater was sampled using a modified Hydropunch (MHP). This approach allowed PRC to collect an adequate number of representative groundwater samples without incurring the costs associated with the installation and sampling of monitoring wells. This paper describes the approach taken for the NSC Oakland SI and the advantages of the MHP.

The NSC Oakland SI was performed as part of the preliminary assessment/site inspection (PA/SI) requirements as outlined in the NCP. Based on information gathered during the PA, two sites suspected of being contaminated, due to inappropriate hazardous materials handling, were studied under this SI. The objective of the SI was to determine the presence of contamination at the sites. After evaluating potential sampling methods, the MHP was chosen for groundwater sampling. PRC chose this sampling device because it allowed a sufficient number of representative groundwater samples to be obtained at costs significantly less than those associated with traditional sampling methods. Specific site factors that contributed to choosing the MHP as a means of determining the presence of groundwater contamination included:

- Large area to investigate
- Unknown subsurface conditions
- Unknown depth to groundwater
- Limited background information on possible contaminants
- Short schedule for project completion
- Budget limitations

Typically, SIs are conducted using standard investigative methods such as exploratory borings to determine subsurface geology and the monitoring wells to provide information on groundwater contaminant levels. Additional information can be obtained using a variety of nonintrusive methods that include geophysics and soil gas analysis.

At NSC Oakland, the SI focused on the collection of soil and groundwater samples to determine the presence of contamination. Monitoring wells were not proposed for the SI because the areas potentially affected by contamination were very large and sufficient background information was not available for determining effective placement of monitoring wells to detect releases from poorly defined sources. Costs associated with installing the number of monitoring wells needed to study the sites would have been. By using the MHP, however, a sufficient number of groundwater samples could be obtained, providing large area coverage at a significantly lower cost than that associated with installation of monitoring wells. Based on groundwater data gathered using the MHP, areas of significant contamination could then be identified, thus satisfying the objectives of the SI. These data could then be used to determine the effective placement of a limited number of monitoring wells if further studies or remedial investigations are deemed necessary.

DESCRIPTION

The MHP (Fig. 1) is composed of a 30-inch long by 1.5-inch diameter Teflon screen attached to a standard steel well point. The screen and well point are placed inside a 5-foot section of 2-inch inside diameter stainless steel pipe and secured with Teflon tape. This apparatus is then lowered into the hollow-stem augers and driven ahead of the lead auger with the drill rig hammer, in the same manner as a split-spoon sampler. As necessary, 5-foot lengths of pipe are added to place the MHP at

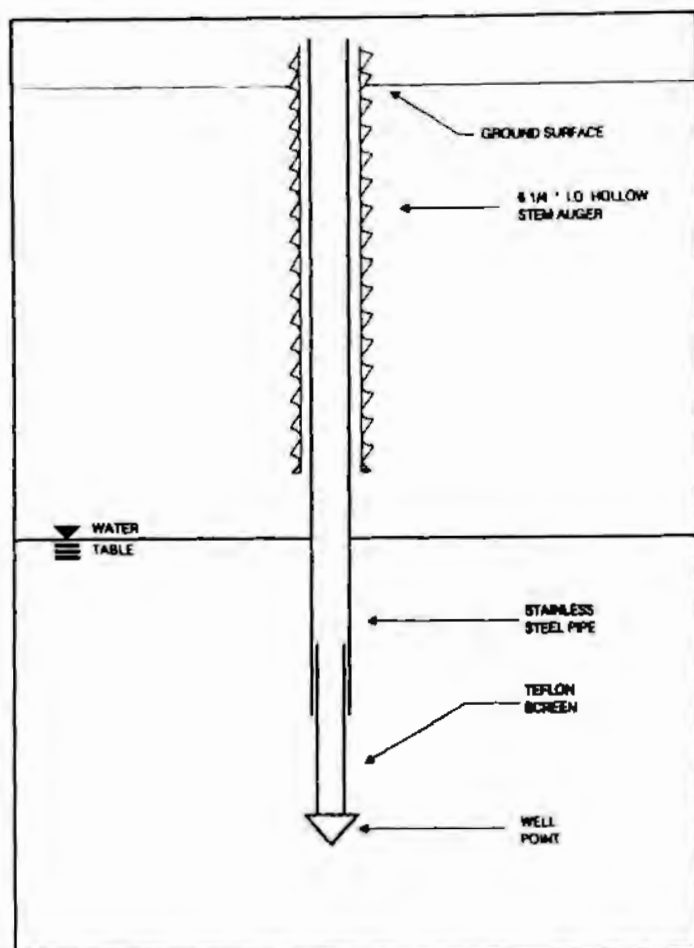
the desired location within the saturated zone. After reaching the appropriate depth, the stainless steel pipe is pulled back, leaving the well point in place and exposing the bottom 20-inches of the Teflon screen (Fig. 2).


Figure 1
Modified Hydropunch

Under its own hydrostatic head, groundwater enters the screen and fills the MHP. Groundwater samples can then be collected using a 1-inch diameter bottom filling bailer. The bailer is lowered through the stainless steel pipe and down into the Teflon screen. After sampling, the stainless steel pipe is removed and the Teflon screen and well point are left in the ground.

By driving the MHP ahead of the lead auger, groundwater samples can be collected from a section of the aquifer unaffected by the drilling process. In addition, a seal is created between the piping and the aquifer formation. This seal allows the collection of a sample that is undisturbed and representative of true subsurface conditions.

In the past, an inexpensive method for obtaining groundwater samples was to drill into the aquifer and sample directly from the hollow-stem auger. This method is technically unsound because of the many drilling processes that can obscure groundwater contamination. (The MHP is a patented instrument and is a derivative of the standard Hydropunch sold by QED.)

INVESTIGATION

During this study, two sites were investigated to confirm or deny the presence of contamination: a hazardous waste storage lot and an area surrounding two large buildings.

At the hazardous waste storage lot (Fig. 3) the primary areas of concern are eight uncovered storage bins and a staging area adjacent to

the bins. Each storage bin is approximately 20 by 20 feet. The staging area is approximately 75 feet wide and 250 feet long. The entire area is paved except for the exposed surface along the railroad tracks that lie adjacent to the storage bins. Prior to 1981, this area was used to store drummed hazardous materials from numerous military installations in the San Francisco Bay Area. The storage bins at the site are now used for storage and redrumming of hazardous wastes generated at the facility prior to shipment off-site. The floors of all storage bins have significant cracking and exposure of the soils below. Soil staining is evident within the storage bays. The asphalt in the staging area, however, is intact and has very little visible signs of staining. The staging area was no longer in use at the time of the SI.

Figure 2
Well Point, Teflon Screen and Stainless Steel Pipe of the MHP
Figure 3
Hazardous Waste Storage Lot

At this site, many possible sources of contamination exist, including each of the eight storage bins and the staging area. By using the MHP, each possible source was evaluated without the need to install monitoring wells. To determine if contamination was present, 14 borings were performed, with a groundwater sample collected from each boring. One boring was performed within each of the storage bins, two were performed in an area believed to be downgradient from the storage bins and four borings were performed in the staging area adjacent to the storage bins. Borings were performed with 6.25-inch inside diameter

hollow stem augers. Soil samples were collected at 5-foot intervals for both stratigraphic control and chemical analysis. Upon reaching the top of the water table, approximately 10 feet below land surface, drilling was stopped and the MHP was placed inside the augers. The MHP was then advanced 3 feet ahead of the augers and opened to allow water to accumulate inside the sampler.

The MHP worked very well in the conditions found at this area. The top 7 to 10 feet of each boring consisted of fine sand fill and bay muds. Below this, clean to clayey medium grain sands were encountered. Depth to groundwater was approximately 10 feet below land surface. The aquifer at this area had a flowrate large enough to allow the collection of a large volume of water. Also, the medium grained sands were coarse enough so as not to flow into the Teflon screen and clog the sampling device. These conditions proved to be ideal for application of the MHP.

Results of chemical analyses of groundwater and soil samples collected at this area indicate that significant contamination is not present. Only low concentrations of toluene and diesel were detected in each sample matrix.

The area surrounding Buildings A and B (Fig. 4) is located on the southwest side of NSC Oakland and consists of two large buildings and a paved parking area between them. The paved parking area between each of the buildings slopes slightly downward to a low lying depression. Cracks are visible in the low lying paved area as are stains from standing water. Two other features of interest behind Building A are a large Imhoff tank and a suspected underground storage tank. The surface around the Imhoff tank is not paved. Railroad tracks lie along the west side of each building.

The western side of Building B and the eastern side of Building A were used in the past to stage drummed materials such as lubricants, solvents, paints and motor oils. No visible signs of spills or disposal

Figure 4
Buildings A and B

Table 1
Cost Comparison: Installation of the Monitoring Wells Compared to Installation of the Modified Hydropunch Process

MONITORING WELLS

Time and materials needed to install 5 monitoring wells:

Drillers costs		
17 hours at $130/hour		$2,210.00
Materials		
25 feet slotted casing	$7/foot	175.00
75 feet blank casing	$5/foot	375.00
15 sacks sand	$6/sack	90.00
5 buckets bentonite	$50/bucket	250.00
35 sacks cement	$10/sack	350.00
5 cristy boxes	$50/each	250.00
5 locking caps	$25/each	125.00
Develop and purge wells		
15 hours	$95/hour	1,425.00
	TOTAL	$5,250.00

MODIFIED HYDROPUNCH

Time and materials needed to collect 5 ground-water samples:

Drillers costs		
10 hours	$130/hour	$1,300.00
Equipment Rental (MHP)		
1 day	$200/day	200.00
Materials		
5 Teflon screens and well points	$35/each	175.00
35 sacks cement	$10/sack	350.00
	TOTAL	$2,025.00

activities are present in these areas. The area surrounding the Imhoff tank was used for personal automobile repair and hobby activities. Waste materials included sandblasting grit, lubricants, solvents, paints and motor oil. There are also signs of tar and creosote.

This area is very large and although handling and disposal of hazardous material was known to have occurred, point sources of contamination could not be identified. PRC, therefore, decided it was necessary to evaluate the entire site. The cost of installing the number of monitoring wells needed to do this would have been excessive. By providing a means of collecting many groundwater samples in a cost-effective manner, the MHP proved to be a valuable tool. To determine if contamination was present at this area, seven soil borings were performed. Because conditions found at this area were less than ideal, groundwater samples were collected from only five of the seven proposed sample locations.

The top 3 to 4 feet of each boring consisted of fine sand fill material. Below this, interbedded clayey medium grained sands and silty clays (bay muds) were encountered. Groundwater generally was found in a large sand bed approximately 8 to 10 feet below land surface. Because of the large amount of fine grained material present in subsurface soils, the quality of water samples collected at this area was less than that of the samples collected at the hazardous material storage lot. At two boring locations, insufficient water was available for the collection of groundwater samples. At one boring location, during sample collection, the Teflon screen filled with flowing fine grained sands so that only one half the required volume of water could be collected.

Soil samples at this area typically were collected 2 feet, 5 feet and 10 feet below land surface. Soil samples collected at the 2-foot and 5-foot intervals from the borings between Buildings A and B were contaminated with a family of semivolatile organic compounds known as Polycyclic Aromatic Hydrocarbons (PAH), toluene and diesel fuel. Only diesel and toluene were detected in the 10 foot samples. PAH compounds
detected in soil samples included benzo(a)pyrene, fluoranthene, chrysene and pyrene. These compounds typically are found as a mixture in the products of incomplete combustion. PAHs are believed to be the main, if not only, carcinogenic ingredients in mixtures such as soot, coal, tar and heavy fuel oil. PAHs are known to attach to organic matter and to accumulate in fine grain sediments such as those found at this area. They are immobile, insoluble in water and will not partition into the water column. Groundwater samples collected at this area did not contain detectable levels of PAH compounds, but did contain low levels of toluene and diesel fuel. Because of the known chemical characteristic, PAH compounds would not be expected in groundwater samples. PRC was able to use the MHP to confirm the immobility of the PAHs and to determine that they were not an immediate threat to groundwater.

COST

One of the primary reasons for choosing the MHP as a sampling method is that a large number of representatives samples can be collected for a relatively low cost as compared with standard sampling methods. This cost savings is particularly obvious when compared with the costs necessary for the installation and sampling of monitoring wells. During a single 10 hour work day, five MHP groundwater samples were collected at NSC Oakland. This sampling included collection of 2 to 3 soil samples per boring and assumed a water table depth of 10 feet below land surface. By comparison only three monitoring wells could typically be installed during this same time frame. Also, additional time is needed to develop and purge monitoring wells. These tasks are not necessary for the collection of groundwater samples from the MHP.

Table 1 presents a cost break down comparing the MHP to standard 2-inch schedule 40 PVC monitoring wells. Costs are based on time needed to acquire an equal number of groundwater samples from the same aquifer.

Based on this comparison, groundwater samples can be collected using the MHP at cost savings of approximately 60% as compared to monitoring wells. Additional costs not shown above are associated with monitoring wells, including 55-gallon drums for water storage, disposal of purge and development water and eventual abandonment of monitoring wells. By adding these costs to those already presented for monitoring wells, the advantage to using the MHP in site inspections becomes greater.

CONCLUSION

At both sites of the NSC Oakland SI, there were many variables with respect to possible sources of contamination. These variables prevented the effective placement of monitoring wells. At the hazardous waste storage lot, there were many possible sources; each of the eight storage bins and the staging area. At the Building A and B site, no known point sources existed and because of the lack of specific background information, a large area needed to be investigated. At each of these sites, the MHP was an effective tool for determining the presence of contamination.

Although, the author would recommend this sampling method for SIs, several drawbacks do exist. The large mesh size of the Teflon screen meant that a water sample could not be collected in the presence of fine grained aquifer material. Also, the MHP can only be used for one time sampling, whereas a monitoring well can be sampled repeatedly, thus precluding the MHP's use for detailed site characterizations. Because the steel well point and Teflon screen are left in the ground, drilling beyond the initial sampling point may be difficult.

Nevertheless, by using the MHP for the NSC Oakland SI, PRC was able to collect a large number of representatives soil and groundwater samples. As a result, greater coverage was provided for soil and groundwater sampling and more data were available for studying the sites without increasing field costs.

Baird & McGuire Superfund Site:
Investigation of Arsenic and Lead Removal From Groundwater

Carl T. Wolff
Cinthia L. Rudasill, P.E.
Metcalf & Eddy, Inc.
Hazardous Waste Division
Wakefield, Massachusetts

ABSTRACT

As part of the design effort for the Baird & McGuire Superfund Site Groundwater Treatment Plant, Metcalf & Eddy conducted a series of treatability tests. Since the State of Massachusetts Department of Environmental Protection regulations require that any discharge to groundwater meet drinking water standards, the goal of the tests was to remove metals and organics from the groundwater to federal Safe Drinking Water Act Maximum Contaminant Levels (MCLs). The ROD called for on-site groundwater treatment by metals precipitation, biological treatment using activated sludge, filtration and activated carbon adsorption. Therefore, treatability tests were designed to optimize these processes to meet regulatory requirements.

The topic of this paper is the removal of metals from the groundwater. The metals of concern included arsenic, lead and iron. Tests were run on a groundwater sample collected from a recirculation system installed in the most highly contaminated part of the site during a previous remedial action.[1] Precipitation and coagulation tests were conducted at various Ph values and chemical dosages. Lime and sodium hydroxide were tested for Ph adjustment, and ferric sulfate and ferric chloride were tested as coagulants. Single and two-stage precipitation were investigated. Two-stage precipitation involved adjusting the Ph to the optimum levels for arsenic and iron removal and adding coagulants in one step, settling, removing the supernatant and readjusting the Ph for the removal of lead in a second step. Only by optimizing chemical dosages in the two-stage tests were the MCLs met for all three metals of concern. Water pretreated by single-stage precipitation was used to study the downstream activated sludge and carbon adsorption processes. Following biological treatment and carbon adsorption, samples were analyzed for metals to determine whether additional metals removal could be achieved in these unit operations. No removal was achieved in either process.

INTRODUCTION

The Baird & McGuire Superfund site currently ranks 14th out of 989 sites on the NPL. Baird & McGuire, Inc., operated a chemical mixing and batching facility in Holbrook, Massachusetts, for more than seventy years. Operations at the facility included production of household and industrial products such as floor waxes, wood preservatives, pesticides and solvents,[2] and resulted in widespread contamination of the Baird & McGuire property, as well as the surrounding property, by numerous toxic organic and inorganic compounds. In September 1986, following a number of investigations, the U.S. EPA issued the ROD for the Remedial Alternative for the site. Included in the ROD was remediation of contaminated groundwater by metals precipitation, biological treatment and carbon adsorption and remediation of soil by incineration.

Investigations conducted at the Baird & McGuire site by several groups including consultants for Baird & McGuire, Inc., the town of Holbrook, the U.S. EPA, the Massachusetts Department of Environmental Quality Engineering, Goldberg-Zoino Associates and GHR Engineering Associates have shown arsenic and lead to be present in concentrations above the MCLs. Most recently, Metcalf & Eddy conducted a comprehensive groundwater sampling effort to provide support for design activities. The analytical data from this sampling round documented extensive groundwater contamination by metals, semivolatile organics, volatile organics and pesticides. Of the metals detected in the groundwater, arsenic was found throughout the site in concentrations up to 4.4 mg/L. Lead was detected less frequently, but exceed the MCL in several samples. In addition, iron was detected at concentrations up to 70 mg/L.

For the Baird & McGuire site, the MCL for arsenic and lead in the groundwater discharge is set at 0.05 mg/L (ppm) and for iron, the MCL contaminant level is set at 0.3 mg/L.

TREATABILITY STUDIES

As part of the remedial design effort, Metcalf & Eddy conducted treatability studies on the groundwater in order to confirm the ability of the proposed technologies to meet the discharge criteria and to develop design data. To evaluate metals precipitation, a series of jar tests was conducted at different Ph values and chemical dosages.

Both lime and sodium hydroxide were investigated for Ph adjustment. Review of the literature[4] indicated that arsenic is not removed as a hydroxide but can be removed by coprecipitation with ferric hydroxide floc. Therefore, two ferric salts, ferric chloride and ferric sulfate were tested to enhance formation of the heavy ferric floc. In addition, due to the high concentrations of iron found in the groundwater, tests were run without the iron salts to determine whether arsenic removal would occur with the naturally occurring iron concentrations.

Solubility curves[5] and the literature indicated that minimum solubility of ferric hydroxide and coprecipitation of arsenic occurs near a neutral Ph, while the minimum solubility of lead hydroxide occurs in the 10 to 11 Ph range. Therefore, tests were conducted over a Ph range of 7 to 10. In addition, two-stage tests were conducted in which precipitation was conducted at the Ph value found to be optimum for iron and arsenic removal; then the supernatant from the first precipitation step was adjusted to the optimum Ph for lead removal.

Test conditions are given in Table 1. All precipitation tests were conducted on samples collected from an on-site recirculation system that was installed in the most contaminated part of the site as an interim measure. Arsenic and lead spikes were added to several of the test samples to ensure the presence of these contaminants, since influent sample analysis and groundwater sampling analysis results would not

be available prior to testing. Metals concentrations and groundwater quality parameters concentrations found in the test samples collected from the recirculation system are presented in Table 2.

Test Procedure

A sample of groundwater taken in August 1988 best characterized the nature of metals contamination of the site groundwater. Table 1 shows that the groundwater had an initial total solids content of 134 mg/L, an initial elemental iron content of 56 mg/L and an initial elemental arsenic content of 2.6 mg/L. Lead had been detected in at least one monitoring well, having a groundwater concentration of 4 mg/L.

Based on MCL levels, the groundwater treatment technology chosen for metals removal is required to remove 98% of the elemental arsenic and lead and 99.5% of the elemental iron contained in the recirculation well groundwater.

The first jar test study of the site groundwater used ferric sulfate to

enhance arsenic removal, with limited success.[6] Reagent grade ferric sulfate was added to the contaminated groundwater at a dose of 55 mg/L resulting in 97% removal of arsenic at a final treatment Ph of 10.5. The final concentration of arsenic in the sample was 0.1 mg/L.

The ferric sulfate reagent used was difficult to put into solution with deionized water; also, it was found that ferric sulfate was not readily available in bulk quantity.

Testing sodium hydroxide as a substitute for lime produced an effluent which did not meet the MCLs. Using sodium hydroxide would produce less sludge, but the discharge criteria could not be met.

After we reviewed the data obtained with ferric sulfate in conjunction with both sodium hydroxide and lime conditioning, we decided to test ferric chloride with lime only. To set a basis for ferric chloride dosing quantities, a Taiwanese study on arsenic removal from drinking water was used.[7] In this study, the authors found that a ferric chloride addition of 30 mg/L would remove 92% of arsenic from a well water

sample containing 1.72 mg/L total arsenic and 0.8 mg/L total iron at a natural groundwater Ph of 7.4.

The advantage that ferric chloride has for arsenic removal by coprecipitation over ferric sulfate is its solubility. Ferric chloride is readily soluble in either hot or cold makeup water and does not have to be added to a waste stream as a slurry.

PRECIPITATION TESTING RESULTS

Results of the metals precipitation in the jar tests are given in Table 1 along with test conditions. Also found in Table 1, are the MCLs for the metals of concern.

Treatment chemicals and spike concentrations added to the samples are indicated at the top of Table 1. Jar testing was performed using ASTM Method D2080. Lead spike was added to the raw groundwater at concentrations of 4 mg/L for metals jar test samples 3, 3A, 4 and 4A, in order to indicate a worst-case condition of lead concentrations experienced in the groundwater at the site. Arsenic spikes were not added to any of the test samples, as arsenic concentrations in the raw groundwater sample represented average-to-worst case site conditions. Removal efficiencies of arsenic, lead and iron were determined for both the single-stage and two-stage precipitation processes.

Ferric Chloride Addition Results

Ferric chloride addition was evaluated by running sets of duplicate jar tests, subjecting one set of jars to lime (Ca(OH)$_2$) addition only to a selected Ph and adding ferric chloride to an alternate set of jars prior to adding lime, then adjusting to the same Ph.

The analytical results given in Table 1 show reductions in total iron and total arsenic concentrations in each test using ferric chloride as compared to its analogous test without using ferric chloride. These reductions are largely evident in the two-stage removal tests. In cases (7 and 7A) vs (8 and 8A) and (9 and 9A) vs. (10 and 10A), the reductions in the arsenic concentrations by using ferric chloride were sufficient to bring arsenic level to below the MCL drinking water standards.

Tests 5 and 5A show the effect of coagulant ferric chloride added in larger quantities than those used in the Taiwanese Study (100 mg/L).

Chemicals	Units	Reporting Limit	MCL(b)
Ferric Chloride	mg/l		
Lead in dilute Nitric Acid	mg/l		
Lime (CaOH$_2$)	mg/l

pH	mg/l		

Parameter	Units		
Arsenic (Total)	mg/l	.003(a)	.05
Barium (Total)	mg/l	.010	1.0
Cadmium (Total)	mg/l	.005	.01
Iron (Total)	mg/l	.05	.30
Lead (Total)	mg/l	.005	.050
Nickel (Total)	mg/l	.04	N/A

ND = Not Detected.
NA Not Applicable.
b   MCL refers to the Maximum Contaminant Levels according to the EPA Safe Drinking Water Act Standards.
c   These are the threshold concentration of substances inhibitory to the activated sludge process.

Table 2
Baird & Mcguire Recirculation Data Summary for Test Samples

Groundwater Quality Parameters Analysis (mg/l)

Total Suspended Solids	134
Total Volatile Solids	104
Total Kjeldahl Nitrogen	2.6
Total Phosphorus	1.8
Chemical Oxygen Demand	267
Total Organic Carbon	42
Biochemical Oxygen Demand	72
pH	6.24

Groundwater Metals Analysis (mg/l)

Antimony	ND	0.05
Arsenic	3.4	0.1
Barium	0.14	0.005
Beryllium	ND	0.001
Cadmium	ND	0.005
Chromium	ND	0.01
Copper	ND	0.006
Iron	76	0.05
Lead	ND	0.005
Mercury	ND	0.0002
Nickel	ND	0.04
Selenium	ND	0.005
Silver	ND	0.005
Thallium	ND	0.008
Zinc	ND	0.01

Greater reductions in arsenic and iron treatment concentrations are evident with the increased coagulant addition; however, the reduction induced by increased addition is not substantial as compared to the lower level of ferric chloride dosage (Tests 2 and 2A).

Two-Stage Metals Precipitation Results

The two-stage metals precipitation process was compared to the single-stage process, also by using a series of analogous tests. Tests number 1 and 2 represent analogous single-stage metals treatability tests and test 7 through 12A present two-stage treatability test, related to single-stage numbers 1 and 2. The final target pH for all tests mentioned was 10.5.

Single-stage test (1 and 1A) did not use ferric chloride. Analogous two-stage tests to (1 and 1A) were test (7 and 7A), test (9 and 9A) and test (11 and 11A). First-stage treatment pH values were varied in each of these two-stage tests.

Test (11 and 11A) showed the greatest removal of arsenic in a two-stage system not utilizing ferric chloride, as compared to test (1 and 1A). Iron removal efficiency was adequate in test (11 and 11A). Total lime (Ca(OH)$_2$) consumption for tests (11 and 11A) was averaged at 278 mg/L as compared to 370 mg/L for tests (1 and 1A).

Single-stage test (2 and 2A) used ferric chloride to enhance arsenic removal. Analogous two-stage systems reported were tests (8 and 8A), (10 and 10A) and (12 and 12A). First stage pH values were varied in each of these two-stage tests, along with ferric chloride at 25 mg/L at the first stage.

Test (10 and 10A) showed optimal removal capabilities in arsenic contamination when compared to all two-stage testing performed and also removed iron to concentrations below the analytical detectable limit. Total lime consumption in tests 10 and 10A was an average of 277 mg/L, as compared to 372 mg/L in test 2.

Lead Spike Analytical Results

Tests 3, 3A, 4 and 4A were spiked with 4 mg/L of lead in dissolved nitric acid to simulate worst-case site condition for this metal. The test results show a 50% or better reduction in dissolved lead concentration in tests 4 and 4A in which ferric chloride was added.

CONCLUSIONS

Adjusting the pH to 7 in the first stage and 10 in the second stage by lime addition then ferric chloride at a concentration of 25 mg/L to form a ferric hydroxide floc in the groundwater in the first stage mixing, effectively removed arsenic from the Baird & McGuire site groundwater to the MCL. The removal of arsenic in jar test number 10 and 10A, a two-stage process using ferric chloride at a pH of 7 and pH

adjusting to 10 using lime in the second stage, is shown to be 99%, from an initial arsenic concentration of 2.6 mg/L.

Iron was removed from an initial concentration of 56 mg/L to nondetectable levels using the same set of jar test conditions.

Ferric chloride was also shown to enhance lead removal. Although the two-stage system was not screened for lead removal in comparison with MCLs, it is believed that the two-stage system will be able to appropriately remove any groundwater lead contamination to at or below MCL values.

The two-stage system was also effectively in reduced hazardous metals concentrations below activated sludge MCL limits. The two-stage metals removal process also was shown to reduce lime consumption by 20% or greater over single-stage removal efficiencies as reported in Table 1.

ABSTRACT

A 250-acre island in the Mississippi River was identified as an uncontrolled municipal and industrial waste landfill. This facility, which served a city of 64,000, received various wastes for approximately 35 years before ceasing operation in 1976. The island lies within 2,000 feet of the city's shallow water well gallery. The likelihood that hazardous wastes were deposited at this site, and its proximity to a major municipal well gallery, prompted the Region VII Superfund Branch of the U.S. Environmental Protection Agency (EPA) to investigate the facility.

A Preliminary Assessment (PA) revealed significant exposure potentials in four migration pathways: soil, air, groundwater and surface water. Before field work for the Screening Site Inspection (SSI) commenced, groundwater modeling was employed to allow a thorough evaluation of the potential risk posed by site conditions. Information obtained during the SSI showed significant releases of heavy metals from the landfill to area groundwater. These contaminants were detected in the raw municipal water. Preliminary modeling results applied to field analytical data indicated that the site was a likely source of this municipal well contamination.

The modeling results were used to design the most effective sampling scheme for the final stage of the site assessment process, the Listing Site Inspection (LSI). Well locations were determined, and an aquifer test was designed to allow an empirical check of parameters used in the groundwater model. The LSI delineated the vertical extent of the groundwater plume and identified several alternative potential contamination sources. The aquifer test provided the data necessary to verify the accuracy of the model. The groundwater model effectively assessed the complex hydrogeological environment in the site vicinity and provided information required to design an appropriate sampling scheme. The groundwater model also facilitated interpretation of the field data acquired during the SSI and LSI. An additional benefit of this site assessment approach is that it may provide the city some guidelines for pumping the shallow well gallery in order to minimize the impact of local groundwater contamination on the municipal water supply.

INTRODUCTION

This paper presents a case study of a Superfund Site Assessment in which computer groundwater modeling was employed to aid in designing an effective sampling scheme and interpreting field data acquired from the field work. The modeling results also can be used to manage aquifer pump rates in order to minimize potential contamination of the shallow municipal well gallery. The Superfund Site Assessment process is divided into three parts. The initial site assessment is carried out under the Preliminary Assessment (PA) phase. In the PA phase, no samples are taken, the investigation is limited to on-site reconnaissance,

background file review and interviews. If evidence is acquired during the PA indicating actual or potential contamination of the air, soil, groundwater or surface water pathways, and if significant environmental or human target groups exist, then the site is moved to the Screening Site Inspection (SSI) phase. This second phase involves environmental sampling and continued background data collection. If data from the SSI confirm the presence of contamination and indicate a significant threat via one or more of the exposure pathways, the site is advanced to the third and final phase of the Site Assessment process, the Listing Site Inspection (LSI). The purpose of the LSI is to gather sufficient site-specific data to support the proposal of a site to the National Priorities List (NPL). Within this overall objective, LSIs are designed specifically for the data and information needs at a particular site.

SITE BACKGROUND

The site is located on an island in the Mississippi River. Between the mid-1940s and 1976, the southern three-fourths of the island served as an industrial and municipal waste landfill for a city of 64,000 residents. The landfill operation was used to fill low areas on the island (sloughs) and to raise its overall elevation. On-site borings indicate that the former landfill area has 5 to 30 feet of waste fill; fill may be deeper in former sloughs. The hazardous substances present, identified through on-site groundwater and soil sampling, are listed in Table 1.

Table 1
Hazardous Substances Identified in Soil and Groundwater Samples

Methylene Chloride	Barium	Mercury	Cyanide	DDD
	Cadmium	Nickel	Silver	DDT
Acetone	Chromium	Polychlorinated	Polycyclic	Dieldrin
Toluene	Copper	Biphenyls	Aromatic	Zinc
Arsenic	Lead	Selenium	Hydrocarbons	Xylene
Benzene	Endosulfan	Dibenzofurans		

Sometime after landfill operations ceased, a sand cover was placed over fill areas to produce a more level grade; it was not a formal closure procedure. Currently, the former landfill area is used as a city recreational area. The center of the former landfill is situated 3,200 feet south of the shallow well gallery for the city. The deep municipal wells are located approximately 4,800 feet north of the center of the former landfill (Figure 1).

Past erosion and scouring from the Mississippi River have modified the local bedrock topography. The bedrock surface in the general site vicinity appears to slope eastward from the limestone bluffs which define the floodplain to the main river channel. The bluffs are composed of
Figure 1
Site Map: Major Pumping Wells
Figure 2
Geology of Study Area

Ordovician limestones, dolomites and shales of the Champlainian Series. Moving toward the main river channel, the sandstone members of the Ancell Group found at the bottom of the Champlainian Series are increasingly eroded, eventually exposing the St. Peter Sandstone, which is the bottom formation in the Ancell Group. In the main river channel, the St. Peter is sufficiently eroded to expose the Shakopee dolomites of the Prairie du Chein Group in the Canadian Series. Alluvial sands and gravels ranging in thickness from 0 to at least 350 feet provide the major overburden for the bedrock between the bluffs (Figure 2). These erosional features are caused by the geomorphic processes associated with the flow and meandering of large rivers during past interglacial periods.

The site is located on and within the surficial alluvial aquifer. The upper 30 feet of this aquifer are isolated from the main aquifer body by the presence of the Mississippi River and a side channel which surround the site (Figure 3). This surficial aquifer extends down to the upper bedrock units. The eastern and western boundaries of this aquifer are defined by the Ordovician-aged limestone bluffs. The boundaries of this aquifer are recharge areas for the alluvium, while the alluvium in turn discharges into the Mississippi River.

Seismic Interpretation

Nine water supply wells are used by this city. Five wells make up the shallow gallery and draw from the alluvial aquifer at 80 to 200 feet (Figure 1). The remaining four wells are deep wells which draw from the lower Ordovician and Cambrian units at 300 to 1,800 feet. The city withdraws 6 to 9 million gallons of water per day from its well galleries, approximately two-thirds of which is taken from the alluvial aquifer. To produce this magnitude of water withdrawal, generally two deep and two to three shallow wells are pumped concurrently.

SITE ASSESSMENT

Based on the information generated at the PA, and the proximity of the site to the city's municipal well field, this site was deemed to be a potential threat to human health and the environment and warranted

further Superfund investigation. The site was moved to the SSI phase.

Planning for the SSI was complicated by the site's location on an island and the unknown influence of the Mississippi River on contaminant migration. In order to better define the local hydrogeology, U.S. EPA Region VII Superfund subcontracted HydroGeologic, Inc. to conduct preliminary groundwater modeling at this site. The objectives of this modeling were as follows:

- Determine the zones of influence for the deep and shallow municipal well fields, both separately and together, for normal, peak and maximum pumping rates
- Assess the impact of water infiltration through river bed sediments during the pumping of the shallow municipal wells
- Evaluate the likelihood that water from under the land-fill could be drawn into the shallow or deep municipal wells
- Quantify the impact of smaller water wells, situated around the site, on the capture zones for the municipal well gallery
- Identify input parameters that have the greatest impact on the ground-water flow system
- Provide input on the development of a sampling plan if the site were to move into the LSI phase

To accomplish these objectives, the modeling effort arranged into the following six elements:

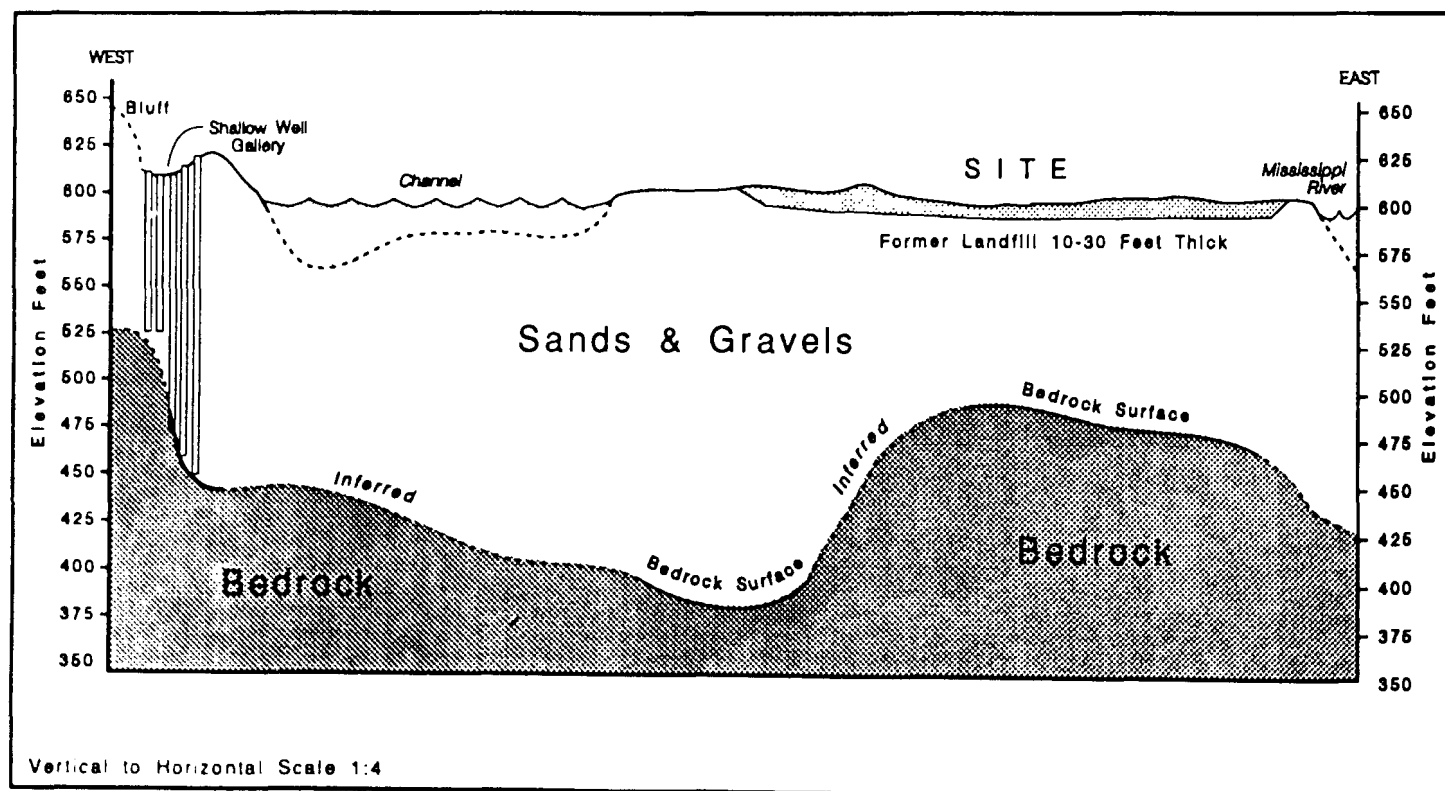
- Formulation of an initial conceptual model which was continuously tested and refined throughout the modeling process
- Identification of input parameters likely to have a controlling effect on the groundwater flow
- Determination of high and low bounds of the input parameters
- Investigation of the effects of key input parameters on the ground-water flow system, both individually and collectively, through a sensitivity analysis
- Simulation of scenarios to predict the effect that alternative pumping procedures would have on the groundwater flow system
- Comparison of aquifer test data obtained from LSI field work with the hydraulic conductivity range used in the modeling


Figure 3
Shallow Well Gallery to Site: Cross-section
Figure 4
Layer Classification and Gridding

The conceptual model of the hydrogeologic flow system was developed using data that included published reports, well logs, laboratory permeability studies, geologic maps river stage and seepage measurements, geophysical information, regional potentiometric surface maps, and well pumpage data. In essence, the hydrogeologic environment beneath the site comprises a series of interbedded aquifers and lower permeability confining units that extend to a depth of approximately 3,000 feet. Groundwater flow is dominated by the Mississippi River, which acts as a regional drain causing strong vertical upward gradients, allowing groundwater to move from the lower aquifers and discharge into the River.

The parameters and processes most likely to influence groundwater flow in the area of interest were identified to be: vertical and horizontal hydraulic conductivity contrasts between hydrogeologic units, pumping rates, depths and locations of the municipal wells, stage of the Mississippi River, conductance of the Mississippi River Bed and areal recharge. A detailed literature search provided the expected high and low values of the input parameters which allowed a bounding approach to be taken during the sensitivity analysis.

Once the conceptual model was formulated, it was quantified by implementing the numerical code MODFLO (Modular Three-Dimensional Finite-Difference Ground-Water Flow Model).

The modeling required that the site be divided into a grid composed of almost 2,000 nodes. A variable grid spacing was used and, in areas requiring greater definition (area of the municipal well field), grid spacings were set to 200 feet and graded to a maximum of 2,000 feet at the model boundaries (Figure 4).

The aquifer system was divided vertically into three distinct hydrogeologic units (Figure 1). The intermediate range model parameters for each layer are presented in Table 2. Within each layer, the hydraulic characteristics, aquifer thickness and other location-specific data were varied over the representative nodal area.

Table 2
Aquifer Parameters

	Layer #1	Layer #2	Layer #3
Unit Thickness (ft)	100–400	1,300–1,500	1,000
$^\wedge$h (ft/day)	65–268	35–70	35–70
^{K}v (ft/day)	0.01	0.1–0.01	0.1–0.01
Composition	Alluvium	Lower Ordovician Upper Cambrian	Lower Cambrian Precambrian
No. of Active Well	6	5	2

Before the LSI, there were no actual field measurements of the parameters and processes which were expected to control groundwater flow in the area of interest. Therefore, the majority of the modeling focused on estimating the probable range of these parameters and conducting a detailed sensitivity analysis.

The sensitivity analysis involved evaluating the groundwater-flow field that resulted from multiple combinations of the various parameters within their expected ranges. In this manner, an approach was undertaken to predict if a potential exists for the migration of contaminants from beneath the landfill to the well field. This approach included both conservative as well as more probable estimates for the expected ranges of parameters.

The parameters exhibiting the greatest sensitivity were vertical and horizontal conductivity, riverbed conductance and pumping rates. Groundwater flow appears to be less sensitive to precipitation (recharge) and river stage.

Confining layers between the aquifers were not explicitly simulated with the model; however, the equivalent effects were obtained using a vertical conductance term between each layer. This design is com-

monly referred to as a quasi-three-dimensional approach. To simulate the long-term effect of the well field on groundwater flow, all simulations were run to steady-state. After completion of the sensitivity analysis, simulation scenarios were performed to evaluate the effect that alternative pumping schemes would have on the groundwater flow system.

Modeling results indicated that even under nonconservative conditions (e.g., low pumping rates and high hydraulic conductivities), the capture zones created by the well field would extend under the landfill, creating the potential for contaminants to move with the groundwater into the well field. Furthermore, with the exception of the immediate area of the well field, a strong upward gradient appears to exist between Layer 1 and Layer 2 as predicted by the conceptual model.

The only wells that appeared to have a significant impact on the regional groundwater gradients were the municipal wells. (Accurate pumping rates for other wells in the area are unknown and were estimated.) As expected, the wells in the deeper, more confined systems had large capture zones. However, the strong upward flow gradients would tend to isolate them from the contamination potentially leaking downward from the alluvial aquifer.

The SSI also had the primary objectives of identifying on-site contaminants, assessing the potential contamination of the shallow municipal wells, documenting contamination in any of the four pathways, creating a geologic cross-section between the site and the bluffs and measuring riverbed seepage. Temporary monitoring wells installed with a Geoprobe unit showed significant total and dissolved metals contamination in the top of the alluvial aquifer. Minor amounts of volatile and semi-volatile organics also were detected. Arsenic, barium, cadmium, selenium and benzene levels were detected above Maximum Contaminant Levels (MCLs). These metals also were detected in the shallow municipal well samples, but at lower concentrations.

The analytical data supported the attribution of the shallow groundwater contamination on the island to the former landfill area. However, this sampling did not provide sufficient data to show attribution for the contamination detected in the shallow municipal wells. The SSI also called for shallow (0 to 2 feet) soil sampling in high use recreational areas. Elevated metals and pesticide concentrations were detected in soils collected from areas of exposed fill. Sediment samples from off-site drainageways showed no contamination. It is likely that the surface water is being contaminated through a groundwater release.

The geological cross-section was developed through a seismic survey and interpretation of well logs (Figure 3). This cross-section provided alluvium thickness data essential to the model. Seepage meter sampling was conducted to evaluate the impact of pumping or alluvial aquifer recharge on the river. Seepage meter sampling indicated that 50 feet off the shore from the pumping wells the flow is upward into the river, and in side channels off the main river channel, a near zero flow condition exists.

The gross contamination of the top of the alluvial aquifer on the island and the contamination detected in the shallow well gallery were sufficient to advance this site to the LSI. The main objectives of the LSI were to measure alluvial aquifer characteristics, allowing the preliminary modeling results to be checked against actual field data, enhancing the validity of the model; another project goal was to define the source of the contamination in the shallow well gallery.

The first project objective was addressed by conducting an aquifer test on the north tip of the island, approximately 1,000 feet south of the shallow well gallery. The second objective was met by installing four well nests composed of three wells each. Each nest had a monitoring well screened at the top (10 to 20 feet), middle (90 to 100 feet) and bottom (160 to 180 feet) of the alluvial aquifer. The vertical spacing was intended to define the vertical extent of contaminant plumes.

The well nests were placed around the municipal well gallery in such a manner to identify the source of the municipal water contamination. The well nests were distributed approximately 1,000 feet south (1 nest), west (2 nests) and north (1 nest) of the shallow municipal well gallery. The preliminary modeling results obtained during the SSI were used to locate possible migration routes and source locations. The well nest

installed on the north tip of the island was also used to conduct the aquifer test. Due to the high water table and noncohesive matrix, special drilling techniques were required for the deep wells. The shallow and medium depth wells were installed with a conventional auger technique, while the deep wells were installed through dual-tube reverse air rotary drilling. Field analytical screening and fast turn-around laboratory analysis were used to determine if drilling wastes and well development wastes were hazardous.

The aquifer test was run on the mid-level well that was installed with a cable tool rig and screened from 100 to 120 feet below grade. This well differed from other monitoring wells in that it was constructed of 6-inch ID PVC casing. During the aquifer test, this well was pumped at a constant 224 gpm. The drawdown phase of the test was run for 1.65 days. Within 13 hours, the pressure transducers recorded steady-state water elevations in the three monitoring points (top, middle and bottom of the alluvial aquifer) around the pumping well. The bottom and middle monitoring points were 29 feet from the center of the pumping well. The top monitoring point was located 13.75 feet from the center of the pumping well. This steady-state condition indicated that the drawdown had intercepted the river boundary.

The city maintained a steady withdrawal rate from the shallow and deep wells for four weeks before the aquifer test to allow the system to approach equilibrium. Approximately 4 days after the aquifer test pump was stopped, the shallow municipal wells were shut off. Within 5 minutes, all monitoring points showed between a 0.2- and 0.5-foot recovery. A similar but reversed response was recorded when the wells were restarted. This rapid aquifer response is indicative of a semiconfined system. Using the Theis solution, the aquifer test data were analyzed. Table 3 shows the results of this aquifer test.

Table 3
Aquifer Test Data

Transmissivity (gpd/ft^2)	10^5 to 10^6
Storativities (dimensionless)	10^{-1} to 10^{-3}
Horizontal Hydraulic Conductivities (ft/day) (assuming 40 feet saturated thickness)	65 268

Measurements taken from river piezometers before and after the municipal well shutdown showed that during pumping, river seepage is into the alluvial aquifer, within 50 feet of shore in the main channel. Once the wells were restarted, the gradient reversed, drawing water through the riverbed into the alluvial aquifer.

To confirm assumed alluvial aquifer porosities and stratigraphy, downhole geophysics was conducted in two monitoring wells. EM and natural gamma logging were conducted at each location. Both logging techniques detected a clay-rich zone from 0 to 7 feet below grade. Porosities in this zone ranged from 54 to 69% range, and natural gamma counts averaged 105 cps. Between 7 and 175 feet, both measurements indicated a relatively homogenous sandy matrix with porosities in the 16 to 34% range and natural gamma counts of 30 to 50 cps. Drilling logs were in agreement with these findings.

The results of the aquifer test indicated that the actual hydraulic conductivities were in the intermediate range used during the modeling sensitivity analysis. If hydraulic conductivities were substantially higher than the highest range assumed during the modeling, it is likely that the capture zones created by the well field would not have reached the landfill.

The LSI groundwater sampling indicated that under current pumping rates the former landfill is an unlikely or minor contributor to the contamination detected in the shallow municipal wells. This conclusion is based on current withdrawal rates. Sampling data suggest that the contamination is attributable to a source south of the municipal well gallery. Two nearby plating facilities, located within 1,600 feet of the shallow well gallery, are potential sources of this contamination. These

facilities have been in operation for fewer than 20 years.

An additional potential contaminant source was identified almost 5,000 feet south of the well gallery. This source is the location of buried foundry wastes. The foundry wastes have been in place for more than 30 years. They were disposed of in a swamp and they are, therefore, likely to be in contact with the water table. Natural groundwater flow into the river creates strong easterly gradients in the vicinity of the plating facilities which may transport contaminants into the capture zone of the shallow well gallery. These gradients also may carry the foundry contamination under the site. It is possible that these contaminants could then intersect with the capture zone of the shallow well gallery.

The groundwater sampling identified two distinct groundwater plumes: one plume occurs in the top of the alluvial aquifer and a second plume was detected in the deep monitoring wells at the bottom of the alluvial aquifer. This plume disparity could be caused by different contributing sources. The nearby plating facilities could be responsible for the shallow plume. The proximity of this source(s) may not allow the metals plume sufficient distance to sink below the top of the alluvial aquifer. The more distant potential source, the foundry wastes, may have a sufficient travel distance to allow the bulk of the plume to sink to the bottom of the alluvial aquifer. For this scenario to occur, the capture zones for the well gallery would have to extend out to the foundry waste area and be stronger than the natural gradients. Only one midlevel monitoring well detected metals contamination. This well is situated directly between the plating facilities and the shallow gallery; it may have detected mixing between the two plumes.

The groundwater modeling showed that the shallow municipal well capture zones in Layer 1 extended under the island and south, close to the foundry waste burial area under low, moderate (current) and high (doubled current) pumping rates. This pattern was held true for all three layers. Layers 2 and 3 were not considered potential targets due to the strong upward gradient between Layers 1 and 2.

The modeling parameters exhibiting the greatest sensitivity were vertical and horizontal conductivity, riverbed conductance and pumping rate. Groundwater flow appears to be less sensitive to precipitation (recharge) and river stage. Limiting the pumping from Layer 1 and increasing the pumping from Layer 3 could greatly reduce the potential for contamination in the alluvial aquifer to migrate into the shallow well gallery.

The results from this modeling are based on relatively broad parameter ranges applied at semiregional scale. Although the parameters were checked against empirical data and found to be representative of actual conditions, a finer mesh model would be required to produce a more detailed analysis of the physical flow or transport process. This additional modeling could be developed into a wellhead protection program, design of alternate pumping schemes or the selection of an alternative well field.

CONCLUSIONS

The field investigation and modeling were implemented using an integrated approach. At the PA phase, a set of questions was developed concerning the potential threat that this site posed to human health and the environment. The SSI was designed to answer these questions. Due to the complexity of the hydrogeological system around the site, groundwater modeling was deemed necessary to fully interpret the potential risks posed by this site. The conceptual model was designed and the data gaps were filled through data acquisition at the SSI phase. The conceptual model and field sampling plan were developed concurrently.

Information produced at the SSI confirmed contamination of the alluvial aquifer and allowed completion of the preliminary modeling. This information indicated that the site was a possible source of observed contamination of the shallow municipal well gallery. Attribution of this contamination was still incomplete.

This site was then advanced to the LSI phase, which focused on contaminant attribution and confirmation of modeling parameters. The preliminary modeling results were used to guide the design of the LSI field work. Well placements and the location of an aquifer test site were based on modeling data. The empirical data produced at the LSI phase allowed confirmation of the parameters used in the conceptual model and identification of the likely sources of the shallow municipal water well contamination. Additionally, based on the findings of this study, the city may be able to greatly reduce the impact of the alluvial aquifer contamination on its municipal water supply. Although not a permanent solution, it allows risk reduction while the appropriate authorities take whatever action is deemed necessary regarding the groundwater contamination. The city was also planning to add an additional well in the shallow gallery; this study shows that this is not a desirable option.

Modeling not supported by field verification is based on assumptions; sampling in a complex environment without first modeling the system may lead to missed or over-emphasized data. The integrated approach of this site assessment, developing sampling plans in conjunction with groundwater modeling, assured the most effective use of resources and the most representative or accurate data interpretation. Implementing this strategy in a phased approach allows for alteration and refinement of the model and sampling plan as information is developed.

Extraction/Interception Trenches by the Bio-Polymer Slurry Drainage Trench Technique

Steven R. Day
Geo-Con, Inc.
Pittsburgh, Pennsylvania

ABSTRACT

Groundwater extraction and interception trenches are often an integral part of contaminated groundwater remediation projects. Deep drainage trenches can provide a means for contaminate extraction for treatment and interception for containment. The construction of these trenches may be costly and risk-filled if conventional methods are employed which require shoring, dewatering, over excavation and personnel working in the trench.

The Bio-Polymer Slurry Drainage Trench Technique (B-P Drain) is a relatively new method, based on the slurry trench technique, which permits the installation of trenches without the problems associated with conventional construction. The B-P Drain method permits the installation of perforated pipes, filter fabrics, free-draining aggregates, sumps and/or wells in relatively narrow trenches under conditions which minimize health risks to workers and costs to the owner.

The design of extraction/interception trenches constructed by the B-P Drain technique requires an understanding of the project requirements as well as an appreciation of the technique. The quality control demands for B-P Drain construction require trained, experienced field personnel capable of determining the actions necessary to preserve the biodegradable slurry during construction and then the destruction of the slurry when the drain is activated.

This paper presents an overview of the B-P Drain technique as it is presently used on waste remediation projects. Case studies of four projects are used to illustrate the various design concepts and field installation procedures.

INTRODUCTION

The installation of deep drainage trenches has long been a risk-filled and costly endeavor. Conventional installation techniques involve dewatering, sheeting and shoring and danger to personnel working in the trench, from trench collapse. Recently, due to the public's concern for the environment and the need to preserve groundwater resources, there has been an increased demand for deeper and more sophisticated groundwater extraction and interception trenches. These trenches are even more difficult to construct because of the volatilization of toxins and increased groundwater and trench spoil disposal restrictions and costs.

The introduction of a new construction method, the Bio-Polymer Slurry Drainage Trench (B-P Drain), now provides a quicker, safer, more cost-effective method to install deep drainage trenches. This new method is a modification of the well-known slurry trench method which uses a biodegradable trenching slurry to temporarily support the trench walls and control trench width. Using the B-P Drain method, the usual drainage structures (e.g., wells, perforated pipes and free-draining aggregates) can be placed without dewatering, sheeting or shoring, or men

working in the trench. Experienced personnel and quality control are especially critical in constructing B-P Drains. This paper provides an overview of the technique and illustrations of a few example projects.

CONSTRUCTION METHODS

Trench Excavation and Support

Slurry trench construction is a well-established technique for installing groundwater control and/or deep foundation systems to great depths at a minimum cost. Generally, a bentonite-clay slurry fills the excavation to support the side walls and permit the creation of a narrow, vertical trench. In the typical slurry trench, the bentonite-clay slurry cakes on the trench walls and plugs porous formations creating a hydraulic barrier. A slurry wall is formed by replacing the slurry with a permanent, engineered backfill. Trench stability is maintained during construction by controlling slurry properties (e.g., density, viscosity, etc.) and by keeping the level of slurry in the trench above the groundwater table.

With the B-P Drain method, a biodegradable slurry is used in a similar manner to bentonite-clay slurry except that the B-P slurry does not form a cake or permanently impede groundwater flow. After excavation and backfilling are complete, the B-P slurry can be treated with additives to convert it to water and a very small amount of natural carbohydrate.

Compared to more traditional trenching methods, B-P Drain construction is far simpler, safer, faster and usually less costly. Trench support is provided by the slurry eliminating sheeting and shoring, trench shields and bracing. Since the trench is filled with slurry, no workers can enter the trench. The slurry trench method also eliminates dewatering and the treatment of dewatering liquids. Usually B-P Drains can be constructed much narrower than trenches constructed by traditional methods since internal supports are unnecessary, thus providing an additional savings in excavation, disposal and backfill material volumes and costs.

B-P Drains usually are excavated with a hydraulic excavator. Depths up to 70 ft are possible using custom-built hydraulic excavators with extended reach capabilities (Fig. 1). The design width of the trench (usually 18 to 36 inches) is ensured by using a back hoe bucket of the same width. An earthen pad (working platform) is created prior to trenching by leveling the trench alignment to provide room for the temporary storage and drainage of trench spoil removed during excavation. A level working platform is required to maintain the slurry level in the trench at an acceptable elevation. In the case of highly contaminated soils, the working platform may be lined to prevent additional contamination. All excavation is carried out under slurry so continuity, depth and soil conditions are determined by observations of the construction process and soils as discharged from the excavator bucket.

Figure 1
Long-Stick hydraulic Excavator Digging Bio-Polymer Drain

Drain Backfill and Structures

Depending on the purpose and design of the drainage trench, different materials and structures can be placed through slurry into the trench. The simplest systems involve the placement of a coarse aggregate (pea gravel) around well casings spaced in the trench (Fig. 2). Well casings are lowered vertically into the trench, through the slurry, with the pea gravel tremie-placed around the well to maintain the alignment of the casing. The trench between wells is also filled with pea gravel by end-dumping backfill down the backfill slope to ensure proper displacement of the slurry. If a finer or graded aggregate (sand or gravel) is used, it must be wetted first with slurry to permit tremie placement. Filter fabrics and geomembranes (geofabrics) also can be placed through the slurry into the trench to line the trench walls (Fig. 3). The placement of geofabrics is facilitated by attaching weights to the geofabric to provide ballast. Continuity of the geofabrics is provided by overlapping the geofabric sheets by at least 5 ft.
Figure 2
Profile of Typical B-P Drainage Trench

When design considerations dictate that a horizontal drain pipe be used along the bottom of the trench, it can be installed by the B-P Drain method. Using a flexible pipe, corrugated for strength, a separate pipe laying machine travels behind the hydraulic excavator laying the pipe through the slurry while simultaneously bedding and backfilling around the pipe (Fig. 4). Additional backfill can be placed by end loader to bring the backfill to grade. Small diameter sumps or wells (4 to 24 inch diameter) are either attached directly to the drain pipe or placed directly beside the drain pipe perforations for continuity.

Figure 3
Installation of Geofabric in Bio-Polymer Trench
Tremie Pipe in Foreground

Figure 4
Pipelaying Machine Placing Flexible Perforated
Pipe in Bio-Polymer Trench

Since the backfill is placed through slurry, the aggregate must extend to near the surface to displace the slurry and maintain trench stability. The top 3 to 5 ft of the drainage trench usually are backfilled with excess trench spoil or other soil to cap the trench. This zone may also support buried vaults, discharge piping and pump controls so that all drainage structures are buried and hidden from view.

DESIGN AND QUALITY CONTROL

Design Considerations

The design of a B-P Drain should combine the project requirements, soil conditions, pollutant characteristics and installation procedure into a reasonable solution. A B-P Drain can serve as a groundwater cutoff, plume extraction trench, groundwater interceptor trench, injection trench and/or shallow groundwater skimmer. In some cases, well points or conventional deep wells may not function effectively or efficiently. Often a B-P Drain with a single well can replace an entire array of conventional wells.

The continuity provided by a B-P Drain can be especially advantageous in the design. Soils that typically produce poor groundwater yield can be effectively drained by B-P Drains. Preferential groundwater conduits such as sand seams, buried conduits and root holes that are difficult to intercept with other methods can be effectively intercepted and collected.

Groundwater conditions and pollutant characteristics may dictate the depth of the drainage trench. A high groundwater table and a floating pollutant (e.g., petroleum) may permit the design of a relatively shallow drainage trench which intercepts the groundwater table at an elevation sufficiently deep to overcome seasonal groundwater fluctuations. A deep groundwater table or a pollutant which is heavier than water may require a much deeper trench.

Soil conditions affect both the type of drainage structures and the backfill requirements. Silty soils can migrate to a drain and plug the backfill, thus limiting the drain's effectiveness or fouling pumps. A filter fabric can be used to protect an open graded backfill, or a backfill with an engineered gradation can be designed for the trench based on filter criteria.

When the drainage trench is designed to provide a positive groundwater cutoff in highly permeable soils, a perforated pipe on the bottom of the trench may be necessary or the drain can be installed deeper to allow a lower operating head. In many cases, a slurry cutoff wall can be economically combined with the B-P Drain for a positive cutoff and more efficient groundwater collection (Fig. 5).

In general, conventional manholes or lift stations are not recommended for a number of reasons. First, conventional manholes typically used for sanitary sewers constitute a confined space which can allow unintentioned access. The presence of contaminated groundwater makes entry into such an environment potentially hazardous even for the well-trained worker. Second, pumps, control facilities and access to same can be provided through conventional well equipment at a much lower installation cost. Duplex systems can be provided using multiple well casings for backup pumps. Third, conventional manholes must be constructed by conventional means (sheeting, shoring and dewatering) negating a significant portion of the savings and time provided by the B-P Drain installation. Finally, concrete manholes are sealed structures which are only attached to the drain field through the perforated pipe. A much larger radius of influence can be provided by using a perforated sump or well and in the case of failure of the drainage pipe, the perforated sump or well provides a safety factor for ensuring the continued service of the drainage trench.

Quality Control

The control and monitoring of construction quality for a B-P Drain installation focus on the properties of the bio-polymer slurry. Adequate control of the slurry is required to support the trench and permit the proper placement of the backfill during construction. In addition, the safe and effective treatment of the slurry after construction is necessary to ensure that the drain is activated and fully functional.

The bio-polymer slurry consists of ground guar beans, water and proprietary degradable additives. A suspension of the guar and water at very low percentages (approximately 1%) creates a viscous, pseudoplastic slurry capable of supporting an earthen trench. Additives are used to control and extend the life of the slurry. Without additives, enzymes in the soil will quickly cause the slurry to "break" or degrade and become ineffective in approximately one day.

Primary quality control parameters for the slurry are viscosity, density, filtrate loss and pH. All monitoring and testing should be performed by an experienced Bio-Polymer Slurry Engineer. Chemical adjustments to the slurry are made to both fresh and trench slurry to extend the working life. Depending on the grade of guar, a target viscosity of 40 cP is typically used to ensure adequate guar content. Titrations of the slurry are performed as needed to calculate additive requirements. The slurry pH is maintained at 8.0 or higher to limit enzyme action during excavation. Tests on the filtrate properties of the slurry indicate that the slurry does temporarily seal off the trench wall, but instead of a filter cake (as with bentonite slurry), a very thin, slimy, gelatin-like substance bridges over porous formations to support the trench with its high gel strength.

Once construction is complete, the slurry must be broken and the drain developed much like a water well is developed. First, the pH of the slurry is reduced to below 7 to initiate enzyme action, then a proprietary enzyme breaker solution is added to ensure biodegradation. The drain is now functional, but residue from the guar can degrade slowly or incompletely due to toxins in the groundwater causing anaerobic digestion in the trench and/or an unpleasant odor. To alleviate this problem and to ensure that the drain is fully functional, the drain is continuously pumped and recirculated while metering in additives to inhibit anaerobic digestion. Chlorine, typically used in water well development, can be used to help develop a B-P drain but only under the strictest controls since an untimely or over-application of chlorine can produce toxic byproducts. Pumping and flushing continue for one day or several days depending on the size of the drain and the permeability of the native soils.

When the drain is fully developed, the flush water should be clear and free of slurry and the trench continuity obvious. Excess waters usually have been disposed of through a municipal wastewater treatment plant or held for priority pollutant testing and flushed into the storm water sewer system.

Evidence from past projects has shown that construction creates a small groundwater mound around the trench which temporarily limits the inflow of contaminated water. Usually, pollutants in the groundwater are absent in the recovered B-P slurry. With continued pumping, the drain installation results in a line sink and pollutants are again collected in the groundwater.

APPLICATIONS

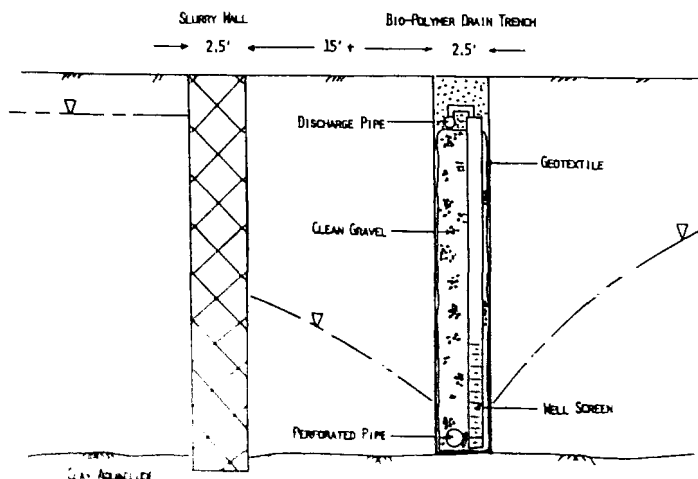
Over the past decade there have been several dozen B-P Drains con-


Figure 5
Cross-Section of Groundwater Contaminant and Extraction System

structed in the United States and Europe. Most applications in Europe were intended for the interception of groundwater to stabilize and dewater slopes along highways, while applications in this country have concentrated on contaminated groundwater remediation. The following recently completed projects illustrate recent applications in the United States and the variety and magnitude of projects now being pursued.

PILOT PROJECT IN NEW JERSEY

An older pharmaceutical manufacturing plant in a highly developed urban area discovered that it had leaked vinyl chloride, trichloroethylene (TCE), PCBs and other toxins into the groundwater. The congestion of the site and cost of conventional construction provided encouragement for the engineers to seek a solution to the groundwater extraction problem by using a B-P Drain. The pilot project design called for a 100-foot long trench, 2 to 3 ft wide and 27 ft deep constructed through silts, peat and a groundwater table within 2 ft from the surface. Since TCE is heavier than water, the drain used a 6 inch perforated, corrugated pipe along the bottom of the trench which terminated in an 18 inch diameter polyethylene sump. The B-P Drain was installed in approximately one week, flushed, developed and ready for pumping into an on-site treatment plant. Monitoring wells were placed inside the trench and alongside the trench perimeter.

Over a year of monitoring and testing have proven the success of this drainage trench. Pumping rates of 3 to 10 gpm are currently used. The pea gravel backfill used has shown no plugging or fouling problems to date. Due to the success of the pilot project, 10 more short, deep B-P Drains are planned to fully remediate the hot spots on the two square block area at the site.

One of the most significant advantages of the installation was the complete lack of toxic volatilization. Monitoring wells within 4 ft of the trench alignment gave consistently high readings of volatiles. The B-P slurry temporarily blocked these toxins during construction and permitted the safety level of the work to be down graded from Level B (supplied air respirators) to Level D (street clothes).

Interceptor Trench in Missouri

A munitions plant in Missouri found that solvents used in the manufacturing process, including TCE, had escaped the property and the plume was traveling toward a nearby river. Soils at the site consisted of clay over gravel over bedrock with the plume traveling on top of the bedrock. Conventional well spacing design was found to be so close that a deep drainage trench became a practical necessity. The trench was 250 ft long, 3 ft wide and 30 ft deep with a woven geotextile envelope around a pea gravel backfill. A six inch diameter stainless steel well casing was placed in the center of the trench for pumping with six inch diameter PVC monitoring wells on each end of the trench. The trench was installed in approximately one week. The B-P slurry was broken and the drainage trench developed by pumping. Prior to completion, the continuity of the installation was demonstrated by pumping the central well and observing the immediate response of the monitoring wells.

Extraction Trench in Central California

An oil company in central California owned a service station which was found to be leaking gasoline into two aquifers under the site. Silty sands and cemented sands limited the effectiveness and continuity of conventional extraction well systems. In addition, the groundwater gradients in the two aquifers flowed in different directions making two deep trenches with different alignments a distinct advantage. Two trenches were constructed with 18-in diameter stainless steel wells placed in a graded filter backfill. The deeper trench was 65 ft deep and 170 ft long and had an impervious backfill material placed over the graded filter backfill zone to maintain the separation between the aquifers. The second trench was 35 ft deep and 240 ft long. Total construction time for both, trenches including earthwork to level the site topography, was approximately three weeks.

Collection Trench in Northern California

A major manufacturing plant feared that past spills of processing chemicals might have leaked into the groundwater and affected the pending sale of the property. An on-site treatment and containment system was designed which called for 2,000 ft of B-P Drain and a soil-bentonite slurry wall to provide a downgradient groundwater recovery system. A soil-bentonite slurry cutoff wall and a B-P Drain were selected as the most cost-effective method for this project.

The B-P Drain was constructed through clays and silts approximately 15 ft upgradient and parallel to the cutoff wall. The trench was constructed 3 ft wide and approximately 30 ft deep and lined with a woven geotextile. The pipe laying machine laid and bedded a 6 inch diameter perforated pipe through the slurry. Pumping wells 12 inches in diameter and 4 inch diameter monitoring wells were placed in the trench alongside the perforated pipe. Construction time for the entire project was less than two months.

CONCLUSION

The Bio-Polymer Slurry Drainage Trench method represents a significantly improved method for the construction of deep drainage trenches. The primary advantages are in safety, cost and the ability to employ deep trench applications in problem soils and polluted groundwater. The quality control requirements of the B-P slurry demand that all projects be supervised by experienced, competent experts.

The design of deep drainage trenches by the B-P method should recognize the advantages and limitations of the B-P Drain method in design. Most conventional drainage structures and systems can be employed, except large diameter manholes and rigid piping are impractical. The most critical aspects of quality control are in extending the slurry's life during construction and then eliminating the residues of the slurry when the drain is developed.

The B-P Drain projects illustrated in this paper show the method to be practical in a variety of soil types, applications, project sizes and with different pollutants. Construction is generally rapid and quite cost-effective. The number of new applications for the B-P Drain technology continues to grow as more engineers and owners become familiar with the real advantages offered by this new technology.

Evaluation of Groundwater Extraction and Treatment Scenarios Using Quasi-Three-Dimensional Transport Model

Melih M. Ozbilgen, Ph.D.
James M. Montgomery, Consulting Engineers, Inc.
Walnut Creek, California

Denise Caron
Sandra Cuttino
George Air Force Base
Victorville, California

ABSTRACT

A Remedial Investigation (RI) was conducted for trichloroethylene (TCE) contamination of the groundwater underlying the Northeast (NE) Disposal Area at George Air Force Base (GAFB), San Bernardino, California. A Feasibility Study (FS) was performed to select a preferred alternative selected previously for the remediation of the TCE contamination in the Upper Aquifer underlying the NE Disposal Area. One of the primary objectives of this RI for the NE Disposal Area was to reassess the effectiveness of the preferred alternative developed in the previous FS for remediation of the Upper Aquifer. To accomplish this objective, a three-dimension numerical model of the groundwater flow within the Upper Aquifer was refined with the hydrogeologic parameters calculated from the aquifer pump test conducted within the NE Disposal Area. The refined model was then incorporated into a solute transport model used to assess the extent and rate of TCE plume movement, as well as to reevaluate the groundwater extraction and disposal components of the preferred alternative.

RI activities focused on an evaluation of TCE contamination within the Regional Aquifer to the center, north, east and southeast of the TCE plume identified within the Upper Aquifer. Water quality sampling results suggest that the Regional Aquifer is not contaminated to the east of this plume where the Upper and Regional Aquifers merge. Contamination to the east currently does not present an immediate threat to any potential receptor and can be addressed as part of the Upper Aquifer TCE remediation efforts. TCE was also detected in the Regional Aquifer to the southeast of the Upper Aquifer TCE plume at concentrations below the 5 ug/L State Action Level (SAL) and Federal Maximum Contaminant Level (MCL). This contamination is believed to be unrelated to the TCE plume observed within the Upper Aquifer.

The five Upper Aquifer monitoring wells installed during this RI indicated the presence of a TCE plume covering approximately 500 ac, in comparison with the previous estimate in the FS of approximately 400 ac. When measured through the center, the TCE plume having concentrations greater than 5 ug/L is approximately 7,000 ft long and 4,000 ft wide, extending approximately 5,000 ft from the northern GAFB boundary. The mass of the TCE present within this plume located in the Upper Aquifer is estimated to be approximately 430 lb.

The preferred alternative selected previously included nine on-base and off-base extraction wells, two packed-column air stripping towers operated in series and two deep wells for injection of treated groundwater into the Regional Aquifer. The quasi-three-dimensional solute transport model results suggested that the

groundwater extraction component of the preferred alternative would not successfully remove the TCE from the Upper Aquifer. The reasons on which this conclusion was based included the restricted pumping rate per extraction well due to lower transmissivities calculated for the area and the larger plume extent to the northeast.

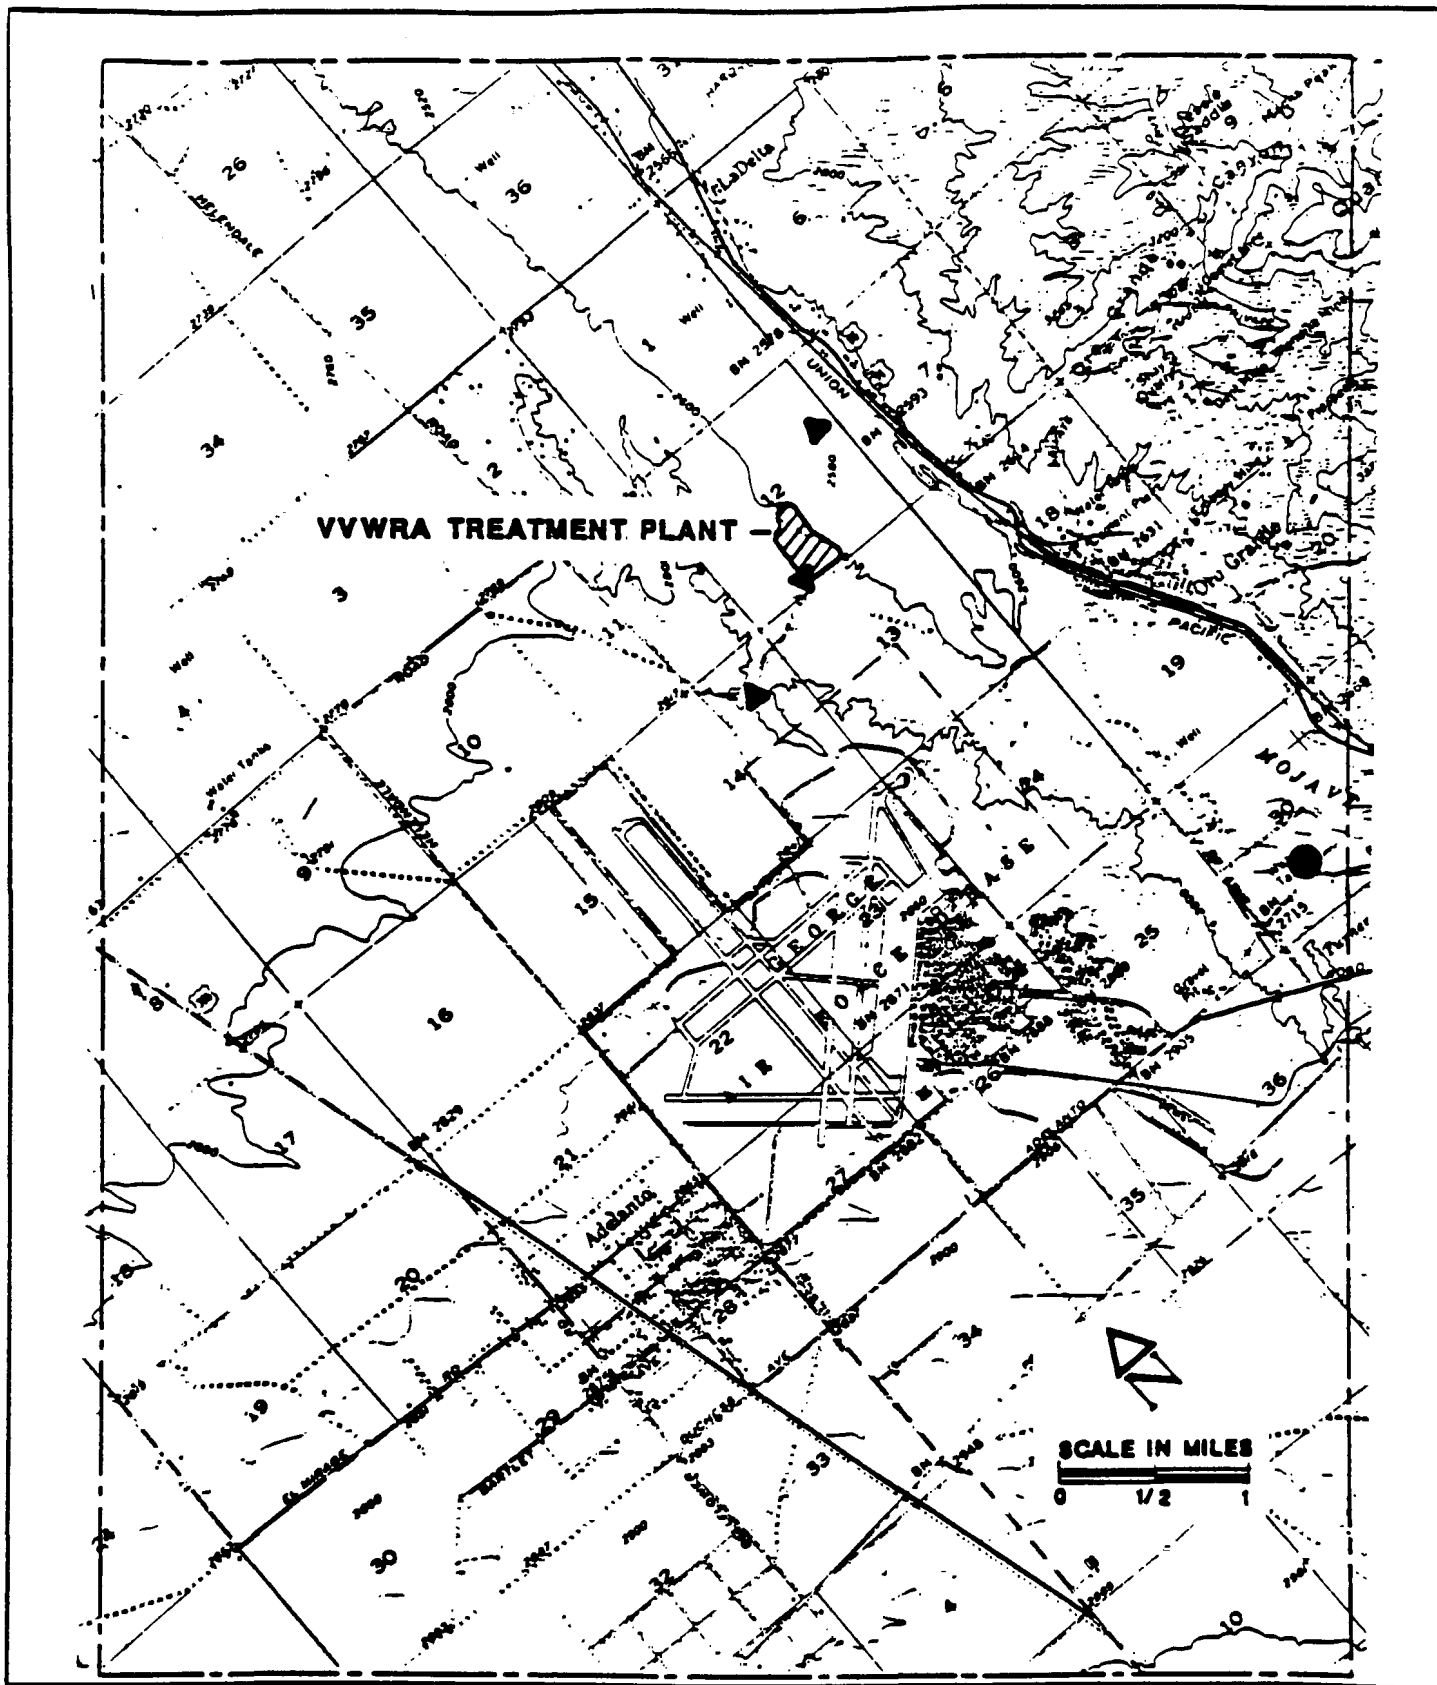
Six detailed alternative groundwater extraction and disposal scenarios were developed and modeled. All six scenarios incorporated a 19-well groundwater extraction component to expedite remediation. The additional extraction wells were placed primarily to address the larger plume extent observed within the merged Upper and Regional Aquifers located to the east and northeast. Three of the scenarios modeled include a component which recharges the Upper Aquifer with the extracted and treated groundwater in order to create a circulation zone within which the TCE would be trapped. Recharging of the Upper Aquifer emerged as an applicable control measure primarily because of the limited availability of the groundwater (due to lower aquifer thickness) for high rate extraction. In addition, recharging the Upper Aquifer will have advantages of minimum resultant drawdowns and flushing of any contaminants remaining in the soil.

Following a detailed technical evaluation, the extraction and disposal component of the preferred alternatives for the remediation of the Upper Aquifer TCE plume was selected as Scenario 7. This scenario would consist of extraction of the contaminated groundwater with 19 wells and percolation of a portion of the treated water back into the aquifer via the former Sewage Treatment Plant (STP) Percolation Ponds.

THREE-DIMENSIONAL GROUNDWATER FLOW MODEL

The three-dimensional finite difference groundwater flow model of the NE Disposal Area and its surroundings is based on the code developed by the U.S. Geological Survey.[1] This code has been applied to groundwater studies throughout the United States and has been extensively tested and verified. Minor changes to the code have been made by James M. Montgomery, Consulting Engineers, Inc. (JMM) to enable its execution on an IBM Personal Computer and to handle specific input-output requirements of the solute transport model.

MODEL GEOMETRY

To model the three-dimensional groundwater flow system around the George AFB site, the natural system was simplified. The area modeled covers approximately 54 mi² of Victorville fan deposits and includes a portion of the Mojave River deposits (Fig. 1). The modeled area extends well beyond the base boundaries so


LEGEND

  LOCATIONS FOR MODEL

—··— MODEL BOUNDARY

Figure 1
Base Map Showing Boundaries of Model

that the extraction wells on or near the base are not affected by the boundary flows.

The aquifer system is modeled in three layers. The top layer simulates the conditions in the Upper Aquifer (above elevation 2,600 ft) and the portions of the sandy and gravelly Mojave River deposits. The two lower layers represent upper and lower portions of the Regional Aquifer and are separated to simulate the three-dimensional flow effects near the river. Each layer is divided into 2,040 blocks (34 columns and 60 rows). Smaller blocks are used in the vicinity of the NE Disposal Area so that flows can be modeled in more detail. Figure 2 shows the boundaries of the modeled area and the finite difference grid specified to represent those areas where the TCE plume shows the highest concentrations.

Boundary Conditions

To calculate the flows in and out of each block within the model area, the flow and/or head conditions at the boundaries of the modeled area must be specified. Model boundaries to the north and southwest of the base are defined by controlled flux. These boundary conditions simulate flux of groundwater to and from the modeled area at a rate proportional to the head difference between either side of the boundary. The heads outside the model boundary are based on the observed values. The heads inside the model boundary are calculated during each iteration. The resulting controlled flux is simulated for groundwater discharge from the model area along the northeast boundary, above the river, and for groundwater inflow along the southwest boundary. A no-flow boundary is specified west of the base where the non-water-bearing bedrock crops out or is located very near the surface. Northwest and southeast of the base, flow in the aquifer is approximately parallel to the model boundary, and thus, no-flow conditions also are specified for these boundaries. The top model layer (layer 1) is simulated as a dynamic boundary represented by the water table conditions. The lower boundary in the third model layer is simulated as no-flow at the bottom of the Regional Aquifer where the alluvial sediments intersect the basement complex.

Additional inflows and outflows to the aquifer system include artificial recharge, community production wells and the Mojave River (Fig. 1). The Victor Valley Wastewater Reclamation Authority (VVWRA) facility, located northeast of the base on the west bank of the Mojave River, percolates approximately 0.7 mgd to the Upper Aquifer. Seven production wells, located southeast of the base, supply potable water to the George AFB and the City of Adelanto. The groundwater at this location is extracted from the Regional Aquifer at an approximate rate of 3.6 mgd. Within the modeled area, the Mojave River causes a net discharge from the Upper and Regional Aquifers (base flow). The boundary conditions for the river involve input of constant head in the river, the elevation of the bottom of the riverbed and the vertical hydraulic conductivity of the riverbed deposits. The flux is calculated by the model based on the rate of leakage between the river and aquifer nodes adjacent to the river. The net flow due

Table 1
Aquifer Parameters

Parameter	Initial Estimate	Similar Aquifer	Values From Literature(1)	Aquifer Tests	Calibrated Values
Transmissivity (sq ft/d)					
Upper Aquifer alluvium	5,400 to 270		5,000 to 5	1,650 to 144	9,000 to 50
Regional Aquifer	7,800 to 650	2,800 to 5,700 1,800 to 2,500	15,000 to 25		4,990 to 700
River Deposits	70,000 to 2,500	8,500 to 11,400	100,000 to 5	279,000 to 33,000	
Storage Coefficient (dimension-less)					
Upper Aquifer	0.02 to 0.10	1.5 to 5.7×10^{-4}	0.01 to 0.3	1.4×10^{-2} to 9.5×10^{-4}	0.1
Regional Aquifer	2.6×10^{-4}		5×10^{-3} to 5×10^{-5}	0.003	0.001
River Deposits	0.20		0.01 to 0.3		0.1 to 0.001
Vertical Hydraulic Conductivity					
Between Upper and Regional Aquifers	0.05	0.05	1.0 to 1×10^{-5}		0.0001 to 0.03
Within Regional Aquifer	0.05		1.0 to 1×10^{-5}		0.01 to 0.02
Within River Deposits	20		50 to 0.1		0.09

to precipitation and evapotranspiration is considered negligible for the aquifer system. The average annual precipitation for the Victorville area is less than 5 in., which is exceeded by the potential evapotranspiration estimated at more than 82 in. annually. Evapotranspiration along the river is incorporated into the model input of river elevations.

Aquifer Parameters

Aquifer parameters of transmissivity, vertical hydraulic conductivity and storage were initially set at values estimated by JMM. These parameters were adjusted within an acceptable range during the calibration process. Three sources were used to delineate this range of reasonable values: (1) parameter values for similar aquifers estimated for other sites in the vicinity of George AFB, (2) parameter values measures for similar soil types,[2] and (3) parameter values calculated from aquifer tests conducted at GAFB. Table 1 lists the initial parameters, the range of parameters given by each source and the range of final parameters used in the model.

Calibration

Calibration of the model was achieved by simulating long-term average conditions of the aquifer. The initial input heads to the model were those observed in the natural system. The aquifer parameters, boundary fluxes and the interaction of the aquifer with the Mojave River were adjusted until the simulated steady-state heads matched the observed heads. The anisotropy of the natural aquifer material was simulated to match observed gradients.

The three-dimensional groundwater flow model was calibrated by first setting the thickness of the first model layer to the actual values observed during drilling of new monitoring wells which are believed to have penetrated through the total thickness of the Upper Aquifer. In areas south of the NE Disposal Area, the first model layer thickness was set at 60 ft. The thickness was then gradually reduced toward the north where the Upper and Regional Aquifers merge. Reduced aquifer thickness resulted in reduced transmissivity of the Upper Aquifer, which, in turn, resulted in higher than observed hydraulic gradients near the TCE plume. A number of simulations were conducted to obtain a reasonable match. These calculations included several simulations of the aquifer test performed at the northeast portion of the base. Although direct comparison to observed drawdowns was difficult due to the relatively large size of the model grid (400 ft by 800 ft), the calibration efforts resulted in model transmissivities (1,450 ft²/day or 10,922 gpd/ft, near pumped well) that matched reasonably well to those calculated analytically from aquifer test data.

The adjusted transmissivities resulted in a reasonable match (+ 10 ft/mi) of the Upper Aquifer hydraulic gradients observed near the NE Disposal Area. However, simulated Upper Aquifer piezometric heads were 30 to 50 ft higher, and the head differences between the Upper and Regional Aquifers were 20 to 40 ft lower than those observed. To overcome simulated high water level conditions, inflow from the southern model boundary was reduced by lowering the prescribed head outside the model area. To overcome the low head differential between the Upper and Regional Aquifers, the vertical hydraulic conductivity of the silty clay layer underlying the Upper Aquifer was reduced until a reasonable match (± 20 ft) was obtained. The final calibrated verti-
