cal hydraulic conductivity values for this aquitard ranged from a low to 1.5×10^{-9} cm/sec to a high of 6×10^{-7} cm/sec, with an average value of 2×10^{-8} cm/sec near the NE Disposal Area TCE plume. Such low vertical hydraulic conductivity values are verified in the field by presence of a thick (more than 100 ft) unsaturated zone separating the Upper and Regional Aquifers and by no TCE contamination in the Regional Aquifer measured from deep monitoring wells.

The model calibrated piezometric surface and water levels of the Upper Aquifer are shown in Figure 3. Comparison of model-predicted water levels to observed water levels suggest a very good match within the area of interest (i.e., the TCE plume). For example, the predicted and measured water levels in wells NZ28 and 43 are within less than 0.5 ft of each other. The piezometric water levels of the second and third model layers are shown in Figure 4. The Upper Aquifer water levels shown are assumed to represent the long-term average conditions in the vicinity of the NE Disposal Area and therefore are used as initial conditions for calibration simulations of the transient solute transport model.

SOLUTE TRANSPORT MODEL

The solute transport model of the NE Disposal Area and its surroundings was developed to simulate the rate and the extent of contaminant movement as well as to evaluate groundwater extraction and/or recharge scenarios. Although the flow model is developed as a three-dimensional model, only a two-dimensional solute

transport model is used to simulate the transport of TCE in groundwater. This change is primarily due to the results of the field investigations suggesting: (1) presence of TCE contamination only in the Upper Aquifer (where the two aquifers are separate units) and (2) shallow depth of TCE contamination in the Upper Aquifer (less than 60 ft). The observed shallow depth of the TCE contamination makes the two-dimensional approximation a valid one.

The two-dimensional solute transport and dispersion model code (known commonly as the MOC Model) developed and subsequently modified by the U.S. Geological Survey is used to simulated the transport of TCE and to evaluate the effectiveness of various groundwater extraction and/or recharge alternatives. The computer program solves two simultaneous partial differential equations; one equation describes the head distribution (the groundwater flow equation), and the second equation describes the concentrations of chemical species (the solute transport equation) in the aquifer. The solution to the groundwater flow equation is computed by an iterative alternative direction implicit (ADI) procedure, while the solution to the solute transport equation is computed by the method of characteristics (MOC, and

hence the nickname of the Code). The coupled flow and transport equations can simulate both the steady-state and transient flow problems.

The objective of the solute transport model is to compute the concentration of a dissolved species in an aquifer at any specified place and time. Changes in chemical concentration occur within a dynamic groundwater system primarily due to four distinct processes:

- Convective transport, in which the dissolved chemicals are moving with the flowing groundwater
- Hydrodynamic dispersion, in which molecular and ionic diffusion and small-scale variations in the velocity of flow through the porous media cause the paths of dissolved molecules and ions to diverge or spread from the average direction of groundwater flow
- Fluid sources, where water of one composition is introduced into water of a different composition
- Reactions, in which some amount of a particular dissolved chemical species may be added to or removed from the groundwater due to chemical and physical reactions in the water or between the water and the solid aquifer materials.

Model Setup

The solute transport model developed for the NE Disposal Area is an integral extension of the three-dimensional groundwater flow model. The two-dimensional solute transport model is arranged to function under the groundwater flow conditions prescribed by the first model layer of the three-dimensional model. This layer depicts the flow conditions in the Upper Aquifer only, where the Upper and Regional Aquifers are separated, and in the upper part of the Regional Aquifer (approximately 60 ft thick) where the two aquifers are merged. As shown in Figure 2, the solute transport model is set up within a subgrid area of the three-dimensional model. It consists of 48 model rows 400 ft wide and of 26 model columns 800 ft long. The model covers an area of approximately 14.3 mi^2 within and around the NE Disposal Area. The modeled area is surrounded by the constant head boundaries on all four sides.

The solute transport model first solves the flow equation to calculate groundwater velocities, which are then used in the solute transport equation. The boundary conditions to the flow equation are prescribed by the three-dimensional flow model. A postprocessor is developed for the three-dimensional model to calculate the appropriate flow boundary conditions to the two dimensional model. The simulation process for the models is as follows:

- The three-dimensional groundwater flow model is set up with appropriate boundary conditions and executed. Appropriate fluxes are included in those simulations involving extraction and/or recharge wells.
- The post-processor is executed which reads the output file from the three-dimensional model and creates an input file for the two-dimensional model. Calculated by the post-processor are the groundwater elevations, including those along constant head coundaries, and vertical leakage to the Regional Aquifer, as well as vertical groundwater discharge from the upper to lower part of the Regional Aquifer. These values are then input to the two-dimensional model as initial head and recharge (or discharge) to each model grid.
- The two-dimensional solute transport model is then executed, which calculates groundwater velocities and TCE concentrations throughout the aquifer.

The process of utilizing three-dimensional groundwater flow models to generate boundary conditions to the solute transport model has several advantages. First, the assumption of "no vertical flow component" associates with two-dimensional models is eliminated since vertical fluxes are calculated from the three-di-

mensional model. Second, the change in vertical and/or horizontal flux can always be accounted for by simulating the three-dimensional model each time the aquifer stresses are changed. Third, since the initial conditions are precalculated by the three-dimensional model, the flow part of the two-dimensional model is unconditionally stable and uses computing time at fractions of seconds to calculate velocities. Finally, for conditions which may be justified in the future by field monitoring of plume progress, three-dimensional solute transport conditions can be simulated at lower Regional Aquifer layers. This can be accomplished by simply creating a second post-processor which links the output files of the two models described above to generate an input file to a second two-dimensional solute transport model. This model would then simulate the solute transport in the second model layer of the three-dimensional model.

The disadvantage of the above-described approach to solute transport modeling is that for simulations involving transient conditions with small time steps (e.g., less than 6 mo), the process of calculating fluxes from a three- to two-dimensional model becomes time-consuming. However, for simulations involving large time steps, the solution to groundwater flow equation approaches steady-state, and hence, no recalculation of fluxes is required.

Model Calibration

The input conditions for the groundwater flow part of the two-dimensional solute transport model are calculated from the three-dimensional groundwater flow model. Hence, no calibration of flow conditions is required. Solute transport calibrations were accomplished by back-calculating from the location(s) of potential sources of assumed magnitude which would create the currently known extent and mass of the TCE plume.

A longitudinal dispersivity value of 90 ft was selected based on experience in modeling solute transport within similar aquifers in southern California. Although values ranging from 70 to 150 ft were tested during model calibration runs, 90 ft for longitudinal dispersivity appeared to result in the most reasonable predictions. This value is also within the range reported in the literature for similar geologic formations. The transverse dispersivity value of 72 ft (80% of the longitudinal dispersivity value) was used since the width of the currently known TCE plume appears to be approximately 80% of the length of the plume. Simulation with several ratios of transverse to longitudinal dispersivity suggested 80% to be the most appropriate value.

In contrast to the dispersivities, which increase the distance any dissolved compound would travel within a given time period, adsorption will slow the movement of a particular compound. This is accounted for by estimating retardation factors. The retardation factor depends on several parameters, including: chemical compound specific octonal/water partitioning coefficient (K_{ow}); and aquifer specific bulk density (K_d) and fraction of soil organic carbon (f_{oc}). The K_{ow} value of 195 for TCE is reported in the literature.[3] A soil density of 2.65 g/cm^3 for typical sand and silt material would result in a K_d value of 1.99 g/cm^3 at an assumed soil porosity of 25%. The f_{oc} values reported in the literature for similar geologic formations in southern California range from a low of 0.0001 (0.01%) to a high of 0.005 (0.5%). Several model calibration simulations suggest that a f_{oc} value of 0.001 is representative of conditions in the Upper Aquifer. Using the values given above, the retardation factor for the TCE is calculated to be 2.63 for these conditions. In simple terms, this means that TCE moves at an average velocity which is 2.63 times slower than average groundwater velocity.

To calibrate the solute transport model, each potential source was assumed as a source and a resultant TCE plume was simulated for the start of the operational period through 1988. Model simulations had suggested that none of the 12 potential source sites alone would result in forming the currently known TCE plume. Alternative simulations were performed whereby contri-

butions from one or more of the sources were considered. To formulate the potential source combination, the sites were separated into two groups; one that would form the western limits of the plume; and one to form the majority and the eastern portion of the plume. The final calibrated model simulation involved percolation of TCE into the groundwater from the arroyo during the period from 1945 through 1975 (when most of the operations believed to have contributed to contamination ceased) as the first potential source.

A secondary source of TCE to the groundwater, from Site S-5, was then added for the period from 1970 to 1985. The resultant TCE plume formation is shown in Figure 5. Source concentrations of 500 ug/L for the arroyo and 1700 ug/L for Site S-5 were back-calculated to form the 1.95×10^{11} ug (or 430 lb) of TCE mass currently believed to be present in the groundwater. The resultant plume at the end of 40 yr of simulation is assumed to represent the current conditions and, therefore, is used as initial concentration distributions to subsequent model runs.

under the no-action alternative has been made by simulating conditions expected under a no-action alternative. Figure 6 shows the migration of the TCE plume during the next 30 yr at 5-yr intervals. As shown in Figure 6, the center of the TCE plume moves approximately 1 mi from the northern GAFB boundary in 30 yr. Model results suggest that the average peak effective transport velocity within the TCE plume over a 30-yr period would be approximately 236 ft/yr. This 236 ft/yr velocity would translate into a TCE displacement of approximately 90 ft/yr (plus some additional displacement due to dispersion) based on a retardation factor of 2.63. It should be noted that, for the purpose of the modeling discussion presented here, the "peak effective transport velocity" is defined as the highest velocity calculated by the model in any direction within the aquifer domain bounded by the TCE plume at any given time. TCE mass balance calculations done by the model suggest that, of the 430 lb total mass of TCE currently in the aquifer, 364 lb are associated with the soil matrix during the 30-yr period due to the soil adsorption process. The remaining 66 lb of TCE remain in solution. This portion would continue to adsorb to soil surfaces and move until all mass is discharged to the

Mojave River.

To develop the groundwater extraction scenarios, some combinations of 21 potential extraction well locations have been selected based on: (1) minimum distance required between extraction wells to minimize drawdown effects on each other (estimated at 400 ft from the aquifer test conducted at well NZ43), (2) known or predicted available saturated thickness and (3) site access to avoid areas of steep slopes. Locations of these potential extraction wells are shown in Figure 7.

A number of groundwater extraction and disposal scenarios have been formulated. Of these, only seven scenarios have been modeled and evaluated in detail since they represent a unique combination of control measures. The description of each modeled scenario is tabulated in Table 2 together with the number (referenced in Fig. 7) and rate of the extraction wells.

Tables 3 and 4 are developed to aid in comparison of the technical performance of each scenario. Model predicted piezometric water levels and the drawdowns at two existing monitoring well locations are tabulated in Table 3. Also shown in this table are the model calibrated steady-state piezometric water levels and the actual water levels measured in the field during September 1987 from monitoring wells NZ43 and NX28. As shown in the table,

the measured and model calibrated water levels are in agreement (less than 0.5 ft difference). The calculated drawdowns are relative to the model steady-state calibrated heads.

Table 4 shows the technical performance summary of the simulated groundwater extraction and disposal scenarios, reduced from the lengthy computer output from each model run. Shown

in the table are the peak effective transport velocities, as well as the TCE mass and concentration remaining in the groundwater after approximately 30 yr of simulation. The significance of peak effective transport velocities is that higher velocities result in faster contaminant removal, up to a certain limit. The extraction system needs to be able to extract the contaminant before the higher velocities transport it past the wells. This is clearly evident in comparing Scenario 5 with Scenarios 1 through 4, where higher velocities do not necessarily result in better contaminant removal. The percent removal values reported in the table are calculated as percent removal in comparison with the initial 430 lb of TCE in the aquifer.

DESCRIPTION OF THE PREFERRED ALTERNATIVE

Following detailed evaluation of groundwater extraction and/or recharge scenarios, Scenario 7 was selected as the preferred alternative for groundwater remediation at NE Disposal Area. This scenario involves extraction of 500 gpm groundwater from 19 wells located throughout the known extent of the plume. The existing unused STP Percolation Ponds would be utilized to percolate the extracted and treated groundwater. It is assumed that 160 gpm of the 500 gpm extracted groundwater would be utilized for irrigation (domestic and/or golf course) or would evaporate during the percolation process. The objective of Scenario 7 is to reduce the high effective transport velocity calculated for Scenario 6, while increasing TCE capture efficiency and providing a beneficial use of the extracted water.

The predicted piezometric groundwater levels and the surface of the Upper Aquifer for this groundwater extraction and percolation scenario are shown in Figure 8. The predicted TCE concentrations for the 20-yr period from the start of remediation are shown in Figure 9. The three-dimensional groundwater flow model results suggest that reducing the percolated amount by 160 gpm forms a smaller groundwater mound beneath the percolation ponds, with a resultant 132 ft/yr lower peak effective transport velocity. The solute transport model, on the other hand, suggests that the lower velocities would result in better TCE removal efficiency. In fact, the reduced velocities result in all of the plume remaining in the capture zone of the extraction system.

Hydraulic Performance of Horizontal Wells

David E. Langseth
Arthur D. Little, Inc.
Cambridge, Massachusetts

INTRODUCTION

Environmental applications for horizontal wells, a technology developed for and routinely used in the petroleum recovery industry, are being recognized and explored with increasing frequency in other applications. For contaminated groundwater recovery operations, horizontal wells have clear technical advantages over vertical wells in situations involving fractured rock aquifers; dense nonaqueous phase liquid recovery; and recovery from below landfills, lagoons, buildings, wetlands, lakes or other surface obstructions.

Bedrock contamination is being encountered with increasing frequency at contaminated sites, and traditional vertical well recovery systems frequently do not provide effective recovery. As already demonstrated in the oil and gas industry, the ability to cross multiple bedrock fractures at a high angle will provide enhanced product or contaminant recovery where traditional vertical extraction methods have proven ineffective.

Horizontal wells are also ideally suited for recovering dense non-aqueous phase liquids (DNAPLs) in groundwater. DNAPLs, such as chlorinated solvents, tend to sink through porous media, regardless of water table gradients, until they encounter a low hydraulic conductivity layer. At this point, the DNAPLs spread out along the boundary, which in most cases will be horizontal to subhorizontal. Since the horizontal wells can be easily oriented parallel to horizontal bedding planes, the cleanup can be much more effectively accomplished than with vertical wells, which typically perform poorly in such situations.

Horizontal wells, unlike vertical wells, do not have to be drilled directly above a contaminant source to effectively remove contaminants. Rather, the bore hole can be advanced in the direction of contaminants for a distance of up to 500 feet. This advantage has obvious implications for remediating obstructed areas such as under buildings, lagoons, landfills and wetlands in terms of monitoring capability, cleanup rates and overall effectiveness. In addition, horizontal wells have hydraulic characteristics that may prove advantageous for groundwater recovery in numerous unobstructed situations.

Other environmental applications are related to activities such as vadose zone soil gas vacuum extraction, steam injection remediation, bioremediation and grouting. Remedial applications for unsaturated conditions, such as gas extraction or steam injection, may benefit from the enhanced exposure within the contaminant zone available through a continuous well screen of up to 500 feet in length. By combining an injection and recovery dual horizontal system, significant progress may be realized in cleanup effectiveness. Bioremediation applications may benefit from increased exposure to the contaminant for injection of both nutrients and nonindigenous organisms in either saturated or unsaturated conditions.

Horizontal wells may also be useful for grouting for remedial systems. Horizontal wells can provide direct grout access below, above and along

any side of an existing contaminant plume or a potential threat to ground-water quality. In this capacity, horizontal wells can function as a preventative or remedial measure to isolate contaminants.

Significant progress has already been made towards applying horizontal well extraction to remediation of contaminated soil at the Savannah River Laboratory located in Aiken, South Carolina. Two horizontal wells were installed by Eastman Christensen along a leaking sewer line to test a new method of in situ remediation. Additionally, during fiscal year 1990, the Department of Energy (DOE) plans to conduct further studies of horizontal well applications at the Savannah River Station. Current DOE plans for this program include: (1) in situ bioremediation of groundwater, (2) in situ characterization techniques, (3) remote monitoring techniques and (4) innovative technologies for soil cleanup. The DOE recognizes the limitations of vertical wells for stabilizing contaminants and the previous untapped capability of horizontal wells to succeed in stabilizing migrating contaminants.

Recent updates in the capability to sample through horizontal drilling will provide a means for effective lateral characterization of dispersed waste for both chemical sampling purposes and geologic logging. Horizontal wells will also offer the unique ability for remote characterization, sampling and extraction in areas characterized by either high toxicity or radioactivity. This capability is not only technically attractive, but also will likely produce overall cost savings due to decreased levels of safety requirements for drilling and sampling crews.

In summary, horizontal wells show potential for providing both significantly better performance and lower total remediation costs than systems relying on only vertical wells for a large number of situations. These situations include not only areas where surface obstructions interfere with vertical access, but also areas where hydrogeologic or contaminant distribution conditions render vertical wells ineffective; situations where continuous horizontal exposure to the subsurface materials is advantageous; and areas where human health and safety concerns are of unusual severity.

The purpose of this study is to compare, through the use of computer modeling, the technical performance of horizontal and vertical well contaminant removal systems and, subsequently, to evaluate cost-effectiveness of those systems when combined with typical groundwater treatment systems. The scope of work includes; (1) developing of a hypothetical model to evaluate horizontal and vertical well contaminant recovery performance under a variety of conditions, (2) performing a numerical model evaluation based on real site hydrogeology in order to compare horizontal and vertical well performance under specific real world conditions and (3) evaluating the relative cost-effectiveness of horizontal and vertical well contaminant recovery systems when coupled with typical groundwater treatment systems.

The hypothetical modeling study of horizontal wells and vertical wells

was designed to evaluate contaminant removal effectiveness under a variety of controlled conditions. We used numerical models of groundwater flow and contaminant transport to evaluate the performance of several different well arrays for a variety of contaminant plumes and hydrogeologic parameters. We presented the results principally in terms of contaminant recovery rates and total contaminant recovery, but we also developed a variety of other information such as streamlines and flow velocities to help develop a more thorough understanding of horizontal well hydraulics. The results from this hypothetical phase of the study were used to design the horizontal well system used for the real site modeling effort.

The case study modeling was based on hydrogeology at a contaminated site. We developed a numerical model of groundwater flow and contaminant transport for this site and selected vertical and horizontal well systems. The vertical well system design was taken from a previous proposal by others for remediating the site. The strategy for maximizing effectiveness of the horizontal well system was based on principles developed during the hypothetical modeling study. The two systems are roughly equivalent in pumping rate and well location, using eight vertical wells and four horizontal wells. The two systems were compared on the basis of total contaminant recovery rates.

Subsequent to the contaminant recovery modeling we estimated groundwater treatment costs for three commonly used groundwater treatment systems; air stripping, air stripping with vapor phase carbon adsorption and air stripping with liquid phase carbon adsorption. We then combined the treatment costs and groundwater recovery costs and performed a comparative economic analysis, accounting for the faster contaminant recovery achieved by the horizontal well system.

HYPOTHETICAL MODELING STUDY

Background

Horizontal wells work on the same theoretical principles as vertical wells. Both are governed by Darcy's Law for groundwater flow. Direct analytical solutions numerical approximations for the hydraulic performance of vertical wells are widely known and used. Bear[2] provides a good discussion of many of these solutions and a list of references where further information can be found. In addition, the scientific/technical community that works with the hydrogeology of contaminated sites is generally very familiar with the theory of vertical well hydraulics and actual vertical well performance data.

Horizontal well hydraulics, however, while theoretically similar to vertical well hydraulics, are not as well known. Hantush[3] and Hantush and Papadopulos[4] present solutions for flow to horizontal wells, but these solutions are not widely known or used in the environmental restoration business. Further, since horizontal wells are not widely used for environmental restoration, there are minimal field data documenting their performance for this purpose. The extensive horizontal well performance data developed by the petroleum industry are not widely known in the environmental field. Also, much of the information developed in the petroleum industry, while useful for developing a general understanding of horizontal well performance, is not directly relevant to the problems faced during groundwater contamination recovery.

In theory, horizontal well performance can be approximated by a series of closely spaced vertical wells with short screens, and vertical well performance can be approximated by a series of closely spaced (vertically) horizontal wells with short screens. Both practical and cost considerations, however, frequently dictate against either of these options.

This hypothetical modeling study is a first step towards developing a base of knowledge about horizontal well performance for the environmental restoration business.

Approach

Our approach to this hypothetical modeling uses numerical models of groundwater flow and contaminant transport to simulate the performance of horizontal and vertical wells. For the numerical model development, we used the MODFLOW[5] code to simulate the groundwater hydraulics and the MODPATH[6] code to simulate contaminant transport. MODFLOW is a finite difference solution for fluid flow in porous media. MODPATH is a particle tracking model designed as a companion to MODFLOW.

The general scope of this hypothetical modeling effort includes the following elements:

- Selection of representative contaminant scenarios
- Development of three-dimensional groundwater flow and contaminant transport numerical models for hypothetical scenarios
- Selection and optimization of representative horizontal and vertical recovery well arrays
- Assessment of relative contaminant capture effectiveness for the various well arrays and contamination scenarios
- Assessment of the effects of hydrogeologic and contaminant plume variations on contaminant capture effectiveness of vertical and horizontal wells

We selected three contaminant scenarios for evaluation in this work. Two of the scenarios represented hypothetical existing contaminant plumes, and the third scenario represented active leachate from a landfill or lagoon. The two existing plume scenarios had the same lateral dimension, but different thicknesses. This selection allowed us to evaluate the relative performance of horizontal and vertical wells with respect to plume geometry. The thick plume also allowed us to more easily evaluate the horizontal well hydraulic performance at larger vertical distances from the well and for multiple wells separated vertically. The active leachate plume was selected to allow us to evaluate the performance of horizontal wells placed directly under leachate sources and compare that to vertical wells surrounding the sources.

In selecting and optimizing representative horizontal and vertical extraction well arrays, we first developed a wide variety of well configurations and then selected a group from among these for further evaluation. As part of this process, we optimized the well placement within each configuration. For example, for the single horizontal well perpendicular to the groundwater flow direction, we optimized the location of that well prior to developing the results shown here.

We assessed the relative contaminant capture effectiveness principally by evaluating the contaminant mass captured as a function of time. In addition, for selected scenarios we also developed graphic displays of contaminant streamlines, time of travel contours, contaminants not captured and contaminant particle velocities. ADL[1] presents a more complete set of results than we present here.

After evaluating all the selected scenarios for a base set of model parameters, we investigated the impact of variations in hydrogeologic parameters such as hydraulic conductivity and gradient.

Model Development

Model development for the hypothetical model consists of selecting a numerical grid and then assigning parameter values and, where appropriate, boundary conditions to the grid cells.

We selected a three-dimensional grid which was 25 meters on each side, in which each cell measured 1 x 1 x 1 meter. Figure 1 illustrates the grid.

Table 1 summarizes the selected hydrogeologic parameter values. The key hydrogeologic parameter values assigned to the model are horizontal and vertical hydraulic conductivities. We used a base horizontal and vertical hydraulic conductivity value of 8.64 meters per day (m/day) (which corresponds to 0.01 centimeters per second). For the sensitivity analysis, we lowered the horizontal conductivity to 0.864 m/day, lowered the vertical conductivity to 0.864 m/day, and both raised and lowered the transverse horizontal conductivity to 86.4 m/day and 0.864 m/day.

We used fixed head boundary conditions at two ends of the modeled grid, no flow boundary conditions at the sides and bottom and a free surface boundary condition at the top. The fixed head boundary conditions were set to produce a gradient of 0.05 for the base parameter set and varied to produce a gradient of 0.005 during the sensitivity analysis. The thick and thin plume geometries had length times width times height dimensions of 9 x 9 x 9 and 9 x 9 x 1 meters. The leachate source had lateral dimensions of 9 x 9 meters and was applied at the groundwater surface. This combination of grid dimensions and plume
Figure 1
Model Grid 25 x 25 x 25

size provided a high degree of resolution, allowing clear distinctions between horizontal and vertical well performance and minimization of edge effects from boundary conditions. The absolute size of these plumes is smaller than the typical sizes of real plumes which require remediation. The objective in modeling plumes of these dimensions, however, was not to mimic the size of a typical plume, but rather to maximize the detailed resolution of groundwater extraction by both vertical and horizontal well orientations. The modeled plume size is largely irrelevant since the purpose here is to compare the effectiveness of various withdrawal schemes per unit volume of contaminant plume. The principles for extraction effectiveness and sensitivity to parameter changes demonstrated here apply also to larger plumes.

These two ambient plumes were represented in MODPATH by assigning particles to each block for the plume at time zero. The particles were then transported with the water and either captured by the extraction wells or carried past the wells by the ambient flow. For the active landfill or lagoon simulation scenario, we prescribed an initial loading of particles in each cell. We then applied water recharge to the landfill cells, which carried the particles down into the rest of the aquifer.

Another key parameter is the pumping rate from the wells. We recognize that horizontal well production rates are typically higher than for vertical wells. This phenomenon is due in part to the greater screen length typical of horizontal wells. In order to provide a reasonable basis of comparability, we used a pumping rate of one cubic meter per day (m³/day) per meter of screen length for all of the wells. Each well simulated in this study, unless otherwise noted, had nine meters of screen and was, therefore, pumped at 9 m³/day. Therefore, scenarios with two wells had total pumping rates of 18 m³/day and scenarios with three wells had total rates of 27 m³/day.

Pumping Well Orientation

In real remediation problems, well orientations are decided on a case-by-case basis. The exact locations are based on site access, contaminant distribution and geologic and hydrogeologic conditions. Previous studies of well removal effectiveness as a function of orientation have compared well placements at the center of the plume, downgradient of the plume and along the flanks of the plume.[7] The number of vertical wells modeled in these previous studies ranged from 1 to 4 and are generally oriented symmetrically about the plume. Our modeling of well orientations followed a similar approach and we used many of the same vertical well orientations.

Figure 2 shows the set of vertical and horizontal well arrays we selected for this study. Within each array, we refined the well locations to optimize a combination of the contaminant capture rate (mass per time) and total mass of contaminants captured. For example, the best location for the single horizontal and vertical wells was somewhat downgradient of the centroid of plume mass. In the absence of an ambient gradient, the best location would be at the plume centroid. The steeper the gradient, the further downgradient the wells should be located. Locating the wells closer to the downgradient edge of the plume enables the wells to achieve a higher total capture rate in many instance, but at the cost of reducing the rate of capture. The tradeoff between capture rates and total capture of contaminants is a consideration that is most often resolved by regulatory constraints or cleanup goals.

Contaminant Capture Performance

Figure 3, 4 and 5 illustrate contaminant capture effectiveness for a variety of pumping well orientations (Figure 2) under the base parameter set (Table 1). These results show the following:

- For the thick plume, several horizontal and vertical orientations can produce generally comparable performance orientations, though the fastest capture rate is produced by horizontal well orientation G.
- For the thin plume, horizontal well orientations G and B provided the best performance.

horizontal, vertical, and transverse hydraulic conductivity and groundwater gradient. Table 2 summarizes these results. ADL[1] provides more details and illustrations of these results.

CASE STUDY EXAMPLE

This portion of the study focused on numerical modeling incorporating real site hydrogeology and an approximation of real site contaminant history. The site used in this study was selected solely for the purpose of demonstrating horizontal well performance; we are not proposing an alternative remedial strategy or cleanup criteria for this site. For purposes of this study, volatile organic contaminants are assumed to be present in the groundwater.

The site is underlain by glacially derived, unconsolidated overburden of variable thickness, which rests unconformably on crystalline basement rock. These unconsolidated sediments range in thickness from approximately 30 feet in the northern part of the site to more than 100 feet thick in the central part of the site.

Glacial sediments consist of stratified sands and gravels in the upper portion, which overlie a dense glacial till at the bedrock interface. Thin, discontinuous clay rich layers are interstratified throughout the upper sand and gravel material. The basal till, consisting of clays and silt, is not continuous, and at some locations the sand and gravels and the underlying bedrock are in direct contact. Where the till is present (in thicknesses of up to 30 feet), it is characterized as a clay and pebble-rich, densely packed material of high compressive strength. Crystalline bedrock underlying the till consists of gneisses and schists. The upper 5 to 10 feet of bedrock are characterized by a high degree of fracturing and chemical weathering. The bedrock surface was sculpted by glacial activity resulting in a trough which slopes to the southwest at the northern end of the site and to the south at the southern end of the site.

The site hydrogeology is characterized by an upper stratified sand and gravel unconfined aquifer, ranging in thickness from 30 feet to more than 100 feet, a basal aquiclude consisting of densely packed till and a thin lower confined aquifer in the upper weathered bedrock surface. A groundwater divide is present on-site, crossing from east to west. Rainfall recharge entering the site either flows south toward a small river or north toward a small brook. Lateral groundwater flow across the site, toward the north and south, is interrupted by a number of surface geologic features, including glacial ponds and surface seepage areas. The depth to groundwater varies from a maximum of 40 feet to essentially 0 feet at surface seeps and ponds. Horizontal hydraulic conductivities vary across the site from a minimum of 0.02 meters per day (m/day) in dense till material to a maximum of approximately 40 m/day in highly transmissive sands and gravels. Vertical hydraulic conductivities vary from a 0.0003 m/day minimum to a maximum of approximately 1.8 m/day. Recharge flux to groundwater across the site ranges from a minimum of 0 to a maximum of 0.74 m/year. Specific yield is generally in the range of 0.2 to 0.3.

Groundwater flow within the highly weathered upper bedrock aquifer is significant under the entire site due to its fractured nature. The low permeability till and silt aquitard overlying the fractured bedrock insulates the hydraulic characteristics of the upper bedrock aquifer from the overlying aquifer within the unconsolidated glacial sediments and moderates the movement of contaminants downward.

Groundwater Flow and Contaminant Transport Modeling

The MODFLOW and MODPATH groundwater flow and contaminant transport codes used for the hypothetical modeling study also were used for modeling this site. ADL[1] provides a complete description of the model development. A few issues are summarized below.

We discretized the site into five layers, three upper layers of predominantly sand and gravel, a fourth layer of predominantly glacial till and a bottom layer of fractured weathered bedrock. The average thicknesses of these layers are approximately 15 feet each for the upper three layers, 10 feet for the till, and 6 feet for the bedrock. Horizontally, we established a 97 x 97 grid which extended to the streams on the north and south, to the drainage basin divide on the west and far enough east to minimize the influence of that boundary on the results. We used a uniform horizontal cell size of 25 meters (82 feet) in each

Table 2
Performance of Horizontal and Vertical Well Orientations as Measured by Rate Of and Total Particle Capture

	Base Case Parameter Set		Reduction in Horizontal Hydraulic Conductivity		Increase in Groundwater Gradient		Reduction in Vertical Hydraulic Conductivity		Reduction in Transverse Hydraulic Conductivity		Increase in Transverse Hydraulic Conductivity

T = Tie

dimension. This relatively fine mesh was selected to assure that the hydraulics of horizontal wells could be adequately characterized at any location on-site.

Parameter values such as hydraulic conductivities and recharge values were based on the site data and the experience gained from previous modeling work reported by others. The model was calibrated against measured groundwater head values in a network of wells on-site. We achieved adequate calibration with relatively few changes to the initial parameter set.

The contamination was simulated in two steps. First we developed base line conditions by modeling each contaminant source as a constant strength source during its period of operation until it closed. In order to accomplish this task, three steady-state groundwater flow fields were developed to allow for the changing contaminant source and hydrogeologic conditions. This base line condition was used as the initial condition for containment removal operations.

Well Field Design

We evaluated two arrays of wells for this simulation. One evaluation was conducted on a set of eight vertical wells that had been previously proposed for use at the site. The other was a set of four horizontal wells we selected. The proposed design total pumping rate for the vertical wells was 709 gallons per minute (gpm), based on maximum acceptable drawdowns in each well of approximately 10 feet. Vertically, these wells were placed in the most highly contaminated layer, the glacial till. We established the pumping rates by specifying a maximum acceptable drawdown of approximately 10 feet. Using this drawdown produced a total pumping rate of 662 gpm, approximately 6% less than the vertical wells.

Well Field Performance

Figure 6 summarizes the vertical and horizontal well field performance in terms of containment removal versus time. Tables 3 and 4 list contaminated aquifer volumes, contaminant mass balances and concentration data for distinct time periods. The well field performance

after 5, 10 and 20 years of operation is discussed below.

After 5 years of pumping, the horizontal wells removed approximately 77% of the contaminants that were on-site in 1984. Also, the average concentration of contaminated cells was reduced by approximately 56% from base line conditions. The contaminants not captured by the wells are either still on-site or have migrated off-site into one of the rivers. By comparison, over the same 5-year time period, the vertical well array removed only 59% of the contaminants on-site in the base line condition, 18% less than removed by the horizontal well array. Additionally, the average concentration of contaminated cells was lowered only 22% from 1984, compared to the 56% reduction achieved by the horizontal wells.

After 10 years of pumping, the horizontal wells removed approximately 84% of the contaminants, decreased the average concentration of contaminated cells by 77% and essentially eliminated the two lagoon plumes. Conversely, the vertical wells over this time period removed 75% of the contamination, 9% less than the horizontal wells after 10 years, and not yet up to the 5-year horizontal well performance. Also, under vertical well pumping, the average concentrations of con-

taminated cells are approximately 4% higher than for the horizontal wells, and none of the plumes have been eliminated. The trends observed between 5 and 10 years suggest that with time the total cleanup differences between vertical and horizontal wells decrease at this site. Most of the contaminants that eventually will be captured by the wells already have been captured after 10 years and continuing to operate either pump-and-treat system becomes less and less efficient on a contaminant extraction per gallon of groundwater removal basis. This phenomenon is due to a combination of the relatively high ambient flow rates at this site, the proximity of the landfill to the river, the well field design and the reduction in contamination available to be pumped.

At 20 years of pumping, 85% of the contaminants have been removed by the horizontal wells, only 1% more than at 10 years, and the average concentration of contaminated cells has leveled off at about the 10-year level. By comparison, the vertical wells have achieved a total capture that is still approximately 9% less than the horizontal wells, and they have also removed only about one additional percent of contaminants over the 10- to 20-year time period. Also, the average concentration of contaminated cells is approximately 6% less than the horizontal wells. The last result regarding average cell concentrations is a reversal in trends from previous years. It does not, however, represent improved extraction efficiency by vertical wells, but rather subtle variations in the flow field generated by the two well arrays. The horizontal wells tend to keep contaminants on-site longer than vertical wells, rather than allowing flow to surface water discharge points. The overall results for this time period confirm that the contaminant removal effectiveness decreases with time at this site. Additionally, most of the contaminants that will be captured at this site have been captured after 10 years. Therefore, it is likely that the vertical well system will never be able to capture as much total contamination as the horizontal wells. Most of the contaminants on-site after 20 years that have not been captured by wells are located in the southern portion of the site in a plume area that is not directly addressed by either well system.

ECONOMIC EVALUATION

Approach

In some situations, the appropriateness of horizontal wells may be determined on a purely technical basis; in others, there may be economic advantages available from using horizontal wells. As part of the site modeling study, we conducted an economic analysis of groundwater extraction and treatment alternatives. We selected three treatment

technologies, air stripper, air stripper with emission controls, and carbon adsorption, for cost comparisons. These technologies are commonly used for groundwater remediation.

We developed cost estimates, including capital and O&M (operations and maintenance) costs, for the groundwater extraction and treatment options using a U.S. Environmental Protection Agency computer program entitled CORA (Cost of Remedial Action) for all cost elements except the horizontal wells. The horizontal well cost estimates were based on information supplied by the Eastman Christensen company. CORA is a model which consists of an expert system and a cost system designed to estimate site-specific remedial action costs for Superfund sites. We prepared cash flow projections under three assumptions, including no inflation, 5% annual inflation and 10% annual inflation. These cash flow estimates were then used to develop net present value estimates at three hurdle rates (10, 12 and 15%) and cumulative cash flow estimates.

Groundwater Recovery and Recharge System Costs

As described earlier, the vertical well groundwater recovery system consists of eight extraction wells pumping at a total rate of approximately 710 gallons per minute (gpm), and the horizontal well groundwater recovery system consists of four extraction wells pumping at a total rate of approximately 660 gpm. Using vertical well diameters of 6 inches and an average depth of 70 feet, we estimated installation costs to be approximately $85,000 for the eight vertical wells, or slightly more than $10,000 per well. Using horizontal well diameters of 6 inches, average vertical depths of approximately 60 feet, and horizontal lengths of 500 feet per well, we estimated installation costs to be approximately $300,000 for four horizontal wells, or $75,000 per well.

Operations and maintenance of the groundwater recovery system includes regular inspection, monitoring and sampling. The differences in O&M cost between vertical and horizontal extraction systems are negligible, and were not, therefore, considered further in this comparative economic evaluation.

Recharge or groundwater disposal facilities also need to be constructed. Since we anticipate that the same system would be used for either vertical or horizontal wells, recharge system costs were not considered in this comparative economic evaluation.

We assumed that personal safety protection levels D or C would be used for either vertical or horizontal well installations. It should be noted that in some situations, use of horizontal drilling would allow work at lower levels of protection, thereby achieving a relative cost savings.

Treatment System Costs

Data requirements for estimating costs associated with treatment system construction and operation include flow rate, contaminant concentration, nature of contaminants, length of transfer piping and required effluent concentration. Extraction rate of contaminated groundwater determines the required capacity of the treatment system. In general, higher flow rates through a treatment system result in higher capital and O&M costs to construct and maintain the operation. We used a 700 gpm flowrate to estimate both capital and O&M costs. We performed sensitivity analyses with respect to flowrate and found that the cost differences between flowrates of 660 gpm (horizontal well flow rate) and 710 gpm (vertical well flowrate) are negligible.

Influent contaminant concentration influences O&M costs of carbon adsorption systems to a greater degree than air stripper systems. Carbon loading rate is increased as contaminant concentration increases, resulting in more frequent regeneration of carbon. We used an influent concentration of 1000 μg/L for VOCs and 2000 μg/L of total organic carbon in our cost estimates. While measured VOC concentrations at the site reach 10,000 μg/L, the average concentrations from pumping wells are much lower. For example, after five years, vertical wells have removed 7.04 x 10^9 liters of water and 6.5 x 10^{12} μg of contaminant, producing an average contaminant concentration of 923 μg/L. Similarly, horizontal wells remove 6.58 x 19^9 L of water and 7.79 x 10^{12} μg of contaminant over 5 years for an average contaminant concentration of 1184 μg/L. The cost implications of the concentration difference (923 μg/L versus 1184 μg/L) is negligible for comparative cost purposes. We

therefore used an average VOC concentration of 1000 μg/L consistently for treatment cost estimations. Influent VOC concentrations are likely to decline over time for both horizontal and vertical well extraction systems. We neglected the influence of this decline in our cost estimates.

Natural groundwater contains variable quantities of TOCs, generally in the form of fulmic or acetic acid. TOC content may have a significant effect on treatment costs for carbon adsorption systems because it is adsorbed on the carbon and, therefore, reduces the useful life of the carbon. We chose a value of 2000 μg/L TOC for inclusion in treatment cost estimates.

Connecting eight vertical wells to a treatment system will require more piping than connecting four horizontal wells to a treatment system. We used 5000 feet of transfer piping for vertical well extraction systems and 2500 feet of piping for horizontal well systems.

The required effluent concentration ultimately determines residence time of contaminated groundwater within a treatment system. This impacts the flowrate and directly influences the cost of the treatment system from both a capital and O&M standpoint. We used an effluent VOC concentration of 20 μg/L when developing our cost estimates.

We estimated capital costs for an air stripper system handling approximately 700 gpm, to be approximately $180,000. The capital cost does not change significantly at the lower horizontal well flowrate of 660 gpm. We estimated annual O&M costs, including power, repair, etc., to be approximately $50,000.

We estimated capital costs for an air stripper plus a vapor phase carbon collector to be approximately $450,000. Operation and maintenance costs of the carbon system are a function of flowrate and contaminant concentration. Using an air flowrate of approximately 2000 cubic feet per minute (cfm), we estimated a carbon loading rate of approximately 9 pounds per day based on average contaminant concentrations. Under these conditions, vapor collection O&M costs are approximately $130,000 per year, for a combined O&M cost of approximately $170,000 annually.

We estimated capital costs for the carbon adsorption system to be approximately $1,100,000 for a contaminated groundwater flowrate of 700 gpm. Operations and maintenance figures are a function of the carbon loading rate, which is directly proportional to the product of influent contaminant concentration and flowrate. At a flow rate of 700 gpm, with VOC concentrations of 1000 μg/L and TOC of 2000 μg/L, carbon usage will approach 175,000 pounds annually. Using a unit rate of $1.50 per pound for carbon use and regeneration, this will cost approximately $260,000 annually. Additional O&M factors increase annual costs to approximately $330,000.

Comparative Economic Evaluation

The principal issue addressed in this economic evaluation is whether the increased contaminant capture rate achieved by the horizontal wells can shorten remediation periods enough to justify the additional capital cost generally needed to construct horizontal wells. This question can be addressed in general terms by simply evaluating the O&M costs associated with the treatment technology selected for a given site and then comparing the differences in net present value of the O&M for various treatment periods. If the cost of investments needed to shorten the treatment period is less than the reduction in O&M, then the investment is financially worthwhile. We present the evaluation here in terms of the specific site modeled above, considering the specific performance of the selected horizontal and vertical well systems.

We recognize, as discussed earlier, that where drilling access to an unfractured aquifer containing dissolved contaminants is not restricted, it generally is possible to construct several vertical wells in a manner that will approximate the hydraulic performance of a horizontal well. The cost of drilling those several vertical wells, relative to the horizontal well cost, will depend on the depth at which the screens must be placed. As the screen depth increases, the horizontal wells become relatively less expensive. At the particular site modeled earlier, additional vertical wells could be installed to increase the contaminant capture rate, though possibly at the expense of also increasing the flowrate to the treatment system. If site conditions were more restrictive, the options for vertical well placement could be more limited. For example, if there

were a building just southeast of the landfill, which is the principal source of contamination, the horizontal wells still could be placed as shown, but vertical well placement would be restricted.

The evaluation focuses on the comparative economics of the remediation systems under consideration. There is also an intangible value associated directly with reduced remediation time. While this value cannot be quantified easily, for many companies faced with remediation obligations, there is significant value in simply shortening the cleanup period and hastening the day when that liability can be written off their books.

For a real site remediation, cleanup criteria and methods of measuring when those cleanup criteria were met are established on a site-specific basis. Issues such as regulatory requirements, results of a health risk assessment and technical feasibility typically are considered when establishing the cleanup criteria. Issues such as sensitive receptor location, site hydrogeologic characteristics, contaminant distribution, treated water discharge system and the degree of public health or environmental quality risk posed by the site typically are considered when establishing the method of measuring whether the cleanup criteria have been met.

Instead of site-specific criteria, we used total contaminant mass removed as the comparison criterion between the horizontal and vertical well systems. As shown in Figure 6, the characteristic of the ambient groundwater flow, combined with the extraction system design, produce a situation in which after 10 years of operation, neither the vertical nor the horizontal wells achieve significant additional contaminant capture. The horizontal well system requires somewhat less than 5 years to achieve the cleanup level achieved in 10 years by the vertical well system. We therefore focused our cost comparisons around the first 10 years of operations for the vertical wells and 5 years for the horizontal wells. Depending on the actual cleanup criteria, the treatment period could extend considerably longer for either system.

We present three forms of financial data in this evaluation: (1) annual cash flow estimates, (2) cumulative cash flow estimates and (3) net present value estimates. First we present the basic cash flow values under two inflation assumptions, 5% and 10%. We did not tabulate the cash flow under the no inflation scenario since it is simply a continued annual expenditure of the year one costs. While our comparative evaluation focuses on the 5 and 10 year time frames, we presented cash flow estimates for a 30-year period to facilitate the reader making other comparisons for different treatment periods or other assumptions. Second, we present and compare net present values (NPV) of capital and O&M costs for three hurdle rates, 10, 12 and 15%. In most economic evaluations, NPV of all costs is the principle value used for decision-making. The cash flow values can easily be used to estimate NPVs for other hurdle rates. Third, we present and compare cumulative cash flow values. While we recognize that NPV is typically used for decision-making, cumulative cash flow requirements must be considered for budgeting purposes.

ADL[1] presents the complete tables of these cash flow, NPV and cumulative cash flow values. Summary tables and figures for selected representative scenarios are presented in the following discussions.

Table 5 presents a summary of NPV and cumulative cost values for the groundwater treatment O&M costs at treatment periods of 5, 10, 15, 20, 25 and 30 years of operation. These values, when combined with the capital costs described above and the extraction effectiveness shown in Figure 6, can be used to develop economic comparisons. As described earlier, the most appropriate comparison for the specific site and extraction system evaluated here is 10 years of operation for the vertical wells against 5 years of operation for the horizontal wells. Table 6 presents these computations for the three treatment systems evaluated here using 5% inflation and a 12% hurdle rate. These results show that for the 5-year treatment period differential considered here, and with the stated economic assumptions, the higher capital cost of horizontal wells is more than compensated for by the reduced O&M costs for the air stripper with vapor phase carbon adsorption and the carbon adsorption systems. For the simple air stripper system, a 5-year treatment differential is not enough to offset the increased capital cost associated with the horizontal wells in terms of NPV. The horizontal well system does, however, produce a lower total cash flow.

Figure 7 presents summaries of remedial costs and remedial effectiveness in terms of NPV. The evaluation shown in Figure 7 corresponds to Case 2 in Table 6. The bottom portion of this figure is taken from Figure 6, the summary of contaminant extraction effectiveness. The top portion of this figure presents graphical summaries of the NPV, including capital costs, for the three treatment alternatives.

CONCLUSIONS AND RECOMMENDATIONS

Conclusions

The principal conclusions which can be drawn from this study include:

- The hypothetical model study results provide introductory comparison of vertical and horizontal well performance for recovering contaminated groundwater. These results not only demonstrate contaminant recovery performance, but also illustrate the flow patterns produced by single and multiple horizontal wells.

- In many situations, horizontal wells can provide groundwater contaminant recovery performance superior to that available from greater numbers of vertical wells. For example, in our real site case study, four horizontal wells substantially outperformed eight vertical wells, even though the horizontal wells were pumping at a lower total rate than the vertical wells. In situations where direct vertical access to the plume is restricted, better performance of horizontal wells is even more dramatically apparent than that of vertical wells. In situations where vertical access is not restricted, however, a sufficient number of vertical wells can, theoretically, approximate the performance achieved by a horizontal well. Horizontal wells generally offer better performance than vertical wells when dealing with relatively thin plumes. As plumes get thicker, however, or as the vertical

2) NPV	$ 744,000

[1]Based on 5% inflation rate
[2]Based on 12% hurdle rate

hydraulic conductivity decreases, vertical well performance improves relative to horizontal wells.

• The real site modeling and comparative economic evaluation showed that for two of the three treatment technologies evaluated, the initially higher cost of a horizontal well system is more than compensated for by the reduced treatment system operation and maintenance costs associated with the shorter cleanup period. For the third treatment system, air stripping without air emission control, the initially higher costs of the horizontal wells are approximately balanced by the reduced treatment system operation and maintenance costs. It should be noted, however, that increasingly strict regulatory guidelines on air emissions limit the application of air stripping without air emission control. As operation and maintenance costs for a treatment system increase, the economic advantages of faster contaminant recovery also increase.

Recommendations

The results presented in this study provide a solid foundation for understanding how horizontal wells perform when used to recover dissolved groundwater contamination. Studies which would provide additional useful information about horizontal well performance include:

• Expanding the hypothetical model study evaluation to include contaminant removal performance normalized by the total pumping rate. This evaluation would provide an enhanced understanding of the relative performance of vertical and horizontal wells.
• Evaluating the performance of alternative vertical and horizontal well systems at the site used for the case study presented in this report or other case studies.
Figure 7
Extraction Effectiveness and Treatment Cost Summary:
Net Present Value

- When horizontal well pump test data become available, performing a numerical modeling study of the test. This study would provide an opportunity to calibrate a groundwater model to test data generated by horizontal wells and provide further confirmation of the modeling method.
- Evaluating the relative costs of horizontal and vertical wells as a function of the depth to the contaminated groundwater for well designs which produced comparable hydraulic performance.
- Evaluating the benefits of horizontal wells in situations where minimizing the hydraulic stress on the aquifer is important, such as areas where salt water intrusion is an issue.
- Evaluating nonaqueous phase contaminant recovery using horizontal wells.
- Evaluating horizontal well performance in the unsaturated zone, especially related to design parameters for landfill or lagoon monitoring.

Use of Specialized Mining and Petroleum Drilling Technology for Environmental Applications

Albert Vogel
Harrison Western Drilling Co.
Lakewood, Colorado

ABSTRACT

Numerous types of drilling and coring techniques and equipment have been developed for specialized applications in the mining, construction and petroleum industries which have direct use in environmental characterization and site remediations.

The emphasis of this paper is primarily toward applications of non-fluid sonic coring to environmental applications. In addition to a cursory discussion of the sonic drilling technology, other topics discussed focus on applications of this drilling method for gaining uncontaminated samples in adverse conditions such as deep unconsolidated sediments where poor core recoveries are a problem; drilling in areas of high groundwater flows where sample collection and monitor well completions are difficult; drilling in the ecologically sensitive areas of wetlands, tundra, karst and permafrost where the movement of equipment and the act of drilling can cause serious damage; directional drilling techniques to allow for sampling and groundwater remediation under ponds pits, landfills and occupied, operating buildings; and remote controlled drilling when working in areas of high chemical and radiation contamination.

Other technologies such as large diameter drilling and pipe jacking are summarized.

INTRODUCTION

There are many types of drilling and coring technologies that have been developed in the mining, construction and petroleum industries that are essentially unknown in the environmental arena. Many of these technologies have direct application to site characterization and remediation. One of these techniques is the use of sonic drilling and coring. Uses of this technology are particularly applicable when:

- Working in areas of abundant boulders
- There are loose overburden conditions
- Working in areas of very high groundwater flows
- Working in very ecologically sensitive areas such as wetlands, tundra, karst and permafrost
- There is a history of poor core recovery
- There is a need to sample under a waste lagoon or pond or an occupied, operating building
- There is a need to initiate an interim drainage control system for leaking ponds, pits and landfills.

The emphasis of this paper is on the application of sonic drilling technology to environmental problems. Sonic drilling tools were developed for use in gold placer exploration where the economic success of an operation absolutely requires an uncontaminated sample and is most often carried out in very remote areas where the weight of the rigs must be kept to a minimum. The technology relies on establishing resonance within the drill string through means of a sonic hammer, does not use any conventional drilling media such as air, water or mud, provides very pure samples, is readily adaptable to directional drilling techniques and can be readily transported by helicopter, boats, barges or "swamp buggies."

SONIC DRILLING TECHNOLOGY

Sonic drilling differs substantially from conventional drilling techniques. The technology was perfected in Canada in about 1974 under patents held by the late Dr. A.G. Bodine.

Operationally, there is neither a conventional drill bit nor a conventional drill pipe. The drill bit consists of relatively large diameter hardened steel with tungsten carbide inserts set into the hardened steel. Drill casing, similar to auger tools without the flutes, constitutes the rest of the drill string.

Drilling is accomplished by means of a sonic head located on the drilling derrick (Fig. 1). This sonic head produces a frequency close to the natural frequency (approximately 70-150 hz) of the drill column allowing the drill string to act as a flywheel transferring the entire energy of the drill string in bursts to the bit. Drill cuttings are displaced into the annular space or into the core barrel with the core. The disposition of the cuttings is dependent on the bit configuration. In practice, the bit does not leave the cutting surface when drilling. The significance of this point is discussed later.

Actual drilling is affected three ways depending on the rock or soil material being drilled:

- Displacement where soil or rock particulates, such as unconsolidated sands, are fluidized by the vibration of the drill column. This occurs only when there is sufficient porosity in the drilled medium to accept the drill cuttings. In this instance, the sonic drilling method is similar to driving casing.
- Shearing which is affected when drilling in plastic clays and shales. In this instance, the induced amplitude must be sufficiently large to overcome the inherent elasticity of the medium. When not used with rotation, the sonic method is similar to split tube sampling. When rotation is used, the drilling is similar to conventional coring.
- Fracturing occurs when the inertial moment of the bit is sufficiently large to cause fragmentation. Typically, this will occur when drilling in brittle material. A analogy is to a hollow downhole hammer.

Penetration and bit life may be improved when groundwater is present or water is introduced through the drill string at the surface. The penetration rate is improved by more efficiently moving the cuttings from the bit face. However, water is not required since there is more than adequate room for the displacement of these cuttings either into the annular space or into the core barrel. It is important to remember that any introduced fluids are only under the pressure of the liquid fluid column — there is no mud pump or air compressor to force the cuttings away,

to spread contamination or to cause hydrofracturing.

It should be pointed out that it is possible to use sonic drilling technology with fluids through the use of a modified water swivel. We have successfully used this adaptation in the drilling of exceptionally hard conditions on a freeze pipe installation project in Milwaukee, Wisconsin. The conditions of this effort required the drilling through a buried steel slag dump. Materials encountered were lake sediments, wooden piers, slag from a rolling mill and nodules of rolled steel up to 7 inches thick.
Figure 1
Basic Principles of Operation of the Sonic Drill

LIMITATIONS

Sonic drilling utilizes only limited weight on the bit surface, relying on the inertial moment of the induced vibrations and slow rotation to affect penetration. Thus, in terms of depth limitations, any significant damping effort of the drilled medium will obviously inhibit the vibration and eventually cause penetration to stop. To overcome this limitation, especially where there are surface clays, a high torque rotary head can be added and conventional auger tools used to refusal. At refusal, the rotary head is moved out of the way and with the auger tools still in place, sonic tools are deployed through the auger tools. Should the need arise, such as when drilling through deeper clay units, downsizing is easily accomplished. Simply leave the tools in place, put on a reducing coupling and continue drilling with smaller diameter tools—through the entire existing drill string! The maximum depth reported thus far is more than 700 feet.

Another limitation, especially when drilling without fluid, is the length of the core. The combined friction of drill cuttings and of the cut core in the core barrel, the lack of any significant weight from the drill string to force the core into the core barrel and the lack of lubrication from a drilling medium, sometimes cause early core refusal. This may necessitate short core runs. However, through the use of modified wireline core recovery tools, this drilling speed is not significantly affected.

A third limitation is that there is a degree of uncertainty of the porosity and permeability laboratory measurements from cores derived in this method. That is, there is the possibility that additional micro-fracturing and/or compaction from the drilling action may be present and artificially influence these measurements. Until these variances, if present, are quantified, the use of sonic drilled cores is not recommended.

APPLICATIONS

Sample Collection

The most immediate application and the one for which this technology was developed, is to produce a sample of very high purity through highly variable conditions such as clays and sands and boulders and rock. Since the drill bit never leaves the drill face and since most of the cuttings are most often directed into the core barrel, there is only a remote possibility of cross-contamination. Even so, any cross-contamination will be confined to samples of a particular core run unless groundwater is present. Further, boulders, the bane of all drillers, are easily cut and included as part of the sample. Boulders to four feet in diameter have been cored and sampled in the drilling of gold placer deposits in Alaska, California and Montana.

This application has been successfully used at the Radioactive Waste Management Complex at the Idaho National Engineering Laboratory in Idaho and at the Rocky Flats Site in Colorado.

In a drilling demonstration at the Rocky Flats Site in Colorado, actual penetration through the Rocky Flats Alluvium was in excess of 15 ft/hr. Actual on the job performance at the Rocky Flats Site is not available for inclusion in this paper. In this instance, it was necessary to downsize the drill rods and to modify the core barrel assembly. Following the sampling effort, the smaller diameter drill tools were removed and larger diameter tools were used for well installation. This will be discussed in greater detail below.

At the RWMC at INEL, the sampling was affected without rotation. The reason for this is that there was a concern while sampling through buried containers of uncertain materials related to the possibility of generating sparks and other safety concerns. Again, smaller diameter drill tools, albeit larger than those used for the Rocky Flats work, were employed. Following the sampling event, epoxy resin fiberglass casing was installed through the drill string.

A substantial time savings can be realized by using this drilling methodology versus conventional auger and rotary drilling methods. These figures were part of a technical proposal made to a large environmental contractor at his request. The first bar represents the contractor's estimate of the time required using conventional methods (Fig. 2). The second column is our time estimate and the basis for our bid. The percentage estimate of the time saving is shown in the first column on Figure 3. Depending on the task, this time saving (time in the field) is from 5% to almost 30%. Thus, a significant savings can be made from the time required to have people in the field and the coincident PPE requirements.
Figure 2
Estimated Drilling Days by Task

Conversion to Other Drilling Methods

A second application which was alluded to earlier is the ability to change from conventional drilling methods to sonic drilling. This can also be done in reverse. The specified plan called for auger drilling to install surface casing, then moving from the well while the cement set, moving back over the hole and sampling, coring and installing

piezometers and/or wells. Conventional drilling through hollow stem auger tools had resulted in abandoning the well because the augers were stuck in the hole. This is the justification for the surface casing phase. Since it is not necessary to change rigs or remove the tools from the hole, this operation is relatively easily affected and results in an even greater time saving.
Figure 3
Estimated Time Savings by Task

Again referring to Figure 2, column 1 represents the contractors estimate of the field time and column 3 represents our estimate of the time required to complete the task without the need to change rigs. Figure 3, column 2 illustrates the percentage time estimate of these savings and ranges from 30% to 45%. Thus, the ability to convert between sonic and conventional drilling tools dramatically reduced the field time.

Minimizing Ecological Damage

A third application is where there is the need to drill in very ecologically sensitive areas, such as wetlands, tundra and permafrost. There is no need to consider the need for disposal of drilling fluids, except in areas of artesian flow, or of the drill cuttings, except when sampling is not being undertaken in conjunction with well installations.

Further, since the equipment does not require a heavy superstructure, does not need an air compressor or mud pump, uses a lightweight drill string and the rig itself is light in weight, tools are easily transported by helicopter or modified for use on swamp buggies, Unimaks or barges. This method of operation has been used successfully while drilling on the ice of the Bearing Sea in Alaska. Water depths were on the order of 90 feet. However, freezing of the samples was a problem.

Well Installations

The next application concerns well installations. As previously mentioned, monitor wells can be installed either conventionally, i.e. removing the drill string, or installed through the drill string. There is no need to discuss conventional well installation. After the well string is put into place, installation of casing, sand pack, seals and cement can take place inside the drill string. This method is particularly important in areas of high groundwater flow or where there is a consideration of loose material caving above the interval being drilled.

The time of extraction of the drill string depend on local conditions. If warranted and risks associated with this process are deemed acceptable, the drill string can be left in place until the grout or cement has set and extracted by drilling inside the initial drill string with smaller diameter tools.

When installing monitor wells in cases where there is the potential to lose the hole, such as in loose ground, by cavings or high groundwater flows, it is preferable to disconnect the sonic head from the drill string, install the casing, reconnect the sonic head, remove the appropriate length of rods, install the sand or gravel pack, measure the depth to insure that an appropriate amount of sand has been installed, reconnect the rods, remove the appropriate length of rods, install the sealing material and measure. Depending on the conditions, cement

can then be installed through the drill rods and vibrated as the rods are extracted to assure an effective seal or the drill string can be extracted and the cement conventionally installed.

It should be further pointed out that at any time during the installation procedure, the drill string can be vibrated to set the material thereby greatly minimizing void space. This process greatly facilitates the time required to install the well installation materials.

This method of well installation has also been used successfully at the RWMC at INEL for possible geophysical and in situ vitrification uses.

Directional Drilling

Another application of this technology is in the field of directional drilling. By incorporating existing petroleum and mining technology to wedge or shim at the drill face, using the lightweight drill string and maintaining a close survey of the hole, it is possible to drill up, down, left and right from the original vector of the hole.

In practice, this is relatively commonly accomplished at 5° deviation on a 100 foot radius. We do not yet know the limits to this application with sonic drilling technology but we feel that it is greater than 10° on a 100 foot radius. Thus, high purity samples can be taken underneath waste storage lagoons, ponds, landfills or occupied, operating buildings. Since there is no need to use drilling fluids, there is no possibility of hydrofracturing through a waste storage pond or lagoon, thereby spreading contaminants.

As an extension of this technique, interim remedial actions can be initiated. A possible application is shown in Figure 4. By drilling an arcuate array of drainage wells, cementing casing and employing various types of petroleum perforating technologies, a series of "French drains" can be created. These would then drain into a geotextile, concrete lined sump. Thus, the volume of hazardous fluids which previously had been entering the groundwater can be significantly minimized.
Figure 4
Application of French Drain Installation

Another extension of directional drilling applications is to identify fracture systems and anastomosing, fluvial channel systems. Combining first the identification of the geologic setting and second, interim remediation as discussed above, environmental hazards from chemical and radiation contamination can be substantially mitigated (Fig. 5).

Well Abandonment

Conventional methods of abandoning inadequate wells involve various combinations of methods of cementing, perforating, milling, pulling, etc. These methods have an inherent uncertainty to them unless it is possible to completely extract the original well casing. Figure 6 is an illustration of this technique. Through the use of the large diameter sonic drill steel, it is possible to 'overcore' the entire drill string

employing a large kerf to create a relatively large annular space. Then, after the well casing is free and with the large diameter steel still in place, go inside the casing with smaller diameter rods, attach an interior pipe clamp at the bottom of the casing string, and then pull the casing as a complete unit.

Cement which is adhered to this casing is removed to allow cutting the casing into manageable lengths and removing it to the appropriate location on the site for storage pending ultimate removal.

An alternative method, and the method proposed for the deeper wells which may be beyond the drilling capacity of sonic technology, is to not drill around the existing casing, relying on the sonic rig's vibration capability to free the casing and cement en masse. However, the alternative method probably will require removal in stages with the casing cut as appropriate with either conventional petroleum engineering technology such as explosive or chemical casing cutters. This is a less desirable alternative for the shallow wells because of the uncertainties.

Following removal of the existing casing from the well, open hole geophysical logs can be run at the discretion of the contractor and the well can be recompleted or abandoned.

These techniques were responsible for extraction of casing from drilling evaluations conducted on the Athabasca Tar Sand deposits in Alberta. Here, literally thousands of feet of otherwise serviceable steel casings were removed where all other methods had failed.

Remote Controlled Drilling

A final application of this technology deals with remote controls to the drilling apparatus. Specific use of this technology is in areas where contaminant levels are very high and apply to either chemical or radiological hazards. The drilling rig is very easy to operate and readily adaptable to electronic controls. In an area of high contamination where drilling in Level A or B personal protective equipment (PPE) is required, the driller could be situated relatively far from the rig and be exposed only for rig up and rig down; the helper(s) could be exposed only long enough to seal the core and for rig up and rig down. Similar equipment was developed for site characterization at Three-Mile Island.

It must be pointed out that while we have every confidence that this can be done, we have not yet made the necessary modifications to attempt this.

OTHER TECHNOLOGIES

There exist a great number of other technologies which can have a very direct, positive influence on Site Characterizations, RI/FS, Site Remediations, Environmental Restorations and other activities such as these for which "wheels" have already been invented. With only slight modifications, these "wheels" can be adapted to help solve the problems which are encountered. Two of these that I would like to address are pipe jacking and large diameter drilling.

LEAKING LANDFILL
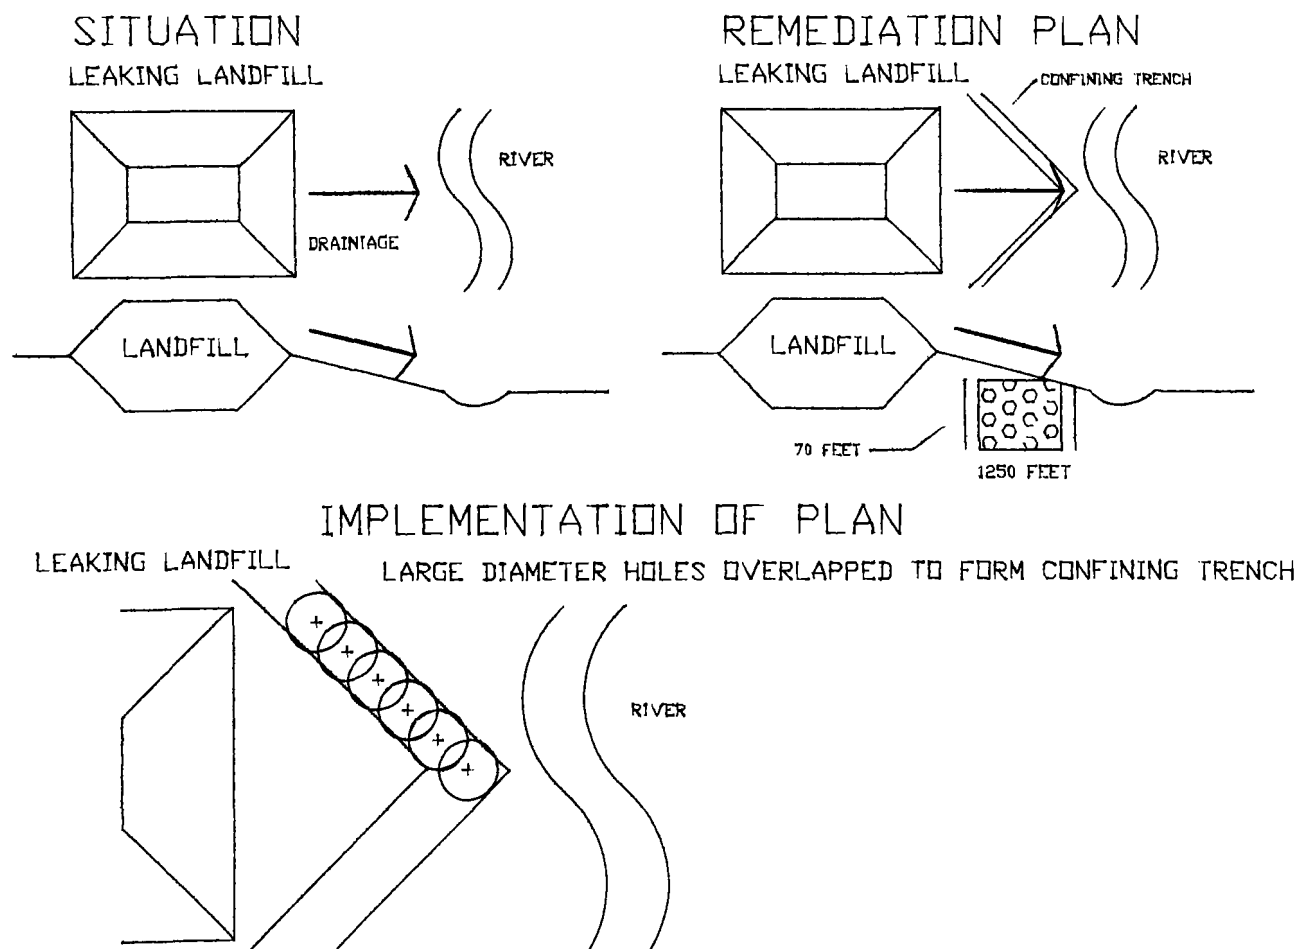

Figure 7
Demonstration of Well Extraction Procedures

Pipe Jacking

Pipe jacking is a process of using a tunnel boring machine or as they are called in the vernacular, a "mole," to excavate a tunnel. The size of these moles range from 4 inches to 9 feet and perhaps larger. The smaller diameter moles are obviously remotely controlled. As the mole is advanced, the excavated materials are evacuated, usually in a slurry, and sections of pipe are pushed or "jacked" into the tunnel with a separate slurry of mud acting as a lubricant. Typical applications for this technology are for the installation of water lines, sewerage lines, dewatering systems and fiber optic cable installations.

Applying this technology to remediation activities, there is little reason that these cannot function as "French Drains" beneath leaking landfills. A format for this application was shown earlier.

Large Diameter Surface Drilling

Drilling of large diameter (four to six feet) holes from the surface was developed in Europe where there is a great need to install caissons and pilings into saturated rock. This installation is typically beyond the capabilities of pile drivers. This technology has subsequently been adapted to the bulk sampling of mineral deposits where there is a need for treatability studies or for economic considerations.

Aside from an obvious application to the environmental arena for bulk sampling, perhaps in terms of a feasibility study, there are two other applications which come to mind: first, installation of grout walls with quite a high degree of certainty of forming an impermeable boundary and second, application as a confining trench. An example of the latter is shown in Figure 7.

CONCLUSION

Throughout this short paper, I have tried to emphasize that there are many applications for use of mining, petroleum and construction equipment which perhaps are little known outside these industries. While there has been and probably will continue to be a significant influx of people from these industries to the Environmental industry, it has been my experience that we, as humans, most often choose to emphasize our differences rather than our similarities. However, there is little difference between sampling for a PA/SI and a reconnaissance survey for metals exploration; sampling for an RI is very similar to an exploratory drilling program; a feasibility study is a feasibility study regardless of the reason for which it is undertaken; soil remediation activities are in reality mining operations; and groundwater remediations are directly analogous to petroleum exploitation.

There is a wealth of technology and expertise available at what at first blush may be considered a most unlikely source. I would urge those among you who are prime government contractors to work closely with your subcontractors to affect solutions to your characterization and remediation problems which may save the government money and may result in your getting a contract which would have gone to another contractor.

Similarly, subcontractors and potential subcontractors who wish to be involved in these efforts absolutely must gain contacts to the thought processes of the prime contractors. By working together, we all stand to increase our reputations, reap financial rewards and have a better world in which to live.

Groundwater Extraction System to Control Both Vertical and Horizontal Migration of Contaminants

Roger H. Page, Ph.D.
Gail A. Cederberg, Ph.D.
M. F. N. Mohsen, Ph.D.
ENVIRON Corporation
Princeton, New Jersey

ABSTRACT

ENVIRON Corporation has performed groundwater modeling work for the conceptual design of a groundwater extraction system to remediate groundwater contamination at a Superfund site in New Jersey. The extraction system has been conceived to protect the quality of deeper, uncontaminated groundwater and halt migration of dissolved contaminants to the adjacent river and residential area. To achieve the desired vertical capture zone, the remedial system aims to maintain an upward flow component beneath the contaminated areas. ENVIRON's three-dimensional model of groundwater flow indicates that reversal of natural downward flow components calls for shallow extraction wells distributed throughout the contaminated area. Each well can reverse downward flow out to a radius of approximately 400 feet. Model sensitivity tests show that this radius and the resulting well density depend on the vertical hydraulic conductivities of the silty units separating the major sand units.

The pumping rates required to prevent horizontal migration off the site and into the river have been calculated by setting a target water level at each well. Each target water level has been estimated based on the surface water heads on streams surrounding the site. The target head method, which controls the gradient between a line of extraction wells and a stream, assures capture of contaminants and minimal capture of water from the stream's channel and its opposite bank.

INTRODUCTION

ENVIRON has used a numerical groundwater flow model for the conceptual design of an innovative groundwater pump-and-treat system. This system has been developed for the special needs of a Superfund site, shown in Figure 1, to remediate shallow groundwater contamination in a complex aquifer system. The system's objectives are: (1) to protect the quality of uncontaminated groundwater, and (2) to expedite remediation of groundwater in areas where contaminants have migrated off-site. These objectives were selected to be protective of public health and the potable groundwater resources of the region. To conform to regulatory requirements, the system must also contain all contaminated groundwater currently migrating toward the river adjacent to the site.

The conceptual design of the pump-and-treat system was based on the results of previous investigations of the site's hydrogeology and contaminant distribution by AWARE Incorporated (now ECKENFELDER INC.) and a numerical model by ENVIRON of groundwater flow in the principal aquifers underlying the site. Results of these investigations that significantly affected the conceptual design of the remedial scenarios are summarized below.

Hydrogeologic Conditions

The principal hydrostratigraphic units at the site are described in Table

1 and shown in cross section in Figure 2. More than 1000 feet of unconsolidated deposits exist under the site. Of that the upper 200 feet (approximately) have been investigated and modeled. The significantly contaminated zones are within approximately 100 feet of the surface. The unconsolidated deposits in the zone investigated include thick layers of well sorted coarse, medium and fine sands. Between these sand units are layers composed of fine sand, silt and, in some cases, intervals of clay. Some of these silty and clayey units have sufficient areal extent and sufficient vertical flow resistance to act as aquitards. Field water level observations show that heads and flow directions in the second and third sand units are close to those in the first sand unit. By contrast, heads and flow directions in the fourth sand unit are distinctly different from those of the shallower units.

Site Map with Shallow and Deep Plume

Table 1
Hydrostratigraphy at the Site

Hydrostratigraphic Unit	Relative Hydraulic Conductivity	Thickness Where Penetrated (ft)	
First sand unit	High	10	50
First silty unit	Moderate	5	32
Second sand unit	High	2	36
Second silty unit	Moderate	17	39
Third sand unit	High	16	34
Third silty unit	Low	37	46
Fourth sand unit	High	4	11
Fourth silty unit	Low	16	21
Figure 2
Typical Hydrostratigraphic Cross Section at the Plant

Groundwater flows within the first, second and third sand units are controlled by surface water features, with flow in all three being to the east and southeast toward the river. East of the river, flow in these units is predominantly southward to southwestward toward the river. The river acts as a drain to intercept the eastward movement of contaminants from the site within the first, second and third sand units. Because of the greater depth of the fourth sand unit and the semi-confining character of the unit above it, groundwater flow there is less influenced by surface water features than are flows in the overlying aquifer.

Although the sand units are separated by sediments of lower permeability, to some extent they are all interconnected. Areas exist to the west and east of the river where the vertical component of groundwater movement is downward. Near the alluvial valley of the river, the movement is upward due to the river's draining effect, which causes the heads to be lower in the near-surface zones than they are in the deeper aquifers. Wherever a downward component of seepage exists at the base of a contaminated unit, the potential exists for contaminants to be transported to a lower unit such as the third sand unit. The prevention of such possible future movement is a primary constraint in the selection of remedial alternatives.

Contaminant Distribution

Organic contaminants originating from the plant have been found primarily in the first and second sand units in the areas outlined in Figure 1. Although no organic contaminants have been detected in the third sand unit, localized inorganic contaminants detected there may represent the leading edge of the plume. The eastward movement of contaminants within the first and second sand units will be limited by the draining effect of the river, even in the absence of remedial pumpage. Note in Figure 1 that most of the plume is on the plant site and the southern edge extends into a residential subdivision southeast of the plant. Although contaminants may locally move east of the river channel (as they have at a meander near the plume's north edge on Figure 1), both field data and numerical groundwater flow simulations have shown that the contaminants discharge into the river without leaving the alluvial

valley of the river. For this reason, the contaminants do not pose a threat to regional groundwater resources in the first and second sand units.

Numerical simulations of flow have shown that water in the fourth sand unit may flow eastward under the river due to a combination of natural hydraulic gradients and public water supply pumpage a mile east of the river. If contaminants were allowed to move downward into this aquifer, they might eventually become a threat to drinking water supplies east of the river. For this reason, remedial alternatives that limit the possibility of downward contaminant migration have been emphasized.

Development of the Numerical Flow Model

A three-dimensional, steady-state, numerical flow model for the plant site and surrounding region was developed by ENVIRON. The model was first applied to demonstrate that the adjacent river effectively limits eastward migration of contaminants. The model later helped to confirm that another Superfund site is probably responsible for contaminants discovered east of the river. In addition, it has been used to test a wide range of proposed remedial scenarios.

The model developed is a detailed representation of the regional water balance, including natural surface infiltration, stream base flow, water supply demands and stratigraphy. The regional model encompasses the important surface water bodies surrounding the site and a large area to the east of the river. The flow model was developed using MODFLOW, the USGS modular groundwater flow simulation program by McDonald and Harbaugh.[1] The three-dimensional model developed has five layers, two for the first sand unit and one each for the second, third and fourth sand units. The resistance to flow between adjacent layers includes the resistance of any intervening silty unit. The model can provide high resolution using software developed by ENVIRON to create a wide range of local models based on the regional model input and output. The simulation results presented in the following sections were produced by a local submodel using a relatively fine cell size of 125 feet.

NUMERICAL EVALUATION OF THE GROUNDWATER EXTRACTION SYSTEM

The extraction system described here was selected based on three-dimensional numerical simulations of numerous remedial alternatives. Site-specific experience gained from those analyses leads to the conclusion that the objectives could not be achieved without installing a widely distributed network of recovery wells in the uppermost sand units. Only by pumping from the first and second sand units can the natural downward seepage of groundwater and contaminants into the third sand unit be reversed under contaminated areas. With a remedial system not specifically designed to protect against downward migration, contamination of the third sand unit and, conceivably, the fourth sand unit could occur even during remediation of the first and second sand units.

Assuring a Net Upward Component of Flow

Tests with the current best-fit flow model indicate that a single well can easily reverse the downward seepage due to surface infiltration out to a radius of approximately 400 feet. That radius of flow reversal is much less sensitive to the pumping rate than one might anticipate. The radius depends largely on the local intensity of recharge, the vertical permeability of the silty units, the horizontal permeability of the sand units and the spatial variations of layer thickness. Of these controlling parameters, the horizontal permeabilities and layer thickness are relatively well-established so the most important material property uncertainty is the vertical permeability. Identifying areas of greater than average recharge intensity also is critical. These numerical model results have been confirmed with the help of an analytical model by Jacob[2] of a fully penetrating well in a leaky aquifer.

The limit on the flow reversal radius imposes a constraint on the spacing between wells. The well layout needs to assure that every point in the contaminated zone is within the flow reversal radius of at least one recovery well.

A swale running from the area of the former landfill eastward toward

the river appears to be an area of higher than average surface infiltration where upward flow is more difficult to maintain. The model showed that locally increasing the density of wells can control the downward migration.

The model indicates upward flow under the critical areas of the residential subdivision southeast of the plant, but some areas of suspected or known low-level contamination are beyond the reach of the recovery wells. The model indicates that maintaining upward flow may not be possible in these areas without placement of wells in the residential area.

Stopping the Horizontal Spread of Contaminants

The recovery wells need to be located to control further horizontal migration. Wells need to be positioned at or near the river boundaries and other property lines where contaminants can potentially leave the site. Where contaminants have already moved off-site, extraction wells are required to intercept them before they reach the river. Capturing contaminant mass as close as possible to the areas of concentration recovers the greatest mass with the least tendency to spread it. Thus, wells are situated downgradient of each potential source area.

At this site, the combination of property line wells, river wells and source wells does not by itself provide a dense enough network to maintain the upward component of vertical flow required to protect underlying aquifers. The additional extraction wells required upgradient of the boundaries and sources add to the initial cost of the system, but their impact on the overall volume rate to be treated is relatively modest.

Wherever the second sand unit exists in sufficient thickness and contains significant levels of contamination, recovery wells in that unit are

currently planned to supplement the recovery wells in the overlying sand unit. Each deep recovery site will have a pair of wells to separately screen the first and second sand units. The separate well approach will require careful balancing of pumpages to maintain prescribed conditions of head difference between the two aquifers. However, this approach affords more control over flow than two less costly alternatives, capturing second sand unit contaminants with wells in the first sand unit or screening several sand units with one well.

Selected Well Layout

Figure 3 shows the layout of the 42 proposed well sites. Each site has a well screened in the first sand unit. These sites were selected by a committee of engineers from the site owner's company and hydrologists from ENVIRON and ECKENFELDER. Figure 3 also marks the nine sites where an additional well screened in the second sand unit is proposed. Of the sites shown, seven are at sites of existing recovery wells.

The recovery well configuration consists of wells on the downgradient side of each potential contaminant source, wells to intercept the plume where it can reach the river and wells on other property lines where the plume might leave the property. Wells at the perimeter of the southeast subdivision promote flushing of the first sand unit by inducing upward seepage under as much subdivision as possible without intrusive placement of wells inside the residential area. Additional recovery wells are planned for the intermediate zones between the property boundaries and the sources to assure upward flow in those areas. Supplementary recovery wells upgradient of the sources are proposed to assure upward seepage beneath the remainder of the facilities on the

site. Finally, recovery wells along the entire length of the plant's southeastern property line will prevent downward and outward migration of possible contaminants that may be present south of the identified plume.

PUMPAGE SELECTION WITH THE ASSISTANCE OF THE NUMERICAL MODEL

Excessive pumpage can cause a number of problems. Pumpage will inevitably reduce the base flow to the river. If the pumpage rate is high enough, the groundwater movement toward the river reverses, either locally (e.g., at certain loops in the meandering channel) or over a long segment of the river. When pumpage withdraws water from the channel, the simulations show that it also draws groundwater from the opposite bank (where groundwater movement is naturally directed toward the river). Drawing excess water from the river would unnecessarily increase pumping and treatment costs. The flow model has shown that groundwater contaminants from another Superfund site are present on the opposite side of the river and excessive pumping on the plant property would risk spreading them.

Excessive pumpage causes problems in vertical flow as well. Simulations have shown that excessive pumpage at one location can induce downward seepage in other areas. For example, according to the model, excessive shallow pumpage limited to the source areas would pull water from deeper aquifers, water that might be replenished in part by increased downward flow in other ares of the site. Excessive pumping could even significantly alter the upward flow zone along the river.

The Target Head Method for Pumpage Selection

Various methods are available for estimating the appropriate pumpage with the help of a groundwater flow model. The specified discharge method we have used for many early pumpage scenarios requires the analyst to select and simulate a trial set of pumping rates, create and analyze a set of vertical flow direction maps (Fig. 4) and path line maps and judge which pumping rates to adjust for the next trial. The result of many trials is an approximate distribution of pumpage. Fine comparisons between two similar scenarios are difficult because the bias of the manually selected approximation is not consistent from one scenario to the next.

An alternate method that has been used with excellent results is to specify a target head value at each well and allow the simulation program to calculate the required pumpage. Because the water level and discharge of a pumping well are interdependent variables, either the water level or the discharge can be preselected and the other variable will be controlled by the aquifer characteristics. Target heads can be modeled by representing each well as a single-point drain, as described in the Appendix. The procedure is similar to that of the specified discharge method described above except that target heads rather than discharges are selected for each trial.

Selecting target heads is particularly good for adjusting pumpage near the river to rates that capture contaminated water moving toward the river without drawing river water. Each well in the line closest to the river has a target head a few feet below the time-averaged river elevation so that the highest heads between wells in the line will be approximately even with the nearest surface water heads. Groundwater heads controlled in that fashion assure that the line of wells, rather than the river, will intercept the contaminated groundwater from the west. As a first approximation, the target head for each well in the second sand unit has been set to match its counterpart in the first sand unit. The target head method is a reliable way to control head gradients between the wells and the river. Reliable control over those gradients is needed to limit the withdrawal of water from the river channel or from the east bank. As the capture zone of Figure 5 shows, very little water comes from the channel or the opposite bank except at the northern edge of the plume. There, cross-river flow is needed to accelerate the flushing of contaminants that currently are found under the river channel's meander.

The target head method has been extended from river wells to all recovery wells on the site with very good results. Target water levels

are based on the surface water elevations of the river and smaller streams surrounding the site. The target water level calculation for each well uses the surrounding stream water elevations, the weighting being based on the well's distance from the various stream reaches. The calculated target heads are tested by the model. When most of the wells meet the desired standards of vertical and horizontal capture, target levels of individual wells can be adjusted to achieve the standards. Such adjustments have been used for wells along the plant's southeastern property line which must prevent groundwater migration into the adjacent residential area.

Capture Zone and Equipotentials in the
First Sand Unit Forecasted by Model

Figure 3 graphically shows the calculated pumpage for each well. The overall recovery pumpage is 2.5 million gal/day.

Adjusting Pumpage to Field Conditions Using Target Heads

The actual pumpage rates required to produce the target heads in the field may differ from the pumpage rates estimated by the model. Target water levels can be used to adjust pumpages to accommodate field conditions that differ from the model assumptions. Field permeabilities near individual wells (and thus individual well pumping requirements) will differ from those modeled. However, the total pumpage requirement of the entire set of wells is likely to be close to the predicted value. The engineering design of the recovery well needs to allow individual well pumping rates to be adjusted to meet the water level targets without modification to any of the facilities. Maintaining heads at target levels based on the adjacent stream water level provides strong hydraulic evidence that the system is capturing contaminated groundwater in accordance with regulatory requirements.

Model Results for the Selected Layout

Figure 4 delineates zones of upward flow across the second silty unit, based on a simulation of the well layout in Figure 3. The model results indicate an unbroken area of upward flow beneath the potential contaminant sources and the known on-site contaminant plumes.

The potentiometric surfaces and capture zones modeled in the first and second sand units are shown in Figures 5 and 6, respectively. The overall capture zone for the well network is outlined by a solid curve. At wells immediately upgradient of the eastern plant property line, pumping rates and well spacings have been adjusted to prevent off-site migration. At wells further upgradient, the requirement for adequate pumping and spacing is to maintain upward flow. Extraction wells in the first sand unit capture second sand unit water as well. This indirect capture occurs within the solid capture zone boundary line in Figure 6. Extraction wells screened in the second sand unit provide direct capture to expedite remediation of that unit, especially under the river channel meander near the plume's northern edge. A broken curve in Figure 6 delineates the direct capture zone.

CONCLUSIONS

The conceptual design simulations show that a carefully planned system of recovery wells can stop off-site contaminant migration, remediate existing off-site contamination and prevent additional groundwater contamination. Such a system of wells would be completed in both the first and second sand units with a total pumpage of approximately 2.5 million gal./day. The well layout consists of 51 extraction wells, 42 in the first sand unit and nine in the second sand unit. This system of wells induces upward movement of groundwater from the third sand unit to the first and second sand units, thus protecting the quality of water in the third and fourth sand units.

In terms of horizontal capture zones and upward flow zones, the well layout assures that the modeled upward flow zone covers the con-

taminated areas on-site. Additional wells at the periphery of the known contamination widen both the upward flow zone and the capture zone for horizontal flow.

Reasonable methods have been identified to cope with problem areas where downward groundwater migration has been difficult to reverse. In one of those potential problem areas, a swale, the proposed well layout has a locally higher density. In another area, the southeast subdivision, wells are situated close to the residential area to achieve the greatest possible extent of upward flow without intrusion of wells into the residential area.

The pumpage rate at each recovery well is calculated using a target water elevation to reliably prevent migration into uncontaminated areas without excess pumpage. Setting target water levels based on the time-averaged stages in the river and other bounding streams can assure that on-site groundwater cannot reach the streams. At the same time, the target levels can prevent unnecessary capture of water from the river's channel or its far bank.

APPENDIX

A single-point leakage in a numerical model can approximate a well that has a specified target head. The leakage equation for a finite difference cell is:

$$Q = C (h - z) \qquad (1)$$

where Q is the volume rate of leakage out of the domain, C is a conductance coefficient, h is the head the simulator will calculate at the cell and z is the target head in the well casing. The coefficient C can be derived from a technique for representing a well in a two-dimensional areal numerical model.

The drawdown a numerical model calculates at a well cell matches the analytical model drawdown at some radius r_e, the equivalent cell radius. That radius depends on the cell geometry and material properties rather than the well's actual radius, r_w. Beljin[3] reviews techniques to estimate r_e for two-dimensional models. For rectangular cells, the Trescott et al. program[4] uses:

$$r_e = .104 (\Delta x = \Delta y) \qquad (2)$$

where Δx and Δy are the cell's horizontal dimensions. For anisotropic aquifers, Peaceman[5] derived:

$$r_e = .28 [(\Delta x R)^2 + (\Delta y/R)^2]^{1}/2/(R+1/R) \qquad (3)$$

where

$$R = (K_y/K_x)^{1/4} \qquad (4)$$

Here K_x and K_y are hydraulic conductivities in principal directions normal to the cell faces. Given r_e, C can be derived from an analytical model of steady-state flow toward a well such as the one for a nonleaky aquifer, which yields:

$$C = 2\pi (K_x K_y)^{1/2} b / \ln(r_e/r_w) \qquad (5)$$

where b is the aquifer thickness.

ABSTRACT

This paper discusses the operation and performance of the groundwater treatment plant at the Old Mill Superfund site located in Rock Creek, Ohio. The paper also summarizes the history of the remedial activities at the site and the site's selected remedy.

INTRODUCTION

The Old Mill Superfund site is located in the Village of Rock Creek, Ashtabula County, Ohio. The site consists of two parcels of land known as the Henfield and Kraus properties. The Henfield property is approximately 3 ac in size, and the Kraus property is approximately 10 ac in size. Land use in the vicinity of the site consists of a mixture of residential, agricultural and commercial/industrial developments. The closest residences are approximately 75 ft from the site boundary. The closest commercial business, the Rock Creek Aluminum Company, is located south of the Henfield property.

This paper presents a review of the remedial actions conducted to date and a description of a groundwater treatment plant at the site. The plant performance data are provided to demonstrate the capability of the groundwater treatment plant.

HISTORY OF REMEDIAL ACTION

Response activity at the Old Mill site began in 1979 when the U.S. EPA and Ohio EPA found approximately 1,200 drums of toxic waste, including solvents, oils, resins and PCBs, stored on both properties. The Henfield property was considered to be an immediate hazard because a significant quantity of the drummed waste was flammable and access to the site was not controlled.

Superfund emergency removal activities and enforcement actions resulted in drum removal that began in November 1981 and was completed in October 1982. In addition, approximately 80 yd³ of soil from the drum storage areas on the Henfield property were removed in November 1982. A 6-ft cyclone fence was installed around a portion of the Henfield property in April 1984 under the authority of Section 106 of CERCLA in order to minimize the potential for direct contact with contaminated soil.

Between August 1983 and December 1984, a remedial investigation was conducted at the site. Soil on the Henfield and Kraus properties was found to be contaminated with organic chemicals, especially trichloroethene (TCE), as well as with heavy metals such as lead. Groundwater was contaminated with TCE, tetrachloroethene, trans-dichloroethene, 1,1-dichloroethene, vinyl chloride, 1,1,1-trichloroethane, ethylbenzene and xylene. TCE is the principal contaminant in the groundwater.

The remedy selected for the Old Mill site as identified in the August 1985 Record of Decision consisted of:

- Removal and off-site disposal of 95% of the contaminants in the soil and sediments in the drainageway
- Demolition of buildings and silos located on the site with disposal of resulting debris in an off-site sanitary landfill
- Groundwater extraction and treatment (using air stripping and carbon adsorption) for an estimated period of 30 yr
- Placement of aquifer use restrictions for as long as contaminant concentrations in the plume remain above 10^{-6} carcinogenic risk levels
- Hookup of one residence to the public water supply

Implementation of the remedy for soils required removal of approximately 5,000 yd³ of contaminated soil from 13 areas on the Henfield property with the depth of excavation varying from 6 in to 5 ft. Removal of approximately 1,300 yd³ of contaminated soil was required from two areas on the Kraus property with a 15-in depth of excavation. Approximately 100 yd³ of contaminated drainageway sediments (37 yd³ from the Henfield property and 66 yd³ from the Kraus property) were removed. Five buildings and four silos located on the Henfield property were demolished.

Remedial design incorporating the selected remedy was completed in September 1987. Remedial action was completed in August 1989 and consisted of the following:

- Cleanup of soil and sediments from the Henfield and Kraus properties
- Demolition of buildings and silos on the Henfield property
- Installation of three extraction wells (one on Henfield and two on Kraus properties) to a depth of 30 ft to extract contaminated groundwater from the deep aquifer
- Installation of a trench system on each property to extract contaminated groundwater from the shallow aquifer
- Construction of a groundwater treatment facility
- Installation of 16 compliance monitoring wells on the properties (four shallow and four deep wells on each property)
- Regrading and seeding of the properties

The contaminated soil and sediment removals from both the Henfield and Kraus properties are based on achieving the Allowable Residual Contaminant (ARC) levels as shown in Table 1. To verify that soil and sediment excavation and removal has achieved these limits, the following numbers of verification samples were collected:

	Soil	Sediment
Henfield Property	63	5
Kraus Property	40	14

In addition to testing soil and sediments for parameters shown in Table 1, 10 samples (five soils and one sediment from the Henfield property and three soils and one sediment from the Kraus property) were tested

for Extraction Procedure (EP) Toxicity parameters.

Following completion of soil and sediment removal and demolition of buildings and silos, a groundwater extraction system and treatment facility were constructed. The groundwater extraction and treatment system has been in operation since January 1989. Remedial action was completed in August 1989. Minor modifications requested during the final inspection were completed in March 1990. These modifications included installation of an autodialer alarm system in the floor sump and a ventilation system at the treatment facility.

The site is considered clean-closed and only the treatment plant proper remains fenced.

OVERVIEW OF GROUNDWATER EXTRACTION AND TREATMENT SYSTEMS

The extraction system at the Old Mill site is designed to recover contaminated groundwater from both the shallow and deeper aquifers for treatment. Intercepting trenches are used for extraction of groundwater from the shallow aquifer and extraction wells are used for the deeper aquifer. The extracted groundwater from the shallow and deeper aquifers is pumped through a 2-inch diameter stainless steel underground pipe to a treatment plant located near the southern edge of the Henfield property. Groundwater treatment consists of air stripping followed by two-stage activated carbon adsorption.

The construction of extraction and treatment systems was overseen by the U.S. Army Corps of Engineers under a contract with Aptus Environmental Services. Following completion of treatment plant construction, the plant was operated in two phases consisting of system start-up using clean water (Phase 1), followed by operation using extracted groundwater (Phase 2). Phase 1 operation was initiated in January 1989, and Phase 2 operation was initiated in February 1989.

The operation of the treatment plant was transferred to WESTON under the U.S. EPA Region V Alternative Remedial Contracts Strategy (ARCS). WESTON assumed operation of the plant in August 1989 and will continue to operate the plant until May 1998. The responsibility for operating the system will be transferred to the Ohio EPA in 1999.

TREATMENT FACILITY DESCRIPTION

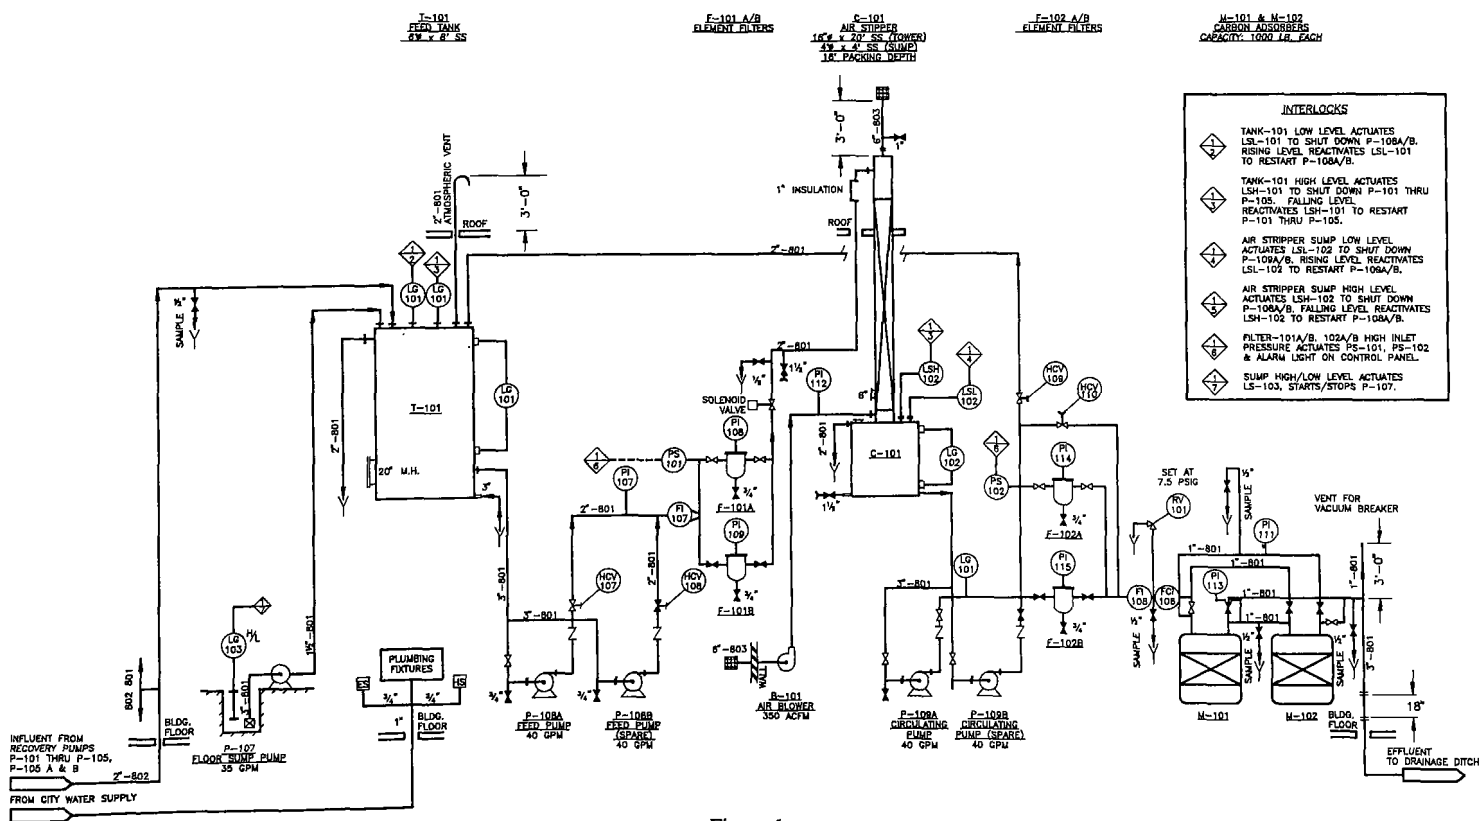
The treatment plant is capable of treating 10 gpm of contaminated groundwater; however, the normal operating rate is 5 gpm. The treat-


Figure 1
Process Flow Diagram
Groundwater Treatment Plant

ment plant includes a holding tank which collects groundwater pumped from the extraction system. The water from the holding tank is pumped at a rate of 15 gpm through cartridge filters to an air stripper for removal of volatile organic compounds. A portion of the effluent from the air stripper (10 gpm) is recycled back to the holding tank and the remainder (5 gpm) is pumped through cartridge filters to two-stage activated carbon columns. The final effluent is discharged by gravity to an underground stormwater drain and ultimately flows to Rock Creek.

A process flow diagram of the treatment plant is shown in Figure 1. The details of major treatment units are presented in Table 2. The extraction and treatment systems are built with sufficient instrumentation to assist in efficient operation. Pumps located in sumps and extraction wells operate independently based on level controls. The operation of these pumps can also be controlled from the main control panel at the treatment plant. The treatment plant instrumentation consists of several interlocks for pump operation, pressure switches on cartridge filter systems (set at 40 psi) to activate a light alarm at the main control panel and an autodialer alarm system activated by level switches in the floor sump. The autodialer is programmed to dial the home telephone number of the WESTON operator and the office number of the Ohio EPA office in Twinsburg, Ohio, in the event of an overflow of the sump.

TREATMENT PLANT OPERATION

The results of treatment plant operation for the period between Sept. 1, 1989 and July 31, 1990 are discussed in this paper. Prior to WESTON's assumption of operation, 727,000 gal of groundwater were extracted and processed in the treatment plant. From September 1989 to July 1990, approximately 2,015,000 gal of groundwater were treated. The monthly flow handled by the treatment plant shown in Table 3 indicates that

Krauf Modified Sump	Shallow	7.21-27.80	22.77
Kraus Well	Deep	2.40-7.86	4.15
Kraus Modified Well	Deep	0.53-6.52	1.75

[1]Martin Sump is located in a property contiguous to the Henfield property.

the average monthly flow is approximately 183,000 gal/mo (6,030 gal/day). The relative flow contributed by the trench system and extraction wells to the overall flow to the treatment plant is shown in Table 4. The shallow aquifer contributes approximately 71% of the flow to the treatment plant. The relative contributions to the total flow from the Henfield and Kraus properties are 61 and 39%, respectively.

TREATMENT PLANT PERFORMANCE

The treatment plant is designed to remove volatile and semivolatile organic compounds from groundwater. The effluent discharged from the treatment plant is required to meet the criteria shown in Table 5. The treatment plant effluent is sampled on a monthly basis from sampling locations shown in Figure 2. The samples are analyzed for 12 volatile organics, eight semivolatile organics and 15 other parameters (BOD$_5$, TOC, pH, specific conductance, alkalinity, chloride, sulfate, ammonia and nitrate nitrogen, calcium, iron, manganese, magnesium, sodium and suspended solids).

The compliance monitoring wells are not sampled as part of the treatment plant operation. To date, these wells have not been sampled.

The influent concentration used as the basis for the design of the treatment plant and the range of concentrations encountered at the treatment plant are shown in Table 6. The result indicates that most of the constituents are well below the design value with the exception of trichloroethene, tetrachloroethene and 1,1,1-trichloroethane.

The performance of the air stripper in removing volatile organics from groundwater, shown in Table 7, indicates that the air stripper very efficiently removes volatile organics. This efficiency results from the concentration of influent being lower than the design value and maintenance of a high air/water ratio of 175. The air stripper was originally designed to handle a flow of up to 40 gpm, compared to the present normal flow of 15 gpm. As would be expected, the semivolatile organics are only marginally removed by the air stripper.

The characteristics of effluent from the second stage carbon column are shown in Table 8. Comparison of the discharge criteria to be achieved (Table 5) with the effluent from the second stage carbon column indicates that the treatment plant achieved compliance except for one incidence when trichloroethene exceeded the limit in June 1990. It should be emphasized that due to very large removals of volatile organics by the air stripper and very low levels of semivolatile organics in groundwater, the activated carbon columns are not organically loaded to the extent anticipated in the design. The levels of other constituents present in the second stage carbon column effluent are shown in Table 9. There are no specific discharge criteria for constituents listed in Table 9.

PROBLEMS ENCOUNTERED IN
TREATMENT PLANT OPERATION

Minor problems have been encountered in the operation of the groundwater treatment plant during the first year of operation. The level switches installed in the holding tank are of the floatless type, consisting of a counterweight that moves on a rod to activate the level switches. High iron concentrations in groundwater have caused the counterweight

on the rod to stay in an intermediate position. This fouling has resulted in overflow of the tank and activation of the autodialer alarm system a number of times. This problem is being corrected by installing float-operated level switches.

The spent cartridge filters currently are being stored within the treatment plant awaiting disposal. Analysis of the spent filters has been completed and a landfill disposal facility in Ohio has been contacted regarding landfilling of the spent filters.

CONCLUSION

The treatment plant provides treatment for an average monthly flow of approximately 183,000 gal. The shallow aquifer contributes approximately 71% of the groundwater treated at the plant. The air stripper achieves a very high level of removal of volatile organic compounds. This high removal performance has resulted in lower than anticipated organic loading to the activated carbon columns.

Risk Reduction Engineering Laboratory
Cincinnati, Ohio

ABSTRACT

This paper presents the field evaluation results of a microfiltration technology jointly developed by E.I. DuPont de Nemours & Company, Inc. (DuPont) and Oberlin Filter Company (Oberlin). The field evaluation was performed in April and May 1990 at the Palmerton Zinc Superfund (PZS) site in Palmerton, Pennsylvania, under the U.S. Environmental Protection Agency's Superfund Innovative Technology Evaluation program.

The DuPont/Oberlin microfiltration system uses Oberlin's automatic pressure filter and DuPont's Tyvek T-980 membrane filter media to remove solids larger than 0.1 micron in diameter from liquid wastes. At the PZS site, the microfiltration technology was evaluated for treating groundwater contaminated with metals (primarily zinc). At the optimum operating conditions for the microfiltration system, the zinc and total suspended solids (TSS) removal efficiencies were approximately 99.95%; and the filter cake was approximately 41% solids by weight. At the 95% confidence level, the filtrate met the applicable metals and TSS limits for discharge into a local waterway. However, the filtrate did not meet the pH discharge standard. The filter cake passed: (1) the paint filter liquids test, (2) the extraction procedure toxicity test and (3) the toxicity characteristic leaching procedure test.

INTRODUCTION

The U.S. Environmental Protection Agency (EPA) is finding new solutions to hazardous waste remediation through its Superfund Innovative Technology Evaluation (SITE) program. The SITE program was created by the U.S. EPA to evaluate new technologies that may destroy or permanently change the composition of hazardous waste by significantly reducing the waste's toxicity, mobility or volume. The SITE program generates reliable performance and cost data for these treatment technologies to be used in evaluating cleanup alternatives under the Superfund remediation process.

In January 1989, E.I. DuPont de Nemours, Inc. (DuPont) and Oberlin Filter Company (Oberlin) submitted a joint proposal for their microfiltration technology to the U.S. EPA's Office of Research and Development (ORD) and Office of Solid Waste and Emergency Response (OSWER) under the SITE program. The U.S. EPA selected the DuPont/Oberlin microfiltration technology and identified the Palmerton Zinc Superfund (PZS) site, located in Palmerton, Pennsylvania, as an appropriate site for the technology demonstration. The technology was demonstrated at the PZS site in April and May 1990 through a cooperative effort between ORD, OSWER, U.S. EPA Region III, DuPont and Oberlin. PRC Environmental Management, Inc. was contracted by U.S. EPA ORD to assist in the technology evaluation.

MICROFILTRATION TECHNOLOGY: PROCESS AND EQUIPMENT DESCRIPTION

DuPont/Oberlin's microfiltration technology is designed to remove solids from liquid wastes. Since the microfiltration system can remove particles that are 0.1 micron or larger in diameter, dissolved contaminants must first be converted to a particulate form. For example, groundwater with dissolved metals must first be treated with a precipitating agent, such as lime, to convert the dissolved metals into particulate form, such as metal hydroxides. After the dissolved metals are converted to a particulate form, the liquid can be filtered through the microfiltration unit. The microfiltration unit produces two products: filter cake and filtrate. To produce a filter cake that has a low moisture content and a filtrate that has a low solids content, DuPont/Oberlin normally uses a filter aid or filter aid/cake stabilizing agent. For this project, DuPont selected a silicate-based filter aid/cake stabilizing agent known
Figure 1
Schematic of Dupont/Oberlin Microfiltration Unit

* DuPont registered trademark

as ProFix, which is manufactured by EnviroGuard, Inc. of Houston, Texas.

A schematic of the DuPont/Oberlin microfiltration unit is shown in Figure 1. This microfiltration unit is an automatic pressure filter (APF) that operates on pressure signals and uses a low-cost, membrane filter—Tyvek T-980—a thin, durable spunbonded olefin fabric developed by DuPont. The APF, developed by Oberlin, has two chambers—an upper chamber for feeding waste through the filter media and a lower chamber for collecting the filtrate. The upper chamber moves vertically, while the lower chamber is fixed. The Tyvek filter lies between these two chambers. The APF unit utilized at the PZS site was 64 inches long, 33 inches wide, 83 inches high and weighed approximately 1,300 pounds. The unit had a filtering area of 2.4 square feet.

At the start of a typical filter cycle, the upper chamber is lowered to form a liquid-tight seal against the Tyvek. The liquid feed waste containing particulate matter is then pumped, at an initial air pressure of 10 psig, into the upper chamber and filtered through the Tyvek. Filtrate is collected in the lower chamber, where it drains by gravity to a filtrate collection tank. During this process, solids are deposited on the Tyvek filter. This solids buildup increases resistance to liquid flow through the Tyvek. To keep the filtration rate constant, air pressure to the pump is automatically increased throughout the filter cycle. During the initial 30 seconds to 60 seconds of the cycle, the filtrate is recirculated to the precipitation tank to keep the quality of filtrate high. At the end of 60 seconds, recirculation stops and the filtrate is drained to an effluent collection tank.

Liquid waste is pumped to the microfiltration unit until the air pressure to the pump reaches 55 psig (a pressure drop of approximately 45 psig across the filter). Liquid feed waste to the microfiltration unit is then shut off, and pressurized air (30 to 45 psig) is fed into the upper chamber to dry the filter cake. The air forces any liquid remaining in the upper chamber and in the filter cake pores to pass through the Tyvek into the lower chamber. The air pressure applied to drain the liquid remaining in the upper chamber, and dry the filter cake, is called the blowdown pressure. Once the liquid is drained from the upper chamber and the filter cake, air breaks through the filter cake. After breakthrough occurs, air continues to be fed through the upper chamber for a preset time interval to further dry the cake. The preset time interval is called the blowdown time. During the cake drying period, the filtrate is sent back to the precipitation tank to keep the quality of filtrate high. At the end of the blowdown time, the air supply to the upper chamber is automatically shut off, the upper chamber is raised and the filter cake is automatically discharged. Clean Tyvek is then drawn from a roll into the APF for the next cycle.

To avoid diluting the feed stream to the APF unit for the SITE demonstration, the filtrate was collected in a separate tank (recirculation tank) instead of being pumped back to the precipitation tank during the initial filtration and cake drying steps.

PZS SITE HISTORY

The PZS site is located in the Lehigh Valley along the Aquashicola Creek in Palmerton, Pennsylvania. During the last 70 years, zinc smelter operations resulted in 33 million tons of zinc residue accumulating and forming an extensive cinder bank at the site. The cinder bank has contaminated the surrounding areas, including the groundwater and surface water. Because of the contamination, the cinder bank was placed on the National Priorities List in 1982.[1] The shallow groundwater at the PZS site was selected as the waste stream for evaluating the microfiltration technology. Groundwater samples collected in June 1989 indicated that the shallow groundwater is contaminated with high levels of zinc (300 to 500 mg/L) and trace levels of cadmium (1 mg/L), copper (0.02 mg/L), lead (0.015 mg/L) and selenium (0.05 mg/L).

TECHNOLOGY DEMONSTRATION

The objectives of the technology demonstration were to: (1) assess the technology's ability to remove zinc from the groundwater at the PZS site under different operating conditions; (2) evaluate the system's ability to dewater the metals precipitate from treated groundwater at the PZS site; (3) determine the system's ability to produce a filtrate

and a filter cake that meet applicable disposal requirements; and (4) develop the information required to estimate the operating costs for the treatment system, such as electrical power consumption and chemical doses.

Testing Approach

The technology evaluation was performed in four phases. Phases 1 and 2 involved nine runs each, and Phases 3 and 4 involved two runs each. In Phase 1, chemical operating parameters (precipitation pH and ProFix dose) were varied, and the filter operating parameters (blowdown pressure and blowdown time) were kept constant. In Phase 2, the filter operating parameters were varied, and the chemical operating parameters were kept constant. Phase 3 runs were performed to evaluate the reproducibility of the microfiltration system's performance. Phase 4 runs were performed to evaluate the reusability of the Tyvek filter.

Table 1 summarizes the operating conditions for the demonstration runs. For Phase 1 runs, the initial operating conditions (Run 1) were based on a pilot-scale treatability study performed by DuPont/Oberlin on the PZS site groundwater. During the demonstration, the chemical operating conditions and the filter operating conditions were optimized in Phases 1 and 2, respectively. Since Run 5 conditions were selected as the optimum operating conditions for Phase 1, these were set as the initial conditions for Phase 2. Phases 3 and 4 were performed at Run 13 conditions because these conditions were selected as the overall optimum operating conditions. This experimental design assumes that there is no interaction effect between the chemical and filter operating parameters. Although this assumption is not critical to evaluating the microfiltration system based on the technology demonstration objectives, the technology developers agreed with this assumption based on their experience.

Table 1
Operating Conditions for the Demonstration Runs

Sampling and Analytical Procedures

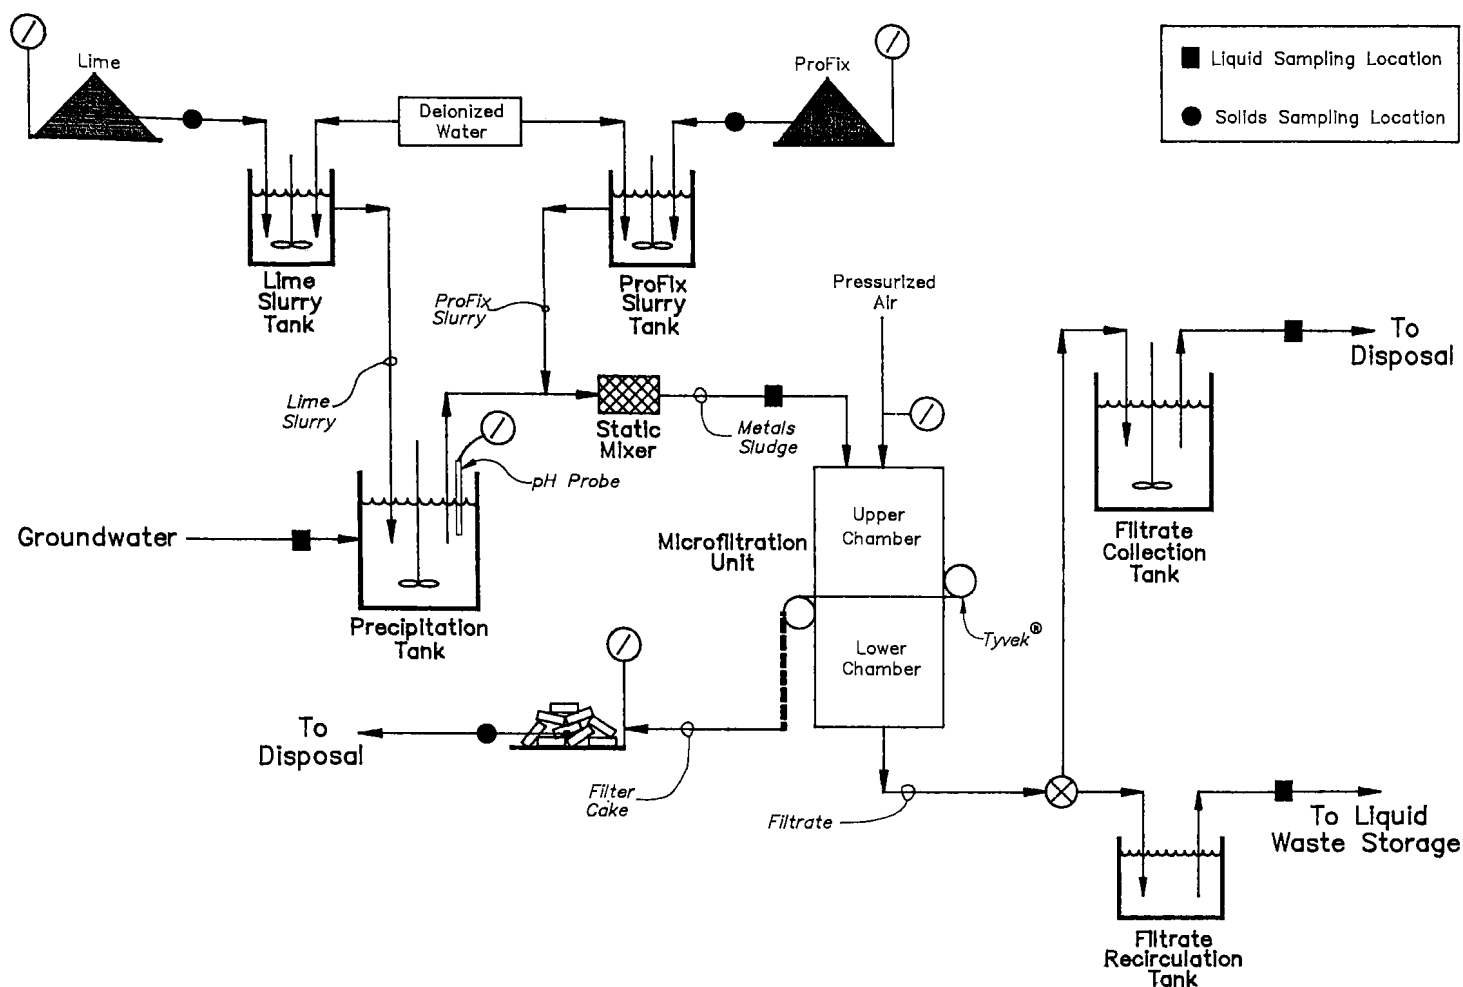
Solids and water samples were collected from the microfiltration system at the locations shown in Figure 2. The following measurements were considered critical to evaluating the microfiltration system: (1) zinc in the untreated groundwater and filtrate; (2) total suspended solids (TSS) before and after the microfiltration unit; (3) free liquids (paint filter liquids test) and moisture content in the filter cake; and (4) pH of the untreated groundwater and filtrate. Several noncritical measurements were performed, including the extraction procedure (EP) toxicity test


Figure 2
Microfiltration System Sampling Locations

and toxicity characteristic leaching procedure (TCLP) test for the filter cake and particle size distribution for solids remaining in the filtrate. For the critical measurements, three to six replicate samples were collected depending on the data variability. Duplicate samples were collected for noncritical measurements.

U.S. EPA-approved sampling, analytical, quality assurance and quality control (QA/QC) procedures were followed to obtain reliable data.[2,3,4,5] Details on QA/QC procedures are presented in the demonstration plan.[6]

RESULTS AND DISCUSSION

This section of our paper summarizes the results of both critical and noncritical parameters for the DuPont/Oberlin microfiltration system demonstration and evaluates the microfiltration technology's effectiveness in treating groundwater contaminated with zinc.

Summary of Results for Critical Parameters

Results for the critical parameters were evaluated for each of the four phases.

Phase 1 Results

The total zinc concentrations in the untreated groundwater and filtrate are presented in Figure 3 for varying precipitation pH and ProFix dose. The zinc concentrations in the untreated groundwater, ranging from 417 to 493 mg/L, were reduced to approximately 0.1 mg/L (except in Run 6), yielding a typical removal efficiency greater than 99.9%. In Run 6, the filtrate zinc concentration was an order of magnitude higher than the typical filtrate zinc level; this increased concentration cannot be explained. No definite trend was identified for effluent zinc levels

or zinc removal efficiencies with varying pH or ProFix dose.

During the demonstration, a sample of the influent to the microfiltration unit was filtered through a standard 0.45-micron membrane filter (commonly used to measure dissolved metals) to compare the resulting filtrate with T-980 filtrate. In all cases, the zinc concentration was less in the T-980 filtrate, indicating the possible superior performance of Tyvek T-980 filter media over standard membrane filters.

Figure 4 presents the TSS concentration profiles for influent and filtrate. These data show that the influent TSS concentrations ranged from 6,560 to 18,900 mg/L and the filtrate TSS concentrations ranged from 8.4 to 31.5 mg/L. The TSS removal efficiencies ranged from 99.69 to 99.95%. Neither filtrate TSS levels nor TSS removal efficiencies seemed to follow a definite trend with varying pH or ProFix dose.

The filter cake solids concentrations are shown in Figure 5. Cake solids ranged from 30.5 to 47.1%. This figure also shows that the cake percent solids increased as the pH or ProFix dose increased. The filter cake passed the paint filter liquids test in all runs, making it suitable for landfilling.

The filtrate pH was typically 11.5, irrespective of the precipitation pH due to the high pH (about 12.6) of the ProFix slurry added at the influent to the microfiltration unit.

At the end of Phase 1, Run 5 conditions were selected as the optimum chemical operating conditions based on (1) zinc and TSS removals; (2) zinc and TSS levels in the filtrate; (3) percent solids in the filter cake; and (4) the cost of treatment chemicals (lime and ProFix).

Phase 2 Results

Figures 6, 7 and 8 present the concentrations profiles for zinc, TSS and filter cake solids, respectively. These results are similar to Phase 1

Zinc Concentration, mg/L
Figure 3
Zinc Concentration Profiles for Phase 1 Runs

TSS Concentration, mg/L

Figure 4
Tss Concentration Profiles for Phase 1 Runs

Cake Solids, %

Figure 5
Filter Cake Solids for Phase 1 Runs

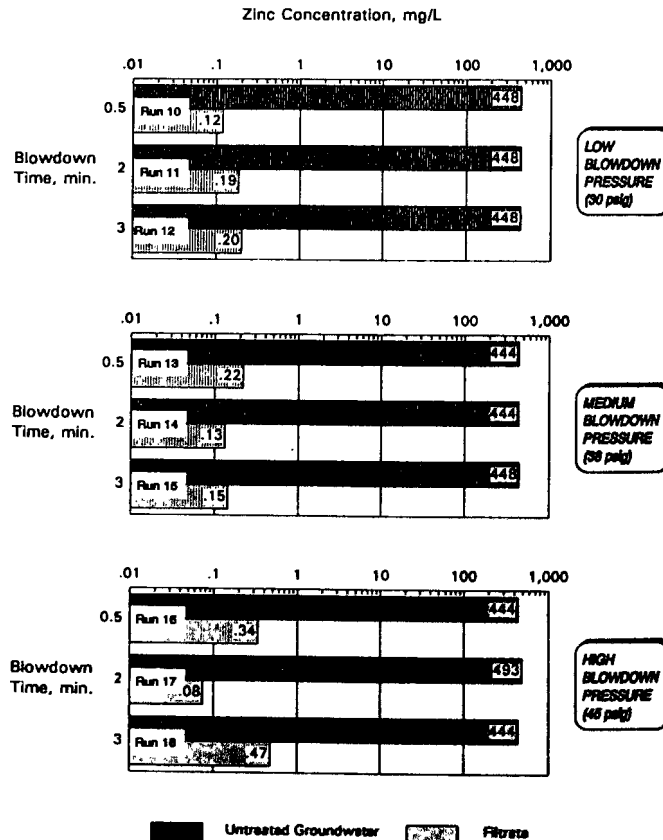
Zinc Concentration, mg/L


Figure 6
Zinc Concentration Profiles for Phase 2 Runs

results. The filter cake passed the paint filter liquids test in all Phase 2 runs and the filtrate pH was typically 11.5 (the same as in Phase 1 runs).

A dissimilarity noted between the Phase 1 and Phase 2 results is that in the Phase 2 runs, the zinc concentrations in the Tyvek T-980 filtrate were not always less than the 0.45-micron membrane filtrate. This dissimilarity cannot be explained.

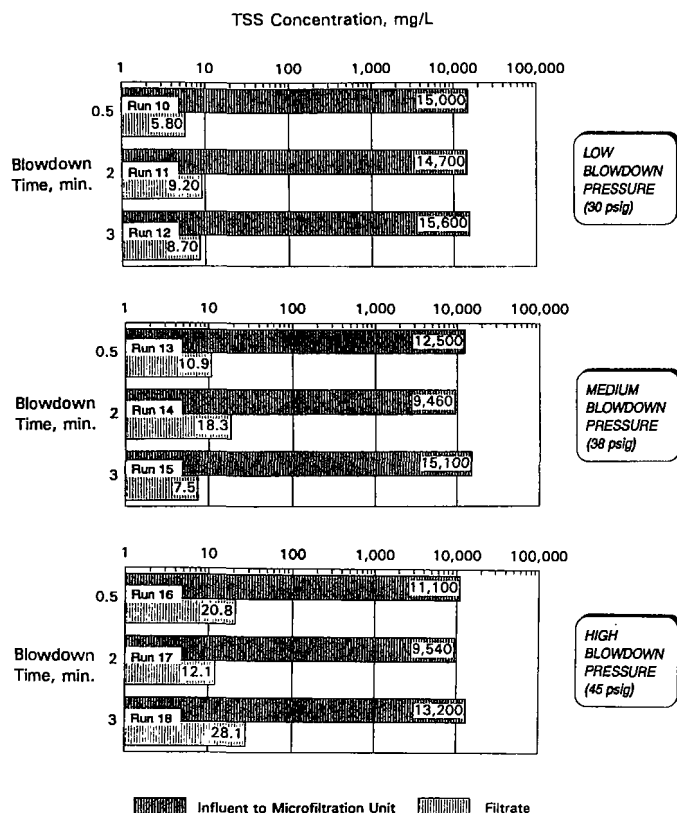
At the end of the Phase 2 runs, Run 13 conditions were selected as the optimum operating conditions based on the criteria discussed for Phase 1, plus waste processing time (which includes blowdown time).


Figure 7
TSS Concentration Profiles for Phase 2 Runs

Phase 3 Results

The total zinc concentration in the untreated groundwater in Runs 19 and 20 (reproducibility runs performed at Run 13 operating conditions) was 465 mg/L. The zinc concentration was reduced by 99.95 and 99.94%, resulting in 0.24 and 0.28 mg/L of zinc in the effluent of Runs 19 and 20, respectively. These removal efficiencies agree with the removal efficiency achieved in Run 13 (99.95%), indicating that the microfiltration system's performance in removing zinc was reproducible.

The TSS concentrations in the influent to the microfiltration unit were 14,300 and 14,000 mg/L in Runs 19 and 20, respectively. The TSS were reduced by 99.95%, resulting in 7.7 and 6.8 mg/L of TSS in the effluents of Runs 19 and 20, respectively. This removal efficiency also agrees with the TSS removal efficiency observed in Run 13 (99.91%), indicating that the system's performance in removing TSS was reproducible.

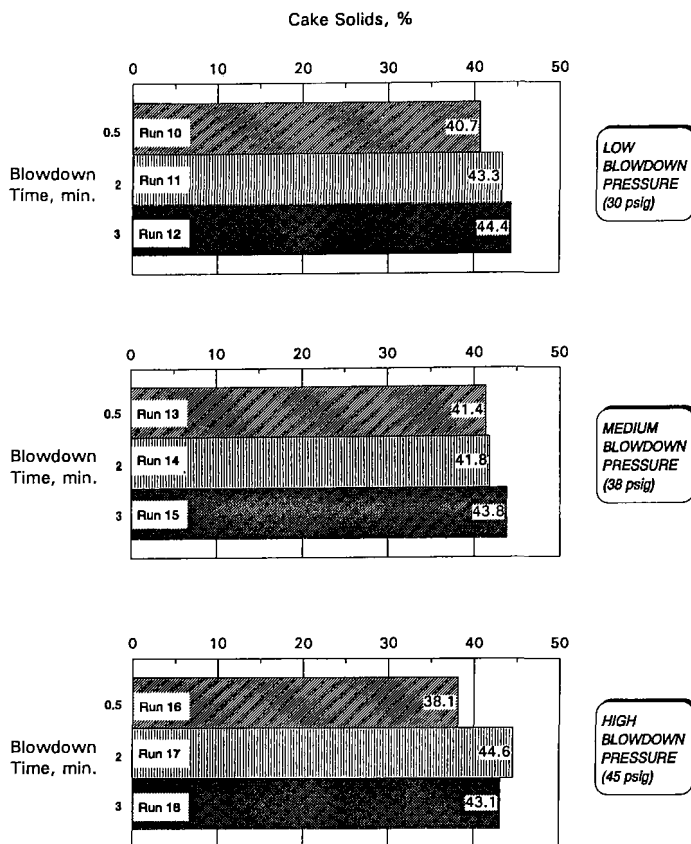
Figure 9 compares regulatory thresholds with: (1) the 95% upper confidence limits (UCL) for filtrate metals (cadmium, lead and zinc) and TSS and (2) the average filtrate pH value. The regulatory thresholds are those that would be required for discharge into a local waterway (Aquashicola Creek) if a National Pollutant Discharge Elimination System (NPDES) permit were required. The UCLs were calculated using the one-tailed Student's t-test. To calculate UCLs for cadmium and lead, which were present below detection limits, their mean concentrations were estimated using standard statistical procedures. Figure 9 shows that the filtrate met the NPDES limits for metals and TSS. However, the NPDES limit for pH was not met.


Figure 8
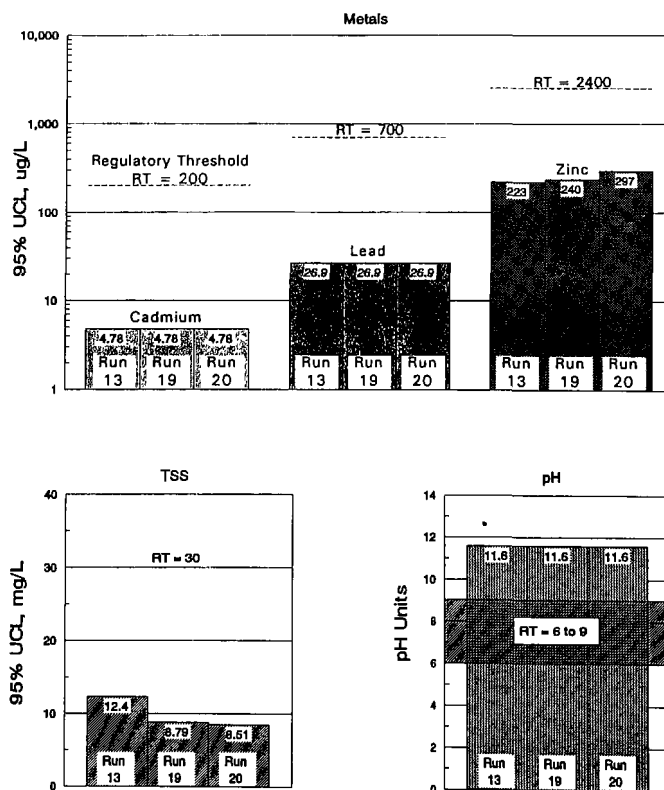
Filter Cake Solids Levels for Phase 2 Runs


Figure 9
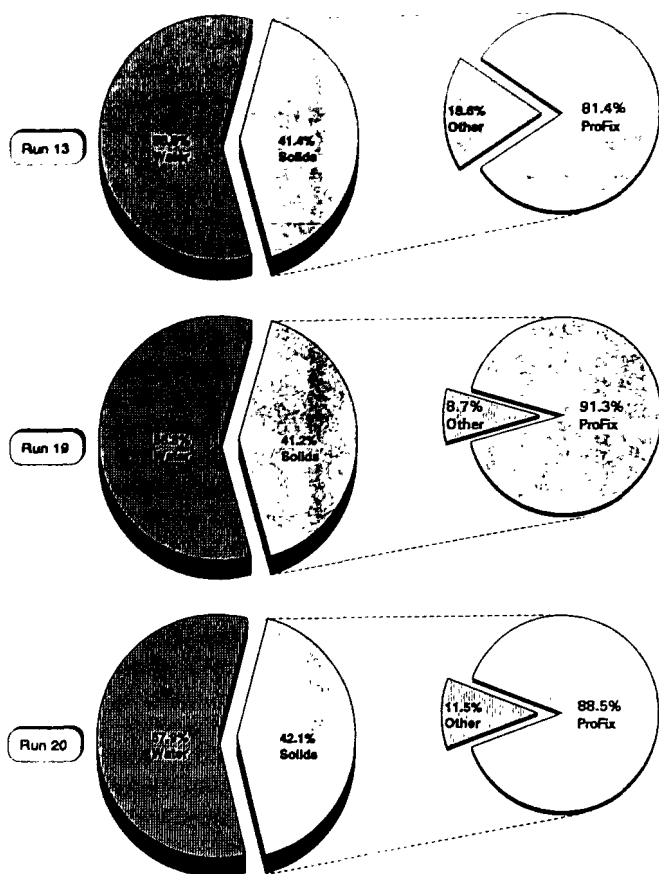
Comparison of Filtrate Quality for Reproducibility
Runs with Regulatory Thresholds


Figure 10
Filter Cake Composition for Reproducibility Runs

Figure 10 presents the composition of the filter cake in the reproducibility runs. The filter cake has approximately 41% solids. Of these solids, approximately 80 to 90% were from ProFix and the remaining were from: (1) TSS present in the untreated groundwater, (2) metals precipitated during the treatment and (3) unreacted lime from pH adjustment.

As a quality control check, a mass balance was performed for zinc and TSS in Runs 19 and 20. Figures 11 and 12 present the mass balance results for zinc and TSS, respectively. Figure 11 shows that the difference between zinc in and zinc out is approximately 15%, which is within the analytical precision for zinc measurement ($\pm$ 25%). Similarly, Figure 12 shows that TSS measurements are within the analytical precision ($\pm$ 30%).

Phase 4 Results

The results for the Tyvek reusability runs (Runs 21 and 22) are presented in Figure 13. In these runs, the same portion of Tyvek was used repeatedly for six cycles. Samples were composited after the first three cycles (Run 21) and the last three cycles (Run 22). Figure 13 shows that the microfiltration unit's performance was unaffected even after multiple uses of Tyvek.

Summary of Results for Noncritical Parameters

The demonstration also evaluated the results for noncritical parameters such as filter cake toxicity characteristics and the filtrate particle size distribution. Toxicity characteristics were considered a noncritical parameter because EP and TCLP metals were present at very low levels in the untreated groundwater. The particle size distribution measurement was included primarily to evaluate the developers' claim that the Tyvek filter can remove particles up to 0.1 micron. The filter cake toxicity characteristics were determined using EP and TCLP tests. A composite filter cake sample collected from the demonstration runs passed both these tests, indicating that the filter cake could be disposed of as a nonhazardous waste.

Zinc In = 100 g

Zinc In = 103 g

Zinc Out = 85.2 g

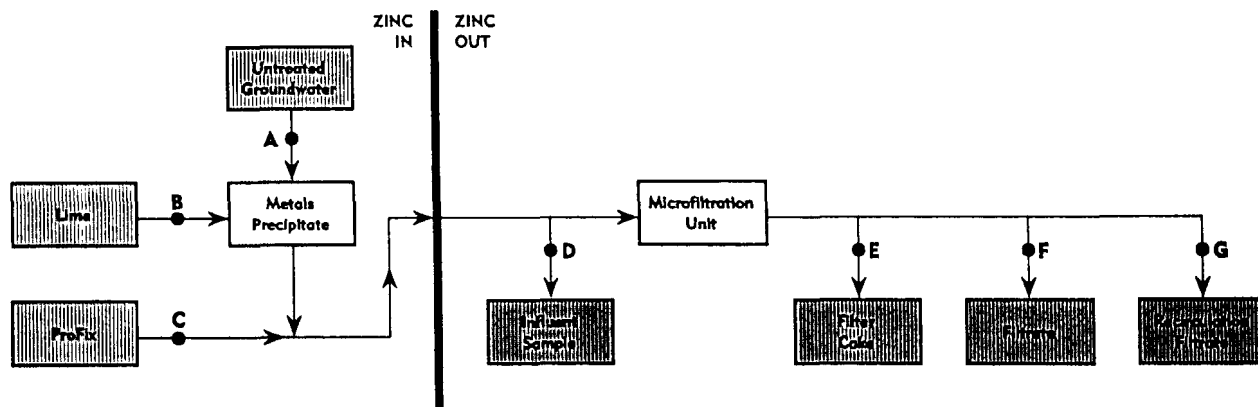
Not to Scale


Figure 11
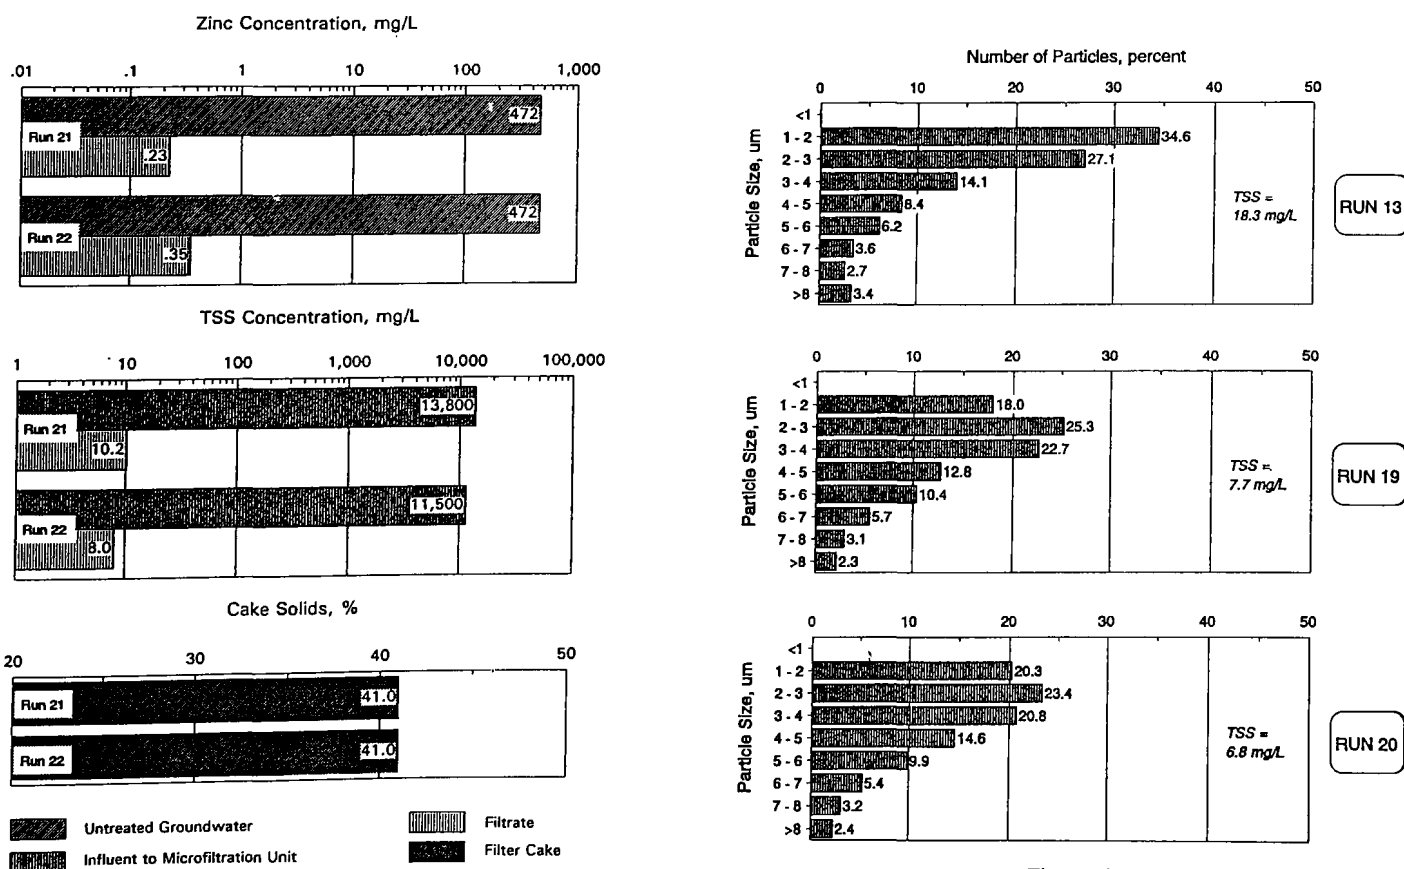
Zinc Mass Balance for Reproducibility Runs
Figure 12
TSS Mass Balance for Reproducibility Runs


Figure 13
Tyvek Performance for Reusability Runs

Figure 14
Filtrate Particle Size Distribution
for Reproducibility Runs

Figure 14 presents the filtrate particle size distribution and TSS results for the reproducibility runs. The particle size was measured using a Coulter counter with a 0.5- to 500-micron measurement range. The data presented in this figure indicate that the majority of particles present in the filtrate were 1 to 4 microns in size. The TSS data for these runs were used together with the particle size distribution to estimate the particle concentration in each size range. In Run 13 for example, filtrate particles ranging from 1 to 2 microns and greater than 8 microns were present at 6.3 mg/L and 0.63 mg/L, respectively. These results do not support the developers' claim that the Tyvek filter can remove particles down to 0.1 micron. Similar observations were made for Runs 19 and 20.

CONCLUSIONS

The DuPont/Oberlin microfiltration system achieved the following results: (1) zinc and TSS removal efficiencies of 99.69 to 99.99% and (2) solids in the filter cake of 30.5 to 47.1%. At the optimum conditions (Run 13), the zinc and TSS removal efficiencies were 99.95%, and the filter cake solids were 41%.

ProFix contributed a significant portion (80 to 90%) of solids to the filter cake. The remaining solids were due to precipitated metals, TSS from the untreated groundwater and any unreacted lime.

The zinc and TSS removal efficiencies and the filter cake percent solids were unaffected by the repeated use (six cycles) of the Tyvek filter medium. This indicates that the Tyvek medium could be reused without adversely affecting the microfiltration system's performance.

The filtrate met the applicable NPDES standards, established for disposal into a local waterway, for metals and TSS at the 95% confidence level. However, the filtrate did not meet the NPDES standard for pH. The filtrate pH was typically 11.5, while the NPDES discharge standard is 6 to 9.

The filter cake passed the paint filter liquids test for all runs. Also, a composite filter cake sample from the demonstration runs passed the EP toxicity and TCLP tests.

Response of Shallow Sandy Aquifers to Groundwater Remediation

William J. McElroy, P.E.
CH2M HILL
Gainesville, Florida

ABSTRACT

The recovery of contaminated groundwater, usually through wells, with subsequent treatment by one of several techniques (often referred to as "pump-and-treat"), is one of the more common remedial measures used to hydraulically control the under-ground movement of contamination and/or achieve some degree of aquifer restoration. Assessment of the aquifer response to remediation is a key aspect in system design and operation, as the expected degree and duration of the cleanup effort will affect operational costs and the ability to meet regulatory schedules.

A complex range of variables affects the response of an aquifer to the withdrawal of contaminated groundwater. As a result, it is difficult in most cases to accurately estimate at the beginning of recovery and treatment the length of time that will be required to reduce contaminant concentrations to a specified level. However, a common analytical approach to predicting aquifer response to contaminated groundwater withdrawal is based on the concept that contaminant concentrations in the groundwater will decline exponentially over time.

Four case study sites where groundwater contamination was addressed by the pump-and-treat method were selected from CH2M HILL projects in Florida. At all four sites, gasoline leaking from underground storage tanks had contaminated groundwater with dissolved volatile organic aromatic compounds. The use of exponential decay to describe the aquifer remediation process and the complexities created by influencing factors are illustrated by application of operational data from these sites.

INTRODUCTION

Contaminated groundwater is often recovered through wells and subsequently treated by one of several techniques in efforts to hydraulically control the underground movement of contamination and/or to achieve some degree of aquifer restoration. Designing and operating these "pump-and-treat" systems requires consideration of several important issues; of which prediction of aquifer response is one of the most critical and most difficult issues. Operational costs and the ability to meet regulatory schedules are highly dependent on the degree and duration of cleanup, but many factors influence those variables for a particular aquifer. The effect of these factors on the usefulness of the concept of exponential decay for estimating the time required to reduce aquifer contamination to a specified level is illustrated by application of data from four sites in Florida where groundwater contamination was addressed by the pump-and-treat method.

STUDY SITES

The four sites selected as case studies are located within the eastern coastal terrace areas of Florida, as shown in Figure 1. CH2M HILL has provided site assessment and remedial design for numerous pump-

and-treat projects throughout Florida; the case study sites were selected on the basis of the length of time that the remedial system had been in operation, the completeness and accessibility of the operational data base and client permission to use the available data.
Figure 1
Case Study Site Locations

At all four sites, gasoline leakage from underground storage tanks had contaminated the groundwater with dissolved volatile organic aromatic (VOA) compounds, which include benzene, toluene, ethylbenzene and total xylene components as measured in the laboratory by U.S. EPA Method 602. Free hydrocarbon contamination also was found in the shallow groundwater beneath the Jacksonville and Miami sites. Generalized maps showing the lateral extent of groundwater contamination and the locations of monitor wells and remedial systems are provided for the Jacksonville, Macclenny, Cooper City and Miami sites in Figures 2, 3, 4 and 5, respectively.

Geologic profiles and estimates of the average horizontal hydraulic conductivity for the effective saturated depth of the surficial aquifer zone for the case study sites are summarized in Figure 6. The Macclenny site displays some characteristics atypical of the Florida coastal region in that layers of silty and clayey sands are interspersed with thin

seams of fine sands in the upper profile. The two sites in southeast Florida are underlain by the Biscayne aquifer, a highly productive limestone unit that occurs at relatively shallow depths and is overlain by sands and sands with limestone. As seen in Figure 6, the average unconfined water table surface occurs between 0.6 to 1.5 m (2 to 5 ft) below land surface at the sites.

EXPONENTIAL DECAY METHOD

Contaminant concentrations in groundwater will theoretically decline exponentially over time. The exponential decay method, which has been incorporated into current Florida regulations, extends this theory to recognize contaminant partitioning between solid and liquid phases; thus, it is assumed that at any point in time, a certain portion of the contamination is dissolved in the groundwater and the remainder is retained on the aquifer medium. As groundwater is withdrawn through the contaminated aquifer zone at a particular volume, the contaminants adhering to the medium are dissolved in the cleaner groundwater that flows into the area and is subsequently recovered from the aquifer system.

Mathematically, the concept of exponential decay starts from the statement that contaminant concentrations at any time are proportional to the amount present in the contaminated aquifer zone. The corresponding mathematical expression is a well-known, first-order, linear differential equation that is solved by separating variables and integrating. Table 1 shows the derivation and presents useful forms of the analytical solution. The decay constant in this application reflects the removal of contamination from the groundwater system by various remediation processes instead of by some specific form of biological decay activity alone.

INFLUENCING FACTORS

In assessing the usefulness of the exponential decay equation in this application, the major factors that influence aquifer response must be considered. Recovery of contaminated groundwater by wells with the objective of aquifer remediation generally assumes that the well system can create the capture zone required to recover the water and that
Figure 6
Hydrogeologic Profiles at Case Study Sites

Table 1
Derivation of First-Order
Exponential Decay Equation

Base Equation: $\dfrac{dC}{dt} = -KC$

Separating Variables: $\dfrac{dC}{C} = -Kdt$

Integrating: $\ln C = -Kt + C$

Solving: $C = e^{-Kt\,+C} \to C = e^{-Kt}e^{C}$
at $t = o,\ c = e^{C} = C_o$

Solution: $C = C_o e^{-Kt}$

Rearranging: $t_c = (\ln \dfrac{C}{C_o}) + -K$

Note: C in last equation is concentration at any time.

the contamination can be withdrawn from the aquifer system. These assumptions apply best where geologic conditions are simple, the aquifer is relatively homogeneous and only a dissolved form of contamination exists. More frequently, one or more of these conditions are not met.

Also, the need to achieve a prescribed degree of cleanup within a certain period appears to make it desirable to move large quantities of groundwater at the highest flow velocities practicable through the contaminated aquifer zone. Where aquifer conditions reasonably accommodate this objective, however, a corresponding reduction in contaminant concentrations may not be readily observed or extended periods of operation may result.

Some of the major factors that influence aquifer response to the remediation process are summarized in Table 2 and further discussed below.

Aquifer Characteristics

Aquifers comprising more permeable media yield higher pumping rates than aquifers with low permeability characteristics. Accordingly, higher groundwater withdrawal volumes and flow velocities are possible in more permeable aquifer systems, which increases the potential to achieve more timely aquifer remediation.

Heterogeneity within the aquifer system also affects remediation. Where silty or clayey layers are interspersed with sands, preferential flow paths are created during recovery in the more permeable zones. If contamination is present in the lower permeability layers, it can remain as a residual source and lengthen the remediation process, especially where groundwater fluctuations occur within these zones. If contamination is not present in the higher producing zones being pumped, dilution effects are incurred that not only impact remediation but can affect treatment system costs.

Low permeability aquifers and/or aquifers with high water table conditions may limit the volume and duration of on-site treated water discharge that may be part of a remedial system. As a result, the rate and duration of groundwater withdrawal are also restricted, which affects the remediation period.

Contaminant Partitioning

Many contaminants can be retained by the aquifer medium. This chemical partitioning to solid particulates tends to retard contaminant movement and lengthens remediation. The degree to which contaminants are sorbed and retained depends largely on the nature of the contaminants and the aquifer medium.

Generally, contaminants that are more soluble will adsorb less to solid particles and be more mobile in the groundwater system. Aquifers in which the medium has higher percentages of total organic carbon and/or clayey particles tend to adsorb and retard contaminants more than

aquifers composed primarily of clean sands.

Well Placement and Pumping

To minimize remedial system operating time, the goal in well placement is to reduce the travel time of contaminants to a point of recovery. Generally, in more permeable aquifers, a recovery well often can be located near the center of contamination to create the required capture zone. The use of a single well minimizes the hydraulic interferences and occurrence of groundwater stagnation points common with multiple-well systems. In less permeable aquifers, however, more recovery wells may be required throughout the lateral extent of the contamination plume. Special consideration may be necessary in recovery operations (e.g., alternate well pumping schemes) to mitigate well hydraulic interferences and groundwater no-flow zones and to improve contaminant travel time. The vertical distribution of contamination is an important consideration in well placement. In certain circumstances, some forms of dissolved contamination sink to lower portions of an aquifer, while other forms tend to remain at more shallow depths. The design of the recovery system must consider this vertical distribution in attempting to restore the aquifer, minimize treatment of uncontaminated groundwater and prevent contaminants from entering clean zones.

The rate of groundwater recovery may also affect the remediation process. Where contaminant partitioning or non-aqueous forms of contamination occur in the aquifer, the optimum recovery rate may be governed by the contact time required for the contamination in the solid and liquid phases to approach equilibrium conditions. If recovery rates are too high, large amounts of less contaminated groundwater may be generated, which affects the number of pore volume extractions and treatment costs.

Nature and Source of Constituents

Aquifer remediation at sites where contamination is present in the form of non-aqueous phase liquids (NAPLs) will generally take significantly longer than at sites where only dissolved contamination exists. Constituent concentrations in NAPLs are usually much greater than the concentrations that can be dissolved and transported in the groundwater flow system. As a result, a significant period of time may be required for the leaching process to culminate.

NAPLs can be more or less dense than groundwater. Where NAPL contamination is present as a floating layer on the groundwater surface, it usually is included in the recovery scheme. Residual saturation, however, may leave a percentage of the floating NAPL within the aquifer medium as a relatively immobile source of contamination. De-

pending on the degree of cleanup required, additional measures may be necessary to address residual contamination in both the saturated and unsaturated portions of the aquifer. Where NAPL contamination is more dense than water, residual saturation can be spread throughout the aquifer depth and remediation becomes even more difficult.

To achieve successful restoration, all potential sources of contamination that may affect performance of the remedial system must be identified and abated to the extent practicable, including off-site sources. The off-site migration of the contaminant plume most also be fully defined to provide a recovery system with the potential to achieve remediation. Thus, adequate field investigations are essential to remedial system design and operation.

Aquifer Remediation Criteria

Depending on the nature of contamination present, federal, state or local regulatory criteria may govern the design and evaluation of remediation. In some cases, site cleanup criteria are developed by the consultant based on a contamination and risk assessment and approved by the regulatory agencies. Florida regulations governing groundwater remediation involving hydrocarbon contamination include requirements that total VOA concentrations be reduced to 50 ug/L or less, with benzene reduced to less than 1 ug/L, in contaminated aquifers that are used or can be potentially used for drinking water. A risk assessment establishing alternative cleanup criteria may also be approved.

The performance goals of the remedial system should be realistic, based on in-depth consideration of the influencing factors, and reflected in the required degree of remediation. Once performance goals and schedules are established, they should be documented in written agreements or other legal instruments to provide a clear basis of understanding for all parties. It may not be possible to do so at the outset of projects where initial remedial actions are instigated to recover NAPLs discovered during excavations or in monitor wells, contaminated soils are excavated during removal of underground storage tanks or identified contamination poses immediate public health or environmental threats.

CASE STUDY COMPARISON

At the four case study sites, concentrations of VOAs in recovered groundwater have been routinely measured as influent to treatment systems since remedial system operations began. The data for each site were plotted for the available period of operational records as points on a graph.

The volume of groundwater within the contaminated aquifer zone at each site was then estimated based on the defined horizontal and vertical extent of dissolved contamination and effective porosity values considered representative of the saturated aquifer media at the sites. This volume was compared to the cumulative volume of contaminated groundwater recovered over time at a site to assess the number of pore volumes that had been withdrawn.

The exponential decay equation was solved using the measured data, and the resulting theoretical time distribution of dissolved VOA contamination was compared with the plotted operational data, as shown in Figures 7 through 10. For the last operational data point in the record, the figures also provide the duration of recovery, average decay coefficient, the estimated number of pore volumes that had been extracted through the contaminated aquifer zone and the ending VOA concentration.

Jacksonville Site

The theoretical exponential decay curve for the Jacksonville site shown in Figure 7 describes the general trend in decreasing VOA levels fairly well. However, after more than 2.5 years of recovery and extraction of 25 to 30 pore volumes of groundwater, influent VOA levels remained at approximately 800 ug/L, significantly above the 50 ug/L regulatory cleanup criteria. The results and the observed variations in the influent concentrations probably reflect the presence of NAPL floating on the water table, chemical partitioning of the contamination to the solid phase and the fluctuations of the water table into the vadose zone containing residual contamination.

Based on the theoretical equation and continuation of the decay coeffi-

cient, reduction of the influent VOA concentrations to the 50 ug/L level would take approximately another 2.5 years of groundwater withdrawal at the average pumping rate for the system of 10 gpm. If that were the case, an estimated total of 55 to 60 pore volumes would be extracted through the contaminated aquifer zone from startup through shutdown. With the presence of NAPLs, however, the required time and recovered volume could be even greater.

After an extended shutdown, remedial operations have been continued at the Jacksonville site. It is anticipated that a soil vapor extraction system will be installed to address NAPL contamination in the vadose zone and to supplement the existing free product and groundwater recovery system.

Macclenny Site

Influent VOA concentrations at the Macclenny site have been erratic, but a general exponentially decreasing trend can be observed in the data shown in Figure 8. After more than 2.5 years of pumping, the influent VOA concentration of 900 ug/L remains significantly above the 50 ug/L cleanup criterion. These results and the observed variations in the influent concentrations probably reflect the heterogeneity of the subsurface profile with the presence of low permeability silty and clayey layers, chemical partitioning of the contamination to the solid phase and the fluctuations of the water table into contaminated portions of the vadose zone.

Based on the theoretical equation and continuation of the decay coefficient, reduction of the influent concentrations to the 50 ug/L level would require an additional 6.5 years of groundwater withdrawal at the average pumping rate for the system of 4 gpm. This additional recovery added to the amount of groundwater already withdrawn would roughly correspond to an estimated total of 35 to 40 pore volumes extracted through the contaminated aquifer zone since operations began.

Remedial operations continue at the site. Modifications to the remedial action plan are being developed to address contamination in the vadose zone. It is anticipated that soil excavation and thermal treatment will be recommended to supplement the groundwater recovery system.

Cooper City Site

Initial VOA concentrations were relatively low at the Cooper City site and decreased fairly rapidly upon startup of the recovery system. The theoretical exponential decay curve in Figure 9 tends to underpredict the decreasing trend in influent concentrations. The observed decline in the relatively short period of remediation probably reflects the low levels of dissolved groundwater contamination initially present, the relatively simple geologic profile, the lack of significant levels of contamination in the vadose zone, the permeable nature of the aquifer medium, and the ability to withdraw large volumes of groundwater through the contaminated aquifer zone over a relatively short period.

Remedial operations continue at the site. Groundwater influent concentrations remain below the regulatory cleanup criteria. Most site monitor wells generally yield groundwater samples that are also below the cleanup criteria, although a few exceed the allowable VOA and benzene levels. According to state regulations, remediation can generally be considered complete when samples from all monitor wells meet the criteria after recovery operations have ceased for 1 year.

Miami Site

The theoretical exponential decay curve in Figure 10 tends to underpredict the decreasing trend in influent VOA concentrations at the Miami site. Although a relatively quick decline in concentrations was experienced, the decline was followed by extended periods where little change in VOA levels occurred. Influent concentrations remained above the cleanup criteria after extraction of 35 to 40 pore volumes of groundwater over almost 2.5 years of recovery. The results may reflect the presence of NAPL floating on the water table, some chemical partitioning of the contamination to the solid phase and the fluctuations of the water table into the contaminated vadose zone. Negative effects of high withdrawal rates also may be indicated; large volumes of less contaminated groundwater may have been generated if the withdrawal rate exceeded the contact time required for the solid and liquid phases of contamination to approach equilibrium conditions.

Based on the theoretical equation and continuation of the decay coefficient, reduction of the influent VOA concentrations to the 50 ug/L level would take an additional 0.75 year of groundwater withdrawal at the average pumping rate for the system of 12 gpm. This additional recovery added to the amount of groundwater already withdrawn would roughly correspond to an estimated total of 90 to 95 pore volumes extracted through the contaminated aquifer zone since operations began. Because of the presence of NAPLs (and possibly the high withdrawal rates), however, this theoretical duration could be extended even further. Remedial operations continue at the site. Additional measures are being considered to address NAPL contamination in the vadose zone to supplement the existing free product and groundwater recovery system. Modification of the groundwater recovery system also is being considered.

CONCLUSIONS

For assessing aquifer response to continuing recovery operations, the first-order exponential decay equation appears to generally describe the decline in dissolved VOA concentrations over time. This function may, however, underpredict the actual reduction in VOA concentrations when the aquifer medium is highly permeable and large volumes of groundwater can be withdrawn through the contaminated aquifer zone over a fairly short period. The results indicate that groundwater recovery is most likely to achieve timely aquifer restoration where geologic conditions are relatively simple, the aquifer medium is permeable, residual contamination in the vadose zone is low and contamination exists only in the dissolved form. An excessive rate of groundwater recovery may extend the remediation period at some sites, and the presence of NAPL and/or residual vadose zone contamination may require a combination of soil and groundwater remedial technologies to achieve timely and cost-effective cleanup.

Aquifer remediation is an extremely complex process. Design and performance requirements for remedial systems should be developed based on in-depth consideration of major influencing factors. Site characterization, delineation of the horizontal and vertical extent of contamination, and the identification of source constituents are especially important. While the expected duration of remedial operations is often of interest to facility owners and regulatory agencies, accurate predictions are virtually impossible to make in most cases and are potentially litigious. When such predictions are required, they should be provided only with the clear understanding of their qualitative nature and with sufficient disclaimers to reflect the difficulties in making such forecasts.

The Effects of Creosote-Contaminated Groundwater On Slurry Cutoff Wall Soil Backfill

ABSTRACT

Slurry cutoff walls have been used frequently in recent years to contain creosote-contaminated groundwater during the cleanup of wood preserving plants. However, the effectiveness of slurry cutoff walls could be limited by long-term degradation of the soil backfill from chemical reactions with creosote-contaminated groundwater. Because most of the slurry walls installed to contain creosite-contaminated groundwater have been for private-sector industries, little information is available to evaluate the effectiveness of this technology.

This paper discusses the results of compatibility tests performed on several laboratory-prepared soil backfill mixtures of on-site and off-site and creosote-contaminated groundwater from the Bayou Bonfouca Superfund site in Slidell, Louisiana. These results were used to evaluate the expected performance of a slurry cutoff wall installed at this site.

Each backfill mix tested was judged compatible with the creosote-contaminated groundwater and suitable for use as the slurry cutoff wall backfill material. Atterberg limits and flocculation tests also were conducted with both tap water and creosote-contaminated groundwater. Although inconclusive, these tests revealed no significant adverse changes in the characteristics of the bentonite.

INTRODUCTION

Slurry walls effectively reduce groundwater flow beneath dams and controlling inflow into deep excavation. Within the last decade, slurry wall technology has been used extensively to contain hazardous waste and to prevent clean groundwater from entering a contaminated site. However, the effectiveness of slurry wall technology is limited by the potential for degradation resulting from contamination with site-specific leachates.

The long-term effectiveness of slurry walls used to contain contaminated groundwater has not been determined with certainty. Most of the slurry walls installed for pollution control have been in place for relatively short periods of time. Little information is available to evaluate the effectiveness of this technology. Therefore, the long-term performance of the walls in the presence of chemical contaminants has not been well documented.

The information regarding the long-term (10 to 20 years) interaction between contaminated groundwater and soil-bentonite backfill can be obtained only from field performance. In the laboratory, the long-term effect is generally predicted by permeating at least two pore volumes of contaminated groundwater through the soil-bentonite samples and determining whether any measurable changes occur in the permeability of the soil-bentonite backfill.

Mitchell and Madsen[12] reported that the previous available results of compatibility tests in which organic chemicals were used as permeants have been both conflicting and confusing for the following reasons:

- Two million organic chemicals are known to exist
- Different test types and test parameters are used
- Permeant concentrations have varied
- Synergistic chemical effects are unknown
- Clay mineralogical properties vary widely

Although soil-bentonite slurry cutoff walls have been used to contain creosote-contaminated groundwater, these slurry walls were constructed primarily for privately owned firms. Quantitative information about the long-term performance of such walls was obtained by permeating soil-bentonite backfill with creosote-contaminated groundwater. These tests have revealed no significant increase in the permeability of soil-bentonite backfill.

CLASSIFICATION AND INDEX PROPERTIES OF AS-RECEIVED SOIL SAMPLES

Two 5-gallon buckets of off-site non-contaminated soils and 11 5-gallon buckets of on-site contaminated soils were used for testing. The index properties and classifications of the soils are described in the following paragraphs.

Off-site Non-Contaminated Silty Sand

The off-site non-contaminated soils were visually classified as light brown slightly silty sand containing approximately 8 percent of fines passing the No. 200 sieve with a coefficient of uniformity of 2.3. The soils were classified as SP-SM in accordance with the Classification of Soils for Engineering Purposes (ASTM D-2487).

On-site Contaminated Sandy Lean Clay

The on-site contaminated sandy lean clay had a natural moisture content of 30.4 percent, a liquid limit of 35 percent and a plastic limit of 15 percent. This soil contained approximately 59 percent of fines passing the No. 200 sieve. The soil was classified as CL in accordance with ASTM D-2487.

On-site Contaminated Clay

The on-site contaminated clay was generally yellowish-brown and brownish-gray. The natural moisture content of the clay was 31.1 percent; the liquid limit was 62 percent; and the plastic limit was 17 percent. This soil contained 94.3 percent fines passing the No. 200 sieve. The clay was classified as CH-type soil in accordance with ASTM D-2487. The particle size distribution is presented in Figure 1 and the Atterberg limits are shown in Figure 2.

The Atterberg limits of the composite fat clay sample also were determined after hydration in creosote-contaminated groundwater for 24 hours at a moisture content near the liquid limit. After hydration in the creosote-contaminated groundwater, the plastic limit equalled 17

percent; the plasticity index was 40 percent and the liquid limit was 57 percent. Although the liquid limit and plasticity index decreased slightly, the creosote-contaminated groundwater does not appear to affect the plasticity of the fat clay significantly.

CHARACTERISTICS OF CREOSOTE OIL AND CREOSOTE-CONTAMINATED GROUNDWATER

Fifteen 2-liter amber bottles of creosote oil and creosote-contaminated groundwater were used in the testing program. A summary of the results of chemical analyses conducted on the creosote oil and creosote-contaminated groundwater is shown in Table 1.

Before being used in the laboratory compatibility tests, the 11 creosote-contaminated groundwater samples were mixed together to create one composite sample. The composite sample was then filtered with Watman 541 filter paper (98 percent retention efficient of 20- to 25-μ size particles) to remove suspended particles.

CHARACTERISTICS OF BENTONITE PRODUCT

Federal Gel 90 bentonite was selected for use in preparing the soil-bentonite slurry wall backfill mixes. The Federal Gel 90 bentonite had an as-received moisture content of 7.7 ±0.1 percent as determined on three samples and a fines content of 96.9 percent.

Plasticity Characteristics and Effect of Creosote-Contaminated Groundwater on Clay Mineral Plasticity

The bentonite was hydrated in de-ionized water and creosite-contaminated groundwater to determine the effects of creosote-contaminated groundwater on the plasticity of the bentonite. As shown in Figure 3, after hydration in de-ionized water for 24-hours at a moisture content near the liquid limit, the Atterberg limits of the Federal Gel 90 bentonite were characteristic of a highly plastic clay with a liquid limit of 57.6 percent and plasticity index of 54.3 percent. in creosote-contaminated groundwater for 24 hours before testing at a moisture content near the liquid limit resulted in no effect on the plastic limit, a slight reduction in the liquid limit and a corresponding slight reduction in the plasticity index. Therefore, the creosote-contaminated groundwater does not appear to have a significant effect on the swelling ability and plasticity of the Federal Gel 90 bentonite clay minerals. The addition of creosote oil to the creosote-contaminated groundwater-bentonite "paste" after hydration for 24 hours at about the liquid limit resulted in a more significant reduction in the liquid limit and plasticity index was although the Atterberg limits were still characteristic of a highly plastic clay.

Settling/Flocculation Tests with Creosote-Contaminated Groundwater

The settling/flocculation characteristics of Federal Gel 90 bentonite in creosote-contaminated groundwater were compared with the behavior in de-ionized water to determine if the creosote-contaminated groundwater adversely affected the ability of the bentonite clay minerals to remain in suspension (i.e., not to floc and rapidly settle). Samples of Federal Gel 90 bentonite were hydrated in de-ionized water and creosote-

contaminated groundwater at a bentonite content corresponding to approximately 40 Marsh-seconds as determined with a Marsh funnel viscometer in accordance with API RP 138 Standard Procedure for Field Testing Drilling Fluids.

The test results indicate that bentonite contents of approximately 5.2 percent in de-ionized water and 6.5 percent in creosote-contaminated groundwater are needed to achieve a viscosity of 40 Marsh-seconds. Accordingly, the creosote-contaminated groundwater had some effect on the swelling behavior of the bentonite clay minerals, as indicated by a higher bentonite content to achieve the same viscosity.

Settling tests were then performed with a slurry of Federal Gel 90 bentonite in de-ionized water at a viscosity of 37 Marsh-seconds and Federal Gel 90 bentonite in creosote-contaminated groundwater at a viscosity of 38 Marsh-seconds. The settling tests were performed in 10.2-cm diameter plexiglas cylinders with an initial height of slurry of 24.3 cm. After 68 days, the bentonite was still in suspension in both slurries, with no visible clear water interface above the clay slurry. Accordingly, the creosote-contaminated groundwater did not cause the Federal Gel 90 bentonite to floc or affect its ability to remain in suspension.

PREPARATION OF SOIL AND SOIL-BENTONITE BACKFILL MIXES

The following seven soil and soil-bentonite backfill mixes were

prepared with the off-site non-contaminated slightly silty fine sand, on-site contaminated fat clay and sandy lean clay and Federal Gel 90 bentonite:

- On-site contaminated fat clay soil backfill
- On-site contaminated fat clay and on-site contaminated sandy lean clay (at a ratio of 3:2 by volume) soil backfill mix
- On-site contaminated fat clay and on-site contaminated sandy lean clay (at a ratio of 3:2 by volume) with 4 percent Federal Gel 90 bentonite (by dry weight) soil-bentonite backfill mix
- Off-site non-contaminated slightly silty fine sand with 4, 6, 8 and 10 percent Federal Gel 90 bentonite (by dry weight) soil-bentonite backfill mixes

On-site Contaminated Fat Clay Soil Backfill

The composite sample of the on-site contaminated fat clay was mixed with tap water to moisture contents of 62 to 75 percent, and the slump was determined in accordance with ASTM C 143 Standard Test Method for Slump of Portland Cement Concrete. As shown in Figure 4, the test results indicate that moisture contents in the range of 60 to 70 percent are required for a slump of 4 to 6 inches, which is typically used for slurry wall backfill.

Slump vs Moisture for On-site Fat Clay, Sandy
Lean Clay and Fat Clay-Sandy Lean Clay Backfill Mixes

On-site Contaminated Fat Clay/Sandy Lean Clay Soil Backfill Mix

A composite sample of the fat clay/sandy lean clay mix was prepared by combining these soils at a ratio of 3:2 by volume at the as-received moisture contents and then thoroughly homogenizing the soils in a rotary-type mixer. The particle size distribution is presented in Figure 1, the Atterberg limits are shown in Figure 2 and the index properties of the mix are as follows:

- Moisture Content, $w_c(\%)$ 29.8
- Fines Content, -200(%)   75.3
- Liquid Limit, LL(%)   46
- Plastic Limit, PL(%)   14
- Plasticity Index, PI(%)   32
- Classification (ASTM D 2487)   CL

The mixture consisted of a brown and gray mottled lean clay with sand, classified as a CL-type soil in accordance with ASTM D-2487.

The slump test results shown in Figure 4 indicate that moisture contents in the range of 52 to 55 percent are required for a slump of 4

to 6 inches, as typically used for slurry wall backfill.

On-site Contaminated Fat Clay/Sandy Lean Clay with 4 Percent Federal Gel 90 Bentonite Soil-Bentonite Backfill Mix

A composite sample of the fat clay/sandy lean clay mix was prepared by combining these soils at a ratio of 3:2 by volume at the as-received moisture contents, adding 4 percent Federal Gel 90 bentonite by dry weight at its as-received moisture content and then thoroughly homogenizing the soils in a rotary-type mixer. The Atterberg limits of the mix are presented in Figure 2. The index properties of the mix are as follows:

- Moisture Content, $w_c(\%)$ 29.0
- Fines Content, -200(%)   78.2
- Liquid Limit, LL(%)   54
- Plastic Limit, PL(%)   14
- Plasticity Index, PI(%)   40
- Classification (ASTM D 2487)   CL

For a slump of 4 to 6 inches, which is typically used for slurry wall backfill, moisture contents in the range of 52 to 58 percent are required (Fig. 4).

Off-site Sand/Federal Gel 90 Bentonite Soil-Bentonite Backfill Mix

The off-site slightly silty fine sand was mixed with Federal Gel 90 bentonite at the as-received moisture contents at proportions of 4, 6, 8 and 10 percent bentonite by dry weight. The measured fines contents of the four sil-bentonite backfill mixes are 10.6, 12.2, 14.0 and 15.7 percent, respectively.

A summary of the slump versus moisture content determined on each off-site sand-bentonite backfill mix after hydrating for 24 hours with tap water at the test moisture contents is shown in Figure 5.

The four backfill mixes exhibit the expected trend of increasing moisture content for a given slump with increasing bentonite content. Achieving a 5-inch slump requires moisture contents of approximately 37, 41, 53 and 56 percent for bentonite contents of 4, 6, 8 and 10 percent, respectively, corresponding to an increase in moisture content of approximately 3.4 percent per 1 percent increase in bentonite content.

Slump vs Moisture Content for Off-site
Sand-Bentonite Mixes

PERMEABILITY TESTS AND COEFFICIENT OF PERMEABILITY OF SOIL AND SOIL-BENTONITE BACKFILL MIXES

The coefficient of permeability of each of the seven prepared soil and soil-bentonite backfill mixes was determined at one moisture content corresponding to a slump of between 4 and 6 inches. The test specimens were "spooned" into 3.57-cm diameter by 8.0-cm long stainless steel rigid-wall permeameters at the 4- to 6-inch slump consistency, simulating the placement of the slurry wall backfill in the field. A thin film of bentonite paste (approximately 0.5 to 0.7 grams net weight) also was applied to the inside face of the steel mold to minimize potential side wall leakage.

The specimens were then permeated with de-ionized water with net hydraulic head of 58 to 127 cm of water under a backpressure of 90 lb/in^2 to maintain saturation during flow. The hydraulic head was applied in increments, and the sample allowed to consolidate under the applied hydraulic gradient. The inflow to and outflow from each sample were monitored with time in calibrated burettes and the applied hydraulic head was measured with a pore pressure transducer. The coefficient of permeability was calculated for each recorded flow increment from the average of the inflow and outflow quantities and the average applied hydraulic head. The tests were continued until steady-state flow was achieved, as evidenced by values of inflow and outflow within approximately ±10 percent of the mean of the inflow and outflow for each increment and stable values of coefficient of permeability were measured.

A summary of the initial specimen conditions and coefficients of permeability measured on the various soil and soil-bentonite backfill mixes is shown in Table 2. The coefficient of permeability of the various soil and soil-bentonite backfill mixes varied from 2.8 x 10^{-8} to 9.2 x 10^{-8} cm/sec. The following criteria were established for an acceptable backfill:

- Slump of 4 to 6 inches
- Total Unit Weight >95 pcf
- Laboratory Coefficient of Permeability <5 x 10^{-8} cm/sec

Accordingly, the on-site fat clay soil backfill, on-site fat clay/sandy lean clay with 4 percent Federal Gel 90 bentonite backfill mix and off-site sand/Federal Gel 90 bentonite backfill mix with 6, 8 and 10 percent bentonite tested satisfy the specified criteria. Of the seven prepared backfill mixes, only the on-site fat clay/sandy lean clay and off-site sand/4 percent Federal Gel 90 bentonite backfill mixes did not satisfy the specified coefficient of permeability criterion.

Table 2
Coefficients of Permeability of Various Soil Bentonite Backfill Mixes

Sample	Moisture Content, w_c(%)	Total Unit Weight, γ_t(pcf)	Slump (inches)	Permeability Coefficient k_{rw}(cm/sec)
	Initial Conditions			
Onsite Fat Clay Soil Backfill	63.0	98.0	4.6	2.8 x 10^{-8}
Onsite Fat Clay/Sandy Lean Clay Soil Backfill Mix	52.3	96.1	4.5	9.2 x 10^{-8}
Onsite Fat Clay/Sandy Lean Clay with 4% Federal Gel 90 Bentonite Backfill Mix	51.8 / 55.8	102.0 / 99.5	4.0 / 5.2	2.9 x 10^{-8} / 4.0 x 10^{-8}
Offsite Sand/Federal Gel 90 Bentonite Backfill Mix				
4% Bentonite	35.2	109.1	4.3	7.2 x 10^{-8}
6% Bentonite	40.6	107.1	4.6	4.6 x 10^{-8}
8% Bentonite	51.5	100.7	4.7	3.7 x 10^{-8}
10% Bentonite	55.3	95.5	4.8	3.5 x 10^{-8}
10% Bentonite	55.8	98.1	5.0	2.9 x 10^{-8}

COMPATIBILITY TESTS AND EFFECT OF CREOSOTE-CONTAMINATED GROUNDWATER ON COEFFICIENT OF PERMEABILITY OF BACKFILL MIXES

The results of the above permeability tests led to the selection of four backfill mixes for compatibility testing to determine the effect of permeation with creosote-contaminated groundwater on the coefficient of permeability. The following four backfill mixes were selected for compatibility testing:

- On-site fat clay soil backfill
- On-site fat clay/sandy lean clay soil backfill mix
- On-site fat clay/sandy lean clay with 4 percent Federal Gel 90 bentonite backfill mix
- Off-site sand/8 percent Federal Gel 90 bentonite backfill mix

The samples selected for compatibility testing were extruded vertically from the stainless steel rigid-wall permeameter mold onto the bottom pedestal of a flexible-wall permeameter and encased within two 0.008-inch-thick latex membranes. The samples were consolidated in increments under an isotropic effective consolidation stress of 4 lb/in^2 with a backpressure of 94 lb/in^2. The specimens were then permeated with de-ionized water with hydraulic heads of 250 to 300 cm.

The inflow to and outflow from each sample were monitored with time in calibrated burettes and the applied hydraulic head was measured with a pore pressure transducer. The coefficient of permeability was calculated for each recorded flow increment with the average of the inflow and outflow quantities and the average applied hydraulic head. Permeation with de-ionized water was continued until steady-state flow was achieved, as evidenced by values of inflow and outflow within ±10 percent of the mean of the inflow and outflow for each increment and stable values of the coefficient of permeability were measured.

A summary of the coefficients of permeability measured on the selected soil and soil-bentonite backfill mixes with the flexible-wall permeameters and compared with the coefficients of permeability measured with the rigid-wall permeameters is shown in Table 3.

Table 3
Summary of Permeabilities Measured with Flexible-Wall and Rigid-Wall Permeameters

Sample	Rigid-Wall k_{rw}(cm/sec)	Flexible-Wall k_{fw}(cm/sec)	Ratio k_{rw}/k_{fw}
	Coefficient of Permeability		
Onsite Fat Clay Soil Backfill	2.8 x 10^{-8}	1.0 x 10^{-8}	2.8
Onsite Fat Clay/Sandy Lean Clay Soil Backfill Mix	9.2 x 10^{-8}	2.0 x 10^{-8}	4.6
Onsite Fat Clay/Sandy Lean Clay with 4% Federal Gel 90 Bentonite Backfill Mix	4.0 x 10^{-8}	1.2 x 10^{-8}	3.3
Offsite Sand/8% Federal Gel 90 Bentonite Backfill Mix	3.7 x 10^{-8}	1.1 x 10^{-8}	3.4

As a result of consolidation under the isotropic effective consolidation stress of 4 lb/in^2 and greater imposed hydraulic head, the coefficients of permeability measured with the flexible-wall permeameters were 2.8 to 4.6 times less, with an average of 3.5 times less, than those measured with the rigid-wall permeameters.

Because the measured coefficient of permeability was lower than expected, the test specimens were then dismantled, reduced from the initial length of 7.5 to 7.9 cm to approximately 4.0 cm and reset within the flexible-wall permeameters to meet the requirement of permeating the specimens with a minimum of two void volumes of flow within approximately 6 weeks. The specimens were then again consolidated under an isotropic effective consolidation stress of 4 lb/in^2 with a backpressure of 94 lb/in^2 and permeated with de-ionized water at hydraulic heads of 250 to 300 cm. The coefficients of permeability to de-ionized water were measured on the shortened specimens and, as expected, found to be essentially identical to the coefficients of permeability shown above ($k_f w$) as measured before the specimens were shorted.

The specimens were then permeated with creosote-contaminated

Table 4
Summary of Compatibility Test Results on Soil and Soil Bentonite Slurry Wall Backfill Mixes

Sample	Initial Conditions[a]		Consolidated Conditions[b]			Final Conditions				Compatibility Test Duration		Coefficient of Permeability, k_{fw}(cm/sec)

Figure 6
Coefficient of Permeability vs Void Volumes
of Flow from Compatibility Test
groundwater for 63 to 90 days, during which time 2.29 to 2.55 void volumes of creosote-contaminated groundwater were permeated into the test specimens. The test durations, void volumes of flow, initial and final coefficients of permeability and final physical properties of the test specimens are presented in Table 4. The measured coefficient of permeability versus void volume of flow for each backfill mix is shown in Figure 6. As shown in Figure 6, for the permeated quantities of creosote-contaminated groundwater, the coefficients of permeability remained essentially unchanged.

CONCLUSIONS

From the experimental results described above, the following conclusions can be drawn:

- After hydration in creosote-contaminated groundwater for 24 hours, the Atterberg limits of Federal Gel 90 showed no significant change from those hydrated in de-ionized water.
- Creosote-contaminated groundwater did not cause the Federal Gel 90 bentonite to flocculate or affect its ability to remain in suspension.
- After permeating soil-bentonite backfill with 2.3 to 2.5 pore volumes of creosote-contaminated groundwater, the permeabilities of the backfill remained essentially unchanged.

Waste Without a Place—The Pentachlorophenol Problem

Gary H. Collison
Golder Associates Inc.
Atlanta, Georgia

ABSTRACT

The tangled web of RCRA hazardous waste classification presents a situation where hazardous waste generated through implementation of a remedial action may have no viable treatment or disposal options available under present regulations. This situation could apply to actions at RCRA Subtitle C permitted facilities, state-led or voluntary remedial actions which have to meet RCRA or equivalent state regulations and CERCLA actions by application of ARARs. The situation is particularly complicated for waste generated by remedial action which consists of soil, surface water and groundwater. The problem exists because of the RCRA Subtitle C classification and treatment standards for hazardous waste containing dioxin compounds, but also pertains to waste containing pentachlorophenol and related compounds when no specific dioxin compounds are present in the waste.

A state led remedial action, currently confidential, is used to illustrate the complexity of the regulations, their impact on potential treatment and disposal options and the lack of commercially available hazardous waste management facilities which are permitted to accept these wastes. The various RCRA hazardous waste classifications for soil, water and debris containing pentachlorophenol and 2,4,5-trichlorophenoxy-propanoic acid (2,4,5-TP, Silvex) are reviewed. These waste classifications yield three different treatment and disposal situations which are based on knowledge of the origin of the waste materials, even though the presence and concentration of the constituents are similar:

- Waste materials which cannot be commercially treated or disposed as hazardous waste
- Waste materials which can be treated and commercially disposed as hazardous waste
- Waste materials which are classified as solid waste or which can be treated and disposed as solid waste

This case history illustrates the application of RCRA classification of "listed" waste, "characteristic" waste by EP Toxicity and "characteristic" waste by the new TCLP test for soil, water and debris. It also addresses wastes classified by the "derived from" rule and the "mixture" rule. It examines the impact to treatment and disposal options, including delisting, brought about by the regulatory approach to hazardous waste classification on the basis of waste origin as well as constituent concentrations.

INTRODUCTION

The site is located in what is currently a combined residential and commercial area of a major city. It was used previously for the manufacture, formulation, storage and distribution of a wide variety of agricultural herbicides and pesticides. A preliminary assessment of the site indicated the presence of residual organic compounds associated with the past activities in the structural members of the buildings, in the soil above the groundwater and in the groundwater. The geology of the site is essentially low permeability clay soil to a depth of approximately 15 feet, underlain by strata of sand, silt and clay of varying thickness. The water table is at a depth of approximately 4 to 6 feet below the surface. The ground surface at the site is flat and nearly horizontal with building floor slabs at grade. Because of the low permeability clay soil and topography, lateral gradients are almost nonexistent, except for localized lateral flow toward the storm drains surrounding the site. Organic compounds which had been released during past facility operations are essentially confined to the upper few feet of the soil, shallow groundwater within the upper clay soil and backfill around the storm drains.

The site was voluntarily remediated and there was an agreement with the state regulatory agency to document the proposed remedial actions. Since the site is within a metropolitan area, is not on the NPL and could be valuable for future commercial or light manufacturing use, the selected remedial action was removal of hazardous and solid waste materials for off-site commercial treatment and/or disposal. Land disposal was selected for a majority of the soil and debris, but provisions were made for incineration of some materials as required because of high constituent concentrations in localized areas. The essential elements of the program consisted of:

- Demolition and disposal of one building
- Decontamination of one building
- Excavation and disposal of soil containing pesticide, herbicide and other organic chemical compounds
- Investigation of the groundwater to confirm the lack of migration of the site-related compounds

The remedial action was developed and implemented on a fast-track basis; the project involved sampling and analyses of the soil and building materials concurrent with the remedial activities. The analytical data were used to determine the specific areas of the site which required remedial excavation. They also were used to determine the applicable waste coding of the excavated soil and debris, to determine the appropriate method of soil and debris disposal and to complete the waste manifest forms. Because of the wide variety of organic compounds present at the site and the timing of the project, the California list restrictions and the soft hammer provisions of the first third land disposal restrictions were applicable.

RCRA WASTE CLASSIFICATION

Because the constituents detected were judged to have been caused by releases from past manufacturing and formulation activities at the

site, the waste materials containing hazardous constituents were subject to the hierarchy of RCRA hazardous waste classification. The contaminated soil and below ground debris were judged to be listed wastes by the "cleanup of a spill into or on any land or water" provision of 40 CFR Subpart D, Section 261.33(d). Thus, the "P" and "U" waste codes were applicable to most of the constituents detected. Determination of whether building demolition debris was hazardous waste was made pursuant to the "characteristics" provisions of 40 CFR 261.24.

Pentachlorophenol

During the program, samples of soil and debris from below ground were reported to contain pentachlorophenol and 2,4,5-TP. Although these compounds are listed with the "U" waste codes in 40 CFR 261.33, they are not given a "U" code number. Instead, they are referenced to waste code F027 in 40 CFR 261.31. Because of past site operations, the waste materials containing these constituents could also be classified as waste code F020. The distinction between F020 and F027 is not critical since both codes are considered as a dioxin class waste which includes codes F020 through F023 and F025 through F028. It is noted that there is no requirement to determine if waste containing pentachlorophenol actually contains dioxin, it is simply coded as a dioxin waste by association. These dioxin code waste materials are subject to the land disposal restrictions and treatment standards of 40 CFR 268.41 and 268.42.

The 40 CFR 268.42 treatment standards require incineration as the specified treatment technology if the total constituent concentration in the waste (CCW) of halogenated organic compounds (HOCs) is greater than 1,000 mg/kg (California restriction for HOCs). For concentrations less than 1,000 mg/kg total HOCs, treatment standards have been established by incineration for specific dioxin compounds in 40 CFR 268.41, but the regulations do not mandate incineration as the required treatment technology. The treatment standard for pentachlorophenol is 0.01 ppm based on constituent concentration in the waste extract (CCWE) from the TCLP test. Land disposal of dioxin class waste containing pentachlorophenol is permitted for concentrations below this treatment standard.

In addition to being included as a constituent within the F020 and F027 "listed" waste codes, pentachlorophenol is also included as a hazardous waste constituent within "listed" codes F039, K001 and U050. The F039 waste code is for multisource leachate and the treatment standard for pentachlorophenol is 0.089 mg/L (CCW) in wastewater and 7.4 mg/kg (CCW) in nonwastewater. The K001 code is applicable only to the disposal of bottom sediment sludge from the treatment of wastewaters from wood preserving processes that use creosote and/or pentachlorophenol. Pentachlorophenol is also regulated as a constituent in creosote within waste code U050. The treatment standards for pentachlorophenol as a K001 and U050 waste constituent are 0.18 mg/L (CCW) for wastewater and 7.4 mg/kg (CCW) for nonwastewater (40 CFR 268.43). Wastes with pentachlorophenol concentrations below the treatment standards can be land disposed. These "listed" waste codes did not apply at the example project site because wood treating was not performed at the site. They are included in this discussion to indicate the different land disposal treatment standards which are applied to the same constituent for different "listed" waste codes.

If a waste is not able to be classified as "listed" waste, the determination of whether the waste is hazardous is made by the "characteristics" of reactivity, ignitibility, corrosivity or toxicity. The recent revisions to 40 CFR 261.24 implementing toxicity characteristic (TC) by the TCLP test now include pentachlorophenol as a regulated "characteristic" hazardous waste constituent. By these TC revisions, solid waste which contains pentachlorophenol, but which is not a "listed" waste, is hazardous by "characteristic" if its leachate concentration by TCLP is greater than 100 mg/L. The hazardous waste code for pentachlorophenol by "characteristic" is D037. If the leachate concentration is less than 100 mg/L, the waste is not a hazardous waste and may be managed as a solid waste; consequently, it is permitted to be land disposed as a solid waste.

In summary, waste containing pentachlorophenol may be a "listed"

hazardous waste which can be land disposed at concentrations below the various treatment standards for the "F," "K" and "U" codes. Alternatively, it may be a D037 code "characteristic" hazardous waste which may be land disposed at concentrations at or above the established "regulatory level," but which is not a hazardous waste below the "regulatory level." It should be noted that the "regulatory level" is not a land disposal restriction level, but is a level which has been established solely to determine if a waste is hazardous. The applicable "F," "K" and "U" "listed" hazardous waste treatment standards and the D037 "characteristic" hazardous waste "regulatory level" are as follows:

Waste Code	Waste Form	Standard/Level	Basis
F020 et. al.	All	0.01 ppm	CCWE
F039	Wastewater	0.089 mg/L	CCW
F039	Nonwastewater	7.4 mg/kg	CCW
K001, U050	Wastewater	0.18 mg/L	CCW
K001, U050	Nonwastewater	7.4 mg/kg	CCW
D037	All	100 mg/kg	CCWE

2,4,5-TP

The compound 2,4,5-TP is no simpler to deal with. Although it is included as an F020 and F027 "listed" waste constituent, there is no treatment standard established in 40 CFR 268.41. Thus, as a dioxin "listed" waste it cannot be land disposed at any concentration according to 40 CFR 268.31. It also is included within multisource leachate "listed" hazardous waste code F039 with a treatment standard of 0.72 mg/L (CCW) for wastewater and 7.9 mg/kg (CCW) for nonwastewater. This compound was previously included as "characteristic" hazardous waste code D017 in the 40 CFR 261.24 regulations and also is included in the revised 40 CFR 261.24 regulations as a "characteristic" waste by the TCLP test. As a "newly regulated" waste by revised 40 CFR 261.24 regulations, it has a "regulatory level" of 1.0 mg/L by TCLP (CCWE) for wastewater and nonwastewater. However, because it was previously regulated under 40 CFR 261.24, it also has a land disposal treatment standard of 7.9 mg/kg (CCW) for nonwastewaters. Thus, as a "characteristic" waste, if the total concentration of 2,4,5-TP is less than 7.9 mg/kg, the material is hazardous and can be land disposed, but if the concentration is less than 1.0 mg/L in a TCLP extract, the material is not hazardous waste. It is noted that a primary drinking water standard of 0.01 mg/L has been established for 2,4,5-TP. Thus, even though solid waste material with this compound cannot be accepted for land disposal at a commercial hazardous waste disposal facility, it can be consumed in drinking water.

Proper disposal of waste containing pentachlorophenol, 2,4,5-TP and other dioxin class constituents is a complex matter based on the waste code (waste origin specific) and the constituent concentration. As a K001 or U050 waste code, pentachlorophenol may not be land disposed at a concentration above 7.4 mg/kg. As an F020 or F027 waste code, pentachlorophenol may not be land disposed at a concentration above 0.01 ppm in the TCLP extract, but it is not even a hazardous waste up to 100 mg/L in the extract as code D037. It is arguable that a compound should be regulated on the basis of its total concentration and on the basis of its TCLP leachate characteristics. However, in the author's opinion it makes no technical sense that a compound be regulated at different levels on the basis of its total concentration. Furthermore, it is ridiculous that a compound is not considered to be a hazardous waste at a leachate concentration 10,000 times greater than its hazardous waste land disposal leachate concentration restriction. It is also ridiculous that a compound cannot be accepted for disposal at a commercial disposal facility, but is permitted to be in drinking water.

TREATMENT AND DISPOSAL OPTIONS

The technically available treatment options for waste containing pentachlorophenol vary depending on concentration and waste form. As is

the case with other organic compounds, treatment by incineration or biologic processes is technically feasible, particularly at higher concentrations. Wastewater can be treated by a variety of means such as UV Peroxide oxidation and carbon adsorption. However, the practical treatment and disposal options are a nightmare because of RCRA regulation waste classification and the lack of commercial RCRA disposal facilities which accept dioxin class wastes.

At present, there are no commercial treatment or disposal facilities permitted to accept pentachlorophenol as a "listed" dioxin class waste, waste codes F020 and F027, even though a land disposal treatment standard has been established. Industry representatives have indicated that a special permit is required along with a separate public comment period. Apparently, those commercial facilities which did apply were denied a permit, but most did not apply for fear of jeopardizing their existing permits because of potential emotional issues about dioxin raised during the public comment process. It is understood that there are commercial facilities intending to apply for permits to incinerate dioxin class wastes, but as of September 1990, none have been permitted. The only available commercial disposal option is for disposal of liquids at a few deep injection well sites which recently received "no migration permits."

Although there are no commercial treatment or disposal facilities for solid materials, there is one commercial facility which is permitted to accept dioxin class waste for containerized storage. Even though commercial facilities cannot accept waste containing pentachlorophenol as a dioxin class waste, they are permitted to accept pentachlorophenol with the other "listed" and "characteristic" waste codes. It is interesting to note that the pentachlorophenol concentration permitted to be land disposed under these other codes is significantly higher than the concentration permitted under the dioxin codes.

At the example site, some of the soil from the cleanup contained pentachlorophenol and/or 2,4,5-TP. This soil was judged to be an F020/F027 waste, a "listed" dioxin class waste. This classification was deemed appropriate since the remedial action at the site was a cleanup of a spill "into or on any land or water" (40 CFR 261.33(d)) from the formulation and manufacture of pesticides containing these and other, compounds. The facility did not produce, manufacture or otherwise deal with creosote or wood preserving products so the K001 and U050 codes were not applicable. The detected compounds were not from multisource leachate so the F039 code was not applicable.

The site is not on the NPL, so the cleanup could not take advantage of the on-site remediation preference of CERCLA or the waiver of RCRA regulations as ARARs under CERCLA. At CERCLA sites, soil containing pentachlorophenol is often treated and placed back in the ground at the site. In most of these cases, the "placement" provisions of RCRA are considered to be not applicable or appropriate. Even though the majority of the soil which did contain pentachlorophenol was determined to have concentrations well below the applicable land disposal restrictions, it could not be commercially landfilled because the commercial disposal facilities do not have permits to accept the dioxin class wastes. Because the soil was classified as a "listed" waste, on-site treatment would not eliminate the off-site commercial disposal problem because the "derived from" rule would cause the treated soil to continue to be a "listed" waste.

On-site biologic treatment or soil washing may have been technically feasible and on-site incineration certainly would have been technically feasible as treatment options to deal with the soil which contained pentachlorophenol. On-site incineration as a treatment option was discounted because it was judged essentially impossible to obtain an incinerator permit for this site because of its location within a residential neighborhood of a large city. More critical, however, was that all technically feasible treatment options require excavation of the soil for treatment. Consequently, after treatment the soil would have to undergo "placement." Such "placement" has to be in a RCRA permitted landfill, but the soil would continue to be an F020/F027 "listed" waste by the "derived from" rule provisions of 40 CFR 261.3(c).

Since there are no commercial landfills to accept the F020/F027 dioxin class wastes, there was no commercial means of disposing of the soil after treatment. The option of constructing a landfill on-site and ob-

taining a RCRA permit for soil disposal or storage was considered to be infeasible because of the site location and characteristics. Delisting of the treated soil is theoretically possible, but practically impossible. To even consider delisting, the treatment option would likely have to be incineration in order to reduce the pentachlorophenol and other chemical constituent concentrations to extremely low or nondetectable levels. Unfortunately, the option cycle returns to the probable impossibility of obtaining a permit for an on-site incinerator and the lack of permitted off-site commercial incinerators. Since there was insufficient space at the only commercially permitted storage facility for the estimated volume of soil which contained pentachlorophenol and because of the enormous cost of storage (approximately $5.00/day/drum) for an unspecified time, any remedial option requiring excavation and later placement was considered to be not viable.

In the absence of a commercial facility to accept the soil which contained pentachlorophenol, the majority was left in the ground. Because of the inability to commercially handle dioxin class wastes under present regulations and permit conditions, such materials remain in the ground at many sites. The small amount of soil which was excavated or removed by investigation drilling and sampling and a small volume of soil which was excavated in very limited areas, are presently warehoused at the only available commercial facility. By RCRA regulations, this material must remain in storage until it can be transported to a different facility with a RCRA treatment, storage or disposal permit.

The building debris from the site did not require a "listed" waste classification since the constituents which were present in the building materials were not from the cleanup of a spill "into or on any land or water." The structural building materials in the building which was decontaminated were analyzed for both total concentration and TCLP extract concentration of pesticides and herbicides to determine if they would be hazardous waste by "characteristic" in the event the building was demolished in the future. Both analyses were employed because it was presumed that if the building were demolished in the future the new toxicity characteristics would be in effect and both analyses would be required for pentachlorophenol as previously noted. The analytical results indicated such building debris would be solid waste.

It was decided to dispose of the debris from the building which was demolished as part of the remedial program at a permitted hazardous waste landfill, even though it could have been disposed at a solid waste facility. There was a slightly higher cost for disposing of the debris at a hazardous rather than solid waste landfill, but disposal at the hazardous waste facility was selected as a more responsible means of dealing with the debris which contained hazardous constituents.

As part of the remedial action, precipitation and groundwater which accumulated in the excavations on the site and precipitation which could have potentially come into contact with materials containing site related constituents (contact water) were collected for treatment and/or disposal. A small carbon treatment unit was installed on-site to treat approximately 200,000 gallons of collected contact water and a temporary permit was obtained to discharge the treated water to the storm drain system. The collected contact water was judged to be "listed" hazardous waste by the "mixture" rule in 40 CFR 261.3(a)(2)(iv) for a variety of site related constituents. However, some of the contact water contained very low concentrations of 2,4,5-TP and was segregated from the remaining contact water.

About half of the treated water met the constituent specific discharge requirements; the other half failed to meet the requirements for constituents other than the 2,4,5-TP. Because there were no commercial disposal facilities available at the time for the contact water containing the listed dioxin class waste, the on site treatment provided a mechanism to reduce the F020/F027 waste from thousands of gallons to a few drums of solids residue. During the course of the project a deep injection well disposal facility received a "no migration" permit and it was decided to dispose of the contact water which did not initially meet discharge requirements at this facility rather than provide additional treatment. This decision was primarily based on schedule considerations even though it was slightly more expensive than additional treatment.

The solids from the water treatment were filter pressed to reduce

their water content and also mixed with lime to further solidify them. The solids were analyzed for the F020/F027 constituents and they were not detected. Even so, by the "derived from" rule and the "mixture" rule these solids were also "listed" F020/F027 waste. Due to the F020/F027 compounds, these solids could not be commercially land disposed. Delisting the solids was considered so they could be disposed of rather than stored. However, there is no regulatory mechanism to delist a material for a specific constituent or set of constituents. If there were, the residual solids could have continued to have been classified as "listed" waste without F020/F027 constituents and could have been land disposed. However, because of concentrations of other "listed" waste constituents in the solids, and because of the tremendous time and expense involved in a delisting petition, it was decided to commercially store these drums of solids.

When the carbon unit was selected for treating the collected contact water, the carbon suppliers indicated the carbon could be regenerated, even with the F020/F027 compounds. They would not regenerate carbon containing 2,3,7,8-TCDD. The collected contact water was analyzed for this 2,3,7,8-TCDD at levels of 0.2 ng/L (ppt). None was detected at this level. However, near the completion of the project the suppliers of the carbon refused to regenerate the carbon because the regeneration ash would be considered a "listed" F020/F027 waste by the "derived from" rule and could not be disposed of. It is presently contemplated that the spent carbon will have to be drummed and commercially stored.

It is noted that if the soil at the site had been determined to have been hazardous by "characteristic" and not by "list," it could have been directly landfilled or could have been treated on-site. If it could have been treated to a level where the constituents causing it to be a "characteristic" waste cease to be detected, or were at concentrations below the TCLP levels for the newly identified waste, the materials would no longer be a hazardous waste. Also, the "derived from" and "mixing" rules would not have applied to the water or any treatment residue. Classification as a "characteristic" waste would have been appropriate if the origin of the constituents had been unknown. In this case, ignorance may have been more blissful.

COMMENTARY

The RCRA regulations were not initially contemplated to address the classification and disposal of soil and debris. The treatment standards have been set based on manufacturing and production waste streams, not for contaminated soil. Although the U.S. EPA has indicated they will deal with this issue, they have failed to do so thus far and it is not known when they will promulgate standards for soil and debris.

The present regulations and waste classification system are complex in themselves, but the system becomes irrational when the waste has different constituent treatment standards based on classification by its origin. The situation is exacerbated when one of the origin based classifications eliminates disposal of hazardous waste by accepted methods and at constituent levels below all of the established treatment standards. It is ridiculous that the regulations have yielded a situation where contaminated soil is left in the ground because of a regulatory inability to properly deal with it because of its origin, while it can be dealt with at similar and higher constituent concentrations because of a different origin or because of ignorance of its origin.

The regulations do not encourage proper disposal of hazardous waste; they inhibit it. When the cleanup of a site is more dependent on the origin of a constituent rather than its concentration, the system has failed. Knowing a constituent's origin does not enhance protection of the environment. The U.S. EPA and Congress need to be more aware of situations like this in order to develop actions which will foster voluntary cleanup of sites without having to resort to CERCLA in order to sidestep RCRA. RCRA and CERCLA are for environmental protection and need to be refocused to address this goal.

Land Ban Wastes: Pitfalls in Certification/Demonstration Submittal

U.S. Environmental Protection Agency, Region IV
Atlanta, Georgia

ABSTRACT

The HSWA include specific restrictions on the land disposal of RCRA-defined hazardous wastes. The Land Disposal Restrictions "soft hammer" regulations prohibited the disposal of wastes in surface impoundment or landfill units unless the receiving unit met the RCRA minimum technology requirements and generators certified that they had made a good-faith effort to locate and to contract with treatment and recovery facilities for treatment that was practically available.

The generator was required to submit to the Regional Administrator a demonstration and certification that the requirements of 40 CFR 268.8(a)[1] had been met. The demonstration had to include a list of facilities contacted, each facility official's name, facility addresses, telephone numbers and each contact date. The correct certification to be submitted depended on whether the generator determined that there was or was not practically available treatment. The certification statement had to be signed by the generator prior to submission.

The Agency has identified several treatment technologies that are generally considered appropriate for handling soft hammer wastes. Those technologies that are deemed appropriate for the non-wastewater forms of soft hammer wastes include: metal recovery, leaching/oxidation, metals stabilization, ash stabilization, chemical oxidation, biodegradation, incineration and PCB incineration. Technologies generally considered for wastewater soft hammer wastes include: aqueous metal recovery, chromium reduction, metals precipitation, steam stripping, carbon adsorption, oxidation/reduction, chemical oxidation, biodegradation, incineration and PCB incineration. The actual choice of a particular treatment technology would depend on the physical and chemical characteristics of a specific waste.

For soft hammer wastes that were to be land disposed or treated off-site, generators had to comply with the Land Disposal Restrictions notification, certification and demonstration requirements. This paper presents an overview of land disposal restrictions with particular emphasis on soft hammer certification/demonstration submittals and pinpoints the EPA review process to evaluate the validity of the certification.

INTRODUCTION

The HSWA[1] to RCRA[2], signed on Nov. 8, 1984, prohibited the land disposal of specified RCRA hazardous wastes beyond statutory dates established by Congress unless: (1) the wastes are treated to a level or by a method specified by the U.S. EPA, (2) it can be demonstrated there will be no migration of hazardous constituents from the land disposal unit for as long as the wastes remain hazardous or (3) the wastes are subject to an exemption or variance from meeting the treatment standards.

HSWA directed the U.S. EPA to establish treatment standards for each of seven groups of RCRA hazardous wastes by specific dates[3] These

dates are referred to as statutory deadlines and will eventually restrict land disposal of all RCRA hazardous wastes as follows: spent solvent- and dioxin-containing wastes (Nov. 8, 1986), California List Wastes (July 9, 1987), First Third Wastes (Aug. 8, 1988), spent solvent-, dioxin-containing and California List Soil and Debris from CERCLA/RCRA Corrective Actions (Nov. 8, 1988), Second Third Wastes (June 8, 1989), Third Third Wastes (May 8, 1990) and newly identified wastes (within six months of identification as a hazardous waste).

HSWA provided that if the Agency failed to set treatment standards for First or Second Third Wastes by their statutory deadline, then the wastes would become restricted under the soft hammer provisions until the U.S. EPA set treatment standards for them, or until May 8, 1990. The soft hammer provisions specified certain restrictions that would have to be met before the wastes could be land disposed in landfills or surface impoundments.

Generators of soft hammer wastes had to comply with the Land Disposal Restrictions (LDR) certification and demonstration requirements as well as the notification requirements for all LDR wastes. Notification requirements (40 CFR 268.7) include name and address of facility, the U.S. EPA hazardous waste number, the U.S. EPA I.D. Number, manifest associated with shipment of waste and waste analysis data, where available. The required language for certification statements may be found in 40 CFR Part 268.8. Prior to disposal, the generator had to demonstrate that he had made a good-faith effort to locate and contract with treatment and recovery facilities practically available, which provided the greatest environmental benefit. The demonstration had to include a list of facilities, facility officials contacted, addresses, telephone numbers and contact dates. The generator also should have provided information on the chosen treatment technology selected or why treatment/recovery was not practical for the waste.[4]

To help the U.S. EPA expedite its evaluation of certifications/demonstrations, certain pitfalls should be avoided. An examination of some of these pitfalls and a discussion of effective submittals are presented below.

OVERVIEW OF LDR

For purposes of the LDR program, the statute specifically defines land disposal to include, but not be limited to, any "placement" of hazardous waste in a land, fill, surface impoundment, waste pile, injection well, land treatment facility, salt dome, salt bed formation, underground mine or cave. The LDR Rule of Nov. 7, 1986, added to this definition the placement of waste in a concrete bunker or vault intended for disposal.[5] The LDR apply only to RCRA hazardous wastes that are land disposed or placed after the effective date of the restrictions.

LDR contained in RCRA Section 3004 and 40 CFR Part 268 will eventually prohibit land disposal of all RCRA hazardous wastes that

do not meet LDR treatment standards. LDR treatment standards were established by the U.S. EPA on the basis of the best demonstrated available technology (BDAT) rather than risk-based or health-based standards. The LDR treatment standards may be expressed as constituent concentration levels (which must be attained before the waste or treatment residuals may be land disposed) or specified technologies (which must be applied to waste before the residuals may be land disposed).[6]

Most of the LDR treatment standards are expressed as constituent concentration levels and compliance with LDR is achieved by meeting the numerical performance standards established for each constituent. Any technology that can achieve the required levels may be used unless the technology is otherwise prohibited: the BDAT used by the U.S. EPA to set standards need not be used.[4]

"SOFT HAMMER" REQUIREMENTS FOR NOTIFICATIONS, CERTIFICATIONS AND DEMONSTRATIONS

"Soft hammer" provisions fell on those First Third and Second Third Wastes for which the U.S. EPA did not set treatment standards by the statutorily-mandated date (Aug. 8, 1988 and June 8, 1989, respectively). The soft hammer provisions specified certain restrictions that had to be met before the wastes could be disposed in landfills or surface impoundments. As of May 8, 1990,[3] "soft hammer" provisions are no longer in effect.

Under soft hammer, generators, treatment and disposal facilities were required to meet special restrictions if the wastes or residues were to be disposed in a surface impoundment or landfill unit. Prior to disposing of the untreated wastes, generators had to determine if treatment was "practically available." If treatment was "practically available," generators had to send these wastes to a facility that would provide the "best" type of treatment. Whether the wastes were treated or not, they had to be disposed in a unit that is in compliance with the RCRA minimum technology requirements. Facilities also had to complete soft hammer certifications and demonstrations to show whether treatment was practically available and submit these to the Regional Administrator.[7]

Cost factors were allowed in the soft hammer determination of "practicable." If the cost of transporting and treating the waste was more than twice the pretreatment cost of disposal by whatever practice the generator was using previously, then that treatment could have been considered not to be "practically available." Generators had to provide a one-time demonstration, certification and notification if wastes were to be disposed in a landfill or surface impoundment and as long as the waste stream did not change or some other major aspect of the demonstration did not change before the waste was shipped off-site. The demonstration, which showed whether treatment was practically available, had to be sent to the treatment facility with the initial shipment and to the Region in which the generator was located. Generators also had to prepare and sign a certification, a copy of which had to be sent with each shipment to the treatment facility. The exact certification language depended on whether practically available treatment existed.[7]

In some cases, soft hammer wastes could have been California List Wastes (HOCs or PCBs) and should have been considered as such under treatment standards that were promulgated for California List wastes. The statutory California List levels represent the minimum level of treatment for these wastes. If there is overlap between the requirements, the waste must meet the most stringent requirements before being land disposed.[8]

THIRD THIRD SCHEDULED WASTES

All remaining listed hazardous wastes and all wastes identified as of Nov. 8, 1984, by one or more of the characteristics as defined in 40 CFR Part 261 were identified as Third Third scheduled wastes. On May 8, 1990, Third Third Wastes became restricted and were therefore subject to a number of land disposal restrictions. However, the effective date for compliance with treatment standards for these waste codes was extended to Aug. 8, 1990, by granting a three-month national capacity variance. The effective date is being delayed because the Agency realizes that even where data indicate that sufficient treatment capacity exists, it is not immediately available.[9] This delay also would provide adequate time needed by generators to adjust existing treatment

systems, segregate waste streams in accordance with the dilution prohibition to enter into contracts with commercial treaters.

The Agency has the authority to grant national capacity variances from the statutory effective dates, not to exceed two years, if there is insufficient alternative protective treatment, recovery or disposal capacity for the wastes. In order to make capacity determinations, the U.S. EPA compares the nationally available alternative, treatment, recovery or protective disposal capacity at permitted and interim status facilities, which will be in operation by the effective date, with the quantity of restricted waste generated. If there is a significant shortage of such capacity nationwide, the U.S. EPA will establish an alternative effective date based on the earliest date such capacity will be available.[9]

PITFALLS IN CERTIFICATION/DEMONSTRATION SUBMITTAL

The U.S. EPA's evaluation of certification/demonstration submittal involved many parameters. Pertinent information had to be supplied in order to determine whether the certification was valid, invalid or incomplete. The Regional Administrator could invalidate a certification for two reasons: (1) practically available treatment existed where the generator certified otherwise; or (2) some other method of practically available treatment which yields greater environmental benefit existed. In many instances, additional information was needed to evaluate the validity of the certification.

Evaluation of a submittal was conducted in four parts: (1) general information—generator's name, address, the U.S. EPA I.D. Number, waste code, submission of both certification and demonstration; (2) certification—[correct certification statement (treatment vs. no treatment), wording of certification as specified in 40 CFR Part 268.8 and certification signed by generator]; (3) demonstration—adequate description of waste or waste residue, waste quantity, frequency of generation, waste analysis, treatment previously used, treatment technologies considered, including recovery/recycling, name of treatment facility, individual contacted, telephone number, date contacted, treatment method selected (if treatment rejected; justify and if treatment based on cost; justify) and (4) conclusion,—was certification valid and was additional information needed. The majority of pitfalls can be summarized as a lack of information needed to review the submittal efficiently.

CONCLUSION

This paper has discussed a general overview of land disposal restrictions and pitfalls observed in certification/demonstration submittals. It is apparent that the Land Disposal Restrictions place important new constraints on how owners and operators can close and/or cleanup their facilities. Any generator who treats, stores or disposes of hazardous wastes on- or off-site should have a working knowledge of the types of wastes that he has in his inventory. This knowledge should include maintaining accurate files pertaining to manifests, biennial reports on generator activities, test results, waste analyses and reports concerning the quantities and disposition of wastes.

The Third Third Final Rule imposes new waste analysis requirements on generators who treat in tanks or containers in a 90-day accumulation area. This Rule promulgates LDR treatment standards for almost all RCRA hazardous wastes not previously addressed and expands the restrictions of earlier rules, particularly with respect to the dilution prohibition. To summarize, LDR treatment standards are in effect for solvents and dioxins (Nov. 8, 1986); California List Wastes (July 8, 1987); First Third Wastes (Aug. 8, 1988); Second Third Wastes (June 8, 1989); and Third Third Wastes (including First and Second Third soft hammer wastes) [May 8, 1990].

The U.S. EPA granted a three-month national capacity variance until Aug. 8, 1990, for Third Third Wastes because sufficient treatment capacity was not immediately available.

The In Situ Vitrification of Subsurface Containment Barriers-An Overview

Mark T. Murphy, PhD
James A. Stottlemyre, PhD
Pacific Northwest Laboratory
Richland, Washington

ABSTRACT

In situ vitrification (ISV) is an environmental engineering process in which soil or soil/waste mixtures are melted through the direct application of electrical current and subsequently cooled to a glassy solid. The technology was developed by Pacific Northwest Laboratory (PNL) in the 1980s and has been tested on transuranic, mixed-hazardous and PCB/organic waste similar to that found at U.S. Department of Energy (DOE) and other facilities nationwide. These tests have led to endorsements of ISV from DOE, the National Association of Professional Engineers and the U.S. EPA. PNL is conducting a wide range of field tests, expanding the scientific basis of ISV and assessing its extension into new applications. One such project is ISV—Selective Barriers, an investigation into the construction and performance of ISV-generated, vertical and/or horizontal subsurface barriers to groundwater flow and biogenic intrusion. In some situations, it may be impractical or unnecessary to either excavate or vitrify an entire waste site. Vitrified barriers could minimize the diffusive or fluid transport of hazardous components with either a groundwater diversion wall or an in situ, "box-like" structure.

During the first year of this project, engineering-scale tests are being conducted between graphite electrodes within a 1.8-m diameter, 2.4-m high test cell. The experiments are designed to investigate the initiation of melts within the subsurface and the control of melt size and shape and to evaluate the performance of the resulting ISV structures. Several methods are being tested, including passive metal electrodes, electrode feeding systems, fluxed soil and fluxed boreholes. In addition, basic data have been collected on the thermal and material properties of ISV melt and solidified glass.

These experimental and analytical studies will support a series of field-scale melting experiments, refinements to ISV theory and computer modeling. This work was performed by PNL operated by Battelle Memorial Institute for the DOE under Contract number DE-AC06-76RLO 1830.

INTRODUCTION

The U.S Department of Energy (DOE) requires technical options for the cleanup and long-term isolation of variably contaminated subsurface structures, soils and groundwaters at a number of sites nationwide. These sites are diverse in geology, hydrology and design. Generic technical solutions or methods that are easily adapted to local conditions remain the most appealing, and solutions that can isolate waste sites through the use of hydrologic or geotechnical barriers are particularly important. The purpose of the Selective Barriers project is to research, develop, evaluate and demonstrate the most promising new concepts in subsurface barriers to fluid migration.

The Selective Barriers project was funded for FY 1990 by DOE and

is managed by the Pacific Northwest Laboratory (PNL), a multiprogram DOE national laboratory operated by Battelle Memorial Institute. For the first two years the project will focus on barriers formed through in situ vitrification (ISV). The five technical project tasks are

- Conceptual, Computational and Laboratory-Scale Studies
- Engineering-Scale Testing and Performance Assessment
- Pilot-Scale Testing and Performance Assessment
- Field-Scale Testing and Performance Assessment
- Technology Transfer and ISV Coordination

Following a brief discussion of general ISV science, each of the technical task will be presented in detail.
Figure 1
Typical ISV Engineering-scale Layout.

GENERAL ISV METHODOLOGY

In situ vitrification is a waste/soil treatment process that grew out of PNL's long-term research efforts in nuclear waste vitrification (glass formation). The technology has enjoyed strong national regulatory support, great interest among state agencies and several engineering awards. For a typical ISV application (Fig. 1), electrodes are inserted in the ground in a desired array (depth and spacing). A mixture of flaked graphite and glass frit is placed between the electrodes to act as a conductive starter path. An electrical potential is then applied to the electrodes, establishing an electrical current in the starter path. The current generates resistive heat along the starter path and the temperature of the surrounding soil is raised to between 160 and 2000° C.

A working relationship between resistivity and melt/electrode geometry is given by:[1]

$$R_{e,d} = \rho \, \frac{\ln \left(2 \frac{S_{e,d}}{D} \right)}{\pi \, D_g}$$ (1)

where,

$R_{e,d}$ = resistance across edge (e) or diagonal (d) electrodes
$S_{e,d}$ = electrode separation distance
D_g = depth of melt
D = electrode diameter
ρ = electrode resistivity of the glass

A mean resistivity combined with Ohm's Law gives a general idea of the heat available to dissipation during current flow. A more physically explicit expression is derived[2] from Gauss's Law using an analogy to electrodynamic theory,

$$\oint E \cdot dA = \frac{Q}{\varepsilon_0}$$ (2)

where

E = the electrical field
A = area of the plate
Q = charge on the plate
ε_0 = permittivity constant

given parallel plates and a constant field. The scaler product of the E field and the current density results in

$$E \cdot J = \frac{QJ}{A\varepsilon_0}$$ (3)

with, J = current density or charge density over unit time. If the work done by the moving charge is dissipated as heat (herein called H, to avoid confusion with charge) over the separation distance, L, then,

$$H = \Delta W = QEL$$ (4)

and

$$E = \frac{\sigma}{\varepsilon_0}$$ (5)

therefore,

$$\frac{H}{V} = \frac{\sigma Q}{A\varepsilon_0}$$ (6)

and Equations 3 and 6 are equivalent and

$$H = \int_v E \cdot J \, dV$$ (7)

which is the electrodynamic description of Joule heat. Using Joule's Law,

$$J = \sigma E$$ (8)

and some algebra, one can derive

$$J \cdot E = \sigma E^2 = \frac{J^2}{\sigma}$$ (9)

where σ now represents electrical conductivity.

Since the conductance is explicitly not homogeneous in an ISV melt, any thermomechanical model of the process must account for or simplify the coupled variation in current density and the electrical field. Because of the strongly nonlinear, probably chaotic nature of a turbulently convecting, current-carrying fluid, an analytical description of the temperature or velocity field is not available. The code TEMPEST is being adapted to give an improved numerical solution to this problem (see below). Equation[7] also demonstrates the requirements for directing melt progression. If a designed spatial deviation of the mean current density or electrical field can be produced, heat can be spatially focused and melt progression can be directed.

The graphite starter path eventually is consumed by oxidation and the current is transferred to the molten soil. The melt is maintained at temperatures between 1450 and 2000° C. Between the electrodes, the temperature greatly exceeds the liquidus and turbulent convection homogenizes the melt. Organic material pyrolysizes at the melt front and is swept upward to the off-gas hood where it combusts or is captured by the off-gas filtering system. Mass balance calculations[3] suggest that retention of 99.999% of strontium and 99.88% of cesium within the glass monolith are attainable. Under ambient cooling, the melt becomes a monolithic, vitreous mass. Varied cooling rates and compositions result in crystallization, often spherulitic in habit. Observed mineral phases include anorthite, pseudowollastonite and silica minerals.[4]

After cooling, the resulting ISV product is composed of glassy and crystalline phases, superficially resembling volcanic glass. Unweathered ISV glass has a higher leach resistance than granite or marble, approaching Pyrex glass.[5] For typical soils, final ISV block density varies from 2.3 to 2.65 g/cm^3.[5] This material is approximately 3 to 19% more dense than concrete. The tensile and compressive strength of unfractured ISV product is an order of magnitude greater than unreinforced concrete. Power requirements for the ISV process can be met by local distribution lines or portable generators. Total power requirements are less than 0.8 kwh/kg of solidified mass. The presence of water in the soil increases the power requirement to less than 40% for fully saturated soils.

The process is operated at four scales. Bench- and engineering-scale experiments use a 1.8-m diameter by 2.4-m deep, corregated-metal test cell. The PNL facility is located in a high-bay, engineering-development laboratory. Pilot- and field-scale applications occur outdoors in natural soil and require one to three trailers for process and power equipment. Figure 2 shows a typical pilot-scale operation. The dimensions of the four scales are listed in Table 1.

CONCEPTUAL AND COMPUTATIONAL STUDIES

In situ vitrification is still an emergent technology and many of the modifications required for the Selective Barriers project are untested. For this first year, our objective is a survey of methods that can be applied to the project goal: the construction of vertical and horizontal, planar ISV monoliths. The three methods under review are

• Controlling melt geometry
• Starting melts at depth
• Constructing multiple-melt welds

If absolute isolation is essential or if a specific subsurface design must be met, then it will be important to control the melt size and shape in a predictable fashion. The presence of active underground facilities, pipelines and/or storage tanks must be assumed; therefore, the con-

Large	3.5 to 5.5	400 to 800 t	5

struction and use of barrier structures must not degrade preexisting site facilities. Finally, QA, environmental and safety concerns require the barrier technology to be as controlled and predictable as is practical.

Work during FY 1990 has uncovered three key methods of melt control that will be tested through computer simulation and experimentation. These are:

- Fluxes and other low melting temperature materials
- Passive electrodes
- Changes in current phase

In general, these three methods all shift the melt isotherms such that the steepest temperature gradient is collinear to the direction of melt progression. This results in a concentration of heat in that direction and an equivalent distribution of melt. In an ideal ISV melt, free convection is maintained between turbulent "hot spots" near the electrodes and the cooler sides, walls and surface of the melt. The melt along the margins is more viscous than the core and buoyancy is insufficient to overcome the high drag. For this reason, heat exchange across the walls is dominated by conduction across a stagnant boundary layer. If material has been placed (backfilled boreholes, buried trenches, saturated zones and/or buried layers) that can melt and convect at a lower temperature than the melt core, a change in melt-front geometry will occur. Presumably the convective cell would disturb the stagnant boundary, allow a spike in the isotherms to develop and focus heat transfer in the direction of interest.

One can evaluate this effect[6] through the Rayleigh number (Ra), where

$$Ra \equiv \frac{g\beta\Delta TH^3}{\alpha\nu} \tag{10}$$

g = gravitational acceleration
β = coefficient of thermal expansion
ΔT = temperature differance
H = length scale
α = thermal diffusivity
ν = kinematic viscosity $\left(\frac{\mu}{\rho}\right)$

When the temperature difference, ΔT, over length scale, H, exceeds a critical value (set by the geometry and boundary conditions), the system becomes unstable and begins to convect. At a nominally subcritical ΔT, a drop in viscosity or an increase in thermal expansion will increase the Rayleigh number for the fluid.

For this reason, it is important to choose a flux that changes not only the melting temperature of the soil, but also the mechanical properties of the molten soil (i.e., increases the Rayleigh number). Numerous fluxes and viscosity reductants are used by the glass industry, including soda ash, borax and sodium or potassium metasilicate. Figure 3a is an equilibrium phase diagram for the system $SiO_2-CaO-Na_2O$ taken from Morey and Bowen.[7] Plotted on Figure 3a is an average composition for Hanford Formation alluvium and the composition of sodium metasilicate (Na_2SiO_3). A tie line between these compositions comes very close to the minimum melting cusp in the liquidus line. Figure 3b, also from Morey and Bowen,[7] is similar except that isokoms of equal log viscosity are given for 1100°C. The same tie line is superimposed upon the diagram and indicates a 1 to 1.5 log unit decrease in viscosity resulting from the addition of sodium metasilicate. These results are supported by Buelt et al.[5] showing that the addition of sodium causes a greater than 2 log unit decrease in the viscosity of melt derived from Hanford Formation alluvium (700 to 6 poise). Unfortunately, there is a limit to this effect in ISV (approximately 35 wt% in Na_2O). Increased sodium also increases the electrical conductivity of silicate melts, resulting in less efficient Joule heating.

Passive electrodes in electric glass melters have been used by the glass industry and investigated at PNL during ISV testing of soils with high metals concentrations. The idea relies upon the relationship between current density, J and heat indicated in Equation.[9] If δ, electrical conductivity, is not constant but is distributed in space, then the current density and E field and the thermal profile will vary. Because of the high electrical conductivity of most metals, any concentration of metals in the soil will increase current density and Joule heat in the adjacent soil. Further, because most metals are significantly more dense than silicate melt, they will stably stratify in the lower part of the melt. In ISV practice, the metal sublayer does form and the electrode array is lowered such that no direct "short" occurs across the sublayer. The electrodes are slowly fed downward, following the descending melt and metal sublayer and concentrating current and heat at the base of the melt.

Variations in the electrical field can provoke "hot spots" in the melt, as shown by results of numerical simulations. These results appeared when current phase was varied in a nonstandard fashion. The ISV power supply system has been designed to optimize the load balance such that Joule heat is evenly distributed over the space between the four electrodes and the power factor approximates unity, the most energy-efficient arrangement. If the load balance was unevenly distributed and the mean voltage varied with position, the current density would be altered and "hot spots" would grow in the melt. The details of this plan are yet to be worked out. In FY 1991, numerical modeling will be used in conjunction with E-field theory to determine the most appropriate electrical design to explore these ideas.

The ISV barriers technology must include some method for initiating melting at depth (< 7 m). Although it may be possible to "weld" vertical walls to a relatively impermeable, natural or treated substratum, such a requirement would severely limit the application of ISV barriers. A more useful plan would begin with an ISV-generated horizontal subbase, created with minimal disturbance. The problem lies in the melt startup process, developed and optimized to surface conditions. Surface starting of an ISV melt requires a fixed, square array of graphite elec-
Figure 3
(a) Ternary Phase Diagram for the Na$_2$O-CaO-SiO$_2$ System Based On Experimental Work by Morey and Bowen[7] (b) Viscosity Variation Over the Same System. Isokoms (equal viscosity) in Log Poise.

trodes inserted into the ground. Without an initially conductive starter path, which will elevate temperature in the soil to its melting point, the process cannot begin. Further, the starter must be consumed so that current and Joule heat are initiated within the melt.

One scenario would begin with large diameter (approximately 50-cm) boreholes drilled on a line (Fig. 4). Special electrode arrays would be mounted on the end of a drill string and lowered to the base of the hole. The electrodes would be seated within a graphite starter layer and a melt would be formed at the bottom of the hole. Meanwhile, a second melt would be started in the neighboring hole. Because of the two adjacent melts, the intervening soil would experience relatively high temperatures and the "septum" between the melts would preferentially melt. The two melts would grow until they joined. Similar melt pairs could be started within other holes and joined and so forth, extending the melt in any direction or geometry desired.

Another possible solution would begin with the subsurface injection of a nonhazardous metal salt or other conductive solution (Fig. 5). If circulation could be achieved between adjacent holes, it might be possible to use the solution as a subsurface starter path. If natural permeability was not sufficient, hydrofracing could be used. As current is conducted along the path, the solution would heat up and water would be driven off. Thus it is important that the dry salt have a low melting temperature (< 500 °C, approximate temperature of the off-gas) for melting to begin and current to continue to flow once the solution has completely devolatilized. One possible candidate is salt sodium carbonate and/or borax (Na$_2$B$_4$O$_5$(OH)$_4$• 8H$_2$O).

Finally, perhaps the least exotic, deep startup method would use a buried graphite/frit starter path (Fig. 6). The path would be injected at the desired "floor" depth as a slurry or paste injected through horizontal boreholes located directly beneath the electrodes. The electrodes would access the buried starter path through vertical boreholes. These vertical electrode access holes would also allow the direct discharge of induced soil vapor and combustion products to the off-gas hood. Given adequate room for an angled drilling mast, such a geometry and directional precision is well within reason.

Results from tests at the Savannah River Laboratory indicate that

accuracies within 0.1% are possible at a minimum depth of 18 ft. The graphite/frit slurry could be pumped into either the vertical wells or the horizontal boreholes, whichever resulted in a more uniform path. If four starter path boreholes were drilled, the standard, single-phase, two-electrode circuit would be logical. Drilling only two horizontal boreholes would clearly be less difficult. Melts would start as independent, single-phase circuits between each pair of electrodes until melting began. Continued heating would result in propagation of the melt front toward the center of the square. At this point, a standard circuit would be initiated.

A major effort has begun to modify the PNL, TEMPEST, finite difference, fluid mechanical and heat transfer computer code to simulate ISV melting. Several traditional ways of solving the moving boundary/phase change condition at the melt front are being evaluated, including the possibility of including a melting range, or "mushy zone." A related project will improve the ability of TEMPEST to operate over rapid viscosity variations. TEMPEST currently is capable of determining the electrical field; however, the nonlinearity, suggested by the E-field formulation, Equation 9, demonstrates that this problem will require thermal boundary conditions that are challenging. Scaling and code verification/sensitivity analyses will be used to test all idealizations and simplifications.

These efforts will be guided by investigations into the physics of melting and cooling at the University of Washington geophysical fluid dynamics laboratories. Work on the fundamental aspects of partial melting using similitude analysis and bench-scale experiments will elucidate the geometry of the melting front. Parallel development of silicate-melting models applicable to geophysical problems will be a side benefit of this project. At PNL, residual stress analysis of a cooling, infinite slab will determine the viscoelastic behavior of an ISV-generated barrier wall. Current efforts include one-dimensional simulations and a development of appropriate mechanical parameters for silicate liquids.

In FY 1991 to 1993, other concepts will be tested and refinements to the modeling capability are planned. The problem of multiple ISV melts will be a major concern. Specific investigations of nonstandard electrical configurations, hydrologic testing of barrier walls and materials properties of glassy slabs are all planned.

ENGINEERING- AND PILOT-SCALE
EXPERIMENTAL PROGRAM

The purpose of the engineering-scale program is to test concepts. Pilot-scale testing, on the other hand, will verify/demonstrate the most promising barrier generation concepts identified at the engineering scale.

Engineering-scale testing will be continuous over the life of the project as different conceptual questions are raised; however, pilot-scale experiments will be fewer in number and more tightly focused. Wall and floor tests will be a key part of the pilot-scale program, with innovative hydrologic testing (verification) an important part of the program.

A major objective of the pilot-scale testing will be the production of multiple, welded or contiguous melts, resulting in a laterally extensive, vitrified barrier wall. Previous work at PNL has suggested that the fusion of equidimensional melt monoliths is possible; however, it has not yet been demonstrated that planar wall components can be assembled into a "tight" structure. The pilot-scale program will also test our ability to create large horizontal base layers. Investigation of the ISV melt interaction with natural or vitrified base material liners will provide important information relative to sealing volumes of soil from water infiltration and biotic or human intrusion.

Field techniques developed independently by the drilling, well testing and measurement industries and the DOE Subsurface Science Program and Horizontal Wellbore Research Program will be an important part of the pilot-scale program as the project planning narrows in on a full field-scale configuration.

FIELD-SCALE VERIFICATION AND TESTING

The objective of this project is to demonstrate, calibrate and verify the most promising ISV barrier system at an actual DOE waste site. The anticipated scope includes:

- Design and procurement of large-scale processing equipment
- Testing of barrier installation under DOE field site conditions
- Monitoring the barrier performance
- Final reporting and recommendations

At the field-scale stage of the project, decisions will be made on the specific barriers technology that best satisfies remedial needs. A final site will be chosen and testing plans will be prepared by PNL for DOE approval. The candidate barrier technology will be tested by the production of field-scale barrier walls joined to a natural or ISV-generated layer as the base. A full hydrogeologic investigation of the site will be conducted, including site characterization, well testing and groundwater monitoring. All barriers produced will be nondestructively tested and sampled for petrographic, chemical and geotechnical analysis and partially exhumed for visual inspection and examination. A site monitoring project, including equipment installation, will be established to provide long-term performance assessment information.

Project researchers will provide an economic assessment of the developed barriers technology. Also, in conjunction with the other ISV projects, it is anticipated that the modified version of TEMPEST would be available to predict vitrified barrier viability, performance and cost at the selected DOE site. This assessment and computer model would include a parametric-type presentation, which would allow DOE to estimate characteristics for specific applications of vitrified barriers as they occur.

TECHNOLOGY TRANSFER AND ISV COORDINATION

Each major DOE site now plans to use ISV for remediation of certain wastes. Programs to develop ISV are being funded individually from each site's environmental remediation budget and from DOE research and development funds. Because of the unique yet widely applicable nature of the ISV barriers concept, special attention has been paid to the technology transfer process. To ensure that duplication of effort is minimized and that these emergent applications of ISV are disseminated, PNL will prepare an overall ISV program plan for review by interested parties. In FY 1990, a workshop was convened to provide interested persons the opportunity to present their needs and plans in order to sharpen and refine the overall ISV technology development plan. Future ISV workshops are being planned.

CONCLUSION

Admittedly, this is a very ambitious project. The basic ISV technology is still young and significant advances in design and application could emerge during the Selective Barriers project life. On the other hand, unforeseen problems are to be expected in emergent technologies. Despite these uncertainties, the ISV barriers concept could represent an enormous savings over either "pump-and-treat" environmental remediation or "conventional" ISV treatment of buried waste. In a time of decreasing technical options and increasing programmatic costs, the great practical advantage of a successfully developed ISV barrier technology is a reward worthy of such risk.

ACKNOWLEDGEMENTS

Simulation of Subsurface Barrier Wall Performance Near a River

ABSTRACT

Subsurface barriers (including slurry walls, diaphragm walls and grout curtains) have been widely used to contain groundwater contaminant plumes or control their movement by placing the low-permeability wall either upgradient, downgradient or surrounding the plume. In addition to containing a plume, barrier walls often are used in conjunction with groundwater extraction systems to minimize the volume of uncontaminated water withdrawn from an aquifer. A combined barrier/extraction system is particularly advantageous when the contaminant plume is located near a surface water body; in this case, the barrier serves to reduce greatly the volume of surface water drawn into the extraction system. When a barrier/extraction system is placed near a river or other body of water, care must be taken to minimize the volume of water that is drawn around the edge of the barrier from the water body while continuing to contain the contaminated water. Additional reduction of inflow to an extraction system located near a river may be possible by altering the geometry of the barrier wall ends.

A finite-difference model is used to investigate the performance of a combined subsurface low-permeability barrier and groundwater extraction system adjacent to a river. Various geometries of barrier wall ends are simulated in order to evaluate their ability to minimize the withdrawal of river water while providing adequate plume containment and allowing for efficient and timely aquifer restoration.

INTRODUCTION

Subsurface barriers have been widely used to control the movement of groundwater either into or out of waste sites and are often used in conjunction with other groundwater control systems. In general, there are three common barrier wall configurations with respect to the contaminant plume:[1]

- Upgradient wall placement
- Downgradient wall placement
- Circumferential wall placement

While the circumferential wall placement is most common and greatly reduces the amount of uncontaminated groundwater passing through the contaminated site, it is also the most expensive to construct.[1] Upgradient wall placement serves to divert uncontaminated groundwater away from the contaminated area and downgradient wall placement prevents further downgradient migration of contaminated groundwater.

Downgradient walls are commonly used to enhance the performance of an active groundwater recovery system by preventing further migration of the contaminant plume and reducing the amount of uncontaminated groundwater drawn into the extraction system. This is particularly true when the groundwater recovery system is located adjacent to a surface water body. Under the induced stress of a groundwater recovery system, infiltration from this surface water body can greatly increase the amount of uncontaminated water mixing with the captured contaminant plume and increase the total volume of recovered groundwater that must be treated. In this case, the barrier wall can be used to minimize the amount of surface water drawn into the recovery system.

The basic operation of a combined barrier/extraction system involves maintaining a lower groundwater level on the upgradient side of the barrier wall to capture the contaminant plume and to prevent the movement of contaminated groundwater around the wall. However, when such a system is placed near a river or other surface water body, care must be taken to minimize the volume of uncontaminated water that is drawn around the ends of the wall from this water body. The amount of surface water inflow depends on the length of the barrier wall in relation to the extraction system, the shape of the barrier wall ends and the effective drawdown created by the extraction system.

To quantify the effects of barrier wall shape and length and of effective drawdown on the amount of surface water drawn into a groundwater recovery system, a series of groundwater model simulations has been performed using several combinations of wall configurations and drawdowns. The length and shape of the barrier wall were varied for three drawdowns in the recovery system. The results of these simulations have been evaluated in terms of the aquifer restoration time and the total inflow from a nearby surface water body versus total volume of recovered groundwater.

GROUNDWATER MODEL SIMULATIONS

A hypothetical groundwater flow system and contamination scenario were defined to evaluate the performance of a combined barrier/extraction system operating near a river. The groundwater flow was simulated as a steady-state system using the Modular Three-Dimensional Finite Difference Groundwater Flow (MODFLOW) computer model.[2] The following guidelines were assumed for defining the scenario to be modeled:

- The contamination fully penetrates the aquifer
- The barrier wall is keyed into the impermeable base of the aquifer
- The river has a constant head
- Aquifer restoration is achieved when 5 times the initial contaminant plume pore volume is removed
- The hydraulic conductivity of the barrier wall remains constant over time
- The groundwater flow field is two-dimensional

Model Scenario

The scenario simulated for this evaluation, shown in Figure 1, assumed that a groundwater contaminant plume had been detected in the shallow unconfined aquifer underlying an industrial facility. This shallow aquifer
Figure 1
Model Scenario

discharges to the river immediately adjacent to the facility. The contaminant plume is 200 ft by 200 ft with its leading edge located less than 100 ft from the river. The unconfined aquifer underlying the site has a hydraulic conductivity of 10^{-3} cm/sec and an average saturated thickness of approximately 29 ft. An impermeable layer is present immediately below this shallow aquifer. The average groundwater flow gradient across the site is 0.013 ft/ft and the river gradient is 0.001 ft/ft.

Due to the expected low yield of this aquifer unit, it was decided that an interceptor trench would be used to collect the contaminated groundwater for treatment. In addition, a slurry wall with a hydraulic conductivity of 10^{-7} cm/sec was selected to minimize the volume of river water drawn into the system. To evaluate possible barrier/extraction system configurations, a series of groundwater flow simulations was performed. The goal of these simulations was to determine if the length of the barrier wall could be kept to a minimum while maintaining an adequate upgradient capture zone and a timely aquifer restoration period.

Model Simulations

The groundwater domain defined above was simulated using the MODFLOW computer model. The discretized domain is shown in Figure 2. The model grid, 600 ft by 800 ft, is composed of one layer with 70 rows and 70 columns of model cells. Cell size was varied to reduce the overall number of cells while allowing sufficient detailed

Figure 2
Discretized Domain with Interceptor Trench
and Slurry Wall Placement

discretization in the area where the barrier/extraction system is to be placed.

Two types of boundary conditions were used in these simulations (Fig. 2). The cells representing an upgradient groundwater boundary, the cells representing the river and the cells representing the interceptor trench were defined as constant head boundaries. The cells along the two sides of the domain perpendicular to the river were defined as no flow boundaries.

Initially, the groundwater recovery system was simulated without a barrier wall. An interceptor trench aligned perpendicular to the direction of groundwater flow and having a length of 220 ft was placed immediately downgradient of the contaminant plume. Four simulations using the trench alone were performed, each having a different defined drawdown (percent drawdown as measured from the original water table elevation at the trench location). The constant head defined in the cells representing the trench for each simulation was, respectively, (1) the average river stage level (approximately 32.1 ft), (2) 30% drawdown, (3) 50% drawdown and (4) 70% drawdown.

Three slurry wall shapes were then simulated in conjunction with the interceptor trench defined above. The first shape evaluated was a straight wall extending past both ends of the interceptor trench (parallel to the trench). The second shape evaluated was a wall that angled around the end of the trench away from the river at an angle of approximately 30 degrees. The third shape evaluated was a wall that angled away from the ends of the trench toward the river at an angle of approximately 30 degrees. Wall shapes were simulated with overall lengths varying from 220 to 340 ft. Each configuration of wall length and shape was simulated using drawdowns in the interceptor trench of 30, 50 and 70%.

RESULTS AND DISCUSSION

Performance of Interceptor Trench without a Slurry Wall

The simulation results obtained from four different water levels (Fig. 3) maintained at the interceptor trench are summarized in Table 1. The drawdown values given in Column 2 represent the percentage of the total available drawdown at the trench. The total flow in Column 3 represents the amount of flow contributed from the river (Column 4) plus the flow from the upgradient region (Column 5). The percentage of the total flow contributed from the river (i.e., Column 4 divided by Column 3 multiplied by 100) is given in Column 6. The time required to remove five times the initial contaminant plume pore volume is given in Column 7. Assuming a total porosity of 0.3, the five pore volumes of the 200 ft by 200 ft plume was estimated to be 1,410,000 ft^3. This pore volume was divided by the flowrate contributed from the region upgradient of the trench (Column 5 multiplied by 365 days) to obtain the cleanup time given in Column 7.

As shown in Figure 4, the percentage of the total flow contributed from the river depends on the drawdown level prescribed at the trench. The entire effluent flow from the trench was drawn from the upgradient region only when the drawdown at the trench was maintained equal

to the river stage level (RL). However, this resulted in the longest cleanup time of approximately 9 years. When the drawdown is increased to 70%, the cleanup time is drastically decreased (2.9 years), but approximately 61% of the total effluent flow from the trench would be uncontaminated water drawn in from the river.

A significant decrease in cleanup time can be achieved by lowering the head maintained in the trench from the RL to 30% drawdown (i.e., reduction from 9 to 4 years, respectively). It is apparent that further reductions in the cleanup time resulting from drawdowns beyond 30% are relatively insignificant. Even at 30% drawdown, however, the amount of uncontaminated river water that must be treated with the contaminated water from the upgradient region is about one half of the total effluent outflow from the interceptor trench.

The above simulations indicate that a subsurface barrier wall should be used in conjunction with the trench system in order to reduce the cleanup time while minimizing the induced inflow from the river. The flow patterns generated by simulation No. 1 (trench water level equal to RL) and simulation No. 4 (70% drawdown) are shown in Figures 5 and 6, respectively.

Performance of Interceptor Trench with a Slurry Wall

The results obtained from a total of 12 simulations simulated with

a combined straight slurry wall and interceptor trench system located downgradient of the contaminant plume are summarized in Table 2. It was assumed that a 5-ft thick keyed-in slurry wall was placed 5 ft downgradient of the trench. All 12 simulations were performed with the slurry wall downgradient and parallel to the trench. For the first three simulations (Nos. 5, 6 and 7), the length of the slurry wall was set equal to the length of the interceptor trench. Subsequent simulations (Nos. 8 through 16) were performed with the slurry wall extending beyond both ends of the interceptor trench.

14		30	968.63	14.12	954.51	1.46	4.04
15	340	50	1292.19	107.96	1184.23	8.35	3.26
16		70	1504.56	196.06	1308.51	13.03	2.95

The effect of the slurry wall length on the percent inflow from the river was evaluated at three different drawdown levels (30, 50 and 70%) and is shown graphically in Figure 7. The aquifer restoration time computed for each slurry wall length and corresponding drawdown level are illustrated in Figure 8.

It is apparent that the percent inflow from the river can be significantly reduced by placing a slurry wall downgradient of the interceptor trench. For example, with 30% drawdown in the trench, the placement of a 220-ft slurry wall can reduce the percent inflow from the river from approximately 50% (simulation No. 2, without a slurry wall) to 17% (simulation No. 5). When the length of the slurry wall is increased to 340 ft, the percent inflow from the river is further reduced to less than 2% (simulation No. 14). However, the performance of the slurry wall becomes less effective with increasing drawdown levels in the trench. At 70% drawdown level, the percent induced flow can be reduced from 61% (simulation No. 4, without a slurry wall) to 32% by placing a 220 ft slurry wall. Increasing the slurry wall length to 340 ft, however, still allows 13% of the total interceptor trench effluent flow to result from river inflow. The total reductions in the induced river flow resulting from the increase in slurry wall length from 220 ft to 340 ft are 91, 69 and 59% for 30, 50 and 70% drawdown levels, respectively; i.e.,

30% Drawdown: (16.74 - 1.46)/16.74 $\approx$ 90% reduction
50% Drawdown: (26.71 - 8.35)/26.71 $\approx$ 69% reduction
70% Drawdown: (31.51 13.03)/31.51 $\approx$ 59% reduction

As indicated in Figure 8, the length of the slurry wall does not appear to affect the cleanup time because the wall length controls the amount of inflow from the river, but has little influence on the flow from the region upgradient of the trench. However, the cleanup time is still affected by the drawdown levels in the trench. In particular, the cleanup time is reduced from approximately 4 to 3 years by increasing

Effect of the Length of a Straight Slurry
Wall on the Aquifer Restoration Time

the drawdown levels from 30 to 70%. Such a reduction is nearly identical to the results for the simulations without a slurry wall present [3.91 years at 30% drawdown (simulation No. 2) compared to 2.93 years at 70% drawdown (simulation No. 4)].

The above simulation results indicate that conjunctive use of a slurry wall with an interceptor trench can be highly effective in minimizing the inflow from a river, provided that a relatively low drawdown level is maintained in the trench (i.e., 30% of the total available drawdown). The flow patterns generated from simulations No. 14 and No. 16 are shown in Figures 9 and 10, respectively.

Effect of the Slurry Wall End Configuration

Six additional simulations were performed to evaluate the performance of a slurry wall with an angled end configuration. Both ends of the slurry wall which extend beyond the ends of the interceptor trench (with the trench length remaining constant) were either angled away from the river or towards the river as shown in Figure 11. The Type A con-

figuration has both ends angled 30 degrees upgradient (away from the river) and the Type B configuration has both ends angled 30 degrees downgradient (toward the river). Table 3 summarizes the results obtained from the above simulations and provides a comparison to those simulations for a straight slurry wall (simulation Nos. 8, 11 and 14). All of the above simulations were performed with a 30% drawdown level in the interceptor trench. The above results are presented graphically in Figure 12.
Figure 9
Flow Pattern for Simulation of a Straight Slurry
Wall (Length=340 ft) and Interceptor Trench with
30% Drawdown (Simulation No. 14)

Figure 10
Flow Pattern for Simulation of a Straight Slurry
Wall (Length=340 ft) and Interceptor Trench with
70% Drawdown (Simulation No. 16)

The results indicate that the performance of the slurry wall can be further improved with a proper end design. In particular, bending both ends of the slurry wall away from the river can provide additional hydraulic impedance to the induced river inflow drawn around the ends of the slurry wall. For example, a 340-ft slurry wall angled away from the river (simulation No. 19) resulted in zero percent inflow from the river. On the contrary, a noticeable reduction in the performance can be observed when the barrier wall ends are angled toward the river; this guides the induced river inflow around the ends of the wall.

CONCLUSION

A series of model simulations was conducted to evaluate the performance of a slurry wall/interceptor trench system for recovering a groundwater contaminant plume near a surface water body (e.g., a river). The simulation results indicate that a barrier wall will not fully perform

its intended function of eliminating the induced inflow from the river unless the drawdown from the original static level at the interceptor trench is maintained relatively low (i.e., 30% of the available drawdown at the trench). High drawdown levels at the trench will result in uncontaminated surface water being drawn around the ends of the slurry wall and into the trench.

The increase in the length of the slurry wall beyond both ends of the trench reduces the induced inflow from the river, provided that the drawdown level at the trench is maintained relatively low. With low drawdown levels, the performance of the system can be further improved by angling the ends of the barrier wall away from the river. A properly designed end configuration provides additional hydraulic impedance to the induced river inflow. The increase in the wall length would only contribute a slight reduction in the induced river flow when the drawdown is greater than 30%. The only advantage to having a high drawdown level in the interceptor trench is that the time required for aquifer restoration to occur would be reduced. However, a significant portion of the total effluent volume recovered from the trench would be uncontaminated water from the river.

The sensitivity of the system's performance (i.e., aquifer restoration time and reduction of induced flow) to the physical geometry of the barrier wall as well as the drawdown level at the trench can be evaluated via model simulations. For a given set of design criteria (extraction and treatment capacities) and constraints (total project cost and duration), a linear programming approach can be employed to obtain an optimum design of a barrier/interceptor trench system.

Closure of the Industrial Waste Lagoon at Tooele Army Depot

Steven B. Johnson, R.G.
Robert H. Ramsey, C.P.G.
James M. Montgomery, Consulting Engineers, Inc.
Salt Lake City, Utah

ABSTRACT

The Industrial Waste Lagoon (IWL) was an unlined evaporation pond, measuring approximately 400 feet by 200 feet, into which an average of more than 140,000 gallons of industrial wastewater and stormwater were discharged daily via 15,000 feet of unlined ditches from the mid-1960s until November 1988.

The closure plan for the IWL and wastewater ditches consisted of removing the most highly contaminated soil from the wastewater ditches and placing it in the IWL where it was covered with a multilayer cap. The wastewater ditch excavations were backfilled with clean material and also were capped. Soil and sludge in the IWL was mixed with clean soil to absorb free moisture and then compacted to create a firm foundation for the overlying cap. The IWL sludge did not yield hazard constituents when subjected to laboratory leach tests. Consequently, the sludge did not require treatment except to reduce its free moisture content.

The multilayer cap was designed according to U.S. EPA guidelines for closure under the Resource Conservation and Recovery Act (RCRA). After the sludge/soil mixture had been emplaced and compacted, it was covered with soil excavated from the wastewater ditches followed by a 2-foot layer of clay. A synthetic membrane was placed on top of the clay layer followed by a 6-inch thick, permeable drainage layer composed of uniformly sized sand. Finally, the drainage layer was covered with 3.5 feet of clean backfill and 6 inches of topsoil. Native vegetation was established in the topsoil to minimize erosion. The surface of the cap was mounded to promote run-off, and benchmarks were installed in the surface for periodic monitoring to detect settlement that would allow water to accumulate on the cap.

INTRODUCTION

The Industrial Waste Lagoon (IWL) received an average of more than 140,000 gallons of industrial wastewater and stormwater run-off daily from the maintenance area of Tooele Army Depot (TEAD) in Utah from the mid-1960s until discharges were discontinued in 1988. It was closed by the U.S. Army in 1989 under the terms of a Consent Decree with the State of Utah. This paper describes how the IWL and its associated wastewater ditches were closed using a design prepared by James M. Montgomery, Consulting Engineers, Inc. (JMM) under contract to the U.S. Army Corps of Engineers, Huntsville Division.

Description of Tooele Army Depot

The Tooele Army Depot (TEAD) is located approximately 35 miles southwest of Salt Lake City, Utah, in the southern portion of the Tooele Valley. The Tooele Valley covers approximately 250 square miles and is bounded by the Oquirrh Mountains, South Mountain and the Stansbury Mountains on the east, south and west, respectively. To the

north, the valley opens to the Great Salt Lake. Tooele Valley is sparsely populated and land is used primarily for agriculture and ranching. Principal population centers include the City of Tooele, approximately one mile east of the Depot, the City of Grantsville, approximately two miles to the northwest, and Erda, approximately three miles to the northeast.

The primary activities of TEAD are storage and demilitarization of conventional and chemical munitions and rebuilding of military equipment. TEAD consists of two areas: (1) the north area, which occupies approximately 39 square miles in Tooele Valley; (2) and the south area, which occupies approximately 30 square miles in Rush Valley, located approximately 10 miles south of the north area (Figure 1). Hazardous materials are or were used, generated or disposed of in the north area at the demolition grounds, the maintenance area, the IWL and the trinitrotoluene (TNT) washout ponds. In the south area, hazardous materials are present in the demilitarization area/disposal pits, the chemical agent storage areas and the demolition grounds.

Physical Setting

The Tooele Valley is bounded on the north by the Great Salt Lake at an elevation of approximately 4,200 feet. The eastern border of the valley is the north-south trending Oquirrh Mountains which rise sharply from the valley floor at an elevation of approximately 5,200 feet to a maximum height of 10,350 feet. The western border of the Tooele Valley is formed by the Stansbury Mountains which reach a maximum altitude of 11,031 feet at Deseret Peak. South Mountain, a relatively low-lying east-west trending structure, bounds the valley on the south.

The topography of the valley floor is shaped by coalescing alluvial fans formed by erosional debris washed from the mountains. The IWL is situated on the bajada formed by alluvium derived from the southern portion of the Oquirrh Mountains. The alluvial fans which form the valley floor slope gently toward the north at a gradient of approximately 40 feet per mile near the Great Salt Lake. The TEAD site is characterized by a gently rolling surface intersected by a series of shallow gullies.

The Tooele Valley is typical of Basin and Range physiography in which fault-block mountains rise above flat, intermontane valleys. The Oquirrh Mountains to the east and South Mountain to the south are composed mainly of alternating quartzite and limestone beds of late Mississippian, Pennsylvanian and early Permian age. The Stansbury Mountains to the west contain similar formations in addition to quartzite of Cambrian age. The rocks in all three mountain ranges bordering the valley have been extensively folded and faulted.

The Tooele Valley is filled with a thick sequence of unconsolidated sediments of Tertiary and Quaternary age. The older Tertiary sediments comprise the Salt Lake Group and consist of moderately consolidated sand, gravel, silt and clay with an abundance of volcanic ash (Everitt

Figure 1
Vicinity Map

ranged up to approximately 8 feet deep. Wastewater in the IWL was alkaline and contained elevated levels of chromium, lead and organic solvents such as 1,1,1-trichloroethane, trichloroethene, toluene, carbon tetrachloride, and other organic compounds. However, the composition of wastewater was highly variable due to the many industrial processes that contributed to the flow. Sludge from the IWL yielded similar inorganic and organic contaminants.[3]

Description of the Wastewater Ditches

Four parallel wastewater outfall ditches extended from the vehicle maintenance area 1,200 to 2,700 feet to the northwest where they terminated into a single wastewater ditch. The single ditch extended to the north approximately 6,000 feet to the IWL. The ditches were constructed in gravelly soils and were unlined with broad U-shaped cross-sections. The ditches ranged from 1 to 3 feet deep with the bottoms 1 to 3 feet across. The ditch widths at the top ranged from approximately 10 to 20 feet.

CLOSURE ACTIVITIES

The IWL was closed in place by removing the liquid, stabilizing the sludge, placing contaminated soil from the wastewater ditches into the IWL and installing a multilayer cap. Closure activities are briefly described below, and the design parameters are presented in detail in the next section.

Liquid Removal and Disposal

Liquid remaining in the IWL after wastewater discharge ceased was pumped into tank trucks and discharged into the industrial wastewater treatment plant (IWTP) in the TEAD maintenance area that was constructed to replace the IWL. Most of the wastewater in the IWL was lost to infiltration when discharges ended before closure activities began, and the remaining liquid was taken to the IWTP.

Sludge Treatment, Backfill and Compaction

Sludge samples from the IWL subjected to the Toxic Characteristic Leaching Procedure (TCLP) yielded concentrations of metals and organics below their toxic thresholds. Consequently, it only was necessary to mix clean, fine-grained soil with the IWL sludge to absorb any free liquid. The sludge/soil mixture was placed in the IWL and firmly compacted to construct a strong foundation for the cover.

Wastewater Ditch Excavation, Backfill and Cover

Sludge and contaminated soil from the wastewater ditches were excavated and placed in the IWL on top of the sludge/soil mixture. The objective of the wastewater ditch excavations was to remove the majority of contaminated materials and to generate adequate volumes of soil to construct the final cover on the IWL. After the wastewater ditches were excavated, they were backfilled with clean soil and covered with a synthetic membrane.

IWL Cover

Soil excavated from the wastewater ditches was placed in the IWL and graded and compacted to form the slope of the final cover. The cover, in ascending order from the wastewater ditch soil, consisted of a 2-foot low-permeability layer, a synthetic membrane, a protective geotextile, a 1-foot drainage layer, a geofabric filter and 2 feet of natural fill and topsoil covered with a geofabric to prevent erosion. The cover also was constructed with run-on/run-off control and subdrains to receive water transmitted by the drainage layer.

CLOSURE DESIGN PARAMETERS

This section describes how closure design parameters were developed for stabilizing the IWL sludge, for compacting the cover foundation and for installing the cap.

Summary of Bench Tests on IWL Sludge

Laboratory bench tests were conducted on various sludge mixtures to select the design admixture. The objective of the bench test was to identify a mixture of sludge and additive that met the following requirements:

and Kaliser, 1980). The younger Quaternary sediments consist of interlayered and unconsolidated sand, gravel, silt and clay including sediments deposited before, during and after the existence of Lake Bonneville. The thickness of the valley sediments ranges from a feather edge at the margins of the valley to more than 8,000 feet in the north central part of the valley.

Description of the Industrial Waste Lagoon

The IWL is an unlined evaporation pond, measuring approximately 400 feet by 200 feet, into which an average of more than 140,000 gallons of industrial wastewater and stormwater were discharged daily until November 8, 1988. It was originally excavated for gravel borrow material and began receiving wastewater about 1965, according to TEAD personnel. However, the total amount of wastewater discharged to the IWL is unknown. Wastewater generated by the boiler plant, metal parts cleaning, degreasing, steam cleaning and dynamometer test cells flowed into the IWL through four unlined ditches.

The results of a study by the U.S. Army Environmental Hygiene Agency[1] conducted between March 15 and September 26, 1982, showed that of the 139,800 gallons per day (gpd) of wastewater discharged to the IWL during that period, 96% or 134,000 gpd infiltrated from the ditches and the IWL and the remaining 4% evaporated. On October 8, 10, 11 and 15, 1985, the USAEHA measured the discharge to the ditches and IWL at 161,100 gpd.

A limited amount of information was collected regarding the volume and composition of liquid and solid waste in the IWL. It contained approximately 2,000 cubic yards of sludge and approximately 2,000,000 gallons of liquid as of December 1984.[2] The sludge accumulated primarily in the south end where it was up to 3 feet thick, and wastewater

- Contains no free water
- Can be classified as non-toxic when subjected to the TCLP (Toxic Characteristic Leaching Procedure)
- Minimizes the increase of the volume of the mixture
- Makes use of readily available, non-proprietary additives
- Is the least expensive of the additives that meet the other criteria

The selected mixture was subjected to geotechnical tests to identify the optimum moisture and density at which it should be emplaced in the IWL to resist settling. Complete details of the bench-testing program can be found in JMM's 1987 Report.[4]

The materials for the bench-testing consisted of sludge and various materials for mixing with the sludge. Approximately 5 gallons of sludge were collected from the IWL from several points in the south end. The additives for the bench tests included fly ash, type I portland cement, a 60/40 mixture of fly ash and type I portland cement, hydrated lime and imported soil from an approved borrow area.

Several sludge/additive mixtures were subjected to the Paint Filter Liquids Test (U.S. EPA Method 9095) to determine when the mixtures contained no free liquids. The test for free liquid consists of placing a predetermined amount of sample in a paint filter. If any portion of the sample passes through and drops from the filter within the 5 minute test period, then the test sample is considered to contain free liquids. The test results indicated that a 1:1 ratio of sludge and any of the additives was the approximate minimum dosage to eliminate free liquid from the mixture. Mixtures containing twice as much additive as sludge were tested to evaluate the ability of the larger dosage of additive to stabilize any mobile chemical species. Samples of raw sludge were subjected to the TCLP to evaluate the degree to which the additives stabilized the sludge.

The raw sludge sample yielded low concentrations of five volatile and three semivolatile organic compounds and three metals at concentrations greater than laboratory detection limits. None of the identified compounds exceeded their respective TCLP regulatory levels and, consequently, the raw sludge did not exhibit the toxic characteristic. Similarly, all the sludge mixtures were nontoxic on the basis of TCLP testing. In addition, the analyses indicated that there were not large differences in the abilities of the five additives to treat the IWL sludge; each of the mixtures was nontoxic according to the TCLP and produced a stable solid containing no free liquid. The differences among the analyses of the mixtures were not considered to be significant from the standpoint of admixture design. The alkaline sludge apparently immobilized the hazardous constituents so the additives were necessary only to absorb free liquid. There was no need for the additives to chemically bind the metals and organic compounds.

Table 1 lists the percentage increases in the sludge mixtures for each additive. Table 2 presents estimated costs for each additive, taking into consideration the material costs, volume increase and handling costs. The unit costs for materials were obtained from a Salt Lake City supplier and include delivery to TEAD. TEAD soils were assumed to be excavated from within 2 to 3 miles of TEAD and hauled to the IWL. A handling charge for mixing the sludge and additives was assumed to be $5.00 per cubic yard for each additive. The estimated total cost for TEAD soil was the lowest among the mixtures and was highest for lime. Lime must be transported from South Dakota, which added considerably to its cost. TEAD soil was selected as the most appropriate additive because its use was least expensive, and the volume increase of the sludge/soil mixture was similar to the other mixtures.

Sludge/soil mixtures were subjected to compaction tests to determine moisture-density relationships of the mixture and a one-dimensional compression test to estimate long-term settlement of the mixture under its own weight plus the weight of overlying cover. The compaction test determined that the optimum moisture content of the sludge/soil mixture would be 22.8% with a maximum dry density of 96.3 pounds per cubic foot (pcf). At 95% of this compaction, the sludge/soil mixture can support the maximum load of the IWL cover, which was estimated to be approximately 3,000 psf, with a total differential settlement of less than 0.3 feet.

Table 1
Increase in Stabilized Sludge Volume

Additive	Increase in Volume (% of Unstabilized Sludge Volume)[a]

Fly Ash	27	$ 54,000	2520	$ 12,600	$ 66,600	$ 26
Type I Portland Cement	94	188,000	2720	13,600	201,600	74
60% Fly Ash/40% PC	54	108,000	2920	14,600	122,600	42
Lime	150	300,000	2600	13,000	313,000	120
TEAD Soil	5	10,000	2840	14,200	24,200	8.50

* 2000 cy for a 1:1 mixture.
**The unit handling cost is assumed to be the same for all additives for comparison purposes.

Material costs are from the Resource Materials Corporation, Salt Lake City, and include delivery to TEAD.

Mixture volume includes the 2,000 cy of IWL sludge (JMM, 1986) and the increase in volume due to each additive is shown in Table 1.

IWL Cover Design

The cover design for the IWL meets the requirements of RCRA Guidance Documents[5,6] and the U.S. Army Corps of Engineers.[7] In addition, the cover meets the design requirements in Utah Hazardous Management Regulations (UHWMR) Section 7.21.4(a) which include the following:

- Provide long-term minimization of migration of liquids through the closed IWL
- Function with minimum maintenance
- Promote drainage and minimize erosion or abrasion on the cover
- Accommodate settling and subsidence so that the cover's integrity is maintained
- Have a permeability less than or equal to the permeability of any bottom liner system or natural subsoils present.

The cover was designed to meet the following post-closure responsibilities of the Owner or Operator as specified by UHWMR 7.21.4(b):

- Maintain the integrity and effectiveness of the final cover, including making repairs to the cover as necessary to correct the effects of settling, subsidence, erosion or other events
- Maintain and monitor the groundwater monitoring system and comply with all other applicable requirements of 7.13 of these regulations
- Prevent run-on and run-off from eroding or otherwise damaging the final cover
- Protect and maintain surveyed benchmarks used in complying with 7.21.3

On the basis of these regulations, the cover design consists of three layers. The lowermost layer is constructed from low permeability material to prevent infiltration from precipitation and surface water to enter the waste. The middle layer is relatively permeable to allow infiltrating water to flow along the top of the lowermost layer to the perimeter of the cap. The upper layer consists of native fill and topsoil to sustain vegetation and resist erosion.

The lower permeability layer consists of 2 feet of clay or clay-amended soil with a recompacted permeability less than or equal to 1 x 10-7 centimeters per second (cm/sec) which is covered with a synthetic membrane (Figure 2). The synthetic membrane is covered by a protective geotextile. The middle drainage layer consists of 12 inches of relatively permeable, uniformly graded sand or fine gravel with a permeability of at least 1 x 10-3 cm/sec. The purpose of this layer is to carry infiltrating water to the perimeter of the cap for collection and discharge. This layer is covered by a geofabric filter to prevent infiltration and clogging by soil from the upper soil layer. The upper layer consists

of 6 inches of topsoil and 3.5 feet of fill to sustain native vegetation for erosion control and to protect the underlying layers from frost penetration. The vegetation will consist of persistent but shallow-rooted plant species whose roots will not extend into the drainage layer.

The shape of the cover was based on providing run-on/run-off control and creating an adequate slope on the surface of the cover (Figure 3). The perimeter of the cover is approximately 2 feet above the existing grade to prevent surface water from running onto the cover. Run-on ditches surrounding the cover were sized for the 100-year storm based on precipitation events using Richardson's data.[8] The surface of the

Figure 4
Wastewater Ditch Cover Construction Design

cover was designed with a 3.8% slope to promote drainage without erosion and to fall within the 3 to 5% slope recommended by the U.S. EPA[9] even if settlement occurs. Water running off the cover on the top of the synthetic membrane will be intercepted by 6-inch diameter, perforated Schedule 40 PVC subdrains along the edges of the cover. The collector subdrains discharge to an 8-inch PVC drain on the downhill side of the cover. The volume of fill in the cover was calculated from cross-sections drawn at 25-foot intervals over the entire length of the IWL.

The composition of the synthetic membrane was specified to meet the requirements of the National Sanitation Foundation (NSF) Standard Number 54 for flexible membrane liners. The NSF standard is widely accepted, and it is endorsed by the U.S. EPA.[5] The membrane material must also withstand the organic compounds that may be present in the sludge/soil mixture and wastewater ditch soil.

The thickness of the membrane was specified at 40 mils to ensure that it has sufficient tensile and elongation strength to withstand the effects of the gravelly and cobbly soil at TEAD.

Cover Design for the Wastewater Ditches

The purpose of excavating the wastewater ditches is to remove sludge and contaminated soil to a depth of 20 inches and to obtain foundation material for the IWL cover. At least 6,000 cubic yards of material were excavated from the ditches under the assumption of 1:1 slopes of the sides of the excavation and a 15% shrinkage rate.

The wastewater ditch excavations were backfilled with material from TEAD borrow pits or other locations and were free of roots and other organic matter, trash, debris, frozen materials, stones larger than 2 inches and materials classified as Pt, OH, OL, MH or ML (Unified Soil Classification) The backfill was compacted to 95% of the maximum dry density obtained in the laboratory by the test procedure presented in ASTM D-698. Although the wastewater ditches were not loaded to the extent of the IWL, the backfill was compacted firmly to resist settling.

The purpose of the wastewater ditch covers is to prevent infiltrating run-off and precipitation from contacting soil that may still contain contaminants (Figure 4). The cover consists of the same material selected by the contractor for the IWL cover. The tops of the covers were 2.5 to 5 feet below grade, and the edges were anchored 4 to 6.5 feet below grade. This depth of burial was designed to provide protection from frost. The finished grade of the covers will be 2% from the centerline to the edges to direct precipitation and surface drainage away from the ditches and to allow for settlement. The covers will range from 10 to 20 feet wide.

In Situ Vitrification Treatability Study

Marie Bushway Zanowick
U.S. Environmental Protection Agency, Region VIII
Denver, Colorado

Carol Ondrusek Edson
Colorado Department of Heatlh
Hazardous Materials and Waste Management Division
Denver, Colorado

ABSTRACT

The Denver Radium Site consists of 31 properties contaminated by low level radioactive waste that could endanger public health, welfare and/or the environment. The soil from Operable Unit (OU) VIII of the Denver Radium Site contains both radioactive and nonradioactive contaminants and thus may not meet the acceptance criteria of existing commercial facilities. During the remedial investigation, in situ vitrification (ISV) was identified as a technology which could provide a permanent solution to the waste types on-site. A bench-scale test was conducted to determine if the ISV process is appropriate to the specific soil-waste mixture present at the site. At the time of this publication, the test results were still in draft, preliminary form. Because this site involves enforcement of actions directed to potentially responsible parties, the results cannot be released in draft form. The results of this test will be used to determine if a full-scale ISV field test will be conducted on-site.

INTRODUCTION

The Denver Radium Site was placed on the National Priorities List in September 1983. The site was divided into 11 Operable Units (OU) which contain both open areas, some paved areas and structures. The contaminated soils from all but one of the OUs are being excavated and hauled by rail to a permanent disposal facility.

OU VIII of the Denver Radium site is currently in the Remedial Investigation/Feasibility Study phase. It was the site of metal processing activities beginning in the early 1920s. Throughout the 1930s vanadium ore, uranium ore and radium salts were received at the site. From 1939 to 1941, this property was one of two radium producers in the United States. In 1942, radium production stopped and emphasis shifted to the production of molybdenum; however, the plant continued to receive shipments of vanadium ore until 1943. The plant was actively producing uranium compounds in the 1960s and ceased operations in 1984 due to a decrease in the market price of molybdenum.

Processing involved dissolution of the ores with acids and caustics and extraction using various processes, some involving organic compounds now considered hazardous or potentially hazardous. Because of the nature of the production process, wherein reagents, solvents and processing solutions were stored in vats and pumped to different reaction vessels, the chance of spills and leaks was high and spills resulted in soil and possibly groundwater contamination.

Studies of the radiological conditions on the site have identified radiation fields and radionuclide concentrations in various media due to the presence of uranium, radium and associated decay products.

Metals used on the property include, but are not limited to:

Arsenic	Lead	Selenium
Barium	Magnesium	Nickel
Manganese	Iron	Uranium
Cobalt	Mercury	Vanadium
Copper	Molybdenum	Zinc

Chemicals or other materials that were either used in the ore processing, used in the laboratories on the property, or stored on the property include:

Inorganic Reagents	*Organic Reagents*
Ammonia	Acetic acid
Ammonium hydroxide	Chloroform
Ammonium nitrate	Methyl isobutyl ketone
Barium carbonate	Tributyl phosphate
Calcium hydroxide	1,1,1-trichloroethane
Hydrochloric acid	Tertiary amines
Hydrogen peroxide	
Hydrogen sulfide	*Others*

IN SITU VITRIFICATION

ISV was developed in 1980 by Battelle Memorial Institute and Geosafe Corporation. ISV is a thermal treatment process involving electrical melting of soil. A square array of four electrodes is inserted into the ground to the desired treatment depth. In order to establish a path of conductance, a mixture of flaked graphite and glass frit is placed around the electrodes. An electrical potential of more than 12,000 volts is applied to the electrodes which establishes an electrical current in the graphite and glass frit. The resultant power heats the path and surrounding soil to above fusion temperature. The melt advances at a rate of 1 to 2 inches per hour.

Most contaminants in the soil typically exist in a solid or liquid phase. During processing, most undergo a change of state to a liquid or gaseous phase. The physical state of contaminants is directly related to their movement during ISV processing. Many organic components vaporize during processing. Organic vapors increase in temperature to their pyrolysis temperature where they break down into successively smaller chains of molecules and eventually reach the state of elemental or diatomic gases. Upon pyrolysis, the concentration of the original compound vapor is diminished, resulting in a concentration gradient of the original vapor toward the melt. Some of these gases may dissolve into molten mass; the remainder may be expected to escape the treatment volume. Such vapors are collected and treated to below air emission requirements in an off-gas treatment system.

Inorganic compounds may thermally decompose or otherwise enter into reactions with the melt. Nitrates and sulfates yield decomposition products which may dissolve into the melt or may evolve through it and be collected at the surface. Some volatile or semi-volatile inorganics (i.e., Pb and Hg) are removed from the treatment area and recovered in the off-gas system. Pyrolytic destruction of hazardous inorganic elements (CN, for example) is possible; however, destruction of heavy metals is not possible. Heavy metals ultimately are dissolved and incorporated or encapsulated in the residual product. Radioactive elements cannot be destroyed, but are incorporated (immobilized) into the final product.

The processing area is covered by an octagonal shaped off-gas collection hood which is much larger than the treatment area. Flow of air through the hood is controlled to maintain a negative pressure. Air provides oxygen for combustion of pyrolysis products and vapors. Off-gases, combustion products and air are drawn from the hood by an induced draft blower into a treatment system. Unit processes within the treatment system include quenching, pH controlled scrubbing, dewatering, heating, particulate filtration and activated carbon adsorption.

A self-controlled cooling system is utilized to cool the quenching/scrubbing solution. The filters and carbon adsorption columns are utilized as secondary or backup stages to ensure safe air emissions. After processing for a time, the scrubber solution, filters and activated carbon likely contain sufficient contaminants to warrant treatment or disposal themselves. Typical treatment may include passing the scrubber water through a diatomaceous earth filter and activated carbon. The water may be recycled or discharged to a sanitary sewer, and activated carbon filters may be placed in a subsequent ISV setting for reprocessing. In this way, the only secondary waste resulting from the ISV processing is that contained in the off-gas treatment system after the last setting at a site.

Upon completion of the ISV processing, the cooling time of the molten mass affects the relative extent of glassy phase and crystalline phase present in the residual product. Typically, the mass solidifies into a silicate glass and microcrystalline product which is physically and chemically equivalent to natural obsidian.

BENCH-SCALE TEST: MATERIALS AND METHODS

The performance objective of the bench-scale ISV test was to identify the effectiveness of this treatment alternative for the radioactive and heavy metal soil contaminants at this site. The contaminants of primary concern are Ra-226, Th-230, natural Uranium, As, Se, Pb, Hg, Cd and Ba. The bench-scale test was conducted on April 12, 1990. Several different types of materials were involved in the test. They included: (1) bore hole soils (BH) - soils located on-site with high concentrations of radionuclides, (2) surface soils (SS)- soils located on-site with high concentration of heavy metals and (3) background soils-noncontaminated soils collected from an off-site location.

The physical properties of these soils were evaluated prior to the bench-scale test. The results of these analyses are presented in Table 1.

Table 1
Physical Characteristics

	Moisture wt%	Dry Density	Wet Density
Surface Soil	10	1.3 g/cm³	1.44 g/cm³
Borehole soil	41	0.72 g/cm³	1.23 g/cm³
Background soil	8	1.48 g/cm³	1.60 g/cm³

Compositional analysis of these soils was also performed. Whole rock analyses, using x-ray fluorescence, were performed on the soils used in the test to determine their bulk chemistry. These analysis quantified the concentration of glass-forming ions, electrically conductive ions and other ions which serve as fluxing agents during ISV melting.

A bench-scale vitrification unit was used to conduct the treatability test. The levels of radioactivity in the test soils prevented the performance of the test at the Geosafe laboratory located at the University of Washington without a license; therefore, the test equipment was transported to OU VIII.

The test was conducted in an 85-gallon drum which was placed inside a steel box for double containment safety purposes. The four 0.5-inch diameter by 24-inch long molybdenum electrodes were sheathed by 1.5-inch diameter by 20-inch long graphite collars to prevent oxidation of the molybdenum and to induce subsidence of the melt zone. The molybdenum and graphite electrodes were placed in the soil to a depth of 16 inches. The electrode assemblies were designed to have a center to center spacing of 8 inches in a square array. Due to the unexpected high iron content of the contaminated soils, this spacing array was moved out to a 10-inch center to center square array to reduce the potential for molten iron to form at the bottom of the melt. This molten pool, if formed, could serve as a path for the electric current, thus short circuiting the vitrification process.

The bench-scale tests are designed to challenge the vitrification process with the highest contaminant concentrations on-site. Because the highest radioactive and nonradioactive soil concentrations are not coincident with each other, the contaminated soil was placed in two distinct layers in the test drum. The contaminated soil was stratified and placed in an 8-inch square area in the center of the drum. The first contaminated zone consisted of the surface soils (SS), which were primarily contaminated with heavy metals, and had a height of 5 inches. The second contaminated zone consisted of borehole (BH) soils, which were primarily contaminated with radionuclides, also to a height of 5 inches. The contaminant zone had a height of 10 inches and was covered with 3 inches of clean soil. The clean soil was added to ensure that a full vitreous zone was established prior to encountering any contaminants. The ISV boundaries (adjacent to and beneath the contaminated soils) were surrounded by clean soils.

In order to monitor processing depth, type K thermocouples were installed in the center of the test drum extending from the surface down to the bottom of the drum (32 inches) in 2-inch intervals. In addition, three type K thermocouples were installed on a horizontal axis, 10 inches below the surface grade at 2-inch intervals to measure horizontal melt dimensions and the temperature isotherms in the surrounding uncontaminated soil. Geosafe continued to vitrify the soil until the thermocouple located at the 16-inch depth reached the 2192°F temperature.

A flaked graphite/glass frit mixture was placed in a 1-inch by 1-inch path laid in an "X" and square pattern on the surface of the soil to provide direct electrical conductive path between the electrodes. This spacing is consistent with full-scale remediation operations. Approximately 2 hours after the startup of the test, it was evident that a melt was not being established. The vitrification process was stopped and an additional layer of graphite and glass frit was added to promote electrical conductance. A melt was established, and the test was completed in six hours and eight minutes.

During the ISV testing, the vitrification zone was covered with a 2-inch kaowool insulation blanket, leaving a small gap around the electrode for venting. The insulation helps promote subsidence of the molten surface and improves the melting efficiency of the operation. This technique is consistent with full-scale operations.

The power system consists of a 30 kW capacity Scott-Tee transformer. The transformer is equipped with 12 voltage taps and two silicon controlled rectifiers for controlling power input to the melt. The test was run at a target control power of 15 kW to closely simulate full-scale operations (power density). The transformer was equipped with metering on the secondary side (output to the electrodes) for power, voltage and amperage. Electrical and thermocouple data were recorded at 0.5 hour intervals.

The off-gas stream from the test unit is equipped with a condensate collection tank for the collection of water and particulates released from the melt. This tank simulates the performance of the quencher and scrub tank in the Geosafe large-scale system. In addition, the system contains a desiccant, HEPA filter and activated vapor phase column to remove any particulate or gaseous emissions from the melt. Off-gases generated from the melt were sampled continuously during the test. Three side stream samples were drawn through 2-inch ports located

in the off-gas line. U.S. EPA Methods 1 and 2 were used to determine stack gas velocity, temperature and volumetric flow rate. U.S. EPA Methods 3 and 3A were used to determine the molecular weight of the stack gas. U.S. EPA Method 4 was used to determine the moisture content of the stack gas. U.S. EPA Methods 108, 12 and 101A techniques were employed to collect the multiple metals screen sample.

The pretest measurements include various physical, nonradioactive nuclide and radionuclide measurements of the background soil and of the contaminated soil. The physical measurements include moisture, dry density, fusion temperature, 100 poise temperature, electrical conductivity at 100 poise temperature, melting temperature and test sample mass. Chemical measurements include HSL metals, Al, Cu, Fe, K, Li, Na and Si by modified U.S. EPA method 6010. The radiochemical measurements include isotopic U, Ra-226, Th-230, Pb-210, gross alpha and gross beta/gamma radiation.

The test measurements which were conducted with the bench test include gas pressure at three points in the test apparatus, air flow at one point in the test apparatus, temperature at 18 points in the test matrix and one point in the test apparatus, electrical power, voltage, and amperage supplied to the electrodes, and total organic vapors in the off-gas effluent control discharge.

The post-test measurements which were conducted on the vitrified block and surrounding soils include: one physical measurement, bulk density; chemical measurements, including HSL metals; and radiochemical measurements, including isotopic U, Ra-226, Th-230, Pb-210, radon flux on the full block and gross alpha, beta and gamma.

Leaching tests and associated analyses were performed on the pretest soils and vitrified product using the Extraction Procedure Toxicity Test (EP Tox). The laboratory tests and analyses were performed to meet the Level III analytical category requirements.

RESULTS

Post-test sampling of soils adjacent to and beneath the vitrified mass were taken by a combination of driving a PVC sampling tube into the soil and by compositing representative grab samples at appropriate depths. These two sampling procedures were used because the large rocks in the soil limited sample recovery when driving a sampling tube.

Upon completion of the adjacent background soil sampling, the remaining adjacent soil was removed to allow examination and removal of the glass monolith. During the test, a solidified layer of glass formed on the top of the melt (cold cap). The cold cap (approximately 1.5 in. thick) was broken, and when it was removed, a large void measuring approximately 8 in. X 8 in. X 6.5 in. deep was observed under the cold cap. This void indicated that volume reduction had occurred during treatment. The base of the treatment zone consisted of a vitrified mass approximately 8 in. thick and 15 in. wide. Based on measurements of the void volume and the vitrified mass, the volume reduction appeared to be approximately 25%. All samples taken of the vitrified mass were subjected to radiation scans prior to packaging for transport to the laboratory for analysis.

Retention efficiencies for each contaminant of concern were calculated based upon the following equation:

$$RE \quad \frac{W \text{ in } - W \text{ out}}{W \text{ in}} \quad X \text{ 100} \tag{1}$$

Where
W in = mass of contaminant in the pre-test container
W out = mass of contaminant in the off-gas
RE = retention efficiency

CONCLUSIONS

The results of this treatability test will be used to determine whether ISV is a viable treatment alternative at the site. Specific data to be gathered and evaluated include:
(1) the effects of ISV on soil radiation/radon gas emissions;
(2) effects on contaminant immobilization and leachability;
(3) levels of contaminants in the off-gas system; (4) performance of a mass balance for contaminants of concern; and (5) cost estimates for full-scale remediation.

Design and Construction of Soil Caps Over Sludge Ponds

V. Chouery-Curtis
S. Butchko
Tensar Environmental Systems, Inc.
New York, New York

ABSTRACT

Most existing sludge ponds are either being capped or being proposed for capping due to tighter regulations and a growing serious concern over the environment. Capping is necessary to inhibit rainfall penetration, protect migratory waterfowl and shore birds, to prevent escape of gases, to control odors and in some cases for land reclamation. Most sludge deposits have very low shear strength which prohibits conventional construction equipment and even construction personnel from accessing the site. This paper describes design considerations and construction techniques that have been successfully used to place soil covers over soft sludge deposits.

Placement of soil over soft subgrade requires a careful balance between the fill thickness required to support construction equipment and the overburden weight that may cause excessive consolidation and/or bearing failure of the sludge, i.e. mudwaving. With stiff polymer geogrids, the amount of fill required to support construction equipment can be significantly reduced, making it possible to place the initial fill lift without exceeding the bearing capacity of the soft foundation. In many cases, the thickness savings of fill can mean the difference between successful construction using conventional equipment and having to resort to very costly and time consuming specialized construction techniques.

INTRODUCTION

With the growing concern for the environment, the stringent rules and regulations are now considered as standards needed to keep the pollution problems in balance with nature. To comply with the new regulations, several sludge lagoons that have been in operation for more than 20 years have to be closed and capped. Capping is necessary to inhibit rainfall penetration, to keep migratory waterfowl and birds out, to prevent escape of gases, to control odors and, in some cases, for land reclamation. Most sludge materials are very soft, highly compressible and have shear strength values rarely exceeding 200 lb/ft² These characteristics create serious construction and bearing capacity problems.

Due to the inherent very low shear strength of most sludge material, it is extremely difficult, and in some cases impossible, for construction equipment and manpower to access the site. Construction of a soil cover over soft sludge requires a careful balance between the fill thickness required to support construction equipment and the overburden weight that may cause excessive consolidation and/or bearing failure of the sludge, usually occurring in the form of mudwaving. With the use of stiff polymer geogrids, the amount of fill required to support construction equipment can be significantly reduced, making it possible to place the initial soil lift without exceeding the bearing capacity of the soft foundation. This paper describes the design procedure and con-

struction techniques that have been successfully used to place the soil covers over soft sludge deposit without creating bearing capacity failures. The paper also address the important geogrid properties required for such applications.

EMERGING TECHNOLOGY

The concept of designing a reinforced soil platform to allow access on top of soft materials is not new. This particular application started in Canada, in conjunction with oil drilling operations. The existing material referred to as "Muskeg" and the heavy weight of oil drilling equipment necessitated placing a geogrid directly on top of the existing material. A 3-foot thick soil layer was then placed on top of the geogrid. This reinforced soil platform provided a means for the heavy equipment to access the site without failing the subgrade.

When dealing with very soft subgrade and/or sludge materials, the primary objective of the engineer is to design an access system without having the subgrade fail. An indication of failure of the existing material is heavy rutting and creation of uncontrollable mudwaves. Rutting can slow down construction operation and substantially increase the cost and the construction time. Once a mudwave develops, it is extremely difficult to control and contain. Failure of the subgrade can lead to catastrophic failures endangering both loss of life and/or heavy equipment.

Stiff (as defined by the Geosynthetic Research Institute Test Methods GRI-GG3 and GG4)[8,9] biaxially oriented geogrids are used to distribute the loads and prevent overstressing and punching shear failure of the subgrade. The use of geogrid allows the existing sludge material to remain undisturbed and maintain its original design strength.

MATERIAL PROPERTIES

Geogrids were first introduced into North America in the early 1980s. According to The American Society for Testing of Materials definition, a geogrid is any planar structure formed by a regular network of tensile elements with aperture of sufficient size to allow interlocking with the surrounding soil, rock, earth or any geotechnical material to perform the functions of reinforcement and/or segregation.

Geogrids are produced in biaxial and uniaxial load carrying configurations, as illustrated in Figure 1 and were specifically developed for long-term reinforcement of critical structures. Biaxially oriented geogrids typically are used as access tools on top of sludge materials. Geogrids are prestressed during the manufacture to provide high tensile modulus and high tensile strength at very small elongation. A geogrid must be strain compatible with the medium it reinforces, i.e, a geogrid must generate high tensile strength at very low strains.[1,2] The geogrid tensile strength is defined based on GRI Standard Test Method GG1.[6] Again the primary goal is to get access to the site without failing the subgrade.

If the reinforcing structure does not provide high tensile strength at very small elongation, the existing soft material will have to undergo excessive deformation prior to mobilizing the tensile strength of the reinforcing element.[2,3] Excessive deformation can lead to catastrophic failures.

Figure 1
Typical Uniaxial and Biaxial Geogrids
(a) Uniaxial Geogrid (b) Biaxial Geogrid
Figure 2
Effect of Geogrid Interlocking with Surrounding Material

Biaxially oriented geogrid structures should possess sufficient stiffness to enable them to resist shear stresses and deformation under load.[5,8] The geogrid should have a high interlock capacity. It is this interlocking capacity that enables the geogrid to rigidly confine, the surrounding material to its structure. Figure 2 illustrates the interlocking capacity of a biaxial geogrid. Another important property of the geogrid is its high junction strength (as defined by GRI-GG2)[7] that allows full load transfer from one rib to the adjacent rib. Thus the geogrid can distribute concentrated loads over a wider area of the weak underlying material. Figure 3 illustrates the ability of the geogrid to distribute a concentrated load. Notice that the laborer is standing at the edge of the geogrid layer, yet he is not sinking into the material. The consistency of the surrounding material is close to that of water. If the laborer was to step away from the geogrid he could sink in up to 3/4 of his height. It is this ability of the geogrid to distribute concentrated loads that prevents overstressing and bearing capacity failure of the underlying soft material, thus allowing the sludge to remain undisturbed and maintain its original

Figure 3
Surveyor Standing on Geogrid Placed on Top of
Existing Material which has Consistency of Water

strength. To ensure adequate load transfer from one rib of the structure to the adjacent rib, the geogrid must have high junction strength,[7] high interlock capacity and high resistance to construction induced damages. Table 1 outlines typical biaxial geogrid specifications.[1]

DESIGN CONSIDERATIONS

With the poor consistency of sludge materials, the fundamental question is the feasibility of constructing a stable platform or base layer suitable for construction of the final closure capping system and/or other specific operational needs like wick drain placement. An important design consideration is the determination of the maximum initial soil cover thickness required to support construction loadings without creating bearing capacity failures. Using classical soil mechanics principles one can determine the required fill material thickness to prevent overstressing of the underlying sludge.[1] If a very thick soil layer is used, the bearing capacity and the allowable shear strength of the sludge material can be exceeded which can result in a localized rotational deep seated failure that could lead to loss of equipment and life. Knowing the sludge shear strength, one can determine the allowable initial soild lift thickness and the maximum allowable contact pressure for placement of the initial life.[1]

The properties of the initial soil lift are important to ensure the stability and integrity of the cover system.[1,2,3] The initial soil layer to be placed directly on top of the biaxial geogrid should possess good filtration and drainage properties.[2,3,5] This soil layer should allow for pore water pressure dissipation and/or collection of the leachate material. Mixing of the sludge with the new fill material can be prevented with adequate selection of the appropriate fill material.[5] Finally, the geogrid and the initial soil layer will provide the stable platform for construction of the final cap. Most sludge material have very low solids content varying between 3 and up to 10%. The composition and the mode of deposition of highly compressible material can result in total settlement magnitudes in excess of 8 to 10 feet depending on the maximum weight of the closure fill material.[2] If a leachate collection zone is designed to be located below the final cap cover, design and construction of a stable platform are required to protect the integrity and the survivability of the leachate and gas collection systems.

CONSTRUCTION REQUIREMENTS

Adequate design should be complimented with good construction practice to ensure successful installation at a particular site. Several construction details should be carried out very carefully to avoid developing an uncontrollable mudwave or a bearing capacity failure. The geogrid can be unrolled easily by one or two laborers. The geogrid is installed directly on top of the existing sludge material. The width and length of the area to be covered prior to placement of the initial

Table 1
Typical Biaxial Geogrid Specifications

The geogrid shall be a regular grid structure formed by biaxially drawing a continuous sheet of select polypropylene material and shall have aperture geometry and rib and junction cross-sections sufficient to permit significant mechanical interlock with the material being reinforced. The geogrid shall have high flexural rigidity and high tensile modulus in relation to the material being reinforced and shall also have high continuity of tensile strength through all ribs and junctions of the grid structure. The geogrid shall maintain its reinforcement and interlock capabilities under repeated dynamic loads while in service and shall also be resistant to ultraviolet degradation, to damage under normal construction practices and to all forms of biological or chemical degradation normally encountered in the material being reinforced.

The geogrid shall also conform in all respects to the property requirements listed below.

Notes:

1 MD dimension is along roll length. CMD dimension is across roll width.
2 Maximum inside dimension in each principal direction measured by calipers.
3 Percent open area measured without magnification by Corps of Engineers method as specified in CW 02215 Civil Works Construction Guide, November 1977.
4 ASTM D 1388-64 modified to account for wide specimen testing as described in Tensar test method TTM-5.0 "Stiffness of Geosynthetics".
5 Secant modulus at 2% elongation measured by Geosynthetic Research Institute test method GG1-87 "Geogrid Tensile Strength". No offset allowances are made in calculating secant modulus.
6 Geogrid junction strength and junction efficiency measured by Geosynthetic Research Institute test method GG2-87 "Geogrid Junction Strength".

Figure 4
Height of Leading Edge Initial Lift Should
be Maintained Relatively Uniform

Figure 5
Geogrids Do Not Need to be Anchored at Roll Ends

soil lift will vary based on the consistency and shear strength of the underlying sludge material.[5] Figure 4 shows several adjacent geogrid rolls placed on top of the existing sludge material. The adjacent layers of geogrid can be overlapped to prevent lateral spreading, as illustrated in Figures 3 & 4. The amount of overlap is directly related to the shear strength of the sludge material and can vary from a minimum of 1 foot and up to 3 feet. Plastic ties can be used to secure the adjacent rolls. The geogrid is stiff, has a high modulus, high tensile strength,and excellent junction strength. Thus, the sludge material does not have to undergo excessive deformation prior to mobilizing the tensile strength of the structural element. The ability of the geogrid to interlock with the surrounding material provides high shear stresses thus developing the tensioned membrane effect which allows a man's weight to be supported on materials that have consistency close to that of water.[2]

Once the appropriate area is covered with geogrid, the first soil lift

is placed using low ground pressure dozers with wide width track. Figures 4 and 5 illustrate the sequence of construction. A front-end dozer with rubber tires should be avoided, due to high loads concentration which could lead to catastrophic failures. The first layer should be placed in one lift. A well-graded sand layer can provide a stable platform, yet at the same time allow for pore water pressure dissipation and provide the base for a gas or leachate collection zone prior to placement of the final cap. The initial soil lift can be compacted by several passes of the dozer and/or by the weight of water used to keep the initial soil lift at an appropriate moisture content. Another advantage to the sand layer is that it can be used as a filtration medium and prevent mixing of the new fill with the sludge material. If other types of materials are used, care should be given to insure proper filtration and drainage, in order to avoid mixing with the sludge and/or pressure buildup. The thickness of the initial lift is critical and should be kept to the maximum allowable which can vary between 2 and 3 feet.[2] The leading edge of the initial lift should be maintained relatively uniform with no section advancing more than the initial lift thickness ahead of the remainder of the leading edge.[2]

CONCLUSION

For a successful closure of a sludge lagoon, it is extremely important to insure that construction techniques and sequences are carried out in such a manner as to prevent development of mudwaves and

eliminate potential for catastrophic failures. Each project should be designed and constructed based on the site-specific information. To successfully construct the final cap system, one must first be able to access the sludge. The use of a biaxial geogrid provides the necessary foundation upon which the initial soil lift can be placed. This initial reinforced soil lift then becomes the required construction platform upon which one can build the final cap system and/or any other earthen structure without compromising the integrity of the cap or jeopardizing loss of life and equipment.

ABSTRACT

An abandoned rock quarry, named Kerr Hollow Quarry (KHQ), near the Department of Energy, Oak Ridge Y-12 Plant, Oak Ridge, Tennessee, was used from 1951-1988 as a site to treat RCRA wastes which were reactive, corrosive or ignitable and which posed major concerns for personnel safety. The wastes were generated from operations at the Y-12 Plant and Oak Ridge National Laboratory and were previously treated by allowing the wastes to react with the water in KHQ, which has a surface area of approximately 4 acres and is up to 65-feet in depth. Ample water quality monitoring data were available to show that the water of the quarry was not being degraded by the treatment operations.

When closure of the site was required by the RCRA regulations, a closure method was selected to allow for clean closure of the quarry without treatment or removal of the water in KHQ. The method proposed to and approved by the Tennessee Department of Health and Environment (TDHE) was one of surveying the containers in the quarry by a submersible Remotely Operated Vehicle (ROV) using sonar and visually inspecting the containers by camera to confirm that all containers are breached and empty. Any container found intact would be breached to allow the contents to react with water and form non-hazardous residue. The progress of this unique type of closure is presented along with a summary of the problems encountered, planning activities, equipment utilized and other information about the closure.

The containers range in nature from compressed gas cylinders to drums, buckets, pipe sections, small containers and glass bottles, many of which, it had to be assumed, still contained explosive material.

Work rules require all personnel to be out of line of sight (around the shoulder of a hill) during all survey, inspection and work activity. All work was therefore done with remotely operated equipment. Work tasks at the site include survey and mapping, handling explosives, removal of mud and stone overburden, reaction of any unexploded material, cleaning and detailed inspection of containers and fragments, transportation of empty containers and fragments to a staging area from which they can be removed to a landfill and final detailed site inspection to insure that all hazardous materials were removed. Remotely operated tools, instruments and work systems include a mobile work platform, a hoist, a remotely operated system to carry containers, acoustic and a video positioning systems, video surveillance system, tools to rupture, clean and inspect containers and a dredge system for removal and screening of mud.

Software includes an integrated four-function package running on interconnected PC compatible 386 computers for real-time tacking/navigation of mobile equipment, display of locations of containers, data base management and data logging for permanent records of disposition of each container or other hazardous item. This work is being per-
formed by Sonsub, Inc., under the direction of Martin Marietta Energy Systems, Inc., under Contract DE-AC05-84OR21400 with the U. S. Department of Energy.

This closure project showed the practicality and cost benefits of telerobotic systems for work on hazardous waste sites. In addition to the intangible benefit of reduced exposure of workers, insurance costs are much lower and efficiency is higher. Daily start-up time is reduced since there is no need to don protective suits or other gear. Productivity is higher since personnel work only in clean areas where they are not hampered by masks, breathing apparatus, gloves or other protective gear. Cleanup time at shift end is minimized since the remote equipment does not leave the hazardous area and personnel need not go through decontamination.

INTRODUCTION

KHQ, shown in Figure 1, was operated in the 1940s as a rock and gravel quarry but was abandoned when it filled with water. Between 1951 and 1988, the Department of Energy's (DOE) Oak Ridge Y-12 Plant and the Oak Ridge National Laboratory used KHQ to treat water-reactive materials, potentially explosive chemicals and pressure cylinders. Materials were defined as hazardous wastes only by virtue of being reactive, corrosive or ignitable. The KHQ facility was used for emergency treatment and was not intended as a waste storage or disposal facility.

Figure 1
Aerial View of Kerr Hollow Quarry

In 1989, a remotely operated vehicle was used to survey the quarry and determine container locations and types. Survey results were used to plan closure work, which began in July 1990. The closure plan required all work to be done remotely, including making each container safe.by breaching or shredding, recovering the containers for transport to a landfill and performing a final survey to document closure. It was determined that the closure of KHQ was to be comparable to a clean closure under the TDHE Hazardous Waste Management Rules. No unreacted materials or explosive compounds were to be left in KHQ.

PAST TREATMENT PRACTICES

KHQ was a permitted facility under NPDES for treatment of certain potentially explosive chemicals or water-reactive metals. The permit required monitoring of KHQ water after a treatment operation and results were reported quarterly to the Tennessee Department of Health and Environment. Treatment operations were not permitted when there was surface discharge at the outfall.

A chute was constructed on a bluff high above the water surface to deposit materials directly into the water. A separate area was cleared on the opposite bank where compressed gas cylinders were placed for venting by rifle fire. Prior to the early 1970s, gas cylinders were placed in the water after venting. Containers floating in the quarry were penetrated by rifle fire to initiate reaction. Rifle fire was provided by security guards who were protected by a special metal building on the bluff.

Water-reactive metals including lithium, potassium, calcium, sodium or sodium-potassium alloy were normally packaged in 5, 30, or 55-gallon containers, taken to the quarry, placed in the chute and dropped into the water. The floating containers were punctured by rifle fire so water could enter. Water reacts with these metals, releasing hydrogen gas and forming oxides and hydroxides with the alkaline metal. Complete reaction of the metals is assured by the violent nature of the reactions. A limited number of 500 gallon pressure vessels containing sodium were treated in the quarry.

Potentially explosive chemicals such as picric acid were taken to KHQ in special containers, suspended above the water, punctured with rifle fire and dropped into the water.

An estimated 50 tons of hazardous and nonhazardous materials, including the weight of the containers, were sent to KHQ after record-keeping began in 1962. Table 1 shows a listing typical of materials reacted or vented in the quarry. Use of the Quarry as a treatment site ended in 1988 and closure work began soon thereafter.

Table 1
Description of Typical Wastes Treated in Kerr Hollow Quarry

```
Alkali Metals and Metal Hydrides (water reactive):
    -    Lithium and Lithium Hydride
    Sodium and Sodium Hydride
        Potassium and Potassium Hydride
        Calcium and Calcium Hydride
        Zirconium Hydride
        Titanium Hydride
        Lithium Hydride
        Lithium Aluminum Hydride
        Sodium   Potassium (Nak) Metal

Unstable Organics (explosive):
        Picric acid and related compounds
        Ethers
        Peroxides
        Hydrazine

Metals (reactive):

        Magnesium

Mechanical Hazard (explosive):
        Stressed Steel Parts (shrapnel danger)
        Vacuum Tubes (implosive)
        Blasting Caps
        Gas Cylinders (with frozen/broken valves)

Miscellaneous Hazards:
        Ammonia (irritant)
        Inorganic Acids (corrosive)
```

PRE-CLOSURE SURVEY

In 1989, a remotely operated vehicle was used to survey the KHQ site and map container locations. The X and Y coordinates and a description of each container were stored in a data base. Survey results were used as the basis for planning the closure, designing special tools and equipment and defining closure work.

Survey results were also used during closure work. The data base was linked to graphics software which displayed the location of each item on an overlay of the site plot plan. Each container in the data base was displayed as a single character, such as "D" for a drum or "G" for a gas cylinder. The color of each character showed whether the container was open (empty), closed or of unknown status. The real-time positions of the mobile vehicles also were superimposed on this display and used for navigation.

CLOSURE WORK

Two remotely operated vehicles were used for closure work at KHQ. All personnel were required to stay well back and around the shoulder of a hill during closure tasks to insure their safety. In addition to handling containers, the vehicles installed, operated, maintained, decontaminated and removed special purpose equipment including the metal shredder. The small remotely operated vehicle performed light work tasks such as handling empty 5-gallon buckets. The large remotely operated vehicle with its 15-ton lift capability installed the metal shredder, handled heavy containers and deployed the dredge system. Control consoles for the vehicles and other equipment were in a control van located approximately 300 feet from the hazardous area and around the shoulder of a hill.

Some of the more pertinent closure tasks are listed in Table 2. All tasks were done exclusively with remotely operated equipment. The job was made more difficult by the need to do much of the work underwater where visibility was poor, electrical equipment required waterproof containers and practical methods of sensing and telemetry are severely limited. Pressure compensation was needed for the hydraulic systems, and special precautions were needed to prevent leakage of hydraulic fluid and lubricants into the water. In most other regards, the work was similar to work on dry land.

Table 2
Closure Tasks

```
Breach and recover gas cylinders

Collect and shred drums and buckets

Clean and inspect containers

Breach large pressure vessels with explosive charges

- Remove and inspect all containers and materials

- Move containers to approved landfill

- Dredge and store sediment

Recover small containers exposed by dredging

Do a final inspection of site

Decontaminate and recover equipment

Prepare closure documentation
```

CLOSURE FACILITIES

Temporary facilities were installed to support closure work. Twenty-foot vans were set approximately 300 feet from the hazardous area to house the control consoles and provide work space and storage for supplies. An office van was parked near the gate in the security fence surrounding the site.

A PVC-lined sediment storage facility, shown in Figure 2, was built to hold approximately 150,000 ft^3 of sediment and dredge water. A

gravity flow pipeline was installed to return clarified dredge water from the sediment storage area

Figure 2
PVC-lined Sediment Storage Area
Shown During Construction

Five video cameras were used for fulltime surveillance of the restricted area. A public address system provided voice communication, and an alarm output of the gas monitoring system was connected directly to the public address system. Sensors for the gas monitor were installed on the large mobile vehicle and around the site perimeter.

EQUIPMENT

Use of existing designs and equipment made it possible to go from concept to full operation on-site in 4 months. Systems were assembled at Sonsub's Houston facility and delivered by dedicated trucks. The mobile vehicles were deployed first and then used to install freestanding equipment such as the acoustic transceivers and the metal shredder. Equipment used included:

- Small remotely operated vehicle
- Large remotely operated vehicle
- Dredge system
- Gas cylinder breacher
- Metal shredder
- Collection baskets
- Acoustic tracking system
- Data management system.

This equipment is described below.

Small Remotely Operated Vehicle

The small vehicle, shown in Figure 3, is one of several owned and operated by Sonsub. It is approximately 6 feet long and weighs about 1,000 pounds. It carries video cameras, lights, sonar, gyrocompass, instrumentation suite and a six-function manipulator. Table 3 is a partial list of manipulator tasks performed by the small vehicle.

The vehicle is operated from consoles in the control van, as shown in Figure 4. Vehicle motion is controlled by a helicopter type joy stick. The spatially correspondent manipulator is controlled from a master arm mounted on the console. Instrument dials, video displays and the acoustic tracking system display also are mounted in the console.

Large Remotely Operated Vehicle

The large remotely operated vehicle provided heavy lift capability and, as shown in Figure 5, deployed the dredge system. Table 4 shows typical tasks performed by the large vehicle. It can lift loads up to 15 tons. A 60-horsepower electrohydraulic unit provides power for

propulsion and lifting. Separate electric motors on the vehicle provide power for dredging.

Figure 3
Small Remotely-operated Vehicle

Table 3
Small Vehicle Manipulator Tasks

- Set and recovering acoustic navigation transceivers
- Take sediment samples
- Set shaped charges for breaching
- Recover 5-gallon buckets and smaller containers
- Set and release latches on shredder hopper
- Rig lines and connect slings for:
- Installation and recovery of shredder
- Placement and recovery of shredder hopper
- Routine recovery of chip collection basket
- Contingency control
- Recovery of 500 gallon containers
- Operate tubing cutter
- Latch/unlatch shredder modules
- Clear jams from metal shredder
- Decontamination
- Clean containers with water jet
- Clean dredge head before recovery
- Clean shredder before recovery

The large vehicle has a control console similar to that described for the small vehicle. Automatic control functions enable it to return to a specific location, such as a collection basket, upon command. The automatic station keeping feature overcomes load forces and keeps the vehicle on station while working. Lights and multiple video cameras make the vehicle suitable for 24 hr/day operation.

Its grapple type hand, shown in Figure 5, was used to lift and carry large steel containers, collection baskets and heavy tools such as the gas cylinder breacher. For dredging, the grapple tool was removed and a 60-foot boom with a dredging head was installed on the large vehicle.

Figure 4
Control Consoles for Remotely-operated Vehicle

Figure 5
Large Remotely-operated Vehicle Fitted with Dredge Boom

Table 4
Large Vehicle Lifting and Positioning Tasks

- Install shredder
- Transport shredder modules
- Assemble shredder modules
- Acquire and breach gas cylinders
- Lift and carry
- Large containers
- Container collection baskets
- Shredder chip collection basket
- Deploy dredge system
- Provide dredge power
- Position suction head
- Place restraint net in breaching area

Gas Cylinder Breaching Tools

All gas cylinders required breaching to vent any internal pressure before recovery. A freestanding tool was built to make a hole in each cylinder. The large remotely operated vehicle transported and installed the freestanding breaching device which accepted gas cylinders and punched a one inch diameter hole in them. The breaching function was incorporated into the grapple shown in Figure 5 when poor visibility made it difficult to recover gas cylinders from the freestanding breaching device.

Figure 6
Grapple Used by Large Remotely Operated Vehicle for Grasping and Carrying Large Containers

After being breached, gas cylinders were placed in a collection basket and lifted out of the quarry in batches. They were then examined by a health physics specialist and transported to approved landfills.

Metal Shredder

A 200-horsepower metal shredder reduced most containers to steel chips to help insure that any residual explosive materials in the containers would be fully reacted before recovery. The shredder was installed by the remotely operated vehicles. The vehicles prepared an area in the deepest part of the quarry by removing all containers and dredging down to rock. The large vehicle carried the shredder stand, set it in the prepared area, and leveled it. It then carried the 26,000-pound cutter assembly and set it on the stand, while the small vehicle provided observation and alignment. This procedure was repeated to set the hopper atop the shredder and place the hydraulic hoses.

The vehicles then gathered waste containers and placed them in collection baskets. The small vehicle gathered 5-gallon cans and smaller containers while the large vehicle gathered drums, steel boxes, pipe sections and other large items. Large containers were inspected to avoid introduction of large quantities of explosives into the shredder. When the collection basket was full, the large vehicle carried it to the shredder and dumped it into the shredder hopper. Chips from the shredder fell into a basket which the large vehicle periodically carried to a location

from which the basket could be recovered by crane.

When shredding operations were complete, the small vehicle cleaned and inspected the shredder and hopper and made it safe for removal. The large vehicle then carried each module to a location from which it could be recovered by crane.

PYROTECHNIC BREACHING PROCEDURE

The larger, heavy walled containers exceeded the shredder capability. The large vehicle carried these to a special breaching area and covered them individually with a restraint net. The small vehicle then placed explosive charges at several points on the container to burn holes through which the water could react with any contents. The small vehicle then inspected the containers and the large vehicle carried them to a location from which they could be recovered by crane. The small vehicle attached sling lines and engaged the slings to the crane hook.

ACOUSTIC POSITIONING SYSTEM

The size of the quarry and the poor visibility made it necessary to use an acoustic system to show the precise locations of the containers, freestanding equipment such as the shredder and the mobile vehicles. Transceivers, installed by the small vehicle, sent acoustic signals to each other and measured the transmission time. The acoustic system computer used the transmission times and the known speed of sound to calculate the relative positions of the transceivers. With this grid as a reference, the computer could then calculate the position of transceivers on each mobile vehicle twice per second and feed the coordinates to the displays and to the automatic control systems.

DREDGING

After the larger containers had been removed, the sediment was dredged away to expose small containers. The dredge system met three unusual requirements.

- Precision capability to clean around rocks and in cracks
- Fully remote operation
- Ability to exclude any item over 0.5 inches in diameter to insure that no small explosive items would be carried to the sediment storage area

Dredge pumps were set well below the water surface to increase the suction head. Pump intakes were connected to a self-cleaning intake grill with 0.5 inch openings, and the grill was mounted on an articulated boom on the large vehicle. Intake grill position was controlled by positioning the vehicle and moving the boom. An acoustic transceiver on the intake grill tracked its position and provided records to show 100% coverage.

Discharge hoses ran up to a temporary sediment storage facility on the hillside above the quarry. As shown in Figure 1, the storage facility was a specially constructed, PVC lined earthen berm with 150,000 ft³ capacity. Dredge water was clarified and returned to the quarry by gravity flow.

FINAL INSPECTION

Primary documentation required for closure is 100% video survey of the site with resolution adequate to detect any manmade item of 0.5 inch diameter or larger. This survey will be conducted in much the same manner as the 1989 preclosure survey, with three video cameras mounted vertically on the small vehicle with overlapping fields of view. When held 2 to 3 feet high, they provided an 8-foot wide composite view.

The vehicle moves slowly along parallel grid lines to perform the survey. The acoustic system provides real-time feedback of vehicle position as an aid to the operator and coordinates are recorded to the computer disk. These coordinates are traced onto a plot plan of the site to provide documentation of 100% coverage. The date and time also are recorded with each coordinate change. This survey technique provides convenient cross reference to the video tapes which were filed by date and time of recording.

Video tape records of all survey video were required as closure documentation. On-screen annotation shows the camera number, date, time and precise coordinates as the camera moves. This provides convenient cross reference to other records.

DATA MANAGEMENT AND GRAPHICS DISPLAYS

The system makes extensive use of high end personal computers for vehicle navigation, telemetry, alarms, automatic control, data management and efficiency enhancement.

As part of the survey work in 1989, a data base was created to show the location and description of piles and scattered containers. The data base was linked to mapping software which displays the site perimeter and the location of each container. The zoom feature can expand any sector to fill the screen.

The full data base record of any container is shown in a window on this display when the operator clicks the computer "mouse" on the corresponding item. When any work is performed on a container, the computer operator updates the data base by entering simple two character codes to show breaching, inspection, transport to collection basket, or recovery for transport to landfill. The computer then automatically updates the data base with date, time and, if appropriate, the new coordinates of the container. When a container is made safe and removed the computer prints its history on a certificate of removal.

All breaching was video taped. Annotation on the video recording shows the date, time, camera number and X,Y coordinates of the vehicle carrying the camera. All video tape was filed according to the date and time it was taken. The information in the data base (or on the removal certificates) can now be used to quickly locate any item of interest in the nearly two thousand hours of video tape.

SAFETY PLAN

A Safety Assessment, conducted by Y-12 during 1988 and 1989, evaluated whether containers in KHQ could be moved while ensuring the protection of human health and environment. The remote vehicle approach to closure work was selected partially as a result of this assessment. A more detailed safety assessment and safety plan were prepared after Sonsub was selected as the closure contractor and the details of closure work had been defined.

The work involved handling potentially explosive wastes, but the exclusive use of telerobotic equipment in the hazardous area greatly reduced the necessary scope of provisions for health and safety. Primary safety concerns were for construction site hazards common to operations in remote, wooded hillside areas. Other concerns included projectiles and gases released during neutralization of containers in the hazardous area.

A central gas monitoring system used sensors on the remotely operated equipment and at locations around the perimeter of the hazardous area. In addition, all personnel were required to be inside the steel control vans during routine breaching and shredding operations and all personnel were required to fall back to a remote area during breaching with explosive charges. Gas monitor alarms were connected directly to the sitewide public address system. Readings from each monitor were automatically logged at 5-minute intervals and more frequently in the event of an alarm condition.

FUTURE APPLICATIONS

The closure work at KHQ proved the practicality and advantages of using remotely operated systems for environmental restoration. The KHQ project was made more difficult by the need to perform much of the work underwater where visibility is poor, telemetry techniques are limited and special provisions are needed to insure reliability of equipment.

The principles and equipment used at KHQ are directly applicable to many other sites which present hazards to workers. Prime examples include sites with toxic chemical or toxic gas environments, radioactive wastes or explosive wastes.

Sheet Pile Barrier Walls as an Alternative to Slurry Walls for Temporary Containment Actions at Hazardous Waste Sites

Randall W. Grachek, P.E.
U.S. Army Corps of Engineers—Omaha District
Omaha, Nebraska

Gregory Johnson, P.E., CHMM
EA Engineering, Science, and Technology, Inc.
Sparks, Maryland

ABSTRACT

A common technology for temporary waste containment and ground-water flow diversion at Superfund and other hazardous waste sites is the subsurface barrier wall. In most cases, the wall has been constructed from a soil-bentonite-concrete slurry. These walls are effective for most conditions, but sometimes are subject to constructability, cost and compatibility problems.

This paper presents a case study of the use of an interlocking sheet pile barrier wall for containment and demonstrates both the technical and economic advantages of this approach.

INTRODUCTION

Under certain site conditions, a sealed sheet pile barrier wall offers advantages over slurry walls for containment at uncontrolled hazardous waste sites. Such a wall was used at the Southern Maryland Wood Treatment (SMWT) Superfund site to contain soil and groundwater contaminated with creosote, pentachlorophenol and other wood preserving chemicals. The wall was used to overcome site constraints related to steep grades, structural considerations, dewatering, chemical compatibility and ultimate disposal/reuse of wall materials.

BACKGROUND

The U.S. EPA, Region III, performed a RI/FS at the SMWT site. The RI/FS identified remediation alternatives which were rated based on their applicability, implementability, cost-effectiveness and other criteria as defined in the U.S. EPA's NCP.

ROD, signed in June 1988, provided for on-site thermal treatment of contaminated soils and tank liquids; treatment of contaminated groundwater by ultraviolet radiation and ozone or carbon adsorption; demolition of existing process buildings and facilities; and installation of a barrier wall to limit contaminant migration and to facilitate dewatering.

In October 1988 it was determined that the project would be designed and implemented in two phases (operable units). Operable Unit 1 (OU1) consisted of the design and installation of the barrier wall and a vehicle decontamination facility. Under Operable Unit 2 (OU2), the contained area will be dewatered, and contaminated soil within the barrier wall will be excavated and incinerated at an on-site thermal treatment facility.

Remedial design for OU1 was initiated in December 1988 when the U.S. Army Corps of Engineers (USACE)—Omaha District, under a working relationship with U.S. EPA, developed a scope of work for remedial design. USACE—Omaha retained EA Engineering, Science and Technology to implement this work scope. Construction for OU1 was initiated in January 1990 and was scheduled for completion in September 1990.

SITE DESCRIPTION

Physical Conditions

The SMWT site is located off Route 235 in Hollywood, St. Mary's County, Maryland (Fig. 1). The site comprises approximately 25 acres in the northwest portion of a 96-acre property. Approximately 4 acres were previously devoted to a wood treatment operation. The site is surrounded by residential and agricultural areas. Site elevations range from approximately 119 to 154 ft above mean sea level and run-off is to tributaries on the east and west which discharge to the Potomac River via Brooks Run and McIntosh Run.
Figure 1
Location Map-Southern Maryland
Wood Treating Site

Site History and Use

The SMWT facility was owned and operated by Southern Maryland Wood Treating Co. from 1965 to 1978 as a pressure treatment facility for wood products. Locations of various features, structures and surface waterbodies, as well as the property boundary, are shown in Figure 2. Creosote and pentachlorophenol (PCP) were used as wood preservatives during the facility's active period. Wastes generated included retort and cylinder sludges, process wastes and material spillage. These wastes were placed in six unlined lagoons south of the process area.

Contamination of an on-site freshwater pond with VOCs, PAHs and other organic contaminants prompted legal proceedings by the Maryland Department of Health and Mental Hygiene. Pursuant to these pro-

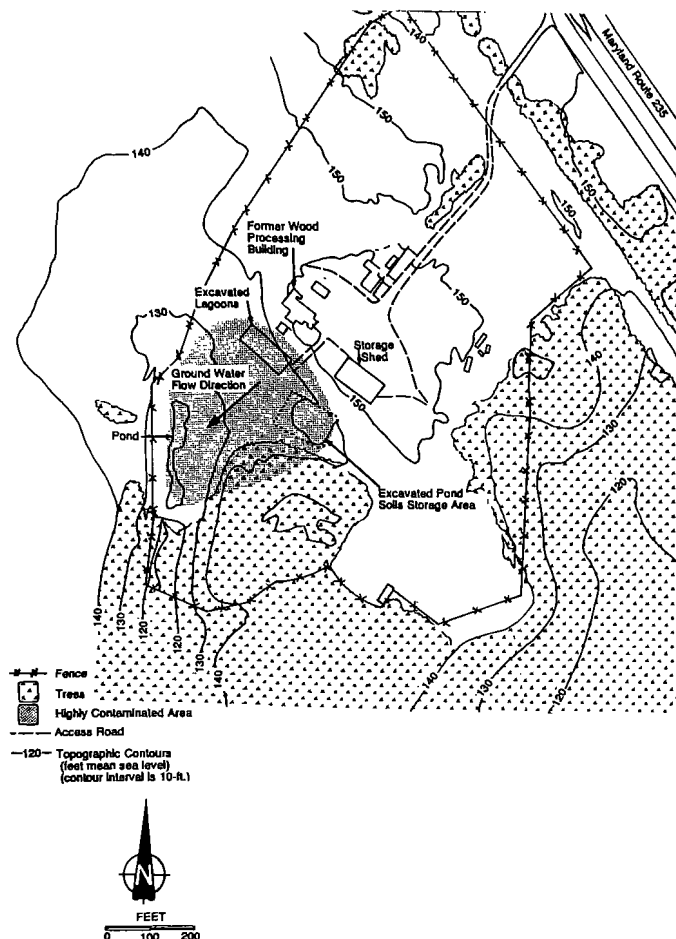
ceedings, the PRP, L.A. Clarke and Sons, Inc., initiated cleanup actions in 1982. Liquids from the lagoons were spray-irrigated onto the nearby woods. The six waste lagoons were excavated, and the area was backfilled and graded. The freshwater pond was partially excavated. Excavated sludges were mixed with composted sludge, topsoil and grass seed, then spread in a level treatment area on the property.


Figure 2
Existing Site Conditions (Sept. 1989)

Geology/Hydrology

The site lies within the Atlantic Coastal Plain physiographic province which consists of unconsolidated gravel, sand, silt and clay deposits ranging in age from Cretaceous to Holocene. The thickness of unconsolidated sedimentary deposits at the site is estimated to be 3,500 ft. Figure 3 shows the geologic profile at the SMWT site.

The region of primary interest with respect to OU1 is confined to the upper 30-60 ft of strata where saturated sandy Pleistocene and Holocene age Upland Deposits have been contaminated. The water-table aquifer in the Upland Deposits is a source of drinking water and provides recharge to streams and other surface waterbodies. The Upland Deposits are underlain by a 20-ft-thick blue clay layer known as the St. Mary's Formation. Physical testing of soil samples from this zone indicates that it functions as a competent confining layer between the Upland Deposits and the underlying Piney Point—Nanjemoy Formation with a permeability ranging from 3×10^{-8} to 1×10^{-7} cm/sec.

Contaminants/Pathways

Primary contaminants at the site include creosote and PCP in both the soil and groundwater within the Upland Deposits. Other soil contaminants include polyaromatic hydrocarbons (PAHs), acetone, benzene,

toluene, ethyl, benzene, xylene (BTEX) and dioxins. Other ground-water contaminants include BTEX, PAHs and phenols. On-site surface water also is contaminated, most notably in the drainage pond at the southwest corner of the site.

Contaminant transport is primarily via groundwater flowing laterally through the Upland Deposits in a southward direction. Vertical transport is impeded by the St. Mary's clay.
Figure 3
Geologic Profile at SMWT Superfund Site

GENERAL APPROACH

The General Approach to site remediation was predicated on consistency with the NCP and other state and local applicable or relevant and appropriate requirements (ARARs). Throughout the remedial process, the U.S. EPA, State of Maryland and local requirements were applied to site characteristics to formulate remedial action objectives and alternatives.

Value Engineering Considerations

Army Corps of Engineers regulations require the preparation of a Value Engineering (VE) Report to evaluate items in the design criteria that may result in cost savings. For this site, the major subject of the VE Report was the type of barrier wall to be implemented. While the feasibility study concentrated on various combinations of soil-bentonite-concrete slurry walls, the evaluation in the VE Report indicated various difficulties with such walls:

* Site slopes were not suitable for slurry wall construction without implementing significant benching and regrading activities
* For this project, the barrier would need to be a structural wall so that it could be free-standing during soil excavation activities planned for OU2
* Data indicated that soil-bentonite-concrete materials are particularly nonresistant to chemical attack by various site contaminants (creosote, PCP, etc.)
* Since the barrier wall would become contaminated prior to final remedial action, the cost of removal and disposal of the wall materials must be considered
* It was estimated that a structural slurry wall for this site would cost in the range of $7,000,000 to $8,000,000 and would still likely be subject to chemical attack

By comparison, interlocking "Z" section sheet piles offered the following advantages:

- Using tie-backs at selected locations, sheet piles can be utilized to produce a structural wall for excavation purposes
- Sheet piles can be installed on highly sloped surfaces and eliminate the concerns of bridging
- Sheet piles did not exhibit susceptibility to chemical attack inherent in slurry wall implementation
- Sheet pile walls can be easily removed after the completion of the final remedial action, decontaminated and reused
- Sheet piles are relatively more impermeable than slurry walls. (The vast majority of the sheet pile surface area is impermeable, with use of a joint sealant further minimizing potential for leakage through the wall. A slurry wall's entire surface area is permeable and will allow low-rate flow through a large surface area. Calculations indicated that the actual throughput volume of water penetrating the sheet pile wall will be less than through a low permeability slurry wall.)
- This site is particularly suited for sheet piles because a competent, consistent clay layer is available for embedment of the piles
- The cost of the sheet pile barrier wall/decontamination facility was estimated to be approximately $2,600,000 (a considerable savings over a structural slurry wall)
- Design and predesign costs are considerably lower utilizing a sheet pile wall

Based upon the above, the VE Report recommended a sheet pile barrier wall as a constructible, lower cost and technically appropriate alternative to a slurry wall for the site conditions at SMWT.

Regulatory and Statutory Considerations

Under SARA, the U.S. EPA was required to initiate remedial construction on 175 new sites between October 1986 and October 1989. This project was chosen as one these "SARA 175" starts, thus resulting in an extremely tight design and award schedule. Due to this schedule and since use of sheet piles as a hazardous waste containment system is relatively unique, it was essential that the U.S. EPA and State of Maryland concurrence be obtained at the earliest possible time. In numerous consultations with representatives of the U.S. EPA Region III and the Maryland Department of the Environment, design objectives, details and the merits of the sheet pile wall were discussed. Both the U.S. EPA and the State of Maryland were provided review copies of preliminary and final design documents and comments were received and incorporated as appropriate. A cooperative effort on the part of all regulatory agencies involved and general concurrence with the design rationale greatly aided in a successful design and award of a construction contract on Sept. 30, 1989, thus meeting both the Oct. 16, 1989 SARA mandate and the fiscal year 1989 deadline.

Design Considerations

The design of the sheet pile barrier wall system was driven by a number of variables. Important considerations included containment of the most highly contaminated portion of the site and design of a vertical perimeter barrier which would be consistent with final remedial action. The design phase included predesign site characterization studies and detailed engineering design. Since the project was conducted for the Army Corps of Engineers, design deliverables included construction plans and specifications, a Design Analysis report, a government cost estimate, a submittal list and a bid form. Three design submissions (30, 90 and 100 percent) were used to assure sufficient opportunity for review comments from interested parties.

DESIGN APPROACH

Many factors were major considerations in developing the final design for OU1 of the SWMT site. The following sections describe some of the key design considerations associated with this project.

Alignment

Several concerns were noted with respect to the wall alignment identified in the ROD. The first concern had to do with slope stability and

the foundations of existing structures. In order to protect foundations of existing structures, it was recommended that the wall alignment be moved north of the existing structures. This resulted in a relatively flat alignment (<4 percent) along most of the north section of the barrier wall and protection of the structures within the contained area. Another concern related to relatively steep grades (6-10 percent) encountered along the east and west sections of the barrier wall. Use of a slurry wall barrier in these areas would have required extensive regrading and benching to create the appropriately sloped work platforms needed for slurry wall construction. Driving sheet piles in these areas did not present similar problems.

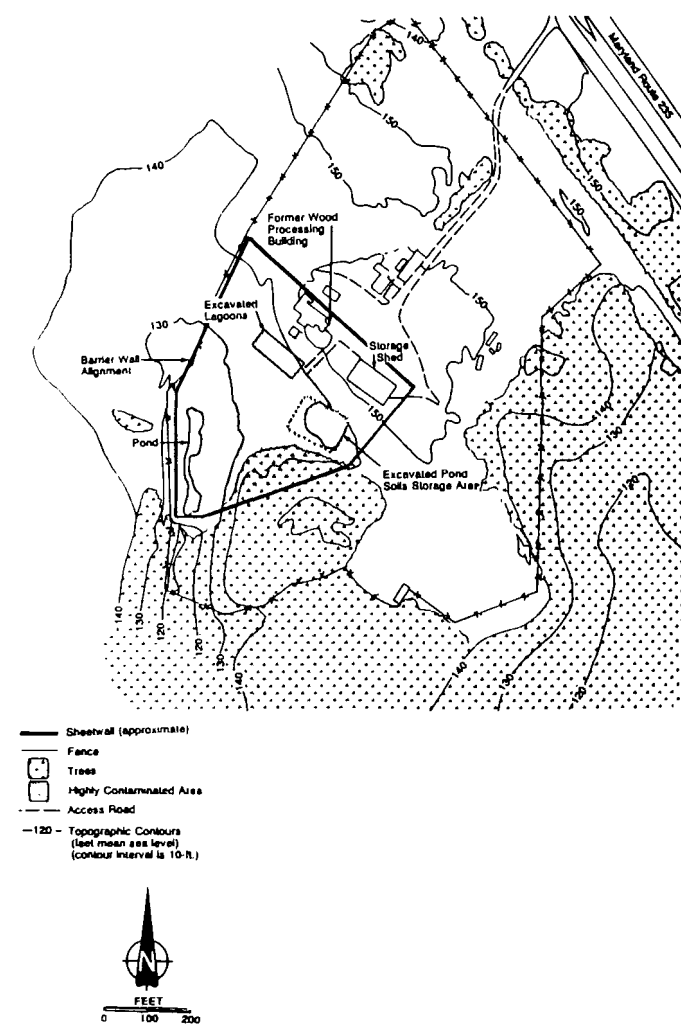
Another alignment consideration was the proximity of contamination to other property owners west of the site and the location of the drainage pond in the southwest corner of the site. As a result, the barrier wall had to be located as close as possible to the property line to prevent contaminant migration to other properties. In addition, the wall needed to have structural integrity to remain intact during excavation activities to be conducted in OU2. This alignment consideration once again pointed toward a sheet pile barrier wall as a logical approach. The final wall alignment is shown in Figure 4.


Figure 4
Sheet Pile Barrier Wall Alignment

Probably the most significant alignment consideration was the necessity to design a free-standing structural barrier wall. Excavation activities in the southern and western portions of the site will remove soil right up to the limits of the wall. In order to allow excavation up to this limit, the wall must be able to prevent soil or groundwater from

the other side of the wall from impacting the excavation. A sheet pile barrier wall will effectively satisfy these conditions. If a slurry wall was used, it would be necessary to relocate the wall alignment beyond the existing limits since slurry walls cannot withstand lateral soil pressures to as great a degree as sheet pile walls.

Materials

Once it was determined that a sheet pile barrier wall would be used, it was necessary to identify the size, shape and type of steel sections to be used and the approach to sealing the piles in place. The preliminary design indicated that interlocking steel "Z" section piles would be most appropriate for site conditions. The sizing of the "Z" sections required geotechnical characterization of the wall alignment and concern for wall integrity required that the steel be subjected to contaminated liquid from the site to determine chemical compatibility.

Interlock Sealing

The issue of interlock sealing was considered at length. Various approaches were considered including pressure injecting grout into the interlock, both during and after driving and coating the interlock with a sealant prior to driving. Based upon chemical contamination concerns, it was felt that a bentonite grout mixture would be most appropriate. The project specifications did not specifically identify a grout material or procedure, but left the selection to the Contractor as a submittal item to encourage creativity. In retrospect, it would have been preferable to clearly specify the grout material and procedure to be used.

Sizing of "Z" Sections

A geotechnical site characterization program was conducted in April 1989 to examine subsurface conditions along the proposed wall alignment. The program consisted of drilling boreholes every 200 ft along the wall alignment. Continuous samples were collected using a 2-in. diameter split-barrel sampler (ASTM D-1557) and blow counts were recorded for each 6-in. penetration of the sampler. Two to three samples were selected from each boring for physical soils testing which included sieve analysis (ASTM D-422), hydrometer analysis (ASTM D-422), Atterburg limits (ASTM 4318), natural moisture content (ASTM D 2216), specific gravity (ASTM D2216) and USCS Classification (ASTM D2488). All other samples usually were classified in accordance with the Unified Soil Classification System (USCS) nomenclature.

Other geotechnical testing conducted to better characterize the St. Mary's clay included collecting 2-in. diameter Shelby tube samples from within the clay layer. A total of 20 samples was collected and tested for unconfined compression. Of these samples, three were also subjected to triaxial shear testing. The results of these soil characterization tests were used to design the steel sheet pile sections. It was calculated that a "Z" section comparable to the Bethlehem Steel PZ35 would be required (maximum design stress = 25,350 psi).

Compatibility Testing

Corrosion testing in accordance with U.S. EPA Method 1110 was conducted to examine potential impacts of contaminated groundwater on the barrier wall. Steel coupons, obtained from the sheet pile manufacturer, were immersed in contaminated groundwater collected from on-site monitoring wells. Two separate groundwater samples were used for compatibility testing. Test results indicated that the steel corrosion rate when immersed in contaminated groundwater was less than 7 mil per year (0.007 in./yr). This rate is considered to be an acceptable corrosion rate in accordance with U.S. EPA Method 1110.

Tie Backs

The wall alignment and depth of pile embedment were designed to minimize the need for tie-backs during OU2 excavation activities. In general, the wall was designed as a cantilevered retaining wall with a depth of embedment of approximately 11.5 ft Greater depth of embedment was avoided to prevent puncture of the St. Mary's clay. Structural calculations indicated a maximum allowable freestanding cantilever section length of 13.4 ft for most of the site; this design will not impact excavation activities. However, along the western section of the wall,

where depth to clay is up to 40 ft and excavation will be conducted right up to the wall, it will be necessary to provide tie-backs. A preliminary design was performed to locate tie-backs. Detailed design was delayed until OU2 when the limits and procedures for excavation are more clearly defined.

Disposal

The final issue considered is ultimate disposition of the barrier wall. According to the ROD, the barrier wall is intended to be a temporary, not permanent, remedy. As such, it will need to be removed at the conclusion of OU2 to allow reestablishment of local groundwater flow patterns. By using a sheet pile barrier wall, it will be relatively easy to remove the barrier wall after it is no longer needed. The steel "Z" sections could then be decontaminated and reused. Other types of low permeability barrier walls, such as sheet pile walls, would need to be excavated and disposed of as contaminated soil with no potential for subsequent reuse.

IMPLEMENTATION

The implementation of the OU1 remedial action at this site involved the construction of the sheet pile barrier wall and a permanent decontamination facility. The bid price for the installation of this wall was $1,383,113. With site preparation, decontamination facility, contaminant containment, site maintenance and miscellaneous costs the total bid price for the project was $2,599,852.

For the most part, the construction proceeded as planned starting with the construction Contractor developing the work plans required for construction at an NPL site. These plans include a Site Health and Safety Plan, Chemical Quality Control Plan, Site Construction Quality Control Plan and other documents. Upon Corps of Engineers approval of these documents in December 1989, the contractor began work. By August 1990, the vast majority of the piles had been installed and the decontamination facility and appurtenant facilities were in place. The expected construction time for this project was 6 months.

Successes

The primary objective of the OU1 barrier wall was to contain the contaminated soil and groundwater south of the process buildings at the SMWT site until OU2 excavation and removal actions are initiated. The barrier wall was designed to minimize infiltration both into and out of the contaminated area, thus minimizing potential contaminant transport. Predesign studies indicated that a sealed sheet pile barrier wall would effectively satisfy these objectives. Post-action inspection of the construction indicates that the sealed sheet pile is effectively providing a barrier to subsurface flow through the watertable aquifer and is effectively containing the contaminated material at the SMWT site.

A major success in the project implementation was the relative ease with which the design was translated into construction. The decontamination facility was constructed without change, and most of the sheet pile wall was installed using the minimum driving force. Above all, the measure of success on this project can be characterized best by the cooperative effort on this project between the federal and state government, the architect-engineer and the construction contractor to provide an innovative, cost-effective and timely remedial action. The remedial action met regulatory and statutory requirements, met the SARA mandate requirement and was highly cost-effective.

Lessons Learned

Many lessons can be drawn from this project. Various operational difficulties with driving sheet piles on a fixed-price contract became apparent. However, none of these difficulties was insurmountable. The major problem involved approximately 80 piles that could not be driven, with either a vibratory hammer or a large impact hammer. Apparently, a combination of high soil density and subsurface anomalies contributed to this problem. The problem was resolved by drilling an 8-in. auger boring at each sheet pile joint at an angle allowing the boring to reach underneath the undriven pile. This process reduces soil density and allows for complete driving of the piles. This increased the cost of the

overall installation by approximately $500,000. The lesson learned here is that contingencies need to be built into fund allocations for these types of projects to make adjustments when site conditions merit.

Adequate time should be allowed to perform geotechnical borings along the expected perimeter of the wall prior to design so that pile size, driving force and type of driver can be appropriately evaluated.

Prior to on-site work under the construction contract, a local business had to be moved outside the property so as not to interfere with the remedial action. Also, a temporary construction easement to allow use of a small strip of property on the south and west side of the site had to be acquired to facilitate construction. The lesson learned is that it is very important that real estate concerns be addressed early in predesign or design so that site access is not affected.

Finally, sufficient time must be provided for design. Reasonable time schedules facilitate better design and greater cost-effectiveness.

CONCLUSIONS

The use of an interlocking "Z" section steel sheet pile barrier wall was found to be an effective approach to containment of contaminated soil and groundwater at the Southern Maryland Wood Treatment Superfund site. The sheet pile barrier wall was implemented to overcome constructability, cost and compatibility concerns identified with use of a soil-bentonite-concrete slurry wall at the site. Factors that may influence selection of a sealed sheet pile barrier wall over a slurry wall include structural integrity, chemical compatibility, constructability, property access constraints, cost and compatibility with the final remedy. Based upon experience at the SMWT Superfund site, the sheet pile barrier wall offers a constructible, cost-effective and technically sound option to the traditional slurry wall for temporary containment at hazardous waste sites.

Site Safety Equipment: Moving Towards Improved Protection

ABSTRACT

The Final Rule of OSHA's Hazardous Waste Operations and Emergency Response regulation became effective in March 1990. The Interim Rule of that regulation had been in effect since 1986. Although this regulation has been in effect for four years and Superfund for ten years (since December 1980), only minor advancements have been made in site safety equipment for hazardous waste site workers. This paper discusses advancements and refinements in air quality monitoring techniques and personal protective equipment that would enhance the safety of workers in the hazardous waste industry. Limitations of available site safety equipment also are highlighted.

INTRODUCTION

Employees working with hazardous waste may be exposed to hazardous materials primarily through two routes: skin contact and inhalation. Skin contact is prevented or minimized by requiring employees to wear chemical protective clothing. Inhalation of hazardous materials is prevented or minimized by testing the ambient air for the presence of air contaminants and by requiring employees to wear respirators.

Unfortunately, these protective measures are not fail-safe. Chemicals can permeate gloves and other chemical protective clothing. Air purifying respirators may leak around the face seal: moreover, they do not completely filter all air contaminants. Gas detection devices are not ideally designed for use at sites where the air contaminants and concentrations are unknown.

In late 1980, the Surgeon General of the United States reported to the U.S. Senate Committee on Environment and the Public Works Committee on exposure to toxic chemicals. The Surgeon General's report emphasized: (1) the lack of scientific methods for evaluating the health effects of chemical waste dumps on human health, including the lack of adequate tests to evaluate the effects of chemicals in human populations; (2)the lack of data and experience in testing mixtures of chemicals for potential health effects; (3) the lack of information identifying complex mixtures of chemicals; and (4) the lack of ways for dealing with the time lag between chemical exposure and the manifestation of health effects.[1] Although advancements have been made since the Surgeon General's report, there is still much room for improvement. This paper briefly discusses improvements in air quality monitoring techniques and personal protective equipment that would provide increased protection for hazardous waste site employees.

AIR QUALITY MONITORING

Industrial hygiene monitoring for air quality employs two basic techniques. The first is the use of direct-reading instruments. These instruments must be calibrated to respond accurately to a limited number of chemicals. Direct-reading instruments respond quantitatively, are generally used for acute-acting toxic substances and generally have both a visual and an audible alarm system for predetermined concentration(s) of the chemical substance(s).

The second technique requires laboratory analysis of samples which are obtained with collection devices. The collection device may be a Tedlar or similarly constructed bag, a filter, a solid sorbent, or a liquid sorbent. Both techniques require accurate identification of the air contaminants in order to be most useful.[2] For example, when using a direct-reading instrument that measures only carbon monoxide, other chemicals will not be analyzed. Also, a laboratory will analyze only the chemicals for which tests were requested. Therefore, unknown chemicals on a site may remain undetected, creating a potentially hazardous situation for the workers who may be exposed to those chemicals.

Instruments most commonly used to screen atmospheres containing both known and unknown organic contaminants are the flame ionization detector (FID) and the photoionization detector (PID). A combined O_2/LEL meter, otherwise known as an oxygen/combustible gas indicator, is used in confined spaces.

The PID is relatively simple to use but has a limited application, since it yields total concentration of many organic and some inorganic compounds present in the atmosphere. Because only the total concentration of vapors present is provided, it is difficult to determine the concentration of a particular substance. In practical terms, this means that if two substances are present in the atmosphere, one with an exposure limit of 50 ppm, the other with an exposure limit of 1,000 ppm, a PID reading of 200 ppm is inconclusive with respect to the need for personal protective equipment. The use of air-purifying respirators would be required in that situation, since an overexposure is likely.

In the above situation, detector tubes help to determine the approximate concentrations of the two substances. The results of a detector tube test would show whether respirators were required in that situation. But it is a rare site that has only two air contaminants.

Another potential problem with the PID is that the instrument uses lamps of certain energies to detect air contaminants. Often, only one lamp is brought onto a site. The lamp that is used to detect petroleum hydrocarbons such as gasoline (10.2eV) will not accurately detect the presence of chlorinated hydrocarbons.

The FID operated in the survey mode also provides a total organic vapor reading. Unlike the PID, the FID can also be operated in the gas chromatography (GC) mode. In the GC mode, the instrument is capable of identifying and measuring the concentrations of specific organic gases and vapors. However, the GC mode requires a higher level of expertise than many users have. As a result, the FID is usually operated in the survey mode, which provides nearly the same information as the PID.[2]

The following case example discusses the monitoring of hazardous

waste workers at a dumpsite. The industrial hygienist on this site has records of 113 hazardous materials that were disposed at the site. Many of those 113 materials have most likely decomposed to other substances. Other chemicals were probably disposed at the site, but how many and which ones are unknown since the records are incomplete.[3]

The industrial hygienist is able to determine with the records that 32 chemicals plus 21 decomposition products are the most likely substances to be present in significant concentrations. Of those 53 chemicals, 38 can be tested with grab sample detector tubes at a cost of $6.00 per test. Eight of the 15 remaining chemicals can be analyzed in one week using standard methods at a cost of $30.00 per substance. The remaining seven chemicals require special analytical work that will take three weeks to complete at a cost of $100.00 per substance. The other chemicals, present in insignificant concentrations, must be analyzed with a general adsorbent grab sample tube at a cost of $200.00. The total analytical cost is $1,368; the total elapsed time is four weeks.[3]

On-site safety would be significantly improved if air monitoring techniques were developed to provide on-site results for all substances. By making grab sampler detector tubes available for more substances and increasing their accuracy, many of the analyses currently done in a laboratory could be done on-site, reducing costs and lag time.[3]

NIOSH successfully used the SDRITS (the Simultaneous Direct Reading Indicator Tube System) to monitor for acutely toxic concentrations of chemical substances when performing Health Hazard Evaluations. The SDRITS uses battery-operated pumps to draw air through ten indicator tubes simultaneously. This system, or a similar one, used in conjunction with other direct-reading instruments may provide the needed on-site air quality information.[4]

Screening techniques currently used on the gas chromatograph/mass spectrophotometer to analyze unknown organic chemicals need to be improved. This procedure is very expensive ($400 - 800 per test), must be done off-site and typically cannot positively identify many of the substances that are present. Wide spectrum, on-site screening techniques for unspecified substances would protect workers from potential exposures to hazardous chemicals of which the industrial hygienist is unaware. Also, low-cost direct-reading monitors for more substances would provide hazardous waste workers with improved protection. Currently, direct-reading monitors are available for approximately fifteen substances.[3]

PERSONAL PROTECTIVE EQUIPMENT

Employees working with and around hazardous materials wear personal protective equipment (PPE) to prevent or minimize exposure to those hazardous materials. Often, too much reliance is placed on the PPE: air purifying respirators do not effectively filter out all air contaminants; air purifying respirator cartridges have breakthrough times; chemicals can permeate the materials that comprise the PPE; and wearing PPE creates other potential health hazards, most commonly heat stress.

Respirators

A potential route of exposure that is often difficult to control is linked to the life span of the cartridges used in air purifying respirators. The lifespan of a cartridge is dependent on two main factors:

- Contaminants in the ambient atmosphere
- Humidity and temperature of the ambient atmosphere

It is often incorrectly assumed that a cartridge to be used in atmospheres containing organic vapors will effectively filter out all organic vapors. Unfortunately, this is not the case. Many chlorinated hydrocarbons will break through the cartridge in less than one hour of use. Methylene chloride, a common industrial solvent, will break through in one to two minutes.[5] The term "breakthrough" means that the chemical is not adsorbed on the filter; instead, it passes through and is inhaled by the wearer of the respirator. Respirator breakthrough may inadvertently expose hazardous waste site workers to methylene chloride and other common chlorinated solvents in this way.

The current NIOSH/MSHA respirator approval methods are also misleading to the average respirator user. An organic vapor cartridge which is stamped "NIOSH/MSHA APPROVED" has only been proven to provide protection for 50 minutes against 1000 ppm carbon tetrachloride in 50 +/- 5% relative humidity air at 25 °C and at a test air flow rate of 64 liters/minute for the "as received" cartridges. Since the cartridges are used in atmospheres with wide ranges of temperature and humidity and usually with several air contaminants present in the ambient atmosphere, relatively little is known of the actual effectiveness of air purifying respirators.[6]

The cartridge's life span is affected not only by the contaminants in the ambient atmosphere, but also by the temperature and humidity. Any outdoor worker frequently works in atmospheres of high humidity. The atmospheric concentrations of the contaminants and water vapor have a significant effect on the saturation capacity of the charcoal bed in the respirator cartridge.[7]

Another factor which affects the saturation capacity of the cartridge is the relative humidity of the conditioning environment. (Respirator cartridges are conditioned prior to use.) It has been determined that a high humidity (20 to 90%) in the conditioning environment has little effect if the humidity in the use environment is low. However, if the humidity in the use environment is over 20%, the breakthrough time may be significantly decreased. One study determined that a three-fold decrease in breakthrough time resulted under such conditions when the atmosphere contained 50% carbon tetrachloride.[7]

Respiratory protection for hazardous waste site workers would be improved by increasing the effectiveness and lifespan of air purifying cartridges and refining the current test approval procedures for air purifying cartridges.

Air purifying respirators are virtually ineffective if the user has not been fit-tested with the respirator to be worn. Fit-testing determines if an adequate seal exists between the user's face and the respirator. Fit-testing is currently performed using either quantitative or qualitative techniques. Qualitative techniques are generally used because they are less time-consuming, less costly and are performed with the actual respirator that the worker will wear. However, OSHA prefers that quantitative fit-testing be performed. The quantitative method currently used is awkward and very expensive. In addition, the actual respirator is not worn by the test subject. Since a surrogate mask is used, differences in shapes and pliability between masks are not taken into account.[8]

A quantitative fit test is performed by measuring the concentration of an aerosol inside the test respirator while it is worn on the test subject. The fit test is performed inside a chamber containing a certain known concentration of the aerosol. A probe is inserted in the respirator to measure the concentration of the aerosol. The accuracy of this method is compromised in two ways. The probe is invasive, meaning that the probe itself may affect the fit of the respirator. Also, if the aerosol enters the respirator through a seal leak, it may not equalize quickly in the space between the wearer's face and the respirator. Therefore, the results are dependent on the location of the probe in relation to the leak.[8]

An improved fit-testing method has been developed by two scientists at the University of Cincinnati. An invention by one of these scientists, K. Willeke, uses a dynamic pressure sensor which is directly connected to the respirator cavity. The fit test is performed by attaching the pressure transducer to a modified filter cartridge and placing it on the respirator. After making some other minor modifications and determining the volume inside the respirator, pressure measurements can be easily taken and recorded. Since pressure changes instantaneously, any leaks occurring as a result of the wearer's movement will be instantly recorded.[8]

This method offers several advantages over other quantitative fit-test methods:[8]

- The measurements are a unique and sensitive function of air leakage into the respirator and therefore of respirator fit
- The method is less expensive and requires less equipment than the currently used quantitative method
- The test is fast, requiring only a few seconds
- The test is non-invasive

- The respirator that the subject will use is worn for the test
- The method can be performed anywhere

Chemical Protective Clothing

Chemical protective clothing is worn by people working around hazardous materials to prevent skin contact with those hazardous materials. However, wearing chemical protective clothing (CPC) presents other problems. When the entire body must be protected by a chemical-resistant suit, heat stress becomes a potential health hazard even in moderate temperatures. Tiny pinholes in gloves may cause skin contact with chemicals without the wearer being aware of it. Chemicals may permeate the materials the CPC is made of, particularly gloves because hands are the most likely to contact hazardous materials.

The same materials that resist chemicals also prevent the evaporation of sweat, creating a potential heat stress problem. The immediate, and for the time being the simplest, solution to heat stress is finding a means to cool the body so that it can comfortably work longer. Long-term solutions to heat stress should emphasize finding a means to allow the evaporation of sweat while still providing chemical resistance.[9]

The most popular cooling device is the ice vest. The basic ice vest consists of frozen packets of phase change solution, sewn into a vest lined with Nomex or a similar material. The advantages of wearing an ice vest are that the worker is mobile and can work in intense heat for up to ninety minutes without resting. Working in intense heat without an ice vest may require rest periods after fifteen to forty-five minutes. The disadvantage of the ice vest is that it weighs approximately ten to fifteen pounds. If a worker is performing heavy physical labor, the added weight can negate any cooling effects provided by the vest.[9]

Another cooling method uses forced air. The air is pumped inside the suit at key points. This cooling method generally is impractical for hazmat teams since the worker must be tethered to the air supply.[9]

A new cooling device uses pressurized tanks of a coolant such as Freon. The tanks are worn on the person's back and weigh approximately three to six pounds. This system is ideal for a hazmat worker since the tanks are lightweight and the worker is still mobile. However, this system is very expensive. The expense is due to the cost of the coolant canisters rather than the cost of the vest, which is approximately $1,300. The canisters last only thirty minutes and cost approximately $25.00 each.

Since heat stress is probably a more widespread potential health hazard among hazmat workers than chemical exposure, advances in cooling systems would greatly benefit these workers. An inexpensive system that also provides the worker with mobility is needed.[9]

As stated earlier, CPC may not necessarily provide the worker with full protection from chemical contact. Chemicals can permeate gloves and other CPC. Also, some solvents can extract chemical additives in gloves or can break down glove material. These reactions alter the glove, increasing the potential for permeation, in addition to exposing the wearer to the reaction products.[10]

Effective decontamination of the CPC will minimize the amount of chemical permeation and maximize the safe usefulness of the CPC. CPC must be decontaminated before field personnel leave the site, even if the CPC is disposable. Most decontamination procedures use a basic rinsing of the garment followed by a detergent wash and another rinse. Sometimes the contaminated clothing is aerated for several days.[10]

The most practical decontamination method for hazmat workers is the detergent wash and rinse method. This method allows decontamination to take place quickly and easily in the decontamination zone. However, a study performed using the ASTM permeation test method determined that for several chemical and CPC material combinations, this decontamination method was not effective. This determination was made by comparing the breakthrough times for new and decontaminated materials. The breakthrough times for decontaminated materials were less than for new materials in most cases, indicating that permeation was gradually occurring, even after decontamination.[10]

The same study determined that thermal decontamination was effective. CPC materials were heated for sixteen hours at 100 °C. The breakthrough times for new and thermally decontaminated materials were nearly equal, indicating that heating the materials stopped chemical permeation.[10]

Thermal decontamination, although more effective than wash-rinse decontamination methods, is not easily performed in the field. Gloves and boot covers, the items most likely to contact chemicals, can be fairly easily decontaminated in this manner. Other items, such as butyl rubber suits and respirators, may have to be washed and rinsed. Further testing should be done to study the effects of heat on the CPC materials and the effectiveness of other decontamination methods.

CONCLUSIONS

The safety of hazardous waste site workers would be significantly improved with these refinements in site safety equipment:

- Improved on-site air monitoring techniques to accurately analyze a wide range of air contaminants
- More effective air purifying respirators and refined fit-testing methods
- Improved systems for alleviating heat stress
- More effective decontamination methods that can be easily performed on-site

Increased awareness of the limitations of site safety equipment and the potential for heat stress when wearing protective clothing would also enhance the health and safety of the hazardous waste site worker.

Contaminant Stratification at a Deeply Penetrating, Multiple Component DNAPL Site

David B. Holmes
Ken W. Campbell
Hydro-Search, Inc.
Brookfield, Wisconsin

ABSTRACT

An estimated 150,000 liters of solvent, including at least 13 halogenated and six aromatic hydrocarbon compounds as well as three ketones and one alcohol, were released over a 20- to 30-year period at a solvent reclamation facility in the midwestern United States. These chemicals contaminated the groundwater and produced dense nonaqueous phase liquids (DNAPLs) to a depth of at least 55 meters. To date, seven major investigations of groundwater and soil impacts at the site have been completed.

The seventh investigation was performed during 1989 to more precisely define the nature and extent of groundwater impacts within the bedrock. The investigative procedures consisted of a carefully packaged combination of methodologies, including rock coring, packer installation, in situ hydraulic conductivity testing and groundwater sampling in three boreholes ranging in depth from 69 to 85 meters. These procedures provided a nearly continuous profile of bedrock stratigraphy and structure, hydraulic conductivity, and groundwater chemistry.

One significant result of the investigation was recognition of at least two types of stratification of contaminants beneath the site. The first type of stratification is the occurrence in downgradient areas within the bedrock of three physically distinct plumes separated by low or nonimpacted zones and apparently coinciding at least partially with zones in which extensive accumulation and lateral spreading of DNAPLs has also occurred.

A second type of stratification is in the types and physical properties of the VOCs found at different horizons. Within the unconsolidated deposits, the predominant compounds are ketones and isopropyl alcohol, which have very high solubilities and low specific gravities. Within the bedrock, the predominant compounds are chlorinated hydrocarbon compounds, which have very low solubilities and high specific gravities. As a result of differences in the solubilities of the predominant compounds, total VOC concentrations in the unconsolidated deposits are as great as 17,000 mg/l, whereas the maximum concentration measured within the bedrock, even for wells from which DNAPLs have been recovered, is 1619 mg/l.

Recognition of these types of contaminant stratification may be essential to development of effective remediation programs at sites where multiple-component DNAPLs occur.

INTRODUCTION

The mechanisms which control the subsurface migration of soluble organic and inorganic compounds and to some extent "light nonaqueous phase" compounds are relatively well understood. The migration or potential migration of these compounds are predictable to the extent that earth scientists with an insight into the nature of the compounds can execute field programs using conventional investigatory techniques to evaluate the nature and extent of subsurface impacts.

The hydrogeological understanding of the mechanisms that influence the migration of dense nonaqueous phase liquids (DNAPLs) in the subsurface is, however, less well understood by the hydrogeological community. The state of our understanding of DNAPL migration in 1990 is perhaps most clearly summarized by Schwille[1] who states that the forces dominating the migration of DNAPLs are gravitational in nature rather than hydraulic. Simply put, DNAPLs will sink through a water saturated medium until the body no longer holds together as a single related continuous phase, but rather lies in isolated residual globules in the so-called condition of residual saturation.

As is apparent from Schwille's experiments,[1] the migration pathways of the DNAPLs are dominated by gravitational forces and modified by what may appear to be subtle changes in the magnitude and nature of the hydraulic conductivity. The result is a migration pathway that may appear both tortuous and difficult to rationalize.

In complex and hydrogeologic settings, conducting a hydrogeological investigation can be extremely expensive to implement with the inherent safety and QA/QC protocols. Nonetheless, in order to develop an effective remedial program, the nature and extent of the potential impacts must be evaluated in sufficient detail to allow for the design of the remedial measures.

INVESTIGATIONAL PROCEDURE

The methodology discussed in this paper was developed and applied at a RCRA-permitted solvent reclaiming facility in the United States Midwest where up to 150,000 liters of organic solvents may have been released from leaking drums over a period of several years. The contaminants released include at least 13 high density halogenated hydrocarbon VOCs and 10 low density VOCs including aromatic hydrocarbons, alcohols and ketones. Five phases of investigation using conventional investigation techniques were performed at the site between 1982 and January, 1988 to define soil and groundwater impacts. Based on these investigations, it was believed that vertical and horizontal migration of the DNAPL was limited. Vertical migration of the DNAPL beneath the facility was believed to be restricted at the bedrock surface at a depth of approximately 25 m. Although soluble organic impacts were measurable several hundred meters downgradient from the site, these soluble impacts were viewed as being manageable. The sixth phase of investigation, performed in July 1988, resulted in the discovery of DNAPLs in monitor well P-38 (Figure 1) at a depth of 55 m below ground level at a distance of 100 meters from the facility boundary.

With the discovery of the DNAPLs in the P-38 monitor well, it became apparent that the distribution of the DNAPLs had not been adequately determined and that significant additional investigatory work was necessary before final remedial measures could be selected, designed and installed.
Figure 1
Site Location

In order to produce a maximum understanding of the impacts and hydrogeological setting of the deeper bedrock units, a method was developed that provides a nearly continuous profile of rock core, hydraulic conductivity and groundwater chemistry.

The scope of the Phase VII investigation consisted of packer testing of three deep boreholes (P39, P40 and P41) ranging in depth from 69 m to 85 m. One borehole was located on-site in the area of highest contaminant concentrations in the unconsolidated deposits. A second borehole was located 100 meters southeast of the site in the apparent migration direction for impacted groundwater. The third borehole was located approximately 122 m south of the site, in alignment with previous locations in which DNAPLs had been found. The work performed at each borehole location included collection of continuous bedrock core samples and, at selected intervals, purging and collection of groundwater/DNAPL samples, and performance of hydraulic tests.

Coring

A total of 158 meters of bedrock was cored as part of this investigation. Bedrock coring was performed using a Mobil B-57 drill rig equipped with a Longyear HQ wire-line system with a 3.3-m core barrel. The diamond coring bit produced a 96-mm diameter borehole and 63.5-mm diameter core samples.

During coring, the approximate volumes of drilling fluid lost to the borehole were estimated and recorded. PID measurements of rock core were also recorded.

Temporary and/or permanent 254, 152 and 102-mm diameter steel casings were installed in the boreholes during drilling to seal off multiple impacted, highly transmissive or incompetent zones present in each borehole (Figure 2). Permanent 254-mm diameter steel casings were installed in all three boreholes prior to the start of packer testing to seal off the incompetent sand and gravel surficial deposits and upper 1.5 to 3.0 meters of bedrock.

The permanent casings were cemented in place by pumping a 15:1 cement (Portland Type I)/bentonite (Aquagel Goldseal) grout through a tremie pipe into the annular space between the casing and the borehole wall.

The temporary 102-mm diameter casing was fitted with a reaming shoe, which allowed it to be advanced by rotating the 102-mm casing and reaming out a thin rim of rock at the edge of the 96.5-mm diameter core hole.

Packer String

After removal of the core sample from a test interval, the drilling rod was raised to expose the borehole walls within the test interval. An inflatable packer was attached by a stainless steel nipple to 3-m sections of stainless steel pipe which were inserted and lowered through the center of the drill rod to the precise top of the planned test interval. The pipe was 50.8-mm inner diameter, 314 stainless steel with flush threaded joints and the packer was a Tigre Tierra Model 34B-60-1.0 with stainless steel heads and center tube. The packer had a maximum inflated diameter of 127 mm and an uninflated diameter of 54.1 mm. The center tube had a 25.4-mm inner diameter.

After lowering the packer to the desired depth, the packer inflation line was attached to a pressure regulator on a nitrogen tank and the packer was inflated to a pressure of between 1,380 to 1,517 kPa.

Figure 2
Testing Configuration

Hydraulic Testing

For hydraulic testing and sampling, a QED Well Wizard Model HR-4200 gas displacement pump made of stainless steel and Teflon and equipped with a drop tube inlet was connected to bonded 19-mm and 12.7-mm outside diameter polyethylene tubing and inserted into the packer string to a depth of 17 meters. A drop tube of 12.7-mm outside diameter Teflon lined polyethylene tubing, attached to a one-meter long 12.7-mm diameter stainless steel pipe was attached to the bottom of the purge pump. The use of the inlet drop tubing allowed progressively deeper intervals to be tested by adding sections to the drop tubing, while maintaining the pump at a relatively shallow, optimal pumping depth. The Model HR-4200 purge pump was used throughout the investigation.

A 345-kPa pressure transducer was inserted into the stainless steel riser pipe at a depth of approximately 0.5 meters above the top of the purge pump. The transducer was connected to an In Situ SE 1000B data logger. The data logger was used to record water level changes in the test interval during the purging interval and during the recovery

period following purging. The recovery data were used to calculate the hydraulic conductivity of the test intervals using two methods: (1) the Jacob method[2] and (2) the Cooper method.[3]

Groundwater and DNAPL Sampling

As the well was being purged, field measurements, including pH, specific conductance, temperature and photoionizable constituent concentrations, were conducted on the purged water. Photoionizable constituents were measured using an HNu Model PI-101 PID equipped with an 11.7-eV probe.

Groundwater samples collected during testing were initially analyzed for VOCs immediately after collection by the site laboratory.

Duplicate groundwater samples were analyzed by a contract laboratory for VOCs using U.S. EPA's SW846 Manual, Method 5030 for sample preparation and extraction and SW846 Methods 8010, 8015, 8020 and 8030 for determination of the compound concentrations.

Packer test equipment, including the packer, packer inflation tubing, stainless steel riser pipe, purge pump and pump tubing, were decontaminated by pressure washing and selected steam cleaning. This procedure was adequate until DNAPLs were exposed to the system during the 20th and 21st tests performed. Pump blanks were collected prior to subsequent tests, to evaluate the adequacy of decontamination procedures. These samples were immediately submitted to the site laboratory for VOC analysis.

Installation of Monitor Well

After completion of the final packer test in each borehole, the temporary 102-mm casing was removed and the borehole was reamed using a 149-mm diameter tricone bit.

Monitor wells were constructed according to Wisconsin state protocol using 50.8-mm I.D. schedule 80 PVC riser pipe with flush-threaded joints and three-meter long 0.010-mil slotted PVC screens.

IMPACT ASSESSMENT

Groundwater Impacts

Impacted groundwater at the site has a complex chemistry due to the large number of contaminant compounds released. A total of 23 compounds was detected, including 13 halogenated hydrocarbon compounds, six aromatic hydrocarbon compounds, three ketones and one alcohol. Table 1 summarizes the major physical and chemical properties of the VOCs detected in the groundwater samples. The halogenated hydrocarbons all have high specific gravities (1.17 to 1.68 g/cm³) and extremely low to moderately low solubilities in water (79 to 20,000 mg/L). The aromatic hydrocarbons have low specific gravities (0.861 to 0.880 g/cm³) and very low solubilities in water (130 to 1,750 mg/L). The ketones have even lower specific gravities (0.79 to 0.806 g/cm³) and variable solubilities ranging from 19,100 mg/L for methyl isobutyl ketone to complete miscibility within water for acetone. In addition

to the complex chemistry, the geometry of the impacted groundwater is complex due to the occurrence of numerous high permeability zones within the bedrock and multiple zones of DNAPLs potentially acting as individual sources for groundwater impacts.

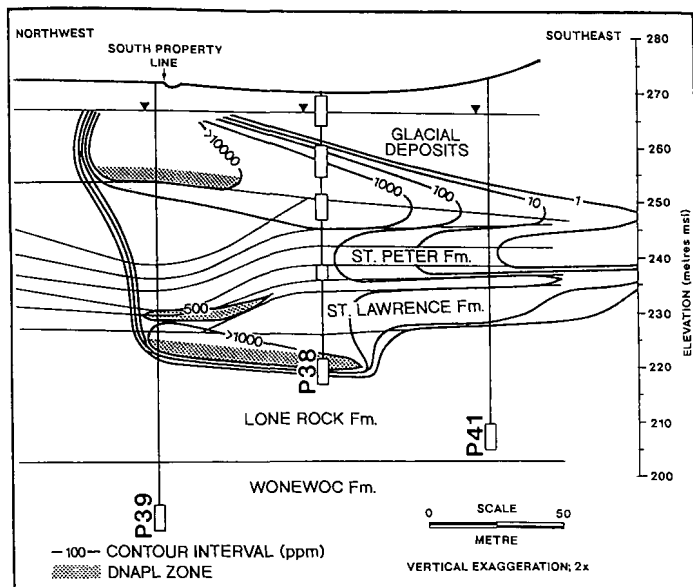
Previous investigations at the site defined the magnitude and extent of impacts within the unconsolidated deposits, but not within the bedrock. Figure 3 is a conceptual isoconcentration profile of total VOCs in the groundwater at the site.


Figure 3
Extent of Impacts

Directly beneath the site, the groundwater impacts appear to be present in all zones from the water table surface in the unconsolidated deposits to the upper portion of the Lone Rock Formation within the bedrock. In downgradient areas, the impacted groundwater appears to form three distinct plumes which occur mainly within the upper and lower sandstone units of the Readstown Member of the St. Peter Formation and the upper portion of the Lone Rock Formation.

The upper and middle bedrock plumes occur within the permeable sandstone beds situated at the top and base of the formation and are separated by a low permeability siltstone, mudstone and shale unit. The plumes were differentiated based on relative contaminant concentrations and stratigraphic position. In boreholes P39 and P41, the position of the packer test intervals did not allow precise differentiation of the plumes; however, in the other borehole (P40), the plumes were clearly demonstrated to be separate by the occurrence of an intervening zone with a total VOC concentration of only 0.001 mg/L.

The deep bedrock plume occurs within the upper 6 to 10 meters of the Lone Rock Formation. Groundwater impacts in the upper Lone Rock were present in two of the boreholes. In P40, the groundwater sample from the upper Lone Rock Formation contained a total VOC concentration of 75,125 mg/L, the highest concentration present in tests performed at the borehole. In P39, the groundwater sample from the upper Lone Rock Formation had a total VOC concentration of 1,619.10 mg/L and contained up to 20^4 by volume of DNAPLs. In both of the P39 and P40 boreholes, groundwater samples from the subsequent deep packer test intervals contained total VOC concentrations approximately 150 to 300 times lower than those in the upper Lone Rock Formation. These low level concentrations were attributable to contamination of the deeper zones as a result of drilling, sampling and decontamination procedures. However, even with contamination from the procedures, the packer test methodology still was able to demonstrate the existence of an extremely sharp concentration gradient between the upper and middle portions of the Lone Rock Formation.

At least two major trends are apparent from the present data. First, there are major differences in the maximum total VOC concentrations that have been observed at different horizons beneath the site. Within the bedrock, the maximum total VOC concentration found in any groundwater sample collected from any well or packer test interval, including the three impacted by DNAPLs, is 1,619 mg/L. Within the unconsolidated deposits, particularly within wells intercepting the water table, total VOC concentrations greater than 17,000 mg/L have been measured in the groundwater in three wells. The differences in total VOC concentrations are due primarily to the presence of very high concentrations of high solubility compounds (ketones and isopropyl alcohol) within the unconsolidated deposits and their near absence within the bedrock.

The predominance of ketones and isopropyl alcohol as groundwater contaminants within the unconsolidated deposits, and halogenated and aromatic hydrocarbon compounds as groundwater contaminants within the bedrock, is the second major trend apparent in the groundwater chemistry data.

The differences in contaminant chemistry are evidence that the bedrock groundwater contamination probably is a secondary result of initial contamination by sinking DNAPLs composed of halogenated hydrocarbon and aromatic hydrocarbon compounds. In contrast, within the unconsolidated deposits, highly soluble contaminants, including the ketones and isopropyl alcohol, dissolved rapidly upon entry into the groundwater and have migrated downward only to a limited extent.

Extent of DNAPLs

Prior to this investigation, the extent of DNAPLs at the site was inadequately defined. It was known that DNAPL was present in at least three site wells; two were completed within the base of unconsolidated deposits, and the other within the upper portion of the Lone Rock Formation. The occurrences indicated only that DNAPL was present in some form at one or more horizons that intersected with the well completion interval. The exact elevation at which the DNAPLs entered the well and the nature of the DNAPLs' occurrence (i.e., isolated ganglia versus continuous bodies of DNAPL in pools) were unknown.

Insights into the nature of the DNAPL occurrences were gained through careful observation and monitoring of the DNAPLs as they were recovered during the packer tests. The DNAPLs recovered during test P39-4 occurred in the form of extremely small dispersed droplets which initially were invisible, but which coalesced after five to ten minutes to form a thin layer of large droplets on the bottom of the sample jar, representing approximately 1 to 2% of the total sample volume. This finding suggests that the DNAPLs in the P39-4 test interval may have occurred in the bedrock in the form of small droplets dispersed in intergranular pore spaces.

In contrast, the DNAPLs recovered during test P39-5 occurred as large globules of DNAPLs which were readily visible and settled immediately to the bottom of the sample jar. The DNAPLs initially represented as much as 20% of the total sample volume. An extended pump test was performed at P39-5 to determine the rate at which the proportion of DNAPL (as a percent of total fluid pumped) would decrease over time. The test was performed for 5 hours, during which the volume of DNAPL decreased steadily from 20% to 1.2% of the total fluid volume. An estimated total volume of 83 liters of DNAPLs was recovered.

The volume of DNAPLs recovered and their occurrence in the form of large globules, suggests that the DNAPLs in the P39-5 test interval may occur as a continuous body of DNAPLs concentrated within open fractures. A likely location for such a fracture would be at an elevation of 221 meters msl., where a 100% loss of drilling fluid occurred during coring of the P39-5 test interval. It is very significant that a 100% drilling fluid loss occurred at the same elevation in a second site borehole (P41). This finding suggests the existence of a continuous high permeability layer in the upper portion of the Lone Rock Formation with a lateral extent of at least 122 m. This same elevation also coincides with the test interval in which the greatest impacts were present in the third borehole (P40).

The maximum lateral and vertical extent of DNAPLs within the upper Lone Rock Formation at the site is unknown. Based on the known occurrence within the Lone Rock Formation of interbedded high and low permeability rock units that are nearly horizontal and laterally continuous over wide areas, it is possible that DNAPLs have spread outward in several directions within one or more high permeability layers in the upper Lone Rock Formation. The maximum vertical extent of DNAPLs within the Lone Rock Formation is unknown.

Two DNAPL samples (both from the upper Lone Rock Formation) have been analyzed for VOCs by an outside laboratory. By weight, halogenated hydrocarbons as a group account for 83.3% and 90.1% of the total organic concentrations in the two DNAPL samples, versus 16.7% and 9.9% for the aromatic hydrocarbons. The concentrations of individual DNAPLs compounds, as a percentage by weight of total detects, vary greatly. The DNAPL is composed, in order from greatest to least percentage by weight of total detects, of the following compounds:

- 1,1,1-trichloroethane (40.8% and 47.0%)
- trichloroethene (22.2% and 23.9%)
- tetrachloroethene (11.8% and 13.9%)
- toluene (5.2% and 7.4%)
- 1,2-dichloroethane (5.3% and 6.1%)
- xylenes (3.6% and 7.6%)
- ethylbenzene (1.1% and 1.7%)
- methylene chloride (0.8% and 0.9%)

Several new insights into the migration and dissolution dynamics of DNAPLs at the site were gained from evaluation of the DNAPL and groundwater chemistry data. For each compound, the concentrations measured in the DNAPL samples (in units of mg/liter) were converted to units of moles/liter, based on the molecular weight of each compound. The mole concentration of each compound was divided by the total molar concentration of all the compounds in each sample to

calculate the mole fraction of each compound of the total organics in each DNAPL sample. The mole fractions were then multiplied by the solubility in water for each compound to derive the estimated concentration for each compound for groundwater saturated with respect to the DNAPLs. These predicted values can be compared with the measured values in groundwater samples collected from each DNAPL zone (Table 2).

The validity of this analytical method can be demonstrated in DNAPL and groundwater samples by the relatively close correlation between the predicted and observed concentrations of various compounds, in particular for the aromatic compounds. The only anomalous values are for 1,2-dichloroethane, for which the observed concentrations are approximately 30 times lower than the predicted concentrations.

The application of this procedure provides several significant insights. First, the relative concentrations of individual compounds present in the groundwater may vary greatly from their proportion in the DNAPL. Methylene chloride comprises approximately 1% of the DNAPL, but 10% to 25% of the total organic concentrations in the groundwater. In contrast, ethylbenzene, which also comprises 1 to 2% of the DNAPL, comprises only 0.3% of the measured concentrations in the groundwater.

One implication of this relationship is that removal of methylene chloride will occur far more rapidly than removal of ethylbenzene or other lower solubility compounds. A second implication is that as the DNAPL is depleted over time, the ratio of the concentrations of high and low solubility compounds should change, as the high solubility compounds are depleted at a higher rate. These changes potentially could be monitored and used to estimate the rate of DNAPL removal over time during remediation.

The evaluation of the distribution of organic compounds in groundwater samples also potentially could be used to provide insights into the location and nature of DNAPL sources based on concentrations measured in downgradient monitor wells. For example, the mole fractions of the compounds in the P40-4 sample are virtually identical to

8. Average of reported values for m-xylene, o-xylene, and p-xylene.

the fractions in the P38 groundwater sample, and the concentrations are approximately 10% of those observed in the P38 groundwater sample. This finding suggests that the source of the contaminated groundwater plume at P40-4 is DNAPL with a composition identical to the P38 DNAPL sample, and a relatively near source.

CONCLUSIONS

The detailed investigation conducted at the facility confirmed extensive migration of DNAPLs in the subsurface. The physical and chemical dynamics of the migration are not well understood; however, it is apparent that chemical stratification of groundwater impacts does occur. This stratification is strongly influenced by the solubility of the individual components within the DNAPLs. Predictions of the relative combinations of compounds that will dissolve into the groundwater using the Bannergee[4] method compared well with results of analysis groundwater samples collected from the site. Additional detailed groundwater chemical analysis is necessary at this site prior to selection and design of remedial technologies.

Use of MINTEQA2 and MULTIMED Models to Evaluate Soil Cleanup Levels at a Lead Battery Superfund Site

Gordon J. Ruggaber
NUS Corporation

Jerry D. Allison
Terry L. Allison
Computer Sciences Corporation
Athens, Georgia

ABSTRACT

Two computer models, MINTEQA2,[1] a state-of-the-art equilibrium metal speciation model, and the U.S. Environmental Protection Agency's Multimedia Model (MULTIMED),[2] a contaminant fate and transport model, were coupled and applied to the C&R Battery Site, a CERCLA site characterized by extensive lead contamination in the soil (0 to 15 ft deep). Downgradient groundwater lead concentrations were predicted for a no action and two remedial action scenarios. Development of a soil cleanup level for lead based on compliance with the Maximum Contaminant Level (MCL) for drinking water also was investigated. The results of the study were used to supplement the comparison of remedial alternatives included in the Feasibility Study (FS) for the site.

INTRODUCTION

To date, CERCLA has not adopted a standard methodology for determining soil cleanup levels for metals based on the potential for inorganic contaminants to migrate and contaminate groundwater. Lack of such an approach is a result of the complex behavior of metals in the soil-water system, in which the various reactions among solution species, gases, solids and sorbed phases are not easily described. Characterization of the behavior of metals in the soil-water equilibrium system requires quantification of their distribution between solid and liquid phases as well as the speciation of the resultant soluble components. Due to their complexity, the reactions of metals in the soil-water system are most easily quantified through the use of geochemical computer models.

In this study, the MINTEQA2[1] and MULTIMED[2] models were applied in series to the C&R Battery Site to achieve the following objectives: (1) predict downgradient groundwater lead concentrations for a no action and two remedial action scenarios (10,000 mg/kg and 1,000 mg/kg cleanup levels); and (2) develop a soil cleanup level for lead based on compliance with the Maximum Contaminant Level (MCL) for drinking water. The 1,000 mg/kg cleanup level is a risk-based level applicable to the "non residential" or industrial environment of the C & R Battery Site.[3] The 10,000 mg/kg cleanup level corresponds to remediation of only the highly contaminated "hot spots" at the site and is designed to optimize the amount of lead remediated with respect to soil volume and cost.[3] Information about MINTEQA2 and MULTIMED is available from the Center For Exposure Assessment Modeling, U.S. Environmental Protection Agency, Athens, Georgia.

SITE BACKGROUND

The C&R Battery Site was a battery-sawing and shredding facility which operated from the early 1970s until 1985. The facility was located on a 4.5-acre tract of land approximately 650 feet south of the James River in Chesterfield County, Virginia. A Remedial Investigation (RI)[4] and FS[5] were completed by NUS Corporation in January 1990. Lead was detected in both the surface and subsurface soils throughout most of the site in concentrations ranging from 16 to 122,000 mg/kg and 15 to 41,400 mg/kg, respectively. Because no inorganic contaminants were detected in the dissolved metals fraction in groundwater at concentrations above the National Primary Drinking Water Standards, groundwater remediation was not included in the FS.

The lithology beneath the site consists of a surficial layer of clay and silt with minor amounts of sand, ranging from 20 to 60 feet in thickness. Below this clay layer is an extensive fine to coarse sand and gravel deposit whose thickness is unknown.

GENERAL APPROACH

Development of Test Cases

MINTEQA2 was used to predict the equilibrium lead concentration in the leachate leaving the area of contamination, or source volume, whereas MULTIMED was used to simulate lead transport downgradient from the source. MINTEQA2 simulations were also conducted to calculate the distribution coefficients, or retardation factors, required by the MULTIMED unsaturated and saturated zone transport modules.

Based on the results of a sensitivity analysis,[5] pH and total inorganic carbon were determined to have the greatest influence on the amount of dissolved lead in the soil-water system. To bracket the uncertainties associated with these two parameters, average and worst case scenarios were formulated for the three cleanup levels developed in the FS; no action, 10,000 mg/kg and 1,000 mg/kg.

For the average case simulations, the mean pH values for the saturated and unsaturated zones were used (4.82 and 6.17, respectively). For total inorganic carbon, the median of observed CO_2 partial pressures in soil from the literature (3.5×10^{-3} atm) was used. For the worst case simulations, the 10 percentile soil pH value for the site (4.08) was used for the unsaturated zone, and the lowest measured groundwater pH value (approximately 4.08) was used for the saturated zone. For total inorganic carbon, atmospheric CO_2 partial pressure (3.5×10^{-4} atm) was used.

Maximum lead concentrations were predicted for two downgradient receptor wells located at distances of 10 and 100 meters, respectively, from the source volume. The 10-meter well location was chosen to represent a worst case scenario in which a drinking water well is installed directly downgradient from the source, near the site boundary. The 100-meter well location enabled the rate of contaminant migration to be estimated as well as the amount of attenuation and dilution offered by the aquifer. As a conservative approach, the receptor wells were placed along the centerline of the plume, and the well screens were assumed to be located at the water table.

A series of MULTIMED simulations was performed to predict whether or not the maximum lead concentration at each receptor would

ever exceed the current or proposed[6] MCL values for lead (50 ug/L and 5 ug/L, respectively) and, if so, the time required to surpass these values.

Back-calculation of a Soil Cleanup Level

Back-calculation of a soil cleanup level from a groundwater concentration requires estimation of the dilution-attenuation factor (DAF), which quantifies the amount of dilution and attenuation provided by the unsaturated and saturated zones. Source and downgradient lead concentrations are related to one another by the DAF as follows:

$$C_L = DAF*C_{RfD} \qquad (1)$$

where

C_L = leachate concentration (mg/L)
C_{RfD} = concentration limit at the well (i.e., MCL) (mg/L)

Equations 2 to 5 below show how the soil cleanup level, C_s, is related to the concentration limit at the well (C_{RfD}) through the DAF:

$$CS = A*d*D_{cs} \qquad (2)$$

where

CS = mass of contaminated soil (kg)
A = area of contaminated soil (m²)
d = depth of contaminated soil (m)
D_{cs} = density of contaminated soil (kg/m³)

$$CSc = C_s*CS*10^{-6}D \qquad (3)$$

$$CSc = q*A*C_L*T_p*10^{-3}D \qquad (4)$$

where

CSc = mass of chemical contaminant (kg)
C_s = soil contaminant (cleanup) level (mg/kg)
q = net infiltration rate (m/yr)
T_p = source duration time (yr)

Combining equations 1 to 4 and rearranging yields:

$$C_s s = [q*DAF*C_{RfD}*T_p*10^{-3}]/[d*D_{cs}] \qquad (5)$$

MINTEQA2 ANALYSIS

Characterization of the soil-water system using MINTEQA2 requires specification of basis species or components which represent reactants in all reactions considered by the model. The free metal ion, Pb^{+2}, was used as the component for lead. Only ions expected to have a major influence on the complexation and solubility of lead, either directly or indirectly, were chosen as components. Components were estimated from dissolved groundwater concentrations and are presented elsewhere.[5] Because of the uncertainties associated with measured Eh values,[7] redox reactions were ignored in the MINTEQA2 simulations.

Source Specification

The contaminated soil at the C&R Battery Site was depicted as a homogeneous, rectangular source volume with a depth of 15 feet. To simplify calculations, the volume of contaminated soil was held constant for all test cases, while the average lead concentration in the source volume was varied according to the amount of lead remaining in the soil following remediation. The source volume lead concentrations (soil

Table 1
**Average Initial Source Volume Lead Concentrations
for Three Cleanup Levels and Corresponding Initial
Pore Water Lead Concentrations**

Cleanup Level	Average Initial Soil Lead Concentration (mg/kg)	Initial Pore Water Lead Concentration (mg/l)
No Action	4,146	18,533
10,000 mg/kg	699	3,125
1,000 mg/kg	127	565

and pore water) for the three cleanup levels (Table 1) were calculated by dividing the total amount of residual (untreated) lead in the soil by the source volume. The residual lead quantities were estimated from measured site data using lead isoconcentration contours developed in the FS.[3]

Solids Selection Procedure

The solid phase lead speciation at the C&R Battery Site is not well-defined. X-ray diffraction analysis indicates that the lead is distributed among several minerals including lead sulfate ($PbSO_4$), lead carbonate ($PbCO_3$), lead oxide (PbO_2) and metallic lead (Pb^{-8}). The relative amounts of these lead minerals in the soil were not quantified during the mineralogical analysis. For this reason, finite solids were not input into MINTEQA2, but rather the total system concentration for lead was specified by the Pb^{+2} component and entered into the model as a pore water concentration (Table 1). MINTEQA2 was then allowed to determine which solids control the solubility of lead in the soil at the C&R Battery Site. Based on MINTEQA2 analysis, these solids include Anglesite ($PbSO_4$), Cerrusite ($PbCO_3$), Lanarkite ($PbSO_4 \bullet PbO$) and Diaspore ($AlO(OH)$).

Adsorption Modeling Approach

The diffuse layer algorithm of MINTEQA2 has been experimentally verified in the laboratory for the adsorption of lead (and other metals) onto a pure-phase amorphous iron oxide (FeO) surface.[9] Loux et al.[10] have demonstrated that the diffuse layer model, as incorporated into MINTEQA2 with the surface species given by Dzombak,[9] performs well in predicting the adsorption of lead onto amorphous FeO contained

Figure 1
Average Case Adsorption Isotherm for Saturated Zone

in a natural aquifer material. Hence, the diffuse layer algorithm of MINTEQA2 was used in this study to model adsorption of ions onto an FeO surface. The amount of amorphous FeO in the soil at the site was estimated to be approximately 1700 mg/kg.[5] Other input data required to run the diffuse layer algorithm were derived from Dzombak.[9]

MULTIMED requires specification of the distribution coefficient, K_d (ml/g), for both the unsaturated and saturated zones. A number of other input parameters, such as longitudinal, transverse and vertical dispersivities, are required by MULTIMED and are presented elsewhere.[5]

To determine K_d values for the unsaturated and saturated zones, a series of MINTEQA2 simulations was performed and adsorption isotherms were plotted under average and worst case conditions. The average case adsorption isotherm for the saturated zone is shown in Figure 1. The shapes of all four isotherms were best described by a Freundlich or Langmuir equation. MULTIMED, however, can only accommodate a linear adsorption isotherm, or constant K_d value, for both the unsaturated and saturated zones. Therefore, to determine K_d values for both zones for the three cleanup levels, linear approximations were made over the predicted equilibrium lead concentration range for each scenario using a simple linear regression program.

MINTEQA2 RESULTS

Using the calculated initial source volume lead concentrations (Table 1), the total dissolved equilibrium lead concentrations were determined by MINTEQA2 for the three cleanup levels under the average and worst conditions as shown in Table 2. The values shown in Table 2 represent the total concentrations of all dissolved lead species in the source volume leachate for each cleanup scenario. The influence of pH and total inorganic carbon on the solubilization and adsorption of lead species are illustrated by the differences in the equilibrium leachate lead concentrations between the average and worst case conditions.

The unsaturated and saturated zone K_d values for the three cleanup levels are shown in Table 3. The differences in K_d values between the unsaturated and saturated zones under average case conditions are a result of the different pH values used for the two zones (4.82 and 6.17, respectively). The unsaturated and saturated zone K_d values for the worst case scenarios are identical because the same pH value was used for each zone (4.08). A very high saturated zone K_d value (45,091 mL/g) was calculated for the 1,000 mg/kg cleanup level under average pH and inorganic carbon conditions. The high K_d value, which is outside of the range of observed K_d values,[11] is a result of the very low equilibrium lead concentrations used in the regression calculation. A value of 1000 mL/g was substituted for the 45,091 mL/g value because

it was considered a more realistic estimate of K_d when compared with the K_d values calculated for the other test cases.

MULTIMED ANALYSIS

To accommodate the constraints of the MULTIMED framework, the unsaturated zone beneath the source volume was represented by a homogeneous, isotropic layer having a thickness of 22 feet. The saturated zone was represented by a single layer with a uniform thickness of 100 feet. The boundary condition for the saturated zone transport module was specified as a Gaussian distribution in the lateral direction and uniform over the vertical mixing zone or source penetration depth (100 feet).

MULTIMED was run under a transient state condition in which leachate leaving the source was represented by a step function. Using the Hydrologic Evaluation of Landfill Performance (HELP) Model,[12] the net amount of annual infiltration into the soil was estimated to be 0.24 in./yr. The small amount of annual infiltration is a result of the low hydraulic conductivity of the soil (8.87 x 10^{-6} cm/sec on average). The duration of the source step function was determined for each test case by dividing the total mass of lead in the source volume by the leachate flux rate (annual infiltration volume times leachate concentration). Source duration times for the three cleanup levels are shown in Table 4.

Table 4
Source Duration Times for Three Cleanup Scenarios
Under Average and Worst Case Conditions

Cleanup Level	Source Duration Time (years)	
	"Average" Case	"Worst" Case
No Action	2,580	611
10,000 mg/kg	4,500	1,121
1,000 mg/kg	1,622	439

MULTIMED RESULTS

The times required to exceed the current and proposed[11] MCL values for lead for the three cleanup levels are presented in Tables 5 and 6 for the 10-meter and 100-meter receptor wells, respectively. The DAFs for the three cleanup levels ranged from 19 to 3,900 for the average case conditions and from 19 to 33 under worst case conditions.

1,000 mg/kg	Never	411	275,000	396

DISCUSSION

For a given soil cleanup level, the time required for the groundwater lead concentration to reach the current and proposed MCL values at each receptor well (Tables 5 and 6) is dependent on the equilibrium leachate lead concentration (Table 2) as well as on the estimated unsaturated and saturation zone K_d values (Table 3). For both receptor wells, the variation in times to reach the current and proposed MCL concentrations among the three cleanup levels is much greater under average pH and inorganic carbon conditions than under worst case conditions. This difference is a direct result of the large variation in K_d values between the three cleanup levels calculated under average conditions compared with the much narrower K_d range obtained under the worst case scenario. Consequently, under average case conditions, removal of lead from the source volume produces the desired result of retarding contaminant migration, whereas under low pH and inorganic carbon conditions, the effectiveness of source remediation is severely impaired.

A comparison of the times required to reach the MCL value at the 10-meter and 100-meter receptors (Tables 5 and 6) reveals that the time differences between these two locations are much greater under the average case scenario than under worst case conditions. This variation is another manifestation of the different K_d values calculated under average and worst case pH and inorganic carbon conditions. Under average conditions, lead concentrations are significantly attenuated both with depth and laterally, decreasing lead concentrations in the contaminant plume while slowing its rate. Under the worst case scenario, once the contaminant front has reached the water table, little time is needed for the plume to travel from the 10-meter to the 100-meter well.

The strong influence of the adsorption process on predicted groundwater lead concentrations in the downgradient receptor wells is also reflected in the wide variation in the calculated DAF values between the average and worst case conditions.

Adsorption Analysis

Many of the K_d values calculated using MINTEQA2 fall below the range of values typically estimated in the laboratory (4.5 to 7640 mL/g).[11] The low K_d values used in this study (Table 3) are a result of using only amorphous FeO as the adsorbent in the MINTEQA2 simulations and using a linear approximation to estimate K_d. Other types of adsorbing surfaces present in the soil at the C&R Battery Site, such as the natural clay, organic and other metal oxide surfaces, provide the soil with additional adsorptive capacity than that offered by amorphous FeO alone. Because of the nonlinearity of the adsorption isotherms, the estimation of K_d values using a linear approximation introduced additional uncertainty into the adsorption analysis.

Source Specification

Although a step function was used to characterize the leaching of lead from the source volume over time, the use of an exponentially decaying function is expected to be a more physically representative approach. Because no data were available to estimate the source concentration decay rate, however, the step function approach was used. Conceptually, the source duration time should be directly proportional to the amount of lead contained in the source volume. As shown in Table 4, however, the calculated source duration times for the 10,000 mg/kg cleanup level are longer than those estimated for the no action test cases. This inconsistency is a result of all of the adsorption sites being full (i.e., breakthrough) under the no action cleanup level, which yields much higher equilibrium lead concentrations in the source volume for this scenario than those calculated for the 10,000 mg/kg and 1,000 mg/kg cleanup levels (Table 2). As evidenced by the MULTIMED results (Tables 5 and 6), the shorter pulse duration used for the no action cleanup level is balanced to some extent by the high equilibrium lead concentration used (Table 2).

Back-calculation of a Soil Cleanup Level

Under both average and worst case conditions, the DAF values vary according to the cleanup level used. This variation is due to the fact that the DAF is a non-linear function of various source-specific parameters, such as lead concentration and source duration time. Consequently, Equation 5 could not be solved directly for the soil cleanup level, C_L. Instead, derivation of a soil cleanup level from a groundwater concentration, in this case the MCL value, would require the following trial-and-error approach:

- Choose (estimate) soil cleanup level
- Determine source-specific parameters required by MINTEQA2
- Run MINTEQA2 to determine equilibrium lead concentration in leachate, K_d values and source duration time (using HELP)
- Run MULTIMED to determine lead concentration at receptor well
- Compare lead concentration at receptor well to MCL value and refine soil cleanup level estimate accordingly
- Repeat steps 1 through 5 until receptor lead concentration = MCL value

As shown in Tables 5 and 6, under the average case scenario, a soil cleanup level based on the current MCL value for lead (50 ug/L) would fall between the 1,000 mg/kg and 10,000 mg/kg cleanup levels. To support comparison of alternatives in the FS,[3] further refinement of a soil cleanup level using the above trial-and-error approach was not required.

CONCLUSION

The MINTEQA2 and MULTIMED simulations indicate that the adsorption process plays a key role in determining the long-term effectiveness of a remedial action at the C&R Battery Site.

The wide variation in modeling results suggests that accurate contaminant fate and transport predictions for metals are dependent on a well-defined set of physical/chemical parameters since uncertainties in model inputs, particularly K_d, may lead to false conclusions. Nevertheless, the application of the MINTEQA2 and MULTIMED models to the C&R Battery Site exemplifies their potential to serve as valuable engineering and management tools in the development and evaluation of soil cleanup levels.

Regimen and Practical Considerations for Cross-Training of Industrial Hygiene and Health Physics Technicians

Richard F. Haaker, C.I.H.
Thermo Analytical Inc., TMA/Eberline
Albuquerque, New Mexico

ABSTRACT

Historically, the characterization and remediation of radioactive waste sites have been treated as if the only hazards present were due to radiation and radioactive materials. However, it has become apparent that work on many of these sites poses a number of industrial hygiene and safety concerns as well. Hazards created by heat stress, heavy equipment, excavation, silica dust and noise may pose much more significant health hazards than the radiation. In addition, most of the radioactive waste sites that are being remediated have an inventory of process chemicals or hazardous wastes that must be reckoned with. For these reasons, companies that traditionally have been in the health physics field services industry are finding it advantageous to employ individuals who are cross-trained in both health physics and industrial hygiene technologies. This paper:

- Summarizes those changes in the regulatory environment that have accelerated this trend
- Summarizes the minimum requirements set by regulatory agencies
- Describes a training sequence that TMA/Eberline has used to producing cross-trained technicians

INTRODUCTION

Health physics and industrial hygiene are very similar in their stated purpose, but for the most part have progressed through parallel evolutions. Health physics is often thought of as being the younger of the two disciplines although it became organized and regulated earlier than industrial hygiene in the United States. Formation of the U.S. Advisory Committee on X-Ray and Radium Protection (forerunner of the National Council on Radiation Protection) in 1929[1] was a milestone in the organization of health physics. Authority to regulate radioactive materials and radiation protection practices was provided by the Atomic Energy Act of 1954. Meanwhile, the American Conference of Governmental Industrial Hygienists was established in 1938. Authority to regulate occupational safety and health did not occur until passage of the Occupational Safety and Health Act of 1970.[2] The authority to regulate chemicals and chemical wastes was established during the 1970s and 1980s with the passage of a number of environmental laws.

The twenty five year lapse between the passage of the Atomic Energy Act of 1954 and the OSHA of 1970 resulted in rapid growth in the field of health physics. More recently, the passage of the OSHA, the enactment of environmental protection legislation, and the publication of OSHA's hazardous waste operations standards in 1986 has meant increased attention to chemical pollutants and the occupational safety and health of mixed-waste site workers.

Much of our nation's inventory of mixed hazardous and radioactive waste was generated under contracts with the U.S. Atomic Energy Commission and its progeny. During the 1980s, an upswing in environmental restoration activities at the U.S. Department of Energy's nuclear weapons plants stimulated the demand for field technicians who are cross-trained in industrial hygiene and health physics sampling and monitoring methods.

MINIMUM REQUIREMENTS

At this time, the minimum legal training requirements for working on a mixed-waste site are provided by a combination of OSHA regulations and one of the following: DOE Orders or Nuclear Regulatory Commission regulations or state radiation protection regulations.

The OSHA training requirements are primarily found in 29 CFR 1910, Section 120 (Hazardous Waste Operations and Emergency Response), Section 134 (Respiratory Protection) and Subpart Z (Toxic and Hazardous Substances). Depending on the job description, 24 to 40 hours of training can satisfy the OSHA requirement. A detailed discussion of which subjects should be included in hazardous waste operations training may be found elsewhere.[3]

In the case of work done under contract to the DOE, the radiation protection training requirements are specified in DOE Order 5480.11, "Radiation Protection for Occupational Workers." The minimum radiation protection training program specified by the DOE includes indoctrination in the following topics:

- The risk of low-level occupational radiation exposure, including cancer and genetic effects
- The risk of pre-natal radiation exposure
- Basic radiation protection concepts
- DOE and company radiation protection policies and procedures
- Employee and management responsibilities for radiation safety
- Emergency procedures

Where work is done for a Nuclear Regulatory Commission licensee in a restricted area, the minimum radiation protection training requirements for workers are specified in 10 CFR 19. The following information must be provided to workers:

- Locations and levels of radiation
- Health protection problems associated with exposure to radiation
- Precautions and procedures to minimize radiation exposure
- Purposes and functions of protective devices
- Applicable regulations
- Responsibility to inform licensee of violations of Commission regulations and unusual occurrences

Radiation protection training can be included as an integral part of the 40 hours of hazardous waste training required by OSHA standards. This level of training generally is adequate for drillers, surveyors and other individuals with limited responsibilities on a mixed-waste site. Unfortunately, this level of training is insufficient to qualify individuals

as entry level radiation protection or industrial hygiene technician.

INDUSTRIAL HYGIENE TECHNICIAN TRAINING

The goals of our industrial hygiene training program are to acquaint the hazardous waste site worker with using direct reading instruments, air sampling hardware, and noise monitoring equipment. In order to use the equipment properly, a worker needs to understand the basic operational principles, calibration procedures, simple trouble-shooting techniques, limitations of the device and interpretation of instrument readings.

The amount of training required will depend on how sophisticated the individual must become in industrial hygiene measurement techniques. Approximately 40 hours of training are required to make employees comfortable with the following training topics:

- Concentrations: ppm, mg/m3, volume percent, percent of LEL
- Use of bubble tube meters and mass flow meters to measure the flow rates of air sampling pumps; correcting air sample data to reference conditions
- Air sampling procedures requiring the use of particulate filters, sorbent tubes, impingers and dust cyclones
- Use and interpretation of colorimetric detector tubes
- Combustible gas indicators (CGI): how they work, how to calibrate them, and how to use them
- Portable flame-ionization detectors (FID): how they work how to calibrate them, how to use them
- Portable UV photo-ionization detectors (PID): how they work, how to calibrate them, how to use them
- Type II sound level meters: how to calibrate and use them o perform noise surveys

The employees who receive industrial hygiene measurement training are often health physics technicians who have training or experience which satisfies the requirements of 29 CFR 1910.120. Their response to the training is remarkably positive. The typical student is very concerned about missing even a few minutes of training! Most of the students are anxious to get their hands on the equipment and learn how to operate and calibrate it. Hands-on practice serves to clarify and reinforce what the mind has learned; so it is helpful to have students go through each operation several times.

During the course of the industrial hygiene measurements training, students realize that the procedures of operating CGI, PID and FID detectors are rather simple. They also learn that calibration procedures for many direct reading instruments are rather similar even though there are differences in detail.

RADIATION PROTECTION TECHNICIAN TRAINING

The goals of a radiation protection training program are to acquaint the hazardous waste site worker with health physics concepts, procedures and instrumentation. The training sequence is a two-step process. First, the individual is given an 8-hour overview of basic radiation pro-

tection concepts, computations and procedures. The trainee then must pass a lengthy take-home examination. On an as-needed basis, the employee is provided with site-specific supplemental training in procedures and instrumentation. On the average, workers receive approximately one week per year of site-specific supplemental radiation training.

Upon satisfactory completion of the basic radiation training, the employee is certified as having radiation protection technician training which satisfies the requirements of DOE Order 5480.11. It is a DOE requirement that refresher training be provided once every two years.

The following topics are presented during the 8-hour overview of radiation protection:

- Basic atomic structure
- Characteristics of ionizing radiation
- Radioactivity and radioactive decay
- Radiation units and measures
- Biological effects of ionizing radiation
- Radiation detection instruments
- Radiation survey techniques
- Radiation exposure and contamination control
- Federal radiation protection regulations

CONCLUSIONS

Hazardous waste operations training which satisfies the requirements of 29 CFR 1910.120 can provide the essential information which all mixed waste site workers must know. This level of training often is sufficient for surveyors, craftsmen and utility technicians who are not involved with taking occupational health or radiation measurements. In addition to hazardous waste training, approximately one week of radiation protection training may be provided to entry level workers who need to become proficient in health physics instrumentation and procedures. Approximately one week of industrial hygiene measurements training is enough to provide basic proficiency in chemical air sampling procedures, noise monitoring hardware and direct reading chemical detection equipment.

The training regimen outlined in this paper has worked well for TMA/Eberline. Training programs that are adequate for one type of mixed waste site, type of work or type of management philosophy may prove inadequate when used in different circumstances. Training programs always should be carefully reviewed by qualified safety and health professionals before being accepted.

Remediation of a Lead Contaminated Site in a Central Business District

C. Dale Jacobson
Jacobson Helgoth Consultants
Omaha, Nebraska

Craig G. Osborn
HDR Engineering, Inc.
Omaha, Nebraska

ABSTRACT

The City of Omaha/Douglas County Central Park Mall project is part of a multiyear riverfront redevelopment plan. The plan involves several commercial developments including a $275 million corporate headquarters campus, research and development center and 30 acres of public green-belt park space.

A major hazardous waste site was identified within the urban redevelopment during the early planning stages. The result was a fast-track, multimillion dollar site investigation, remedial design and remedial action conducted to make way for the now-completed public park, lake/marina complex and corporate headquarters.

The RI/FS was completed while the final design and early construction packages for other project phases were underway. The investigation concluded that the soil on the proposed park site was contaminated primarily with heavy metals.

The remedial design provided for multiple technologies to reach the project's overall objectives. This paper focuses on two technologies:

* Resource recovery through off-site smelting of the lead contaminated soil
* On-site stabilization of lead contamination with subsurface placement

This paper discusses how the hazardous waste site was remediated in only 18 months from remedial investigation to completion of remedial action allowing for successful public and corporate projects on the site. Fast-tracked site characterization, off-site and on-site contaminant treatment alternatives are reviewed and the lessons learned during the remediation are presented.

INTRODUCTION

The Central Business District of Omaha, Nebraska, lies immediately west of the Missouri River. Through the years, the land adjacent to the river, which was principally industrial and warehousing in nature, had fallen into disuse with many abandoned buildings. In late 1987, the City of Omaha and Douglas County reached an agreement with several corporations for a major urban redevelopment project in this area. ConAgra, a major food processing corporation, would relocate its corporate headquarters as the anchor of the redevelopment. The project would include six multistory buildings in a campus setting adjacent to a 30 acre park. The principal feature of the park would be a 15 acre lake and fountain. Development of the park was undertaken by Douglas County. Other major elements of the redevelopment included renovation of the historic Union Pacific Railroad freight house for use as a system-wide-dispatch center and construction of a major office building/computer center by U.S. West Communications. Also planned is construction of a hotel complex and parking garage.

Due to the former land use, Douglas County elected to conduct an environmental investigation of the park site in 1988. Former industrial facilities included a battery breaking and secondary smelting facility that operated from 1963 to 1982, a metal salvage operation, a railroad freight handling facility (which had been destroyed by fire), a World War II alcohol production plant and numerous railroad tracks serving the area. The project area is shown in Figure 1.
Figure 1
Project Area

SITE DESCRIPTION

The site lies west of the Missouri River on a floodplain that is approximately 1200 feet wide. The western portion of the site occupies

a higher mantled alluvial terrace and the ground surface slopes gently to the east. Ground elevations range from approximately 1,010 feet msl on the western edge to 975 feet msl near the eastern edge.

The soil in the floodplain consists of a clayey sand overlying limestone bedrock at a depth of 27-35 feet below the ground surface. The water table of the area is greatly influenced by the water level of the river and is generally 15 feet below ground surface. The site is bounded on the east by the Missouri River, on the north by the I-480 bridge, on the south by Jones Street and on the west by 8th Street.

DISCOVERY OF ENVIRONMENTAL PROBLEMS

Several environmental investigations were initiated during 1987 and 1988. Results from those investigations indicated that the soil on the proposed park site was contaminated with heavy metals with lead being the most prominent. These findings had an immediate impact on conventional park construction activities in the area. The contaminated areas were fenced and more detailed site investigations began. With the limited information available, the opinion was that before construction of the park could proceed, the site would require remediation.

SITE INVESTIGATIONS

In late 1987, random environmental samples from soil borings and monitoring wells were collected. Analysis of these samples revealed metal contamination in the upper few feet of soil. Groundwater samples indicated that metal contamination was confined to the soil overlying the aquifer. Petroleum hydrocarbon contamination was discovered in one of the monitoring wells. Elevated concentrations of VOCs and pesticides/PCBs were not detected in any of the soil and water analyses.

As the limits of contamination became better defined, subsequent investigations focused on approximately five acres of land encompassing the former secondary lead smelting facility. A detailed remedial investigation of this area was conducted in 1988. The assessment indicated that the area contained high levels of total arsenic, antimony, cadmium and lead. Twenty-five percent of the soil samples revealed cadmium in concentrations which exceeded the EP Toxicity standard, and 70% revealed lead in concentrations exceeding the EP Toxicity standard. Monitoring well samples did not indicate an exceedance of the U.S. EPA Maximum Contaminant Levels (MCLs) for drinking water metals. In addition to the metals, the investigation revealed the presence of petroleum hydrocarbons in the soil.

A subsequent investigation of petroleum hydrocarbons was conducted at the site to determine the magnitude and extent of contamination. Results of that investigation indicated that the contamination was primarily confined to the soils and no measurable thickness of floating product was detected on the groundwater.

In summary, the site investigations detected soil metal contamination with concentrations highest near the ground surface and decreasing with depth and distance from the smelting facility property boundary. Findings of the remedial investigation indicated the presence of the following soil contaminants:

Contaminant, Total Metal	Maximum Concentration, (mg/kg)
Lead	152,400
Arsenic	1,700
Cadmium	1,900
Antimony	3,400

REMEDIAL ACTION PLAN AND IMPLEMENTATION

In January 1989, a draft feasibility study which evaluated remedial action alternatives for the site was completed. Remedial action objectives contained in the feasibility study were based on contaminant specific applicable or relevant and appropriate requirements (ARARs), input from public meetings, health assessment information and a corrective action agreement between the State of Nebraska, Department of Environmental Control (NDEC) and Douglas County. The principal regulatory guidelines for the site contaminants include federal criteria

documents, epidemiologic studies, state regulations and health advisories.

Several technologies were made a part of the initial feasibility study screening process, including immobilization, landfilling, soil washing, resource recovery, vitrification and storage/capping. From that list, five technologies were selected for a detailed evaluation of alternatives. Rankings for each remedial alternative are presented in Table 1.

Table 1
Evaluation of Remedial Alternatives

Alternative	Effectiveness	Implementability	Cost	Compliance
No Action	Low	High	Low	No
Resource Recovery	High	Medium	Medium	Yes
Resource Recovery/ Immobilize on-site	High	Medium	Medium	Yes
Hazardous Waste Landfill off-site	High	High	High	Yes
Immobilization on-site	High	High	Medium	Yes

The feasibility study concluded that EP Toxic soils could be remediated through a combination of resource recovery or stabilization and that non-EP Toxic soils, generally containing total lead concentrations between 1,000-10,000 mg/kg, should be excavated and covered. It was determined that placing all soils left on-site under a cover of native fill would greatly reduce both potential airborne and direct contact exposure pathways and allow for future management of the material from the standpoint of maintenance and deed restrictions. Highlights of the corrective agreement with the NDEC are as follows:

- Douglas County would submit a Remedial Action Workplan, including a schedule to NDEC for review and approval.
- Douglas County would treat soils contaminated at or above 1000 mg/kg total lead or exhibiting EP Toxicity for metals using the treatment method approved by NDEC before covering the site with native fill.
- Douglas County would propose procedures for preventing fugitive dust emissions from the site.
- Once excavation, treatment and consolidation of soils was completed, the site would be regraded and covered with 3 feet of uncontaminated soil.
- Douglas County agreed to maintain the park throughout its ownership of the site or until it receives approval from NDEC for a change of use. Douglas County would place a notice in the deed to the property restricting any change of use without prior notification and approval of NDEC to ensure that the integrity of the cover is preserved and maintained.
- Douglas County would submit a worker Health and Safety plan to NDEC for review and comment.
- In the Remedial Action Workplan, Douglas County would propose, for NDEC review and approval, treatment of contaminated soils. Prior to NDEC approval, Douglas County shall provide documentation which demonstrates their effectiveness.
- Douglas County would submit to NDEC written monthly progress reports of remedial action activities.
- NDEC would provide oversight and review of documents and site operations on a frequent basis to ensure that the requirements of law and the goals of the Agreement are diligently met.

REMEDIAL DESIGN

The remedial design called for conventional construction activities to be initiated under a separate contract which would begin after site remediation had been completed. Additionally, all soil which was identified as recyclable following trial tests, that could be recycled within the scheduled remediation period, would be shipped to a primary smelting facility.

In March 1989, Douglas County advertised for sealed bids to secure a contract for the Central Park East - Site Remediation Project. The contract documents, including drawings and specifications, detailed the character and scope of work to be performed and standards applicable to the work.

The site remediation project was divided into nine bid items. Each bid item set forth a request for the price of the work and services to be performed under the contract. These items included:

- Mobilization/Demobilization
- Earthwork (EP Toxic Soil)
- Earthwork (Non-EP Toxic Soil)
- Earthwork (Landscape Fill)
- Soil Stabilization Treatment
- Structural Demolition
- Pipeline Removal
- Miscellaneous Removal
- Rubble Disposal

REMEDIAL ACTION

Soil stabilization and resource recovery were selected as the remediation processes. For remediation purposes, contaminated soils were grouped into three categories based on lead content and remediation method:

- Soil that contained greater than 20,000 mg/kg lead and was of proper gradation was considered a lead ore and could be used as feedstock for a primary smelting facility.
- Soil that exhibited EP Toxicity characteristics for metals required stabilization if not recycled in the smelter.
- Soil that did not exhibit EP Toxicity characteristics for metals, but had total lead concentrations greater than 1000 mg/kg, required excavation, placement and covering.

By using resource recovery, the lead was reclaimed as a substitute for raw material and the process qualified as recycling. Initially, 300 tons of soil were shipped by gondola railcar to a Missouri smelting facility for processing. Test results from that shipment indicated that the soil was compatible with their operations although somewhat lower in quality than initial bench tests indicated. As a result, a second shipment of approximately 500 tons of soil from the site took place in early summer 1989.

The stabilization process was used for the on-site remediation of the remaining EP toxic soils. Stabilization is a chemical fixation and solidification process designed to produce a nontoxic, environmentally safe material that can be used as fill. The process utilized a two-part inorganic chemical system which reacts with polyvalent metal ions and with certain other waste components. It also reacts within itself to form a chemically and mechanically stable solid. This system is based on the reaction between silicates and silicate-setting agents which react in a controlled manner to produce a solid matrix.

The chemical stabilization process used for this project involved three classes of soil/chemical interactions. First are the very rapid reactions between silicates and polyvalent metal ions, producing very insoluble metal silicates. A second set of reactions occurs between the silicate and reactive components of the setting agent. The third class of reactions occurs between the setting agent and the waste and/or water as it undergoes a series of hydrolysis, hydration and neutralization reactions.

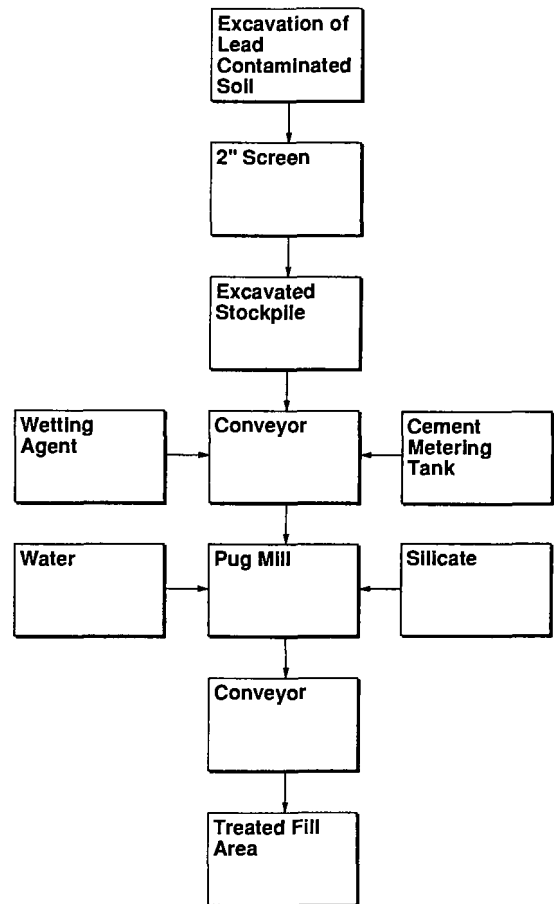
The soil was excavated using scrapers and back-hoes and was screened to remove debris. Pockets of slag discovered on the site had to be crushed in order to make the material compatible with the stabilization process. Following excavation and crushing, the soil was stockpiled for screening. Front-end loaders were used to sift material through a two inch shaker screen with soil falling onto a conveyor belt for transfer to the chemical feed system. Following chemical addition, the soil was dropped into a pug mill for thorough mixing. Following mixing, the treated soil was dropped onto a conveyor belt and moved to its designated fill area where the material was shaped and compacted. The stabilization process flow diagram is presented in Figure 2.


Figure 2
Stabilization Process

SUPPORT ACTIVITIES

Samples of treated EP Toxic soil were collected to confirm that the soil treatment process had stabilized the metals to remedial action levels. A sampling frequency of one sample per 1000 yd^3 of stabilized soil was used for quality control. If a sample failed to meet the remedial action level, the batch representing the failed run was returned to the stockpile of untreated material for reprocessing. These soils were retreated until testing confirmed acceptable treatment levels had been achieved.

Excavation areas established during the remedial design were subdivided into sample areas of approximately equal size with defined boundary coordinates. Within these sample areas, coordinate point references were established to aid in developing a sample grid. Twenty aliquots were gathered using an Oakfield manual sampler from each area and composited to represent the level of remediation for that area.

After the general contractor had excavated the contaminated soil to planned depths, the exposed ground surface was sampled by the field team. These analyses were used to confirm that site excavation activities had removed the contaminated soil to the remedial action levels.

If the remaining soil was determined to have a metal concentration greater than the remedial action levels, the area was excavated an additional one foot. After the additional one foot of soil was removed, the newly exposed ground surface was retested. These same procedures were followed throughout the project until the remaining soil exhibited a metal concentration which met the remedial action levels.

Air monitoring was performed using four high volume air samplers to determine if dust suppression activities were minimizing fugitive dust emissions during remediation. Background samples were collected at the site prior to remediation activities to serve as a baseline for measuring the effectiveness of dust mitigation. A goal of the site

remediation team was to reduce off-site releases of dust through tasks such as frequent application of water for dust control and modification of excavation and treatment practices contributing to off-site releases.

FINDINGS

Many problems were experienced throughout the project. Some initially were thought to be minor obstacles, while others went undiscovered until the site remediation was well underway. All impacted the project from a cost and schedule standpoint.

Underground Storage Tanks

The discovery of five underground storage tanks (USTs) occurred during various stages of excavation throughout the project site. Three of these tanks had suffered gross failures making it necessary to deal with the petroleum hydrocarbon-contaminated soil underlying the UST to clear the area for conventional construction.

Excavation and removal of 20,000 yd³ of petroleum-contaminated soil was accomplished in three weeks using a back-hoe and several bottom dump trucks to haul the material to a local site where landfarming of the soil took place over a period of two months.

Pipeline

It was determined that a four inch diameter abandoned pipeline ran parallel to the project site for a distance of 1600 feet. The pipe was removed and capped at both ends of the project site. Petroleum hydrocarbons, discovered in the soil near the pipeline, were suspected to have leaked at some time during its 40 years of operation. The pipeline contained several hundred gallons of product which were removed and hauled away by an oil recycling company.

Slag

It was determined during the site investigations that slag was a component of the contaminated fill material which required remediation. During construction, it was determined to be a major component of remediation requiring a change order. This change over resulted from the discovery of burial pits containing chunks of slag, measuring four to ten inches in diameter. In total, 2000 yd³ of slag were excavated from the site. Due to the large particle sizes, it was necessary to crush the slag in order to stabilize it with the soil for placement on-site. The large volume of material requiring crushing caused significant delays in the scheduled completion of the project.

Rubble

Although some rubble was expected to be encountered, the actual amount was greatly in excess of expectations. This was the result of long abandoned storm sewers and building foundations not shown on any existing plans. This unanticipated material resulted in additional project cost for removal as well as schedule impacts.

Ingots

Three ingots of nearly pure lead, approximately eight feet in diameter and one foot thick, were discovered. These ingots were transported to a local smelter for recycling. Considerable extra cost was incurred in procuring a crane of sufficient capacity to lift the ingots to a flatbed truck.

Smelting

Problems were encountered during the transportation and recycling of the lead-contaminated soil at the smelting facility in Missouri. The smelting facility is a primary smelter designed to handle homogeneous crushed lead ore from a mine and not material of various sizes. The smelter's feed specifications resulted in a one inch screening size requirement being placed on the soil shipments. Screening the soil to this size was time-consuming and in some instances required several screenings of a single load. When the soil became damp, it was nearly impossible to sift soil through a one inch screen. This problem was unfortunate because metal assays indicated that a large percentage of the soil on the site would have been suitable for smelting from the standpoint of the lead content, but it could not be processed in a timely manner.

The other problem encountered during smelting was coordination of the shipments by railcar and storage capacity at the smelter. Storage bins at the smelting facility had a limited capacity and restrictions were put on the number of railcars that could be sent at one time. Scheduling the relatively small number of railcars, by railroad standards, was difficult to coordinate because the length of time to screen the material was variable. Several days of time were lost due to screening and late arrival and departure of railcars.

Resource recovery ended up being a cost rather than a benefit. The smelting fee of $150 per ton, the transportation costs of $25 per ton and screening costs exceeded the lead ore value. When all factors were considered, a unit price of approximately $100 per ton was the resulting cost for soil disposal.

Remediation Volume

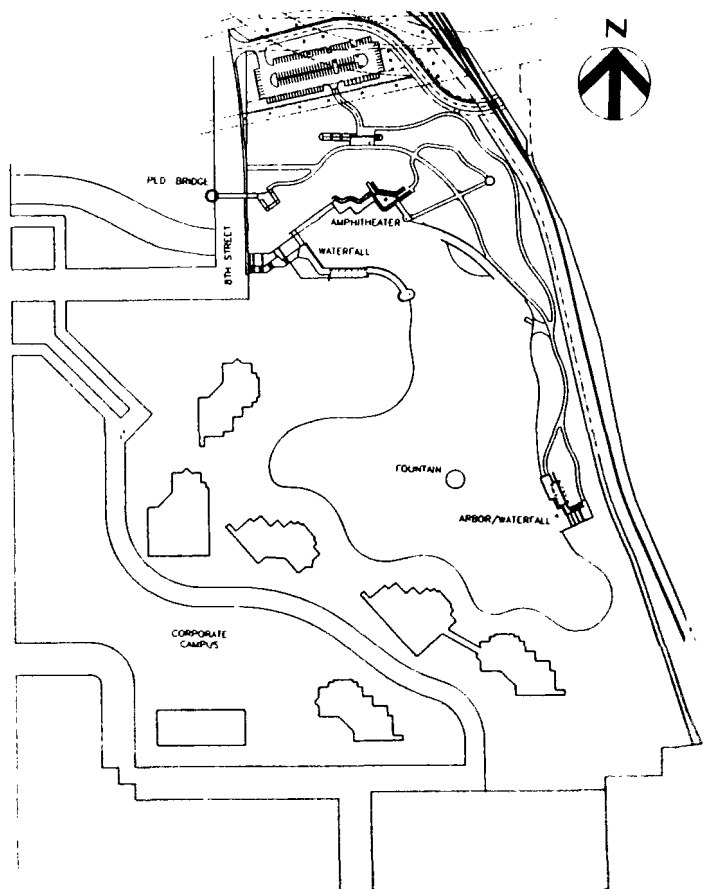
Initially, based on soil borings, it was estimated that 30,000 yd³ of soil would fail the EP Toxicity test and require remediation by chemical fixation and stabilization. An additional 20,000 yd³ were estimated to have total lead concentrations between 1,000 and 10,000 mg/kg. However, this material generally would pass the EP Toxicity test. Thus, remediation could consist of excavation, placement and covering. In the end, the EP Toxic soil volume increased to approximately 49,800 yd³ while the non-EP Toxic soil volume decreased to approximately 13,400 yd³. Thus, the total volume requiring remediation increased by 13,200 yd³ or 26% of the total. Of greater significance is the fact that the increase in EP toxic soil resulted in considerable extra cost since this soil had to be processed through the treatment process, the most costly phase of the remediation on a unit price basis. Soil borings, being discreet in nature, resulted in an underestimation of remediation quantities.


Figure 3
Corporate Campus and Public Park

POST REMEDIATION

A total of 63,200 yd^3 of contaminated soil was excavated and managed in some fashion either by stabilization, recycling, or excavation and covering. Of that volume, 48,000 yd^3 of soil were stabilized on-site. The remainder was either managed on-site or sent to the smelter.

The project which began with a remedial investigation in May 1988 was completed in December 1989 at a cost of $7,100,000. Of this total, $1,200,000 was reimbursed to the County by the previous owner of the site.

The willingness of Douglas County to address the hazardous waste issue in a technically sound, yet rapid manner, resulted in remediation of the site at much lower cost and in much less time than typically would have been required. The detailed cooperation of the state regulatory agency, which has delegated authority for RCRA from the U.S. EPA, also contributed to project success.

Today the site is nearly complete with six office buildings and a 15 acre lake containing two water fountains as shown on Figure 3. The development has become an integral element of redevelopment of Omaha's Central Business District.

Status of Developing Land Disposal Restrictions for Superfund Soils

ABSTRACT

RCRA Land Disposal Restrictions (LDRs) for contaminated soil and debris at Superfund sites are currently being developed. This paper discusses the steps the U.S. EPA is taking to gather data for the development of LDR treatment standards for contaminated soil and debris (CS&D) and discusses the challenges of treating contaminated soils, sludges and debris wastes.

The unique physical and chemical characteristics of Superfund soil and debris make these wastes more difficult to treat than more homogeneous industrial process wastes. In response to this, the U.S. EPA is in the process of developing separate LDR standards for soil and debris. LDRs for CS&D are being developed under section 3004 of the Hazardous and Solid Waste Amendments of 1984 to RCRA. Until the final CS&D standards are in place, the National Contingency Plan specifies that Best Demonstrated Available Technology (BDAT) standards are generally inappropriate for Superfund soils and that treatability variance levels, based on the actual treatment of soil, will be used. This paper discusses the U.S. EPA's accomplishments in the collection of existing soil treatment data, the development of variance procedures and variance levels for remedial/removal actions (Superfund LDR guidelines 6A and 6B) and the issues involved in treating soil and debris. In addition, the paper discusses some preliminary findings on the treatment of debris and the analytical methods used for determining the BDAT for CS&D. The schedule for rulemaking also is discussed.

INTRODUCTION

The U.S. EPA's Office of Solid Waste and Emergency Response (OSWER) recognized that contaminated soil is more difficult to treat than RCRA industrial process (hazardous) wastes and that it is not likely to meet the LDRs developed for RCRA hazardous wastes. In response, OSWER began a program to develop Contaminated Soil and Debris (CS&D) Treatability Variances, which are alternate treatment levels, based on actual treatment of Superfund and RCRA soil and debris. Data were collected, and in 1989, Treatability Variance Levels were established for soils (Superfund LDR guides 6A and 6B).[1,2]

OSWER, the Office of Solid Waste (OSW) and the Office of Emergency and Remedial Response (OERR) determined that the existing soil treatment data base is not comprehensive enough to support a formal set of LDRs for CS&D. Sixty-seven data sets were suitable for calculating treatability variance levels; however, several technologies had little or no data so they were not included in the data

base. OSWER implemented a research program to obtain all of the necessary data to support LDRs for CS&D.

In 1988, OSWER including the new Technology Innovation Office (TIO), and the Office of Research and Development (ORD), Risk Reduction Engineering Laboratory (RREL) in Cincinnati, Ohio, established a work group to develop BDAT standards for CS&D. The work group objectives include a review of the current data base, recommendations for additional studies on treatment performance, implementation of treatability studies, identification of newly available data and development of BDAT regulations based upon new and available data. There has been significant progress with these efforts.

DATA COLLECTION

OERR, in its initial data collection effort, examined more than 500 studies conducted by the U.S. EPA, federal agencies, industries and universities. Of these studies, 67 met the criteria established for the development of variance levels for contaminated soils. The criteria require that: (1) the soil originates from contaminated sites (soils are not spiked with contaminants); (2) data are of sufficient quality; and (3) the untreated and treated soil contamination is measured. The criteria for setting final LDR treatment standards are more rigorous than the criteria for variance levels, requiring more documentation of QA/QC procedures and bench, pilot- and full-scale data. Of the 67 studies used for variance levels, only 13 were adequate for consideration in the development of LDR treatment standards.

Lack of soil treatment data prompted a more aggressive data collection effort by OERR, OSW, TIO and ORD. Figure 1 shows the basic approach for data collection in the CS&D program. Additional data will be collected from recent remedial/removal actions, including DOD and DOE actions, SITE program demonstrations and treatability tests conducted by the CS&D program. Twenty-seven additional data sets already have been obtained. Currently the CS&D data base contains not only the original data base, but also studies that have been collected since the variance levels were published.

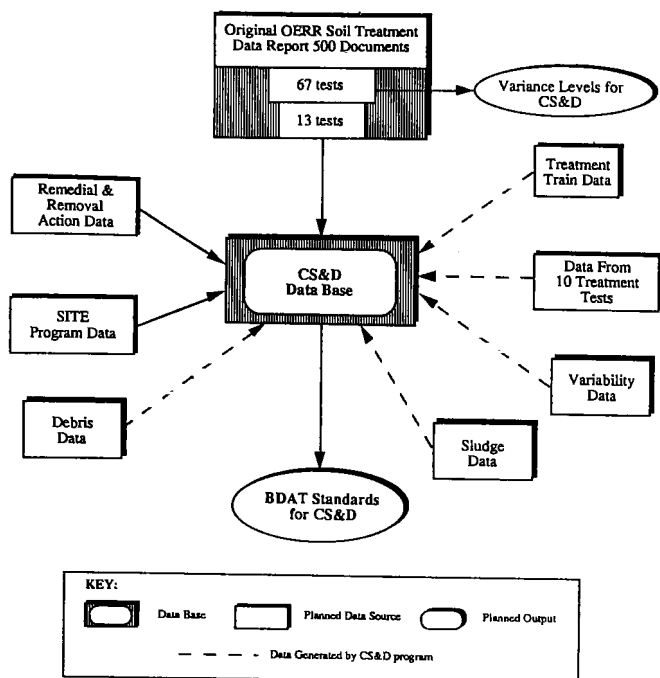
OERR developed a strategy for calculating variance levels from a quantity-limited data base. OERR grouped the data by "contaminant groups" which are groups of contaminants having similar chemical and physical characteristics. Contaminants are categorized into 13 groups; examples of contaminant groups include nonpolar halogenated aromatics and PCBs/dioxins/furans including their precursors. The variance levels that were developed quantified the effectiveness of various available technologies on the contaminant groups (Table 1).


Figure 1
Development of LDRs for CS&D
Data Collection Approach

SOIL TREATMENT TESTS

The CS&D Program, after reviewing available data sets, identified technologies that lacked treatment performance data, but would be available technologies for treating CS&D (Table 1). Ten treatment tests are planned; the technologies that will be tested include bioremediation, low temperature thermal desorption, chemical extraction, soil washing, stabilization and high temperature distillation (Table 2). The technologies are applied to different types of soils and wastes. For example, the biotreatment tests will be conducted on three soil types. The soil classifications range from sandy to clay. In addition, different types of wastes, including wastes high in PNAs, PCBs and metals, will be tested. The stabilization technology will be tested as both a primary technology and as a residual treatment.

The treatability tests will be conducted according to the OSW Quality Assurance Project Plan for Characterization Sampling and Treatment Tests Conducted for the Contaminated Soil and Debris Program[3] and site-specific Sampling and Analysis Plans. The individual sampling plans specify holding times, analytical methods, chain-of-custody and quality control measures, such as blanks and spikes. The tests will include measurements of contaminant concentrations before and after treatment, and measurements of the waste characteristics that affect the performance of soil treatment technologies. Examples of waste characteristics that affect treatment performance are moisture content, oxidation/reduction potential and particle size distribution and are listed in the QA Project Plan.

DEBRIS

OSWER has collected and continues to collect existing data on debris treatment programs. This collection and assessment project determined that debris could constitute as much as 50% of the contaminated media at a wood preserving site. The assessment also found that the sampling procedures were not well documented. Recognizing the importance of debris, the CS&D Program has implemented a comprehensive review of debris sampling, analysis and treatment. The treatment technologies that require treatment performance data will be tested by the CS&D Program. The characteristics of debris that have been determined to affect treatment include permeability and destructibility. The potential treatment technologies for debris are destruction, chemical extraction, physical removal and sealing/solidification (Table 3).

Table 3
Potential Management Practices for Debris Decontamination

DEBRIS MATRICES \ CONTAMINANT GROUPS	ORGANICS * (EXCEPT NITRATED ORGANICS)	NITRATED COMPOUNDS	METALS	CYANIDE
PERMEABLE DESTRUCTABLE	Destruction	Destruction	Chemical Extraction Physical Removal Sealing/Solidification	Destruction

* Organics include volatile, acid extractable, and base neutral organics, pesticides, dioxins and PCBs

SLUDGE

An OSWER survey of Superfund sludge data found that sludges are not consistently defined in the studies by the authors. Further-more, sludges, when identified, had higher concentrations of contaminants than soils and, as a result, did not meet variance level standards as frequently as soil. Of the OSWER survey data, 55% of the sludge treatment met variance levels, while 78% of the soil treatments met variance levels. These results indicate that sludge may require its own treatment standards and that additional data on the definition and treatability of sludges should be obtained. If required, treatability tests will be conducted.

VARIABILITY

The OSWER study of Superfund soil treatability has found an order of magnitude difference in treatability between remedy selection testing and full-scale treatment. The factors that affect treatment effectiveness include mixing effectiveness, homogeneity of the soil matrix, feed specifications and contaminant concentrations. Variability of the treatment results for the relatively homogeneous RCRA waste streams have been accounted for using classical statistics which assume a less variable data set than Superfund soils.

A study has begun to identify the historical approaches to quantifying variability of treatment results for Superfund soils. Once completed, a testing program will be developed and implemented. This program will be designed to quantify the effects of soil classification, contaminant concentration heterogeneity, diverse technology feed specification, mixing requirements and scale-up factors on the full-scale treatment results.

CONCLUSIONS

The current schedule provides for completion of data collection and data analysis in the summer of 1991. We are soliciting existing treatment data and new tests which may meet these needs. We welcome comments on this program to advance this study effort on soils, sludges, debris and variability. If you have data, comments or questions regarding the LDRs for contaminated Superfund soils and debris, please contact:

ABSTRACT

The 80-acre Helen Kramer Landfill Superfund site in Mantua Township, New Jersey is currently undergoing remedial action by IT-Davy, a joint venture of International Technology Corporation (IT) and Davy McKee Corporation (Davy). The $55.7 million, two-year construction effort represents the second largest single remediation contract awarded to date under the Superfund Program. The Army Corp of Kansas City District, as the U.S. EPA's project manager, awarded IT-Davy a contract to carry out remedial action in October 1989. On-site construction has commenced with a planned completion date of January 1992.

The Helen Kramer site received municipal solid wastes, hazardous chemical wastes and hospital wastes from 1963 to 1981. Contaminated leachate has been detected in both surface and groundwaters near the site. The site is physically and chemically hazardous, with wastes, surface rifts and sharp objects (including hypodermic needles) exposed at the surface. Landfill gas and particulates are being discharged into the atmosphere, and several large fires have occurred at the site

The remedial action for this site includes isolation of the contamination through the installation of a multilayer cap over the site and a slurry wall around the site to isolate the contamination from the surrounding environment. Leachate and run-off liquids will be collected and treated utilizing airstripping and carbon absorption. Landfill gas also will be collected, treated and flared. IT-Davy has total site remediation responsibility including construction and implementation of site security, health and safety programs, personnel training programs, chemical and geotechnical testing and facility operation for one year.

This paper presents an overview of this large superfund site remediation project and the status as of September 1990.

INTRODUCTION

The Helen Kramer Landfill Superfund Site is currently undergoing remedial action to isolate toxic contaminants from the local community and environment. The Army Corps of Engineers (COE), Philadelphia District is acting as project manager for the U.S. EPA. IT-Davy, a joint venture of International Technology Corporation (IT) and Davy McKee Corporation (Davy), is the remedial action contractor (RAC) for this site. IT-Davy has total site remediation responsibility including construction and implementation of site security, health and safety programs, personnel training programs, chemical and geotechnical testing and operation of the site treatment systems for one year.

At the time of award, October 1989, the remedial action contract value, $55.7 million, represented the largest single site remediation contract awarded to date under the Superfund program. The size of the project and its proximity to residential and farming communities have generated substantial public interest in the progress of the remedial action and the process leading up to the actual construction activities.

This paper presents a description of the site and reviews its progress through the Superfund process. The remediation project is described, and the current status as of September 1990 is discussed. Problem areas encountered in the remediation effort are identified.

SITE DESCRIPTION

The Helen Kramer Landfill is located in Mantua Township, Gloucester County, New Jersey, approximately 20 miles south/southeast of Philadelphia, Pennsylvania. The site encompasses an 80-acre refuse area and an 33-acre stressed area. The site is bounded on the north by Jessups Mill Road, the south by Boody Mill Road, the west by Leave Road and the east by Edwards Run. The stressed area lies between the refuse area and Edwards Run. Centre City, the nearest residential area, is 1200 feet east of the site. Active farms are located just west of Leave Road and south of Boody Mill Road.

A north-south ridge, approximately 1500 feet long, divides the site. The western slope is moderate, whereas the eastern slope is long, steep and extends into Edwards Run. Edwards Run flows into Mantua Creek which is a tributary of the Delaware River.

Table 1
Leachate and Groundwater Contaminants

ORGANICS	INORGANICS
Bromomethane	Arsenic
Dichloroethenes	Chrome
Trichloroethanes	Cobalt
Benzene	Iron
Toluene	Lead
Xylenes	Magnesium
Ketones	Nickel
Phenols	Sodium
	Calcium

A 2- to 3-acre pond, containing approximately 5000 gallons of water is located in the northeast corner of the site. Two smaller leachate

collection ponds are located along the eastern slope. One of these ponds is lined with a Hypalon membrane, that has many visible tears, whereas the other is unlined. Leachate discharges from these ponds to Edwards Run.

The site surface is characterized by surface rifts and loose, uncompacted exposed refuse. Numerous cracks are apparent where methane, steam and leachate are vented. Sharp objects, including hypodermic needles, are exposed. These conditions represent physical hazards for personnel entering the site.

Groundwater and leachate leave the site via Edwards Runs and are heavily contaminated with organic and inorganic compounds. The Mount Laurel aquifer which underlies the landfill is also heavily contaminated. Groundwater from this aquifer flows into Edwards Run. Bioassay and Ames testing indicate the waters in Edwards Run are both toxic to the test species (bioassay) and mutagenic according to the Ames test. Table 1 Lists major contaminants which have been found in the water in Edwards Run.

Methane and other landfill gases discharge into the atmosphere through natural vents or cracks in the landfill surface. Methane concentrations above the lower explosion limits have been detected at the landfill surface. VOCs were measured in the ambient air on and near the site; however, concentrations did not indicate an imminent threat to nearby residents.

SITE HISTORY

The Helen Kramer site was originally used as a sand and gravel pit. Sometime in 1963, the site began receiving refuse while the excavation of sand and gravel continued. When New Jersey enacted a Solid Waste Management Act in 1970, the site operator was given a temporary registration valid until July 1, 1971. By that time, the operator was required to have submitted a sanitary landfill design for permanent registration.

Beginning with this first submittal date, all deadlines for submitting documentation were missed and the Helen Kramer Landfill became the subject of numerous inspections and characterizations. The following chronology highlights the site history from this initial regulatory action up until the issuance of a Notice To Proceed with the remedial action.

- July 1973 — Landfill design submitted to New Jersey Department of Environmental Protection (NJDEP) and rejected as incomplete.
- October 1973 — Site inspection by NJDEP noted disposal of chemical and sanitary wastes on-site.
- January 1974 — NJDEP inspections noted presence of chemicals and drums on-site, as well as chemical waste disposal in at least seven lagoons.
- January/ March 1974 — Revised landfill designs submitted and again rejected as incomplete.
- April 1974 — NJDEP noted leachate discharging into Edwards Run. NJDEP issued a Department Order, a Notice of Prosecution and a Notice of Intent to Deny Renewal of Approved Registration. NJDEP issued a stipulation restricting dumping to municipal household wastes, commercial wastes, sewage sludge, septic tank wastes, leaves, tree stumps and branches.
- November 1974 — Revised engineering design submitted and rejected as incomplete.
- September 1976 — Second Notice of Prosecution issued requiring submittal of an acceptable engineering design within 30 days. Revised engineering design resubmitted.
- April 1977 — Engineering design rejected Notice of Registration Revocation issued informing the owner to cease operation of the landfill. Hearings on the revocation continued until early 1981.
- March 1981 — Gloucester County court ordered the landfill to cease operations effective March 7, 1981.

- June 1981 — U.S. EPA sent out "Information Request" letters to 11 PRPs.
- July/ August 1981 — Several fires broke out in the landfill and were not extinguished until November 1981.
- 1981-1983 — Preliminary site assessments carried out.
- January 1982 — U.S. EPA sent out additional Information Request letters.
- July 1982 — Helen Kramer Landfill proposed for inclusion on the NPL.
- March 1983 — Notice letters to conduct the RI/FS sent to eight PRPs. No response.
- July 1985 — "Draft Remedial Investigation Report and Feasibility Study of Alternatives, Helen Kramer Landfill" was issued by R.E. Wright and Associates. Inc.
- September 1985 — Helen Kramer landfill placed on NPL with a ranking of 4. Final ROD issued by the U.S. EPA. Notice letters offering the opportunity to conduct the remedial design and implementation sent to PRP's.
- 1987-1989 — Remedial Design and construction bid package prepared by URS, Company, Inc.
- May 1989 — Invitation to bid Remedial Action issued by Kansas City District, Army Corps of Engineers.
- Sept. 19, 1989 — Bid Opening.
- Oct. 6, 1989 — Army Corps of Engineers awards Remedial Action contract to IT-Davy. Execution of the contract transferred to the Philadelphia District of the Corps of Engineers.
- Nov. 13, 1989 — Notice To Proceed issued to IT-Davy

REMEDIAL ACTION

The goal of the Helen Kramer remedial action plan is: "The prevention or mitigation of migration of hazardous substances from the site." During the RI/FS phase of the project, a number of different remedial actions were investigated. These actions were then considered as components of different remedial action alternatives. The components investigated include:

- *Security Fence* - This fence would completely encircle the site allowing for controlled access to the site, thus substantially reduce the hazard of direct contact with waste material.
- *Groundwater/Leachate-Collection Trough* - This trench, located along the entire eastern border of the site, would be used to collect groundwater prior to it entering the Edwards Run.
- *Upgradient Soil - Bentonites Slurry Wall* - This component consists of installing the slurry wall along the north, west and south sides of the site. This wall would substantially reduce the flow of groundwater flowing under the landfill, thus reducing the quantities of leachate requiring treatment.
- *Surface Grading and Capping* - This component would consist of filling areas of the site with local borrow, grading the soil to a maximum 20% slope and placing a cap over the site. The cap would serve to prevent direct contact with the exposed waste, assist in landfill gas control and reduce the amount of leachate generated. Both a soil and a multilayer clay cap were considered.
- *Leachate Treatment* - This component consists of three unit operations in series; flow equalization, metals precipitation and air stripping. This component is considered feasible for producing water with a quality acceptable for discharge to a sewer system.
- *Gas Generation/Migration And Treatment* - This component includes a gravel layer under the cap and piping under the cap to collect the landfill gas and transport it to an on-site facility. Treatment would consist of carbon adsorption followed by methane flaring. Both active and passive gas collection systems are considered.
- *Excavation* - This component would remove the source of contamination resulting in an improvement in leachate quality. However, this option would expose the workers and general community to a greater

safety hazard and probably is not feasible due to cost and unavailability of landfill capacity.

* *Construction of On-site RCRA Facility* - This component assumes that a hazardous waste landfill conforming to RCRA requirements would be constructed adjacent to the Helen Kramer site. Waste from this site would be excavated and disposed of in the new landfill.
* *Lagoon Dewatering and Excavation* - The approximately 1.52 million gallons of leachate and 2,400 yd³ of highly contaminated soil would be removed from the existing lagoon and two leachate collection ponds. The leachate would be treated or reinjected into the fill. The soil would be placed beneath the landfill cap.
* *Surface Water Controls* - This component consists of storm water run-off controls to protect the landfill cap from erosion.
* *Alternative Water Supplies* - This component would eliminate the low potential for residential wells to become contaminated by supplying an alternative source of uncontaminated water.
* *Monitoring* - This component would include quarterly monitoring of groundwater, surface waters and ambient air samples at the site to document the effectiveness of the remedial action.

Five categories (and eight cases) of Remedial Action Alternatives were developed for evaluation against U.S. EPA guidance criteria, incorporating various combinations of these remedial action components. Table 2 summarizes the alternatives evaluated in the feasibility study.

Table 2
Remedial Action Alternatives

CASE 1: security fence; site monitoring (No action Alternative).

CASE 2: RCRA landfill; excavation; groundwater/leachate collection trough and treatment; dewater, excavate and fill lagoons; security fence; and monitoring.

CASE 3: clay cap; groundwater/leachate collection trough and treatment; passive gas ventilation; dewater, excavate and fill lagoons, surface water controls; security fence; and monitoring.

CASE 4: clay cap; groundwater/leachate collection trough and treatment; active gas ventilation; upgradient slurry wall; dewater, excavate and fill lagoons; surface water controls; security fence and monitoring.

CASE 5A: clay cap; passive gas ventilation; upgradient slurry wall; dewater, excavate and fill lagoons; surface water controls; security fence and monitoring.

CASE 5B: soil cap; groundwater/leachate collection trough and treatment; upgradient slurry wall, passive gas ventilation; dewater, excavate and fill lagoons; surface water controls; security fence; and monitoring.

CASE 5C: clay cap; passive gas ventilation; dewater, excavate and fill lagoons; surface water controls; security fencing; and monitoring.

CASE 5D: soil cap; groundwater/leachate collection trough and treatment; passive gas ventilation; dewater, excavate and fill lagoons; surface water controls; security fence; and monitoring.

A detailed evaluation of each alternative was performed against the following criteria:
* Performance (effectiveness), reliability and implementability
* Institutional constraints/issues
* Any adverse environmental or health effects
* Cost

Using these criteria, Case 4 was selected as the remedial action of choice as it effectively mitigates all current and potential adverse environmental and health impacts. This case was modified during the remedial design phase with the addition of a roller compacted concrete retaining wall placed along a major portion of Edwards Run and the extension of the slurry wall to completely encircle the refuse area. The purpose of the retaining wall is to support the slurry wall and protect it from storm water run-off in Edwards Run. The extension of the slurry

wall replaced the groundwater/leachate collection trough. Key elements of the remedial action as it is being implemented are summarized below:

* *Clay Cap* - the entire refuse area will be graded and covered first with common fill material and then with a multilayer clay cap. This cap consists of a 12-inch rock gas collection layer, a filter fabric, a 24-inch clay layer, a 12-inch sand drainage layer, an 18 inch common borrow layer and 6-inches of top soil layer.
* *Soil-Bentonite Slurry Wall* - this three foot thick wall up to 75 foot deep will completely encircle the refuse area, thus minimizing migration of leachate into and out of the contaminated zone.
* *Roller Compacted Concrete (RCC)* - approximately 30,000 yd³ of roller compacted concrete will be placed to form a retaining wall along the side of a major portion of Edwards Run.
* *Pretreatment Facility* - a leachate and run-off water pretreatment facility will incorporate a metals precipitation and separation step followed by an air stripping process for organics removal. Treated water will be discharged to the local sewer system. Vapors from the air stripping process will be treated by activated carbon adsorption.
* *Gas Collection and Treatment Facility* - this facility will collect and treat landfill gas using activated carbon adsorption to remove VOCs followed by flaring of the methane.
* *Roads with Associated Grading and Drainage* - gravel roads will be installed connecting the pretreatment facility and other points on the site. Roads will be installed with the approximate grading and drainage features to minimize the amount of surface water percolating into the site.
* *Lagoon Dewatering and Cleanup* - the existing lagoons and leachate collection ponds will be dewatered, and the water will be sent to the pretreatment facility prior to discharge. Contaminated lagoon sediments will be excavated and placed under the multilayer cap. The lagoons will be filled with suitable clean materials from off-site.
* *Security Fence* - a temporary chain link fence with a limited number of locked gates will be installed around the site to protect humans and animals from potential site hazards during construction. A permanent fence will be installed at the completion of construction activities.
* *Monitoring* - a series of monitoring wells will be drilled on- and off-site, and a series of ambient air monitoring stations will be installed.
* *Startup, Testing and Operations* - upon completion of construction, activities of all systems will be started up and tested to ensure that they achieve design goals. The treatment facilities (water and gas) will be operated for one year prior to training and turnover to a permanent operating team.

PROGRESS TO DATE

Upon notice of award in October 1989, IT-Davy mobilized a task force off-site to begin preparation of site operations plans required for approval prior to the Corps of Engineers issuing the Notice To Proceed (NTP). These plans included:

* Contractor Quality Control Plan
* Chemical Quality Management/ Sampling Plan
* Site, Safety, Health and Emergency response Plan
* Fire Fighting Plan
* Materials Handling Plan
* Project Schedule
* Environmental Protection Plan
* Security Plan
* Air Monitoring Plan
* Emergency Leak Response (Spill Control) Plan
* Dust, Odor and Vapor Control Plan
* Lagoon Seawatering Plan/

The plans have been submitted, reviewed, revised as needed and approved by the COE. The NTP was on November 13, 1989. Site work was delayed until early April 1990 while IT-Davy awaited the issuance of a partial Gloucester county soil conservation and erosion control permit. Initial site work included installation of the temporary construction facilities, installation of the site security fence and implementation of the site security and health and safety plans. The IT-Davy task

force moved on-site in mid-May 1990.

Major construction milestones achieved as of September 1990 include:

- Completion of temporary facilities (offices, decontamination pad, personnel decontamination facilities and truck weigh scales)
- Negotiation of a site agreement with major unions
- Completion of site clearing and grubbing
- Commitment of all major purchases
- Commitment of all major subcontracts
- Initial site compaction completed
- Slurry wall platform completed (west side of site)
- Extensive air monitoring program in place (approximately 1000 samples collected and more than 350 analyzed with all giving nondetect values)
- Approximately 50% of the targeted common fill (270,000 yd³) has been delivered on-site.
- Pretreatment facility foundations essentially complete

The project task force is at full strength; however, progress has been limited by problem areas discussed below. Under the current schedule, the project will be completed and ready for operation in January 1992.

PROBLEM AREAS

Until recently, problem areas have not been substantial and have been satisfactorily resolved. These problems have included delays in mobilizing on-site because of difficulties in obtaining the county soil conservation permit and the extended review time required in arranging for local emergency response. The soil conservation permit was received after causing an approximately 45 day delay in starting work in the pretreatment area on-site. Schedule impacts due to this delay are being addressed.

As part of the Emergency Response plan, local fire departments and health care providers were contacted to supply emergency service as required. These agencies initially responded negatively because of concerns over entering a Superfund site. After many meetings and discussions, the following was agreed upon and is being implemented. IT-Davy constructed clean roads on-site so that emergency vehicles and personnel would have minimum contact with hazardous materials when responding to an emergency. IT-Davy also agreed and is proceeding with site-specific hazards training for local emergency response personnel as well as supplying protective clothing to responding personnel.

Two major problems have surfaced recently which may impact significantly the cost and schedule for the remedial action. These are a change in the pretreatment water quality requirements and identification of differing site conditions for the placement of the roller compacted concrete (RCC) retaining wall.

In July 1990, IT-Davy was notified by the COE that the water quality requirement for the pretreatment facility had been made more stringent.

This change in discharge requirements will require additional water treatment facilities in order to produce the required quality. The air stripper capacity must be increased and a polishing aqueous carbon adsorption column must be added to the treatment process. The COE, their engineer (URS) and IT-Davy are currently investigating the cost and schedule impacts of this change in scope. Delay of completion of the pretreatment facility impacts the overall project schedule significantly.

The second major problem area is the discovery of differing site conditions where the roller compacted concrete (RCC) retaining wall will be placed. Soil tests and borings conducted by IT-Davy indicate that the base area for the RCC is saturated and has very low soil-bearing capacity. The test borings indicate that these conditions extend as much as 18 feet below the surface. The soil, as it exists, does not have sufficient soil-bearing capacity for placement of the RCC retaining wall. Investigations of these soil conditions are continuing and alternative concepts are being developed. The solution to this problem may also have significant impact on the overall project schedule as completion of the slurry wall and the multilayer cap follow the installation of the RCC.

CONCLUSIONS

All major contracts are in place, all site plans are approved and IT-Davy is proceeding with remedial action at the Helen Kramer site. When completed, the site improvements will effectively isolate the contaminants from the surrounding environment. Surface water and leachate will be treated to local POTW pretreatment standards prior to discharge to the local sewer system. Landfill gases will be collected and treated prior to being flared. Access to the site will be limited, thus minimizing the potential for humans to be exposed to site hazards. Approximately ten years after first being proposed for inclusion on the NPL, the remediation phase of the Superfund process will be complete.

Recently two problems have surfaced which may substantially impact the overall project schedule. These are a change in the water pretreatment requirements and differing site conditions along the east side of the site where the RCC retaining wall is to be placed. IT-Davy is currently proceeding to identify the magnitude of these impacts and assist the Corps of Engineers in investigating alternatives to minimize these impacts.

After Design, Installation and Start-up, Groundwater Remediation Really Begins

Greg C. Miller

O'Brien & Gere Engineers, Inc.
Syracuse, New York

ABSTRACT

Discovery of contaminated compounds in municipal groundwater supplies has become a frequent headline. Implementation of effective treatment systems is crucial in order to remediate these contaminated aquifers. It is after completion of the regulatory requirements, including design, installation and startup, that the remediation really begins.

The best available technology (BAT) and state-of-the-art systems are rendered useless without a detailed approach for startup and facility operation and maintenance. Selection of the proper operator becomes the critical link between a well designed system and deliverable results. Interaction between the contract operator and design engineer strengthens the link and plays a major role in the system's success. Compliance with effluent discharge permits and avoidance of civil and/or criminal penalties which can result from permit violations are evidence of successful system operation.

This presentation will focus on these issues and will describe to administrators and managers of groundwater remediation systems the critical need for a planned strategy to operate and monitor compliance with the requirements of the remediation program. Supporting and documenting information will be presented from the perspective of the design engineer and contract operator who provided engineering, staffing and management services to a Fortune 500 company. Two facilities at remote sites were involved, where operations issues were complicated by the sale of the facilities (though the original owner remained responsible for environmental remediation).

INTRODUCTION

With increasing frequency, contaminated sites are being discovered. Subsequently, the principally responsible party (or parties) are being required to conduct a cleanup and other necessary remedial action.

In the case study discussed in this paper, a Fortune 500 company was involved with two facilities at remote sites. At the first site in eastern Ohio, the owner notified the U.S. Environmental Protection Agency and the appropriate state agency that soil containing residual concentrations of polychlorinated biphenyls (PCBs) and volatile organic compounds (VOCs) had been discovered at an inactive industrial site. VOC contamination, which presented significant potential for degradation of the municipal water supply, was also reported at the site.

At the second site in western New York, a program was initiated to update and consolidate underground storage facilities. The program involved testing selected underground tanks in accordance with the State Environmental Agency Petroleum Bulk Storage Program and the excavation and removal of several tanks. As a result of this consolidation work, O'Brien & Gere Engineers, Inc. was retained to conduct a Phase I hydrogeologic investigation. The investigation's objectives were to determine the presence of groundwater contaminants resulting from previous manufacturing and storage operations. The state agency reviewed and approved the investigation work, which identified free floating petroleum product and an isolated area of VOCs in the groundwater.

Actual system components will be described focusing on the state-of-the-art technology employed to meet defined effluent limitations; 1,400-gallon per minute (gpm) and 360-gpm treatment systems utilizing recovery wells, pumps, collection vaults, packed column air strippers, blowers, pipelines and electrical controls. Key tasks of the operator will be presented and explained including routine inspections, leachate monitoring of the secure cell, preventative maintenance, emergency repairs, sample and data collection protocol, and record-keeping. Additionally, advantages of effective interface between the owner/client and engineer and system operator will be discussed, supported by actual project experience.

O'Brien & Gere Engineers, Inc., (Syracuse, New York) was retained by the owner to perform remedial investigations, feasibility studies and preliminary and final designs and to provide construction-phase services at both sites.

The program involved coordinated efforts of several companies:

- O'Brien & Gere Engineers, Inc. - study, design and construction phase services
- OBG Laboratories, Inc. - analytical services related to site investigation and construction activities
- OBG Technical Services, Inc. - construction management services including the operation of a mobile treatment system for supernatant removal from the holding pond
- OBG Operations, Inc. startup services and full operation and maintenances services for the groundwater remediation facilities. Services include grounds care, leachate monitoring of the secure cell and mechanical and electrical maintenance of the groundwater treatment system.

The coordination within the family of firms effected a smooth transition from one work function to the next and maximized critical communication links. The net effect resulted in a turn-key approach which created "one-stop shopping" for the owner.

PROGRAM OBJECTIVES

At the eastern Ohio site, the owner's goal was to identify and control the environmental and health impacts associated with the hazardous waste contaminated site. Responding directly to owner/client-identified needs, the remediation program had five objectives:

- Prevent potential degradation of municipal potable water supply
- Secure PCB contaminated materials
- Recover/treat ground water to surface water discharge standards

- Maintain positive community relations
- Keep costs within budget

At the western New York site, the owners objectives were:

- Minimize the migration of free floating petroleum product and VOCs toward the river
- Operate the system as efficiently as possible and to maximize free product recovery and VOC removals

The importance of a well-operated and maintained system at both locations was especially critical due to the nature of the groundwater contamination. Proper operating procedures were required to prevent violation of the National Pollutant Discharge Elimination System (NPDES) permit that was granted for each system: groundwater discharge is not to exceed the concentrations as defined in the discharge permit.

EASTERN OHIO FACILITY

Facility Components

The purpose of the individual system components is to function as a single unit to prevent future migration of contaminants by collecting, transporting and treating the contaminated groundwater. The major components of the remediation system include a secure cell for containment of on-site materials containing PCBs, secure cell leachate collection and monitoring equipment, recovery wells, pumps, vaults, collection vault, air stripper, blower, pipelines and electrical controls.

Secure Cell

An on-site secure cell was designed and constructed to contain the soil and waste containing PCBs. With a final design volume of 20,000 cubic feet, the secure cell employed a 3-foot thick impermeable base of compacted clay and high density polyethylene (HDPE) liner. A 2-foot thick layer of compacted clay and a HDPE liner were also employed for a top cap.

The secure cell design (Figure 1) also included a drainage system

for leachate collection and monitoring components. The design incorporated a system of collection layers and piping discharging to a holding tank. Components of the leachate system outside the cell included an underground tank with secondary containment and state-of-the-art monitors and alarms. The early warning nature of this detection system represents a unique application of vacuum lysimeters coupled with groundwater monitoring wells.

Groundwater Treatment Facilities

Based on groundwater modeling of the contamination plume, eight recovery wells were installed both on and off the plant site. Recovered groundwater is pumped to a central collection vault for treatment in a packed column air stripper. The recovery wells range in capacity from 50 to 200 gallons per minute, and the air stripper is capable of treating approximately 1,500 gpm (2 mgd) of recovered groundwater. The packed column stripper is furnished air through the use of two 6,000 cfm blowers. The system's goal is to discharge an effluent with a concentration of 12 ppb VOCs or less. Current operating data indicates that the stripper is effectively removing in excess of 95% of the VOCs identified as the principal groundwater contaminants. Figure 2 presents a schematic of the system components.

Recovery Wells, Pumps and Vaults

The groundwater recovery wells consist of a steel casing and slotted screen section installed at a predetermined depth in the aquifer. All recovery wells contain submersible pumps discharging the contaminated groundwater via pipelines to the treatment system. The submersible pumps in each recovery well were selected to deliver a flowrate greater than the required design flow.

By adjusting the butterfly valve located in the vault, the flow from each recovery well can be adjusted to fine tune the system. Flow sensors are located in the vaults to help regulate the flow from each recovery well. A sample tap has been provided in the vault to collect groundwater samples and evaluate the contaminants at each well location (Figure 3).
Figure 1
Typical Design of Secure Cell Liner System
Figure 2
Eastern Ohio Facility
Treatment System Schematic
Figure 3
Typical Recovery Well, Pump and Vault

The collection vault receives contaminated groundwater from the various recovery wells and acts as an equalization basin for the air stripper. Equalization provides a steady flow of groundwater to the air stripper while minimizing the cycling of the submersible pumps. Two submersible pumps located in the collection vault have sufficient capacity to individually deliver the total system's flow in the event of one pump's failure.

Packed Column Air Stripper

The air stripper provides the mechanism for VOC removal from the contaminated groundwater. Pumps located within the collection vault discharge the contaminated groundwater to the top of the stripper. Contaminated groundwater travels downward over packing material, while countercurrent air from the blowers is forced upward through the packing material. This action strips VOCs from the contaminated groundwater.

A flowmeter and recorder on the influent line of the air stripper monitor and record the flow from the collection vault. Sample taps were installed on the influent and effluent line of the air stripper (Figure 4).

At the base of the air stripper, two blowers deliver air to the air stripper. Each blower has the capacity to deliver the total required air supply and, therefore, can act as a backup unit if one blower fails.

Pipelines and Electrical Controls

Pipelines, ranging in size from 4 to 12 inches, were installed to convey groundwater to and from system components. Recovery well locations required the installation of cased pipelines under city streets, streams and railroads.

Electrical controls play a major role in the startup and operation of the remediation system. Various controls provide automatic backup of certain equipment and shutdown the system in the event of equipment failure. High-level alarms in the collection vault and air stripper and air flow loss indicators automatically shut off all the recovery well pumps. An automatic dialer alerts the facility operator whenever there is a problem at the facility.

WESTERN NEW YORK FACILITY

Based upon the results of the field investigations, a semipassive groundwater recovery trench system was designed to intercept free floating product migrating radially towards the river. In addition to the recovery trench, a groundwater recovery well was designed to collect and treat an isolated area containing VOCs. A recovery trench, three pump stations, recovery well, oil/water separator and packed column air stripper were installed. Figure 5 presents a schematic of the system components.
Figure 4
Typical Air Stripper and Blower

Recovery Trench

The recovery trench, located between the source and the river, intercepts groundwater contaminated with petroleum products and VOCs. The groundwater enters a perforated pipe within the trench and travels by gravity to the pump stations. Physical separation and accumulation of free floating product occur within the stations.

Level floats are located within the pump stations for on/off control of the pumps. Groundwater that accumulates in the pump stations is pumped through force mains to the oil/water separator for the removal of oil and grease residuals. Petroleum product is periodically removed from the three pump stations and oil/water separator by a local oil reclamation contractor via a vacuum tank. Once removed, the product is transported to a local plant for fuel blending/reclamation purposes.

Recovery Well Pump and Piping

Similar to the Eastern Ohio groundwater system, this facility has one recovery well for the removal of groundwater contaminated with VOCs. The recovery well has a submersible pump that discharges groundwater to the oil/water separator through force main piping. A level transducer within the well allows for the on/off control of the pump.

Oil/Water Separator

Groundwater from the three pump stations and recovery well enters a 4,000 gallon oil/water separator tank for the final removal of oil and grease constituents prior to being pumped to the packed column air stripper. The oil/water separator utilizes coalescer plates and polypropylene filter media to enhance the removal of the petroleum constituents from the groundwater. Groundwater travels by gravity through the separator to a pump-out compartment. A pump located within the pump-out compartment transfers the groundwater to the packed column air stripper for VOC removal.

Packed Column Air Stripper

Similar to the Eastern Ohio groundwater treatment system, this facility utilizes a packed column air stripper for the removal of VOCs from the groundwater. Upon entering the air stripper, groundwater travels
Figure 5
Western New York facility
Treatment System Schematic

by gravity over the packing material while countercurrent air from the blower travels upward through the packing, stripping VOCs. Treated water is discharged by gravity to the river.

OWNER CONSIDERATIONS

Numerous remediation sites across the country are now under design and construction with additional sites that have been identified for future study. Owners of these hazardous sites must be prepared to develop and implement efficient means of remedial operation in order to obtain efficient, reliable and long-term operational results. After design and installation is complete, the owner must proceed with long-term operation and maintenance of the facilities and must remain in compliance with effluent discharge permits. A possible result of inadequate facilities management may result in violations of effluent discharge permits which can lead to significant civil and/or criminal penalties. With the client facing prospects of long-term maintenance commitments (in many cases up to 30 years) a planned management strategy must be implemented. This approach should include routine inspection and maintenance of the facilities with periodic sample collection and analysis.

The owner is responsible for site security including fencing, security gates and signs, routine inspection, and maintenance, service and replacement of system components. Grounds maintenance includes the vegetation cover as well as weed and erosion controls. In the case of the secure cell, leachate collection, treatment and disposal are required in addition to groundwater monitoring conducted by a certified laboratory.

In the instance where groundwater is required to be treated to protect the environment and public health, the owner is required to operate and maintain the treatment system. This requirement may include stripping volatile compounds from the groundwater through the use of air or steam. Inorganic compounds are often precipitated from the groundwater matrix. For both organic and inorganic compounds, ion exchange, under certain conditions, is a workable treatment technique. Therefore, the owner must analyze the available alternatives and understand the potential complexity of each system as well as the effects of operation and maintenance.

The owner, now faced with a long-term maintenance program for the remediation system, must decide how to implement this program.

There are several considerations:

- How will the system be managed and operated; through corporate management or by private contract services?
- Does the system require full-time or part-time service?

Issues can be complicated by remote site locations and by transfer of facility ownership. In the cases described here, the original owner remained responsible for the environmental remediation. The owner of these facilities clearly had two choices:

- The owner can maintain management responsibility and provide operations for the facilities
- The owner can contract management and operations services.

In either case, the owner is clearly responsible for the financial obligations to remediate and to comply with the discharge permit.

The following information will present operator tasks as well as the necessary management tasks to implement a successful program.

OPERATOR RESPONSIBILITY

Required skills of the groundwater remediation system operator vary with the level of the system's complexity. However, the common requirement is to be mechanically-inclined, with an understanding of pumps and electrical control systems. Generally, operators must be self-motivated, capable of performing their job assignments without direct management on a day-to-day basis. Typically these facilities are not large enough to warrant direct supervision on a day-to-day basis; however, management is provided on a broad supervision level.

To properly operate the groundwater remediation systems, the operators at each location must be familiar with the following:

- Operation of all system components
- All maintenance requirements
- Local, state and federal laws which govern the operation of the system (including spill notification requirements)
- Safety precautions for system operation (including satisfactory completion of Health and Safety Hazardous Waste Operations course)
- Record-keeping, reporting and filing maintenance requirements

To execute the operation and maintenance services at the facility without direct supervision, management must provide additional means

of project control. Record-keeping can take the form of bi-weekly or monthly reports of system operation. Routine inspection logs are created for management review and also serve as reinforcement for inspection of critical system components. Figures 6 and 7 are provided as typical log sheets used to develop the monitoring reports. These reports are also critical for effective presentation of data to regulatory agencies regarding the operations of the facilities.

Operation and maintenance activities related to the groundwater remediation systems include caring for the grounds; monitoring system components; coordinating activities with certified analytical firms; and special service activities such as leachate removal and disposal, oil reclamation, electrical and maintenance specialty services.

Routine inspection programs determine if the remediation system is operating at peak efficiency or is in need of maintenance. The major components of these programs are the log sheet forms which are com-

pleted by the facility operator addressing several tasks at the groundwater remediation facilities and secure cell (Tables 1 and 2).

At the facility located in eastern Ohio, a facility operator was provided on a full-time basis. The operator mans the facilities 8 hours per day, 5 days per week, with emergency calling capabilities during off hours and weekends. At this particular facility, the facility operator performs all electrical and mechanical maintenance activities; however, for reasons of safety and the need of additional manpower to perform certain tasks, the contract operator has arrangements with two individuals who are available to support the facilities operator and serve as the backup during vacation and other periods of absence. In addi-

Table 1
Groundwater Remediation Typical Operator tasks

1.	Inspect all indicator run-lights (daily).
2.	Record individual pump operating hours (daily).
3.	Record individual pump flow readings (daily).
4.	Check recovery well vaults for accumulation of water (daily).
5.	Check operation of all butterfly valves (weekly).
6.	Inspect blower belts (weekly).
7.	Inspect air-stripper nozzles and packing (weekly).
8.	Acid cleaning of stripper media (as required).
9	Lubricate equipment as recommended by the operation and maintenance manual (As required).

Table 2
Operator Duties at the Secure Cell

1.	Observe condition of cap and vegetative cover (no trees, shrubs, brush or deep rooting weeds should be allowed).
2.	Observe for signs of erosion, insect damage or thinning of vegetative cover.
3.	Maintain 3 to 4-inch grass height (taller grass can inhibit erosion and increase evapo-transpiration).
4.	Maintain access roads to support maintenance activities as required.
5.	Maintain fencing, gates and signs as a part of security.
6.	Inspect leachate collection system.
7.	Inspect floats and controls, operate periodically to insure their ability to function.
8.	Inspect and maintain protective casings and groundwater monitoring wells.
9.	Calibrate flow measurement devices.

tion to routine maintenance activities, the facility operator is often called on to make facility upgrades and/or modifications and perform corrective maintenance activities. In situations where activities are beyond the operator's capabilities and those of the support staff, the facility operator (through communication with the client/owner) is responsible for contacting and monitoring activities of outside subcontractors who are used to facilitate major repairs and/or capital improvements.

At the second site described herein, a part-time operator was provided for approximately 10 hours per week. The operator performs routine inspections, sample collections and determines system-wide groundwater levels. All electrical, mechanical and oil reclamation activities are coordinated by the contract operator with outside subcontractors on behalf of the owner.

OPERATING PROBLEMS

Groundwater treatment facilities have not been without difficulties during startup and initial phases of operation. The eastern Ohio facility has effectively met the discharge compliance standards; however, there was a period when permit limitations were exceeded.

Some of the problems were minor in nature and were corrected as described in Table 3. On the other hand, resolution of a major problem involved a very interesting step-by-step approach. The corrective measures demonstrate a capability to work with facility equipment, provide for necessary care and maintain compliance with the discharge permit.

Table 3
Difficulties Encountered and Measures Taken to Resolve Them

PROBLEM	RESOLUTIONS
Flow meter losing signal	Soldered bad connection of control board
Stripper channeling (i.e. water by passing air flow/media by short circuiting down side walls)	Installed deflector plates in top portion of stripper
Stripper cleaning pump corroded by HCl acid cleaning resolution	Replaced cast iron and stainless steel pump with PVC unit
Control panels of recovery wells #4,#5,#6 and #7 damaged due to flooding caused by excessive rainfall	Relocated control panels above grade on top of vault
LED level indicators in wells shorting out due to condensation	Placed LEDs in watertight NEMA 4X enclosures; installed dehumidifiers
Wells #5-#8 and blowers tripping out due to excessive temperatures	Air conditioner installed in control room
Controller automatically switches into manual mode	Reprogrammed controller and installed uninterruptable power supply on 110 volt system
Water leaking into wells #3 and #8	Raised well vault castings above grade
Overflow of collection vault when stripper pumps out of service	Installed automatic shutdown for all recovery wells
Motor to recovery well #4 burned out due to lighting and power surge	Installed surge protection and lighting arresters on all eight wells
Secure cell holding tank overflow alarm actuating with weather changes	Installed aluminum rain cap on top of casting
Level indicator probes in recovery wells shorting out	Replaced probes (damaged due to power surges)
Pump in well #6 clogging up and losing capacity (problematic well)	Pull and clean pump on a regularly scheduled basis
Safety hazards involving portable stripper climbing ladder and pulling of inspection window	Installed catwalk with permanent ladder and mansaver cage
Secure cell holding tank vacuum alarm actuating with weather changes	Reduced vacuum in holding tank walls
Chart recorder losing signal	Soldered function card diode
Manhole lids on recovery wells too heavy to remove manually	Installed sockets on each well and purchased portable crane to remove manhole lids

There was a period when the effluent standards were not being met on a consistent basis. Just prior to this period, a decrease in stripper effectiveness and efficiency was noticed. In efforts to remedy the situation, the stripper medium was cleaned using approximately 300 gallons of dilute hydrochloric acid. However, after experiencing an initial and brief recovery period, the stripper again started to discharge effluent in violation of the discharge permit allowable limit of 12 ppb of VOCs.

The facilities operator then initiated the removal and high-pressure washing of the medium after it had become evident that the acid cleaning was no longer completely effective in removing the iron and magnesium

buildup. Following reinstallation of the clean medium, the problems persisted and the stripper continued to exceed the permit limitations. The next course of action involved a three-phase process:

- Inspect spray nozzles; no adjustments were required.
- Inspect stripper for short circuiting of recovered groundwater down the stripper walls; this was not occurring.
- Evaluate the capacity of the blowers; both blowers tested in excess of name-plate capacity.

After these steps, the stripper manufacturer was contacted and all performance data were forwarded to the manufacturer. During their review process, two steps were taken to bring the facility into compliance:

- Both blowers were used in an effort to increase VOC removals.
- Flow from the well with the highest concentration of pollutants (by a factor of 10 or more) was cut back from 200 gpm to 100 gpm.

These measures proved to be temporarily effective; however, the system was not designed to operate without a backup blower or by decreasing the flow at the recovery well to reduce the concentration of contaminants in the groundwater. The manufacturer was committed to effecting the highest level of system treatment and, after analysis of the performance data, made two recommendations:

- Replace spray nozzles to effect a different spray pattern
- Replace the top seven feet of medium with a different type of medium

These recommendations were implemented but proved to be ineffective. It was finally decided, following a review meeting between the owner, engineer and manufacturer, that the height of the air stripper would have to be increased.

The stripper manufacturer installed an additional 10-foot section to the air stripper that effectively met permit compliance with all wells pumping at full capacity and one blower operating.

This effort demonstrates a methodical comprehensive approach to solving problems. By carefully analyzing and evaluating each operational unit, this step-by-step approach addressed and corrected difficulties. The same approach was used to correct the difficulties presented in Table 3.

PREVENTATIVE MAINTENANCE

The development of a preventative maintenance program is key to the success of the operation of the groundwater remediation system. Although redundancy has been designed into the system, the facility operator must take into consideration Murphy's Law. Therefore a systematic schedule has been developed at each facility which provides for a program of preventative maintenance on each component. The maintenance is conducted as recommended by the manufacturer's operation and maintenance manual for the equipment. A critical component of the program is an inventory at the facilities, keeping spare parts available such as floats, drive belts and recovery well pumps. For example, the replacement of the air-stripper blower drive belt is easily accomplished at 2:00 p.m. as opposed to having to replace the drive belt at 2:00 a.m. under adverse conditions.

EMERGENCY REPAIRS

It is axiomatic that emergencies will occur. However, the number and impact of these emergencies can be minimized with proper planning and with preventative maintenance. At the two sites discussed above, a plan has been developed evaluating critical components of systems. The contract operator has also recommended to the owner that critical spare parts be made available in the inventory at the facilities. In addition, emergency contractors, telephone lists and contact persons have been identified in the event that an emergency occurs. Emergency repairs are coordinated through communications between the owner and contract operator to facilitate repairs in the most practical fashion.

SAMPLE COLLECTION

In accordance with the NPDES permit, a sampling and analysis plan has been developed. This plan defines the sampling program from the groundwater remediation system to collect and analyze effluent discharge

in accordance with the discharge permit.

Monitoring data must be reported to the state regulatory agency on a monthly basis, and records must be maintained on file by the operator and owner. It is the responsibility of the operator to coordinate the collection and transmission of the samples from the remediation system effluent and also the complete chain-of-custody records to the laboratory. The certified laboratory performs the analysis and submits the data to the owner and to the contracted engineer. The engineering company monitors compliance of the sampling schedule and completes the necessary monthly reports on behalf of the owner.

Several sampling ports have been provided as part of the groundwater remediation system. These sampling ports are located at the discharge of the force main of the recovery wells and pump stations and at the influent and effluent of the air-stripper.

Sampling and analysis required by the NPDES permit are in accordance with the sampling and analysis plan established for each facility (Table 4). Samples are collected by a local certified laboratory at the eastern Ohio facility, and the data are distributed to the owner and to the contracted engineer for monitoring compliance schedules as well to complete the discharge monitoring reports. At the western New York facility, the operator has been trained to collect and transmit the necessary samples from the air stripper effluent to a certified laboratory. These samples are then analyzed for VOCs, oil and grease, ph and total iron.

Table 4
Sampling, Analytical and Water Level Data Collection

SITE 1 (Eastern Ohio)

SITE 2 (Western New York)

TREATMENT SYSTEM EFFLUENT — FREQUENCY

Flow	Continuous
Volatile Organic Compounds (VOCs)	Twice/Month
Iron	Twice/Month
Oil & Grease	Twice/Month
pH	Twice/Month

WATER LEVEL ELEVATIONS — FREQUENCY

| Monitoring Wells (16) | Monthly |

As mandated by the discharge permit, the facility operator, who plays a critical role in the monitoring and data collection functions, collects at least four unfiltered grab samples over the course of a 24-hour period. Samples are composited in the laboratory under control conditions to minimize volatilization of the sample prior to analysis. It is also the responsibility of the operator to obtain and transmit the samples in accordance with approved methods (including chain-of-custody).

It is management's responsibility to adequately train and to instill in the facility operator the significance and importance of this sampling process. To support this effort, a sampling and analysis plan was developed for the two sites, clearly indicating the locations of sampling, the parameters to be analyzed and the sample frequency. This plan has been issued to the facility operator and is posted at the facility.

REPORTS AND RECORD KEEPING

Depending on the size of the facility and complexity of the components used at the groundwater remediation facility, the operator will be required to complete operating log forms ranging from daily operating logs to monthly operating logs. Copies of the operating logs are retained at the facility to be utilized by the facility operator as well as to be accessible during regulatory agency inspections. In addition, copies are transmitted to the owner for the development of the monthly discharge monitoring reports.

It is the responsibility of the facility operator to collect the appropriate data throughout the month to allow the contracted engineer to prepare and submit, on behalf of the owner, the monthly discharge monitoring reports to the regulatory agencies. To accomplish this task, the facility operator must be familiar with the requirements of the discharge permit and record the information on the appropriate operating log.

Weekly, bi-weekly and monthly operating logs facilitate this function. These logs indicate such data as the date, total gallons discharged, the current flow rate through the system and the status of system components (such as recovery wells, pump stations and air strippers). Operating log forms (Figures 6 and 7) are developed specifically for each facility; however, there are several key items that are common to all systems:

- Identification of the facility
- The date of entry
- Totalizer reading in gallons
- Elapsed time meter readings for appropriate equipment (such as blowers and pumps)

This information is not only critical to the monthly monitoring reports, but also is equally important for the preventative maintenance program. For example, hours elapsed on operating equipment is utilized in the scheduling of preventative maintenance of critical components of the groundwater remediation facility.

In addition to the reports and record-keeping, an operating plan of procedures should be developed by the management team. This operating plan clearly develops an understanding of the interrelationship between the owner, the operator and the engineer, i.e., the management team. The plan also includes normal team operating procedures as well as emergency procedures. This communication link between the owner, engineers and system operator is vital to the success of the project, ultimately measured by the facility's ability to remain in compliance with the discharge permit.

CONCLUSION

Success of the remediation systems is a result of the operator's ability to operate and maintain the system. The facility must also be adequately designed and constructed. Another factor is selection of an engineer experienced in groundwater remediation investigations, feasibility studies, design and construction phase services.

The construction and installation capabilities of the contractor are vital to the ultimate reliability of the system. Therefore, careful consideration must also be taken into account during the selection process of a contractor to perform the construction services.

The true measurement of the system is its long-term operation. The owner must decide whether to provide the facility operator or select a facility operations contracting firm. In either case, the facility operator and the management necessary to overview the facility should possess skills and abilities proportionate to the complexity of the system.

The owner is also responsible for the adequate funding of the project to properly operate and maintain the facility. Funding encompasses items such as operation services including management and facility operators (either internal or external services); power; tools; supplies; spare parts; analytical services; and engineering services.

The owners, administrators and managers of remediation systems must be prepared to develop and implement sufficient means to obtain efficient, reliable and long-term system operation.

Remedial Design Considerations at the Sikes Superfund Site

Richard E. French, P.E.
Lockwood, Andrews & Newnam, Inc.
Houston, Texas

James A. Feeley
Texas Water Commission
Austin, Texas

ABSTRACT

The Sikes Disposal Pits site was one of the first hazardous waste sites listed on the NPL. The Sikes site is located along the banks of the San Jacinto River, approximately 20 miles northeast of Houston, Texas. It was operated as an open dump in the 1960s and received drummed and bulk wastes from many of the area's petrochemical industries.

In 1982, the Texas Water Commission (formerly named the Texas Department of Water Resources) selected Lockwood Andrews & Newnam, Inc. as the prime contractor to conduct a Remedial Investigation at the site. Later contracts extended these services to include a Feasibility Study, Remedial Design and Construction Management.

The selected remedy on the Sikes site was for on-site incineration of approximately 300,000 tons of sludges, waste and contaminated soil. The shear magnitude of the site makes it the largest on-site incineration project attempted in the Superfund program. Remediation of the site is expected to take 5-6 years at a cost of approximately $90,000,000.

This paper will discuss the Remedial Design process used on the Sikes site, the major design issues that were identified and how they were addressed in the development of the plan and specifications.

The Remedial Design process involved conducting a major site sampling program designed to establish the specific physical and chemical characteristics of the wastes and soils required by the incineration contractors. This analytical phase was followed by developing a conceptual design and writing detailed specifications for cleanup.

Many difficult issues had to be addressed in the Remedial Design. These included:

- The entire site is 10-20 feet below the 100 year flood elevation
- Tree and stump removal is required in both contaminated and uncontaminated areas
- Trash and debris in contaminated pits ranges from toys to furniture to appliances
- Thousands of rusting drums and hundreds of tires will have to be incinerated
- Excavations will be up to 20 feet below the water table

INTRODUCTION

The Sikes Disposal Pits Superfund Site is a 185 acre tract of land approximately 20 miles northeast of Houston, Texas (Fig. 1). The site is within the flood plain of the San Jacinto River in an area that has many active and abandoned sandpits. In fact, the entire site is within the 10 year flood plain of the river with the highest portion of the site being 10 feet below the 100 year flood plain.

The Sikes site operated as an active waste dump from the early 1960s until it was closed in 1967. During this period, a variety of chemical wastes from area petrochemical industries were dumped in several abandoned sandpits. In addition, approximately 1500 drums of waste were stacked and scattered across the site.

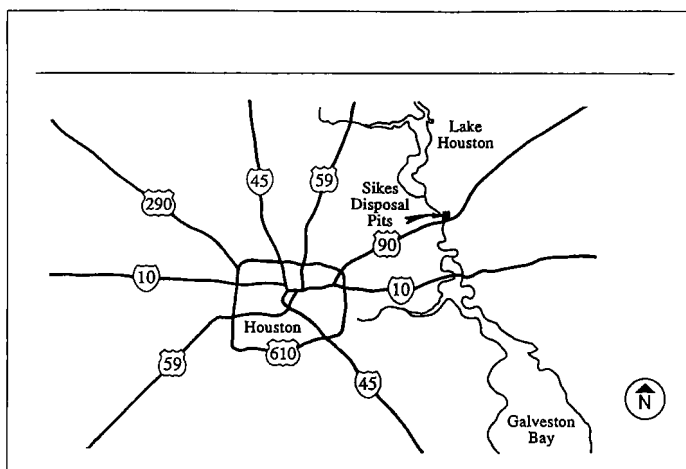
A site map is shown in Figure 2. The site is bounded on the west by the San Jacinto River, the north by the Southern Pacific Railroad, the east by low swampy land and the south by US Highway 90. The primary features on-site are the Small Waste Pits, Tank Lake, the Main Waste Pit and the Overflow Area.


Figure 1
Site Location Map

PREVIOUS STUDIES

The Sikes site was placed on the NPL in 1982. In January 1983, the Texas Water Commission (TWC) contracted with Lockwood andrews & Newnam, Inc. (LAN) to perform a Remedial Investigation on the site. LAN has continued as the prime consultant on the site through the Remedial Investigation, Feasibility Study, Remedial Design and Remedial Action phases.

The RI found high concentrations of volatile and semivolatile organics in the sludges and underlying soils throughout the site. High concentrations of heavy metals also were found in selected areas. Several of the pits also contained contaminated surface waters.

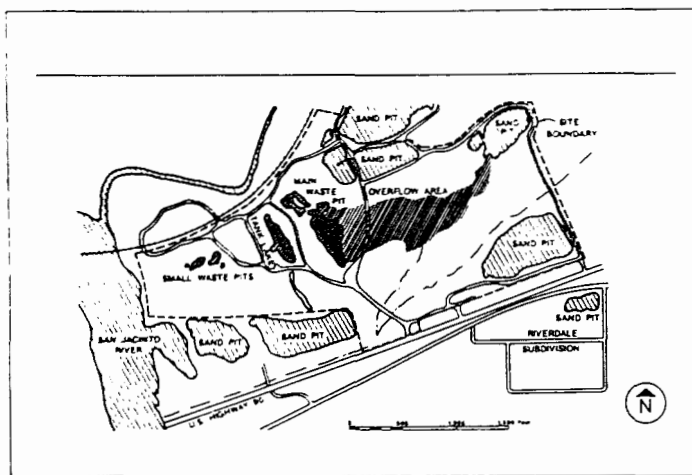
Alluvial sand deposits underlie the entire site. The shallow aquifer (20-30 ft deep) is contaminated with the same volatile and semivolatile organic compounds found in the wastes on the site. A second aquifer lies below the first and is separated from it by approximately 65 feet of highly plastic clays. This deeper aquifer showed only trace concentrations of a few of the volatile organics.


Figure 2
Site Map

Objectives and criteria were developed in the Feasibility Study in accordance with U.S. EPA criteria. Thirteen initial alternatives were developed, and this group was later screened to six for detailed evaluation and consideration in development of the ROD. The ROD, signed by U.S. EPA in September 1986, specified on-site incineration of the wastes and contaminated soils. A cleanup level of 10 mg/kg of any VOC and 100 mg/kg of total PAHs were established as the cleanup criteria. Groundwater modeling indicated that by removing the waste and contaminated soil to the 10 mg/kg level, the groundwater would naturally clean itself to the 10^{-4} Human Health Criterion within a 30 year period. Based on this determination, source control was judged to be the only remediation required.

Another important criterion is that no waste may leave the site and, equally important, no other waste may be brought onto the site.

DESIGN PROCESS

Once the remedy was selected, the TWC and LAN proceeded into the Remedial Design phase. The first task was to review the data collected during the RI/FS process to determine if sufficient data were available to design the on-site incineration remedy.

The RI process was designed to: (1) gather data to characterize the site and assess its risk to the population and environment; and (2) developed and evaluated alternatives in the Feasibility Study. It was not the intent of the RI, however, to develop detailed design data for each alternative that might be considered. Therefore, it was determined that more incineration) specific data would be required to adequately design the incinerators to be used during the remediation. The specific data needed included:

- Density
- Moisture
- BTU
- % Ash
- Viscosity
- Melting Point
- Flash Point
- Reactive Cyanide
- Reactive Sulfide
- Corrosivity
- pH
- TOX
- % Carbon
- % Hydrogen
- % Nitrogen
- % Sulfur
- % Phosphorus
- % Total Chlorine
- Sodium
- Potassium
- Grain Size Analysis

The original RI estimated that the site contained approximately 68,510 cubic yards of wastes and 81,300 cubic yards of contaminated soils for a total volume of 149,810 cubic yards of material to be incinerated. Experience with other remediation projects indicates that final remediation quantities are usually much higher than those identified in the RI. Since this is such a large site, with contamination spread over 33 acres, it was decided that a prime objective of the Remedial Design Sampling Program would be to better quantify the volume of material to be incinerated.

Two hundred twenty-seven locations across the site were investigated to quantify and/or characterize the wastes and underlying soils. The majority of the locations were investigated using a hollow stem auger with either a Shelby Tube or Split Spoon Sampler. A back-hoe was used in some locations, particularly when investigating areas suspected of containing buried drums. Hand sampling with an auger or post hole digger was accomplished in a few areas.

Several areas contained thick waste deposits that were difficult to sample with conventional drilling equipment. We had very good success, however, using a vibracoring technique in these areas. A 3-inch thin walled aluminum pipe was vibrated into the waste and then pulled using an A-frame and winch. The pipe was then cut longitudinally using a power saw to expose a vertical section of the wastes collected. Depths of up to 18 feet were successfully sampled in this manner. Forty-one locations were sampled with the vibracore, both on the Main Waste Pit using a barge and on land using stationary equipment.

One hundred ten samples were collected at 57 of the 227 locations for physical and chemical analyses. The remaining locations were logged and used to visually estimate limits of contamination.

The Remedial Design Sampling Program identified considerably more wastes than had been estimated in the RI. It is now estimated that the site contains approximately 82,900 cubic yards of waste and 131,900 cubic yards of contaminated soil for a total of 214,800 cubic yards of material to be incinerated. This new amount is a 43% increase over the volume identified in the RI. In addition, there are approximately 2600 cubic yards of trash and debris ranging from tires to appliances that were quantified. Given the complexity of the site, we believe that the extra effort expended in the more thorough quantification was worthwhile.

A summary of the physical and chemical characteristics of the wastes and contaminated soils is given in Tables 1 and 2.

PROCUREMENT APPROACH

Early in the design process it was decided to use a two-step procurement approach. This procurement was done under 40 CFR Part 35 and not under the Federal Acquisition Regulations. With a two-step approach, the first step involves requesting and evaluating detailed technical proposals from contractors interested in bidding on the project. At the end of the first stage, a shortlist of contractors that are judged technically qualified to perform the work is developed. The second step is the commercial step where the shortlisted firms are invited to submit bids for the project. The project is awarded to the lowest responsive bidder.

The approach involved the development of a detailed Request for Proposal (RFP). This RFP consisted of a formal RFP, instructions for preparing and submitting the proposal, a proposal form, statement of work, required proposal format and evaluation criteria. In addition, draft contract documents and the entire plans and technical specifications for the project were included in the RFP. All the data collected on the site were made available to the contractors including the RI, FS and Remedial Design Sampling Report. The plans and specifications were specific in the areas that required specific approaches or procedures and were performance based where possible to leave the exact approach up to the individual contractors.

Six detailed Technical Proposals were received in March 1989. After a thorough evaluation, five of the Technical Proposals were accepted and shortlisted for the final bidding.

The plans and specifications were reissued as a bid package for the five shortlisted teams. The list of technical specifications is shown in Table 3.

DESIGN ISSUES

Flooding

One of the first issues to be addressed during the design was that the entire site is within the 10 year flood plain of the San Jacinto River. LAN had experienced with this directly as our site office trailer had been washed one quarter mile downstream during a flood while we were conducting RI field activities. The site has flooded at least three other times during the last 10 years.

Initial thoughts of diking the entire 185 acre site were dismissed as too costly and impractical. In addition, the Harris County Flood Control District had specific requirements about construction in the flood plain:

- The remedial activities could not raise the level of the 100 year flood plain
- Basin storage could not be significantly reduced

The solution was to require flood protection for only two areas, the Facility Area where the incinerator, major equipment and offices would be located and the Main Waste Pit. Computer modeling of the basin indicated that by clearing the entire site of heavy timber, the "n" value could be reduced during a flood. This enabled us to meet the Harris County Flood Control District's requirements.

The Main Waste Pit requires flood protection due to its size and depth. Remediation of this area will require a considerable length of time. If the site were flooded during remediation of the Main Waste Pit, it would be very difficult to prevent the spread of contamination, potentially off-site.

Excavations outside the flood control structures are required to be designed and managed so that any open areas can be closed with clean, stockpiled material in the event of a threatening flood. No more than a 1-day stockpile of waste will be allowed outside of the flood protection structures.

A series of drainage ditches and berms will be used to segregate potentially contaminated and uncontaminated storm water. The potentially contaminated storm water will be sent to an on-site water treatment facility.

Groundwater

The shallow water table on the site, sandy soil and deep excavations make groundwater management a challenging issue. Excavations in the

Overflow Area will average 8 to 10 feet while excavations in the Main Waste Pit will be more than 30 feet below the top of the pit.

The specifications require that the excavation to be done in dry conditions. This requirement will necessitate significant dewatering.

The ROD relies on natural flushing of the upper aquifer for improving the water quality once remediation is complete. This design decision resulted in a specification that prohibits permanent structures to control groundwater, such as slurry walls, which would impede the natural groundwater movement once the source is removed.

Groundwater that is pumped for dewatering will be tested periodically. Water that does not meet discharge criteria will be sent to the water treatment facility. It is anticipated, however, that much of the groundwater will meet the discharge criteria and can be discharged directly to the San Jacinto River.

Clearing

There are an estimated 43 acres of uncontaminated land and 33 acres of contaminated land that will require clearing for construction, remediation and flood control purposes. Trees on-site range from saplings to 4 ft diameter cypress. The majority of the trees are 6 to 18 inch pines.

The entire site will need to be cleared before the flood control structures can be constructed. Trees and stumps in uncontaminated areas will be removed by normal clearing and grubbing operations. Trees in contaminated areas are to be removed in a manner that prevents them from contacting the wastes. The trees and uncontaminated stumps will be chipped and stockpiled to be used as mulch during final site restoration. Stumps in contaminated areas will be removed during the remediation. They will be chipped and incinerated with the wastes and contaminated soils.

Trash and Debris

There are an estimated 2600 cubic yards of trash and debris on the site composed of:

* Debris from the original Sikes homestead that mysteriously burned
* Discarded furniture such as chairs and sofas
* Discarded appliances such as refrigerators and washers
* Hundreds of tires
* Rolls of tar paper, barrels of tar and shingles
* General household trash

This material is scattered in both contaminated and uncontaminated areas. The material in uncontaminated areas will be buried on-site. Large metal items in contaminated areas may be decontaminated and buried on-site. All other material in contaminated areas will be shredded and incinerated.

Drummed Wastes

Approximately 1500 drums were disposed of on-site while it was in operation. Many drums were apparently stacked in one area and later bulldozed into a large mound. Other drums were buried in various locations and still others were scattered throughout the site.

The drums are in various degrees of disintegration with most of them no longer having any structural integrity. Many drums are now empty and others have solidified residues "holding" the drums together. Some appear to have been lab packs.

All of the drums and drum wastes will be incinerated.

Incinerator Facility

One of the first criteria to be established in the design of the incineration facility was to determine the required incinerator size. A thorough review and evaluation of the technologies available was undertaken. We wanted to develop the specifications detailed enough to ensure that the facility would accomplish the intended job but also open enough to provide for competitive bids. At the time that the specifications were developed, the largest transportable incinerators with demonstrated experience were sized for approximately 5 tons per hour, although the technology was developing rapidly. A decision was made to require a minimum burn rate of 15 tons per hour through either one or more incinerators. This feed rate was based on our review of the technology and a desire to complete the project in a reasonable time-frame.

Other specific criteria were developed for maximum feed size, material handling, VOC controls, etc.

The specifications did not define the specific types of feed preparation equipment to use. The specifications did, however, provide detailed performance criteria and limit the maximum size of material to 2 inches.

Air pollution concerns were addressed in several different ways. Performance specifications were written for the air pollution control equipment that had to be installed on the incinerator to allow it to meet all of the identified ARARs. Concern over VOC emissions from the feed preparation area resulted in a requirement that all feed preparation be accomplished within an enclosure as well as specifying requirements for VOC monitoring. Overall environmental concerns resulted in an extensive air monitoring plan for the entire site.

Ash Handling

Ash will be stockpiled in bins as it comes out of the incinerator. The ash will be tested prior to final disposal to ensure that the organics have been completely destroyed and that the ash passes the EP Toxicity test. Ash that meets both criteria will be backfilled in the excavations. The only limit on backfilling is that the ash must have a minimum of 18 inches of final cover.

Ash that does not pass the organics analysis will be reburned at the contractor's expense. Ash that does not pass the EP Toxicity test will be fixed prior to backfilling. Fixed ash may not be placed below the water table.

FINAL DISPOSAL OF WASTES

The specifications require that all wastes currently on-site must be disposed of on-site. This requirement includes uncontaminated trash, incinerator ash, water treatment sludges, etc. Only normal office trash generated during the remediation may leave the site. Any excess material from the flood protection structures must be disposed of on-site.

Equally important, no waste material may be brought on-site including waste oils for firing the incinerator. Concern from local citizens for this site turning into a Regional incineration facility prompted this specification.

CURRENT STATUS

Bids were taken on Mar. 8, 1990. The four bids received ranged from $89,949,100 to $98,380,176; all bids were within 5% of the Engineer's estimate of $94,529,501. A joint venture of IT Corporation and Davy McKee Corporation produced the low bid.

The current schedule for the project calls for the incinerator to be operational and the trial burn complete in late 1991 and for the entire project to be finished in 1996.

CONCLUSION

The Remedial Design of the Sikes Superfund site addressed many unique and challenging problems. The scope of this paper allows us to touch on only a few of the issues and not give a detailed discussion of any.

Integrated Site Remediation Combining Groundwater Treatment, Soil Vapor Recovery and Bioremediation

ABSTRACT

Integration of remedial techniques is an effective means of aggressive site cleanup. This was the approach used to respond to a catastrophic 8,400-gallon surface loss of gasoline due to vandalism at a bulk terminal. Rapid delineation of the contamination was accomplished with soil gas surveying and soil borings. Emergency activities consisted of the excavation of the top two feet of gasoline saturated soil to mitigate vapor exposure and installation of an 8-inch recovery well to prevent off-site migration of the gasoline. The excavated soil was treated on-site. To complete site remediation, an integrated in situ system was chosen. This approach was taken to provide rapid site remediation and to minimize disruption of site activities. The system consists of a bioaugmented soil vent system to treat contaminated soils - both excavated and vadose zone; a saturated phase bioreclamation system to treat contaminated aquifer soils and groundwater; and a groundwater/air stripping system to capture and treat contaminated groundwater. The system was installed in phases over three months. In eighteen months of full operation, the degree of contamination has been significantly reduced. This site demonstrated that integration of in situ technologies results in rapid and cost-effective remediation.

INTRODUCTION

The site pictured in Figure 1 is a bulk petroleum distribution plant which handles gasoline, diesel, fuel oil and propane gas. The plant is located in the Pine Barrens area of southern New Jersey between Atlantic City and Camden. This area is a sensitive ecological area.

In October 1988, an apparent act of vandalism caused a large gasoline spill at a bulk petroleum storage plant in southern New Jersey. Approximately 8,400 gallons of premium unleaded gasoline were spilled onto the ground around four underground storage tanks used for bulk petroleum storage. Plant personnel responded immediately with measures to protect groundwater and assure safety of workers in the area. At the request of local fire officials, approximately 700 yd³ of soil were removed from the spill area to a depth of 18-24 inches and stockpiled on 6-mil polyethylene sheeting. To reduce volatile emissions and to reduce the fire and explosion hazard, the excavated area was covered with polyethylene sheeting and clean fill material to cap the spill area. This temporary response provided a safer work area for remediation workers and plant employees and allowed the bulk plant to be reopened for normal operation during further cleanup operation.

SITE INVESTIGATION

The site is in the Pine Barrens region and is underlain by the Cohansey Sand. The Cohansey Sand is a sole source aquifer and is sensitive to any threat of groundwater contamination. Soils encountered beneath the site consist of fine to medium sands with some silts. These soil types have good permeabilities which made immediate response a primary concern to reduce the threat of groundwater contamination due to leaching of contaminant from the soil.
Figure 1
Study Site Bulk Terminal

A soil vapor survey was performed within two days of the loss to assess the extent of contamination. Vapor samples were drawn from probes and analyzed using a portable gas chromatograph. This process gave real-time data which could be used to modify the scope of the soil vapor survey as it was being performed. Vapor samples were drawn from a large number of locations surrounding the spill site and plotted to determine areas of maximum contamination. Figure 2 depicts the results of the soil gas survey. The primary area of contamination was the immediate tank pit area where the gasoline had pooled. High concentrations of gasoline extended to the south and west of the tank pit.

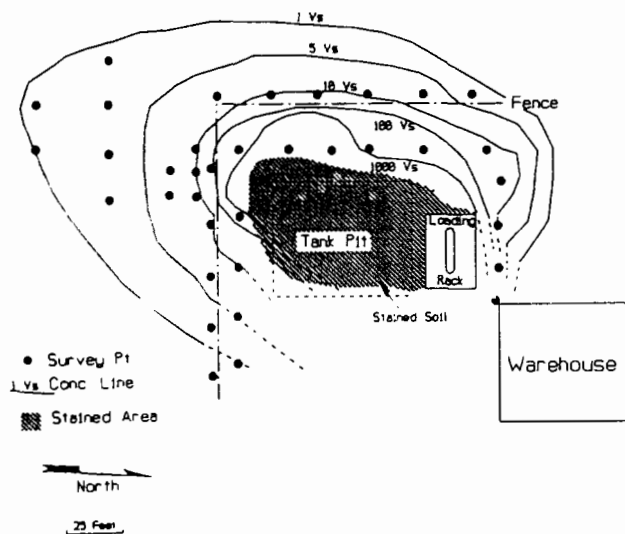
The results of the soil vapor survey were used to select locations for monitoring wells and a recovery system and allowed emphasis to be placed on the area with the maximum potential for groundwater contamination. Based on the soil gas survey, six monitoring wells and two recovery wells were installed surrounding the spill site. Headspace vapor readings were taken during drilling to determine the extent of soil contamination with depth. Additional soil borings were made in the spill area to determine the extent of soil contamination as it varied with depth.


Figure 2
Soil Gas Survey Concentration Lines

Figure 3 presents geological cross sections of the spill area on which the soil contamination results are depicted. The hydrocarbons entered the subsurface through the tank pit. The primary flow direction was vertical leading to a cone of contamination extending to the water table. There was some horizontal spread of product at the bottom of the tank pit along a transition from silty sand to fine sand.
Figure 3
Geological Cross-Sections with
Contaminant Distribution

In all, it is estimated that approximately 6,000 yd³ of soil were contaminated by the spill over an area of approximately 100 feet by 80 feet. An estimate of total amount of gasoline adsorbed in the soil was made using data from the soil vapor survey and soil borings. Based on estimated volumes of contaminated soil and quantitation of contamination with depth, it was estimated that approximately 7,700 gallons of gasoline were adsorbed in the soil of the spill area. An additional estimated 700 gallons were adsorbed in the soil which was excavated and stockpiled immediately following the spill. Due to the significant depth to groundwater (18 to 20 feet) and the quick emergency response actions, it was estimated that initially less than 100 gallons of gasoline reached groundwater under the spill area.

Groundwater samples were taken from the six monitoring wells and two recovery wells. The results, as presented in Table 1, show that the groundwater was contaminated, but that the contamination was confined to the immediate area of the spill.

Table 1
Initial Groundwater Sampling Results, (µg/L)

Well	BTEX	MTBE	Total, VOC
MW-1	BDL	ND	BDL
MW-2	7.9	ND	7.9
MW-3	387.6	290	677.6
MW-4	425	ND	425
MW-5	ND	ND	ND
RW-1	2940	8700	11640

Figure 4 provides an overview of the extent of contamination. Soil contamination is found in the general area of the tank pit and extends from grade to the water table. Groundwater is contaminated and the plume extends to the southeast of the spill area along the direction of groundwater flow. The spread of the groundwater plume was partially blocked by the existence of a trough in the water table elevations running west to east and located south - southwest of the spill area.
Figure 4
Extent of Soil & Groundwater Contamination

Based on these assessments results, the focus of the remedial program was to:

• Contain the spread of groundwater contamination
• Remediate the contaminated soil to remove the source of groundwater contamination
• Restore groundwater quality

REMEDIAL ALTERNATIVES

Two general alternatives were compared for dealing with the spill. The first alternative involved excavation and replacement of all contaminated soil in the spill area, combined with continued groundwater treatment to remove dissolved contaminants and prevent off-site migration of any contaminated groundwater. The results of the soil vapor survey indicated that approximately 6,800 yd³ of soil had been contaminated. If this soil had been excavated and trucked to a secure landfill, the estimated costs would have approached $700,000. The facility owner would retain perpetual liability for the contaminated soil stored in the secure landfill. In addition, soil excavation would require removal of the storage tanks and loading rack. Estimated cost for this alternative, including groundwater treatment, was more than $800,000 and would have effectively put the facility out of the liquid fuel storage business.

The second alternative was to treat the contaminated soil on-site using soil venting and bioremediation. With this alternative, the petroleum bulk plant could remain in operation during remediation. There would be no off-site liability since no contaminants would leave the site. Using a variety of processes to treat soil, groundwater and vapors, the estimated cost for on-site treatment was $500,000-$600,000. The decision was made to treat the contamination on-site.

IN SITU TREATMENT COMPONENTS

There were two basic types of contaminated media: groundwater and soil. The soil contamination was primarily in the vadose zone, although some contaminated soil existed below the water table.

Gasoline is relatively volatile, having an average vapor pressure of ~50 - 100 mm Hg. It is biodegradable, having a BOD'5 of 0.08 - 0.12 mg/L. It is, however, relatively insoluble, having a maximum solubility of ~150 mg/L. Based on these properties, remediation of significant quantities of gasoline is accomplished best by the use of soil vapor extraction and bioreclamation. However, since the groundwater also was impacted, a groundwater recovery system was necessary to remediate the spill. The groundwater system also aided the bioreclamation system by enhancing transport of nutrients and oxygen through the area.

The components of the treatment system selected were:

- Groundwater recovery and treatment
- Soil vapor extraction
- Bioreclamation

The following sections contain descriptions of the technical aspects of each component of the remediation system.

GROUNDWATER EXTRACTION AND TREATMENT

Groundwater extraction and treatment is a process utilized to maintain hydraulic control of dissolved groundwater contaminant plumes. By estimating site-specific hydraulic characteristics, appropriate pumping equipment, treatment systems and recovery well(s) can be located, designed and installed to maintain the necessary hydraulic control.

Groundwater which is extracted from the subsurface can be treated for organic removal using various technologies. Two of the most common technologies employed for removal of gasoline constituents from a water stream are air stripping and activated carbon. In this case, air stripping was employed because of its low maintenance and lower operating costs.

SOIL VAPOR EXTRACTION

Soil vapor extraction is a process for removing volatile organic contaminants from unsaturated soils by induced air flow. In using soil vapor extraction, a series of vertically screened wells is placed in the area of contaminated soils penetrating the horizon of contamination. A vacuum is applied to the vent wells to induce air flow through the subsurface and to volatilize and remove the contaminant.

Soil vapor extraction systems may require treatment of the vapor effluent. Two basic technologies are available for treatment of vapor effluent - carbon adsorption and thermal treatment. In this case, a thermal treatment system was employed because of its low maintenance and low operating cost.

BIORECLAMATION

Simply viewed, bioreclamation is a two step process:

$$\begin{array}{ccc}\text{Contaminant} & \text{Bacteria} & \text{Cell Material} & \text{Bacteria} \\ \text{------>} & & \text{------>} & CO_2 + H_2O \quad (1) \\ \text{(C,H)} & & \text{(C, H, N, P, O)} & \end{array}$$
In the first step, bacteria, which have evolved the specific enzyme machinery, use the contaminant, which is mostly carbon and hydrogen, as a food and energy source. A portion of the carbon and hydrogen is "burned," i.e, used as an energy source yielding CO_2 and water directly. Most of the contaminant, however, goes into the production of additional cell material - other bacteria.

In order to make cell material, the bacteria need a proper balance of nitrogen, phosphorous and oxygen relative to the carbon source. In the natural environment, these factors are all in balance. However, when a loss/spill of organic chemicals occurs there is an overabundance of carbon relative to the naturally available oxygen nitrogen and phosphorous. This overabundance of carbon creates a stress situation which cause the bacteria to be dormant. The same thing happens in activated sludge when one gets a shock loading - one loses the culture. Once, through the practice of bioreclamation, a balance is re-established, the bacteria rapidly convert the carbon to cell material which then becomes food for other soil bacteria. This subsequent metabolism takes the partially degraded contaminant ultimately to CO_2 and water - complete mineralization. The key to the successful application is to transport nutrients and oxygen to the areas of contaminated soil and groundwater.

Successful treatment of the gasoline spill required application and integration of all three components. Figure 5 shows a conceptual view of the integrated system. The groundwater system captures and treats contaminated groundwater. It also aids in the transport of nutrients and oxygen for the bioreclamation system. The vent system removes gasoline from the vadose zone by both direct volatilization and by supplying oxygen to the bioreclamation system. Finally, the bioreclamation system degrades gasoline in vadose and saturated zone soils and in groundwater. It also increases the removal of adsorbed organics by solubilizing them so they can be captured and removed by the groundwater system.
Figure 5
Conceptual View of Integrated Remedial System

SYSTEM DESIGN AND INSTALLATION

Groundwater Extraction and Treatment

Based on the results of the soil gas survey, an initial recovery well location was selected. Recovery well RW-1 was installed in the location indicated in Figure 4. Groundwater was pumped from this recovery well at a flowrate of approximately 20 gpm as an interim measure instituted to assist in establishing hydraulic control of the contaminated groundwater.

The extracted groundwater was treated using air stripping. Air strippers volatilize compounds from the water phase into the vapor phase due to the air-water partition coefficient or the Henry's Law Constant. The air stripper employed at this site was a 24-inch diameter, 22-feet tall unit packed with two-inch media. The air flowrate was 1,000 cfm and hydraulic capacity of the unit was 50 gpm. The treatment efficiency ranged from 98-99.9% removal of VOCs. Influent MTBE concentrations were reduced by 60-85%. The air stripper removed approximately 0.1 lb/hr of hydrocarbon compounds, which represents an equivalent removal of approximately 70 gallons of gasoline per month. The liquid effluent from the air stripper was combined with a nutrient solution and hydrogen peroxide and routed to five nutrient injection wells to assist in the bioremediation process.

Once groundwater monitoring wells were installed and sampled to confirm the results of the soil gas survey, the groundwater pumping was temporarily halted to allow groundwater elevations to return to static levels. A 72 hour pump test was then performed to determine the hydraulic characteristics of the water table aquifer. An approximate transmissivity (T) of 20,000 gpd/ft and storage coefficient (S) of 0.034 were estimated based on site-specific conditions and assumptions. An average daily groundwater flow velocity of 3.0 feet/day was calculated.

The data discussed above were utilized in performing a capture zone evaluation using the following equation:

$$r_{og} = \frac{Q}{(2\pi)\ (T)\ (I)} \tag{2}$$

where:

r_{og} = stagnation point/velocity divide downgradient
Q = extraction rate from recovery well
T = Transmissivity
I = Groundwater gradient
and
r_{ug} (upgradient) = r_{og} (2π)
r_{cg} (cross gradient) = r_{og} (π)

Upon performing the capture zone evaluation on recovery well RW-1 at a flow rate of 20 gpm, we decided that additional hydraulic control was necessary to effectively capture dissolved hydrocarbon compounds.

In order to establish sufficient hydraulic control at the site, an additional recovery well (RW-2) was installed to a total depth of 50 feet below grade at the location depicted in Figure 6. Additionally, Figure 6 depicts the water table elevation under pumping conditions (with RW-2 operational at 25 gpm) versus the originally inferred static water table elevations.
Figure 6
Groundwater Treatment System "RW-2"

The theoretical capture zones created by pumping recovery well RW-1 at 5 gpm and RW-2 at 25 gpm are depicted in Figure 7. The water table elevations depicted in Figure 6 seem to confirm the theoretical capture zones depicted in Figure 7
Figure 7
Capture Zones for Recovery Wells

By examining the influent concentrations depicted over time in Figure 8, the effectiveness of the groundwater recovery system can be seen in maintaining hydraulic control of the dissolved hydrocarbon compounds.
Figure 8
VOC Concentrations in Recovery Well(s)

Upon evaluating the hydraulic conditions of the site while recovery well RW-1 was pumping, we decided to add an additional recovery well (RW-2) to the groundwater recovery system. As indicated in Figure 8, this new well led to the reduction of the combined influent concentrations due to a greater volume of water being recovered by the two recovery well systems. The recovery of dissolved contaminants was increased again after 11 months of recovery system operation by adjusting the flowrates in RW-1 and RW-2 in response to a followup evaluation of hydraulic site conditions. By monitoring and adjusting hydraulic conditions at the subject site, more contaminants have been drawn to RW-2 and hydraulic control of the dissolved hydrocarbons has been established. Hydraulic control is further enhanced by the upgradient injection of nutrient-enriched air stripper effluent. This upgradient injection increases the gradient across the area of dissolved hydrocarbon compounds, thereby increasing the rate at which contaminants can be recovered and nutrients can be circulated.

SOIL VENTING

If ambient soil vapor pressure in a spill area is reduced, hydrocarbons can be removed from soil in the vapor phase. Vacuum blowers

were used to draw air through contaminated soil in the spill area to vaporize adsorbed hydrocarbons and carry them to the surface. Soil venting was utilized in two ways; the first system treated excavated soils from the spill area; the second system treated the remaining contamination in vadose zone soils.

Immediately following the spill, approximately 700 yd³ of contaminated soil were excavated from the spill area to limit volatile emissions and reduce fire and explosion hazards. This material was stockpiled on polyethylene sheeting near the spill site. Perforated PVC laterals were installed in the soil pile and nutrient solution was sprayed on the soil. The entire soil pile was then covered with polyethylene sheeting and the PVC laterals were manifolded to a high vacuum blower, which was operated to remove hydrocarbons in vapor phase from the soil pile.

Separate bail valves allowed adjustment of air flow through the soil pile to optimize removal of hydrocarbons. The operating air flowrate for the soil pile was approximately 100 cfm.

Four vapor extraction wells were installed in the spill area to allow soil venting of approximately 6,000 yd³ of contaminated soil in the unsaturated zone. The vapor extraction wells were 4-inches in diameter and approximately 22 feet deep. Separate laterals from each well were manifolded to a high vacuum blower and separate ball valves on each lateral allowed dedicated control of vapor flow from the different wells to optimize hydrocarbon removal in the vapor phase. The operating flowrate from the vapor wells was approximately 130 cfm.

Hydrocarbon removal through use of the vent system approximately 85 lb/day, equivalent to approximately 14 gallons of gasoline per day. Vapor-phase treatment of the air exhaust was required to meet New Jersey air emission standards. Alternatives for vapor-phase treatment included carbon adsorption and catalytic oxidation. Because site remediation could ultimately result in the removal of almost 50,000 pounds of hydrocarbons (from 8,400 gallons of gasoline), it was determined that catalytic oxidation would be the most cost-effective means of vapor treatment. Catalytic oxidation provides conversion of volatile organic chemicals to CO_2 and water vapor. The process uses a precious metal (platinum) catalyst, operating 600°F to 700°F, which is a significantly lower temperature than used in thermal incineration. Heat released during catalytic oxidation of the hydrocarbon vapors is recovered to reduce the power consumption for heating the catalyst.

A Catalytic Scavenger™ Unit, manufactured by Oil Recovery Systems, Inc., (ORS) was installed to treat vapors at this site. The unit operates on a relatively dilute influent vapor level of hydrocarbons (less than 25% of lower explosion limit) and incorporates safety features to automatically shut the unit down if vapor concentration or operating temperature become too high. At this spill site, this catalytic unit treats approximately 230 cfm of vapors from the soil pile and vapor extraction wells. The unit removes approximately 3.6 lb/hr of hydrocarbons and reduces influent vapor levels by more than 95%.

The layout of the soil vent system is pictured in Figure 9. The figure shows the location and influence of the in situ vapor extraction points.

BIOREMEDIATION

Bioremediation was used to treat adsorbed and dissolved contaminants in the saturated zone. Bioremediation was also used in conjunction with soil venting to accelerate the removal of adsorbed hydrocarbons in the unsaturated zone. An added benefit of the process is that it removes adsorbed hydrocarbons which are not as effectively removed by soil venting from the saturated zone.

Nutrient requirements and optimum conditions for biodegradation were determined by laboratory simulation of conditions using actual soil samples from the spill site. The results are presented in Figure 10. As can be seen, the site required the addition of nutrients at ~100 mg/L level to effectively remove the gasoline.

The layout of the bioremediation system is shown in Figure 11. Nutrient-amended groundwater was independently injected through five injection wells and through a series of shallow infiltration lines. The nutrient peroxide solution was injected continuously through the injection wells and on a batch basis through the infiltration lines. The water content in the vadose zone was kept at ~50% of residual satura-

tion to maintain a balance between bioreclamation and soil vapor extraction.
Figure 9
Soil Venting System
Figure 10
Laboratory Pilot Study BTEX
Degradation with Time

The installed system was a fully balanced and integrated system. As shown in Figure 12, the equipment was laid out so that individual points could be adjusted and the system could be balanced. Groundwater from the recovery wells was air stripped, amended with nutrients and hydrogen peroxide and then reinjected through injection wells. Vapors were withdrawn both from the soil pile and from the in situ points. The vapor stream was sent to the catalytic oxidation unit.

OPERATING RESULTS

The system has been operating for approximately 18 months. Of the approximately 47,000 pounds of gasoline in place after system installation, ~34,000 pounds (or 73%) have been removed/destroyed by the remedial system.

The performance of the different system components is depicted in Figure 13. As can be seen, the bulk of the removal has been due to the vapor extraction system. The soil vapor extraction system provided

a rapid and substantial response to the spill. However, bioreclamation also provided significant removal of hydrocarbons. As can be seen from the data in Figure 13, the removal due to the other processes has increased with time. This result is to be expected as the vapor extraction system removes the highly volatile and mobile fractions leaving a less mobile residue. This residue is more responsive to bioreclamation than it is to soil venting. Hence, the increase in the relative importance of bioreclamation with time.

Figure 13
Treatment Performance Integrated System

The driving force for the remediation was the control and reduction of groundwater contamination. The system has had a substantial impact on groundwater contamination in the source area. Two types of volatile organic contaminants were tracked in Figure 14 BTEX (benzene, toluene, ethylbenzene and xylene) and MTBE (methyl tertiary butyl ether). The BTEX level started at about 1200 μg/L and the MTBE level at 4400 μg/L. In the first part of reclamation, both concentrations increased: to ~22,000 μg/L for BTEX and to 88,000 μg/L for MTBE. This increase was due to the solubilization of the adsorbed contaminants due to water circulation through the vadose zone and biological activity. After the system had been operating for approximately 6-9 months, substantial decreases in BTEX and MTBE concentration were observed. As the source area has been remediated, the impact on groundwater has been mitigated.
Figure 14
Reduction of VOCs in Groundwater in Source Area

Several things should be noted in Figure 14. First, the BTEX results showed an apparent rise in the last sample due to abnormally high results in one well. All other wells remained low and were in line with previous results. The cause of the aberration may be due to sampling error, and the well will be resampled. A second observation is that the MTBE concentration decrease lags the BTEX because MTBE is less volatile

and less biodegradable than BTEX. Consequently, it has taken longer to reduce the source concentration.

CONCLUSION

Using an integrated system to treat groundwater and soil contamination provided an effective and rapid response to large-scale organic contamination. The combination of bioreclamation, soil vapor extraction and groundwater recovery employed at this site has removed almost 34,000 pounds of gasoline in fewer than 18 months of operation. The system has effectively reduced groundwater contamination in the spill area by more than 90% from the maximum levels. The integrated system has been effective because it has made best use of the properties of the contaminant and the nature of the site in remediation. Gasoline is a volatile, biodegradable contaminant mixture. It is not, however, very soluble. As a result, the application of soil venting and bioreclamation has resulted in substantial removals of gasoline.

The effectiveness of on-site treatment at this spill site demonstrates that use of modern technology can reduce costs and limit liabilities for petroleum companies which experience large spills. At the same time, contaminants can be contained within the spill area to reduce threats to groundwater and air quality.

Restoration of a Refinery Site
For Use as a Commercial Center

ABSTRACT

There is often concern that petroleum refining operations cause significant soil and groundwater contamination due to spills, leaks, improper design of storage and pipeline facilities and long periods of operation. In some instances, these concerns have been confirmed by the discovery of significant accumulations of hydrocarbons beneath refineries. Yet, the demolition of the 40 year old Golden Eagle Refinery in Carson, California (Site) demonstrated that contamination is not always significant and that through the use of well-designed demolition efforts and enhanced bioremediation, site restoration can be accomplished easily and quickly.

Restoration of the 76 acre Site was accomplished in five phases: (1) cleaning to remove tank bottom sludges and API-type separator bottoms and delivery of all such materials to an approved disposal site; (2) removal of all above surface structures and underground storage tanks; (3) removal of underground pipelines, pits, sumps and clarifiers; (4) removal and disposal of a small volume of soil contaminated with lead; and (5) consolidation of petroleum hydrocarbon-contaminated soil within the old tank farm area where enhanced bioremediation was accomplished. A Site characterization study was completed while the first three phases were being accomplished. The results of this study established the regulatory agencies' requirements for bioremediation.

Semiperched water and aquifer testing demonstrated that the dissolved concentrations of total petroleum hydrocarbons ranged from below laboratory detection limits to 40 μg/L and chlorinated hydrocarbons ranged from below laboratory detection limits to 27 μg/L at the Site. After repeated monitoring of the contaminant levels in the semiperched water and underlying aquifer, no significant changes in concentrations were noted. Monitoring continues on an annual basis. Development of the Site is ongoing.

Petroleum hydrocarbon concentrations in the contaminated soil ranged from 60 to 32,000 ppm. The Solmar Corporation commercial bacterial formulations were tested for efficacy in reducing the hydrocarbon concentrations to acceptable levels. A selected formulation was used and reduction in hydrocarbons to acceptable levels was completed in approximately eight months. Some residual hydrocarbon concentrations (less that 1,000 ppm) remained in the remediated soil, but they were mostly C15 or higher compounds. Such petroleum residuals, largely asphaltic in nature, do not degrade or move easily through the soil even with extensive water infiltration. Six volatile priority pollutants were detected in the soil at the termination of remediation, but all at concentrations well below 1 ppm. Several nonpriority pollutant volatile compounds also were identified at concentrations of 9.5 ppm of less.

The planned use of the Site is for a commercial complex with extensive buildings and related asphalt-covered parking and landscaped areas. Although the residual hydrocarbon concentrations in the soil were not considered to be a problem, requirements were evolved to limit the potential for any significant impacts from the residual hydrocarbons during future site development.

INTRODUCTION

Petroleum refining, storage and transporting facilities have often been cited as major sources of soil and groundwater contamination. It is not unusual to find several feet of free product sitting on top of groundwater and also to find dissolved product constituents in the groundwater. Loss of product can be due to accidental spills and leaks, improper design of facilities and improper or insufficient maintenance and repair. In many instances, the soil and groundwater contamination is the result of decades of Site use for the same general functions. There is one such site in California which for approximately fifty years has been used for two different refining operations, each with separate storage and crude/product transportation facilities and regional transportation of petroleum products and finally used only for short term storage and distribution of products.

The soil and groundwater contamination is extensive and free product can be found in several locations. The problems are compounded by activities at adjacent industrial facilities which have produced napalm and bomb components, processed phosphate materials containing arsenic and produced vinyl chloride-based materials. This situation is almost a classic example of a site where spills and leaks have been common, where an old design was overused and where maintenance and repair were not timely or sufficient to comply with the ever changing rules and regulations. In many instances, remediation of a refinery would bring to mind most of the conditions described above. This was not the case for demolition of the 40 year old Golden Eagle Refinery, Carson, California.

GOLDEN EAGLE REFINERY SITE

The Golden Eagle Refinery Site (Site) occupies 76 acres surrounded by residential developments on two sides and commercial development, inactive landfills and a major freeway on the other sides. The original crude processing units, excluding the existing tank farm (Fig. 1), were constructed by Sunset Oil in 1945. Over the next 10 years additional processing units were added, reaching a production capacity of 4,000 bbl/day. The products produced included kerosene, fuel oil and gasoline. In 1953, a thermal cracking unit was added to increase production of gasoline, but this unit was taken out of service in 1961/1962. Production of leaded gasoline ceased in 1965, but a tetraethyl lead storage tank remained in place until demolition in 1985. In 1980, a third crude processing unit was added which increased capacity to 12,500 bbl/day. The three crude units, in combination with a naphtha stabilizer unit and

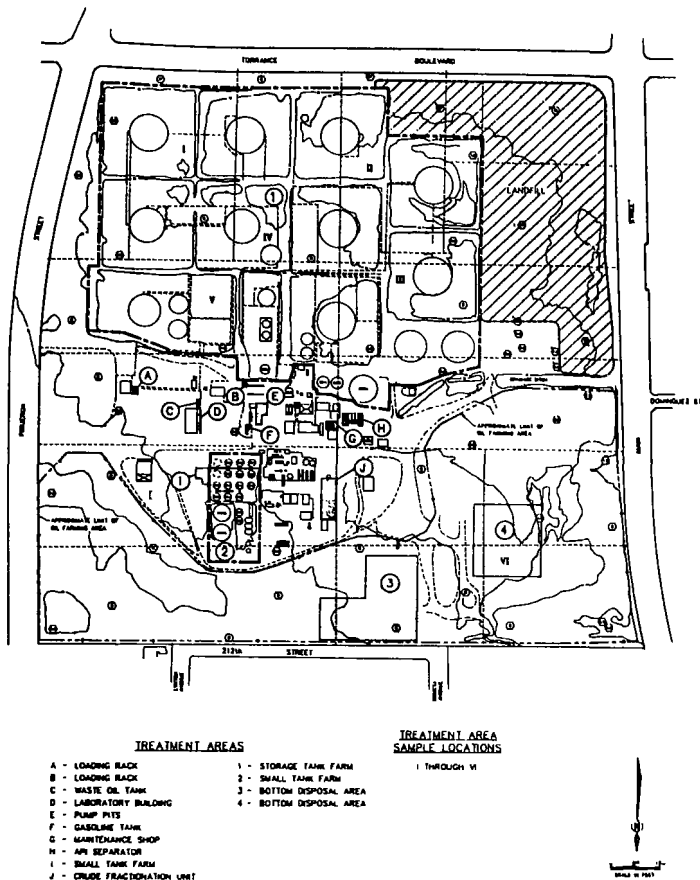
a rerun unit, produced JP-4 and JP-5 aviation fuel, fuel oil and diesel fuel until the refinery stopped production on November 12, 1984.


Figure 1
Golden Eagle Refinery, Carson, California

Primary transport of crude and product to and from the refinery was by a system of pipelines connecting the refinery with oil fields, other refineries and terminals at the Port of Los Angeles. There were truck loading racks but they were used sparingly.

Approximately 10 acres on the northeastern portion of the Site were used as a landfill (Fig. 1). This use was very short, beginning in late 1961 and ceasing in late 1962. The depth of the fill material ranges to about 38 ft below grade, with an average soil cover of 2-5 ft. The contents of the landfill range from concrete and asphalt to household wastes. Some methane gas is produced, but the soils around the landfill are relatively impermeable and constitute a natural barrier to gas migration.

Although there were a few areas on the Site with perched water at depths of 35-40 ft, in general the depth to groundwater is greater than 50 ft below the surface. There are several underlying aquifers which provide potable water.

WASTE DISPOSAL

Until about 1971, tank bottom sludges were placed on the southern portion of the Site and farmed (Areas 3 and 4, Fig. 1). The sludges were allowed to dry and then were disced into the soil to allow for natural bacterial break down of the hydrocarbon components. For a brief period of time, refinery wastewater was disposed on-site into a slough which flowed into the Los Angeles Harbor area. After 1950, all wastewater was discharged into the sewer system.

BASIC SITE GEOLOGY

The surface soils at the Site consist of silty clay and clay formations. These formations effectively limited the downward migration of any

residual contamination in the surface soils. It was typical to encounter hydrocarbon concentrations of 10,000 ppm at a given depth with the hydrocarbon concentration 5 ft lower being Not Detected (ND). The low level of contaminant migration also was due to the presence of mostly heavy hydrocarbons, i.e., hydrocarbons with 12 or more carbon atoms.

ANALYTICAL PROCEDURES

Soil samples were obtained from fifty borings and nine monitoring wells were drilled to or just below the groundwater level. One well was drilled into the underlying aquifer. Soil samples were obtained at 5-ft intervals. Soil and groundwater samples were tested using U.S. EPA Methods 418.1, 8015, 8240 and 8270.

GROUNDWATER ANALYSES

Contaminant concentrations in the semiperched groundwater were very low. Several priority pollutants, chlorobenzene, 1,2-dichloroethane, benzene, ethylbenzene, toluene and trans-1,2-dichloroethylene were found at low concentrations. Only the concentration of benzene and 1,2-dichloroethane exceeded the California Department of Health Services Action Levels for Drinking Water.[1] These concentrations were not considered to be a problem because the semiperched zone is not used for drinking water, the clay layers in the soil essentially preclude extensive downward migration of the contaminants and most of the contaminants are heavy hydrocarbons. Further, introduction of additional contaminants is essentially precluded since the refinery has ceased operations and the existing contaminated soil has been treated.

VOLUME OF SOIL TREATED

After extensive geotechnical and hydrogeological analyses, 14 areas were established where treatment was required. Ten of these areas were excavated (Areas A through J, Fig. 1) and approximately 530 yd^3 of soil were transported to Area 1 (Fig. 1). Most of the soil contaminants were within 0.5 ft of the surface, with only the contaminants in Areas C and F extending down to 20 ft below the surface. The soils in Areas 1 through 4 were treated in place. The largest volume, approximately 20,000 yd^3, was in Area 1. Areas 2 through 4 contained about 3,000 yd^3 Collectively, approximately 23,000 yd^3 of soil were treated using bioaugmentation. This low volume is attributed to good housekeeping during refinery operations even before current rules and regulations were implemented. The treatment areas were arranged so that the contaminated soil was approximately 10-12 in. thick.

LEAD CONCENTRATIONS

The surface soil in two small sites within Area 3 contained lead concentrations which exceeded the Total Threshold Limit Concentration (TTLC) value of 1,000 ppm.[1] Soil from these areas was excavated and transported to an approved disposal site. Four other samples were tested using the California Waste Extraction Test (WET) to determine if the lead concentrations below the TTLC were soluble. All of the soluble lead concentrations were less than 0.03 mg/L, which is less than the Soluble Threshold Limit Concentration (STLC) value of 5 mg/L.[1]

BIOAUGMENTATION PROCEDURES

Samples from the treatment areas were obtained and submitted to Solmar Corporation for treatability studies. The hydrocarbons were extracted from the samples with Freon 113 using a Soxhlet apparatus. Portions of the individual extracts were in turn inoculated with various commercially available Advanced Bio Cultures. Formulation L-104 showed the highest degradation capability based on degradation efficiencies ranging from 47% to 64% after 21 days.

The treatment areas initially were watered using a 2000-gal. water truck. When the soil was moist, fertilizer with phosphorus and nitrogen was added using the water truck. When the phosphorus and nitrogen levels in the soil were 5 ppm and 20 ppm, respectively, the bacteria were added. The cultures, supplied in dry form, were reconstituted by adding approximately 2 gal. of water/lb of culture. After soaking, the cultures were added using the water truck. Treatment was based on an initial inoculation of 50 lb of L-104 per acre of treatment area. This

initial application was followed two weeks later with an inoculation of 37.5 lb/acre. Thereafter, inoculations of 25 lb/acre were added monthly. Other than during inoculation of L-104, watering in Area 1 was accomplished using a portable sprinkler system fed from the refinery fire protection system. The soil moisture content ranged from 25% to 30% during the treatment efforts. The 8-foot high tank farm external berms were left in place so that any excess water was contained within Treatment Area 1. Watering in Areas 2, 3 and 4 was accomplished using the water truck.

The L-104 bacterial formulation included some species which were not initially efficient in breaking down the hydrocarbons in the treatment areas. However, as breakdown products are produced, it is important that all species of the consortium be available to handle the metabolites being formed. The subsequent inoculations assure that all species of the consortium are available in suitable numbers to give complete breakdown.

Since the breakdown process is accelerated by the presence of oxygen, about once a month, the treatment surface area was disced to a depth of approximately 10 in.

TREATMENT RESULTS

Sample stations A through F were established in Areas 1 through 4 (Fig. 1). Samples were collected frequently to determine bacterial plate counts and changes in hydrocarbon concentrations. Often, since it is not possible to repeatedly sample in exactly the same location, hydrocarbon concentrations at a given station increased or decreased during successive analyses.

The highest concentration of hydrocarbons in the treated soil was 32,330 ppm. Initially, the soils contained several purgeable priority and nonpriority pollutants and extractable priority pollutants. Concentrations of benzene, toluene, xylene, ethylbenzene and methylene chloride ranged from ND to 800 ppb; concentrations of hexane, methylcyclopentane and 3-methylpentane ranged from ND to 9,500 ppb; and concentrations of bis(2-ethylhexyl)-phthalate, diethyl phthalate and butyl benzyl phthalate ranged from ND to 204 ppm. Initial bioaugmentation treatment started in February 1986, and the levels of hydrocarbons were sufficiently reduced by October, 1986. The fluctuations in hydrocarbon concentrations at Sample Stations A through F are shown in Table 1. Almost all of the short-chain hydrocarbons were eliminated. The residual hydrocarbons were saturated straight-chains, ranging in size from C20 to C27. The initial concentrations of purgeable and extractable compounds were reduced to ND or below 1 ppm. The nonpriority pollutant levels also were reduced to 9.5 ppm or lower. The extractable priority pollutants, primarily phthalates, were detected in final sample analyses but at levels below 1 ppm.

FINAL SITE DISPOSITION

After treatment of the soil, the Site was generally deemed suitable for commercial development based on implementation of at least the following conditions:

• The landfill site was covered with a sufficiently thick cap and use thereof was limited to parking or other passive uses
• Landscaped areas were watered using a drip system
• Protective membranes were placed under buildings

CONCLUSIONS

Based on the results of several Site studies[2-5] which are summarized in the paper, several conclusions can be drawn:

• The Golden Eagle Refinery Site is unique in that the degree and diversity of soil contamination was limited;

• The Site soil conditions limited the migration of the hydrocarbon contaminants both within the soil and into the semiperched groundwater and underlying aquifers;
• Selection of the bacterial formulation is critical to successful reduction of hydrocarbons in the soil;
• Bacterial degradation of hydrocarbons requires optimum concentrations of phosphorus and nitrogen; application of water is critical and discing the soil being treated will enhance the rate of degradation of the hydrocarbons;
• Bioaugmentation using formulated bacteria is an easy and relatively inexpensive way to reduce hydrocarbon concentrations in soils; and
• Residual concentrations of long chain hydrocarbons (C20 or higher) can be left in place provided the design of future developments includes conditions which minimize the potential for the collection of vapors in buildings or percolation of water through the soil into the ground water regime.

ABSTRACT

Have you ever wondered how to close a one-square-mile Superfund site and still have money left in the bank? This task was the challenge that faced Metropolitan Dade County, Florida (County) and its consultants more than five years ago. Early estimates put closure construction costs at approximately $25 million (1985 dollars), today the estimated cost for closure is just $16 million (1990 dollars), or approximately one half the original cost estimate!

The project team accomplished this savings by dividing the site into separate zones with different potentials for contamination. Landfill and groundwater models were used to quantify the impacts of alternative closure plans. Each zone was treated separately in the closure plan and different levels of treatment were applied as appropriate. Thus, closure costs were reduced by selecting the most cost-effective, environmentally-acceptable closure alternative.

Detailed closure design plans are completed now and construction is expected to begin early in 1991. This paper describes the closure process which made this project successful.

INTRODUCTION

The Northwest 58th Street Landfill (Landfill) is a one-square-mile site located in Dade County, Florida approximately five miles northwest of the Miami International Airport. The Landfill was placed on the NPL (NPL rank 174) of potential uncontrolled hazardous waste sites in October 1981.

The Landfill is one of three NPL sites which are included in the Biscayne Aquifer Superfund Study. All three sites have caused some contamination of the Biscayne Aquifer, which is the sole source of drinking water for 2,000,000 people in the Miami-Dade area. Each site represents an operable unit of the entire remedy for this study area and a separate ROD has been issued for each site as well as for the entire Biscayne Aquifer Study Area.[1]

BACKGROUND

The Landfill is owned by the County and was the County's main disposal facility for more than thirty years. Operations at the Landfill began in 1952, with waste placed at or below the groundwater table in shallow trenches. Until it was banned in 1960, open burning for volume reduction was practiced. Daily cover of waste material was not practiced until 1975 and fires frequently occurred in the uncovered refuse.

In 1975, daily cover was applied to the waste in response to new State of Florida regulations. By this time, approximately 70% of the site had been filled with solid waste and there was little natural soil available for cover material.

Cover material had to be imported from outside sources. The cover

sources included: (1) calcium carbonate sludge from water treatment plants; (2) crushed limestone; and (3) spoil materials such as muck, limestone and sand from construction sites.[2]

The type of waste at the Landfill can be described as municipal solid waste. The Landfill also accepted liquid waste from restaurant grease traps, septic tanks and wastewater treatment plants, which were disposed of with the other wastes.

The Landfill was never operated or permitted as a hazardous waste facility, nor is there any evidence to suggest that hazardous materials were ever knowingly accepted.

Both the Florida Department of Environmental Regulation (FDER) and the U.S. EPA have worked with the County to develop final closure plans for the Landfill. The County and FDER entered into a Consent Order in June 1979. Because of widespread low to moderate groundwater contamination in the study area, the U.S. EPA placed the Landfill on the NPL in October 1981. Two public drinking water supply wellfields downgradient of the Landfill were of particular concern.

The Landfill stopped accepting wastes for disposal in October 1982 but it has never been officially closed in accordance with State of Florida regulations. The Consent Order with FDER is still in effect; however, the County must also meet the U.S. EPA's requirements. Although interim cover was provided, a final closure plan had never been implemented.

On September 21, 1987, the U.S. EPA issued a ROD for the Landfill. The ROD is concerned with on-site soil contamination, site-related groundwater contamination and downgradient private well-users. The remedy selected in the ROD requires: (1) Landfill closure in accordance with the technical requirements of Chapter 17-7 of the Florida Administrative Code (FAC, 1985), utilizing the U.S. EPA guidance document *Covers for Uncontrolled Hazardous Waste Sites* and (2) municipal water to be provided to private well-users east of the Landfill.[1]

The ROD further states that the Landfill closure will include leachate control through a combination of grading, drainage control and capping. On April 26, 1988, the U.S. EPA and the County signed a Consent Decree, which is the legal mechanism for enforcing the conditions of the ROD.

A first attempt at developing a closure plan for the Landfill in the early 1980s, treated the entire site as one unit. Plans for grading, drainage and placement of a low permeability cover were developed with an estimated construction cost of approximately $25 million (1985 dollars). However, the County decided to use a different approach to closing the Landfill, with the goals of reducing the cost and achieving an environmentally-acceptable closure plan.

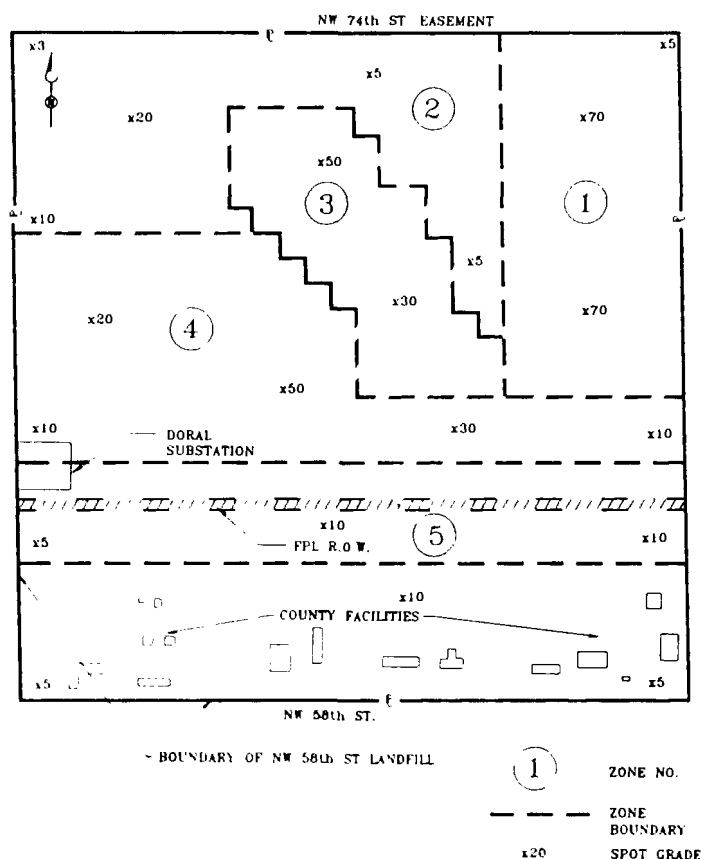
In 1985, the County sold bonds which provided funds for the development and implementation of a final closure plan for the Landfill. During this same time, the County created special taxing districts to finance

plans to put the private well-users on public water supplies. Potable water service has been provided to areas downgradient of the Landfill since early 1988.

LANDFILL CLOSURE APPROACH

The County authorized the Brown and Caldwell project team to initiate work on the Landfill closure project in 1985. The project team began by reviewing existing data and previously prepared reports. During this phase of the work, the project team decided to conduct predictive landfill and groundwater modeling to quantify the water quality impacts of various landfill closure options.

Since landfilling of waste was not accomplished uniformly over the one-square-mile site, waste depth varies from 5 to 10 feet in the southern third of the site to 75 feet in the east mound. Greater potential for leachate contamination is expected from areas on the site where waste is newest and depth is greatest. Therefore, the landfill was separated into five separate zones based on waste depth and varying site characteristics.

Figure 1 shows the five zones which were identified for landfill and groundwater modeling. Zone 1, a 90-acre area, consists primarily of a relatively new 70-foot mound on the east side of the Landfill; it was found to have the strongest leachate concentrations. Zone 2 is a 78-acre area where waste disposal has not taken place. Zone 3 is 61 acres with an older, less well-defined mound than Zone 1. Zone 3 has depths of fill up to elevation 50 feet and lower leachate concentrations than Zone 1. Zones 4 and 5 are 192 and 99 acres in size, respectively, with average fill depths of 15 to 30 feet and 5 to 10 feet, respectively; and as would be expected, there are generally lower leachate concentrations in these zones. The project team required additional information in order to perform predictive modeling of landfill closure options. A data acquisition program was developed to supplement the existing data base. The types of required data can be categorized as: (1) surface and groundwater data and (2) landfill site data.[3]


The program was designed to obtain site-specific surface and groundwater data to allow development and calibration of groundwater models. Data identified in the program included water quality, water elevation, aquifer hydraulic conductivity and aquifer thickness. The objectives of site data acquisition were: (1) to develop sufficient information to make water balance calculations, (2) to establish representative leachate quality characteristics and (3) to obtain subsurface information beneath the Landfill to adequately model leachate movement.

DEVELOPMENT OF ALTERNATIVES

During the alternatives development process, Brown and Caldwell team members used engineering judgement and site characteristics (such as topography, age of fill, depth of fill, strength of leachate and percolation rates) to develop alternatives that meet the requirements of the ROD.[4] The Hydrologic Evaluation of Landfill Performance (HELP) model was used to estimate existing percolation rates by zone. The age of fill material, by zone, was estimated based on historical aerial photographs. Leachate samples from each zone were analyzed for typical indicators of municipal solid waste and included parameters such as chloride, sulfate, ammonia, iron, lead and zinc. Leachate concentrations obtained during the data acquisition phase were used to obtain contaminant mass loading rates. Chloride was chosen as the contaminant for groundwater modeling because it is chemically conservative and does not degrade biologically over time. A decay function was developed by plotting chloride concentrations versus age of waste. A chloride loading rate for a forty-year period was then generated for groundwater modeling purposes. The forty-year period covers early site operations through twenty years beyond the closure date.

Because a cover's primary function is prevention or minimization of infiltration, it corresponds to a prevention or minimization of leachate generation from the landfill. The U.S. EPA guidance document refers to a cover that reduces percolation to some acceptable level as a "leaky roof." A cover that intercepts any water percolating toward the waste is referred to as "watertight."[5] These definitions from the guidance document were used to develop alternatives for the groundwater modeling.

The ROD requires leachate minimization through a combination of grading, surface capping and drainage control. Six closure alternatives were developed that include a wide range of "leaky" and "watertight" covers on the various zones of the Landfill. For the purposes of this evaluation, a leaky roof cover was defined as a cover that allows four inches of percolation each year to infiltrate the wastes. A watertight cover was defined as having one inch of percolation per year.[4]

ALTERNATIVES EVALUATION

The technical performances of six alternatives were evaluated with the help of two groundwater models, a flow model and a solute transport model [INTERSAT and Method of Characteristics (MOC), respectively]. The results of the modeling indicated no significant differences in the technical performances between the alternatives over the 20-year period. The greatest differences between alternatives occur during the early years after closure (up to 1995). These differences become less noticeable over time, and the results are essentially the same by the year 2010.[4] The alternatives were also evaluated based on construction costs. The closure costs for the six alternatives ranged from $10 to $30 million. The relative benefits gained by implementing each closure alternative were compared to the construction costs. Alternative 5 was selected as the most cost-effective alternative because of the relative benefits gained (in the early years after closure) per unit cost.

CLOSURE PLAN

Alternative 5 was recommended for closure of the Landfill because it is the most cost-effective, environmentally acceptable alternative. This alternative consists of improvements to Zone 1 only and includes a watertight cover on the mound; leachate interception on the east side of Zone 1, where leachate seeps exist; storm water management on Zone 1; and lateral gas migration control, where necessary. Zones 3, 4 and 5 would remain in their existing state.

Figure 1
Landfill Zones for Modeling

Alternative 5 was accepted by the U.S. EPA and FDER with several modifications. Most significantly, is the fact that storm water management is required for the entire site, not just for Zone 1. This modification was incorporated to satisfy FDER regulations. Due to the large quantity of rainfall South Florida receives annually (more than 50 inches per year), the estimated closure construction cost approximately doubled because of the large area involved. Portions of Zones 3 and 4 will receive additional calcium carbonate (water treatment plant sludge) as cover material. Calcium carbonate has a relatively low permeability which will reduce the amount of infiltration and, thus, leachate generation. Because the County receives this material at no cost, significant savings on the supplemental cover material required for Zones 3 and 4 were realized. In addition, the leachate interceptor trench (LIT) installation was accelerated to maximize its beneficial use. The regulatory agencies agreed that upon completion of the LIT, its performance would be evaluated and future actions would be recommended at that time.

Brown and Caldwell and another national firm were selected to develop design documents for construction of the closure plan in February 1988. The design team expedited the LIT design and in September 1988, a Technical Memorandum was issued that established the criteria for the LIT construction. The LIT was installed on the east side of Zone 1 during the Spring of 1989 and became operational in March 1989.

Pump tests were performed in November, 1989 on the LIT pump station so that flowrates could be estimated. Calculations utilizing the test data estimated the volume of intercepted leachate at approximately 5.8 million gallons per year. A leachate mass balance analysis was performed and a Technical Memorandum was issued in December, 1989.[6] This analysis evaluated the performance of the LIT and recommended a revised closure plan consisting of a reduced watertight cover on Zone 1. All other aspects of the closure plan remained the same. The U.S. EPA and FDER accepted the revised plan early in 1990. The final closure plan, which is shown in Figure 2, consists of a synthetic cap on the top portion of the mound in Zone 1. The area covered by the synthetic is approximately 20 acres. The remainder of Zone 1 (approximately 70 acres) will be covered with two feet of compacted, crushed limerock. By reducing the area covered with a synthetic material, approximately $2 million was saved.

The design utilizes Zone 2, which has never been filled with waste, as a storm water retention basin. The design includes channels, closed conduits, culverts, roadside ditches, benches and site grading to convey storm water to the retention basin. The construction cost is estimated at approximately $16 million dollars for this 520-acre Superfund site.

CONCLUSION

The County was able to realize substantial savings on the Landfill closure by using an approach that divided the site into five separate zones. Landfill closure alternatives that treated the zones separately were developed and evaluated. The modeling results showed no significant differences between the alternatives at the end of a twenty year period. Therefore, the most cost-effective, environmentally-acceptable alternative focused on the zone with the greatest potential for groundwater contamination.

Finally, this project was made successful through good communications between the County, FDER and The U.S. EPA. As data became available, they were interpreted, shared among all parties and incorporated into the final closure plan.

Using a Computer-Assisted Site Evaluation System: A Case History

Phillip R. Cluxton
Elizabeth B. Spencer
Lawrence C. Murdoch
Center Hill Research Facility
University of Cincinnati
Department of Civil & Environmental Engineering
Cincinnati, Ohio

ABSTRACT

A computer workstation dedicated to characterization and remedial action assessment of uncontrolled hazardous waste sites has been developed. The IBM-PC compatible system is composed of several off-the-shelf software and hardware modules, with software development limited to the creation of utility programs used to transfer data from one software module to another. The component modules include a Geographic Information System, a Data Base Management System, a Computer Aided Design and Drafting System, a Contouring System, a Volume and Mass Calculation System and a Groundwater Modeling System.

The computer system is intended to produce maps and cross sections of the geology, hydrology and distribution of contaminants from data attained at boreholes and sample pits. It is capable of calculating volumes or masses of contaminated material, as well as modeling groundwater flow and contaminant transport.

As part of the development of the system, commonly used interpolation methods were compared to find out which methods are most suitable to use for site characterization. Four surfaces were created to simulate possible plumes at contaminated sites. The plumes were randomly sampled, and the samples were interpolated using 15 different methods. The volumes of the interpolated plumes were then compared with the known volumes of the original plumes.

The system has been implemented in studies of several Superfund sites and Emergency Response sites throughout the United States. The application of this system to the study of a Superfund site in Massachusetts is described.

INTRODUCTION

Data from hazardous waste sites often are collected by several contractors and reported as tables buried in thick reports. The site managers are overloaded with laboratory analyses of contaminants, boring logs, monitoring well logs and survey instrument readings. There is a need to organize and manage these data and present them in easily-understood graphical form.

Beginning in 1986, a project was initiated at the University of Cincinnati to address this problem. The project was centered on the concept that inexpensive, easy-to-use IBM-PC type computer equipment and readily-available commercial and public domain software could be molded into a system useful for waste site characterization. The project was funded by the U.S. EPA, Office of Research and Development, Risk Reduction Engineering Laboratory, in Cincinnati, Ohio. Work is based at the U.S. EPA Center Hill Solid and Hazardous Waste Research Facility, in Cincinnati.

The Computer Assisted Site Evaluation (CASE) system continues to develop and evolve as required by the needs of investigators of con-taminated sites. The specific software and hardware components have changed as new capabilities became available. The results of the interpolation study described in this paper, for example, will enhance the capabilities of the system. The ongoing process of upgrading the CASE system has been concurrent with the application of technical assistance services for U.S. EPA regional offices, other government agencies and contractors.

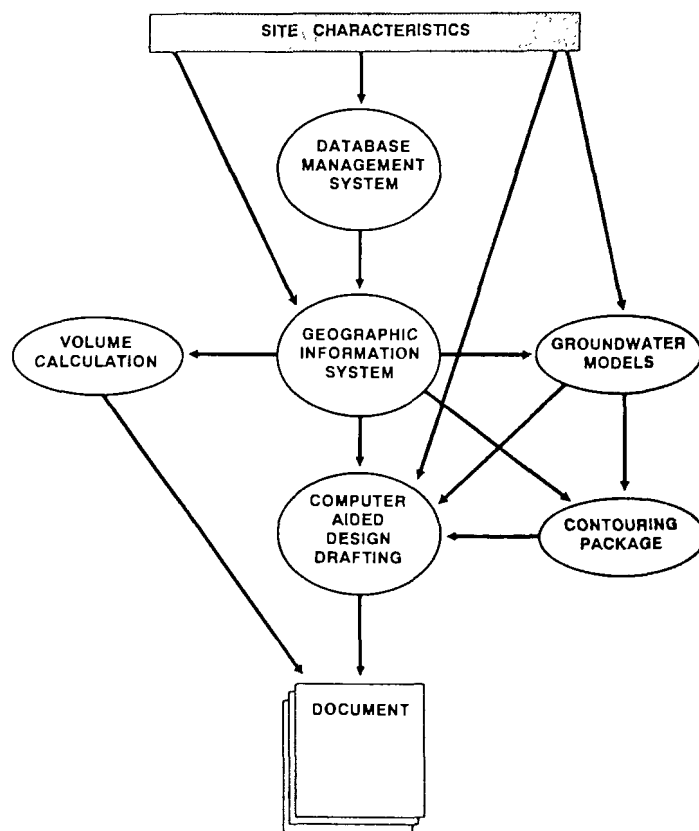
In the following paper, the current configuration of the system is described, a comparison of different interpolation methods relevant to waste site characterization is discussed, and the application of the system in a recent case is presented.


Figure 1
Information Flow Through the CASE System

SYSTEM DESCRIPTION

The system hardware is based on IBM-PC compatible 20 MHz 386 and 12 MHz 286 computers. These machines are equipped with hard disks having capacities of 100 megabytes or more. Core memory capacities range from two to four megabytes of RAM. Standard VGA color graphics monitors are used for display.

Two digitizing tablets are available for input. A 12-in. by 18-in. tablet is used for command templates, freehand drawing and digitizing small maps. A larger 36-in. by 48-in. digitizer tablet is used for entering large maps.

Output devices include a 24-in. by 36-in. multipen drafting plotter, a laser printer, a wide dot matrix printer and a screen camera.

System software is composed of several types of commercial and public domain packages linked with file conversion utilities (Fig. 1). Data transfer linkages are built into some of the packages, such as DXF conversions that permit the contouring package to transfer files to the Computer Aided Design and Drafting (CADD) package. In other cases, small utility programs were developed to facilitate data transfer.

Site characteristics, such as results from soil and water analyses or water levels, are entered into a data base tailored for site characterization. We use the Borland REFLEX Data Base Management System (DBMS). This DBMS, though not as powerful as top-of-the-line packages, is easy to use and capable of meeting all the needs of the project. Since the data base is interactive, rather than programmed and compiled, data files can be extracted, graphs and tables can be created and modifications can be made to the record structure by means of point-and-click operation.

The Geographic Information System (GIS), Spatial Information Systems pMAP, serves as the core of the CASE system. pMAP is a cell-based GIS that is easy to use and well suited for small site studies. It provides an extensive command set that permits precise control of map manipulation. Repetitive operations are facilitated through the use of macros. The GIS is used to create a three-dimensional model of the site hydrogeology. Cross sections showing the geology and hydrology are extracted from this model and ported to the CADD for rendering. The GIS also is used to create contaminant maps, where a spectrum of color hatching indicates level of contamination and black stipple indicates areas where reliable data are unavailable.

Several contouring packages are available for use with the system. Most often we use Golden Software SURFER to make conventional contours, then port the file to the CADD for annotation and final rendering. Radian CPS/PC is used for more elaborate diagrams, and U.S. EPA GEO-EAS is used when kriging is required.

For calculation of volume or mass of contaminated material, a program was developed to work with the GIS to integrate the volume under a surface. SURFER and CPS/PC are also capable of volume calculation.

Groundwater flow and contaminant transport can be modeled using several public domain or commercial packages, depending upon the site requirements. Groundwater modeling within the CASE system typically is done using analytical models and preliminary numerical models. The U.S. Geological Survey MODFLOW numerical modeling system, coupled with the MODELCAD preprocessor, is most often used.

All of the graphical output from the CASE system goes to a CADD system for final production. Three-dimensional drawings are rendered in the Computervision Personal Designer CADD system, whereas two-dimensional drawings are rendered in Generic Software CADD Level Three. These two systems are being superseded by Autodesk AutoCAD 386 version 10.

COMPARISON OF INTERPOLATION METHODS

Many maps, such as those depicting water level, aquifer thickness or distribution of contaminants, are generated by interpolating between a limited number of data points obtained from borings or wells. Computer interpolation programs often are used to generate a regularly-spaced grid of data from irregularly-spaced sample points. There are several interpolation methods available, and each method has several parameters that affect details of the interpolation. Many combinations of parameters are possible for the various methods, resulting in a huge number of possible interpolation schemes. Each possible scheme can produce a unique interpolation, so a large number of different maps could be produced from the same data set.

Selecting the most accurate interpolation method for a given situation is a problem that has been studied in several contexts. In the field of hydrology, comparative studies of interpolation methods have been done with water table elevation data,[1] precipitation data,[2] and aquifer transmissivity data.[3] These studies deal with spatially distributed data that vary gradually, in a "continuous" manner. In contrast to the forgoing studies, contaminant concentration data often consist of a small number of samples having a wide range in value including possible zero values. These data are relatively "discontinuous" and are, thus, more challenging to interpolate accurately.

Because different interpolation techniques can produce considerably different maps for the same set of data, and costly errors can be incurred if inaccurate maps are used for contaminated site characterization, it is important to select appropriate interpolation methods. Therefore, as part of the development of the CASE system, a comparative study of interpolation methods in the context of sparse, discontinuous data sets was initiated.

The objectives of the study were: (1) to measure how accurately various interpolation techniques reproduce a known surface (such as a simulated contaminant plume) by comparing the calculated volumes below the interpolated data fields with the known volumes below the actual fields; (2) to rank the interpolation methods according to their overall accuracy; and (3) to examine how the number of points used in the data sets affects the accuracy of the interpolation.

The following interpolation techniques were evaluated:

- Linear weighted average
- Inverse distance-to-a-power
- Minimum curvature
- Kriging
- Least squares
- Projected (tangential) slope
- Convergent (multi-snap)

Most of the methods require the specification of parameters, such as search radius, extrapolation distance or inverse distance power, all of which can affect the results of the interpolation. Default values for interpolation parameters were used in most instances since the average user is likely to accept the default values and because we needed some rationale to limit the large number of possible combinations of interpolation parameters. Several methods were tested using parameters that differed from the defaults. Fifteen examples of the possible permutations were evaluated in this study.

Four software packages were used to perform the 15 interpolation

Table 1
Key to the Interpolation Methods Used

Packages	Labels	Methods
SURFER	SURK	kriging (linear model)
	INV2	inverse-distance 2nd power
	INV3	inverse-distance 3rd power
	INV4	inverse-distance 4th power
	INV5	inverse-distance 5th power
	SUR6	inverse-distance 6th power
	SURM	minimum-curvature
CPS/PC	RAD1	least-squares (search radius 65 using 10 nearest neighbors)
	RAD2	least-squares (search radius 40 using 8 nearest neighbors)
	RADPS1	projected-slope (search radius 65 using 10 nearest neighbors)
	RADPS2	projected-slope (search radius 40 using 8 nearest neighbors)
	CONV	convergent (multi-snap)
GEO-EAS	GEO	kriging (ordinary, block, fitted models)
pMAP	PMAP	linear, weighted (search rad. 15 using 4 nearest neighbors)
	PMAP2	linear, weighted (search rad. 25 using 6 nearest neighbors)

schemes. These include three commercial packages, Golden Software SURFER version 4.0, Radian CPS/PC version 4.1, and Spatial Information Systems pMAP version 2.6, and one public domain package developed for the U.S. EPA, GEO-EAS version 1.0. A key to the 15 methods is listed in Table 1. The PMAP method differs from the others; it uses a macro program interfaced with a GIS to control the interpolation.

Methodology

Four surfaces labeled B, C, D and P were generated to simulate possible contamination plumes.
Figure 2
Idealized Geometric Polynomial Surface B
Figure 3
Idealized Geometric Polynomial Surface C
Figure 4
Idealized Geometric Polynomial Surface D
Figure 5
Idealized Contaminant Plume Surface P

Surfaces B and D represent geometric polynomial forms generated by superimposing hemi-ellipsoids of various aspect ratios (Figs. 2 and 3). Surface D differs from B in the amplitude of several of the hemi-ellipsoids (one of the hemi-ellipsoids on the B surface is 8 times higher than on the D surface). Both surfaces B and D are bordered by areas of zero values. Surface C was also generated by superimposing hemi-ellipsoids of varying aspect ratios, but it is bordered partly by zero values and partly by finite values and it is more uniform than surfaces B and D (Fig. 4).

Surface P represents an idealized contaminant plume (Fig. 5). This surface was generated using an analytical solution for the concentration distribution downgradient from a point source having a continuous release rate. The shape of the plume is affected by lateral and longitudinal dispersion in a uniform flow field. The elevation of the P surface tapers gradually toward its edges. Most of the surface is bordered by small,

nonzero values that are less than the resolution of the contours in Figure 5. Thus, surfaces B and D are completely bordered, whereas C and P are only partly bordered by zero values.

Volumes below the B, C and D surfaces were calculated exactly by spatial integration, whereas the volume below surface P was determined by integrating the release rate with time. All the surfaces were discretized into regularly-spaced 100 x 100 grids. One hundred points were selected from each grid using a randomizing algorithm. Data sets were in (x,y,z) format with z representing magnitude at location (x,y). From these 100-point data sets, six subsets were obtained consisting of the first 5, 15, 25, 35, 50 and 75 points.

Task 1

Surfaces were generated from each of the 25-point data sets (PR25, BR25, CR25 and DR25) using the 15 interpolation methods. Data sets with 25 points were selected because waste site data sets often contain 25 or fewer samples, but the expected errors in maps created with fewer than 25 samples are so large that comparing interpolation methods would be meaningless. The grid files generated from each interpolation program were numerically integrated to calculate the volume beneath the interpolated surfaces. The resulting volumes were normalized using the actual volumes, with the results shown in Figures 6-9.

Task 2

The absolute values of the errors for the four surfaces generated from the 25 point data sets were averaged for each interpolation method. This average error was used to provide an empirical ranking of the accuracy of the interpolation methods (Fig. 10).

Task 3

Six representative interpolation methods were used to determine the relation between the number of sample points available for interpolation and the accuracy of volume prediction. Normalized volume was plotted as a function of number of points in the data set for each of the four surfaces (Figs. 11-14).

Study Conclusions

Volume estimates using the 25 point data sets typically overestimate the actual volumes, although there are some significant differences among the various methods and surfaces (Figs. 6-9). For example, the volume of the P surface is consistently overestimated by all the interpolation methods; normalized volume ranges over a factor of 0.23, from 1.12 using PMAP to 1.35 using INV2 (Fig. 9). Normalized volumes beneath the B and D surfaces (Figs. 6 and 8), however, span a relatively large range, from roughly 0.9 to 1.1 for several interpolation methods (PMAP, CONV, least-squares and kriging) to markedly overestimated volumes (1.25 to 1.5) for other methods (minimum curvature, inverse distance and projected slope). In contrast, volume under the C surface is estimated reasonably well using all the interpolation methods (Fig. 7).

The shape of a surface clearly affects how accurately it can be determined by a particular interpolation method. Our results are limited, of course, to only four surfaces, but it seems that volumes are overestimated when the surfaces are bordered by zeros, as in surfaces B, D and P. Moreover, topographic irregularities appear to result in a wide range of volume estimates, as indicated by results from the highly-irregular B surface. Some interpolation methods, including CONV, PMAP, least-squares and kriging, appear to estimate the volume under the irregular surfaces better than other methods. These observations could be significant because surfaces representing contaminant distributions are expected to be bordered by zero values and possibly highly irregular.

The averaged absolute error of estimated volume ranges from 8 to 28% for various interpolation methods using the 25-point data sets. The PMAP algorithm yielded the least error, although six methods yielded errors that are less than 13% (Fig. 10). Some methods that are highly accurate using one surface are relatively inaccurate using another surface. Only two methods, RAD1 and CONV, were among the most accurate half of the methods for all four surfaces. The PMAP, SURM and SURK each yielded at least one volume estimate that was relatively inaccurate (e.g., surface C for PMAP and surface B for SURM), although on average those methods were among the most accurate (Fig. 10).

In general, the accuracy of the volume calculation increases with the number of sample points (Figs. 11-14). In all four cases, the rate of improvement is large as the number of points increases to roughly 30. Further increases in the number of points improves the accuracy, but the rate of improvement diminishes markedly as the number of points increases from fewer than, to more than 30. Nearly all the interpolation methods yield volume estimates between 0.8 and 1.2 when using 30 points, whereas they are roughly between 0.9 and 1.1 when using 100 points.

The estimated volume may decrease, increase or increase and then decrease, as additional data points are used during interpolation. The particular response probably depends on both the shape of the surface and the locations of the points. This type of behavior has relevance to site assessment, in that changes in the mass estimated in a contaminant plume at various times may be an artifact of a different number of samples available at the different times, rather than an effect of remediation, continued contaminant release, biotransformation or some other process.

Discussion

Among the methods of interpolation used in this study, the CONV method (Radian CPS/PC Convergent Multi-Snap) performed above average on all four test surfaces and had the best overall accuracy for the 100-point data sets (within 2% of actual volume). The CONV method was fairly easy to use and the time of execution was rapid.

The PMAP method was, on average, the most accurate method using the 25-point data sets; however, it underestimated the volume of the 100-point data sets by as much as 15%. This method is flexible, since the macro program that controls the interpolation process can be adjusted. Learning how to run the pMAP program and write the macros is relatively time-consuming, however, and the execution speed is relatively slow.

SURFER methods in general tended to be the easiest to use and fastest programs to run. The SURM method was the most accurate using the CR25 data set and ranked second for the PR25 data set. However, the inverse-distance methods were the least accurate for the PR25 and BR25 data sets.

Although kriging is a popular and powerful interpolation method, we found that the kriging methods were far from the most accurate at volume prediction and can be tedious to use. The U.S. EPA GEO-EAS program requires a trial-and-error model fitting procedure which

is time-consuming to learn and slow to execute. The SURFER kriging method, since it assumed a linear model, is easy to use and usually was more accurate than the GEO-EAS method.

CASE STUDY OF A SITE

The system has been used in several case studies at Superfund sites and Emergency Response sites throughout the United States. The most recent application of the system has been to a Superfund site in Massachusetts.

The site has a history of hazardous waste dumping dating back to 1946. Eight identifiable sludge pits fall within two main disposal aréas, occupying approximately four acres of land (Fig. 15). The sludge contains high levels of toxic metals and is believed to represent untreated products from leather tanneries and other nearby industries. In addition to the sludge pits, an old landfill, a fly-ash pile and several piles of debris have also been identified on the site. To assist in the Treatment Technology Review, our work has involved extracting and summarizing the relevant analytical data from the Remedial Investigation reports in order to present the data to the Superfund Technical Assistance Branch technology team and the site coordinator in a meaningful, concise manner.

For the study, a series of maps and graphs was prepared which presents the distribution of metals, VOCs, semivolatile organic compounds (SVOCs), pesticides and PCBs found in the sludge pits and debris piles at the site.

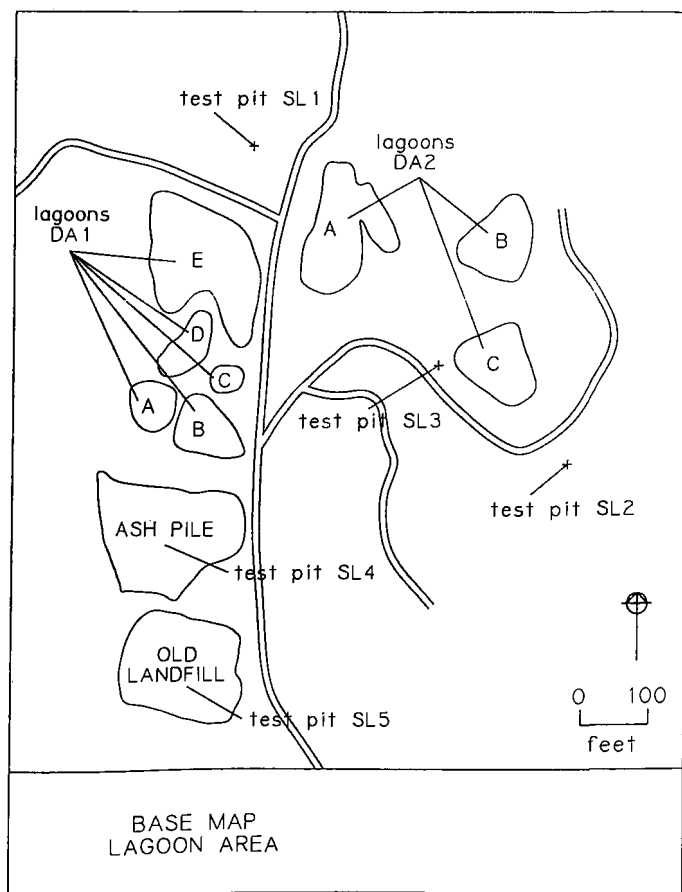
Contaminant concentration maps were created which show the distribution of total volatile organics (TVOCs) over the site (Fig. 16). A spectrum of five colors of crosshatching is used to indicate levels, or ranges, of contamination. An important feature of this map is the


Figure 15
Site Map
Figure 16
Map of Contaminant Distribution.
Concentrations Are Designated By Color On The Original Map

stipple pattern used to indicate masked areas where extrapolation is unwarranted. Maps were created for three different depth intervals. Figure 16 is an example of a color-coded TVOC map for the interval of 2 to 5 ft.

A second type of concentration map prepared for the study makes use of a logarithmic-scaled histogram to depict the maximum available
Figure 17
Contaminant Histogram Keyed To Site Layout Map
Histograms Are Color-Coded On Original Maps

concentration of specific metals within each sludge pit and debris pile. An example of this type of map is illustrated in Figure 17, which shows the distribution of lead contamination in ppm units. The histograms are color-coded for easier interpretation and are superimposed on an isometric view of a site map. This type of map is useful in instances where data are sparse and there is reason to believe that interpolation between samples is unwarranted, as in the case of the metals data collected from different sludge pits.

A third type of map created for the study (Fig. 18) uses pie-shaped symbols superimposed on the site map to indicate qualitatively the presence or absence of VOCs, SVOCs, metals and pesticides at locations north of the main disposal areas. A shaded quadrant indicates that the compound was detected.

In addition to the maps mentioned above, tables and graphs were prepared showing the variation in concentration for specific metals and TVOCs both within individual sludge pits and between pits and other sampling areas. Tables were prepared showing the maximum and average concentrations of SVOCs, PCBs and pesticides at the various sampling locations.

The examples given here for the case study do not utilize all the capabilities of the CASE system. The requirements for understanding a site are evaluated for each case, and suitable tools available to the CASE system are applied and developed as necessary. A case study that involved hydrogeologic cross sections and groundwater modeling is described in an earlier paper.[4]

CONCLUSION

A set of computer hardware and software tools has been assembled into a system dedicated to aid in the waste site characterization and
Figure 18
Detected Contaminants At Off-Site Debris Piles
(Shaded Quadrants Indicate Contaminants Present)

remedial action selection process. During the development of this system, a study of interpolation methods was completed to identify methods suitable for use on waste site data sets. The system has been successfully applied to several sites and although the system continues to evolve, it is currently able to supply services on a regular basis.

DISCLAIMER

The mention of names of commercial products was necessary for the purposes of the paper, but it does not constitute an endorsement of those products by us or by the U.S. EPA. The conclusions expressed are solely the authors'. This paper has not been reviewed or approved by the U.S. EPA.

Thermal Treatment of Oily Soils and Sludges

Mark McCabe
Ramin Abrishamian
Remediation Technologies, Inc.
Concord, Massachusetts

INTRODUCTION

There has been a substantial increase in the costs and liabilities associated with off-site disposal of hazardous wastes in the recent years. At the same time, environmental regulations have imposed demanding requirements for acceptable treatment technologies which emphasize waste reduction and recycling in addition to stringent treatment levels. A number of technologies and processes have been developed in the past 1 - 2 years which attempt to address these requirements. Most significant among them are: cement-kiln incineration, thermal desorption, solvent extraction and biodegradation.

This is a brief review of a thermal desorption process applied to hazardous waste treatment. It is based on ReTeC's thermal desorption process that has been used effectively in treating solids and sludges contaminated with organic constituents. The process uses a conventional Holo-Flite^R thermal desorption unit with ReTeC's proprietary modifications, using an indirect heating source.

The thermal desorption process has been shown to be effective for waste minimization, or as a final treatment option to meet the Best Demonstrated Available Technology (BDAT) standards for a variety of wastes contaminated with organic compounds which are subject to the U.S. EPA imposed Land Ban restrictions.

The benefits of this process are:

- Effective for the treatment and mass reduction of a wide range of organic wastes
- Meets BDAT standards for refinery wastes
- Recovery and recycle of organic components
- Reliability and simplicity of operation
- Low capital and operating costs
- Exempt from RCRA permitting due to recovery and recycling of the organic components of the waste
- Safety and environmental acceptability

PROCESS DESCRIPTION

Thermal desorption is the separation of contaminants from a solid matrix through volatilization. Volatilization may be assisted by adding a stripping agent such as steam or an inert gas.

The complete process consists of the following operations: feed preparation and handling, thermal desorption, off-gas treatment, condensate and treated solids handling (Fig. 1).

Feed Preparation

The configuration of the feed preparation and handling system is strongly dependent on the feed and location. It generally is cheaper to remove free liquids by mechanical means rather than volatilization. Therefore, if the feed contains significant amounts of free liquids, it should be filtered before treatment in the desorber. The feed then is

screened to remove particles larger than 1 to 2 inches, depending on the size of the thermal unit. The feed may be conveyed to the thermal unit by mechanical or pneumatic conveyers, feed hoppers, rotary airlocks and other equipment and devices depending on the type of feed and local requirements.

Thermal Desorption

Desorption can be accomplished using different types of directly or indirectly fired equipment. Applications using indirectly fired methods are preferred, since they generate a significantly smaller volume of off-gas than the traditional direct-fired systems. As a result, the capital and operating costs for the system are reduced significantly.

ReTeC uses an indirectly heated thermal desorption/dryer system, the Holo-Flite^R Screw Processor, such as the unit manufactured by Denver Equipment Company, Colorado Springs, Colorado. Hundreds of these heaters have been installed for heating or cooling service throughout the world since the 1950s.

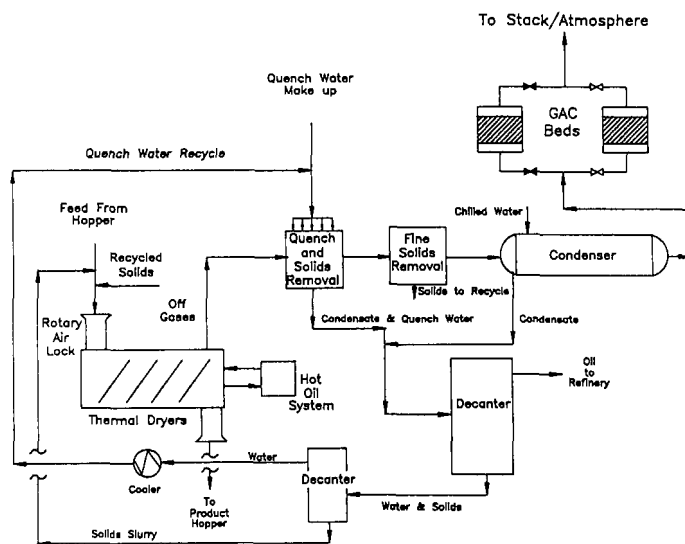
The Holo-Flite^R Processor is commonly used to heat, cool or dry bulk solids/slurries (Fig. 2). The treatment system consists of a jacketed trough which houses a double-screw mechanism. The rotation of the screws promotes the forward movement of the material through the processor. The augers are arranged in the trough so that the flights of the


Figure 1
Block Flow Diagram
Dryer System

two screws mesh, facilitating the movement of material and improving heat transfer.

Figure 2
Orientation of Screw Augers

The processor uses a contained, noncontact circulating heat transfer fluid to raise the temperature of the solids/sludges being treated. The heated medium continuously circulates through the hollow flights of the screw augers, travels the full length of the screws and returns through the center of each shaft to the heater (Fig. 3). The heating fluid is also circulated through the trough jacket to provide additional heat transfer surfaces for improved volatilization.

Figure 3
Holo-Flite Processor

In ReTeC's application of this technology, molten salt may be used as the heating fluid in place of hot oil or steam. Molten salt has the

following advantages:
• It is nontoxic and nonflammable
• It does not produce off-gases
• It provides a wide range of operating temperatures, 500-950 °F
• It can easily be cleaned up if spilled

ReTeC has been successfully operating a 1,000 lb/hr thermal desorption unit (Fig. 4) for a number of months utilizing molten salt as the heating medium.
Figure 4
ReTeC's 1000 lb/hr Demonstration Unit

With the support of the vendor of the thermal unit, several proprietary improvements in the standard Holo-Flite® process have been incorporated that substantially increase its efficiency and improve its overall economy. In addition to the use of molten salt, these improvements include the introduction and distribution of an inert stripping gas and improved contacting between the solids, stripping gas and heating surfaces.

Off-gas Treatment

The off-gases leaving a thermal unit generally consist of water vapor, volatilized organics, noncondensable gases and solids. To limit any fugitive emissions, the thermal desorption unit operates at a slight vacuum. Therefore, regardless of whether or not any inert gas is added, some noncondensable gases always will be in the off-gases. Management of these off-gases is a critical factor in the overall treatment process.

Depending on the configuration of the thermal desorption unit, the moisture content and the amount of noncondensable gases, some fine solids are carried over in the off-gases. Therefore, the off-gas treatment is designed to remove solids and VOCs from the noncondensable gases before their discharge.

The off-gas treatment system should be designed with enough flexibility to remain effective in case of process upsets or, more commonly, wide variations in the waste feed. This system typically consists of: gravity settlers, cyclones, filters and solid scrubbers to remove solids; quench drums and coolers to cool the off-gases and condense water and semivolatile organics; and chillers and activated carbon units to remove volatile organics. The treated noncondensable gases can then be discharged to the atmosphere through an activated carbon bed, to the plant's flare or boilers.

Condensate Treatment

Condensate is generated from the moisture content of the feed and quench water. It contains condensed organics in addition to small amount of suspended solids. The bulk of the organics and solids can be separated

by simple gravity settling. The remaining water stream is generally suitable for disposal in a plant's wastewater treatment facility. If quench water is used, the wastewater stream may be further cleaned by filtration, cooled and recycled to be reused as quench water.

TREATMENT RESULTS

The results from a number of tests indicate that the process has significant potential not only for waste minimization but also for the management and treatment of contaminated soils and sludges. ReTeC has per-

formed treatability tests on numerous wastes contaminated with different high-boiling organics from the petroleum refining, gas utility, wood preserving and chemical process industries. These tests have been carried out at relatively low temperatures, 450-600°F.

Table 1, shows typical mass reductions for a variety of waste feeds. Tables 2, 3 and 4 present results of treatment tests performed on listed petroleum refinery wastes. Table 3 compares results from a conventional Holo-Flite[R] dryer with one with ReTeC's proprietary modifications. It can be seen that ReTeC's modifications substantially increase the efficiency of the standard dryer. Tables 5 and 6 present test results from the treatment of contaminated soils from a wood-treating plant and a manufactured gas plant, respectively.

LIMITATIONS OF THERMAL DESORPTION

There are a number of requirements which limit the range of applicability of thermal desorption:

• *Feed Condition* - The feed has to be sufficiently friable to be fed into the thermal unit. At the same time, low viscosity or watery feeds, < 20% solids approximately, are also unsuitable since they tend to cause bypassing and thus reduce the efficiency of the unit.

• *Metals* - Thermal desorption does not remove or stabilize any metals that may be present in the feed. However, since these units operate at relatively low temperatures, they do not oxidize metals, therefore, in general, the metals do not become more mobile or leachable after treatment (unlike incineration).

• *Dust Control* - The solid product of thermal desorption is a dry material with less than 1% moisture. This material can cause substantial handling problems due to dust formation. The dust formation may be controlled by adding wetting agents/water and using covered conveyers and transportation bins.

TREATMENT COST

Thermal treatment costs vary considerably and ReTeC's pricing typically has been in the range of $100-$300/ton of feed. The cost is strongly dependent on the quantity of the waste, length (period) of the contract, moisture and organic content of the waste stream. Typically the installed cost of a complete thermal treatment system, with off-gas treatment and condensate handling, is 2-4 times the cost of the thermal unit(s).

Selection of Cover and Gas Collection for Municipal/Industrial Landfills

D. L. Hemker
C. A. Bertelsen
Chevron Corporation
San Francisco, California

ABSTRACT

This paper evaluates the selection of cover and gas collection alternatives using a number of criteria related to performance and aesthetics. Case history results are reported for a large (200 acre) southern California municipal/industrial Superfund site. Test results from on-site demonstration plots are highlighted. Cover alternatives included natural materials (i.e., clay), reinforced earth concepts and several synthetic options using both high density polyethylene (HDPE) and very low density polyethylene (VLDPE). Gas migration control alternatives included various well configurations and several surface collectors such as gravel filled trenches.

Performance data were evaluated for 18 parameters including efficiency of gas collection systems, constructability of the overall system selected, cost, vegetation reliability, time to install, maintenance costs, stability and susceptibility to landfill settlement. Due to the proximity of homes in the area aesthetics of the final remedy was also a factor in selection of an alternative.

INTRODUCTION

The remediation of mixed waste (municipal/industrial) landfills has received special emphasis by government agencies in recent years. Not surprisingly, a recent review of sites on the U.S. EPA's NPL indicated that 231 or 19% of the sites on the NPL are mixed waste landfill sites. Mixed wastes sites generally are unique in their size. Because they accepted household wastes or trash and commingled that waste with other types of wastes, mixed waste sites are generally of larger proportions. Small mixed waste landfill sites average on the order of 40 acres while large sites can occupy as many as 250 acres. At many of these sites, much of the waste prism is above ground or above the original ground surface. These "mountains of trash" are often visible to adjacent communities.

The difficulty in selecting an appropriate remedy for these sites is typified in the following excerpt from the U.S. EPA's ROD from the Belvidere Landfill in Belvidere, Illinois:

"The size of the landfill and the fact that there are no on-site hot spots that represent major sources of contamination preclude a remedy in which contaminants effectively could be excavated and treated."

This statement adequately characterizes the fundamental decision which must be made at mixed waste sites. Namely, how best to control the large volumes of wastes at a landfill site which will provide long-term protection of human health and the environment.

At many of these mixed waste landfill sites, because of the similarity of the waste type, site characteristics and size, regulatory agencies have been requiring encapsulation and gas collection as the key elements of the remedy. The focus of this paper is to give a broad overview of encapsulation (cover) and gas recovery from these mixed waste sites and to present an evaluation of some of the alternative solutions or designs which may be considered when remediating a site.

A number of common issues need to be addressed when considering remedial alternatives at these sites, specifically, final cover must minimize infiltration of rainfall and cover and gas recovery must capture methane gas with any associated toxic constituents prior to migration off-site.

In addition to these issues, the chosen remedy for a mixed waste landfill site must consider which standards need be applied. Many of the mixed waste sites on the NPL operated before November 19, 1980, the effective date of RCRA Subtitle C and while these sites may have accepted hazardous wastes as currently defined, the standards of RCRA Subtitle C for landfill design and closure cannot be automatically applied to remediation of the site. At the same time, experts cannot agree that the standards of Subtitle D for design and closure of solid waste landfills are applicable. Since both sets of standards have provisions for landfills, it is reasonable to assume that portions of the standards contained in both Subtitles may apply.

In the following discussion, we present various options which may be considered viable alternatives or solutions for the selection of cover and gas collection at mixed waste sites. In doing this, we make no judgement as to the degree any of these options meet the standards for landfill closure contained in either Subtitle C or Subtitle D.

For purposes of illustration, many of the issues discussed in this paper will be presented with a case history from the Operating Industries Landfill (OII) in Los Angeles. The OII site is a large (190 acre) NPL site located approximately 15 miles east of downtown Los Angeles. The site, which closed in 1984, rises almost 200 feet above its surrounding terrain and is situated adjacent to two housing tracts.

GAS COLLECTION SYSTEMS

Mixed waste sites typically generate landfill gases containing roughly equal amounts of methane and carbon dioxide. Left uncontrolled, these gases can migrate through the subsurface or vent through thin cover on the landfill into the atmosphere causing odor and nuisance problems. These gases quite often carry trace contaminants off-site and therefore pose a potential exposure risk to the surrounding environment. In extreme circumstances, the buildup of explosive concentrations of methane in nearby foundations, sewers and other subsurface structures can also be of concern.

Remediation of the gases generated is split into two distinct pathways of concern: the potential subsurface migration of gas and the emission of gas through the landfill surface.

Deep Well Extraction Systems

Subsurface gas which migrates from the mixed waste landfill through permeable zones to nearby environments is typically addressed or

remediated with the installation of deep wells into the trash prism. A survey of landfills in the Los Angeles basin has shown that various system designs and individual well configurations/spacings have been used to remediate gas. Table 1 summarizes some of the varied designs that have been used.

Table 1
Comparison of Deep Gas Collection Systems
Mixed Waste Sites

Item	Site A Prism	Site A Perimeter	Site B	Site C
Borehole Diameter	6"	12"	30"	14" & 18"
Casing Diameter	6"	6"	4-6"	6"
Well Depth (typ.)	100'	100'	80'	40-80'
Well Spacing	100'	100'	150'	150'
Construction Technique	"Drill/ Drive"	Simple Air Rotary	Continous Flight Auger	Pile Driven

Well spacings are typical. However, closer spacings are many times used in areas of severe gas migration.

Source: Los Angeles County Sanitation District, 1989

The various well configurations or layouts generally fall into two categories of alternatives. In the first alternative (the "gas extraction" method), deep wells are installed throughout the landfill prism at a spacing of approximately 100 feet. The wells are many times installed to the depth of waste in the landfill. The concept of this gas extraction design is premised partly on the assumption that mixed waste landfills are constructed in cells that these individual waste cells within the landfill site are generating gas at various rates and that these cells generally are not communicating significantly with each other. Installing the deep wells throughout the landfill prism allows for collection of the gas near the point of generation so that the gas can be extracted without relying on significant gas movement from cell to cell.

To minimize the capture of excessive oxygen while extracting the gas, the deep wells are not screened near the surface of the waste prism. In the gas extraction well system, to compensate for the deep wells not being screened near-surface, shallow (40 ft maximum) or surface wells are installed. These wells, which can be operated at minimal vacuum, collect gases that build up beneath the cover but do not operate at sufficient vacuum to allow oxygen intrusion to become a concern. Using the combination of deep and shallow wells thereby increases operational flexibility by allowing the operator to independently vary the amount of vacuum applied to the deep and shallow wells.

The second typical design for subsurface recovery uses a well configuration in which the wells are clustered along the periphery of the landfill boundary, with few or no deep interior extraction wells. In this design, referred to as the "gas capture" method, the remediation design may include a combination of wells at various depths. The concept of the gas capture system is to capture only that gas which is moving off-site at the point of escape, the property boundary. In addition, this general design assumes that individual waste cells are in communication with one another which allows gas to move relatively freely through the landfill mass.

The design of individual wells located in trash has been a developing science. The older sites used a traditional rule-of-thumb which called for larger (18 to 36 inches) bored holes with gravel packed perforated casing in the hole. Many of these wells were installed to the depth of trash. The rationale for employing large boreholes was to ensure a long life for the well and minimize plugging. More recent practices (BKK Corporation Landfill and Operating Industries Landfill) have used much smaller wells (6 to 12 inches). These wells have the capability to be installed with either a traditional auger rig or with a "drill/drive" technique which allows the casing to be driven into the waste during drilling to provide more efficient installation of the well through saturated zones in the trash. To date, these smaller wells have not been subject to the same test of time as their larger counterparts, but a simple cost

analysis comparing the capital cost shows that the smaller wells are overwhelmingly more economical to install. For purposes of illustration, Table 2 is included giving a cost comparison of various individual well designs.

Table 2
Estimated Costs for Various Gas
Collection Wells for Mixed Waste Landfills

Borehole (dia.)	Casing (dia.)	Rig Time (cost $)	Cuttings Disposal ($)	Materials ($)	H&S Cost ($)	Total ($)
36"	8" PVC	17,400	9,400	9,100	7,100	43,000
24"	8" PVC	13,800	4,200	7,000	5,600	30,600
14"	6" PVC	7,000	1,400	4,200	4,000	16,600
12"	6" PVC	5,800	1,000	4,100	4,000	14,900
12"	4" PVC	5,800	1,000	2,300	4,000	13,100
6"	6" Steel	6,000	300	4,500	4,400	11,200

Source: Environmental Solutions Inc. and Bryan A. Stirrat & Associates, 1989

As mentioned above, in most cases well spacing is still determined by a rule-of-thumb approach using wells on 100-foot centers. The actual required interval can sometimes be determined more scientifically through gas interference testing (similar to that used in natural gas production fields) to determine the boundary of influence a well of given proportions and vacuum may achieve in the waste conditions specific to a given mixed waste landfill.

Shallow Well Gas Recovery Designs

Near-surface gas must typically be addressed separately from deep gas collection in order to prevent excessive oxygen intrusion. The surface gas design must be integrated as much as possible with the selection of cover type as cover is actually an element of any shallow collection network. Without shallow gas collection, gas can build up significant pressure (up to 20 psig) beneath the landfill cover. At the same time, without the installation of at least some cover, the efficiency of the shallow collection system will be low and oxygen infiltration will be dramatic. Various types of shallow gas collection networks are listed in Table 3.

Table 3
Shallow Well Collection Systems
for Mixed Waste Landfills

Type	Description
Vertical Wells	Shallow (40 foot) collection wells, screened interval approximately 5-40' below landfill surface.
Horizontal Collectors	
Gravel-filled Trenches	2'X2' trenches backfilled with gravel, slotted PVC collection pipe embedded in trench.
Slotted Pipe	Slotted PVC pipe laid directly on landfill surface. Can be installed on overlapping criss-cross pattern for added collection efficiency.
"Geo-grid"	Sections of HDPE "geo-grid" material laid directly on to landfill surface. Collection pipe tied to grid provides vacuum source.
"Geotextile"	One layer of geotextile laid beneath the cover. Collection pipes laid on wide spacing to provide vacuum source.

Surface gas collection networks typically fall into two major types, "vertical well" designs and horizontal "gas collection grids." In the vertical well designs, small diameter wells are installed to depths of approximately 40 feet below land surface and perforated from the bottom of the casing to within 5 feet of the land surface. The wells are operated using small vacuum (3 to 5 inch water column) to sweep the gas out of the waste prism while minimizing the potential for oxygen intrusion into the waste fill.

In gas collection grids horizontal collectors are installed immediately beneath the cover to allow for removal of gas as it collects beneath the impermeable cap. These horizontal collectors may be gravel-filled trenches using slotted pipe collectors (i.e., French drains), slotted pipes installed directly on the waste surface (sometimes laid in a criss-cross pattern), or they may be made up of geogrid, a commercial HDPE product used primarily for liquid drainage layers above the cover. Other designs which provide sufficient space beneath the cover to allow for gas collection also are possible.

In tests of these various designs at the OII site, three approaches (gravel-filled trenches, slotted pipe and geogrid) were compared. The tests showed that all three designs were capable of achieving sufficient collection to qualify them as candidates for the final design. The actual design can therefore be made based on the economics of the construction, which favors options which do not require penetration (trenching) into the waste prism.

LANDFILL COVER SYSTEMS

In determining the appropriate gas collection system, the type of cover must also be evaluated, with the reverse also being true. Integration of both gas collection and cover is mandatory to achieving the best alternative for the mixed waste landfill site. Cover can actually be considered a part of the gas collection network in that it allows for buildup of the gas within the trash prism and increases the efficiency of the collection network. Cover also minimizes oxygen infiltration into the gas collection system, which allows better operating performance, particularly at sites utilizing resource recovery of the methane.

Table 4 lists 18 design considerations that may be used to determine the most appropriate cover system. Cover types may include the more traditional clay cover, clay with soil (either with or without reinforcing structures) or, with the improvements in the production and use of synthetic flexible membrane liners (FML), covers using either high density polyethylene (HDPE) or very low density polyethylene (VLDPE) designs.

Table 5
Design Alternatives for Cover and Gas
Collection - Operating Industries Landfill

Option	Type
A	Clay cover with hydroseeding directly on to clay (no cover soils). Gas collection using combination of deep and shallow wells.
B	Clay cover with top soil vegetation layer. Additional stability with installation of buttress at certain locations. Gas collection using combination of deep and shallow wells.
C	Flexible membrane liner (FML) with surface "grid" gas collectors. Vegetation using reinforced earth layer above FML.
D	FML with surface "grid" gas collectors and vegetation using "geoweb" soil stabilization system.
E	FML with surface "grid" collectors and vines grown over a trellis mesh.
F	FML with surface "grid" collectors and using synthetic grass (possibly with vines) for aesthetics.

Source: EPA, Region IX, 1990

In recent years, the U.S. EPA has moved toward multilayer (FML plus clay plus soil) designs as remedial options. Part of the rationale for these multilayer concepts for mixed waste landfill sites is the reliance on the RCRA Subtitle C standards for design and closure. As discussed earlier, since most mixed waste landfills operated before the passage of RCRA, it may not be appropriate to automatically impose Subtitle C standards as the design criteria for remediations at these sites.

Multilayer designs may be appropriate at a number of these sites and are constructable under certain situations, such as sites with generally flat terrains and stable wastes. However, in many cases multilayer designs are unnecessary and/or may be impractical because of existing steep slope conditions, waste instability, storm water run-off concerns or excessive long-term operation and maintenance requirements.

At the OII landfill in Los Angeles, the alternatives listed in Table 5 have been evaluated by the U.S. EPA, the U.S. EPA's contractors and a group of PRPs. While a final decision has not yet been made by the U.S. EPA, we are using this work as a basis to discuss various alternatives for the remediation of mixed waste sites. The OII site is unique because of its steep slopes (generally >2H:1V) and its location in the seismically active Los Angeles basin. These factors make reliance on multi layer concepts less desirable. As part of the evaluation of cover and gas collection, several demonstration areas were constructed on-site to fully evaluate some of the options.

Until the relatively recent development of synthetic materials, clay has been the material of choice for cover construction. Clay has the attractive features of being relatively impermeable, naturally available and handled with relative ease using normal construction techniques. Clay can be considered the traditional cover material.

A concern with clay as a cover material, particularly in semi-arid parts of the United States, is the need to keep the clay moist to prevent desiccation and cracking of the cover requiring periodic corrective maintenance. Since desiccation of the clay is a concern, the use of surface grid collectors for gas collection under the clay is not advised; the collectors may enhance desiccation by drawing air through and moisture out of the clay.

Because clays generally have poor nutrient content, it is difficult to sustain vegetation and top soil is required as a medium to support final vegetation at the site after closure. It is noted, however, that one large mixed waste landfill in southern California has successfully supported final vegetation directly on the clay cover.

On steep slopes the volume of clay and top soil needed may raise concerns over the long-term stability of the cover system as the trash settles over time or during seismic events.

At the OII site, because of uncertainties over the long-term stability

and the proximity of off-site structures (homes and roads), using clay may require the use of additional support such as buttress walls to provide stability and the area needed to construct clay alternatives. This additional construction combined with some uncertainty over the availability of clay within the Los Angeles basin and long-term irrigation needs has prompted the evaluation of other options, including the use of synthetic cover.

During the 1980s, the use of flexible membrane liners has increased substantially. Their use has been primarily for liner systems at landfills, but their use as cover materials at mixed waste landfill sites (e.g., Charles George Landfill) is also on the rise. FMLs have the desirable characteristics of being lightweight, impermeable, generally chemical resistant and easy to install, even on steeply sloped areas.

Since the FML designs are not susceptible to desiccation as are the clays, these designs allow for a broader range of shallow gas collection options, including the horizontal grid collectors that are not advised for the clay concepts.

Some disadvantages of FMLs can be their susceptibility to weather (sunlight and temperature variations) if left exposed and their failure to provide any aesthetic quality to the final closure. Also, since the use of FMLs as cover material is still relatively new, the long-term performance of FML systems is unknown.

At OII, several synthetic cover options have been evaluated in an attempt to develop an alternative to the buttressed clay option which may be needed in certain areas. A high priority issue at OII was the need for the final solution to be aesthetically pleasing to the community. Consequently, the options using FML (in this case VLDPE) each contained some variation to provide this aesthetic quality. Two options evaluated employed the use of commercially available soil erosion protection products, including reinforced soil using geogrid and soil stabilized with geoweb. These stabilized soil concepts were developed to provide the soil base needed to support final vegetation.

Another variation in design utilized vines which would eventually drape over the FML and provide the final vegetation. Finally, a totally synthetic option was developed using synthetic grass as a means to provide a natural looking final cover. The advantage of the synthetic grass is that it does not require irrigation or large amounts of maintenance.

The two stabilized soil alternatives and the vine cover and synthetic grass option were all constructed as small (40 ft x 40 ft) demonstration plots. The soil plots were successful, but, the vine cover could not be sustained on the black FML/geotextile underbase. Each test plot was constructed, although long-term monitoring of these areas has not yet been completed. All these options are still deemed to have a potential for use on the site. Since these tests are being conducted in southern California, no attempt was made to evaluate the potential affect of freezing on these systems.

CONCLUSION

This paper has provided an overview of various alternatives to the design of cover and gas collection systems at mixed waste landfill sites. With new products and techniques being constantly developed, many options are available. These options must be evaluated in light of the specifics of the individual landfill, the objectives of the remediation and the standards, both federal and state, in effect at the time. However, the integration of gas collection and cover in determining the most appropriate system is critical to the development of the most cost-effective and technically appropriate system to be utilized.

ABSTRACT

Soil vapor extraction (SVE) is an integral part of the remedy selected for the Seymour Recycling Corporation Superfund site in central Indiana. Site conditions created several interesting problems for the design of the SVE system. First, the unsaturated zone, which contains the bulk of the volatile organic constituents (VOCs), is thin relative to the areal extent of the site. Second, site soils are fine-grained with a high moisture content and relatively low air permeability. Finally, the site has internal drainage, and ponding of water on the site provided a strong incentive to cap the site as soon as possible.

The SVE design consisted of horizontal vapor "drains." The system is designed to operate at relatively low air flow rates to minimize exhaust gas treatment costs. The unalterable nature of the drain installation required a predesign study to collect data needed to confidently design the system. The predesign investigation included a soil gas survey, in situ testing of the air permeability, laboratory treatability studies and numerical modeling to determine appropriate drain spacings. The drain spacing evaluation required analysis of the effect of cap loading and soil drainage on the effective air permeability of the soil. The results allowed the drain spacing to be increased, lowering construction costs. The soil gas survey revealed extensive vinyl chloride in the soils which must be vented prior to drain construction.

INTRODUCTION

The Seymour Recycling Corporation site is located in central Indiana approximately 60 miles south of Indianapolis (Fig. 1). The site was a Federal-led cleanup with the RI/FS being performed under U.S.EPA contract. Geraghty and Miller, Inc. is managing Remedial Design/Remedial Action (RD/RA) for the Seymour Site Trust Fund. Geraghty and Miller also acted as primary consultants to the Trust during negotiation of the Consent Decree for the site. Hydro Geo Chem, Inc. acted as a consultant to Geraghty and Miller on soil vapor extraction during the negotiation phase, developed the conceptual design for the SVE system and performed the SVE predesign investigation.

SITE BACKGROUND

The Seymour site is located approximately 2 miles southwest of Seymour in an industrial park surrounded by agricultural land. The primary portion of the site covers approximately 12 acres (Fig. 2). The site was operated as a processing center for waste chemicals from about 1970 to 1980. By March 1980, approximately 50,000 drums, 98 bulk storage tanks and tank trucks were located on the site.[1]

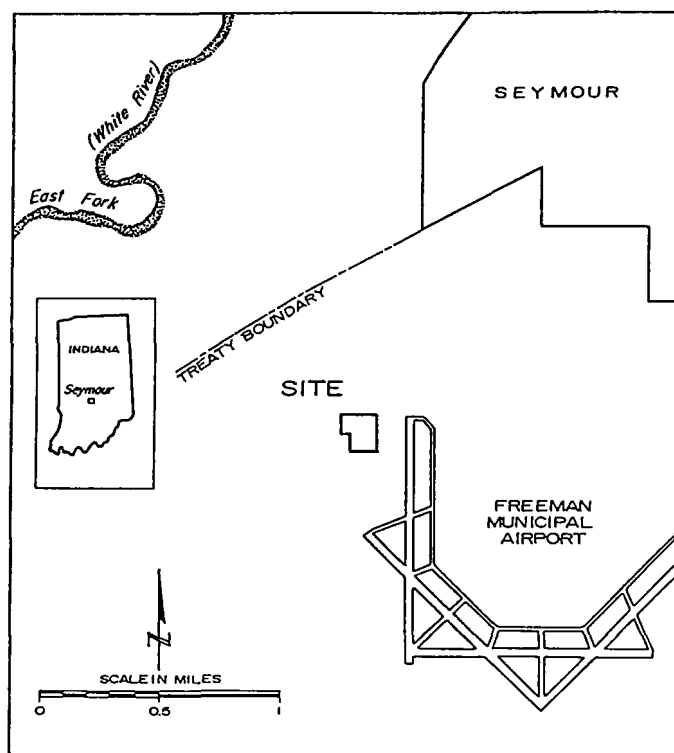
Surface cleanup of the site began in December 1982. The cleanup consisted of removal of containerized waste, surface soil removal, regrading to control surface run-off and installation of a clay cap.


Figure 1
Site Location Map

Contaminant Site

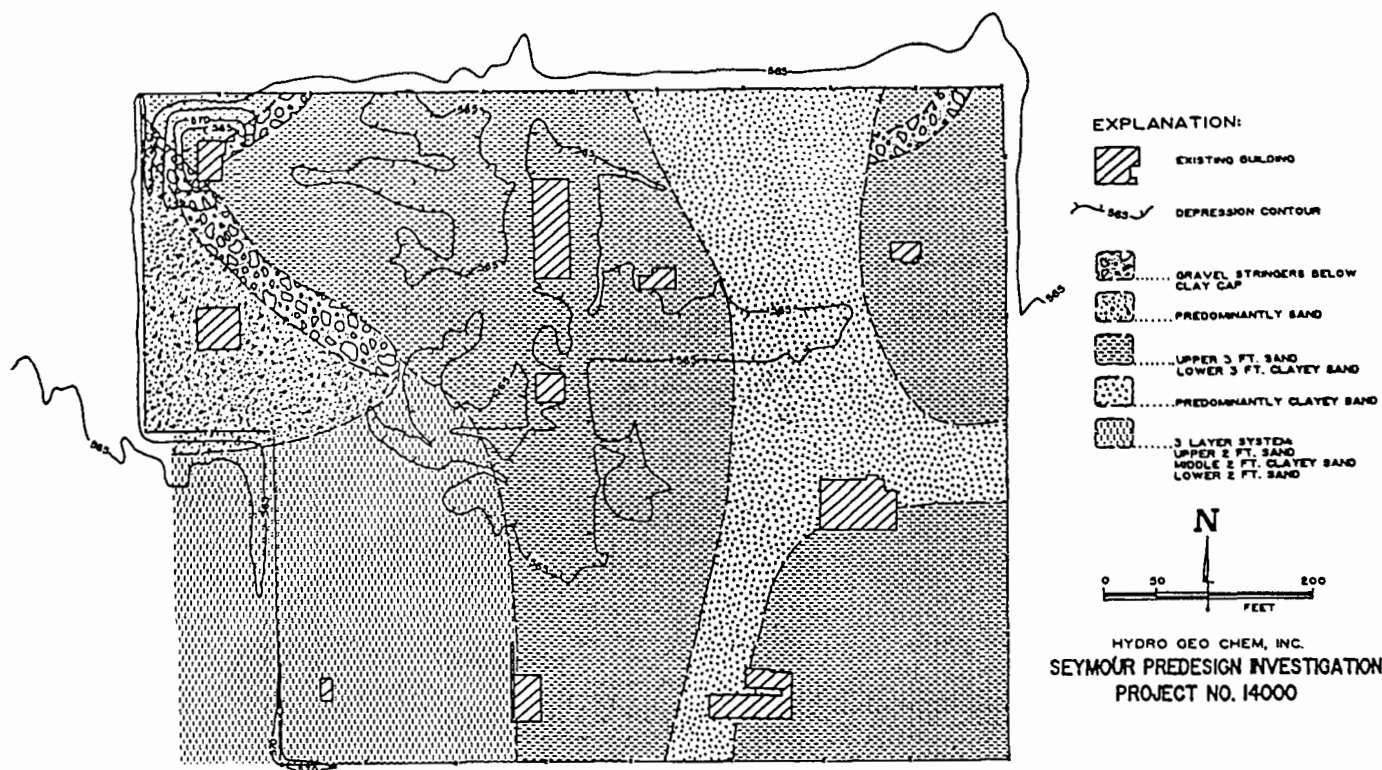
Soils at the site are contaminated with a wide variety of volatile and semivolatile organic compounds as well as some metals and other inorganic constituents. The results of soil analyses performed as part of the predesign investigation indicated that the most abundant VOCs are benzene, toluene and xylenes. The VOCs of most environmental concern and those targeted by the SVE system are chlorinated hydrocarbons, primarily tetrachloroethene (PCE), trichloroethene (TCE), 1,1,1 trichloroethane (TCA), 1,1 dichloroethane (1,1 DCA) and chloroform. As will be discussed later, the degradation products of these constituents also are abundant at the site. A histogram showing the relative distribution of VOCs at the site based on soil analyses is shown in Figure 3.


Figure 2
Site Map Showing Major Soil Types
Figure 3
Relative Abundances of VOCs Based
on Soil Analyses

Soil Conditions

The shallow (to 10 feet below land surface) soils at the site consist of: the surficial clay cap, approximately one foot thick; discontinuous zones of coarse gravel fill; fine- to medium-grained sands; and clayey sand to sandy clay. The lateral distribution of these units is shown in Figure 2.

Hydrologic Conditions

The water table beneath the site occurs at a depth of approximately 7 feet below current grade. The direction of groundwater flow is generally to the north beneath the site. Since the initial site cleanup, a condition of internal drainage has existed at the site. Ponding of water has often occurred and nearly saturated conditions exist during parts of the year near the center of the site.

SELECTED REMEDY

The Remedial Action Plan (RAP) provides for installation and operation of a groundwater extraction system to contain and remove contaminated groundwater, a vapor extraction system to remove volatile organic constituents (VOCs) from the soils above the water table, enhanced bioremediation to reduce the volume and toxicity of semivolatile organic constituents and construction of a multimedia, RCRA cap over the site to eliminate further leaching of contaminants from the soils. The work described here deals primarily with the design of the vapor extraction system.

Soil Vapor Extraction

Soil vapor extraction and enhanced bioremediation were proposed in the Feasibility Study report to meet the requirements of SARA calling for remedial actions which reduce the volume, toxicity and mobility of hazardous constituents at CERCLA sites. As proposed in the FS, the SVE system would have consisted of a conventional system of more than 100 vapor extraction wells and was designed to operate for several years prior to installation of the cap. No site-specific data had been

collected at that time to support the design of the SVE system. This design was found to be undesirable because: (1) it delayed installation of the cap for several years allowing continued leaching of contaminants to the groundwater, (2) calculations showed that the air permeability of the soils was likely to be too low to sustain the airflow rates proposed for the well system, (3) high pressure drops near individual wells would result in significant upconing of the water table and (4) extensive off-gas treatment would be required because of the high mass emission rates from the system.

An alternative SVE design was developed utilizing a network of horizontal "vapor" drains to circulate air through the unsaturated soils and withdraw VOCs. The final drain layout, shown in Figure 4, consisted of 19 drains, with alternating drains maintained at subatmospheric pressure and at atmospheric pressure. The system was designed to be installed beneath the cap (hence the title of this paper), to be operated at low pressure drops and airflow rates and to be operated over the lifetime of the cap (nominally 30 years). This alternative conceptual design avoided long delays in installation of the cap, provided for treatment of low-permeability soils, eliminated the problems with upconing and greatly reduced the mass emission rates from the site. A risk assessment showed that off-gas treatment could largely be avoided by reducing the rate of VOC emission from the site. As will be discussed later, however, a soil gas investigation revealed significant concentrations of vinyl chloride which indicated a need for off-gas treatment during the early stages of SVE operation.

The RAP established technology-based performance standards for the SVE system rather than specifying target soil concentrations. The technological performance standards were: (1) that 500 pore volumes of air be circulated through the soils within 30 years of system installation and (2) that no fewer than 2 pore volumes and no more than 35 pore volumes be circulated in any year. In addition, the RAP stated

that the goal of the SVE treatment was to remove 80% of the vapor extractable VOCs.

The rationale for not specifying particular target soil concentrations was that the cap would prevent any direct exposure to the contaminants. The goal of removing 80% of the vapor extractable VOCs was based on preliminary calculations performed as part of the conceptual design report. Establishing such a relative goal was reasonable because: (1) the actual mass of VOCs was uncertain, and (2) the mass removal rate of an SVE system is approximately directly related to the mass of VOCs present in the soil. The 500 pore volume performance standard was selected based on conceptual design calculations using an exponential dilution model which showed that this volume would reduce the initial contaminant mass by 80%.[2]

The RAP also provided for the use of vapor phase tracers to monitor the sweeping efficiency of the SVE. The selection and application of these tracers will be discussed later.

Finally, the RAP required that a predesign investigation be performed to collect data needed to develop a formal engineering design for the SVE system. Of particular importance were an updated description of the spatial distribution of VOCs and measurements of the effective air permeability of the soils. The predesign investigation also provided for a vapor phase tracer test to test tracers which might be used for performance monitoring and to supplement other techniques for measuring air permeabilities. Also to be determined were total and air-filled porosities of the soil and their organic carbon content. Based on the data collected during the predesign investigation, numerical modeling was performed to evaluate appropriate drain spacings and locations for the SVE system to be capable of meeting the requirements of the RAP.

SVE DESIGN PRINCIPLES

The design and evaluation of the SVE system for the Seymour Site
Figure 4
Schematic Showing Final Layout of the
SVE Drain System

were based on an equilibrium thermodynamic description of the partitioning of volatile organic compounds between the solid, liquid and vapor phases in the soil and on well-established physical principles describing the movement of gases through porous media. The various constitutive relationships and models used in the analysis and design of the Seymour SVE system are described briefly below.

The air-strippability of a particular VOC depends on its concentration in the soil gas phase relative to its concentration in the liquid and solid phases. The vapor phase concentration depends on the compound's physical-chemical properties, its state in the soil and the physical and chemical properties of the soil. The vapor extractable compounds at the Seymour site will be distributed among three-phases in the subsurface: (1) as a vapor in the soil gas phase, (2) in solution within the porewater of the unsaturated soils and (3) adsorbed onto organic matter in the soil (including biofilms). Nonaqueous phase liquids are not believed to be present in the soils at the site.

The vapor phase concentrations will be controlled, in part, by their dimensionless Henry's Law coefficients, H_D, which relate the concentration of a compound in the vapor phase to its concentration in the soil water. The water concentration will, in turn, be controlled by the distribution of contaminants between water and the solid soil matrix.

The strippability of constituents can be evaluated by computing the ratio of their concentration in the soil gas to their total concentration in the soil according to Thomas:[3]

$$\frac{C_g}{C_T} = \left[\frac{K_D \rho_b}{H_D} + \frac{\phi_w}{H_D} + (\phi_T - \phi_w) \right]^{-1} \qquad (1)$$

where C_g is the concentration in the gas [M/V air]
C_T is the total concentration in the soil [M/V bulk volume soil]
K_D is the water-solid distribution coefficient [M/M solid/M/V water]
ρ_b is the bulk dry soil density [M/V solid]
H_D is the gas-water distribution coefficient [M/V air/M/V water]
ϕ_w is the water filled porosity
ϕ_T is the total porosity

The gas-water distribution coefficient is:

$$H_D \approx \frac{C_g}{C_w} = \frac{H}{RT} \qquad (2)$$

where H is Henry's Law coefficient
R is the ideal gas constant
T is absolute temperature

The water-solid distribution coefficient is:

$$K_D = \frac{C_s}{C_w} \approx K_{oc} \cdot foc \qquad (3)$$

where C_s is the concentration in the solid [mass VOC/mass soil]
C_w is the concentration in the water [mass VOC/volume water]
K_{oc} is the water-organic carbon distribution coefficient
foc is the fraction organic carbon in the soil

PREDESIGN STUDY

The purposes of the predesign investigation for the SVE system were: (1) to collect site-specific data on soil properties and contaminant distributions needed for the final system design, (2) to evaluate tracers proposed for use in performance monitoring and (3) to determine drain spacings and locations. An evaluation of the mass of VOCs present in

the soils at the site was also included in the scope of work for the predesign investigation.

VOC Distribution and Mass

Soil gas sampling was the primary technique used to determine the current spatial distribution of VOCs at the site. In addition, soil borings were made at nine locations to collect soil samples for chemical analysis as well as for use in laboratory treatability studies. The locations of the soil borings were selected to yield three borings in areas of low contamination, three borings in areas of moderate contamination and three borings in areas of high contamination, based on the soil gas survey.

Soil gas samples were collected on approximately 100 foot centers using a regular grid designed to coincide as closely as possible with the locations of soil samples collected during the RI. Sixty-eight locations were sampled, most at a depth of three feet below grade. Selected locations were also sampled at a depth of five feet. The soil gas analyses were performed in a close support laboratory (CSL) by thermally desorbing the VOCs from the collection cartridges and analyzing the desorbed compounds by gas chromatography with both Hall and photoionization detectors.[4] Twenty-six constituents were included in the on-site analyte suite. Selected gas samples were also collected in evacuated stainless steel bombs and sent to a contract laboratory for confirmatory analysis by GC-MS.

The results of the soil gas investigation are summarized in Figure 5 in terms of the spatial distribution of total VOCs and in Figure 6 as a histogram showing the relative abundance of the various analytes. The VOC distribution revealed by the soil gas survey was consistent with that based on the CSL soil analyses reported in the RI. The soil gas survey revealed significant concentrations of highly volatile compounds, particularly vinyl chloride and chloroethane, believed to be degradation products of the primary solvents, such as TCE and TCA.

The presence of vinyl chloride, which had not be reported in soil samples analyzed during the RI, was significant because its toxicity and low trapping efficiency on activated carbon indicated that the initial off-gas from the SVE system would require incineration. The presence of vinyl chloride also complicated the construction of the SVE drain system. The spatial distribution of vinyl chloride, shown in Figure 7, was similar to that of the other VOCs, although the center of the vinyl chloride mass appears to be displaced slightly to the north in the direction of groundwater movement.

Of particular interest are the VOC mass estimates based on the soil gas analyses, the predesign soil analyses and the analyses reported in the RI and FS reports. The mass estimates from the soil gas analyses were made using Equation 1 and laboratory determinations of total organic carbon, porosity and moisture content to convert soil gas concentrations (mass VOC/volume gas) to total soil concentration (mass VOC/mass soil). The soil gas mass estimates are summarized in Figure 6. The soil gas survey indicated that approximately 4,000 pounds of vapor extractable compounds were present at the site. A similar estimate based on the soil analyses performed during the predesign investigation indicated less than 3,000 pounds of these constituents.

The mass estimates based on the predesign investigation results were less than the 200,000 pounds suggested by the CSL data in the RI or the 50,000 pounds indicated by the CLP analyses reported in the RI. These latter two estimates were the only ones available during development of the RAP, however.

Although the differences between the mass estimates remain unresolved, it is important to note that the predesign investigation samples covered the same area as the RI samples and some were collected in areas were the RI reported total VOC concentrations of greater than 100 mg/kg, yet showed generally much lower concentrations. Given that the RI was performed in 1984 and that the site has been subject to periodic flooding, was well as losses due to volatilization and biological degradation since then, the lower contaminant levels found during the predesign investigation are not surprising. Ultimately, the actual mass of VOCs currently present at the site is of importance only in terms of the need for off-gas treatment because the rate of VOC

Based on Soil Gas Sampling

Figure 6
Relative Abundances of VOCs based on
Soil Gas Samples

removal by SVE will be proportional to the mass present and the 80% mass removal goal will be achieved regardless of the initial mass.

Air Permeabilities

In addition to the spatial distribution of VOCs, the air permeability of the various soils at the site was a major factor controlling the design of the SVE system. The air permeability of a soil depends both on the intrinsic permeability of the soil and on the moisture content of the soil, because air can flow only through the interconnected voids which are not occluded by water. Air permeabilities at the Seymour site were measured under field moisture conditions by four different means: (1) laboratory tests on soil samples collected using a thin-walled sampler;

(2) step-rate tests performed using the soil gas drive-point in conjunction with soil gas sampling; (3) step-rate tests on individual wells installed in the soil borings; and (4) interference tests performed as part of the field tracer test. Each test measured the air permeability on a different volumetric scale, from smallest to largest. The test results are summarized in the exceedance probability plot in Figure 8. Both the drive-point tests and the laboratory tests indicated a range of air permeabilities over several orders of magnitude, with median values of approximately 2 and 15 Darcies, respectively. The single well tests and interference test results had medians of 10 and 20 Darcies, respectively.

The difference in results is a scale effect resulting from the fact that the single well and interference test results tended to reflect the permeability of the most permeability units penetrated by the extraction wells, whereas the drive-point tests reflected the local permeability of the particular soil in the immediate vicinity of the gas sampling probe and the laboratory test results were dominated by the lowest permeability material in the soil sample. Despite the range in results, the tests all indicated median permeabilities higher than those on which the conceptual design was based.

An interesting special problem which was not considered during the conceptual design of the system was that loading of the native soils by the cap would result in consolidation and a reduction in air permeability. Cap loading was estimated to reduce effective air permeabilities to approximately 20% of their unloaded values, and this reduction in permeability was taken into account in the final system design.

Vapor Phase Tracers

An interesting, but non-critical, aspect of the predesign investigation was the testing of vapor phase tracers to be used in system performance evaluation. The tracers are intended to be injected into the soils at strategic locations to monitor the sweeping efficiency of the SVE system. This process will be accomplished through the use of permeation tubes buried in the soils prior to construction of the cap.

Six tracers were selected for testing: sulfur hexafluoride (SF_6), dibromodifluoromethane (DBDFM), iodotrifluoroethylene (ITFE),

Figure 7
Lateral Distribution of Vinyl Chloride
Based on Soil Samples

Figure 8
Exceedance Probability Plot of Air
Permeability Measurements

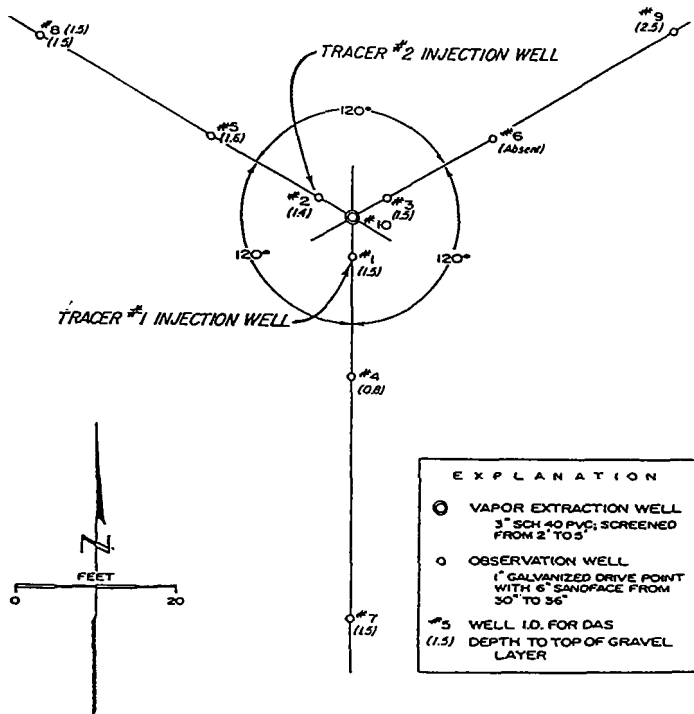
Freon 114 (F114), bromotrifluoromethane (BTFM) and bromochlorodifluoromethane (BCDFM). A convergent flow tracer test was performed by injecting the tracers through drive-points located five feet from a air extraction well at the test site shown in Figure 9. Two tracer tests were performed by injecting tracers after pressures around the extraction well had stabilized for nominal flow rates of 5 and 2.5 scfm. Breakthrough curves for five of the six tracers are shown in Figures 10 and 11. The omitted tracer is ITFE, the analysis of which was compromised by an interfering, unidentified compound.


Figure 9
Layout of the Tracer Test Site
Figure 11
Tracer Breakthrough Curves for Test 2

Analysis of the tracer tests using an analytical model[5] indicated apparent retardation factors between 10 and 20 for all of the tracers. Laboratory column experiments and theoretical calculations indicated, however, that the movement of these tracers should be retarded by a factor of less than two relative to air. The reason for the difference between the field and laboratory results is that the soils at the test site were heterogeneous and that the tracers were injected into lower permeability soils during the field test.

SVE Drain Spacings

Based on the results of the air permeability tests and the spatial distribution of soil types at the site, drain spacing recommendations were developed to assure that the SVE system would be capable of meeting the air circulation requirements of the RAP. An analytic equation was developed for computing the drain spacings required to circulate a specified number of pore volumes in a specified time at a given pressure drop:

$$L = [(k_a t \Delta P^2) / (2\mu P_a N \phi_T \sigma_a)]^{1/2} \qquad (4)$$

where L is the drain spacing
  k_a is the air permeability
  t is extraction time
  ΔP^2 is the difference in operating pressure between the drain and the atmosphere ($P^2 - P_a^2$)
  μ is the viscosity of air
  N is the number of pore volumes to be circulated
  ϕ_T is the total porosity of the soil
  σ_a is the air saturation of the soil
  P_a is local atmospheric pressure.

For the conditions at the Seymour Site and the requirements of the RAP, Equation 1 reduced to the following relationship involving only air permeability:

$$L = 280\sqrt{k_a} \qquad (5)$$

where L is the required drain spacing in feet and k_a is the air permeability in Darcies.

CONCLUSION

A numerical model (TRACRN[6]) was used to test the ability of the

Figure 10
Tracer Breakthrough Curves for Test 1

SVE system to achieve the goal of 80% mass removal. The mass removal goal incorporated into the RAP was based on simplified design calculations using an exponential dilution model which assumed a well-mixed soil volume. The use of a numerical model for the final design calculations allowed consideration of nonuniform soil properties and did not require that the soil volume be assumed to be well-mixed. Three numerical models were constructed, each considering different soil stratigraphies and permeabilities characteristic of the site (Fig. 12).
Figure 12
Conceptual Drawing of the Three Type
Sections used in the Numerical Models

The number of years required to achieve the 80% mass removal goal for typical VOCs is listed in Table 1, along with the times based on the exponential dilution model applied to a clay soil. The results indicated that the exponential dilution model yielded conservative results in terms of soil cleanup times.

Table 1
Seymour SVE Predicted Cleanup Times
(time to remove 80% of mass (yr))

COMPOUND	EXP DILUTION CLAY[1]	SINGLE CLAY LAYER (section 1)	2 LAYER SAND/CLAY[3] (section 2)	3 LAYER SAND/CLAY/SAND[3] (section 3)
Vinyl Chloride	0.8	0.5	0.3	0.2
Dichloromethane	3.6	1.9	1.6	0.7
1,1 Dichloroethane	2.8	1.5	1.2	0.6
1,1,1 Trichloroethane	2.5	1.4	0.6	0.5
Trichloroethylene	4.3	2.3	0.9	0.8
Toluene	9.8	5.0	2.0	2.0
Drain Spacing (ft)	---	25	100	100
Average Pore Volumes (per year)	19.7	19.7	48	65

Notes:

(1) Results based on soil properties and flow rate obtained from the single clay layer simulation.
(2) Pressure drop of 1 psi assumed in all simulations.
(3) In the 2 and 3-layer systems, maximum drain spacing was set at 100 feet to provide flexibility in system operation. This resulted in flow rates which exceed the maximum recommended in the Seymour RAP.

The Trouble With DNAPLs

Susan T. Litherland, P.E.

ABSTRACT

Sites contaminated with Dense Nonaqueous Phase Liquids (DNAPL) present unique challenges during investigation and remediation, not only for the environmental consultant, but for the regulators as well. Unlike lighter-than-water compounds, where soil contamination generally is limited to the unsaturated zone above the water table, residual DNAPL can coat the soil from the ground surface down to the first confining layer, where pools of DNAPL can form. The residual and the pools of DNAPL combine with the relatively low solubility of the DNAPL compounds to provide an almost endless source of contaminants to the groundwater. The large volumes of soils involved and the depths reached by these dense organic liquids, often make source control an unachievable goal. In addition, movement of DNAPL independent of groundwater flow significantly complicates identification of the extent of contamination and limits the effectiveness of traditional remedial techniques.

Addressing DNAPL sites requires not only a thorough understanding of the physical and chemical characteristics of the chemicals present and the hydrogeologic setting of the site, but it also requires creativity in the development and selection of remedial alternatives. For many DNAPL sites, it can be argued that the emphasis for remediation should be placed on preventing future migration, minimizing the impact on human health and the environment and encouraging the development of new technologies to clean up these sites.

INTRODUCTION

Groundwater monitoring, spurred by RCRA and CERCLA, has resulted in considerable interest in the contamination of groundwater by organic chemicals. Several of these chemicals fall into the class of Dense Nonaqueous Phase Liquids (DNAPL) due to the fact that they are immiscible in water and have densities greater than that of water.[1] DNAPL compounds include halogenated solvents commonly used in industries (such as electronics manufacturing, automotive repair and dry cleaning) and creosote, a wood preservative derived from coal tar, which contains hundreds of individual compounds.[2] Approximately one fourth of the organic compounds on the U.S. EPA Priority Pollutant List are DNAPL compounds and DNAPL compounds have been identified at hundreds of Superfund sites.[1,2] Considering the common use of DNAPL compounds, as well as their widespread occurrence as groundwater contaminants, it is important that regulators, industry and consultants develop an accurate understanding of the implications of groundwater contaminated with DNAPL compounds.

This discussion begins with a presentation of the physical characteristics of typical DNAPL compounds, followed by the current understanding of the transport and fate of these compounds in the subsurface. In regards to transport and fate, it should be noted that significantly more information is available for chlorinated solvents than for creosote compounds. After the presentation of this somewhat theoretical information, a series of four case studies involving DNAPL sites is presented. The sites involve either chlorinated solvents or creosote in various hydrogeological settings. These case studies illustrate observed DNAPL migration in the subsurface and some of the difficulties that have been faced in the investigation and remedial alternative selection for these sites. Although there is some discussion regarding the transport in fractured media, the emphasis is on porous media.

PHYSICAL AND CHEMICAL PROPERTIES OF DNAPL COMPOUNDS

The behavior of a fluid in the subsurface is dependent on the physical and chemical properties of both the fluid and the subsurface environment. Table 1 presents a list of common DNAPL compounds along with physical and chemical properties which affect their behavior in the subsurface. These compounds are grouped by their class; the upper portion of the table relates to chlorinated solvents and the lower portion of the table relates to polynuclear aromatic hydrocarbons or creosote compounds. These four compounds account for 20 to 50% of the creosote mixture.

As the name implies, DNAPL compounds are characterized by densities greater than water (1.00 gm/cm^3) and by relatively low solubilities in water, typically less than 5000 mg/L for the chlorinated solvents and less than 1.0 mg/L for many of the creosote compounds. These two properties allow the DNAPL to pass downward through a column of water as a separate phase. They also allow the DNAPL flow to follow the contours of the top of a confining layer as opposed to

Table 1

a Relative to the density of air

flowing along the top of the water table, as is the case with lighter-than-water immiscible liquids.

Beyond the similarities described above for the chlorinated solvents and creosote compounds, the physical characteristics differ fairly widely between the two groups. The chlorinated solvents have viscosities less than water, which suggests that pure chlorinated solvent will move faster through porous media than water [viscosity of 1.005 Cp at 25 °C[3] and the creosote compounds, with higher viscosities, will move more slowly than water. The difference in viscosity between the chlorinated solvents and water also affects their migration through the saturated zone, resulting in fingering of the chlorinated solvent as it displaces the water.[4] This fingering effect may not be as significant for creosote. The high vapor pressures for the chlorinated solvents make groundwater contamination via sinking vapors a concern. This phenomenon is not a significant problem for the creosote compounds. The log K_{ow} values indicate that the movement of dissolved chlorinated compounds will

FIGURE 1a. GROUNDWATER CONTAMINATION FROM A RESIDUAL DNAPL SOURCE IN THE UNSATURATED ZONE.

FIGURE 1b. GROUNDWATER CONTAMINATION FROM RESIDUAL DNAPL SOURCE IN THE UNSATURATED AND SATURATED ZONES.

Figure 1
Scenarios for DNAPL Migration

be retarded somewhat and that the creosote compounds will be significantly retarded when compared with the velocity of water through the soils.

TRANSPORT AND FATE OF DNAPL

Figure 1 presents a series of diagrams illustrating three different scenarios for the migration of DNAPL into the subsurface. Figure 1a represents a scenario in which the volume of DNAPL spilled is less than the retention capacity of the unsaturated zone. The downward migration of the DNAPL, therefore, stops before the water table is reached, resulting in an immobile mass of DNAPL in the unsaturated zone. This is not to say however, that the spill will not impact the groundwater. Organics dissolved in infiltrating rainwater have the potential to continue migrating toward the water table.[2] In addition, vapors from the chlorinated solvents can descend through the unsaturated zone to the water table, where they can dissolve into the groundwater. Due to the low vapor pressures of the creosote compounds, the vapor concentrations in the unsaturated zone would not be as likely to affect the groundwater.

Based on laboratory tests using chlorinated solvents, the quantity of DNAPL which will be retained by the soil (residual saturation) is dependent on the hydraulic conductivity of the soil and the physical characteristics of the DNAPL. For these chlorinated solvents, the residual saturation in the unsaturated zone ranges from 3 to 30 L/m^3 for soils with hydraulic conductivities of 1x10^{-2} to 1x10^{-4} cm/sec, respectively.[2] This figure is equivalent to 1 to 10% of the pore space.[1] It should be noted that Schwille's work was based on laboratory experiments using single contaminant systems in columns of clean homogeneous sand. As a result, these values likely are lower than what would be encountered in a natural depositional setting where subsurface heterogeneities could increase the retention capacity of the system.[2] Work completed by Karikoff[5] indicates that organic compounds will adsorb more strongly to soils containing natural organics. Although his work was based on organic compounds dissolved in water, it is assumed that soils with higher natural organic content would have a higher retention capacity for phased organic compounds as well.

As shown in Figure 1b, if a spill exceeds the retention capacity of the unsaturated zone and if sufficient pressure exists, the DNAPL will penetrate the water table. The behavior of the DNAPL as it reaches the water table is considerably different than that of a dissolved contaminant. Unlike the dissolved contaminant, which will immediately alter its course in the direction of the horizontal groundwater flow, the DNAPL will continue its downward migration apparently unaffected by the groundwater flow.[2] This downward migration will continue through the saturated zone until the residual saturation of the soil is reached. Residual saturation values for the saturated zone differ from those for the unsaturated zone due to differences in interfacial tensions between air and DNAPL and water and DNAPL. These values for chlorinated solvents range from 5 to 50 L/m^3 for soils with hydraulic conductivities of 1x10^{-2} to 1x10^{-4}, respectively.[2] This is equivalent to 2 to 15% of the pore space.[1] As in the unsaturated zone, this residual mass of DNAPL in the saturated zone is essentially immobile. The permeability of the porous media containing the residual mass will be affected by the presence of the mass; however, groundwater will flow through the immobile residual and, theoretically, emerge at concentrations equivalent to the solubility of the DNAPL compound.[1]

As shown in Figure 1c, when the quantity of DNAPL spilled exceeds the retention capacities of both the unsaturated zone and the saturated zone, the DNAPL will accumulate on the top of an underlying confining layer or low permeability lens. This DNAPL accumulation will migrate down the slope of the top of the confining layer regardless of the direction of groundwater flow. This migration will continue until the DNAPL either forms a pool in a depression on top of the confining layer or migrates through the confining layer via root holes or fractures. The downward migration through a confining layer can also occur through improperly installed monitoring wells or ungrouted boreholes. Groundwater flowing across the top of the DNAPL pool will not affect the movement of the pool; however, as this occurs, DNAPL will dissolve from the pool into the groundwater.[1]
Significant observations based on the laboratory work with chlorinated solvents are that the migration through the soil can be very rapid and that even small changes in the permeability of apparently homogeneous material can completely divert the DNAPL flow.

IMPACT ON SITE CHARACTERIZATION

There are three general problems associated with the investigation of sites contaminated with DNAPL: (1) defining the source area, (2) determining whether or not free-phase organics are present and (3) determining the depth of contamination without contributing to further downward migration. The importance of each problem is discussed below.

Defining the Source

Typical site remediation includes source removal. The objective of the remediation is to eliminate a large percentage of the contaminant mass so that remediation can be accomplished in a reduced period of time or in a less costly manner. With DNAPL, the area of residual saturation and any pools, in effect, are part of the contaminant source. As has been discussed previously, the mass of contaminants immobilized in the soil, coupled with the low solubility of the DNAPL compounds, provide an almost endless supply of contaminants to the aquifer.

As with other contaminants, the search for DNAPL begins at the point of release. However, since low permeability lenses and the top of the confining layer will affect the migration pathway, residual saturation can be present upgradient or crossgradient of the original source. This migration path can be erratic and small volumes of soil can retain significant quantities of DNAPL. Even a fairly closely spaced grid may miss fingers of DNAPL that continue to act as a source. The closer the grid, the higher the confidence that the extent of DNAPL has been defined. This type of investigation becomes expensive.

In areas without rock or gravels, cone penetrometer testing can be extremely useful to map the low permeability soils and confining layers. This technique, however, generally is limited to depths of 100 ft or less and would not be used to investigate below an upper-water bearing zone unless casing was used.

Determining the Presence or Absence of Free-Phase DNAPL

If it could be proven that the DNAPL present existed only as residual saturation, an extraction well system could be used to contain the dissolved contaminant plume. However, if DNAPL pools are present, an extraction well system will not be adequate. This inadequacy is due to the fact that pumping water will not significantly impact the migration of DNAPL pools, which may continue to migrate, providing more source material outside of the well network. Determining the presence or absence of free-phase DNAPL is not trivial. Soil samples at residual saturation levels can appear to be very oily. Due to the problems with laboratory analyses at high levels of concentration in the soil, even analytical results may not be conclusive. The best indication of free-phase DNAPL, if seeps or other manifestations are not present, is an increase in concentration just above a confining layer.

As stated previously, laboratory tests have indicated that groundwater flowing through residual DNAPL theoretically can become saturated with the dissolved DNAPL compound. Dissolved concentrations as high as these are seldom observed in the field and typically are less than 10% of the solubility.[1,4] This problem is believed to result partially from aquifer heterogeneities and the mixing of clean and contaminated groundwater during sampling.[4] As a result, the location or presence of residual or free-phase DNAPL normally cannot be determined strictly from dissolved concentrations in the groundwater.

Determining the Depth of Contamination

In the absence of a known confining layer, drilling to define the lower extent of contamination is risky. Although casing can be used to isolate upper zones, there still is concern about creating artificial pathways for downward migration. One approach that has been used is to install wells outside of the area of shallower contamination to the depths of interest. Deeper borings closer to the source would not be completed unless these wells indicated contamination was already present in the lower zones. Defining the depth of DNAPL becomes a moot point in fractured rock or depths below approximately 150 ft since not much can be done to remediate DNAPL in these situations.

Considerable care must be taken when drilling and installing monitoring wells at sites potentially contaminated with DNAPL. First, improper selection of a screened interval within an aquifer can result in incorrect information regarding the presence or quantity of a DNAPL. If a well screen is set too deep into a confining layer, the result can be an over-estimation of the thickness of the free-phase DNAPL. Conversely, if the well screen is set too shallow, the result can be an under-estimation of free-phase thickness or collection of a groundwater sample too far above the DNAPL pool to reflect the presence of the dissolved contaminant. Secondly, drilling a boring through a DNAPL pool and through a confining layer can introduce the DNAPL to deeper strata, potentially leading to disastrous results. At best, this cross-contamination will result in erroneous conclusions regarding the concentrations and depths to which the DNAPL has migrated. At worst, it could result in the contamination of a previously unaffected aquifer.

IMPACT ON REMEDIATION

The movement of the organics in the subsurface and the presence or absence of phased organics becomes important in the evaluation and selection of remedial alternatives. Furthermore, the presence of DNAPL can seriously impact remediation costs and the amount of time required for remediation. It is possible for DNAPL compounds to penetrate into the subsurface to depths beyond the reach of normal excavation techniques and, due to the low solubility of DNAPL compounds, pump-and-treat remediation methods may require centuries to attain dissolved concentrations below the drinking water standards.[1]

For example, assume that an extraction well has been installed in an aquifer contaminated with residual and pooled trichloroethene (TCE). Assume also that groundwater can be extracted from this well at a rate of 10 gpm, which is not uncommon for shallow alluvial aquifers, at an average TCE concentration of 10 mg/L (approximately 1% of the solubility of TCE). At this pumping rate and concentration, only 36 gallons (less than two-thirds of a drum) would be removed from the aquifer in a year. For large spills, it becomes easy to see how pump-and-treat remediation scenarios could take hundreds of years to clean up an aquifer contaminated with DNAPL.

The use of surfactant, alkali and polymer to enhance the removal of the DNAPL has been tested in bench-scale and pilot-scale studies; however, limited information exists regarding the large-scale application of these technologies.[8] Furthermore, it is uncertain whether the use of surfactants alone will facilitate the cleanup of soils to within U.S. EPA guidelines.[9]

Another problem concerning sites contaminated with DNAPL compounds is the depths to which the DNAPL can migrate. In the absence of any shallow confining layer, a DNAPL spill could potentially migrate several hundred feet into the subsurface if the quantity of the spill was sufficient. This deep migration makes excavation of the DNAPL residual and pools impractical and containment at these depths also may not be feasible. In these cases, the best solution may be long-term monitoring and treatment of any contaminated groundwater which must be withdrawn from the aquifer for use.

There appear to be two potential approaches to remediating DNAPL sites. The first approach is to increase the solubility of the DNAPL in water so that pump-and-treat alternatives are more efficient. Although some work with surfactants has been done, additional testing is needed along with investigation of other options such as the use of organics which are miscible with water to increase the apparent solubility of DNAPL in the water. Another option to be considered is the introduction of materials which would effectively seal the affected soils. More research is needed to develop technologies to better address DNAPL sites.

CASE HISTORIES

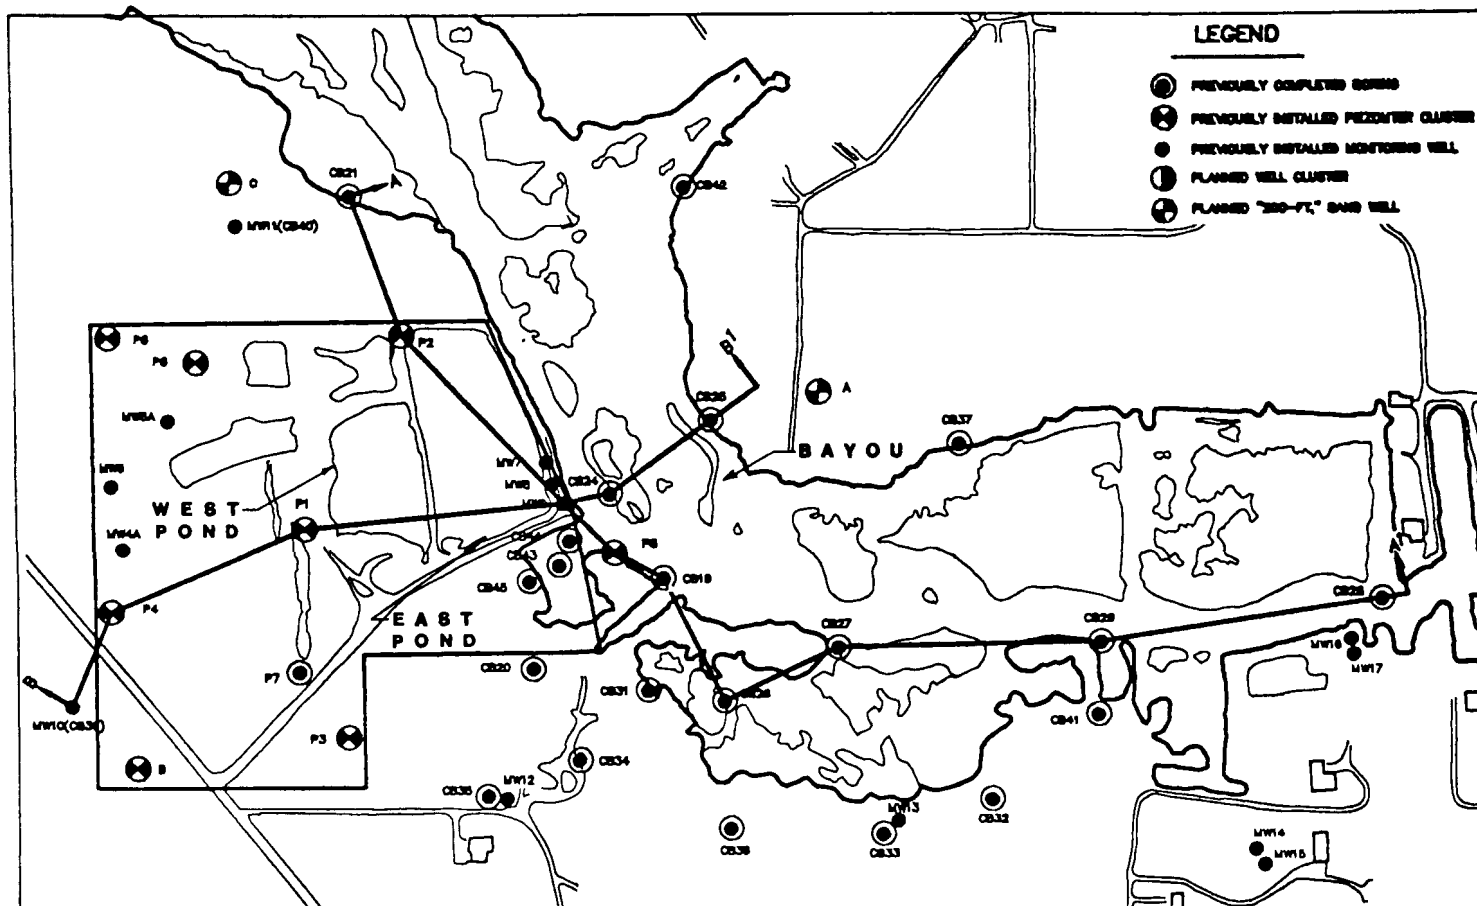
The following contains four case histories of DNAPL-contaminated sites. The first two of the sites involve chlorinated solvents and the second two sites involve creosote compounds. Each case history includes a brief


Figure 2
Case History A
Site Map

discussion of the site history, site geology, results of the site investigation, remedial alternative selection and current project status.

Case History A - Uncontrolled Chlorinated Hydrocarbon Disposal Site

From the early 1950s until the early 1970s wastes were brought to this site from a nearby industrial complex by an independent disposal company. A site diagram is shown in Figure 2. Liquid wastes consisting primarily of chlorinated hydrocarbons were discharged into the large ponds. In 1985 and 1986 a Remedial Investigation was conducted at the site. Among other things was the discovery of approximately 1,000,000 gallons of chlorinated solvents in the West Pond. The chlorinated solvents were composed of ten different compounds with 1,2-dichloroethane and 1,1,2-trichloroethane accounting for approximately 60% of the material present.

The site is located in the Gulf Coastal Plain. In the site area, Pleistocene Age deposits outcrop, while Recent deposits are confined to narrow belts along streams and wider belts in river basins. The Recent deposits are alluvium, consisting of fine sand, silt, clay and thin lenses of coarser sand. A geologic cross-section of the site is shown in Figure 3. Private wells in the site vicinity are screened as shallow as 150 feet MSL.

In an effort to determine the extent of contamination, borings and wells were completed. The borings were sampled continuously and screened in the field with an OVA. When elevated total readings were identified in a headspace analyses, a gas chromatograph was run with the same instrument for a positive identification of site contaminants. In addition, visual signs of contamination were noted. For this phase of the investigation, soil samples were not submitted for laboratory analysis. Based on the work plan, drilling at a particular location would

continue to a depth of 100 feet MSL or 10 ft into clean soils, which ever was deeper. In areas where contaminants were found, casing was used to prevent cross-contamination of lower strata.

A problem that was encountered with this approach is illustrated with the boring log shown on Figure 4. The graph on the left side shows the OVA readings with depth. Clean samples (OVA reading < 10 ppm) were identified at depths of 67, 82 to 92, 103, 118 and 124 feet, with significant contamination in between. As shown, this occurred several times. Although this boring was terminated at 124 ft due to limitations of the rig, there is not a high degree of comfort that the vertical extent of the contamination was identified.

A cross-section across the site is shown in Figure 3. The areas of apparent free-phase chlorinated solvents are illustrated with hatching. The results of the site investigation supported a number of the concepts of DNAPL research work including the diversion of chlorinated solvents by layers of less permeable soils. Significant fingering was apparent along with the identification of differing contaminant foot prints with depth. Another interesting aspect is the appearance that the chlorinated solvents migrated through the thin clay layers. This finding was not supported by the laboratory data and the migration may have been through holes or fractures in the clay layer and not as bulk migration through the clay. Since drilling has not been completed directly beneath the pond, it is not known whether a true confining layer is present.

The most significant problem encountered during the Site Investigation was how to determine the vertical extent of migration of the chlorinated solvents directly below the impoundments. For technical reasons, there has been no desire to drill through the bottom of the pond for fear of encouraging the downward migration. The options being considered include deeper borings adjacent the impoundments, although,

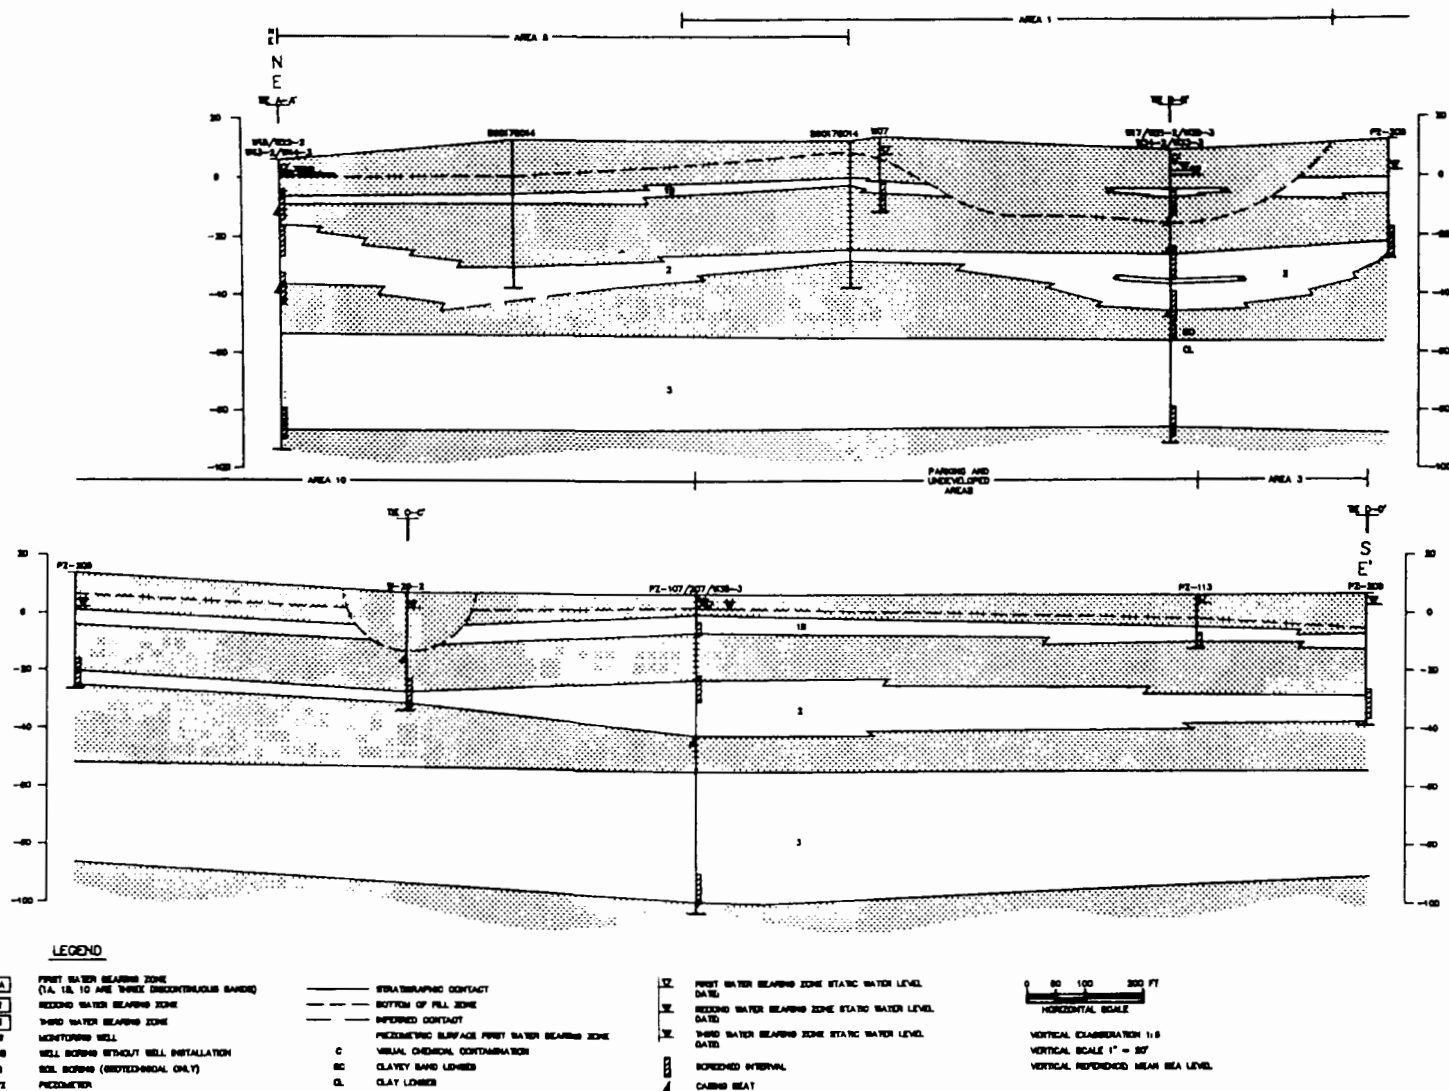
Case History B
Site Map


Figure 6
Case History B
Geologic Cross-Section

to some degree, this approach potentially has some of the same problems as drilling through the bottom of the pond. A second option is the use of directional or horizontal drilling where the vertical portion of the boring would be in a clean area. The drawback to this approach is the expense and the fact that current technology allows only one sampling depth beneath the pond. The third option to investigate the depth of migration is to install wells around the site screened in deeper formations. This option is being implemented currently and the need for additional investigation will be determined based on the results of sampling from these wells. Although not definitive, it will provide additional information regarding the depth of contamination.

In terms of potential remedial options, this site is complicated for a number of reasons. A portion of the migration has been beneath the adjacent bayou and chlorinated solvents have been identified to depths of at least 125 ft. If a confining layer is discovered, it may be possible to isolate this area with interceptor trenches or slurry walls. Without a confining unit, or a with a confining unit at a depth beyond the physical capabilities of any type of barrier, remediation likely will include institutional measures to prevent usage.

Case History B - Chlorinated Solvents Plant

This site is a currently operating, 60-acre chemical plant located along the Houston Ship Channel. A map of the site is shown in Figure 5.

Over the past 25 years, the plant has produced, among other chemicals, carbon tetrachloride, dichloroethene, trichloroethene and perchloroethene. These DNAPL compounds were generated both as products and as components of the plant's waste streams.

The site geology consists of fluvial and deltaic deposits of the Beaumont Formation. As shown in Figure 6, three water-bearing zones have been identified in the upper 120 feet. These include: a five-foot thick discontinuous silty sand at a depth of 20 feet; a five- to ten-foot thick silty sand at a depth of 40 feet; and a 40-foot thick silty sand at a depth of 70 feet. These water-bearing zones are separated from each other by leaky confining layers consisting either of clay or sandy clay. The shallowest known aquifer used in the area for drinking water is located at a depth of 400 feet.

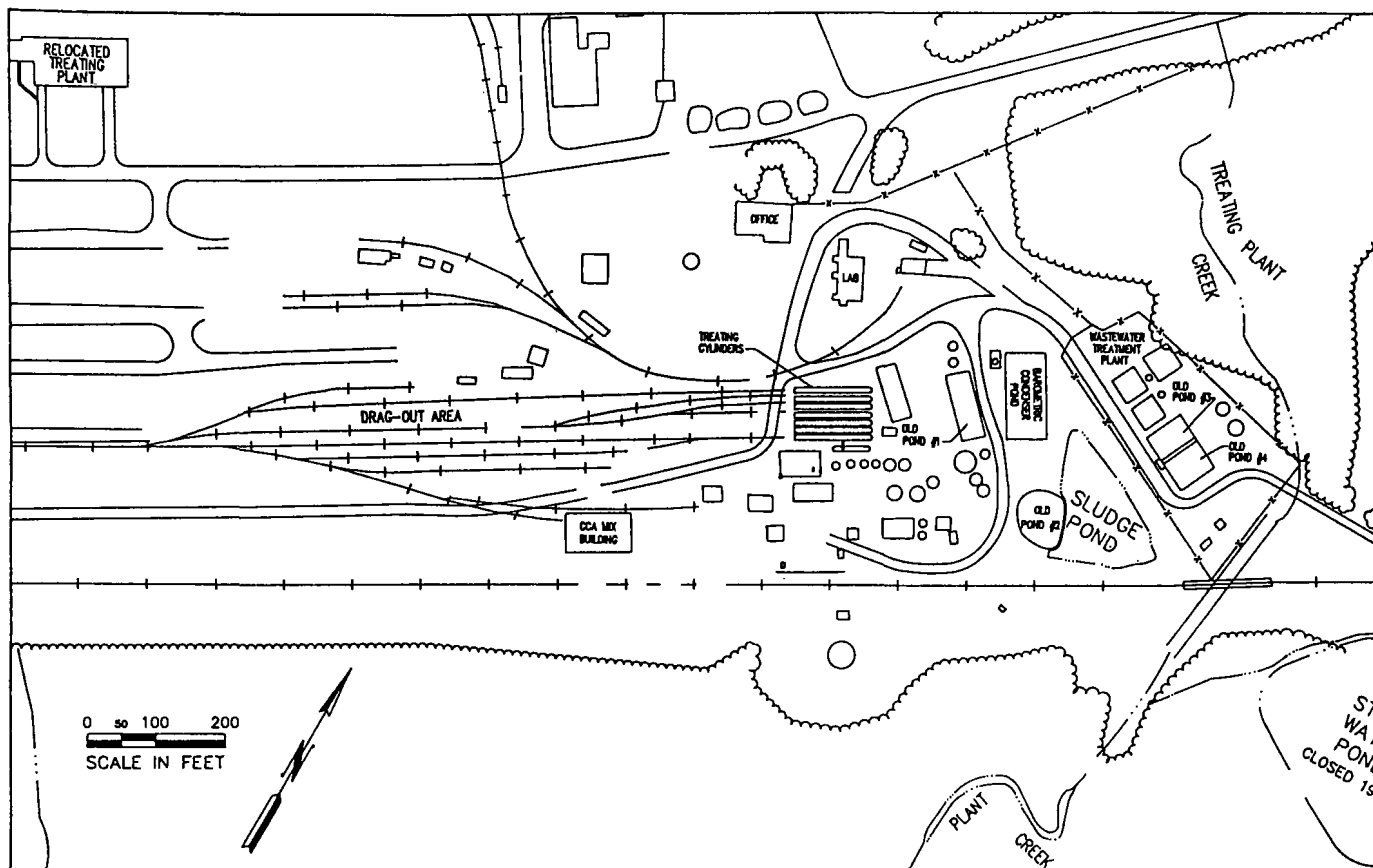
During the investigation, chlorinated solvents were found in all three water-bearing zones, both in dissolved form at concentrations as high as 2000 mg/L (total chlorinated hydrocarbons) and as free phase pools on top of the underlying confining layers. The source of the contamination is believed to be a combination of historical releases from process areas and leakage from former waste management areas. While it is possible that the DNAPL migrated to the lower two zones via natural pathways, such as fractures in the confining layers, it is possible that the numerous geotechnical borings which had been drilled previously at the site contributed to the downward migration. These borings


Figure 7
Case History C
Site Map
Figure 8
Case History C
Wood Treating Plant
Northwest-Southeast Geologic Cross-section

extended as deep as the third water-bearing zone and reportedly had been left ungrouted.

Subsequent work at the site has concentrated on preparing detailed maps of the top of each confining layer in an effort to predict the potential future migration of the DNAPL. Based on these maps and on the known locations of free-phase DNAPL, it appears that the DNAPL pools are migrating in a direction opposite that of the groundwater flow. Geophysical borehole logging has been utilized on nearby water-supply wells in order to characterize the stratigraphy beneath the third water-bearing zone without risking possible cross-contamination of any deeper zones during drilling activities.

Due to the depths to which the free-phase DNAPL had migrated (120 feet), many remedial alternatives, such as excavation, were determined to be impractical. Plans for remediation have focused on the containment and control of the free-phase DNAPL and dissolved DNAPL compounds. Plans are to install a slurry wall to the bottom of the second water-bearing zone in order to prevent further migration of the DNAPL pools in the upper two zones. Groundwater pumping will occur to maintain a negative hydraulic head on the slurry wall as well as to prevent migration of dissolved contaminants. Due to the depth of the third water-bearing zone, a remedial alternative for this zone has not yet been selected.

Case History C - Wood Treating Plant

This site is a currently operating 300-acre wood treating plant located in southwest Arkansas. A map of the site is shown in Figure 7. The plant has been in operation for more than 40 years, during which time wood products were treated either with chromium-copper-arsenate, pentachlorophenol or creosote. As was the practice at many wood treating plants, wastes generated during the wood treatment process were stored in unlined surface impoundments where free-phase treating solutions could be separated from the water and returned to the process area. This method of operation resulted in significant quantities of sludge, a major component of which was creosote oil.

The site geology consists of 15 to 25 feet of alluvium which generally of 12 to 20 feet of interbedded clays, silts and sands interbedded with a three to five foot thick discontinuous gravel unit. This gravel is underlain by the Paluxy Formation which consists of stiff clay with localized lenses of gravel, sand and limestone of depth. A cross-section of the site is shown in Figure 8. The upper-most water-bearing unit is a semi-confined aquifer, which is located in the alluvium and confined from below by the clays in the Paluxy Formation. Most of the water supply wells in the area are set in gravels and sands at depths below 150 feet.

During the investigation, free-phase creosote oil was identified in the gravel unit to the extent shown in Figure 9. The oil appears to have originated from the former impoundments and migrated down the slope of the top of the clay. A small creek, which runs through the site, intersects a portion of the oil-saturated gravel unit and creosote has been observed seeping from the stream bank. Much of the creosote, however, has migrated well beyond the creek by way of the gravel unit which, in places, passes beneath the creek. It is estimated that approximately 1,900,000 gallons of creosote oil are present in the gravel unit beneath the site. Groundwater generally flows in the same direction as the oil migration. This contamination is evidenced by a plume of dissolved creosote compounds which extends beyond the mass of creosote oil. Unlike the two sites previously discussed, a competent confining layer (thickness >20 ft) is present at the site at a depth of 15 to 25 feet. Migration of creosote into this clay is limited to no more than two feet.

Several Interim Remedial Measures (IRM) have been implemented to limit the migration of the oil, including: removal of sludges from several of the impoundments, closure of two of the three main impoundments, diversion of stream flow in the creek through a culvert which bypasses the oil seeps, construction of sumps in the stream bed to collect oils, and an installation of French drains to collect oils from the gravel in some areas.

The presence of a relatively shallow confining layer allows a variety of remedial alternatives which were not possible for the other sites.

The remedial alternatives currently being evaluated include: passive remediation, in situ treatment, excavation and containment/stabilization. Both the passive remediation and in situ treatment alternatives would use a series of extraction trenches to drain the oil from the gravels. In situ treatment would include the injection of surfactants and/or nutrients to flush out the residual oil and promote biodegradation. Although passive remediation would have a capital cost of only $2 million dollars, treatment of the groundwater and oils over 30 year period would cost an estimated $10 million. It is estimated that the injection of surfactants using current technologies would increase the removal rate of the creosote compounds but might not significantly reduce the time required for remediation; therefore, long-term operating costs would not decrease.

Excavation and on-site treatment of all of the contaminated soils would require only 4 years to complete but would cost in excess of $40 million. Containment of the migrating oils with slurry walls and capping to reduce infiltration appears to be the most viable alternative. This process would cost an estimated $4 million in capital costs, but the operating costs could be reduced by 75%. This alternative could be used to prevent further migration until more appropriate remedial technologies can be developed.

Case Study D - Arkwood Superfund Site

Wood treating at the Arkwood site was performed from 1962 to 1984. During this period both creosote and pentachlorophenol were used as preservatives. A map of the Arkwood site is shown in Figure 10. Also shown are the locations of borings and wells completed during the Remedial Investigation.

A geologic cross-section is presented in Figure 11. As shown, the geology is very irregular with soils above karst limestone. Present in the limestone are multiple fractures, joints, fissures and solution channels. This particular stratigraphy would have caused problems during the remedial investigation regardless of the contaminants present. The presence of DNAPL complicated the typical investigation problems

because the extent of contamination could not be defined. A spring approximately 500 feet from the site was contaminated with pentachlorophenol. Aside from this spring, no other contributions of contaminants to the surface water have been identified.

A clean closure of this site is not possible with current technologies. The remedial alternatives being considered focus on the sludges and soils present. The spring will be monitored to determine if natural attenuation is occurring. The decision regarding how to remediate the groundwater, if natural attenuation does not occur, has been delayed.

CONCLUSIONS

Knowing the physical properties and geological setting can provide indications of the migration of DNAPL in the subsurface. Due to the influence of apparently minor changes in stratigraphy on the flow pattern and the limitations of current investigatory techniques, defining the areas of residual saturation as well as the presence of DNAPL pools is difficult.

In the absence of a confining layer, or when migration of DNAPL is extensive, traditional remove-the-source remedial alternatives likely will not be feasible. Remediation of these sites will require an emphasis on containment to prevent further migration (if possible), minimization of the impact on human health and the environment and development of new technologies to truly remediate DNAPL sites.

Remedial Actions for Superfund Sites
With PCB Contamination

Jennifer Haley
Bill Hanson, P.E.
J. Paul E. des Rosiers, Ph.D.
U.S. Environmental Protection Agency
Washington, District of Columbia

ABSTRACT

A summary of pertinent considerations in the development, evaluation and selection of remedial actions at Superfund sites with PCB contamination assists in promoting a consistent approach to addressing sites with similar characteristics. Starting point action levels of 1 ppm PCBs for residential sites and 10 to 25 ppm PCBs for industrial sites have been specified based on standard assumptions of direct contact risks. Within areas contaminated above these levels, high concentration material, identified as material with PCBs at 100 ppm PCBs or greater (residential) and 500 ppm PCB or greater (industrial), should be identified and treated consistent with Superfund expectations. Several innovative technologies are currently being evaluated for treatment of PCBs including dechlorination, solvent extraction, biotreatment and solidification. PCB-contaminated material that remains at the site at concentrations greater than the action level should be contained. The need for containment methods such as caps, liners and leachate collection systems will be determined based on the residual concentrations and site characteristics.

INTRODUCTION

PCBs were employed in the past primarily in capacitors and transformers. They also have been used in plasticizers, hydraulic and heat transfer fluids in heavy industrial use, lubricants and wax extenders. PCBs are no longer produced for industrial or commercial use in the United States. It was estimated in 1977 that, of the roughly 1.25 billion pounds of PCBs introduced into commerce in the United States since 1929, only 55 million pounds had been destroyed by incineration or by degradation in the environment.[5] The remaining PCBs were in landfills, in service or had been released to the environment. It is not surprising that they have become a major contaminant at many Superfund sites. The first PCB disposal regulations were promulgated in 1978.

Approximately 17% of the sites on the National Priorities List involve PCB contamination.[1] The remedy selection process for PCB sites is complicated for a number of reasons. From a regulatory point of view, there are unusually high numbers of potentially applicable or relevant and appropriate requirements (ARARs) and pertinent "to-be-considered" guidelines for actions involving PCB wastes that must be complied with at Superfund sites as required by the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) and the National Contingency Plan (NCP).[2]

PCBs are difficult to address technically due to their persistence and the apparently high toxicity of some isomers. Moreover, a large number of process options are potentially effective for addressing PCBs and deserve consideration.

In an effort to increase the consistency of Superfund site actions, the program is developing general frameworks for remedy selection for particular chemicals and site types. The general guidelines summarized here should provide the information necessary to determine starting point action levels for PCBs, to assess primary remedy components (treatment, containment) consistent with program expectations and statutory mandates and to assemble several focused alternatives within this framework.

REGULATIONS

The primary regulation governing actions taken at Superfund sites is the NCP.[2] The NCP describes a remedy selection process that will achieve the statutory mandates of the CERCLA and defines program goals and expectations. The overall Superfund goal is to select remedial actions that are protective of human health and the environment, that maintain protection over time and that minimize untreated waste. In addition to the overall goal, the Agency expects to develop appropriate remedial alternatives that:

- Use treatment to address the principal threats at a site, wherever practicable
- Use engineering controls, such as containment, for waste that poses a relatively low, long-term threat or where treatment is impracticable
- Use a combination of treatment and containment to achieve protection of human health and the environment as appropriate
- Use institutional controls to supplement engineering controls for long-term management and to mitigate short-term impacts
- Consider the use of innovative technology when such technology offers the potential for comparable or superior treatment, performance or implementability, fewer or lesser adverse impacts than other available approaches, or lower costs for similar levels of performance than more demonstrated technologies
- Return usable groundwaters to their beneficial uses wherever practicable, within a timeframe that is reasonable, given the particular circumstances of the site

The mandates of CERCLA also require that remedial actions comply with ARARs of other laws and regulations, be cost-effective and utilize permanent solutions and alternative treatment technologies or resource recovery technologies to the maximum extent practicable.

ARARs for PCBs are relatively complex because PCBs are addressed by both the Toxic Substances Control Act (TSCA) and the Resource Conservation and Recovery Act (RCRA) and, in some cases, State regulations. Although the basic Superfund approach to addressing PCB-contaminated sites is consistent with other laws and regulations, this consistency must be documented in the feasibility study and Record Of Decision (ROD).

TSCA requires that material contaminated with PCBs at concentrations of 50 ppm or greater be disposed of in an incinerator or by an

alternate method that achieves a level of performance equivalent to incineration. Liquids at concentrations more than 50 ppm but less than 500 ppm and soils contaminated above 50 ppm may also be disposed of in a chemical waste landfill. TSCA outlines several requirements for chemical waste landfills that must be complied with unless it can be demonstrated that operation of the landfill will not present an unreasonable risk of injury to health or the environment. In these circumstances, a waiver of certain requirements may be approved by the Regional Administrator. Municipal sludges and dredged material can be disposed by a method approved by the Regional Administrator. Although TSCA requirements do not apply to PCBs at concentrations less than 50 ppm, TSCA also includes an antidilution provision under which the U.S. EPA can require disposal of PCBs based on the original concentration of the material spilled. This provision was created to ensure that PCBs would not be diluted as a means of relieving TSCA disposal requirements. It has been determined that the TSCA antidilution provisions are only applicable to CERCLA response actions that occur once a remedial action is initiated.[4] In selecting response action strategies and cleanup levels under CERCLA, the U.S. EPA should evaluate the form and concentration of the PCB contamination "as found" at the site and dispose of it in accordance with the requirements of 40 CFR 761.60(a)(2)-(5). Also under TSCA, the PCB Spill Policy was developed. This policy defines the level of cleanup required for recent, small volume PCB spills for different land use scenarios.

RCRA requirements apply to PCBs when liquid waste that is defined as hazardous under RCRA contains PCBs at concentrations greater than 50 ppm or nonliquid hazardous waste contains total halogenated organic compounds at concentrations greater than 1000 ppm. The land disposal restrictions require that when this material is placed on the land, it must be incinerated unless a treatability variance is obtained. Treatability variances are generally warranted for soil and debris wastes at Superfund sites. Superfund guidance on treatability variances for soil and debris indicates that for PCB concentrations greater than 100 ppm, treatment should achieve 90 to 99% reduction of PCBs.

Other requirements that derive from the Clean Water Act (CWA) and Safe Drinking Water Act (SDWA) and their implementing regulations may apply or be relevant and appropriate when the site involves surface or groundwater contamination.

PRELIMINARY REMEDIATION GOALS

The first step in defining the problem that must be addressed is determining the action level, the concentration of PCBs over which some action, either treatment or containment, must be taken. Action levels should be evaluated for each medium that is contaminated. Media considered may include soils, groundwater and sediment.

For soils, the concentration of concern for PCBs will depend primarily on the type of exposure that will occur based on the land use—current and future residential or industrial. Based on direct contact exposure (including ingestion, inhalation and dermal contact) assumptions,[6] starting point concentrations have been set at 1 ppm PCBs for residential settings and 10 to 25 ppm PCBs for industrial settings. The 1 ppm starting point for sites in residential areas reflects a protective, quantifiable concentration. (Also, because of the persistence and pervasiveness of PCBs, PCBs will be present in background samples at many sites.) For sites in industrial areas, cleanup levels generally should be established within the range of 10 to 25 ppm. The appropriate concentration within the range will depend on site-specific factors that affect the exposure assumptions. For example, at sites where exposures will be very limited or where soil is already covered with concrete, PCB concentrations near the high end of the 10-to-25 ppm range may be protective of human health and the environment.

If groundwater that is or may be used for drinking water has been contaminated by PCBs, response actions that return the groundwater to drinkable levels should be considered. The Safe Drinking Water Act (SDWA) provides the basis for determining cleanup levels for the drinking water exposure pathway. Nonzero maximum contaminant level goals (MCLGs) or maximum contaminant levels (MCLs) should be attained in groundwater that is current or potential drinking water. State

drinking water standards may also be potential ARARs. Proposed nonzero MCLGs and proposed MCLs may be considered for contaminated groundwater. The proposed MCL for PCBs is .5 ppb. Since PCBs are relatively immobile in most soil types, their presence in the groundwater may have been facilitated by solvents (e.g., chlorobenzene diluents, mineral oil, etc.) or by movement on colloidal particles. Consequently, once PCBs reach an aquifer, they are difficult to completely remove using traditional groundwater extraction techniques. In some cases, an ARAR waiver for the groundwater may be supported based on the technical impracticability of reducing PCB concentration to health-based levels in the groundwater. Access restrictions to prevent the use of contaminated groundwater and containment measures to prevent contamination of clean groundwater should be considered in these cases.

The cleanup level established for PCB-contaminated sediment may be based on direct-contact threats (if the surface water is used for swimming) or on exposure assumptions specific to the site (e.g., drinking water supplies). More often the impact of PCBs on aquatic life and consumers of aquatic life will determine the cleanup level. Interim sediment quality criteria (SQC) have been developed for several nonionic organic chemicals, including PCBs, and may be considered in establishing remediation goals for PCB-contaminated sediments.[3] The method used to estimate these values is termed the equilibrium partitioning approach. It is based on the assumptions that: (1) the biologically available dissolved concentration of a chemical in interstitial water is controlled by partitioning between sediment and water phases that can be estimated based on organic carbon partition coefficients; (2) the toxicity of a chemical to, and bioaccumulation by, benthic organisms is correlated with the bioavailable concentration of the chemical in pore water; and (3) the ambient aquatic life water quality criteria (WQC) concentrations are appropriate for the protection of benthic communities and their uses.

Table 1 presents the sediment quality criteria and derived PCB-sediment concentrations based on the SQC for freshwater and saltwater environments and two organic carbon (OC) concentrations. These criteria are to be considered in establishing remediation goals for contaminated sediments.

Table 1
Sediment Cleanup Levels for Consideration

DEVELOPING REMEDIAL ALTERNATIVES

The potential response options at any site range from cleaning up the site to levels that would allow it to be used without restrictions to closing the site with full containment of the wastes. Figure 1 illustrates the process for developing alternatives for a PCB-contaminated site.

It is the expectation of the Superfund program that the primary alternatives for a site will involve treatment of the principal threats and containment of the remaining low-level material. As indicated above, for sites in residential areas, principal threats will generally include soils contaminated at concentrations greater than 100 ppm PCBs. For sites in industrial areas, principal threats will include soils contaminated at concentrations greater than or equal to 500 ppm PCBs.

Liquid and highly concentrated PCBs constituting the principal threats at the site should be addressed through treatment. Treatment options that are currently available or are being tested include incineration, solvent washing, chemical dechlorination, biological treatment and solidification. Compliance with TSCA ARARs requires that PCBs at greater than 50 ppm be incinerated, treated by an equivalent method or disposed in a chemical waste landfill. Equivalence to incineration

is demonstrated when treatment residues contain less than 2 ppm PCBs. If treatment is not equivalent to incineration, compliance with TSCA ARARs must be achieved by implementing long-term management controls consistent with the chemical waste landfill requirements. (Liquid PCBs at concentrations greater than 500 ppm may not be landfilled under TSCA regulations.)

Long-term management controls should generally be implemented for treatment residuals and other low-level contaminated materials

for PCB-Contaminated Superfund Sites

remaining at the site. Example scenarios for the use of long-term management controls appropriate for particular PCB concentrations are shown in Table 2. The substantive requirements of a chemical waste landfill specified in TSCA regulations are indicated, along with the justification that should be provided when a specific requirement is waived under TSCA. (Under CERCLA, on-site actions must meet substantive, but not procedural, requirements of other laws.) TSCA requires that nonliquid PCBs that are not incinerated or treated by an equivalent method be disposed in a chemical waste landfill; it may be appropriate to waive certain landfill requirements where treatment has reduced the threat posed by the material remaining at the site, as indicated in Table 2.

Treatment of low-threat material may be warranted at sites involving relatively small volumes of contaminated material, sensitive environments (e.g., wetlands) and floodplains or other conditions that make containment unreliable. Since concentrations remaining will be low in these cases, long-term management controls may be reduced. Containment of principal threats may be warranted at sites involving very large volumes of contaminated material for which treatment may not be practicable, PCBs mixed with other contaminants that make treatment impracticable and PCB wastes that are inaccessible (e.g., buried in a landfill).

SELECTION OF REMEDY

The analysis of remedial alternatives for PCB-contaminated Superfund sites is developed on the basis of the following criteria:

- Overall protection of human health and the environment
- Compliance with ARARs or justification of a waiver
- Long-term effectiveness and permanence
- Reduction of toxicity
- Mobility
- Reduction of volume through treatment
- Short-term effectiveness
- Implementability
- Cost
- State acceptance
- Community acceptance

Primary tradeoffs for PCB-contaminated sites will derive from the type of treatment selected for the principal threats and the determination of what material can be reliably contained. Alternatives that require minimal long-term management will often provide less short-term effectiveness and implementability because large volumes of contaminated material must be excavated and treated. They generally will be more costly but will provide high long-term effectiveness and per-

[1] Cover system may range from 12" soil cap for low concentrations to a full RCRA cap for concentrations exceeding 500 ppm.

[2] The need for a cover system will depend on the land use (i.e., residential or industrial).

[3] 40 CFR 761.75(b)(3) requires that landfills be located at least 50 feet above the high-water table.

[4] In accordance with 40 CFR 761.75(b)(4) if the site is located below the 100-year floodwater elevation, diversion dikes shall be constructed around the perimeter of the landfill site with a minimum height equal to 2 feet above the 100-year floodwater elevation. Flood protection for landfills above the 100-year floodwater elevation is not applicable to closed landfill units.

[5] When the site is located in a permeable formation, incorporation of this long-term management control should be evaluated.

manence and achieve significant reductions in toxicity and volume through treatment.

. Alternatives that involve containment of large portions of the contaminated site generally will have lower long-term effectiveness and permanence and achieve less toxicity or volume reduction through treatment. However, they generally will be less costly, more easily implemented and have higher short-term effectiveness.

A ROD for a PCB-contaminated Superfund site should include the following components under the Description of Alternatives section:

- Remediation goals defined in the FS for each alternative; i.e., concentrations above which PCB, contaminated material will be addressed and concentration above which material will be treated.
- Treatment levels to which the selected action is projected to reduce PCB concentrations before redepositing residuals. The consistency of these levels with TSCA requirements and other ARARs should be indicated.
- Long-term management controls that will be implemented to contain or limit access to PCBs remaining on-site. The consistency with RCRA closure and TSCA chemical waste landfill requirements (and

justification for appropriate TSCA waivers should be indicated).

Aquifer Testing is Essential During Remedial Investigations

ABSTRACT

Characterizing the hydrogeology of a Superfund site is a critical part of the remedial investigation and remedial design processes. During remedial investigations (RIs), it is essential to collect accurate hydrogeologic data for subsequent use in a feasibility study and engineering design(s) so that implementation of remediation is not delayed and remediation costs can be determined accurately. The determination of aquifer coefficients has proven to be a critical factor in the Remedial Investigation/Feasibility Study (RI/FS) process at sites where groundwater pumping may be selected as a remedial technology. Aquifer tests and slug tests are two methods which can be used to determine the aquifer coefficients.

Aquifer tests seldom are conducted during the remedial investigation due to the problems associated with the disposal of the contaminated groundwater. Slug tests usually are conducted as a substitute for aquifer tests but, in many cases, appear to provide inaccurate estimates of the aquifer coefficients.

A case history which compares the results of slug and aquifer tests illustrates that the slug test underestimated the hydraulic conductivity of the aquifer by a factor of two. As a result, the remedial pump-and-treat system was inadequately designed due to the unexpectedly rapid movement of groundwater contaminants. Additional remedial investigations were required to redefine the groundwater plume before the final pump-and-treat system could be designed.

INTRODUCTION

Characterizing the hydrogeology of a Superfund site is a critical part of the remedial investigation (RI) and remedial design processes. During remedial investigations, it is essential to collect accurate hydrogeologic data for subsequent use in a feasibility study and engineering design(s) so that implementation of remediation is not delayed and costs can be accurately determined. Several methods may be employed to obtain the hydrogeologic data for a particular site, including a literature search, subsurface soil borings, geophysical studies, groundwater sampling and aquifer testing. These methods are utilized collectively throughout the remedial investigation process and generally provide the only information to support the remedial alternative selection process, risk assessment and groundwater modeling.

A thorough literature search is important and should be conducted to identify any previous investigations within the study area. Borings may be necessary to determine not only hydrogeologic properties, but also geotechnical properties. Geophysical studies may be useful for determining the subsurface structure and stratigraphy and also may provide information regarding groundwater flow and chemical quality. The installation of monitoring wells and subsequent groundwater sampling will provide data regarding the extent of any groundwater contamina-tion. Aquifer testing provides the most accurate site-specific method of determining aquifer coefficients of hydraulic conductivity (K), transmissivity (T), storage (S) and rates of groundwater flow which are calculated from these coefficients. As remedial alternatives are being evaluated throughout the remedial investigation process, additional information may need to be collected.

Of all the methods that may be used to determine the aquifer coefficients at a site, aquifer testing is the most accurate and reliable method if the following conditions apply: (1) groundwater contamination is apparent; (2) soil borings indicate the presence of medium- or coarse-grained materials; and, (3) groundwater pumping is likely to be selected as a part of the remedial alternative. Aquifer tests usually are not conducted during the remedial investigation process because of the problems associated with the disposal of large volumes of contaminated groundwater.

Slug tests often are conducted as a substitute for aquifer tests even in hydrogeologic environments where they should not be used. Slug tests are similar to aquifer tests in that the coefficient of hydraulic conductivity and transmissivity can be calculated, but slug tests are more appropriately used to determine the hydraulic conductivity of fine-grained materials.[5] Therefore, when slug tests are substituted for aquifer tests, inaccurate estimates of the aquifer coefficients often are obtained.

The case history presented later in this paper will illustrate the importance of conducting aquifer tests. This case history demonstrates how slug test data inaccurately estimated hydraulic conductivity; as a result, the remedial pumping and monitoring systems were inadequately designed for the site.

Aquifer Tests

The constant rate pumping test is the most widely used aquifer test. A well is pumped at a constant rate while drawdown is measured in the pumping well and in several nearby observation wells at specific time intervals. Theoretically, only one fully penetrating observation well (in addition to the pumping well) is necessary, but several wells are recommended so that the average values of K, T and S can be calculated and aquifer heterogeneity can be accounted for. Aquifer tests can also be used to determine vertical hydraulic conductivity and leakage between layers of multiaquifer systems.

The drawdown or recovery data are plotted versus time on logarithmic paper, and the curves generated are matched against type curves for interpretation and evaluation of the aquifer coefficients. Type curves are available for confined, unconfined and leaky artesian groundwater systems.[2,6] In addition, the distances of observation wells from the pumping well may be plotted against the drawdown to determine aquifer coefficients over a large area and the effective capture zone developed.

If groundwater pumping is a potential alternative in the list of remedial alternatives, a properly designed aquifer test will provide more information than simply the average K, T and/or S of an aquifer. Information regarding the specific capacity of wells, well efficiencies, well interference and potential boundary effects also is obtained during an aquifer test. This additional information is sometimes critical to the remedial design and may play an important role in determining the number and location of recovery and monitoring wells.

Slug Tests

Slug tests also are conducted to determine the K of an aquifer.[1-3] Slug tests are an accurate method for determining the K of low-conductivity, water-bearing units.[5] The value of K is determined from the rate of rise, or fall, of the water level in a well after a known volume, or "slug," is removed from or injected into the well.

The water level in the well is measured initially and then at specific time intervals after the slug has been removed until the water level returns to equilibrium. These data are then plotted on a semilogarithmic scale and matched to type curves to obtain values of hydraulic conductivity.[3] Although similar to the methods used during pump test analysis, the data actually represent a relatively short period of time and a very small portion of the aquifer. In addition, slug test analyses require assumptions which oversimplify actual conditions.

Slug tests usually are conducted in existing monitoring wells which

are installed with a gravel pack. Consequently, a slug test conducted in a monitoring well will provide information regarding the hydraulic conductivity of the gravel pack and not the aquifer material. Most monitoring wells are inadequately developed for slug testing purposes and, for this reason, may underestimate hydraulic conductivity.

CASE HISTORY

The following case history illustrates how data obtained from slug tests underestimated the hydraulic conductivity of the site conditions; as a result, the remedial pumping and monitoring networks were inadequately designed for the site.

The geology of the case site is glacial in origin with recent influences from fluvial activities. There are two water-bearing units beneath the site (shallow and deep aquifers) which are comprised of fine-to-medium sands and gravels. The two aquifers are separated by a lacustrine deposit of fine sands, silts and clays. The site boundary and the hydrogeologic cross section are shown in Figures 1 and 2, respectively. Groundwater contamination is restricted to the shallow aquifer in which groundwater travels in a north/northwesterly direction. Groundwater in the deep aquifer is present under confined conditions, and the flow direction is to the south/southwest. The confining layer between the two aquifers appears to have successfully prevented contamination in the shallow aquifer from migrating to the deep aquifer.

The RI provided a large amount of information regarding past studies,

of the Plume Stabilization Well

soil contamination, groundwater contamination, biota studies and surfacewater quality. Approximately 38 monitoring wells were installed, three rounds of groundwater samples were collected and numerous analyses were performed on the soils. Slug tests were conducted to determine the aquifer coefficients. The slug tests were performed by lowering a slug of known volume into the water and measuring the rise of the water level in the well until it returned to the initial level. Similar measurements were taken when the slug of water was removed from the well. The procedure was repeated twice, resulting in four measurements made in the same well.

The slug test data were evaluated using methods in Bouwer and Rice[1] and Hvorslev.[3] The Bouwer and Rice procedure was selected because it makes allowances for field situations where the aquifer is not under artesian conditions and the wells do not fully penetrate the aquifer, but the analysis does assume a homogeneous, isotropic aquifer. The Hvorslev method is simpler to use, but is based on more assumptions and was originally designed for zones of low permeability.

The calculated hydraulic conductivities for the shallow aquifer were 28 feet per day (ft/day) using the Bouwer and Rice method and 78 ft/day using the Hvorslev method. By applying Darcy's law and using average values of K from both the Hvorslev and Bouwer and Rice methods, an average hydraulic gradient across the site and an estimated effective porosity of 0.25, the groundwater velocity was calculated to be between 103 and 289 feet per year.

At the completion of the RI/FS, the groundwater plume was defined to extend approximately 600 feet from the site boundaries, as illustrated in Figure 3. The plume was defined by the total volatile organic compound (TVOC) concentrations detected during three separate groundwater monitoring programs. Based upon the TVOC concentrations detected and the hydraulic conductivity of the shallow aquifer, the RI/FS concluded that remediation of the groundwater contamination would be effectively accomplished through a groundwater pump-and-treat system. The pump-and-treat system was initiated by installing a plume stabilization well to stop further migration of the groundwater plume while the final remediation system was being designed.

The plume stabilization well was designed to pump at a rate of 100 gallons per minute (gpm) which would generate a capture zone that would cover the area of groundwater contamination defined in the RI/FS (Figure 3). A temporary treatment unit was constructed so that an aquifer test could be conducted on the plume stabilization well and the design of the remedial pumping program could be finalized. Once the aquifer test was concluded, it was determined that the K of the shallow aquifer was 122 ft/day, twice the average K calculated from the Bouwer and Rice and Hvorslev methods, and that groundwater contaminants were traveling twice as fast as originally expected.

A comparison of the hydraulic conductivities calculated from the slug and aquifer tests is presented in Table 1. This finding, and calculations of contaminant travel times, indicated that the area of contamination was larger than predicted in the RI report, and that two well clusters theoretically beyond the extent of contamination had failed to detect this additional migration of the plume. Another extraction well was immediately installed downgradient of the original plume stabilization well in an attempt to capture the groundwater plume. Additional monitoring wells and well points were installed to redefine the plume.

The well point program included driving temporary stainless-steel well points to a predetermined depth and collecting discrete groundwater samples. The water samples were then analyzed for VOCs by

an analytical laboratory, and rapid turnaround of the results was requested so that decisions could be made regarding the location of the next well point. The initial program, which was designed to install 10 well points, began in January 1990. By June 1990, 31 well points, five soil borings and 16 piezometers were installed.

The well point program indicated the following: (1) groundwater contamination extended approximately 3500 feet beyond what was originally determined during the RI; (2) the direction of groundwater flow changed from north/northwest to a more westerly direction; (3) the change in flow direction appeared to be the result of a change in aquifer materials and consequently a change in the hydraulic conductivity; (4) the confining layer, which separated the shallow and deep aquifers, pinched out and the two aquifers became one hydrogeologic unit; and (5) the remedial extraction and monitoring well networks designed immediately after the RI was completed were in need of significant modifications. In order to capture the contaminant plume, additional extraction wells were required. The extent of groundwater contamination defined during the well point program, June 1990, and a remedial pumping array which will effect capture of the plume and prevent further migration of contaminants are shown in Figure 4.

If an aquifer test had been conducted at this site during the RI process, much of this additional investigative work and cost may have been avoided. Although aquifer tests are not foolproof, if designed and orchestrated properly, they provide important information that is necessary for a remedial pump-and-treat design.

An Alternate Approach

If, during the course of the RI/FS process, it becomes apparent that a remedial pump-and-treat system will be incorporated into the remedial design, aquifer tests can be conducted even if the groundwater is contaminated. An aquifer test array of pumping and monitoring wells often can be installed off the site where groundwater is uncontaminated. This off-site test obviates the need for treatment, and water from the pumping well can be discharged into the surfacewater drainage system. Sometimes it is possible to discharge directly to a publicly owned treatment works (POTW) if pretreatment standards can be met and the contaminants will not cause upset or pass through the plant untreated.

If access to an area upgradient or sidegradient of the site is difficult to obtain, or if the hydrogeology upgradient or sidegradient is drastically different and will not be representative or if a POTW is unavailable, a temporary and/or portable treatment unit can then be utilized to treat the water prior to discharge. Portable air strippers and granular activated carbon (GAC) units are readily available from many manufacturers. Given the amount and quality of data generated during an aquifer test, the extra cost (even if treatment is required) outweighs the costs of additional post RI/FS studies and the costs of overdesigning a treatment plant which often will be incurred because of a lack of data.

CONCLUSIONS

Based on our experience outlined in this paper, we have drawn the following conclusions:

- Accurately defining the hydrogeology of a site is an essential aspect of the RI, especially in cases where a pump-and-treat system may be chosen as part of the remedial alternative or where contaminant migration in the groundwater is an important issue.
- Aquifer tests provide a means by which aquifer coefficients of hydraulic conductivity (K), transmissivity (T) and storage(s) can be accurately determined. If designed properly, they can be used to determine the average aquifer coefficients over a relatively large portion of the aquifer and can determine well interference effects, boundary conditions and expected well efficiencies.
- Slug tests provide an accurate means by which the aquifer coefficients of K and T can be determined in zones of low permeability. However, slug tests should not be substituted for aquifer tests in a permeable aquifer and should not be done in monitoring wells that have been gravel packed.
- At sites were groundwater is contaminated, aquifer tests often can be done upgradient or sidegradient where groundwater is uncon-

Sampling Structures at Superfund Sites: A Case Study from the Sand Creek Industrial Site, Commerce City, Colorado

Penelope L. Niland, M.A., R.E.A.

Denver, Colorado

ABSTRACT

As is common for RODs on Superfund sites that include buildings and other structures, the remedy identified for the facilities on the Sand Creek Superfund site is demolition and off-site disposal. However, both the new federal restrictions on land disposal and the impending expiration of the variance allowing disposal of certain wastes from Superfund cleanup sites made it necessary to determine if demolition material from the site would be acceptable at land disposal facilities and whether or not treatment of some or all of the material would be necessary.

The structures investigation described below was undertaken by Brown and Caldwell Consultants as a subcontractor to URS Consultants as part of the Remedial Design (RD) phase of an Alternative Remedial Contracting Strategy (ARCS) contract with Region VIII of the U.S. EPA. The field work consisted of sampling and dimensional measurement of the structures. The sampling strategy was developed, in part, based on the data requirements of landfill operators and transporters as well as the requirements for determining if separate handling procedures or actual treatment would be required for portions of the demolition debris. The sampling strategy for the site structures, a summary of analytical results and conclusions about the utility of the sampling strategy for the RD phase are presented in this paper. At this time, the remedial design itself has not been finalized.

SITE HISTORY AND DESCRIPTION

The Sand Creek Industrial site is located in Commerce City, Colorado, a suburb north of Denver. The site was proposed for the NPL in December 1982 and placed on the list in September 1983. The site contains four potential source areas that have been designated as Operable Units (OUs): (1) the Colorado Organic Chemical Co. (COC) property (OU1), (2) the L.C. Corporation acid pits (OU2), (3) the 48th and Holly landfill (OU3), and (4) the area-wide groundwater contamination associated with the Sand Creek Industrial site area (OU4).

This paper focuses on the RD investigation conducted by Brown and Caldwell Consultants at the Colorado Organic Chemical Co. (COC) property (OU1) during December 1989. The property was used to manufacture pesticides from 1960 to about 1984. Two major fires are known to have occurred in manufacturing buildings at COC, one in 1968 and one in 1977. The site is located in an industrial/warehouse area with an active warehouse directly adjacent to COC on the north and a concrete batch plant to the west. The former site of the tank farms for the Oriental Refinery is to the south and east of the COC property.[1]

Sixteen structures, exclusive of standing tanks, were present on the site during the investigation, including: two, single-room, metal buildings and two cinderblock buildings, each with a concrete slab floor; one multi-room office/process building built of a variety of materials with both concrete and dirt floors; four open concrete slabs; one con-

crete pit; two metal tank bottoms; and four locked wooden railroad cars composed of wood and metal (Fig. 1). The standing, intact tanks were excluded from the sampling program because they were to be investigated by another U.S. EPA contractor. However, they were part of the inventory of structural material on the site.

What little is known about the specific chemical processes and uses that occurred in each structure was obtained from a single interview with the owner of the facility.[2] Reportedly, DDT, aldrin, dieldrin and other products were formulated on-site (Metal Building on Figure 1). Solvents were used in the formulation process and parathion and penta were stored in tanks on-site. A diazinon-formulating operation was constructed but never used (Quonset Hut and Addition). The upper floor of the Office/Process complex has been and continued to be used as an office during the time of the field investigation. The lower portion of the building was used as a laboratory and now is used for storage. Methylene chloride was used in the production of DDVP (Vapona) in the northernmost of the two metal structure portions of this complex. In addition to the pesticide manufacturing, metal products, including pipe, were formed, welded and stored on-site (Hains Engineering and Quonset Hut). Nothing is reported about the structures in the portion of the site west of the buildings except that they are located in an area where 2,4-D was formulated.

The RI/FS conducted on this property identified chemicals of concern in the soil (Table 1), but no previous sampling of the structures themselves had been done.[1]

DEVELOPMENT OF INVESTIGATION STRATEGY FOR STRUCTURES

The basic principle used in designing this structures investigation was "work backwards;" that process is one in which one determines data

needs of the steps in the process leading to the ultimate destination of the material and gathers data to assist in the design of the activities associated with the process. The selected remedy for structures within OU1 of the COC site is demolition and off-site disposal.[3] The objectives of the structures sampling and material inventory were:

- Determine if chemical concentrations or material characteristics identified in samples taken from building material exceed limits that would exclude placement of the material in a Subtitle D landfill
- Determine if "hot spots" exist in the building material that would indicate that some material requires treatment prior to disposal
- Provide volume estimates of total demolition debris, debris by material category and volume of material in "hot spots" so that costs of demolition or other disposal or treatment options can be properly estimated
- Provide analytical data on chemical concentrations, RCRA characteristics and the presence or absence of asbestos so that demolition bid documents can be prepared that reflect actual conditions
- Provide sufficient analytical information so that hazardous waste transportation manifests can be prepared
- Provide analytical information that can be used by landfill operators as part of their process of determining if demolition debris can be accepted by their facilities

We reviewed U.S. EPA/Department of Transportation (DOT) manifest requirements and interviewed operators of several Subtitle C landfill facilities to determine requirements for analytical data on manifests and submissions with the profile sheets that accompany waste to land disposal sites. The consensus was that "representative" analytical data from each structure should be submitted with the manifests and that a representative sample from each structure should accompany any delivery of material to their facility. There was no requirement for a representative sample from each truckload of material from the landfill operators. Interestingly, no landfill operator was willing to define the term representative. However, the manifesting requirements of truck transport of potentially hazardous waste are such that some segregation of material by building or type of debris in the loading of transport trucks may be required. It should be noted that this work was done prior to the promulgation of the third-third portion of the land ban. Some differences in landfill practices are emerging that should be taken into account on other projects.

It also was not clear that the sampling should identify any "hot spots" that could potentially contain high concentrations of chemicals or exceed RCRA thresholds for corrosivity, ignitibility, reactivity or toxicity so that consideration could be given to segregating this material and either treating it or disposing of it separately from other debris from the site. This separation obviously could save money in the ultimate disposal of material from this facility.

We set the Data Quality Objectives (DQOs) as follows:

- *DQO I. Confirmation of Selected Demolition and Disposal Remedy.* Perform limited "hot spots" sampling to determine if areas exist with concentrations of Halogenated Organic Compound (HOCs) greater than 1000 ppm that will prevent disposal of all or part of the demolition debris in a Subtitle C landfill.
- *DQO II. Prepare Demolition Bid Package.* Conduct limited sampling to assess general level of contamination in each structure; identify classes of building material and take material measurements to support estimates of material volume.
- *DQO III. Demolition Health and Safety Plan.* Perform limited waste characterization and contaminant screening to determine classes of contaminants present in each structure in sufficient detail to recommend levels of respiratory and dermal protection required for demolition crews.
- *DQO IV. Prepare Documentation for Transport of Demolition Debris that Can Be Landfilled.* Provide analytical information that identifies the types of contaminants present and that demonstrates that no areas sampled showed HOC concentrations greater than 1000 ppm.
- *DQO V. Provide Landfill Operators with Waste Characterization Sufficient for Acceptance of Demolition Debris from Site.* Provide analytical data from pre-demolition sampling conducted during the RD phase

SAMPLING AND MATERIALS MEASUREMENT PLAN

A sampling and measurement plan was prepared based on the DQOs and observed conditions at the site. The first round of sampling originally was intended to identify areas that should be further sampled. However, budgetary and time constraints precluded further sampling. The plan can be summarized as follows:

Chemicals/Characteristics of Concern

Sampling was planned to: identify the chemicals of concern found in the soil during the RI (Table 1); determine the RCRA waste characteristics of corrosiveness, reactivity, ignitability and toxicity; determine if certain suspect materials contained asbestos; and determine if mercury was present in the buildings, which would account for its presence in the soil in certain locations close to buildings. Because of the history of fire in a facility that manufactured 2,4-D, sampling to identify the possible presence of dioxin contamination in several of the buildings also was planned. Table 2 summarizes the analytic methods specified for the samples taken for this investigation.

Table 2
Sand Creek
Analytical Procedures Used for Structures Samples

1.	RCRA Waste Characterization	
	a. Corrosivity.	U.S. EPA Method #9040. Reported as pH. Threshold is less than 12.5
	b. Ignitability.	SWA846. U.S. EPA Method #846 Reference flash point is 75 °F.
	c. Reactivity.	U.S. EPA draft. Positive or negative. Including cyanide and sulfides.
	d. EP toxicity.	Inorganics. U.S. EPA Method 6010. (Includes arsenic, barium, cadmium, chromium, lead, mercury, selenium, and silver). Range of method detection limits is 0.1 to 0.6 mg/L. Organics. U.S. EPA Method #8080. (Includes lindane, endrin, methoxychlor, toxophene, chlordane, dieldrin and heptachlor). Ranges of method limits is 0.05 ug/L to 1 ug/L.
2.	Halogenated Organic Compounds (HOCs).	U.S. EPA Method #9020. The detection limit is 20 mg/L.
3.	Dioxin.	U.S. EPA Method #8280. Tetra-octa chlorinated dioxins and furans. Method detection limit is 0.1-1 ug/L.
4.	Mercury.	U.S. EPA Method #7470. Method detection limit is 0.5 mg/L.
5.	Asbestos.	U.S. EPA Method #600/M4-82-020 for bulk samples. Polarized light method. Analysis is for five asbestos types: amosite, chrysotile, crocidolite, actinolite/tremolite and anthophyllite. The detection limit is 1%.

Note: these analytical procedures were used for all building media sampled. The specified method detection limits or equivalent are included. Wipe samples were reported in milligrams. No corrosivity, ignitability or reactivity tests were performed on wipe samples.

Sampling Methods

Three sampling methods were employed. Wipe samples using Whitman 541 filter paper in 15 cm circles soaked in either hexane or acetic acid were taken of 1 m² of metal and block surfaces.[4] Composite grab samples of up to four subsamples were taken of fiber and wood wall materials, soil in interior dirt floors and suspected asbestiform materials, soil in interior dirt floors and suspected asbestiform material. Composite samples of three subsamples of concrete slabs were assembled by using a hand-held drill with a wide bit to pulverize the material at several locations on each slab sampled. The holes were drilled to a depth of approximately 4 m each.

Sample Locations

General sampling locations were specified in the sampling plan with the actual locations to be chosen in the field based on observation of potential "hot spots." Prior to sampling each structure, a "hot spot" survey was done. The following visually observable characteristics were considered sufficient to label an area a potential "hot spot":

- Staining
- Corrosion or crumbling
- Standing liquid or sludge
- Spilled powder or liquid material
- Stored bags, bottles or drums
- Evidence of fire or explosion
- Pipes, tanks or other closed vessels

All the concrete samples were to be composites from potentially hot areas. Dioxin samples were to be taken from the areas that had visible marks of burning. Wipe samples were to be taken from both inside and outside walls for each structure. Field notes were kept of all identified "hot spots."

Health and Safety Procedures

All building work, whether initial survey, sampling or measuring, was done with teams consisting of a minimum of two people. Prior to the start of the field work, a building hazard survey was conducted to determine if any dangerous structural conditions existed or if any spaces were present that might contain chemical or explosion hazards or that would meet the definition of confined space. None was observed.

With one exception, all sampling was done in Level C respiratory protection. The operator of the drill used for concrete sampling wore a Self Contained Breathing Apparatus (SCBA) (Level B) because of the large amount of possibly-contaminated dust generated in the process. Dermal protection during all field operations was achieved with Saranex-coated Tyvek suits taped at all openings, vinyl undergloves, nitrile overgloves and rubber boot covers. During wipe sampling, surgical overgloves replaced the nitrile overgloves.

MATERIALS ESTIMATES

In addition to collecting samples, the field crew measured the structures in the field, including the standing tanks, to estimate the amount of demolition debris that would be generated. No drawings were available for any of the structures on the site. In the case of buildings, measurement proceeded from the exterior to the interior. A building footprint sketch was made on a grid pad, with a reference direction noted. The exterior dimensions (length, width and height) were measured using handheld tape measures and a measuring rod. Building materials were noted on the sketch. If more than one building material was present on the exterior, the dimensions of each material were measured and noted. Windows and doors were noted on the sketch and measured. Once the exterior procedures were completed, the building was entered and the thickness of the exterior walls was measured or estimated. All internal walls were measured for height, width and thickness. Different building materials were measured separately so that volume calculations by material could be made. The slab width was measured and the size of the foundation was estimated if direct measurements were not possible. Pipes, tanks, other machinery and dry, stored material were measured. Nonbuilding structures such as slabs, tanks, etc. also were measured.

RESULTS

Sixty-five samples were taken in and around structures on the site and from the warehouse building north of the site, and 55 samples were taken from 40 locations in or on structures on the COC site. An additional two samples to be analyzed for dioxin were taken from the active warehouse on the north boundary, which had suffered damage from past fires. Additionally, seven QA/QC samples and one health and safety monitoring air sample were obtained.

The analytic results are summarized below.

Dioxin (TCDD)

Six wipe samples (including two from the off-site warehouse and one blank) were taken from blackened areas in four buildings and analyzed for TCDD. No dioxin was detected above 0.400 pg/cm^2. These results are below the 1 ppb standard for land disposal of treated dioxin waste.

Asbestos

Material that was suspected to contain asbestos was observed in only two buildings, in boiler insulation and in floor tile. The boiler insulation was determined to be 45% asbestos; neither the floor tile nor its adhesive contained asbestiform material.

Halogenated Organic Compounds (HOCs)

Total HOCs in the composite concrete samples ranged from 980 mg/kg to 30 mg/kg. All samples were composites from stained areas. Total HOC concentration was 800 mg/kg in a composite weathered sludge sample from the open tank bottoms. Total HOCs were identified in fiber, wood and soil samples within structures in ranges from 9000 mg/kg to 100 mg/kg. The highest concentrations came from a sample from the railroad cars on-site where unidentified dry chemicals and other materials were stored. Total HOCs in wipe samples were identified in ranges from 0.44 mg/m^2 to 0.012 mg/m^2, with the highest concentration on the inside of a former mixing vessel and the lowest on a wall location inside a process building.

Corrosivity, Ignitability and Reactivity

Of these RCRA waste characteristics, only the test for corrosivity yielded results above thresholds. Most of the concrete samples showed pHs between 12.5 and 12.7. Although the samples were composites from stained areas, it is possible that the naturally basic nature of concrete caused the high pH readings.

Metals

Arsenic, barium, chromium and mercury were identified in composite concrete samples below RCRA maximum concentrations. Two samples contained arsenic at 5.6 mg/L and 7.9 mg/L, levels that exceed the RCRA maximum concentration of 5.0 mg/L for this contaminant. Arsenic, barium, cadmium, chromium, lead and silver from wipe samples taken on building walls were identified at concentrations ranging from 0.0046 to 2.2 mg/m^2. These levels are extremely low and likely to indicate that nothing is present on the walls in concentrations that exceed thresholds. On soil sample taken from inside a structure contained mercury at 1.4 mg/kg, a level that may indicate a concentration that exceeds the RCRA maximum concentration limits for this constituent.

Pesticides

Dieldrin, endrin and/or lindane were identified in every concrete sample in concentrations ranging from 38 to 0.034 ug/L. Lindane and endrin exceeded the RCRA maximum concentrations in every instance where they were identified. A single soil sample from within a structure identified BHC isomers including lindane at 51.4 ug/L. Wipe samples indicated the presence of low levels of p,p'-DDE and DDT, dieldrin, lindane, endosulfan and toxaphene throughout the site at concentrations at or below 3.2 ug/m^2. A single wipe sample identified toxaphene at 740 ug/m^2 on the outside of a process mixing vessel.

Materials Measurement

Material in structures was estimated for six categories: concrete/concrete block; wood/fiber; sheet metal; structural metal, pipes and metal doors; metal in outside tanks; and concrete in outside tanks. Total material in the structures as they stood was estimated to be 1214 yd^3. To account for voids between pieces of rubble, this volume of standing material was increased by a factor of 1.5 to arrive at an estimate for demolition debris of 1821 yd^3. An approximate estimate of the potential landfill volume was made to account for some recompacting of material during disposal. The demolition debris volume was multiplied by 0.80 for estimated landfill volume of 1457 yd^3.

CONCLUSIONS

As a result of our work, the following conclusions were drawn:

1. The sampling techniques used in this investigation yielded results that contributed required information to the RD phase. Specifically, the composite sampling of concrete, weathered sludge on open tank bottoms, wood/fiberboard wall material and soil within structures identified the presence of "hot spots" within these materials in concentrations high enough to indicate the presence of RCRA wastes. The wipe sampling technique, while it did not yield information as to concentration in a form that is convertible to RCRA thresholds, did show relative values that indicate the presence of contaminants associated with a process vessel.

2. Volume estimates of structural material were easily made. Field notes contain sufficient information to estimate the volume of potential "hot spot" material.

3. Asbestos was identified as present in only one location on the site. Thus, the substance will not present a major problem or cost in the demolition process.

4. Sufficient analytic data were gathered to prepare transportation manifests.

5. Assuming that "hot spot" areas are demolished and separated from cleaner material, the results of this study have identified actual "hot spots" through the inventory and sampling process. Further sampling may be required of each unit of drummed or separately handled "hot spot" material.

ABSTRACT

In the wake of the Bhopal disaster, there has been increasing public and governmental concern over the possibility of toxic gas and vapor releases from chemical plants. Title III of SARA, specifically addresses emergency preparedness for such releases. Industry is under intense pressure to provide additional safeguards to prevent gas clouds from threatening populated areas.

Many ways to prevent releases are already in use by industry, ranging from safety-conscious plant design, through safety alarms and interlocks, to backup devices such as scrubbers and flares. However, once a gas or vapor leak occurs, the options for its control are few.

This paper describes the use of foam scrubbing, a novel option for controlling emergency releases of airborne toxics. In this approach, foam is generated with conventional equipment, actually using the contaminated air to form the foam. The foaming solution contains neutralizing agents and may require a special surfactant system for compatibility with these agents and with the contaminants. With the airborne gases, vapors and particulate materials encapsulated in the foam, a large, interior, liquid surface area is available for their sorption. Neutralizing agents present in the bubble walls then react with the entrapped toxic gas or vapor to render it innocuous. The self-collapsing foam yields a processable liquid that may be reusable.

This proposed technology has potential applications for emergency control. Among these are fixed installations in plants, portable field units for use by emergency response teams and mobile units for treating materials handling releases at Superfund sites.

INTRODUCTION

Foam scrubbing can be used as a technique for mitigating emergency releases of gases, vapors, mists, aerosols or particulates by containing and scrubbing the released substances. Foam has the advantages of high surface area and positive control of vapors (through encapsulation). It also can be quickly generated whenever and wherever needed. A reagent can be added to the foaming solution to react with the absorbed gas or vapor.

This paper summarizes the information that is currently available on this subject and describes work currently underway by the U.S. Environmental Protection Agency (EPA). Judging from the literature, industrial experience and experimental results available to date, the potential usefulness of foam in mitigating accidental chemical releases is indeed promising.

Figures 1, 2 and 3 illustrate several possible applications of foam scrubbing to the control of emergency releases:

- For an indoor plant with an existing ventilation system, a foam generator can be installed in the ventilation system near its exhaust point, as shown in Figure 1. Any accidental release of a gas (i.e.,

pressure relief, rupture disk and vessel failure) within the plant could be treated by simply turning on the foam generator or through automatic alarm activation triggered by high contaminant concentration.

- Rapid, high pressure gas releases into the open atmosphere are the most difficult to detoxify. For an outdoor facility with potential leakage points such as flanges, loading connections, etc. that may permit formation of a vapor cloud, a foam generator can collect the released gases under suction, as shown in Figure 2. The generator can be either a portable or a fixed installation (depending on facility size). The gases can be collected using a suction fan and flexible ducts. Emergency response teams would require a portable version.

- A foam generator may be placed at the discharge of a pressure safety valve (PSV), as shown in Figure 3, so that any escaping gas would generate foam using its own pressure. Calculations have shown that some gases may not be directly treatable at high concentration, since the heat required to neutralize high concentrations may destroy the foam. In such cases, dilution air must be drawn into the foam in order to reduce the concentration of the toxic gas.

EXISTING VENTILATION SYSTEM   FOAM GENERATOR

ENCLOSED PROCESSING FACILITY
Figure 1
Schematic of an Application of Foam to Mitigate Vapor Release
at an Indoor Chemical Processing Facility

Handling the foam once it has served its purpose — capture, neutralization and collapse—depends in part on the needs of the specific plant. In some instances, if the collapsed liquid is neutral and innocuous, it can be allowed to drain naturally (like fire fighting foam). Alternatively, the liquid could drain into a catch basin for collection, treatment and environmentally-acceptable disposal or potential reuse.

Use of foam for emergency control is attractive because, unlike conventional equipment such as a scrubber, foam need not involve a large

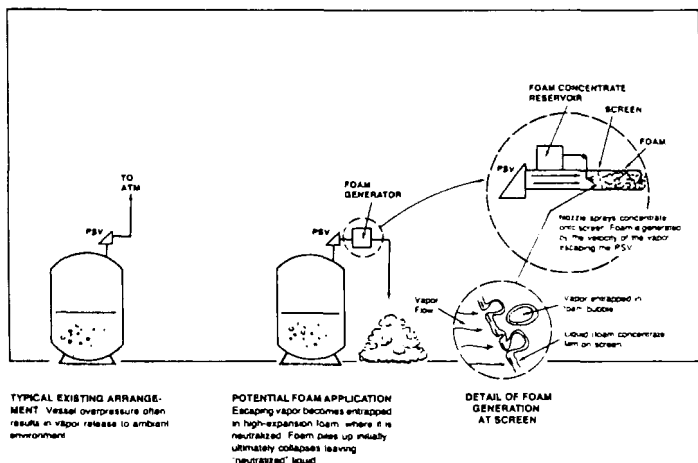
fixed installation. The foam generator and liquid reservoir are relatively small; they can remain on standby until needed. At that time, foam generation can be triggered either by emergency personnel or by an automatic system. The foam mass itself intrinsically provides the residence time needed for control. In conventional equipment, residence time can be extended only by increasing the size of the unit.
Figure 2
Schematic of an Application of Foam to Mitigate Vapor Release
from Miscellaneous Sources


Figure 3
Schematic of an Application of Foam to Mitigate
Vapor Release from Pressure Safety Valves (PSVs)

Potential applications of foam scrubbing for emergency control are many: the chemical industry (ammonia, hydrogen chloride, phosgene, sulfuric acid, formaldehyde and other substances), municipalities (chlorine tanks at water chlorination facilities) and emergency responders (chemical spills, tank truck accidents, etc.).

Foam scrubbing could be used at Superfund sites during excavation to safeguard workers and surrounding communities from the hazards of buried tanks or drums of volatile toxic materials. Nitrogen tetroxide facilities (U.S. Air Force) have been considered candidates for emergency foam scrubbing systems.

FOAM BASICS

Foams have very large surface areas, typically in the range of 1000 to more than 2500 m^2/m^3,[1] which appears very attractive for absorption. Partially offsetting this benefit, however, is the fact that the surfactant present in the bubble walls may retard the mass transfer of contaminants.[2] Most researchers have found some inhibition of absorption, although others have found an improvement.

Foams can be generated over a range of expansion ratios. The expansion ratio is the volume of foam generated per volume of liquid in the foam (foam concentrate).[3] For high expansion foam, the expansion ratio ranges from 200:1 to approximately 1000:1.[4] In practical terms, the expansion ratio is approximately equal to the volume of gas that

is treated per volume of liquid.

Commercial equipment used in foam generation generally consists of a screen or perforated plate against which the foam solution is sprayed. Air is either blown or aspirated through it to form the foam. A second type of device is the flooded plate generator in which the air is bubbled through a plate flooded with foam solution. Based on results to date, it is believed that existing types of foam generators can be used for foam scrubbing purposes.

SUMMARY OF PREVIOUS WORK

Collection of Gases

Researchers have studied the absorption in foam of numerous gases, including carbon dioxide, hydrogen sulfide, formaldehyde, acetaldehyde and mercaptans. Research has generally shown success in the removal of contaminants by foam. Also, tests in which reagents were incorporated into the foaming solution generally were able to both produce stable foams and to neutralize the absorbed gas.

Table 1 provides an overview of studies of absorption of gases into foams. These studies have included compounds that are of concern from an environmental emergency viewpoint, such as hydrogen sulfide, nitrous oxides, ammonia and formaldehyde.

Collection of Particulates

Table 2 presents an overview of studies of collection of particulates and aerosols into foam. Results, again, are generally positive, although complications due to factors such as particle agglomeration were encountered.

These results (e.g., Damle, Ref.[11]) show that collection efficiency increases for longer residence times and for smaller bubble sizes. For a bubble size of 0.8 mm, the particle removal over a residence time of 90 seconds ranged from 80% to nearly 100%.

Comparison with Alternative Techniques

A variety of techniques are currently available to prevent, control or mitigate accidental releases of hazardous air toxics. Preventive techniques include, for example, alarms and interlocks that facilitate corrective action before a release occurs. Control measures such as scrubbers, flares and other devices capture and destroy escaping contaminants before release. Finally, if a release does occur, mitigative measures such as water curtains can be used to reduce off-site impact.

Foam scrubbing falls into the categories of both control and mitigation. A foam generator can be used, like a scrubber, to protect against releases from process equipment or buildings. It also can be used to draw in a gas cloud from, for example, a leaking pipeline or vessel. (Strategic positioning of a unit where it might be needed must be considered.)

In the first case, the advantages of the foam generator are:

- Equipment is relatively small and can remain on standby until needed
- Large volumes of gas can be controlled with relatively small amounts of liquid
- Residence time can be provided within the foam mass, rather than a large, permanent vessel
- The foam generator can be readily sized for a large emergency flow [i.e., up to 30,000 cfm (850 m^3/min) per unit]

Techniques currently used for mitigation of vapor clouds include water sprays and water, steam and air curtains. Where liquid is also present, techniques include dilution, neutralization, temporary covering, freezing and ignition.[15,16]

The water, steam and air curtain techniques are primarily used to disperse the released gases. They have reduced concentrations by a factor of from 1.5 to 4, depending on wind speed.[12] Some scrubbing is also provided by water curtains, but only when very large water volumes are used. In tests with hydrofluoric acid, up to 50% of the acid was scrubbed.[17] The main disadvantages of these techniques are their relatively low efficiencies and the high levels of plant utilities required.

Based on the foam scrubbing efficiencies measured by previous researchers, this technique may, in many cases, provide better mitigation than the currently available alternative techniques.

Table 1

EXPERIMENTAL WORK UNDER THE U.S. EPA PROGRAM

The U.S. EPA is sponsoring an ongoing laboratory-scale testing program. This section describes the testing process as well as its results to date.

Test Setup

The test setup consists of a foam generator, a foam containment chamber and a sampling arrangement. Figure 4 illustrates the apparatus.

The foam generator is a modified 2-in. diameter air-aspirating unit of commercial design. The air intake is sealed and connected to gas cylinders. Nitrogen is used for these tests, and certified gas mixtures purchased from Matheson are used for test runs.

Premixed foam solution is supplied from a small vessel, pressurized by nitrogen to 25 to 50 psi. The nominal flow of foam solution is 0.22 gpm. The test gas flow is adjusted to vary the expansion ratio.

The containment chamber is a square, clear, rigid plastic box 2 ft x 2 ft x 1.5 ft, equal to 6 cu ft (170 L) in volume. At 300:1 expansion, the box will fill in 40 seconds. The box has a hinged top closure so that it can essentially be sealed once it is filled with foam. Top, side and bottom sampling ports are provided.

The chamber is mounted on a digital scale which records the weight of its contents. Drainage liquid, produced as the foam collapses, is collected in a graduated cylinder below the box. A thermocouple is inserted well within the box to monitor the temperature of the foam mass (i.e., for heat of reaction). The entire box is mounted in a laboratory fume hood.

Procedures

Run preparations include premixing the foam solution at 6% concentration. For these tests, MSA "P" Foam[R] was used. This is an anionic surfactant type for salt water containing alkyl lauryl sulfates, alcohols and long chain amides. When a reagent is added, it is mixed with the prepared foam solution. The vessel is then pressurized with nitrogen.

[5] Hexadecyltrimethylammonium bromide
[6] For particle size range of 0.3 to 10.0 um.

For each run, foam is blown, using certified test gas, to fill the test chamber. The chamber lid is open approximately 6 in. during filling and is then closed. Fill time is monitored and recorded for correlation with the estimated expansion time.

Bubble sizes are measured as an average, based on the number of bubble intersections in a 6-in. linear path at the surface of the box. Actual sizes of individual bubbles can vary up to a factor of two in either direction (half or twice the average).

After a specified time (5 min for most tests), the residual foam is collapsed by injecting a small amount of fine silica through an access port (with the chamber lid still closed), and a gas sample is drawn from the center of the chamber. A sample of the liquid drainage is taken at the same time. Liquid and gas samples are then analyzed for the test contaminant.

Analytical

To date, testing has been carried out using ammonia and chlorine as the test gases. The ammonia concentration in the gas phase is determined by titration of the extracted sample. In this procedure a gas sample, drawn from the chamber with a calibrated syringe, is injected through a bubbler into a fixed volume of 0.01 normal certified HCl solution to extract the NH^3 The solution is back-titrated with 0.1008 normal certified NaOH to neutralize the excess HCl and determine the NH^3 content. The free ammonia in the liquid phase is measured by direct titration of samples drawn from the drainage sump. Total liquid-phase ammonia is determined by the Kjeldahl method.

To determine chlorine in the gas phase, gas samples are extracted using potassium iodide solutions and subsequent titration with thiosulfate. For the liquid, samples are treated with KI and then back-titrated with thiosulfate. For tests where chloride is present, a silver nitrate titration is used.

Results

In test runs using a standard foam solution (i.e. not acid-modified) and ammonia concentrations of 1% and 5% by volume, an average of 60 to 65% of the ammonia was collected by the liquid. In most cases, the material balance agreed to within ± 10%. Table 3 presents the data for runs with standard foam solution, using ammonia at a starting concentration of 1%.

Table 3
Capture of 1% Ammonia by Unmodified Foam[1]

Exansion	Bubble size (in)	Final NH₃ (2) Liquid (%)	Gas (%)
147	.20	65.5	32.8
147	.22	65.5	32.2

258	.22	65.5	35.6
258	.25	65.0	35.1
390	.28	65.1	35.3
395	.30	64.2	34.0
500	.30	61.0	31.0
518	.27	61.3	31.4
512	.35	61.2	31.4

[1] MSA "P" Foam[R], 6% concentration.
[2] Percent of original ammonia. Ammonia added to nominal 1% concentration (actual 0.95%).

It should be noted that even the 30 to 35% of the ammonia that was found in the gas phase at the end of the runs is "controlled" (in the sense that it is entrapped within the bubbles). In a spill scenario, this ammonia would eventually be released, but at a much slower rate than the initial spill. Thus, downwind concentrations would be lessened not only by the amount reacted/absorbed in the liquid, but also by the effects of the time delay caused by ammonia entrapment in the foam.

Subsequent runs were made in which sulfuric acid was added to the premixed solution before blowing the foam. As shown in Figure 5, the capture of ammonia in the liquid phase was much improved by this modification. No ammonia was detected in the gas phase at the end of the run when the stoichiometric amount of sulfuric acid was used.

TEST CONDITIONS

Test gas:	1% ammonia in nitrogen
Neutralizing reagent:	Sulfuric acid
Expansion ratio:	150:1 to 500:1
Bubble size:	0.25-in. avg.
Residence time:	5 min.
Temperatures:	Ambient and 150°F

RESULTS
Figure 5
Capture of 1% Ammonia by Acid-modified Foam

Figure 6 shows similar data for the capture of 5% ammonia. Several runs were made in which the temperature of the blowing gas was raised to 150°F using a Calrod[R] sheathed heater with a downstream thermocouple for temperature control. These data are also shown.

A potential concern with foam is that the addition of acids and bases can cause a temperature rise that would lead to premature foam collapse. To this end, the temperature within the box was measured before and after it was filled with foam. Figure 7 shows that up to a 12°F

temperature increase occurred when treating 5% ammonia with acid-modified foam. Despite this temperature increase, the foam collapse rate was not excessive.

TEST CONDITIONS

Test gas:	5% ammonia in nitrogen
Neutralizing reagent:	Sulfuric acid
Expansion ratio:	150:1 to 500:1
Bubble size:	0.25-in avg.
Residence time:	5 min
Temperatures:	Ambient and 150°F
RESULTS

Capture of 5% Ammonia by Acid-modified Foam

GAS-PHASE TEMPERATURE RISE
Figure 7
Temperature Rise Resulting from Capture of Ammonia by Acid-modified Foam

A limited set of runs was carried out using chlorine in nitrogen as the test chemical. In this case, aqueous ammonia was added to consume the products of chlorine decomposition. Although not studied in detail, these products may include hypochlorite and chloramines, probably leading to a final product that is primarily ammonium chloride. Table 4 shows that up to 99% of the chlorine was collected in the liquid phase under the highest stiochiometry used.

Table 4
Collection of Chlorine by Aqueous Form

TEST CONDITIONS

Test Gas:	1% chlorine in nitrogen
Neutralizing reagent:	Ammonia
Expansion ratio:	250:1
Bubble size:	0.20-in average
Residence time:	8 min
Temperature:	Ambient
Foam type:	MSA "P" Foam², 6% concentration

RESULTS

Additive NH₃	Chlorine (% of original)	
% stoichiometric	Gas	Liquid
0	35.0	63.5
150	5.0	94.2
150*	Not detected	99.0

*Plus a copper salt to catalyze conversion of hypochlorite to HCl.

Current test work includes higher concentrations of ammonia (10% and 20%) and chlorine (5% and 10%). Although no quantitative data are yet available, preliminary runs have established that foam can be successfully generated at both the higher ammonia concentrations and the higher sulfuric acid concentrations needed to neutralize it.

Future runs will test phosgene and HF (initially at low concentrations) and will experiment with shorter time intervals.

CONCLUSIONS AND RECOMMENDATIONS

The results of the ongoing U.S. EPA experimentation with foam scrubbing are encouraging, as are the findings of previous researchers. A need still exists, however, for additional testing (with more compounds under varying conditions) and for trial operation on a larger scale to bring the foam concept to an industrial reality.

This project tentatively plans to carry out larger scale tests in a wind tunnel and/or at a host site. This testing will help to prove the process under realistic scenarios.

The accumulated test data indicate that foam technology can be a valuable addition to the range of available techniques for the control of hazardous emissions.

Integrated Zero-Emission Groundwater and Soil Remediation Facility at Lockheed, Burbank

Ron Derammelaere
AWD Technologies, Inc.
South San Francisco, California

Ron Helgerson
Lockheed Aeronautical Systems Company
Burbank, California

INTRODUCTION

The Lockheed Aeronautical Systems Company (LASC) has over 200 acres of aircraft manufacturing facilities located in Burbank, California. Among the famous aircraft that have been assembled at this facility are the P-38 Lightning, the F-104 Starfighter, the U-2 and the L-1011.

In late 1987, solvent-contaminated soil and groundwater were identified near Building 175. As a result, the Los Angeles Regional Water Quality Control Board (RWQCB) issued a Cleanup and Abatement order requiring soil and groundwater remediation to commence by Aug. 1, 1988 and Oct. 15, 1988 respectively.

LASC selected AWD Technologies, Inc. (AWD) to design, install and operate a treatment facility to meet the requirements of the RWQCB. AWD is a corporation created by The Dow Chemical Company, Guy F. Atkinson Company and Woodward-Clyde Consultants. AWD provides a comprehensive range of services for remediation of contaminated soil and groundwater and can draw upon the specialized resources and expertise of its founding companies.

TECHNOLOGIES INVOLVED

Two technologies were integrated in an innovative way. The two technologies were AquaDetox, a low-pressure steam stripping technology developed by Dow Chemical to extract volatile organic compounds (VOCs) from the groundwater, and Soil Vapor Extraction (SVE) treatment of the VOCs in the vadose zone. The following paragraphs describe the unique features of these technologies. Their integration into a zero emission treatment facility is described in a subsequent section.

AquaDetox

There has been an effort over the past several years to improve the efficiency of air stripping in removing contaminants from groundwater. This work has led to the development of the AquaDetox technology, which surpasses more conventional approaches to air stripping in terms of reduction efficiency. In most cases, AquaDetox can reduce contaminants in groundwater to below Maximum Contaminant Levels (MCLs) without liquid-phase carbon bed treatment. Moderate vacuum and deep vacuum AquaDetox steam stripping go even further, allowing the near total recovery of contaminants for possible recycling.

AquaDetox technology can be used to remove a wide variety of volatile compounds and many compounds that are normally considered "non-strippable" (i.e., those with boiling points in excess of 400°). The application of AquaDetox for the removal of compounds with boiling points greater than 400°F and the use of vacuum are patented by The Dow Chemical Company.

Stripping is commonly defined as a process to remove dissolved, volatile compounds from water. A carrier gas, such as air or steam, is passed through the contaminated water, with the volatile components being transferred from the water into the gas phase. While the physical principles involved are straightforward, the practice of stripping has undergone considerable development since the early 1970s.

Dow's effort has focused on:

- Development of the proper technical relationships that provide a clear understanding of the stripping process
- Application of these relationships, along with the correct hardware, to attain higher levels of contaminant removal than previously possible
- Development of the proper scale-up parameters to go from pilot units handling less than 1 gpm to production units handling greater than 3000 gpm
- Development of the conditions under which compounds with very high boiling points (e.g., 400°F) can be stripped from water
- Compilation of a vapor-liquid equilibrium data base with special emphasis on U.S. EPA priority pollutants

The effort necessary to address these criteria has been carried out by the Separations Section of the Applied Science and Technology Department of Dow. The research and development has been under the direction of Dr. Lanny Robbins. By the early 1980s, the result of this effort was the AquaDetox process, an innovative technology for the high efficiency stripping of organic contaminants from water.

AquaDetox can effectively strip more than 90 of the 110 volatile compounds listed in CFR 40, July 1, 1986, by the EPA (Table 1). The ability of AquaDetox to efficiently attain low levels of contamination in the effluent represents a major breakthrough. Conventional strippers will normally achieve only 95 to 98% removal of the contamination, whereas AquaDetox can achieve up to 99.99% removal.

Another major concern raised regarding conventional stripping systems is that they simply transfer contaminants from the water to the air. The contaminated air usually is treated over carbon beds, but still releases sometimes significant amounts of contaminants into the atmosphere. The AquaDetox steam stripper (moderate or deep vacuum) condenses the contaminated steam to form a multiphase liquid from which the liquid phase contaminants can be decanted for possible recycling. Only a small stream of non-condensable gases is emitted following carbon treatment.

There are three versions of the basis AquaDetox technology:

- Air Stripping AquaDetox
- Moderate Vacuum AquaDetox (requires steam)
- Deep Vacuum AquaDetox (does not require steam)

Typical schematic flow diagrams for each type of AquaDetox technology are included in the paper by Street, Robbins and Clark.[1]

Soil Vapor Extraction

Soil vapor extraction (SVE) is a technology commonly applied for

butylbenzyl phthalate	toxaphene

*Needs further pilot study to determine treatability

the in situ removal of VOCs from soil. A vacuum is applied to vadose zone extraction wells to induce air flows within the soil toward the wells. The air acts as a stripping medium which volatilizes the VOCs in the soil. Soil-gas from the extraction wells typically is treated in activated carbon beds before release to the atmosphere. Alternatively, the treated soil-gas is reinjected in the soil to control the direction of air flow in the soil.

LOCKHEED PROJECT

On Feb. 1, 1988, LASC awarded AWD a contract for pilot testing, design and installation of an integrated 1200-gpm groundwater treatment plant and 300-scfm SVE system. Fast-track project techniques were used and seven and half months later all systems of the $4 million project were operational.

Under AWD management, process engineering and design were performed by Dow Chemical engineers, the SVE conceptual design and permit acquisition were performed by Woodward-Clyde Consultants and construction was performed by a division of Guy F. Atkinson.

Integrated System

The integrated system consists of two basic processes: an AquaDetox vacuum stripping tower using low pressure steam and a soil-gas vapor extraction/reinjection process. The system removes VOCs from the groundwater and soil with no gaseous emissions to the atmosphere. Figure 1 shows a schematic flow diagram of the integrated system.

Integrating the two technologies creates a unique system. While the AquaDetox system extracts and treats contaminated groundwater, an array of SVE wells removes contaminated soil-gas from the vadose zone. The soil-gas is treated in activated carbon beds and then reinjected into the ground to sweep through the soil and remove additional contamination. The AquaDetox and SVE systems share a 3-bed granulated activated carbon (GAC) unit. When one of the GAC beds is regenerated, the steam and organic vapors are condensed in the secondary condenser of the AquaDetox system. Condensed organics are pumped to a storage tank for recycle; water condensate is pumped to the recycle tank for further treatment by the AquaDetox process; and non-condensables are transferred to the active GAC bed.

Groundwater Treatment Facility

The groundwater treatment technology at the Lockheed site is the Moderate Vacuum Steam Stripper (MVSS) AquaDetox system. Process flow diagrams are shown in Figures 2 and 3.

Contaminated groundwater is fed from extraction wells to a cross exchanger, where it is heated by the treated water. The heated water then enters the top of the stripping column (9 ft in diameter x 60 ft tall) and flows down the column, contacting the rising vapor flow generated by the introduction of steam to the bottom of the column. Under a pressure of 100 mm Hg absolute, the contaminants are stripped from the liquid into the vapor stream, which exits from the top of the column. The treated water leaves the bottom of the column. The treated water passes through the heat exchanger, where it is cooled and the contaminated feedwater is heated. The water exiting the treatment facility is thereby controlled to 9 to 10° F higher than the incoming groundwater.

The overhead vapors flow to a water-cooled condenser, where the water vapor is condensed and recycled back to the contaminated feedwater. The water for cooling the condenser is provided by diverting a portion of the cool feed stream through the condenser and back to the main feed stream.

Total condensation of the overhead vapors is not possible due to non-condensable gases from vacuum leaks and dissolved gas contained in the contaminated groundwater. These non-condensable vapors, carrying some water, inert gases and VOCs, enter a vacuum pump where they are compressed to atmospheric pressure. Cooling this compressed vapor stream results in condensation of water and VOCs.

The water phase is recycled to the contaminated feedwater and the organic solvent phase is withdrawn for reclamation by a contract recycler. The coolant for this secondary condenser is supplied from the feedwater as is done for the first condensing unit.

The vent stream from the secondary condenser contains the non-condensable VOCs and an equilibrium quantity of VOCs. This stream is passed through vapor-phase GAC prior to discharge into the reinjection wells of the SVE system.

Soil Vapor Extraction (SVE) System

Soil vapor extraction (SVE) is being used at the Lockheed site to remediate contaminated soil because of the relatively volatile character of the reported contaminants, the depth to groundwater in the range of approximately 140 to 150 feet and the predominantly coarse-grained nature of subsurface soils.

Figure 4 shows the locations of the extraction and reinjection wells. The design of the SVE system focused on the distribution of the wells to produce an effective and non-disruptive pneumatic flow regime. The effectiveness of the SVE depends on establishing radially inward flow (toward an extraction well) throughout the areas of probable soil contamination. The term non-disruptive pneumatic flow regime refers to injection well placement such that: (1) fugitive atmospheric emissions are not created and (2) soil-gas within the areas of probable soil contamination is not displaced from the zone of extraction well influence.

Extraction wells connected to a common header feed up to 300 cfm of contaminated soil-gas to the system for processing and decontamination via carbon adsorption. Liquids collected in the SVE scrubber sump are pumped to the water recycle tank for processing through the

Figure 1
Zero Air Emissions AquaDetox/VES
Integrated System

Figure 2
Lockheed Aqua Detox Flow Diagram

Figure 3
Lockheed VES Flow Diagram

AquaDetox tower. Vapors are exhausted to the GAC beds for hydrocarbon removal prior to reinjection.

Three GAC beds remove chlorinated hydrocarbons from SVE system extraction well soil-gas and from the vent gases from the AquaDetox system. The GAC beds are operated alternately, with two beds on-line in series while the remaining unit is being regenerated. Once each 8 hours, the regenerated off-line bed is placed in service and spent carbon bed is removed from service and regenerated. Steam is used to strip chlorinated hydrocarbons from the GAC units. The vapors from this regeneration process are condensed and processed in the AquaDetox separator.

Treated soil-gas is reinjected into the ground at depths ranging from 50 to 150 feet through the vadose zone. The soil-gas then sweeps horizontally through the contaminated soil, picking up additional hydrocarbons and is once again collected in the soil-gas extraction well system, where hydrocarbons are again removed.

SYSTEM OPERATION

The groundwater treatment plant operates at an average flow rate of 1000 gpm and the SVE operates at 170 cfm. The contaminants removed are listed in Table 2. Initially, total VOC concentrations were 12,000 mg/L in the groundwater and 6,000 mg/L in the soil-gas. After the integrated system had been operating several months, these concentrations decreased to 5,000 mg/L and 450 ppm, respectively. At these levels, the AquaDetox/SVE facility removes more than 70 pounds per day of PCE/TCE from the groundwater and 40 pounds per day from the soil-gas.

Table 2 lists the major contaminants in the groundwater feed to the treatment plant. Effluent analyses show that all contaminants were removed to below the analytical detection level (1 mg/L for most contaminants). These data equate to a removal efficiency greater than of 99.99%. The soil-gas treatment by two of three 3,500 pound carbon beds removes VOCs to below 2 ppm before the air is reinjected in the ground. These data equate to a removal efficiency of greater than 99%.

While the treatment plant has operated consistently at average design flow rates (95% availability factor) and has produced water effluents at non-detectable VOC concentrations, it has not been devoid of typical startup problems and one operational problem. Typical startup problems were failures of instrumentation and control software bugs, which have been resolved. A more persistent problem, however, has been caused by the high alkalinity of the groundwater and resulting calcium carbonate scaling in parts of the treatment plant.

The solubility of the calcium carbonate in the groundwater is reduced in two ways as the water is processed through the AquaDetox system. First, the water is heated. Second, carbon dioxide is removed during the stripping process in the column, thereby increasing the pH. Consequently, scaling occurs due to carbonate deposition. The principle disadvantage of scaling is the reduction in the heat transfer efficiency of the cross exchanger, resulting in greater steam consumption. Currently, an anti-scalant is injected in the feed water, but it cannot totally halt the scaling due to the subsequent removal of carbon dioxide and concomitant pH increase. Periodically, the heat exchanger is acid-treated to maintain its heat transfer properties.

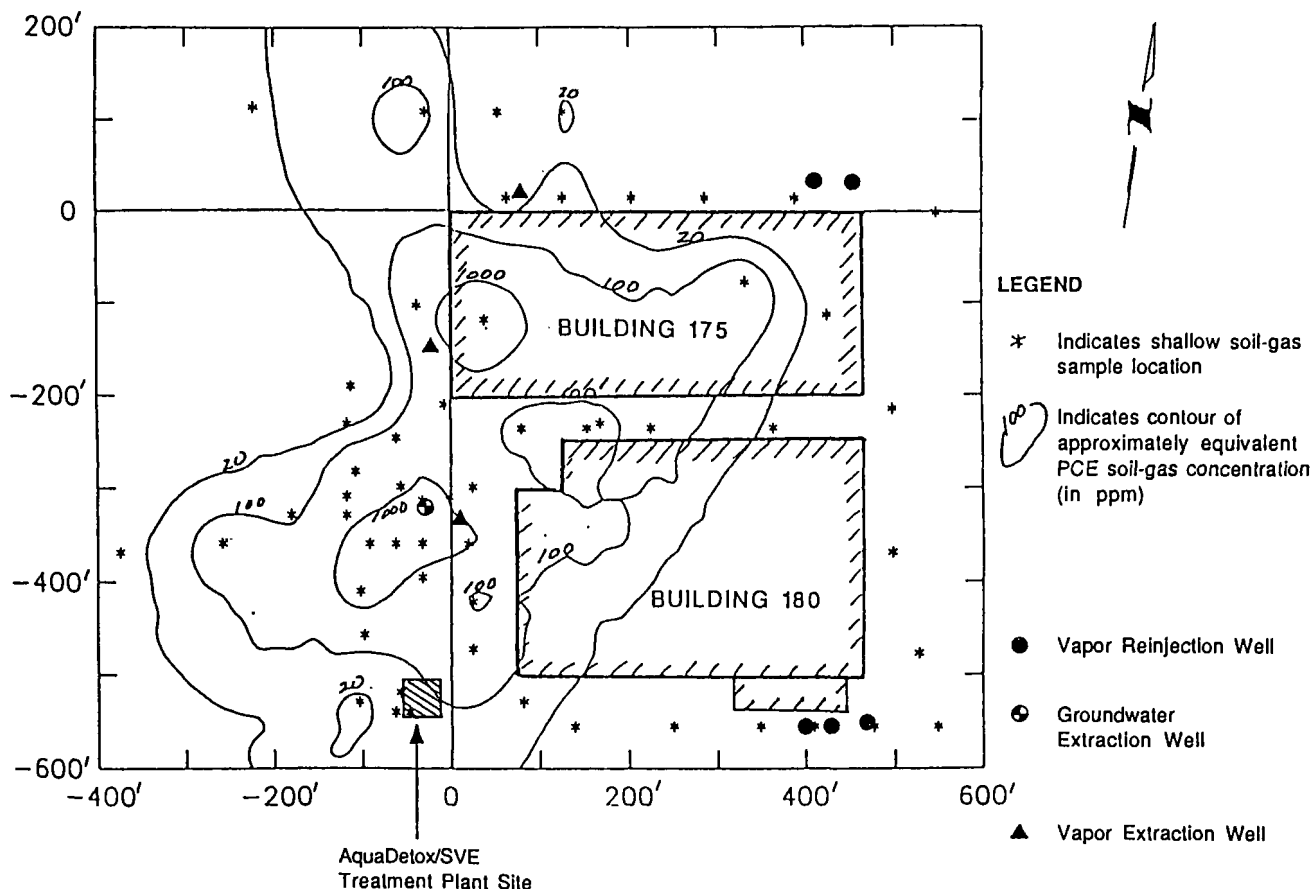
A design project is under way to resolve the scaling problem. A sulfuric acid injection system will be installed to control pH and eliminate scaling. The costs associated with the addition of sulfuric acid will be more than offset by: (1) eliminating anti-scalant injection; (2) eliminating phosphoric acid used to clean the heat exchanger periodically; and (3) lowering average steam consumption by improving heat exchanger efficiency. Less than 20% of the steam consumption in the AquaDetox facility is needed to strip contaminants; the other 80% is needed to raise the incoming water to its boiling point of 120°F at 100 mm Hg. The cross exchanger helps reduce this steam requirement by using heat from the effluent water. This is a highly energy-efficient and cost-


Figure 4
PCE and Soil-Gas Concentrations

effective approach and future systems will have even larger cross ex-
changers.

OPERATING COSTS

Annual operating costs for the AquaDetox/SVE plant are shown below.

Labor

One person was assigned full-time for the maintenance and opera-
tion of the facility, but after the first six months of operation his time
was reduced to three days per week. It is expected that after another
year of operation, no more than one day per week will be needed. Cur-
rent labor costs are approximately $8,000 per month.

Steam

Steam, which is provided by an existing Lockheed boiler, is costed
at $5.70 per 1,000 pounds. At a 1000 gpm flow rate, the steam con-
sumption is 3,500 lb/hr before calcium carbonate scaling shows its ef-
fect on the cross exchanger efficiency. An additional 340 lb/hr of steam
(equivalent continuous average) is used to regenerate the carbon beds.
This results in a total monthly steam consumption of 3,840 lb/hr at a
cost of $14,700.

Chemicals

Significant amounts of anti-scale and scale-removing chemicals are
currently being consumed, with limited success. A more appropriate
solution of sulfuric acid injection is currently being implemented and
will result in a monthly cost of $1,800.

Power

The power requirement to operate the treatment plant is 88 kW. At
a cost of $0.70 per kWh, this represents a monthly cost of $4,200. This
does not include the power consumption for the groundwater extrac-
tion well.

Table 2
Integrated System at Lockheed-Burbank
Design Criteria and Performance Results

AQUADETOX

Design Contaminants	Design Feed Water Concentration (ppb)	Actual (11/88) Influent Concentration (ppb)	Design Effluent Concentration (ppb)	Actual Effluent Concentration (ppb)
Trichloroethylene	3300.0	2200	4.5	<1

SVE

Contaminants	Actual (9/89) Extraction Gas (ppb)	Actual (9/89) Reinjection Gas (ppb)
Total Hydrocarbons	450,000	2,000
Tetrachloroethylene	420,000	365
Trichloroethylene	8,000	60

AQUADETOX/SVE OPERATING COSTS
LOCKHEED-BURBANK

		ANNUAL $	COST PER 1000 GALLONS (1)
Labor:	$8,000/month	$96,000	0.18
Steam:	3,840 lb/h x 8,760 h x 0.92 x $5.70/1000 lb	176,400	0.34
Chemicals:	$1,800/month	21,600	0.04
Power:	88 kW x 8760 h x 0.92 x 0.07 $/kWh	50,400	0.10
Supplies:	$5,000/month	60,000	0.11
		404,400	0.77

(1) Total gallons per year = 1000 gpm x 60 min/h x 8760 h/yr = 525 x 10⁶ gal/yr

Supplies

Miscellaneous supplies such as oil, replacement gauges, pump seals, spare parts, etc. cost about $5,000 per month.

Based on the above data, we calculate monthly operating costs average $33,700 or $.77 per 1000 gallons. Further reductions (particularly labor) are anticipated with time, and further savings in steam costs can be accomplished by installing larger cross exchangers.

Remedial Action Program for the Weldon Spring Quarry

Douglas E. Steffen
Morrison Knudsen Corporation
St. Louis, Missouri

Richard D. Ferguson, P.E.
Jacobs Engineering Group
St. Charles, Missouri

ABSTRACT

The U.S. Department of Energy (DOE) is responsible for conducting remedial actions at the Weldon Spring site, located approximately 30 mi southwest of St. Louis, Missouri. Because the site is listed on the NPL, these remedial actions are being carried out consistent with CERCLA. The site is adjacent to the U.S. Army Weldon Spring Training Area, which is also listed on the NPL.

The Weldon Spring site consists of two distinct geographical areas: (1) the chemical plant/raffinate pits (CPRP) area and (2) the quarry. These areas are approximately 4 mi apart.

The quarry was created by the U.S. Army during World War II as a source of foundation material for the construction of the Weldon Spring Ordnance Works (WSOW). After the war, the WSOW was demolished and the site was used by the Atomic Energy Commission to construct a uranium feed materials plant. Chemical and radioactive wastes for both the WSOW and uranium processing operations were dumped in the quarry. Approximately 95,000 yd³ of chemically and radioactively contaminated bulk waste and 3,000,000 gal of contaminated water, requiring remediation, are presently located in the quarry. The program to remediate the quarry, with the focus on the waste removal, is the subject of this paper.

The quarry is being remediated as two separate operable units. This strategy is necessitated by the fact that the heterogeneity of the quarry waste is such that it cannot be adequately characterized in place. Therefore, the basic strategy is to dewater the quarry and remove the solid waste using an observational approach. The waste will be transported to a temporary storage area located at the CPRP site, where it will be sorted and characterized prior to ultimate treatment and disposal. Waste removal and storage constitute the first operable unit. The second operable unit consists of remediating residual contamination in the quarry and remediating groundwater and vicinity properties.

Details of the remedial action program for the first operable unit are presented in this paper. The discussion includes methods to remove and treat the water, removal of the waste using an observational approach, protection of worker and public health and safety, and operation of the temporary storage area where the wastes will be segregated, characterized and stabilized.

INTRODUCTION

Between 1941 and 1967, the federal government manufactured trinitrotoluene (TNT) and dinitrotoluene (DNT) explosives and processed uranium and thorium ores at a facility located near Weldon Spring, Missouri. A limestone quarry was excavated nearby to provide construction material for the facility. This quarry was subsequently used as a disposal site for residues of explosives manufacturing and ore processing. Contaminated building rubble and equipment were also disposed in the quarry as a result of facility decontamination and demolition activities.

The processing facilities and the quarry have been placed on the NPL. The U.S. Department of Energy (DOE) is remediating the facilities and the quarry under the requirements of CERCLA. DOE contracted with MK-Ferguson Company as the Project Management Contractor (PMC), with Jacobs Engineering Group as the major preselected subcontractor. The PMC is responsible for environmental safety and health, site characterization, engineering, site remediation and waste management activities. Argonne National Laboratory is under a separate DOE contract to prepare environmental documents required by NEPA and CERCLA.

The quarry is being remediated as two separate operable units. The objectives of this paper are to: (1) describe the site operating history, (2) identify the potential hazards posed by the quarry to human health and the environment and (3) discuss the quarry remedial action program with emphasis on bulk waste removal.

WELDON SPRING SITE DESCRIPTION

The Weldon Spring Site (WSS) is located in heavily forested, rolling terrain approximately 30 mi southwest of St. Louis, Missouri. The site consists of two areas: (1) the chemical plant, and (2) the quarry which lies approximately 4 mi south of the chemical plant.

The U.S. EPA listed the quarry on the NPL in July 1987. This listing was expanded to include the chemical plant area in March 1989. At that time, the expanded listing was designated as the "Weldon Spring Quarry, Weldon Spring Chemical Plant and Weldon Spring Raffinate Pits (DOE/U.S. Army)." The quarry and chemical plant/raffinate pit (CPRP) areas are under the control of the U.S. Department of Energy. The CPRP area, covering approximately 220 ac, is immediately west of the U.S. Army Reserve and National Guard Training Area, which is also listed on the NPL, is the responsibility of the Department of the Army. Figure 1 presents a map of the WSS and vicinity.

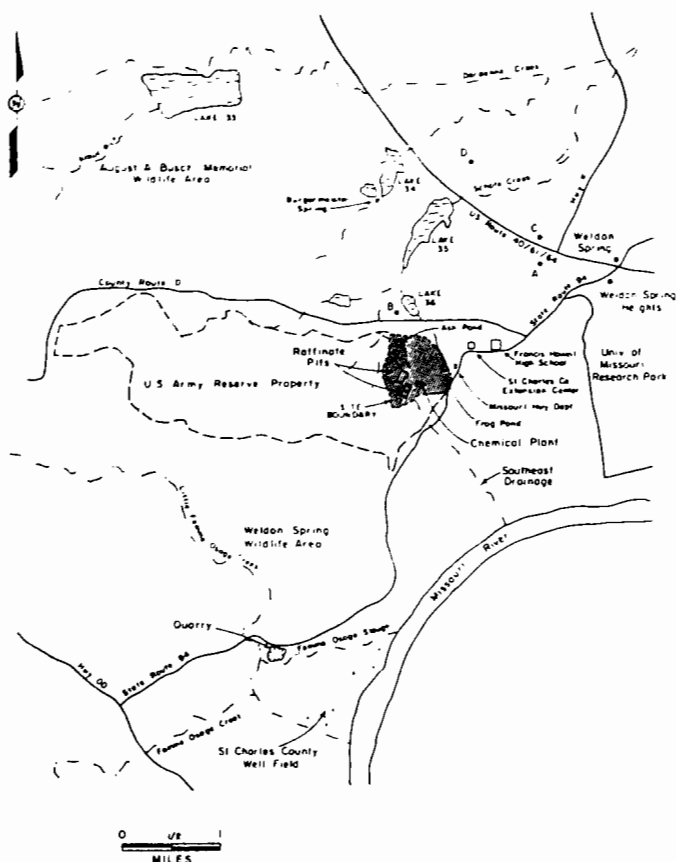
The quarry is surrounded by the Weldon Spring Wildlife Area. The Howell Island Wildlife Area is immediately west of the quarry across the Missouri River. These areas are managed by the Missouri Department of Conservation and are open to the public on a year-round basis for recreational purposes. While the quarry area is heavily wooded, agricultural crops are grown on alluvial terrain to the south.


Figure 1
Weldon Spring Site and Vicinity

The quarry was excavated in a limestone bluff above the Missouri River floodplain. The limestone formation contains cracks and fissures and the waste is in hydraulic communication with the local groundwater. The quarry is approximately 1,100 ft long and 450 ft wide, covering approximately 9 ac. Approximately 95,000 yd³ of radioactively and chemically contaminated waste have been placed in the quarry.[6]

The Missouri River is located approximately 1 mi to the southeast of the quarry. The Femme Osage Slough is located between the quarry and the river, approximately 0.15 mi south of the quarry. In addition, an alluvial well field, which supplies drinking water to more than 60,000 residents, is located 0.5 to 1 mi southeast and downgradient of the quarry. DOE has installed 26 groundwater monitoring wells on the north and south sides of the slough. Data from these wells show that groundwater between the quarry and the slough is contaminated with chemical and radioactive constituents leaking from the quarry. However, the slough appears to act as a hydrologic barrier to contaminant migration as no contamination has been detected in the monitoring or drinking water wells south of the slough.

The area of the quarry is sparsely populated, but sensitive human receptors in the vicinity must be considered. The quarry is adjacent to State Route 94, a well-traveled, north-south highway through the area. In addition, the surrounding wildlife area receives several thousand recreational visitors each year. A permanently occupied residence is located approximately 1 mi to the southwest of the quarry. Also, Francis Howell High School, located on Route 94 approximately 4.5 mi northeast of the quarry, serves approximately 2,300 students and faculty.

SITE HISTORY

In 1941, the U.S. Army acquired approximately 17,000 ac in St. Charles County, Missouri, for construction of the Weldon

Spring Ordnance Works. The quarry was excavated to provide building material for the ordnance works complex. The ordnance works produced TNT and DNT explosives between 1941 and 1944. Briefly reopened during 1945 and 1946, the ordnance works were subsequently closed and declared surplus by the Army in 1946. The excavated quarry was used by the Army during the 1940s for disposal of chemically contaminated materials.[4]

The Atomic Energy Commission (AEC) acquired a portion of the ordnance works property in 1955 to construct and operate a uranium feed material plant. The quarry was transferred to the AEC in 1960. The feed material plant was used to process uranium and thorium ore concentrates. The AEC used the quarry to dispose of radioactively contaminated material.[2] These materials included drummed and uncontained uranium and thorium residues, contaminated building rubble, process equipment and nitroaromatic residues from cleanup of the old ordnance works. The Army reacquired the chemical plant site in 1967 for conversion to a herbicide production facility. Although herbicide was never produced, the Army did partially decontaminate some of the buildings. Some rubble and process equipment were placed in the quarry. Since that time, the chemical plant and the quarry have been unused.[4] Throughout the period of waste disposal, a variety of waste was disposed in the quarry, including structural steel, drums of solid and liquid radioactive and chemical waste, process equipment, concrete, soil, etc.

QUARRY REMEDIATION PROGRAM

Protection of human health and the environment is the primary objective of the project. The proximity of the quarry to the county well field and the knowledge that the quarry is leaking provides a sense of urgency to the accomplishment of this objective. However, the situation is complicated by the fact that the heterogeneity of the quarry bulk waste precludes adequately characterizing the waste in place. Therefore, the Weldon Spring Site Remedial Action Project (WSSRAP) is carrying out a strategy to remediate the quarry as two separate operable units (SOUs); removal and temporary storage of the bulk waste and subsequent remediation of the residual contamination.

The first SOU, removal of the bulk waste, is actually an interim remedial action. Limited characterization data, coupled with historical information, were used to prepare bulk waste remedial investigation and base line risk evaluation reports. The preferred alternative presented in the feasibility study calls for expedited excavation of the waste and truck transport on a dedicated haul road to the chemical plant site for placement and characterization at a temporary storage facility.

Once the bulk waste is removed, the quarry floor and walls, groundwater and vicinity soils will be characterized to determine the nature and extent of contamination. This characterization program will be adequate to support the CERCLA decision-making process for final cleanup of the quarry and associated vicinity properties, which constitutes the second operable unit.

BULK WASTE REMOVAL

There are four basic components to bulk waste removal at the Weldon Spring Quarry:

- Quarry dewatering
- Bulk waste excavation
- Waste transportation
- Temporary waste storage

Quarry Dewatering

Approximately 6 mo prior to the initiation of excavation, dewatering will begin by treating the water in the quarry pond and discharging the effluent to the Missouri River under an NPDES permit. Figure 2 provides a layout of the quarry water treatment plant facilities.

The pond, which contains approximately 3 million gallons of

Figure 2
Quarry Water Treatment Plant Area

will begin flowing into the pond. The rate of inflow is expected to be approximately 3 gpm, based on pumping studies by Richardson.[3] Groundwater levels in the vicinity of the quarry will be monitored during pumping to verify gradient reversal. This water probably will be contaminated due to contact with the quarry bulk waste and contaminated soils in the vicinity of the quarry. In addition, storm water run off within the quarry will also be directed to the pond. The water treatment plant will also treat these sources of water. The plant will operate approximately 6 mo prior to bulk waste excavation in an effort to dewater the bulk waste as much as possible.

Bulk Waste Excavation

The physical characteristics of the bulk waste are not completely known. Therefore, the waste will be excavated using an observational method, which will provide a structured approach for managing uncertainty. This approach is based on available

Table 1
Selected Constituents in the Quarry Pond Water

Constituent	Average Concentration ($\mu g/l$)
Aluminum	45
Arsenic	75
Barium	110
Boron	540
Calcium	86,000

Thorium-232	16 pCi/l
Thorium-230	540 pCi/l
Radium-226	63 pCi/l

Adapted from DOE/OR/21548-039

water, is at the elevation of the water table. Table 1 gives a list of primary contaminants in the water.

The pond water will be pumped to a double-lined equalization basin and hence to the treatment plant. The plant is designed for a nominal treatment rate of 80 gpm. The plant is designed to treat the water to drinking water standards, where applicable. The plant is designed to treat uranium to a level of 30 picocuries per liter (pCi/L). The NPDES permit established a uranium effluent concentration not to exceed 100 pCi/L.[5]

The treatment process includes the following steps or stages:

- Lime addition to remove manganese and uranium
- Clarification/granular media filtration to remove suspended solids
- Activated alumina adsorption to remove arsenic and uranium
- Ion exchange to remove uranium
- Granular activated carbon to remove 2,4-DNT

Waste sludge from the process will be filter pressed to remove excess water and containerized for storage until a final disposal solution can be achieved.

The treated water will be discharged to one of two effluent ponds. The two ponds will allow for verification testing of the water prior to batch release. When one pond is filled to capacity, the treated water will be directed to the second pond. Each pond will have a capacity for approximately 10 days to allow for analytical testing of the effluent. If the effluent meets the discharge limitations, it will be released via a buried pipeline to the Missouri River.[5]

As the pond is drawn down, it is anticipated that groundwater

data and assumptions of field conditions. Reasonable deviations from the basic plan and mechanisms to identify their occurrence are defined. Plans are then developed to address adverse impacts as a result of the deviation. For example, the initial design will assume that waste will be adequately dewatered so that an excavation can be performed safely relative to the environment, operating personnel and equipment. Possible deviations to the plan that could be addressed by the observational method include:

- Additional dewatering requirements
- Greater concentrations of radon or chemical contamination than estimated
- Higher level of protection required for personnel
- Greater time required to perform the work
- Increased cost and schedule due to the inability to adequately dewater the material
- Stability of quarry walls
- Pockets of high concentrations of nitroaromatics

Present estimates place the maximum depth of the waste material at 40 ft.[1] Current conceptual plans call for the excavated waste to be cast directly behind the excavator where room will be available for gross sorting and loading onto trucks to be hauled away. Front-end loaders would be used for sorting and truck loading. A hydraulic crane could be used to remove, sort, stack and load heavy structural shapes. A bulldozer will work in the quarry floor at the face of the waste pile to push the waste to the back hoe. This method assumes the waste will be adequately dewatered. Trenches will be cut in the quarry floor to facilitate dewatering. Dewatering wells could be installed in the waste to enhance dewatering if necessary.

Emissions of airborne radon and radon daughter products may increase as the waste is dewatered and distributed. Ambient radon monitoring will be conducted within the quarry and at the rim for comparison with the annual environmental standard of 3 pCi/L. This level will be used as a guideline to define acceptable hourly average concentrations to protect the public and remedial action workers. If radon concentrations exceed acceptable levels, engineering controls will be implemented to mitigate emissions. In addition, current plans call for workers in the quarry to be outfitted in Level B protective gear with supplied air respirators. As required, equipment cabs will be enclosed and supplied with positive pressure air.[1]

Should engineering controls be required to reduce emissions, the following may be implemented:

- Application of water to reduce dust and radon
- Reduction of the exposed working face
- Cover exposed face with flexible membrane sheeting
- Application of mechanical ventilators
- Cessation of work until airborne concentrations stabilize

Waste Transportation

The quarry waste will be hauled to a temporary storage area located approximately 4 mi to the northeast at the chemical plant site. The haul will be accomplished on a dedicated road constructed for this purpose. Over-the-road 10 to 15 yard trucks will be used for the haul. The trucks will comply with U.S. Department of Transportation requirements for hauling hazardous and low-level radioactive waste.

During waste transportation activities, the following actions will be taken to promote safety and prevent the spread of contamination:

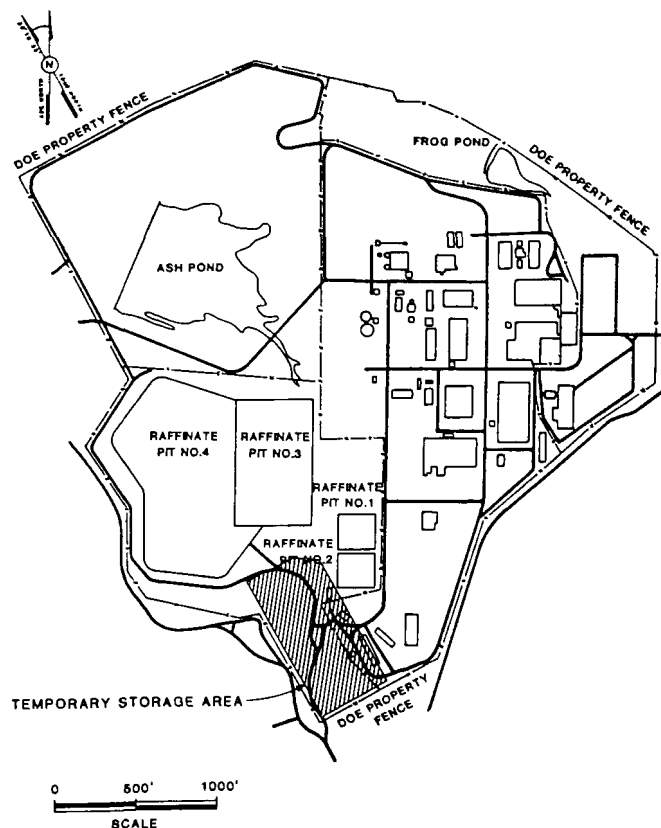
- The trucks will be decontaminated and scanned prior to leaving the quarry.
- The truck cargo boxes will be designed to meet the DOT definition of a strong, tight container, including leak-proof bottoms and secure covers.
- Truck speeds will be limited.


Figure 3
Temporary Storage Area Location

- Loads will be inspected to ensure that they are properly secured.
- Waste-tracking paperwork will accompany each load.
- Trucks will be radio-equipped for communication with other drivers and bulk waste supervisory personnel.
- Grade separation may be constructed at the quarry exit to allow passage of the haul road under Highway 94.
- The haul road will be regularly maintained and repaired.
- Water or chemical palliatives will be applied to the road surface to mitigate fugitive dust emissions.

Temporary Waste Storage Area

The temporary storage area (TSA) will be located in the southwest corner of the chemical plant site, immediately south of the four raffinate pits. The location of the TSA is shown in Figure 3. As the quarry bulk waste has not been adequately characterized to define the exact nature of contamination, the TSA will be designed and constructed consistent with RCRA requirements for a waste pile. A conceptual layout for the TSA is given in Figure 4.

The TSA, covering approximately 13 ac, will be designed to store approximately 140,000 yd³ of excavated material. The design volume will accommodate variations in the quantities of contaminated materials due to swelling of excavated material and will provide some allowance for over-excavation that may occur.

The TSA receiving/sorting area will be a reinforced concrete pad suitable for handling trucks and front-end loaders. The storage area will have separate sub-areas for materials based on their physical or chemical characteristics. A structure could be made available as a dust control contingency measure under the observational approach.

The storage area pad will consist of asphalt concrete surfacing underlain by a compacted aggregate base course over a layer of recompacted in-place clay having a maximum permeability of 1×10^{-7} cm/sec. The design life of the drainage facilities and pavements will be for 10 yr of operation. During this period these

facilities will be maintained in order to protect the environment.

All stormwater run-off and leachate from the TSA will drain by ditches and swales to collection ponds within the TSA. The storm water run-off and drainage system will be designed for a 25-yr, 24-hr storm (approximately 5.67 in. of precipitation). The design will also include a double liner and a leachate collection system. The retention basins will be lined with compacted clay and flexible membrane. Surface water run-on will be controlled by the use of diversion ditches to prevent contamination of clean surface water.

Bulk waste piles will be constructed with stable sideslopes. The top of fine-grained soil waste piles will be sloped to facilitate drainage. Dust suppression measures will be administered to control wind erosion in the nitroaromatically contaminated soil and fine-grained soil storage areas. Periodic spraying with water and binder agents will be used to control dust while the waste pile is being constructed. When a section of pile is completed, more permanent dust and radon control measures such as a flexible membrane liner, crusting agents, geotextile membrane and/or soil cover will be used.

Management of the TSA will include regular inspection of facilities, repair or reinforcement of engineering controls where required, monitoring for radon gas and removal of contaminated water from retention basins to the wastewater treatment facility. All storm water run-off and leachate collected from the TSA in the retention basins will be pumped to a newly-constructed wastewater treatment facility at the chemical plant site.

CONCLUSION

Environmental monitoring in the vicinity of the Weldon Spring Quarry indicates the quarry is leaking and that contaminants are migrating toward a county well field which provides potable water for over 60,000 people. In response to this potential health threat, the U.S. Department of Energy has determined that expedited response is necessary to remove the bulk waste from the quarry, which is the source of chemical and radiological contamination. This action is being carried out as a separate operable unit under CERCLA. The RI/FS process for this action has been completed and the Record of Decision is being negotiated with U.S. EPA Region VII. The proposed action involves:

- Treating contaminated surface and groundwater within the quarry
- Removing the bulk waste
- Transporting the bulk waste to the chemical plant site
- Segregating the waste by physical and contaminant characteristics
- Characterizing the waste to meet the requirements of CERCLA and associated ARARs
- Storing the waste in a secure and stable manner until the final remedial action is accomplished

ABSTRACT

A remediation program has been operating for approximately 20 months at an east-central Florida site contaminated with VOCs. The program consists of a groundwater recovery air strip-recharge system treating between 180 and 256 gpm. A two-dimensional groundwater flow and solute transport model was developed to project drawdowns and the movement of major contaminants. The placement of recovery wells and recharge trenches were subsequently based on the modeling effort. Ten recovery wells were installed to various depths in and around the contaminant plume for the purpose of capturing and retarding the off-site migration of 1,1-dichloroethene (DCE) and other VOCs. The recharge trenches were placed in the most heavily contaminated portion of the plume and along the north, east and southern sides of the plume, effectively recharging the aquifer on the lateral edges of the plume and blocking its downgradient movement.

Three types of data collected verify the effectiveness of the remediation program: (1) significant declines in concentration of various contaminants in monitoring wells placed at four depths throughout the plume; (2) declines in air-stripper influent concentration of DCE, 1,1-dichloroethane (DCA) and 1,1,1-trichloroethane (TCA); and (3) potentiometric surface data showing the drawdown of the water table at or near steady-state operation of the remediation system, indicates capture of the plume. The simulations largely agree with field data but differ because of the two-dimensional nature of the model.

Success of the program is attributed to the ability of transport modeling to optimize the recovery system, an extremely efficient air stripper (CarbonAir Services, Inc.), fully-screened recovery wells and an efficient and continuous maintenance effort.

INTRODUCTION

The purpose of this paper is to present evidence that an operating recovery program for a VOC-contamination problem is effectively removing contaminants and remediating the surficial aquifer. The site is located in east-central Florida near Melbourne adjacent to the Indian River (Intracoastal Waterway) and is the site of an electronics manufacturing firm specializing in high speed printers. The site is located within an industrial park and is largely covered by buildings, asphalt parking lots and concrete surfaces. Groundwater contamination is believed to have occurred as a consequence of discharge of waste VOC into a former holding tank. The site is underlain by coastal deposits of the Anastasia Formation consisting of sands, silts and clays.

Contamination assessment at the site began in 1986. After approval of a Remedial Action Program by the Florida Department of Environmental Regulation (FDER), startup of the air stripper began in October 1988. The contamination assessment revealed that contamination consisted primarily of six VOCs in the surficial aquifer which exceeded the FDER's Maximum Contaminant Levels (MCL) for drinking water. These contaminants included 1,1,1-trichloroethane (TCA), 1,2-dichloroethane (DCA), trichloroethene (TCE), 1,1-dichloroethene (DCE), tetrachloro-ethene (PCE) and vinyl chloride (VC). Two of these, DCE and TCA, have been found at high concentrations within the aquifer.

Seven other VOCs were found in the surficial aquifer but were not in concentrations above any standard or proposed standard. One of these, 1,1-dichloroethane (DCA), was found in significant concentrations within the aquifer.

Of all the contaminants, DCE has the most widespread distribution, and the remediation program was designed to recover contaminated groundwater underlying the maximum areal extent of the DCE plume (Fig. 1). The recovery effort was based on the conservative assumption that if all the DCE was captured, then all other contaminants would be captured as well.
Figure 1
Location of DCE Plume at the Site Based on the Contaminant Assessment

The remediation program was designed as a pump-and-treat system followed by recharge of the treated water back into the groundwater system through a series of trenches. Four trenches were originally constructed. Three supplemental recharge trenches were added in 1989

and early 1990 (Fig. 2). The trench locations were designed with a two-fold purpose: (1) to add water back into the cone of depression generated by the recovery system in order to flush out contaminants and (2) limit the lateral and downgradient migration of the plume.

GROUNDWATER FLOW MODEL

The U.S. Geological Survey Computer Model of "Two-Dimensional Solute Transport and Dispersion in Groundwater" was used to simulate groundwater flow, DCE movement and the action of both the recovery wells and the trenches. The original model was modified to simulate equilibrium controlled sorption-desorption for a linear isotherm. Adsorption of contaminants onto organic carbon in aquifer materials has a profound influence on contaminants as they flow through the aquifer. The rate at which contaminants migrate is heavily influenced by partitioning onto the organic matter which, in turn, is also dependent on both soil and contaminant properties. Modeling of DCE transport assumed retardation by organic material and a DCE velocity of less than that of groundwater.

GROUNDWATER RECOVERY WELLS

Based on the modeling, ten recovery wells were sited in the DCE plume. The recovery wells are 4 inches in diameter. The construction details of the wells are given in Table 1. The wells are screened from five feet below land surface to the bottom of the well. The depths of the recovery wells were adjusted based on the depth of the contamination determined from the monitoring well program. The wells were all equipped cost-effectively with 0.02-inch slotted polyvinyl chloride (PVC) screens. Each well was equipped with a stainless steel Grundfos 1.5 hp submersible well pump (Model SPO4-14).

The pumps were set within the screens at depths at which the maximum contamination occurred within the aquifer, again, based on the monitoring program. The pumps have an operating flow range of 11 to 28 gpm which can be adjusted by a valve on the discharge side of the well. Three of the wells are pumped at 20 gpm and 7 are pumped at a rate of 28 gpm for a total capacity of 256 gpm. Each well is equipped with a paddle wheel flow meter with a totalizer. All of the wells are manifolded together and pumped to the air stripper. Each recovery well is equipped with a water level control probe which will shut down an individual pump should the drawdown in the well fall below the operating level for the pump.

groundwater. JMM's computer modeling indicates that 95% of the originally dissolved DCE will be removed from groundwater during the 4-year remediation period dictated by the FDER.

RECHARGE TRENCHES

The water discharged from the air stripper flows into a distribution box and then flows by gravity to seven trenches located in and around the plume. The total length of the trenches for recharging the treated water to the ground is 2,300 feet. Four of the trenches were constructed to a depth of 5 feet, then lined with filter fabric. Slotted PVC (.040 inch) screen 4-inches in diameter was laid horizontally the length of the trench and the trench was backfilled with 30 inches of limestone gravel (0.75-inch). Two layers of 30 pound roof felt were placed over the filter fabric. The trenches were then backfilled to grade with fill and covered with either concrete or asphalt.

Three of the trenches were constructed to a depth of 16 feet and a width of 13.5 inches using a new technology which will be the subject of a separate paper. The trenches were constructed using a specialized leaky pipe and pipe-laying equipment. Using this equipment, 500 feet of trench could be excavated and the recharge pipe laid in just one hour. These trenches were cut deeper than the previous trenches to penetrate low permeability hardpan layers. The recharge pipe, which is five inches in diameter is installed at the bottom of the trench. The pipe is perforated with up to 32 openings per linear foot and is covered with a geotextile sock to keep sand from infiltrating into the pipe (Fig. 3). A vertical riser pipe connects the perforated pipe to the gravity distribution system.

GROUNDWATER MONITORING PROGRAM

Over the course of the project, 23 monitoring wells have been constructed. Their locations are shown in Figure 2 with respect to the DCE plume. These wells are 2-inch diameter PVC wells and are constructed to various depths into the aquifer (Table 2). The wells range in depth from 15 feet to 140 feet below land surface (bls) and have slotted PVC screens 5 to 10 feet in length.

Groundwater samples have been collected from these wells from two to five times depending on the well since July 1986. Groundwater samples were collected and analyzed before and after startup of the recovery well system and air stripper in order to determine the efficiency of the clean-up operation (Table 3).

Table 1

A total of 41 different VOCs have been monitored during the last four years. VOCs have been detected 198 times in the 23 monitoring wells during that period. Of these, 188 of the detections are associated with primarily decreasing trends. Nineteen of the 23 wells showed decreasing trends for DCE and 21 of 23 wells showed decreasing trends for both DCA and TCA. All wells with VOC concentrations greater than 1,000 μg/L have shown declines except for ML1-15.

A number of wells showed increases in VOC contamination during the May 1988 sampling which was conducted prior to startup of the remediation program. This increased contamination level is believed to be due to expansion of the plume as a consequence of both continuing advection and easy vertical movement due to the fully-screened nature of the recovery wells which were penetrating a significant thickness of the aquifer. The original contamination assessment showed that contaminants are stratified in the aquifer with a tongue of contaminants moving down into the aquifer as they move downgradient (Fig. 4). Prior to startup of the recovery wells, contaminants were free to continue to move both laterally downgradient and, also, to move down into the aquifer through the screens of the recovery wells which in several cases penetrated almost the entire thickness of the aquifer. Because the contamination site is in a recharge area, the vertical gradient is downward in the aquifer.

During the course of monitoring, one well, ML1-15, has shown a significant increase in VOC concentration. This last increase occurred during the last sampling in June 1990. Significant increases occurred in ML-1-15 when compared with previous sampling results for DCE and TCA. This well has been sampled again to confirm the analyses but at this time the analyses have not been completed. An adjacent recovery well was off during the period of time immediately preceding sampling and this may have allowed high contaminant concentrations to flow toward this well.

AIR STRIPPER INFLUENT TRENDS

Influent concentrations, while fluctuating, have shown an overall decline through the nearly 2 years the system has been operating. Figure 5 is a plot of concentration plotted versus time for DCE. Plots for DCA and TCA show similar trends. The fluctuations most likely reflect the influence of recovery pumps which were operating the day sampling was performed. Pump plugging and routine maintenance requires pumps to be taken out-of-service on a routine basis.

Air stripper samples are grab samples and naturally will be affected by which pumps are operating on the day sampling is performed. The overall decline in influent concentrations is a reflection of the declining VOC concentrations in the groundwater at the site. Oddly, the influent has yielded DCE, DCA and TCA concentrations which are higher than would be expected from the monitoring well data. This result may be due to the location of the recovery wells in the most heavily contaminated portion of the plume and because the recovery wells have long screens and may be receiving water from zones of the aquifer which are more heavily contaminated than the monitored zones.

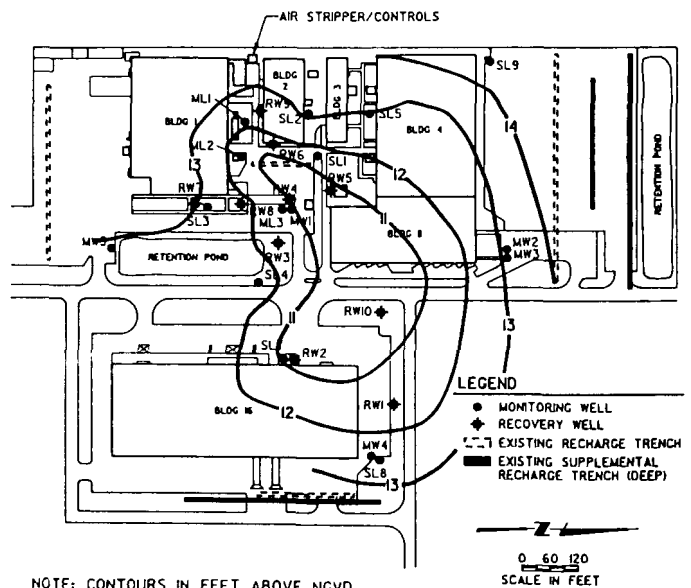
Figure 6
Model Predicted Groundwater Levels Under
Steady State Conditions with Pumpage at 270 gpm

POTENTIOMETRIC SURFACE DEPRESSION

Examination of the potentiometric head surface in the 40 foot deep wells indicates that a cone of depression has been generated by the operation of the recovery well system. Potentiometric surface maps for the wells were constructed to show prepumping potentiometric surface levels (October 10, 1988) and potentiometric surface levels at three different times during pumping (November 15, 1988, January 13, 1989 and April 19, 1989). These data indicate that within one month after starting up the system in October 1988, a significant cone of depression was generated. For all sampling dates, the cone of depression captures the plume which extends eastward and downgradient to monitor well SL-8. The cone of depression is from 2 to 3 feet deep at its center and parallels the northeastern axis of the recovery well system. The cone of depression appears to expand and contract depending on rainfall and the number of recovery wells in operation. Figure 6 shows the model predicted groundwater levels simulating recovery well operation at 270 gpm. Figures 7 and 8 show potentiometric head contours generated for two different times, November 15, 1988 and April 19, 1989, respectively, when actual operation of the recovery system was at a pumping rate of 180 to 200 gpm.

The comparison shows general agreement, but with some differences as would be expected. For the most part, the field data show greater drawdowns than predicted, even though the recovery wells are pumping less than the model simulates. The water levels portrayed in the model results are higher than the water levels found in the 40 foot deep wells. The 11 and 12 foot contours on the field data maps are much broader than on the computer simulated maps. In addition, the model shows greater expression of the recharge occurring from the recharge trenches than is expressed in the 40 foot deep monitoring wells. The limitations of a two-dimensional model in simulating a three-dimensional problem are apparent.

The correspondence between the modeling and the field data show that the model was an extremely effective way of siting the most effective locations for the recovery wells and predicting drawdowns in order to limit the expansion of the plume. Because of the layering and vertical heterogeneity in the aquifer system, the monitoring well network will not agree perfectly with the computer modeling simulations. The field data, however, indicate that the remediation system is working as planned


NOTE: CONTOURS IN FEET ABOVE NGVD.

Figure 7
Field Data Based Potentiometric Head Contours
for November 15, 1988

ELEMENTS OF SUCCESS

The success of the pump-and-treat program is attributed to four different elements. First, use of a groundwater flow and contaminant transport flow model to optimize the location of the recovery wells, predict plume capture and predict long-term recovery of the contaminants was an essential part of the design process for the remediation program.
Figure 8
Field Data Based Potentiometric Head Contours
for April 19, 1988

Second, the highly efficient (99.9%) air stripper has been flawless in operation requiring only periodic cleaning. The effluent from the air stripper has always shown removal of all VOCs to below MCLs even though influent concentrations were higher than anticipated when the stripper was designed.

Third, the fully screened recovery wells are removing contaminants from the entire thickness of the contaminated aquifer rather than discrete intervals. The influent to the air stripper is showing that some horizons in the aquifer are more contaminated than the monitored horizons. These data suggest that flow of the contaminants towards the recovery wells is being controlled to some extent by vertical heterogeneities.

Fourth, operation of the system has shown a continuing need for maintenance. This task has been carried out effectively and responsibly by the owner of the property. The operation of the system requires daily monitoring to ensure that the system is running properly. Pumping rates on all wells and flowrates into metered trenches are recorded daily. A decrease in pumping rate for any of the ten recovery wells indicates a need for maintenance of the pump. Pumps are maintained both in situ and periodically by removal and replacement of the pump. The packing in the air stripper is cleaned frequently to maximize VOC degassing. Trench operation is observed periodically particularly during rainfall events which raise water levels around the trenches. Flow of recharge water into trenches must be monitored to prevent overflow.

How Clean is Clean? The Importance of Using Site-Specific Factors in Developing Cleanup Levels At Hazardous Waste Sites

Basilis N. Stephanatos, Ph.D., P.E.
Environmental Resources Management, Inc.
Exton, Pennsylvania

ABSTRACT

One of the principal objectives of remedial actions at hazardous waste sites is to ensure that residual concentrations of constituents present at the sites following such actions will not pose a threat to human health and the environment. The purpose of this work is to develop target chemical concentrations in soils and groundwater at several hazardous waste sites in the United States to guide the source control remedial design to be undertaken at these sites. Establishing the basis for determining cleanup standards, or "how clean is clean," prior to the commencement of the remedial design activities is necessary because waste and contaminated soil volumes dictate the remedial design and drive the costs of the remedy.

Resolution of the "how clean is clean" question is achieved by designating a threshold level of contamination such that environmental media (soil, river sediments, etc.) containing hazardous residuals at that level or greater would be subjected to excavation, while media containing lower levels would be left undisturbed. A method has been developed for the derivation of cleanup criteria using quantitative risk assessment techniques.

This paper emphasizes the estimation of target release rates by means of environmental fate and transport modeling and the importance of using site-specific factors in developing cleanup levels at hazardous waste sites. The study shows that generic standards need to be modified prior to their application to specific sites because of the conservative assumptions that are incorporated into generic standards. The cleanup levels selected were the most stringent ones produced by the different exposure scenarios. The controlling exposure scenario for a particular compound depended on the physico-chemical and toxicological properties of the compound.

INTRODUCTION

Cleanup standards are developed on a site-specific basis to identify when removal of wastes and affected soils is complete. Establishing the basis for determining cleanup standards, or "how clean is clean," prior to commencement of the remedial design activities is necessary because waste and contaminated soil volumes dictate the remedial design and drive the costs of the remedy.

Cleanup standards are best derived by definition of the potential risks to human health and the environment posed by waste constituents remaining at the site after remediation is complete. Potential risks are defined following standard risk assessment protocols that focus on evaluation of the potential fate of residual waste constituents and their effect on potential receptors (i.e., humans, river organisms, etc.). The residual chemical concentrations at the site should assure protection of groundwater, surface water and air and pose no direct human contact hazard.

In many cases where risk-based cleanup levels are derived, it may be necessary to consider multiple potential exposure pathways and migration pathways for each medium. For instance, where on-site soils are contaminated, evaluation of the following scenarios may be required:

- Protection of the casual trespasser or on-site worker, considering dermal contact, incidental soil ingestion and inhalation of volatile compounds and fugitive dust from contaminated soil
- Protection of a shallow aquifer underlying a site, considering the migration of contaminants from the unsaturated zone to the saturated zone
- Protection of a deep aquifer, considering migration of contaminants from the shallow aquifer to the deeper unit
- Protection of a surface water body adjacent to a site, considering both contaminated surface run-off and contaminated groundwater discharges that may enter the water body

In such cases where multiple scenarios are evaluated, the most restrictive soil concentration for each chemical of concern is selected as the proposed alternate cleanup level.

For sites where the derivation of health-based cleanup levels is proposed, it is essential that comprehensive site data be collected. Rigorous definition of site characteristics is required, including the nature and extent of contamination, the estimation of key hydrologic parameters (i.e., hydraulic conductivity and aquifer thickness) and the determination of soil properties.

In general, conservative worst-case exposure scenarios are used to develop health-based standards or criteria. Unfortunately, real life exposures may differ from those used to develop the risk-based numbers. Thus, a risk-based number may "over protect" the individuals being exposed. This problem can be avoided by developing situation-specific risk-based cleanup criteria or by developing a range of exposure scenarios that can be selectively applied to specific situations. The most conservative approach is to use reasonable worst-case exposure scenarios to protect the most sensitive individual likely to be exposed. This is the approach used in this paper.

The soil cleanup guidelines derived represent contaminant levels that pose an acceptable human health risk and are protective of the environment for both present and future uses of the sites. The soil cleanup levels selected were the most stringent ones produced by the different exposure scenarios.

PURPOSE OF THE RISK ASSESSMENT

The primary purpose of this paper is to demonstrate the importance of assessing the effect various simplifying factors have on the development of cleanup levels. Examples of methods used to develop cleanup levels (in soil or water) at hazardous waste sites are presented.

Soil cleanup guidelines are derived by determining the amount of chemicals that can remain in the soil environment and result in accept-

able risks to human health and the environment. Since risk is a function of toxicity times exposure, an acceptable soil cleanup guideline may be determined by setting an acceptable risk level (e.g., 10^{-6}), determining the extent of human exposure to soil (in mg of soil per day per kilogram of body weight) and then solving for the concentration of chemical that can remain in site soils. In this risk analysis, U.S. EPA cancer potency factors were used to get the acceptable chronic intake values for chemical carcinogens. Reference doses (RfDs) were used to set the acceptable dose for non-carcinogenic chemicals.

The chemicals evaluated include all the compounds that were detected in the waste units; were found in high concentrations; or are toxic, mobile and persistent in the soil or groundwater environment.

The human and environmental exposure scenarios developed below are used as the basis for establishing soil and water cleanup guidelines. Soil and water cleanup guidelines are based upon human exposure to site surface soil, site groundwater, river water and fish ingestion, as well as protection of river aquatic life.

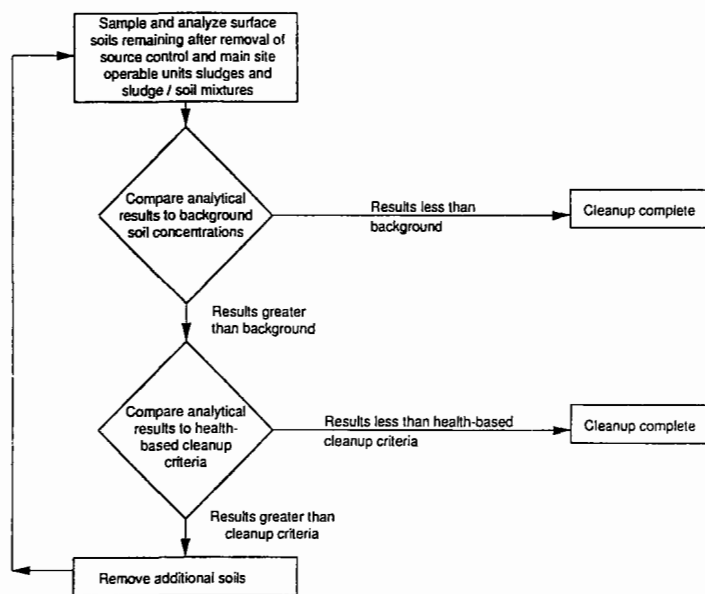
Figure 1 illustrates the general approach for determining when cleanup is complete at the site. The main steps used to determine the cleanup criteria using U.S. EPA-recommended procedures[1] are shown in Figure 2. These steps are briefly outlined below for an example assessment.


Figure 1
Cleanup Completion Decision Network

Step 1—Selection of Indicator Constituents

In accordance with U.S. EPA guidance[1], the indicator chemical list was developed on the basis of site concentration data, physical and chemical properties, fate and persistence information, toxicity and environmental mobility.

Generally, at sites where both carcinogens and non-carcinogens are involved, the carcinogens will drive the remedial design process because concentrations corresponding to the target risk range are usually lower than acceptable concentrations of non-carcinogens.

Step 2—Identification of Potential Exposure Pathways

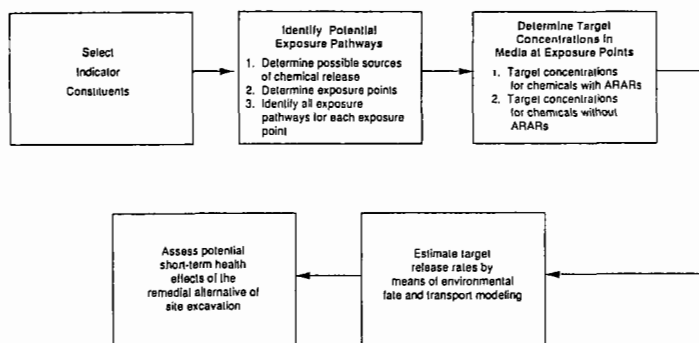
The second step in determining target concentrations for management of the site remediation is identifying potential exposure pathways. A complete exposure pathway has four components: a source of chemical release, an environmental transport medium, a point where human receptors could be exposed and a likely exposure route. In this step, determination is made of the possible sources of chemical release, environmental transport media, human exposure points and exposure routes.


Figure 2
Development of Performance Goals and
Analysis of Risks for Site Excavation

Possibilities of chemical releases to air, surface water, groundwater and soil from the sources on the site after remediation is complete are considered for establishing cleanup levels. Potential exposure pathways and receptors for the site are illustrated in Figure 3. It is always necessary to simplify the total number of exposure pathways illustrated in Figure 3 to include only probable worst-case analyses.

The cleanup guidelines are based on acceptable human health and environmental risks. This risk assessment attempts to establish a soil cleanup level that, among others, protects:

- Human health from direct contact with site surface soil
- Human health from ingestion of affected groundwater
- Human health from ingestion of affected creek water and ingestion of affected fish tissue
- The aquatic life of the creek
- Workers on the site

Step 3—Determination of Target Concentrations in Media at Exposure Points

In this task, target concentrations for each indicator chemical at the points of human exposure are calculated on the basis of applicable or relevant and appropriate requirements (ARARs) or the target cancer risk range of 10^{-4} to 10^{-7}. For all the indicator chemicals that have applicable or relevant and appropriate ambient concentration requirements, those requirements are used as the basis for the target concentration range. Otherwise, target concentrations are based on the target carcinogenic risk range. Where more than one ARAR is available, the requirement most appropriate for site exposure conditions is used.

Step 4—Estimate Target Release Rates

In this step, target release rates at the identified sources of release, after remediation of the affected soils and groundwater, are calculated by means of environmental fate and transport models. The *Superfund Exposure Assessment Manual*[2] describes available models and their limitations that can be used to assess contaminant fate and transport in air, surface water and groundwater. The estimated target release rates will help determine the design criteria for the site remediation alternatives.

Step 5—Assess Potential Short-Term Health Effects

After the target release rates have been estimated, the potential short-term public health effects of the remediation processes are considered. For the remedial steps, fugitive dust generation by heavy equipment and other remedial activities, fume inhalation and other temporary sources of chemical release are assessed and the most appropriate management practices are determined during implementation of the remedial design.

Public health evaluation of short-term effects is similar to the evaluation for chronic health effects. Predicted short-term chemical concentrations are compared with the acceptable intake of chemicals for subchronic exposures (AIS) to assess health risk.

FATE AND TRANSPORT MODELING

This section defines the environmental and modeling parameters and methods used for modeling the potential exposure scenarios described earlier in Step 2. Conservative assumptions are used throughout the modeling process to represent the reasonable worst-case situations.

The modeling process used at ERM, Inc., is a step-wise, interactive process that proceeds below:

Define Objective Criteria

These criteria refer to the level of modeling detail required to meet the objectives of the study. This step is a very crucial part of the modeling and states the questions that modeling is to answer (i.e., "What is the allowable concentration of benzo(a)pyrene that can remain on the site soils such that the resulting concentrations at the exposure point will be less than the health standard?").

Develop Modeling Approach

In this step a model's ability to simulate site-specific transport and fate is evaluated. The evaluation is based on the site's and contaminant's physical, chemical and biological characteristics. Some of the important transformation/transport processes and key factors affecting them are shown in Table 1. The simplest mathematical model that can achieve the defined objectives is usually selected. To quantify the uncertainty associated with modeling, a sensitivity analysis is conducted. In some cases calibration and validation data are used to reduce the uncertainty inherent in the results.

Modeling Results Review

If the questions identified in the first modeling step are adequately answered by the modeling results, the modeling is complete. Otherwise, a model able to better simulate the complex environmental setting is selected and the modeling process returns to the second step. It should be noted that for one constituent, the use of a simple model may be adequate, while for a second constituent a more complex model may be required. The step-wise modeling process ends when the results are accurate and meaningful enough to permit further decision-making.

Selection of Cleanup Level

Once the calculations are done for each of the exposure scenario, the scenario producing the most stringent cleanup requirement is selected

Table 1
Transformation/Transport Processes and Key Factors Affecting Them

PROCESS	KEY FACTOR
Biodegradation	Waste degradability Waste toxicity Acclimation of microbial community Aerobic/anaerobic conditions pH Temperature Nutrient concentrations
Photodegradation	Solar irradiation Exposed surface area

Adsorption	Effective surface area of soil Cation exchange capacity (CEC) Fraction of organic content (foc) of soil Octanol/water partition coefficient (Kow)
Dissolution	Solubility Soil pH and buffering capacity Complex formation

Source: U.S. EPA, 1989b (3)

as the cleanup level. It should be emphasized that the most stringent cleanup levels are not generated by the same exposure scenario for all chemicals. In general, the drinking water scenario is expected to be the controlling one for mobile chemicals, while the direct soil contact scenario is expected to be the controlling one for chemicals that bind strongly onto the soil.

METHODOLOGY FOR DETERMINING CLEANUP LEVELS

The generic equation for calculating cleanup levels (or acceptable chemical concentrations), based on acceptable chemical intakes, can
Figure 3
Schematic of Contaminant Transport Pathways

be written as (1):

$$\text{Intake} = \frac{Risk}{SF} \qquad (1)$$

where:

Intake = acceptable dose of chemical (mg/kg body weight-day)
Risk = acceptable carcinogenic risk (e.g., 1×10^{-6})
SF = carcinogenic Slope Factor (or CPF) (1/mg/kg-day)

The intake can be estimated from the following equation:

$$\text{Intake} = C \times CR \times EF \times ED/(BW \times AT) \qquad (2)$$

where:

C = the average chemical concentration contacted over the exposure period (mg/L or mg/kg)
CR = contact rate; the amount of contaminated medium contacted per unit time or event (L/day or mg/day)
EF = exposure frequency; describes how often exposure occurs (days/year)
ED = exposure duration; describes how long exposure occurs (years)
BW = body weight; the average body weight over the exposure period (kg)
AT = averaging time; period over which exposure is averaged (days)

Each intake variable in the above equation has a range of values. For Superfund exposure assessments, variable values for a given pathway are selected so that the combination of all intake variables results in an estimate of the reasonable maximum exposure for that pathway. Under this approach, some intake variables may not be at their individual maximum values but, when in combination with other variables, will result in estimates of the reasonable maximum exposure (RME). The *Exposure Factors Handbook*[5] provides the range of values for several common intake variables used in exposure assessments. For carcinogens, the acceptable chemical concentrations are determined by setting an acceptable risk level (e.g., 10^{-6}), making assumptions about the exposure factors in Equation 2 and solving Equations 1 and 2 for C.

CASE STUDY 1—SOIL CLEANUP LEVELS BASED ON FUGITIVE DUST EMISSIONS

At the King of Prussia Technical Corporation Site in New Jersey, one of the exposure scenarios involved the determination of soil cleanup levels for metals based on inhalation of fugitive dusts emitted from the site. A residual cancer risk of 10^{-6} under the inhalation pathway of exposure would provide a protective level to site contaminants. The most important parameter for this scenario was the particulate concentration in the air, which the U.S. EPA personnel set equal to 50 ug/m³ (the ambient air quality standard for particulates). However, this number represents the particulate air concentration caused by a number of sources, such as chemical plants, automobiles, etc.

The contribution to the particulate concentration by fugitive dust is very small. By performing site-specific air modeling, ERM personnel estimated this contribution to be 0.03 ug/m³, or more than three orders of magnitude less than the 50 ug/m³ concentration. This finding resulted in 1,667 times higher cleanup levels for the metals. Table 2 shows the cleanup levels obtained by use of the two different exposure levels to dust. This example (which is fairly common in soil cleanup level determinations) indicates the importance of using site-specific assumptions in the development of cleanup levels.

CASE STUDY 2—ESTIMATION OF BIOACCUMULATION OF PAHs IN FISH AT A SUPERFUND SITE IN PENNSYLVANIA

The objective of this work was to estimate the bioaccumulation of coal-tar related constituents by fish and sea lamprey tissue using actual field data and thus develop site-specific sediment cleanup levels. In the absence of actual fish-water concentration data, bioconcentration models have been used to provide estimates of potential bioaccumulation.

Table 2
Determination of Soil Cleanup Levels
Based on Fugitive Dust Emissions

Chemical	Soil Cleanup Level* (mg/kg)	Soil Cleanup Level** (mg/kg)
Beryllium	39	50,624
Cadmium	54	69,809
Chromium	8***	10,386
Nickel	129	25,490

* Assuming 50 mg/m3 as the inhalable fraction of particulates resulting from soil erosion.

** Assuming 0.03 mg/m3 as the inhalable fraction of particulates resulting from soil erosion.

*** Assuming all chromium is hexavalent chromium. That cleanup level becomes 152 mg/kg if assume that only 5 percent of the total chromium is Cr(VI).

It is generally accepted that the use of the available bioconcentration models significantly overestimates the PAH concentrations in the fish/shellfish tissue. To estimate a site-specific bioconcentration factor (BCF), measurements were taken of the subsurface soil, sediment, pore-water and biota tissue concentrations of PAHs. No PAHs were found in the fish tissue; however, the sea lamprey data indicated PAH bioaccumulation was a result of the coaltar discharges to surface water. Site-specific bioconcentration factors were calculated for each compound; these ranged between 1.0 L/kg and 378 L/kg.

Table 3 shows the calculated BCF factors along with some theoretical BCF values. It can be seen that the actual BCF values are several orders of magnitude less than the ones predicted by theoretical methods (such as using $K_o c$ or $K_o w$ values). The result of this work was to avoid cleaning up the sediments and subsurface soils due to the minimal risk posed to the aquatic life. If the theoretical BCF values were used in the sediment evaluation, then cleanup of a large portion of the site would be required.

METHODOLOGY FOR DETERMINING CLEANUP LEVELS BASED ON GROUNDWATER PROTECTION

The acceptable concentration in the leachate (C_L) emanating from contaminated soil for each chemical of concern is derived from the following relation[4]:

$$C_L = (S)(AF)(DF) \qquad (3)$$

where:

S = groundwater standard or guideline to be met at the exposure point (mg/L)
AF = attenuation or loss of contaminant during transport (dimensionless)
DF = aquifer dilution factor, defined as the ratio of the groundwater flow rate to the leachate rate (dimensionless)

Equation 3 will provide the acceptable chemical concentration in the soil water (unsaturated zone) above the groundwater table.

During soil sampling, the total (or bulk) soil concentration of a chemical is obtained. Therefore, the concentrations adsorbed onto the soil and in the vapor phase must also be taken into account. The bulk soil cleanup level is thus given by:

$$C_{bulk} = (n_w\, p_w\, C_L + p_b\, K_d\, C_L + n_a\, H\, C_L)/p_b \qquad (4)$$

where:

n_w = soil water content (cm³/cm³)
p_w = water density (kg/L)
p_b = soil bulk density (kg/L)
K_d = chemical adsorption coefficient (L/kg); for organic compounds, $K_d = (K_o c)\, (f_o c)$ where $K_o c$ is the organic car-

Approximately 100 to 150 sea lamprey larvae were collected, weighing 100 grams; they were ground "whole body."

bon partition coefficient (L/kg) and f_oc is the fraction of organic carbon in the soil

n_a = soil air content (cm³/cm³); conservatively assumed to be zero (i.e., no volatilization is occurring)

H = Henry's Law Constant (dimensionless)

Therefore, Equation 4 becomes:

$$C_{bulk} = (n_w P_w C_L + P_b K_d C_L)/P_b \qquad (5)$$

Substitution of Equation 3 into Equation 4 results in the final equation for the estimation of the bulk soil cleanup levels:

$$C_{bulk} = (n_w P_w/P_b + K_o cf_o c)(S)(AF)(DF) \qquad (6)$$

In order to solve for C_bulk, each of variables in Equation 6 must be determined.

As a chemical travels from the source area to a potential point of exposure, it will undergo attenuation along the travel path. Attenuation results from: (1) partitioning of mass between water (soil moisture), porous media (solid matrix) and air (vapor phase); (2) dispersion; and (3) biodegradation of the chemical. The attenuation factor can be defined (if chemical losses due to biodegradation are ignored) as the ratio of the concentration at the source to the concentration at the point of compliance.

The dilution factor (DF) accounts for the mixing of the percolating leachate produced in the soils with clean groundwater originating up-gradient of the source area. The dilution factor can be calculated by means of the following equation:

$$DF = \frac{(Q_p + Q_a)}{Q_p} \qquad (7)$$

where.

DF = dilution factor

Q_p = volumetric flow rate of the leachate (ft³/sec)

Q_a = volumetric flow rate of groundwater beneath the site (ft³/sec)

The use of this equation assumes that the upgradient groundwater is uncontaminated and that complete mixing will occur.

In order to determine the volume of leachate produced, a mass balance must be performed to estimate the groundwater recharge rate beneath the affected soils. To determine the groundwater flow beneath the site, Darcy's Law is used. It should be noted that conservative estimates of several parameters are made to simulate worst-case conditions, providing minimum dilution factors.

The case study below illustrates the importance of the dilution and attenuation factors in determining site-specific cleanup levels.

CASE STUDY 3—REFUSE/SOIL CLEANUP LEVELS DEVELOPMENT BASED ON GROUNDWATER PROTECTION

At another site in Pennsylvania, the U.S. EPA determined "threshold limits" for several compounds found in leachate (not necessarily the more toxic compounds, more mobile and the ones found at the highest concentrations at the site) by use of statistical techniques. The results are shown in the second column of Table 4.

ERM determined conservative cleanup levels for soils/refuse using Equation 6, incorporating a site-specific dilution factor of 1,928 and a conservative attenuation factor of 10.0. ERM's calculations are shown in column 6 of Table 4. Also shown in that table are cleanup levels for the same compounds determined at several other Superfund sites. The importance of using site-specific dilution and attenuation factors for the development of cleanup levels is clearly demonstrated.

CONCLUSIONS AND RECOMMENDATIONS

This paper has demonstrated the importance of using site-specific factors in the development of cleanup levels at hazardous waste sites. In general, much uncertainty is associated with estimating the residual chemical concentrations that will pose no threat to human health and the environment. There are uncertainties associated with the indicator chemical selection and with the toxicity values for each substance, as well as uncertainties inherent in the exposure assessment and in the

site characterization process. Most of the uncertainties are associated with the exposure assessment and these need to be addressed in the development of cleanup levels: (1) characterization of the physical setting, (2) data analysis and simplifying assumptions made and (3) fate and transport of chemicals and exposure parameter values. Some of the sources of uncertainty can be quantified, while others are best addressed qualitatively.

If a site-specific cleanup level determination is made, a large amount of site- and chemical-specific data may be required. ERM recommends the collection of data in a phased approach that helps focus on the areas of a site that drive the remediation costs. The justification of collecting more data will depend on the benefit of achieving more realistic cleanup levels.

Dynamic Compaction for Hazardous Waste Sites

M. Durrani
Ebasco Services Inc.
Norcross, Georgia

ABSTRACT

The objectives of a site closure scheme under both the Superfund and NRC guidelines are to address specific site concerns and to protect human health and environment. These objectives can be achieved by developing and combining the various available technologies which will fit the needs of the remedial action objectives of a site. Construction of an infiltration barrier or a cap over the waste material is most often considered as one alternative. The major performance requirement of a cap is its stability, which depends upon the compactness of the waste material and subsurface soils. To avoid the cracking or disintegration of the cap, it must be placed over materials which do not settle.

This paper will discuss innovative techniques to treat in situ waste materials and subsurface soils to reduce or eliminate as much as possible the risk of cap failure due to total or differential settlements. The use of the dynamic compaction method in order to reduce the permeability and increase the stability of the waste material and subsurface soils is presented.

Dynamic compaction is an innovative technique which involves repeated dropping of a heavy weight over the waste material in order to consolidate it and the underlying soils. This method has been used successfully in the past on some hazardous waste sites in the United States.

INTRODUCTION

The development of soil improvement methods started with the realization that it could be more cost-effective to increase the mechanical properties of waste materials and soils rather than ignore the problem and select other expensive options. There are various techniques available for the improvement of mechanical properties of waste fill and the soil below it using various types of energies, with and without adding new materials. This paper describes "dynamic consolidation," a method using mechanical energy to improve engineering properties of waste fill and soil at depth, both above and below the groundwater table. This method is ideally suited for loose waste fills and loose to very loose sands with some silt to a depth up to 25 feet within a minimum time frame.

The method basically consists of providing large energy impacts at the top of the waste fill which usually is covered with a few feet thick layer of granular soil. Weights ranging from 12 to 200 tons are dropped from a height varying from 15 to 120 feet. As the waste contents located on the surface or in a trench densify, backfill soil is added to the resulting depressions or craters. The backfill soil is compacted over the compacted materials. The mechanism of this process has been previously explained by many authors. In any type of unsaturated material, the shock wave generated by the impact causes compaction as in a common Proctor test. In waste or soils below the water table, P-wave first causes partial to full liquefaction and then S-wave and Raleigh waves rearrange the waste or soil grain structure into a dense state. The results of using this method are dramatic and immediate. Surface settlement achieved is typically 2 to 5 percent or more of the thickness of the loose layer treated by impacts. Porewater pressure builds up instantaneously with some boiling appearing at the surface which then dissipates rapidly. Strength, in terms of Bearing Capacity of subsurface soils, is typically improved by a factor of 2 to 4. Compressibility in terms of total and differential settlements is reduced by a factor of 3 to 10.

DESIGNING IMPROVEMENT

Designing improvement utilizing the dynamic consolidation process requires the following steps:

Pretesting

The first step, termed as pretesting, consists of determining the in situ condition of the waste material and soils below it. This condition typically can be measured in terms of standard penetration test (SPT) values (ASTM D-1586) or dutch cone test (DCT) resistance (ASTM D-3441). Based on the results of the above, test evaluations are made regarding the existing state of compactness of the waste and soils. A criterion is then established which describes to what maximum density the waste and soils below it can be effectively compacted. This criterion is in terms of higher SPT or DCT values. Sometimes a small test program of actual dynamic consolidation is performed to establish the compaction criterion for a specific site.

Equipment Selection

The next step is the selection of dynamic consolidation equipment and processes which lead to the established criterion. This phase of the program involves theoretical calculations to justify the parameters for the consolidation process. These parameters include the selection of weight and crane, height of drop, grid pattern for drops, number of blows at each drop location and number of passes required. Preliminary values of the above parameters can be established from the relationships previously established based on a large number of dynamic consolidation jobs completed in the past.

Based on 900 sites investigated, we have determined the following relationship can be used:

$$D = CS\ WH \tag{1}$$

where:

D = effective depth of waste/soil to be improved (Meters)
W = weight being dropped (Metric tones)
H = height of the drop (Meters)
C = speed factor (0.9 for cable drop and 1.2 for free fall)

S = Soil structure factor (0.7 for homogeneous fill and 0.3 for layered heterogeneous fill)

Grid pattern and number of phases are selected based on past experience on similar jobs.

Field Test

After establishing preliminary energy parameters, afield test on a small representative area generally is conducted prior to each phase to determine the optimum number of blows required for each phase. Penetration of weight into waste material in terms of depth of the crater formed is measured for each blow. After a certain number of blows, the depth of the crater formed does not increase. This result indicates that the maximum densification has been achieved. At this point, any additional application of energy will be unproductive. General practice is to obtain the number of blows at 80 percent of the cumulative weight penetration at which no significant penetration in the crater takes place. This number of blows is used as the production densification criterion for the rest of the job.

Production Densification

After selecting energy, grid and number of blows required for each phase, production densification is carried out. Instrumentation is provided to measure and control the generation of porewater pressures due to impact loadings. The time interval between two production phases is based on the time required for total dissipation of porewater pressure. If dynamic consolidation is performed in the close proximity of the existing structures, it is desirable to establish a minimum distance between the impact point and the structure based on the surface particle velocity generated by the impact. Generally, a limiting particle velocity of 25 mm per second for new structures and 8 mm per second for old, already cracked structures is used as a guideline.

Post Testing

After production densification, a post-testing program is conducted to verify the accomplished improvements. Usually the same tests are conducted which were used at the pretesting stage. Post-testing locations are selected close to the pre-test locations. Both test results are plotted together with depth to show the improvements.

EXPERIENCE ON HAZARDOUS WASTE SITES

The most recent applications of dynamic compaction on low-level radioactive waste sites are at the Oak Ridge National Laboratory and the Savannah River Project sites. Limited dynamic compaction also has been performed at the Hanford, Washington site with positive results.

Dynamic compaction for the above projects was performed on trenches containing wastes prior to installation of the cap. Penetration tests were used in order to verify that the compacted waste material and soils below it had been consolidated to the consistency similar to the adjacent in situ soils. A volume reduction ranging from 56 to 115 percent in the waste trenches was reported in one of the projects. No radiation exposures exceeding the background levels were reported on any of the above projects.

CONCERNS

There are some major concerns regarding the effects of dynamic consolidation over a hazardous waste site. One concern is that the impact

energy will cause additional leakage of the wastes due to the crushing of waste sealed in drums, fiberboard or cardboard boxes. However, experience shows that most of the sealed containers begin corroding and start progressively degrading with respect to time and are partially crushed due to the weight of overlying materials. All sealed containers must be assumed to fail at some point in the future. Therefore, it may be advantageous to accelerate this process of failure during the dynamic compaction process since any released liquids can be removed and treated more effectively prior to construction of the final closure cap. Based on the above, it is concluded that the benefits of treating wastes by dynamic consolidation process outweigh its risks.

The second concern about the dynamic consolidation process is that it may have an adverse effect on the geological and hydrologic conditions beneath the base of the waste containment. In evaluating this concern, both the vertical force and the generated seismic waves must be considered. Impact stress and its attenuation from an impact point has been researched and tested extensively by many authors.

Based on existing data, by monitoring and optimizating the stresses during the test program, an acceptable production energy level can be selected which will have no adverse effect on subsurface geologic and hydrologic conditions.

The next concern is the effect of dynamic consolidation on workers' safety. The work hazards of greatest concern are those associated with the operation of the heavy equipment such as cranes. Experience has shown that at many low-level radioactive waste sites, the radiation exposures resulting from dynamic consolidation did not exceed background levels. However, because the process has the potential risk of causing releases, the addition of a layer of clean granular material on top of waste material as suggested earlier is recommended. This step will reduce the risk of any potential releases to a minimum. This can be verified by health physics personnel during the test program as well as during the production densification.

CONCLUSION

Worldwide dynamic compaction experience and experience at some low-level radioactive waste sites provides a substantial basis to positively evaluate the possibility of dynamic consolidation on future hazardous waste sites.

Analytical Methods For Petroleum Hydrocarbons

Gary Walters
Kim Zilis
Elizabeth Wessling
Mike Hoffman
Enseco—Rocky Mountain Analytical Laboratory (Enseco-RMAL)
Arvada, Colorado

ABSTRACT

There are currently a wide variety of methods available for the analysis of petroleum products in environmental samples. An indicator test like Total Petroleum Hydrocarbons by Infrared Spectroscopy (U.S. EPA Method 418.1) and analyte-specific tests like Methods 8020, 8240, 8100, or 8270 can only be indirectly related to petroleum products. The goal of our efforts has been to develop alternative techniques to provide reliable measurement of a full range of petroleum products at environmental levels at reasonable cost. These methods can be used at hazardous waste sites in addition to target parameter techniques to provide information on petroleum product contamination.

The suggested methods are all based on gas chromatography with flame ionization detection (GC/FID). This technique has been used extensively to characterize petroleum products and is the basis of many quality control procedures used in the petroleum industry. The methods are designed to provide a "Total Hydrocarbon" value based on the GC/FID area relative to a reference standard. Quantitation is reliable and consistent, and bias to specific projects can be measured. The boiling point or carbon range may be defined, and project identification also is possible.

The analytical methods include a purge-and-trap "Volatile" method termed "Gasoline Range Organics" which includes measurement of gasoline and BTEX. The "Semivolatile" method is termed "Total Chromatographable Organics" and is designed to measure other products (diesel, kerosene and motor oil) and provide carbon range information. An "Oil Spill" method is designed specifically for crude oil and is termed "Petroleum Hydrocarbons."

INTRODUCTION

At many hazardous waste sites, contamination of the environment by various petroleum products has resulted in a variety of laboratory techniques to determine the extent of contamination. An indicator test such as Total Petroleum Hydrocarbons by Infrared Spectroscopy (U.S. EPA Method 418.1) is known to have a low recovery for gasoline[1,2] and is susceptible to a significant positive bias when applied to some soil types.[3] Analyte specific tests (U.S. EPA Method 8020 and 8040) only measure selected components of gasoline (e.g., BTEX). The limitations of these tests have been well-documented.[1,2] A variety of Gas Chromatography/Flame Ionization Detection (GC/FID) methods have been developed including ASTM Method D3328-78[4] for "waterborne oil" and the California Department of Health Services "modified Method 8015."[5]

The wide array of methods available for petroleum hydrocarbon analysis provide data of varying and questionable quality. The approach used in our work was to evaluate the existing methods and establish improved methods based on GC/FID (including documented perfor-

mance). As discussed below, an analytical protocol which provides a reliable measurement of a full range of petroleum products at environmental levels at a reasonable cost was developed.

DESCRIPTION OF PETROLEUM PRODUCTS

Petroleum products are comprised of a range of individual hydrocarbons. Figure 1 condensed from the ASTM *Manual on Hydrocarbon Analysis*,[6] shows the number of carbon atoms and boiling point range of several common products.

No. of Carbon Atoms	C_2	C_4	C_6	C_8	C_{10}	C_{12}	C_{14}	C_{16}	C_{18}	C_{20}	$>C_{20}$
Boiling Pt., °C	-89	-0.5	69	126	174	216	253	287	316	343	

Butanes

Gasoline

Diesel

Fuel Oil

Wax

Figure 1
Description of Petroleum Products

Petroleum product specifications are based on criteria such as distillation start/end points, octane ratings for gasoline and cetane ratings for diesel fuel. Thus, the concentration of individual hydrocarbons (and groups like paraffins, olefins, napthenes and aromatics) may vary significantly from one vendor to the next for a given product. Various products may contain many of the same compounds in different relative amounts. To reliably measure petroleum products, methods must adjust for these variations.

EXISTING ANALYTICAL METHODS

Total Petroleum Hydrocarbons (TPH)

Several versions of the TPH or oil and grease methods are available. Standard Methods 5520A (formerly 503) includes three methods for liquids: the partition-gravimetric method (B), the partition-infrared method (C) and the filtration-soxhlet method (D), plus a soxhlet method for sludges (E).[7] Calibration of the infrared spectrophotometer (Method C) requires a reference oil (by volume—37.5% iso-octane, 37.5% hexadecane and 25% benzene). Method F is silica gel cleanup which removes polar fats from animal and vegetable sources and makes

the test more specific for nonpolar petroleum hydrocarbons.

Method 413.1 measures Total Recoverable Oil and Grease using a separatory funnel extraction and gravimetric determination.[8] Method 413.2 replaces the gravimetric determination with an infrared measurement. Calibration uses a reference oil (by volume 37.5% n-hexadecane, 37.5% iso-octane and 25% chlorobenzene). Method 418.1 (Total Recoverable Petroleum Hydrocarbons) is similar to 413.2 except 418.1 adds a silica gel cleanup. The foregoing are water methods, but 418.1 frequently is modified using a soxhlet or sonication extraction for the analysis of soils. The U.S. EPA has also published two methods, 9070 and 9071, in *SW 846*[9] for oil and grease with gravimetric determination in water and sludge, respectively.

A modification of the TPH method has been developed by the Chevron Research Company.[10] This Modified Oven Drying Technique (MODT) determines the oil, water and solids concentration of wastes and soils. The three phases are recovered separately, allowing for a weight closure check and further characterization of each phase if necessary.

Except for the MODT method, the TPH methods are U.S. EPA approved, well-established and most commercial laboratories are very familiar with the techniques. These methods are relatively quick and inexpensive. However, there are some definite disadvantages to the TPH tests. The extraction solvent used for these tests is Freon, which will become increasingly difficult to obtain. In addition, many heavy distillates are poorly soluble in Freon and are not effectively extracted.

TPH tests have low recovery for volatile hydrocarbons, like gasoline. Volatile components are lost during the concentration step of the gravimetric method. Infrared calibration with the required reference oil assumes the unknown sample is 25% aromatic. This assumption can lead to significant bias if a sample is 100% (or 0%) aromatic. One study[3] has indicated potential false positive TPH IR results when the test is performed on clay or limestone soils.

Without the silica gel cleanup, TPH tests will measure vegetable or animal hydrocarbons (organic acids and fats) which can bias results high. Use of the silica gel cleanup may remove complex aromatic compounds and other hydrocarbons which contain chlorine, sulfur and nitrogen which can bias results low.

Methods 8020/602

Similar to the TPH/oil and grease techniques, Method 8020 is U.S. EPA approved, well established and widely used. Method 8020 is a Gas Chromatography/Photoionization Detection (GC/PID) method which can measure the individual toxic components of gasoline directly (BTEX—benzene, toluene, ethyl benzene and xylenes). Method 602 is a similar technique designed for wastewater applications. The method has good sensitivity for these compounds; nominal reporting limits are 0.5 ug/L in water and 50 ug/kg in soil.

The primary disadvantage of Method 8020 is the difficulty in correlating BTEX values to gasoline. While BTEX is a good indicator for gasoline's presence, particularly in groundwater, the volatile aromatics can originate from sources other than gasoline. Moreover, Method 8020 does not address any of the heavier products like diesel or kerosene.

Method 8240/8270 and 624/625

Methods 8240 and 8270[9] are also target compound analytical methods but use Gas Chromatography/Mass Spectrometry (GC/MS). Methods 624 and 625 are used for wastewater analysis. These methods are U.S. EPA-approved with good sensitivity (5 to 10 ug/L in water and 5 to 330 ug/kg in soil). In addition, through the use of library searches, Tentatively Identified Compounds, and additional nontarget compounds can be measured.

The disadvantages of Methods 8240/8270 are similar to the disadvantages of Method 8020. It can be difficult to correlate individual compound data to particular products. In addition, the GC/MS methods are generally too expensive for routine screening applications.

California LUFT: DHS TPH—Gasoline and Diesel

The above methods are GC/FID techniques designed to measure gasoline and diesel fuel concentrations. Unlike the target compound methods, these techniques provide values for specific projects. The calibration process uses commercial gasoline or diesel fuel and samples are analyzed on a packed GC column. Standard laboratory quality practices including blanks, duplicates and spikes are required.

However, the California methods do have some limitations. The methods lack key method performance data such as recovery and minimal quality assurance criteria. Key details such as start/stop of integration, use of baseline projection and interpretation of weathered samples are not addressed. In addition, the analysis of gasoline is permitted by either Headspace or Purge and Trap (U.S. EPA 5030). Apparently, gasoline may be analyzed by the same extraction/concentration method used for diesel fuel. There is no indication of the equivalence or applicability of these method variations.

ASTM D3328-78

ASTM D3328-78[4] is a GC/FID method for the analysis of water-borne oils. It is designed for qualitative identification and the determination of product matches, primarily distillate fuel, lubricating oil and crude oil. Samples of known oils must be submitted with the unknown samples; there are no provisions for identification of the source of unknown oils. No quantification information is provided.

IMPROVED METHODS

The improved methods being used for oil analysis all have similar characteristics. They provide a "Total Hydrocarbon" value for a particular carbon range which is based on a GC/FID response relative to a synthetic standard. The use of a synthetic standard requires careful attention to the analytical details of the method, but provides a more universally consistent quantification the hydrocarbons present. Each method has the capability to fingerprint particular products. However, the primary goal of the method is to provide reliable, consistent quantification. The basic method can be enhanced for specific applications. The methods are listed below:

- "Volatile" Method—Gasoline Range Organics (GRO)—for the gasoline range, BTEX included
- "Semivolatile" Method—Extractable Petroleum Hydrocarbons reported as Total Chromatographable Organics (EPH—TCO)—for diesel, kerosene and other products
- "Oil Spill" Method—Petroleum Hydrocarbons (PHC)—for crude oil

Gasoline Range Organics

The Gasoline Range Organic (GRO) Method was developed through a laboratory study sponsored by the American Petroleum Institute. The project was designed to develop a reliable method for sampling and analyzing gasoline-range organics in soil. A number of professionals in the petroleum industry recognized that the current analyses for gasoline were inadequate due to the following concerns:

- Loss of volatile organics during sampling and sample handling leading to significant bias
- The wide variety of laboratory techniques for "gasoline" produced data of variable quality
- The generally poor documentation of the performance of "gasoline" methods

The results of this study have been previously described.[11]

The GRO method is a modified Method 8015 (Purge and Trap—GC/FID) for the measurement of gasoline which adds Method 8020 (Purge and Trap—GC/PID) for BTEX. (The BTEX values are based on a single column.) The method complies with the minimum criteria in the California LUFT purge and trap method for gasoline. Calibration uses a synthetic gasoline comprised of ten common components of gasoline. The synthetic gasoline eliminates potential problems from variable commercial gasoline. In addition, the first and last peaks define the gasoline "window" and correspond to the range of C_6 to C_{10}.

Various commercial gasolines had similar recoveries (53%, 58% and 62%) compared to API PS-6 reference gasoline (70%). Using PS-6 gasoline and the methanol extraction, (purge-and-trap GRO), recoveries were similar in Ottawa Sand (70%), Houston Black Clay (67%) and Norwood Loam (58%). Relative differences on the clay and loam were less than 5%.

The soil method used field preservation with methanol which stabilizes the organic components via solubilization and minimizes microbial degradation. This field sample control allows the sampler greater freedom in the actual selection of the sample. Reporting limits for gasoline are 2 to 5 mg/kg for soil and 50 to 100 ug/L for water. Reporting limits for individual components like benzene are lower (0.05 mg/kg for soil and 0.5 ug/L for water).

Extractable Petroleum Hydrocarbons
Total Chromatographable Organics (EPH-TCO)

The EPH-TCO is a modified Method 8100 (GC/FID) designed to measure diesel, fuel oil, kerosene and other products in the range of C_7 to C_{32}. It is also possible to identify gasoline and motor oil, although these products are not recovered as well as diesel. The method complies with the minimum criteria in the California LUFT extraction method for diesel. This method has been previously described in detail.[12]

Organic compounds are extracted from their matrix into methylene chloride and the extract is then analyzed by capillary column GC with a flame ionization detector. The term Total Chromatographable Organics (TCO) is defined as the total chromatographic area responding to a FID with boiling points between 100° C and 470° C as compared to the response of ortho-terphenyl. This definition is very similar to the definition of TCO set forth by the U.S. EPA in 1978.[13] The boiling range of 100° C to 470° C corresponds to the hydrocarbon range of nC_7 to nC_{32}. Quantification is performed using a baseline projection to integrate area for both resolved and unresolved components. Additional information is generated by comparing the chromatogram against standards of known petroleum products for identification and a series of alkanes for a carbon distribution range. In addition, nonpetroleum products such as vegetable oil and vegetative hydrocarbons can be identified in some cases.

The average recovery of fuel oil #2 from reagent water spiked at 250 ug/L was 66% with a relative standard deviation (RSD) of 25% (12 replicates). The average recovery of fuel oil #2 from Ottawa sand spiked at 10 mg/kg was 67% with a RSD of 18% (four replicates). The average surrogate (ortho-terphenyl) recovery was 82% in water (15% RSD) and 84% in Ottawa sand (8% RSD). The surrogate was spiked at 20 ug/L in water and 0.80 ug/g in Ottawa sand.

Petroleum Hydrocarbons

The Petroleum Hydrocarbons (PHC) method has been used extensively for oil spills and is similar to the EPH-TCO Method. The results provide information on fate, transport and weathering of crude oil. These results include a Total Petroleum Hydrocarbon value (C_{10} to C_{36}), n-alkanes (C_{10} to C_{32}), pristane and phytane. This test can be linked with a GC/MS-Selected Ion Monitoring technique to measure trace levels of Polynuclear Aromatic Hydrocarbons.

COMPARISONS OF PETROLEUM HYDROCARBON METHODS

The following tables compare the performance of some petroleum hydrocarbon methods on various soils. Following each table is a discussion of the results.

The field sample contained weathered gasoline. The laboratory spike was artificially weathered (spiked at 50 mg/kg; however, some of the lighter components were lost during the mixing process). Method 8020 results are lower than GRO because only selected components (BTEX) are measured. TPH-IR is known to have a low recovery for the volatile and aromatic components of gasoline.

These samples were field (soil) samples contaminated with diesel fuel. The tests were done to evaluate extraction solvents and the number of extraction steps for a round robin study. The CH_2Cl_2 samples were extracted three times with methylene chloride, while the Freon samples were extracted only once with Freon 113. The average surrogate (1-chlorooctadecane) recovery was 103% for CH_2Cl_2 extraction and 67% for Freon extraction. Although not conclusive, the data indicates that CH_2Cl_2 is more effective for the extraction of diesel fuel from these soils.

Table 1
Comparison of Total Petroleum
Hydrocarbon Methods for Gasoline[11]

Method	Field Sample mg/kg	Lab Spike mg/kg
API-GRO	130	8.3
CALIF-LUFT	64	0.96
8020-BTEX (Total)	5.9	1.8
8240-(RIC total)	51	0.82
TPH-IR	ND (50)	ND (50)

Table 2
Comparison of Extractable Petroleum
Hydrocarbon for Diesel Method

Method	D-S-1, mg/kg	D-S-2, mg/kg	D-S-5, mg/kg	D-S-4, mg/kg
EPH-TCO (CH_2Cl_2)	78	150	10	12
EPH-TCO (Freon 113)	29	24	2.2	6.0

Table 3
Comparison of TPH-IR and TPH-GC Methods[3]

Method	Limestone 1, mg/kg	Weathered Limestone 2, mg/kg	Weathered Silty Clay, mg/kg
TPH-IR	760	3000	366
TPH-GC	67	1000	ND, <25

This study[3] indicated a potential problem with the TPH-IR analysis of certain types of soil-weathered limestones, clays and silts. It is possible that clay-sized inorganic particles do not settle out of the Freon extract. The particles may absorb infrared light and produce a positive TPH-IR response in the absence of hydrocarbons.

ANALYTICAL METHOD SELECTION

If the source of the petroleum product contamination is known, the appropriate method can be selected. The Gasoline Range Organic (GRO) test is the recommended technique for gasoline. For other refined products like diesel fuel, kerosene and jet fuels, the Extractable Petroleum Hydrocarbons (EPH-TCO) should be used. For crude oil spills, the Petroleum Hydrocarbon (PHC) test is recommended.

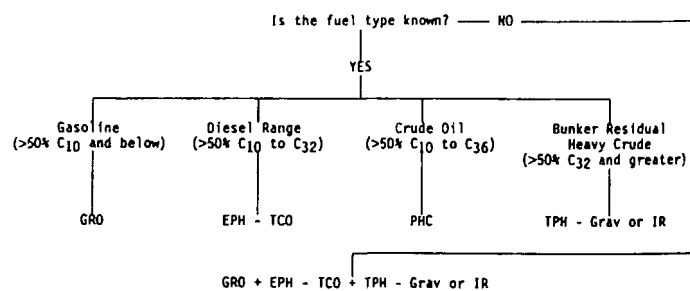
For unknown situations or site characterizations, the GRO and EPH-TCO should be run to provide comprehensive information. In addition, TPH-IR or a TPH-gravimetric procedure should be considered if heavy products (motor oil, bunker oil) may be present (Fig. 2).


Figure 2
Analytical Method Selection

While it would be desirable to propose an additive value from the methods in Figure 2, that may not be practical in all cases. Particularly in unknown samples, interpretation of the GRO, EPH-TCO and TPH results yield useful information. For example, a high GRO value relative to EPH-TCO and TPH confirms that gasoline is the primary product present. Also, if GRO is low and EPH-TCO and TPH are equivalent, the sample is primarily in the kerosene-diesel range (the EPH-TCO should indicate the product). Finally, if TPH is high, motor oil and heavy products can be present. If interferences are suspected, the EPH-

TCO results should qualitatively confirm the presence of heavier products.

ABSTRACT

A full-scale remediation of soils, bedrock and groundwater is underway at the Tyson's Superfund Site (Tyson's) near Philadelphia, Pennsylvania. Ranked number 25 on the NPL, Tyson's is a location where unknown quantities of volatile organic compounds (VOCs) and semivolatile compounds were disposed of over a period of several years. Two former waste lagoon areas are the focus of the remediation activities. The contaminated area covers approximately four ac.

The cleanup involves in situ vacuum extraction in the silty clay soils of the former lagoons and surrounding area which contains upwards of 250,000 ppm total VOCs and semivolatiles. The major contaminants of concern are 1,2,3 trichloropropane, toluene, xylenes and dichlorobenzene, although there are also approximately 20 other identified compounds. In addition, the remedy includes dual extraction of water and vapor from the underlying fractured arkosic sandstone and the collection and treatment of the seep spring water from the off-site area downgradient of the former lagoons.

The remedy includes 180 soil vacuum extraction wells, nine dual extraction wells and six bedrock extraction wells which are manifolded to a central processing plant. The process plant covers 10,000 ft^2 and contains two 700-hp vacuum units and two 250-hp vacuum units. The design air flowrate is approximately 15,000 scfm at 13 in. Hg vacuum. Vapor treatment is by activated carbon adsorption with on-site stream regeneration and solvent recovery. Water treatment is by air stripping with carbon polishing. Since the commencement of remediation activities in November 1988, more than 95,000 lb of contaminants have been removed from the site by the vacuum extraction process for off-site destruction. Overall, the vacuum extraction remedy is successfully treating soils at the site with an innovative in situ treatment process.

INTRODUCTION

Situated in southeastern Pennsylvania is the Tyson's Superfund Site (Tyson's), an abandoned quarry near the Schuylkill River which was used as a disposal facility during the 1960s and early 1970s for mixed septic and chemical wastes consisting primarily of VOCs and semivolatile compounds. Two former lagoons were excavated down to bedrock into which haulers disposed of the wastes atop the fractured arkosic sandstone. The wastes leached into the bedrock and surrounding soils, spreading contaminants laterally over an area of approximately 4 ac and vertically through the fractured bedrock where it remained as DNAPL (Dense Non Aqueous Phase Liquid). The movement of groundwater through the bedrock then carried the contaminants northward toward the floodplain of the river.

Tyson's Site was closed by the Pennsylvania Department of Environmental Regulation (PADER) in 1973. The lagoons were emptied of liquids and backfilled with soil. Following complaints of foul odors from nearby residents in 1983, the U.S. EPA began Emergency Response activities and conducted an RI. The Tyson's Site was added to the NPL in 1984 where it is ranked Number 25.

A ROD was issued, calling for excavation and disposal of the soils backfilled in the former lagoons and surrounding areas. Later, after two vacuum extraction pilot tests were conducted in the former East Lagoon, the ROD was overturned and reissued in favor of an innovative vacuum extraction remedy to address the contaminated soils and bedrock at the site.

The full-scale remedy of soils and shallow bedrock includes vacuum extraction wells, deep dual extraction wells and bedrock extraction wells. The extracted vapors enter the process plant from various manifold lines where they are treated by activated carbon adsorption prior to discharge. The activated carbon beds are regenerated on-site with steam, and the solvents are recovered and stored until they are transported off-site for final destruction.

This paper describes Phase I of the Tyson's Site remediation. The remedy description focuses on the on-site source area, and it includes a description of the site, the geologic setting and chronological chain of events, along with a description of the pilot tests and their performance objectives which led to the ROD being overturned in favor of a more effective and safer treatment using vacuum extraction. The full-scale design, facility layout and results of the first year of cleanup operations are presented with respect to recovery performance and the vacuum recovery system's operations efficiency.

SITE DESCRIPTION

The Tyson's Site is a 4-ac abandoned quarry located in Upper Merion Township, Montgomery County, Pennsylvania, near the city of King of Prussia. It is situated on the south bank of the Schuylkill River, but is separated from the river by the floodplain and a railroad switching yard as shown in the areal schematic diagram of Figure 1. A residential community is immediately adjacent to the site on the west and undeveloped property is located to the east. The fence line, shown by the dashed line in Figure 1, encloses the on-site area.

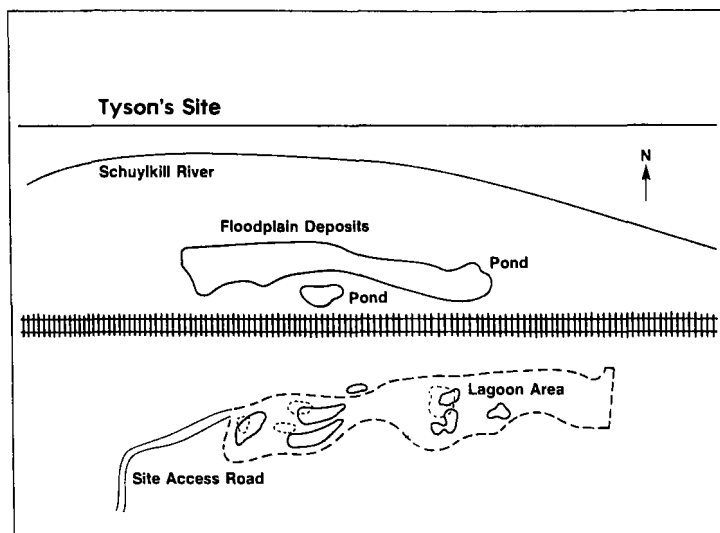
The main sources of contamination are concentrated within two former waste lagoons known as the Former East Lagoon and the Former West Lagoon. The solid lines within the dashed area represent the areas of highest contaminant concentrations within


Figure 1
Tyson's Site

the two lagoons.

Figure 2 is a profile of the site looking west. The topsoils of the former lagoons were excavated to bedrock immediately adjacent to the quarry high-wall on the south. The depth of the lagoons ranges from 8 to 20 ft, making the volume of contaminated soils approximately 50,000 yd³. On the north side of the site, there are the fence line and another high-wall which overlooks the railroad tracks. Moving further north from there, one views the floodplain and then the Schuylkill River.
Figure 2
Cross Section of Tyson's Site

GEOLOGICAL AND HYDROGEOLOGICAL SETTING

The site is situated within the Stockton Formation outcrop area. The Stockton, of Triassic age, is approximately 4,000 ft thick and is composed of fine- to coarse-grained fractured arkosic sandstones, conglomerates, interbedded red shales and siltstones. The Stockton Formation has been subdivided into three members: (1) the upper shale member, characterized by shale and siltstone; (2) the middle member, characterized by fine- and medium-grained sandstone; and (3) the lower member, which consists of coarse grained sandstone and conglomerate. Generally,

the Tyson's Site is located within the outcrop of the lower member. Bedding planes dip to the north and northwest at an average of 12 degrees.[1]

The overburden soils consist of loam, silts and clays, but due to the extensive reworking of the soils during disposal practices, the backfilled soils are anything but homogeneous. In fact, the impact of severe heterogeneity is a primary focus of the ongoing activities of the vacuum extraction operations.

The Stockton is a relatively good water-bearing formation, and some wells in the lower members have recorded an average specific capacity of 3.0 gpm/ft of drawdown and yields of 110 gpm.[2] Beneath the Tyson's Site, however, the flow through the lower member appears to be fracture-dependent, and it is also complicated by the presence of DNAPL within the fractures. Flowrates from the wells on-site range from 5 to 20 gpm.

The groundwater gradient dips steeply to the north from the high-wall, through the lower portion of the former lagoons and down toward the floodplain. Extensive perched water rests in the former lagoons, which makes the Dual Vacuum Extraction and groundwater extraction process a logical remedy for these soils.

SITE HISTORY

From 1960 to 1973, the Tyson's Site was utilized for the disposal of a variety of septic sludges, chemical wastes and solvents. Apparently, the wastes were dispersed throughout the site, with the majority of disposal taking place in the former unlined lagoons. Some of these wastes migrated down into the bedrock and groundwater where they remained as DNAPLs and contaminated the groundwater as it flowed through the bedrock toward the floodplain.

The site was closed to waste disposal in 1973 by the PADER due to alleged regulatory violations. The lagoons were then pumped out, backfilled and vegetated. Following complaints of odors by nearby residents in early 1983, the U.S. EPA initiated emergency response activities to mitigate the direct contact threat to public health and environment posed by contaminant releases from the unsecured site. These activities included the construction of a security fence, drainage controls, topsoil cap and a leachate collection and treatment system.

During the subsequent years, 1983 to 1984, the U.S. EPA undertook a Remedial Investigation which showed that elevated concentrations of volatile and semivolatile organic compounds existed in the soils. The major constituents detected were 1,2,3-trichloropropane (TCP), xylenes, toluene and chlorinated benzenes (chlorobenzene, 1,2-dichlorobenzene and 1,4-dichlorobenzene). Well installation activities during the installation of the vacuum extraction system indicated soil concentrations of organics up to 250,000 ppm in the former lagoon soils, with several areas in the tens of thousands part per million range.

In December 1984, the U.S. EPA issued an ROD requiring excavation and removal of on-site area soils; based on this ROD, the remedial design was initiated. The plan was to excavate approximately 3,500 truckloads of soil, transport them through a residential community and then travel 600 mi up the Pennsylvania Turnpike to a disposal facility in Ohio. After the health risk became apparent, the responsible parties urged the U.S. EPA to evaluate the vacuum extraction technology for cleanup of the site. Furthermore, the ROD for excavation only addressed the soils, but did not satisfactorily address the bedrock contamination which would have recontaminated the clean backfilled soils.

In November 1988 and May 1987, the RPs initiated two in situ vacuum extraction pilot tests in the area of the Former East Lagoon. The tests consisted of four vacuum extraction wells, a water/vapor separator tank, activated carbon units and a vacuum extraction unit. The objectives of the vacuum extraction pilot tests were as follows:

• Quantify the extraction rates of volatile and semivolatile compounds

- Evaluate the radius of influence (Ri) of the extraction wells
- Evaluate the time frame for cleanup using vacuum extraction
- Extract, contain and treat the contaminants safely
- Evaluate the extraction rates in bedrock

The results of the pilot tests showed that TCP, xylenes and chlorinated benzenes had the highest extraction rates, with total extraction rates reaching 150 lb/day during the second pilot test which lasted 3 wk. The vacuum extraction system was also successful in volatilizing DNAPLs from the fractured bedrock at rates up to 15 lb/day with a radius of influence of 100 ft.

Based on the success of the vacuum extraction pilot tests, the RPs petitioned the U.S. EPA to reevaluate the ROD with the following proposed clean-up plan:

- Vacuum extraction in the former lagoon soils and topsoils
- Dual vacuum extraction and groundwater extraction from the bedrock
- Collection and treatment of the seep spring water along the railroad tracks

In March 1988, the PADER and the U.S. EPA agreed to overrule the original ROD and issue a new ROD in favor of vacuum extraction and groundwater treatment for the on-site area soils and bedrock.

FULL-SCALE VACUUM EXTRACTION AND DUAL EXTRACTION SYSTEM

Design of the full-scale vacuum extraction system began in late 1987 and was completed in May 1988. Site activities commenced in May 1988 with the clearing of trees and shrubbery, construction of the support zone and decontamination area, and initiation of the vacuum extraction well installation and process plant construction. Construction activities were completed in approximately 5 mo; system startup and testing commenced on Nov. 15, 1988.

A schematic diagram of the full-scale remedy in place at the Tyson's Site is depicted in Figure 3. The remedy includes 180 vacuum extraction wells throughout the former east and west lagoons and surrounding topsoils, nine Dual Extraction wells along the quarry high-wall and six open-hole bedrock extraction wells along the north side of the former lagoons.

The vacuum extraction wells range from 8 to 20 ft in depth and are arranged so that their radii of influence, which were measured during well development shortly after installation, overlap sufficiently to insure complete coverage of all the contaminated soil. Continuous split spoon samples were taken on each well and analyzed in the on-site laboratory with approximately 10% of the samples sent to a Certified Laboratory for confirmation. In all, approximately 1,300 soil samples were analyzed on-site with turn-around times averaging 36 hr.

The dual extraction wells along the quarry high-wall on the south side of the site are drilled from 70 to 100 ft into the bedrock. Dual Extraction is a patented process in which a vacuum extraction well is outfitted with a groundwater recovery system to simultaneously extract vapors and groundwater from the same well. Thus, the vacuum extraction process takes advantage of the drawdown cone of depression or "induced vadose zone" to extract the residual contaminants which have been left behind as the groundwater table is lowered. Typically, the Dual Extraction process increases overall system performance by removing residual contaminants while substantially accelerating the groundwater recovery process. Well yields of a dual extraction well have been shown to be from two to 15 times greater than a well which pumps groundwater alone.

The bedrock extraction wells are open-hole completions on the north side of the former lagoons. These wells range in depth from 40 to 60 ft; they take advantage of the overall depression in the groundwater elevations throughout the site to volatilize the VOCs and semivolatiles which have migrated down into the fractured bedrock.

The vacuum extraction, dual extraction and bedrock extraction wells are connected at the surface to three main mainfold lines which transect the site. The manifold lines enter the process plant where the entrained liquids are removed by vapor/water separators. From the separators, the process stream enters the vacuum extraction blowers which consist of two 700-hp vacuum units and two 250-hp vacuum units. Generally, only one of each size vacuum unit is on-line at any given time, with the duplication of equipment assuring uninterrupted operations during scheduled maintenance operations or repairs. The design air flowrate for the system is 15,000 scfm at 13 in. Hg.

After passing through the vacuum extraction blowers, the extracted vapor stream reaches temperatures of 350°+. Hence, the process stream is cooled to 100°F prior to entering the carbon adsorption units.

The activated carbon treatment system is comprised of four 7,000-lb primary adsorption units and two 7,000-lb backup adsorption units, allowing continuous operations during regeneration cycles. Vapor removal efficiency is 99.8%. An on-line flame ionization detector with continuous strip recorder automatically samples the outlet of the primary carbon adsorption units and stack discharges every 30 sec. Routine calibrations and verification samples are analyzed twice daily in the on-site laboratory.

A regeneration cycle is initiated upon breakthrough of the primary carbon units. At that time, the other two carbon units are placed on-line while the spent carbon units are regenerated using steam at approximately 7 psig. The contaminant-laden steam is then cooled, condensed and decanted, with the recovered solvents being stored on-site in a 2500-gal holding tank. When full, the tank is emptied and the solvents are transported to a permitted cement kiln for final destruction.

The aqueous phase liquids from the carbon regeneration activities are pumped to an equalization tank where they are mixed with the extracted groundwater from the dual extraction wells, the seep spring collection system and the decontamination water. The water treatment system consists of a vacuum air stripping unit and carbon polishing system prior to discharge of the treated effluent to the Schuylkill River. The air stripper is connected to the main vacuum system via control valves which maintain a constant vacuum on the stripper; in this system, both the vapors from the vacuum extraction system and the vapors from the air stripping tower are processed through the same carbon beds.

PHASE I PERFORMANCE

As of August 1990, the vacuum extraction system had removed

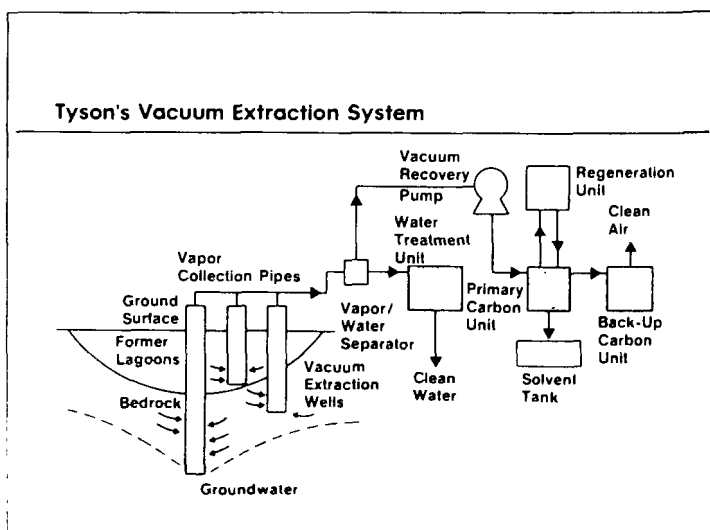
Tyson's Vacuum Extraction System


Figure 3
Tyson's Vacuum Extraction System

more than 95,000 lb of contaminants from the soils and bedrock. Approximately 80 million gallons of groundwater, process water and seep spring water have been treated to nondetectable VOC concentrations in the discharge water. The on-line operation efficiency is 99%, with nominal periods of downtime recorded for scheduled maintenance activities.

CONCLUSION

The activities which have occurred throughout the history of the Tyson's Superfund present but one of many examples of the complicated issues surrounding the presumed disposal activities, subsequent site investigations and evaluations of remedial alternatives which are inherent at nearly every Superfund Site across the nation. However, the chain of events at the Tyson's Site demonstrates the willingness of the U.S. EPA and the private sector to recognize the potential of alternative treatment technologies and to find mutually agreeable solutions to regulatory statutes while directly addressing the issues of cleanup.

Evaluation of the performance of the remedy to date shows that vacuum extraction is successfully cleaning the soils and shallow bedrock at the site. More than 95,000 lb of VOCs have been removed and destroyed, and more than 80 million gallons of groundwater have been treated. Data gathered since project commencement have indicated the extreme heterogeneity of the soils at the site and the presence of DNAPL within the soils. These phenomena are being successfully handled by the vacuum extraction operation.

Finally, the extensive communication and cooperation between the U.S. EPA, the responsible parties and the remedial contractors have resulted in a full-scale remedy at the Tyson's Superfund Site which is successfully treating soils, bedrock and groundwater with an innovative treatment process.

A Detailed Methodology for Estimating VOC Emission Rates from Superfund Sites

Margaret R. Leo
Timothy R. Minnich
Philip J. Solinski
Robert L. Scotto
Blasland, Bouck & Lee
Edison, New Jersey

ABSTRACT

Assessment of long-term health impacts associated with air emissions from Superfund sites generally requires use of an appropriate air quality dispersion model to represent downwind contaminant dispersion and transport. An accurate source emission rate estimate is the cornerstone of any such study, yet this area typically represents the most serious data gap.

This paper presents a detailed methodology for generating accurate VOC emission rate estimates from both point and area sources and is appropriate for use at most Superfund sites. The methodology is a slight variation of the transect technique as described in the U.S. EPA air pathway analysis guidance document, *Estimation of Baseline Air Emissions at Superfund Sites* (Vol. II). The latter technique involves measuring contaminant concentrations downwind of a site at incremental points across the plume to determine the highest plume-centerline concentration. This concentration is then used as input into a basic Gaussian dispersion relationship to estimate a representative source emission rate. The methodology discussed in this paper involves contaminant mass averaging across the plume to obtain a total path integrated contaminant burden which is again used as input into a basic Gaussian dispersion relationship to estimate an emission rate. However, the mass-averaging method is shown to be easier, cheaper and far more accurate. Additionally, it provides data that are inherently more representative of the plume cross section.

The mass-averaging method can be employed using either rapid collection whole air samplers (e.g., Summa canisters) or long-path spectroscopic techniques. Application of each of these monitoring alternatives is discussed in detail and practical examples are provided.

INTRODUCTION

The assessment of health impacts associated with air emissions from Superfund sites generally requires use of an appropriate air quality model to represent downwind contaminant dispersion and transport. An accurate source emission rate estimate is the cornerstone of any such modeling study, yet this area typically represents the most serious data gap. The complexity of many Superfund sites generally makes accurate estimation of source emission rates difficult and very costly using traditional sampling techniques. This paper discusses an alternative methodology for estimating emission rates which relies upon the generation of path-integrated air contaminant data instead of the collection and analysis of contaminant samples at discrete points in space. In actuality, the path-integrated methodology can be considered an extension of the transect methodology, which is a simplistic emissions measurement technique based on the theory of point monitoring.

Accurate estimates of source emission rates are required at sites during every phase of the Superfund process. These phases consist of the site assessment, remedial and post-remedial phases. During the site assessment and post-remedial phases, time generally is not a critical factor as emission rate estimates typically are used to assess health impacts to downwind residents on a long-term basis. The sites are nearly always free of activity and emit VOCs in what may be considered an equilibrium state.

On the other hand, during the remedial phase, time is often of the essence as emission rates may vary rapidly during cleanup or removal activities. Of principal concern in these situations is the exposure to on-site workers and downwind residents on a short-term basis.

Because of these two very different objectives and data needs, a great deal of care must be exercised in specifying air sampling techniques for any given situation. Clearly, a high volume sampling technique that requires several hours of sample collection followed by subsequent off-site laboratory analysis can serve no purpose during a removal operation. Conversely, a direct-readout portable instrument would usually not be recommended for conducting air migration assessments at sites in their base line (undisturbed) states, as detection limits would generally not be comparable to most health-based standards.

THE PATH-INTEGRATED CONCENTRATION

The key to the methodology discussed in this paper concerns the concept of the path-integrated concentration. The concept is not an analytical one, but rather one of a more fundamental nature. Physically, a path-integrated concentration represents a mass average along a given distance or path length. A path-integrated concentration can be obtained instantaneously, as in the case of any of several available long-path spectroscopic techniques,[1-5] or over a short period of time (generally 15 minutes or less) by moving a constant-rate sampling device along a path at a uniform speed.[6] Path-integrated concentrations are typically normalized to a path length of 1 m or 1 km. If, for example, an integrated concentration of 30 ppm-m is reported, no information concerning the contaminant distribution can be inferred and the total mass is identical whether there is a uniform concentration of 30 ppm over a distance of 1 m, 3 ppm over a distance of 10 m, 300 ppb over a distance of 100 m, or 30 ppb over a distance of 1 km. Whether the data are generated via long-path spectroscopy or Summa canister, in each case the reported value is simply the area under the curve of instantaneous concentration versus distance. A second representation of a path-integrated concentration is g/m^3 times path length (m), or g/m^2. Although these units are not reported as extensively as ppm-m, they are frequently required for data analysis calculations as discussed later.

THE TRANSECT TECHNIQUE

Figure 1 presents an example of the transect sampling technique.[7] As discussed earlier, this is a simplistic emissions measurement tech-

nique is based on the theory of point monitoring. Concentrations of VOCs are measured at several cross-plume locations and heights at an appropriate distance downwind of the source.
Figure 1
Example of Transcent Sampling Technique

The total VOC emission rate for a contaminant source is given by:

$$Q = \pi \chi K \sigma_y \sigma_z C u \qquad (1)$$

where:

Q = emission rate of VOC (g/sec)
χ = peak concentration of VOC (ppm)
K = conversion factor (g/ppm for VOC)
σ_y, σ_z = lateral and vertical extent of plume, 1 standard deviation (m)
C = instrument response factor
u = mean wind speed (m/sec)

In practice, σ_y, σ_z, C and u are obtained from field measurements; σ_z may be estimated from σ_y; and χ is determined by application of a Gaussian-fit curve to the VOC concentration measurements obtained by means of transect sampling.

There are several limitations associated with the transect technique. Perhaps the most significant is that the downwind sampling array will usually provide only a coarse measurement grid resulting in the possibility (and, for some sites, the likelihood) that higher contaminant concentrations advected by the wind between two sampling points may be unnoticed. Another limitation is that unless sample collection times are very short, wind fluctuations will cause a shifting plume, thus resulting in a lower peak concentration. A third limitation is the logistics associated with this approach and the relatively high degree of field labor required.

EMISSION RATE DETERMINATION

The mass-averaging measurement technique is a powerful approach for providing accurate estimates of emission rates. By knowing the on-site meteorology, the basic equations of Gaussian dispersion theory can be utilized to directly yield an emission rate. The derivations that follow begin with a continuously emitting point source and are then extended to area sources typical of Superfund sites.

Point Source

For a continuously emitting point source, the general equation for concentration of a contaminant at a ground-level receptor is:

$$\chi(x,y,0;H)) = \frac{Q}{\pi \sigma_y \sigma_z u} \exp[-1/2 (y/\sigma_y)^2] \exp[-1/2 (H/\sigma_z)^2] \qquad (2)$$

where

χ = concentration, g/m^3
x = downwind distance to a receptor, m
y = crosswind distance to a receptor, m
H = effective height of emission, m
Q = uniform VOC emission rate, g/sec

σ_y, σ_z and u are as described above.

It is noted that by setting y and H equal to zero, Equation 2 essentially reduces to the form of Equation 1 for the transect sampling technique.

Integrating Equation 2 with respect to y, from y = $-\infty$ to y + ∞, yields:

$$C(x,0;H) = \frac{2Q}{\sqrt{2\pi} \sigma_z u} \exp[-1/2 (H/\sigma_z)^2] \qquad (3)$$

where

$C(x,0;H)$ = ground-level path-integrated concentration at distance x, g/m^2.

For application of this formula at most Superfund sites, the source may be assumed to approximate a ground-level release. Setting H=0, the equation for ground-level path-integrated concentration becomes:

$$C(x) = \frac{2Q}{\sqrt{2\pi} \sigma_z u} \qquad (4)$$

This equation can be rearranged to give the emission rate, Q, as a function of ground-level path-integrated concentration:

$$Q = \frac{\sqrt{2\pi}}{2} C(x) \sigma_z u \qquad (5)$$

Equation 5 is the general emission rate equation for a point source based on path-integrated measurement data. The value of Q determined using this equation is dependent on current on-site meteorological conditions, specifically wind speed and φ^Z, the latter of which is a function of both atmospheric stability and the distance between the source and the downwind measurement. The total path-integrated contaminant burden may be determined based on data collected using either long-path spectroscopic techniques or rapid-collection whole air samplers (e.g., Summa canisters). Although most Superfund sites are represented better as area sources than as point sources, there are situations where point-source representations are not only acceptable but preferred.[8] One such situation is during air monitoring in support of site remediations, when the principal objectives are to ensure that contaminants do not create adverse off-site community health impacts and to facilitate decisions concerning on-site worker health and safety. For either objective, the concern typically is one of acute health impacts arising from short-term contaminant exposure and on-site personnel frequently cannot afford the time to develop area source inputs to a model. In such cases, the point source assumption facilitates rapid application of Equation 5 to estimate an emission rate and, most importantly, is always conservative. For a given emission rate, the maximum downwind concentration will always be greater if all of the mass is assumed to emanate from a single point within a source area.

As an example of emission rate estimation from a point source based on path-integrated data, suppose a ground-level point source has a uniform emission rate, Q, of benzene. The atmospheric stability class is determined to be D (neutral or slightly stable), the wind speed is measured at 5 m/sec and the path-integrated concentration measured at a downwind distance, x, of 100 m is 10.0 ppm-m.

From the Turner nomographs,[9] the vertical dispersion coefficient, σ_z, is 4.65 m. Based on a benzene conversion of 1 ppm = 3.25 mg/m^3 at standard temperature and pressure (STP), Equation 5 can be applied as follows:

$$Q = \frac{\sqrt{2\pi}}{2} (3.25 \times 10^{-3} g/m^2) (4.65m) (5m/s)$$

$$= (1.25) (0.76) \text{ g/sec}$$
$$= 0.95 \text{ g/sec}$$

Area Sources

As discussed earlier, most Superfund sites are represented better as

area sources than as point sources. When the objectives of an air monitoring program are more closely linked to chronic health impacts arising from long-term contaminant exposure, time is generally is not an overriding constraint and the accuracy afforded by an area source representation is preferred. Such situations would include site assessments, remedial investigation/feasibility study (RI/FS) air monitoring and post-remedial air monitoring.[10]

In practice, Equation 5 may be extended to the determination of emission rates for an area source of known location and dimensions. However, because the vertical dispersion coefficient, σ_z, varies over the along-wind dimension of the area source, an adequate treatment method for σ_z must be developed. In the simplest method, the value chosen for σ_z is based on the distance, x, from the center of the area source to the line of crosswind measurement. It is important to note, however, that because the horizontal dispersion is affected by the cross-wind width of the source, an estimate of distance to a "virtual" point source (upwind of the back boundary of the area source) is required in order to estimate the approximate plume width at the distance of measurement and to determine a path length sufficient to ensure that the mass-averaged measurement encompasses the entire contaminant plume.

As an example of an area source emission rate estimation based on this simplified treatment method for σ_z, suppose that the value for C(x) measured in the previous example, at a distance of 100 m from the center of an area source 40-m square, is used in Equation 5 to determine the total source emissions. As above, Q is calculated as 0.95 g/sec. Assuming that emissions across the area source are homogeneous, this amounts to a unit emission rate of 5.9×10^{-4} g/sec-m^2.

It is clear that a more accurate estimation of the area emission rate may be obtained without reference to a virtual point source, because Equation 5 presents Q as a function of wind speed and vertical dispersion only. For rectangular area sources with dimensions on the order of tens to hundreds of meters, a more sophisticated treatment of σ_z begins with Equation 4, from which the total path-integrated concentration, C(x), can be represented as the sum of path-integrated concentrations attributable to each of n subdivisions of the area:

$$C(x) = \sum_{k=1}^{n} \frac{2q_k}{\sqrt{2\pi}\sigma_{z_k}u} \tag{6}$$

Here, q_k is the emission rate of a rectangular subdivision of the source area with length equal to the crosswind dimension of the area and width equal to 1/n times the along-wind dimension. Because σ_y does not affect the mass-averaged concentration, the emission rate, q_k, may be interpreted as representing emissions from a point along the area centerline at the distance, x_k, from the line of mass-averaged measurement. The total area emission rate may then be written as the sum of emissions from points along the area centerline, with σ_{z_k} selected according to the distance from each subdivision center point to the line of mass-averaged measurement. Ultimately, area emissions may then be written as the limit of the sum of emissions from n subdivisions, as n approaches infinity, where σ_z is integrated over the along-wind dimension of the area.

For an area with uniform emissions, a unit emission rate, q, is usually presented in g/sec/m^2. For a given unit emission rate, an emission rate, q', for a crosswind line of length L and unit width may be defined:

$$q' = q \times L \tag{7}$$

where q' is in g/sec/m^2

It follows that for an area subdivision of crosswind length L and width Δx,

$$q_k = q \times L \Delta x = q' \Delta x \tag{8}$$

where q_k represents total emissions from the kth area subdivision, in grams per second.

Substituting for q_k in Equation 6 yields:

$$C(x) = \sum_{k=1}^{n} \frac{2q' \Delta x}{\sqrt{2\pi}\sigma_{z_k}u}$$

Rearranging, this becomes:

$$C(x) = \frac{2q'}{\sqrt{2\pi}u} \sum_{k=1}^{n} \frac{\Delta x}{\sigma_{z_k}}$$

Taking the limit as n → ∞ yields:

$$C(x) = \frac{2q'}{\sqrt{2\pi}u} \lim_{n\to\infty} \sum_{k=1}^{n} \frac{1}{\sigma_{z_k}} \Delta x$$

which may be written as:

$$C(x) = \frac{2q'}{\sqrt{2\pi}u} \int_x \frac{1}{\sigma_z}dx \tag{9}$$

Rearranging and solving for q' yields:

$$q' = C(x) \frac{\sqrt{2\pi}u}{2} \div \int_x \frac{1}{\sigma_z}dx \tag{10}$$

Solving the q' term is the key to developing an accurate method to treat σ_z. For the entire source area of width W, total emissions are given as:

$$Q = q' \times W \tag{11}$$

At this point, it is noted that the definite integral in Equation 10 cannot be evaluated without employment of some type of numerical method. Such methods rely on the idea that there is a region whose area is given by the integral and then provide a technique to approximate that area. There are several numerical techniques available for solving such a function. Each technique involves breaking up the function into a finite number of subintervals, erecting vertical lines at the division points and approximating the areas of the subregions. The simplest (and least accurate) method of approximating each subregion area is by constructing a series of rectangles, in which the value of the function across each subinterval is approximated by a horizontal line (y=constant).

The trapezoidal approximation of each subregion area is more accurate. This method replaces the horizontal line representing the function value with a first-order equation (y=ax + b), with unique values of a and b determined for each subregion.

An even more accurate method is the parabolic approximation, or Simpson's rule, in which the line representing the value of the function is replaced by a second-order equation (y=ax^2 + bx + c), with unique values of a, b and c determined for each subregion.

This rule is described briefly as follows. The integral,

$$\int_\alpha^\beta f(x)\,dx$$

is evaluated as follows:
- Break the interval $\alpha \le x \le \beta$ into n equal parts of width Δx each, where n is an even number
- Compute $y_k = f(x_k)$, k=0,1,2,...,n; $x_0 = \alpha$, $x_n = \beta$
- Then:

$$\int_\alpha^\beta f(x)\,dx = \frac{1}{3}\Delta x(y_0 + 4y_1 + 2y_2 + \ldots + 2y_{n-2} + 4y_{n-1} + y_n) \tag{12}$$

APPLICATION

Figure 2 illustrates an application of the mass-averaging measure-

.ment technique for area source emissions. Assume that a site contaminated with benzene is being monitored. The site is a rectangular area, 100 m x 80 m, with the longer side oriented in a north-south direction. The site is considered to be emitting at a relatively uniform rate across its surface and a source emission rate must be determined based upon mass-averaged concentration measurements.
Figure 2
Line of Mass-Averaged Measurement

An on-site meteorological tower indicates that the wind is blowing steadily from the west at 5 m/sec. The downwind location for cross-plume monitoring is along a north-south line at a distance 50 m from the downwind boundary of the site. Sky conditions are mostly cloudy and a stability category of "D," or neutral-to-slightly-stable conditions, exists. A downwind path length of 200 m is determined to be sufficient to contain the plume.

Real-time monitoring yields a mass-averaged benzene concentration of 98.5 ppm-m. Based on the benzene conversion factor of 1 ppm = 3.25 mg/m^3 at STP, this is equivalent to a concentration of 320 mg/m^2.

Applying the parabolic rule for integration, we can separate the along-wind axis of the source area into eight equal parts, each of width Δx = 10 m. Constructing area subregion boundaries perpendicular to the along-wind axis at each interval yields eight area subregions, as shown in the following table, where each x_k represents the distance from the kth upwind subregion boundary to the line of mass-averaged measurement, α_{zk} represents α_z at that distance and y_k represents the value of the function, $y_k = 1/\alpha_{zk}$:

k =	0	1	2	3	4	5	6	7	8
x_k(m) =	130	120	110	100	90	80	70	60	50
(m) =	5.84	5.45	5.05	4.65	4.24	3.83	3.41	2.98	2.55
y_k =	0.171	0.183	0.198	0.215	0.236	0.261	0.293	0.335	0.393

The integral may then be calculated from Equation 12:

$$\int \frac{1}{x \, \sigma_z} dx = \frac{1}{3}(10) \, [0.171 + 0.732 + 0.396 + 0.860 + 0.472 + 1.044$$
$$+ 0.586 + 1.340 + 0.393]$$
$$= 19.98$$

Therefore, from Equation 10:
q' = (320) (1.25) (5)/19.98 = 100.10 mg/sec-m.

From Equation 11, the area emission rate is:
Q = (100.10) (80) = 8008.01 mg/sec.

In contrast to the area subdivision treatment of a rectangular area source using Simpson's rule, consider the benzene concentration, C(x), measured as in the above example and determine the total area emissions, Q, using a simplified, point source approximation of the area. Locating the point of emission at the center of the area, we have, from Equation 5:

Q = (1.25) (3.20) (4.24) (5)
= 8,480 mg/sec

This emissions estimate represents a 5.9% error when compared to the emission rate determined using Simpsons' rule. For a more conservative estimate of total area emissions, we may choose to define a point source midway along the upwind boundary of the actual source area. From Equation 5:

Q = (1.25) (3.20) (5.84) (5)
= 11,680 mg/sec

This emission rate is 45.9% higher than that calculated using Simpson's rule for integration.

CONCLUSIONS

A methodology, referred to as the mass-averaging technique, has been presented for estimating VOC emission rates from Superfund sites. The mass-averaging technique can be employed using either rapid-collection whole air samplers or long-path spectroscopic techniques. Procedures are presented for treatment of both point source and uniformly emitting area source representations.

Field Screening of Soil Vapors at a Subsurface Gasoline Contaminated Site in West Liberty, Morgan County, Kentucky

Robert B. Burns, M.S.
Kentucky Department for Environmental Protection
Morehead, Kentucky

ABSTRACT

Leaking underground storage tanks containing petroleum products pose a serious threat to groundwater quality nationwide. Many of the releases from underground storage tanks constitute an emergency situation due to exposure to toxic or flammable vapors and contamination of potable water sources. These conditions require rapid and cost-effective acquisition of data from the contaminated area. Soil vapor field screening techniques permit a rapid assessment of the affected area.

A complaint was lodged by the Kentucky Transportation Cabinet, Department of Highways in August, 1988, concerning the quality and odor of water in its well. Preliminary sampling by the Kentucky Department for Environmental Protection revealed constituents indicating gasoline contamination. Subsequent sampling showed contamination of five potable wells in the area. One operating service station with three underground storage tanks containing gasoline and several abandoned underground storage tanks are in the immediate area where contamination had been identified.

A field investigation was initiated by the U.S. Geological Survey, and the Kentucky Department for Environmental Protection. The objectives of this investigation were to:

- Determine the degree and extent of contamination from gasoline constituents
- Locate and confirm the source(s) of contamination
- Assess the impact of contamination on the quality of soils, groundwater, and surface water in the vicinity

Soil vapors were obtained using an Environmental Instruments soil vapor sampling device. Soil vapors were drawn to the sampling probe via an electric peristaltic pump. A milliliter syringe was inserted through a Teflon septum and vapor was removed from the sampling device. Soil vapor samples were analyzed in the field using a HNU Model 311 portable gas chromatograph. These samples were analyzed for gasoline constituents. Results of the soil vapor and groundwater analyses indicate the contamination originated from the operating service station's underground storage tank system.

Problems encountered with this soil vapor technique included: sampling under dissimilar meteorological conditions produced varying results; extraction of soil vapors at a rate of one liter per minute did not produce optimum results. Advantages of this soil vapor technique included: a cost-effective screening of samples; prompt results in a safe manner; and non-disruption of site hydraulics.

INTRODUCTION

Subsurface hydrocarbon contamination may exist in four phases: as free product on the ground water surface; as a dissolved fraction; as residual contamination of soil particles; or as vapor (Figure 1).[1] Soil vapors are air that fills the space between soil grain surfaces. Soil vapor

surveys utilize the volatility of gasoline components to determine subsurface contamination. The advantages of soil vapor surveys include:

- Non-disruptive of site hydraulics
- Safety
- Cost effective
- Prompt results
- Allows for a detailed assessment of a site.[2]
Figure 1
Depiction of Four Phases of Gasoline
Contamination in the Soil[2]

Several limitations exist with the use of soil vapor surveys. If bedrock or groundwater is near the ground surface, it is difficult to acquire representative samples. Soil vapors acquired from less than two feet below the ground surface may be mixed with ambient air causing dilution of the sample. Dense clay lenses and deep groundwater will decrease soil vapors. Biodegradation will alter the components of soil vapors.[2]

Meteorological conditions will also affect the results of soil vapor surveys. High barometric pressure will result in suppression of volatile flow in near ground surface samples. Ambient air temperature will affect the rate at which volatilization occurs.[2]

SITE DESCRIPTION

A complaint was lodged by the Kentucky Transportation Cabinet,

Department of Highways in August, 1988, concerning the quality and odor of water in its well. Preliminary sampling by the Kentucky Department for Environmental Protection revealed constituents indicating gasoline contamination. Subsequent sampling showed contamination of five potable wells in the area. One operating service station with three underground storage tanks containing gasoline and several abandoned underground tanks are in the immediate area where contamination had been identified (Figure 2).

and naphthalene.

A magnetometer survey of an area approximately 200 feet south of Gose Branch has indicated the possible location of an abandoned underground storage tank (Figure 2). Local residents indicate a store had operated at this location 20 to 25 years ago and did sell fuel oil and possibly gasoline.

A wet weather spring has been noted along Little Caney Creek in the affected area (Figure 3). Analyses of wet weather spring samples have shown the presence of constituents associated with gasoline contamination.

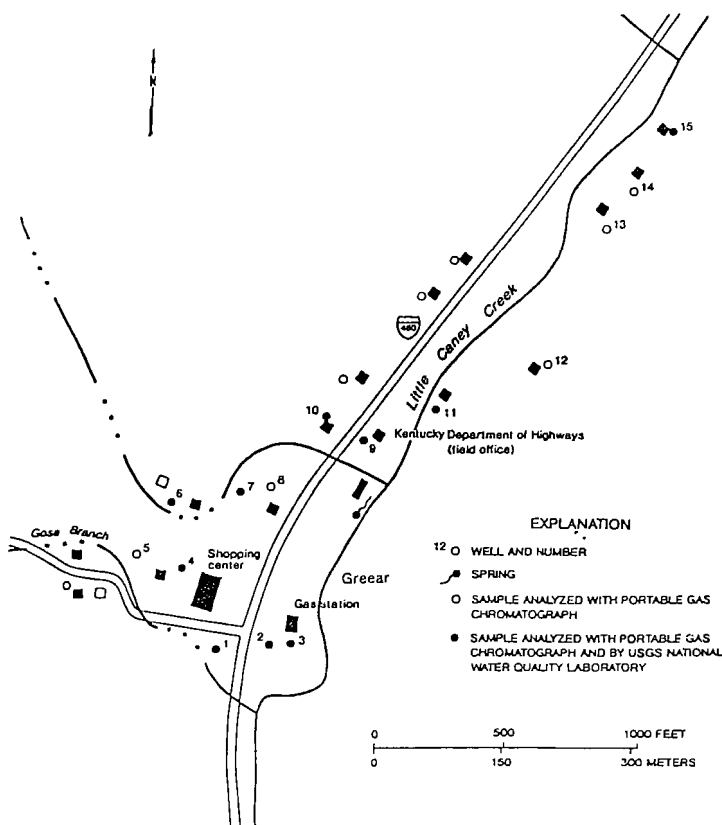
Figure 2
Location of Underground Storage Tanks


Figure 3
Location of Groundwater Wells in the Study Area

A field investigation was initiated by the U.S. Geological Survey and the Kentucky Department for Environmental Protection. The location of this investigation was approximately four miles south of West Liberty on U.S. Route 460. The objectives of this investigation were to:

* Determine the degree and extent of contamination from gasoline constituents
* Locate and confirm the source(s) of contamination
* Assess the impact of contamination on the quality of soils, groundwater, and surface waters in the vicinity

Information received from Department of Highways personnel indicated the removal of three abandoned underground tanks south of the operating service station in 1982, when US Route 460 was rerouted. This area was the former site of Jones' Restaurant, which did sell fuel and operated through the late 1950s (Figure 2).

Reconnaissance of the area resulted in the discovery of an abandoned underground tank west of the operating service station (Figure 2). Local residents indicate that this area was the former site of Hall's service station which had closed in the 1950s. The 550-gallon underground tank at this location was removed by the Kentucky Department of Highways in May, 1989. This tank was badly corroded and pitted. Soil samples obtained from the bottom of the excavation basin showed no gasoline constituents above the limits of detection. A sample taken from the approximately ten gallons of liquid remaining in the tank showed the presence of benzene, toluene, ethylbenzene, xylenes, trimethylbenzenes

Groundwater is the sole source of potable water in the contaminated area. Twelve potable wells were inventoried during the investigation (Figure 3): five wells are developed in the Lee Formation, five wells are developed in the Breathitt Formation and two wells are developed in the Quaternary fill. The Lee Formation is characterized by sandstone and siltstone with lesser amounts of clay, claystone, coal, ironstone and limestone. The Breathitt Formation is characterized by siltstone, sandstone and claystone. The Quaternary fill consists of gravel, sand, and silt.[3]

METHODOLOGY

Soil vapors were procured using an Environmental Instruments soil vapor sampling device. This sampling train consists of a slotted stainless steel screen and several 30-inch steel rod connections with an outer diameter of 0.5 inch and an inner diameter of 0.25 inch. The probe was topped with a "T" junction. Sampling probes were driven into the ground by an electric rotohammer. Modeling clay was packed around the sampling probe at ground level to prevent ambient air from being drawn into the sampling train.

Soil vapors were drawn to the sampling probe via an electric peristaltic pump. An electric pump was used because a gasoline-operated pump might contaminate the samples. Vacuum was applied to the sampling train for one minute at a rate of one liter per minute. However, extracting soil vapors at a rate of one liter per minute may have caused a larg-

er sphere of influence than desired.

A milliliter syringe was inserted through a Teflon septum in the "T" connection and vapor was removed from the sampling train. The syringe plunger was drawn back and allowed to remain in the septum for 5 to 10 seconds with vacuum continuing to be applied. The locking mechanism of the syringe was engaged, and the syringe was withdrawn from the septum. Duplicates were taken at each sample location. The syringes were labeled with the sampling location and transported to the mobile laboratory for analyses.

Samples were analyzed using a HNU 311 portable gas chromatograph with a 20-inch column. The gas chromatograph was set with an isothermal injection temperature of 130 °C and an oven temperature of 75 °C. The carrier gas rate was set at 20 ml/min, and the attenuation was set at the lowest gain setting.

To insure quality assurance and quality control, several measures were instituted. Ambient air was sampled and analyzed using desultory syringes to examine the cleanliness of the syringes. The soil vapor probes were decontaminated after each sampling location using a laboratory grade detergent wash followed by a deionized water rinse and a hexane rise. The probes were then allowed to air dry. Ambient air was periodically sampled through the soil probe and analyzed to insure the effectiveness of the decontamination.

Four plots were chosen for examination using soil vapor survey techniques in areas known or suspected to be contaminated. These areas included Well 3, Well 6, the unidentified abandoned underground tank and the operating service station (Figures 2 and 3). Ten sample points were chosen in the vicinity of Well 3 ranging in depth from 3.5 to 4.5 feet. Four sample points were chosen in the vicinity of Well 6 ranging in depth from 5.5 to 7.5 feet. Eight sample points were chosen in the vicinity of the unidentified abandoned underground tank ranging in depth from 3.8 to 5.5 feet. Forty-one sampling points were chosen in the vicinity of the operating service station ranging in depth from 4.5 to 7.0

feet. Sampling depth was dependent upon depth to saturated soils, physical character of the soil and depth to bedrock.

RESULTS

All soil vapor analyses in the vicinity of the unidentified abandoned underground tank and Well 6 were negative for benzene, toluene, ethylbenzene, and xylene constituents. Soil vapor analyses in the vicinity of Well 3 and the operating service station's underground storage tank system exhibited increased benzene, toluene, ethylbenzene and xylene concentrations. One area was defined by sampling points 14, 15, 16 and 17. The second area was defined by sampling points 22, 23, 36, 37 and 39 (Figure 4). Chromatograms of the standard, background, and sampling point 17 are found in Figure 5.

DISCUSSION AND CONCLUSIONS

This site investigation consisted of groundwater, surface water, soil and soil vapor sampling. Samples were qualitatively screened in the field with a portable gas chromatograph. Duplicate groundwater, surface water and soils samples were quantitatively analyzed by the U.S. Geological Survey, National Water Quality Laboratory.

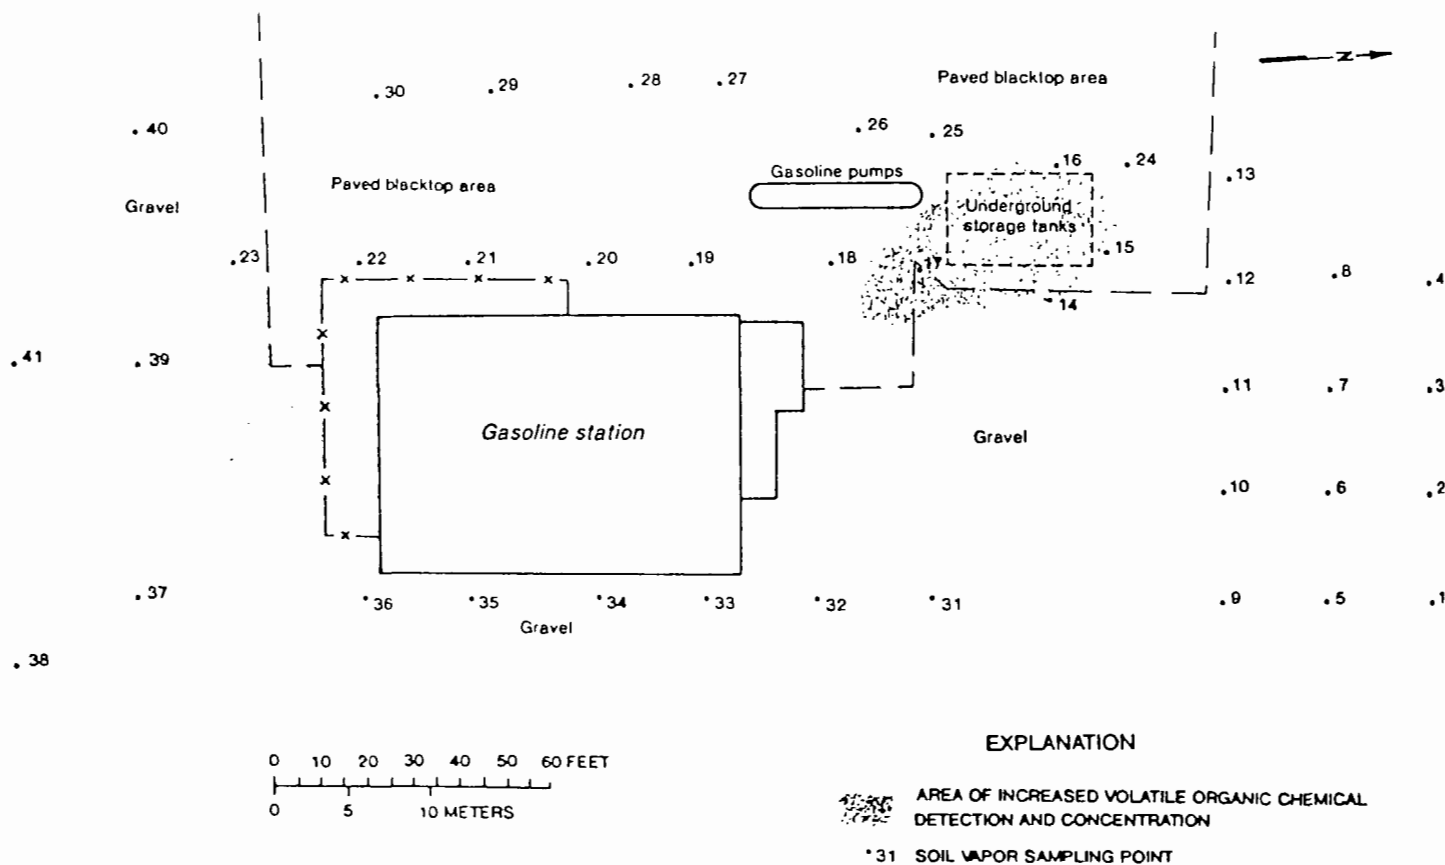
Qualitative analyses of soil vapors indicated gasoline contamination only on the property of the operating service station. Soil sample quantitative analyses also indicated gasoline contamination only on the property of the operating service station. Quantitative analyses of groundwater and surface water showed gasoline contamination of Wells 2, 3, 6, 9, and 11 and a wet weather spring entering Little Caney Creek north of the operating service station (Figure 3). Quantitative analyses of groundwater from monitoring Well 2 and Well 6 indicated the presence of methyl-tertiary-butyl ether. Methyl-tertiary-butyl ether is an additive commonly used in unleaded gasolines and has been commercially produced since 1979.[1] The increased concentrations of volatile compounds in soil vapors and soil, in addition to the presence of


Figure 4
Location of Soil Vapor Sampling Points
on the Property of the Operating Service Station

methyl-tertiary-butyl ether at two groundwater sampling points, indicate that the source of gasoline contamination is the operating service station's underground storage tank system.

Case Study on the Application of Air Sparging as a Complimentary Technology to Vapor Extraction at a Gasoline Spill Site in Rhode Island

Michael C. Marley
Matthew T. Walsh
Peter E. Nangeroni
Vapex Environmental Technologies, Inc.
Canton, Massachusetts

ABSTRACT

Vapor extraction (soil venting) is a successful and cost-effective remediation technology for removing VOCs from vadose (unsaturated) zone soils. However, in many cases, seasonal groundwater table (GWT) fluctuations, GWT drawdown associated with pump-and-treat remediation techniques and spills involving dense, non-aqueous phase liquids (DNAPLS) create residually saturated soils below the water table. Vapor extraction alone is not considered to be an optimal remediation technology to address these areas of contamination.

Artificial water table drawdown is one approach that may be utilized to expose the contaminated soils, thereby increasing the efficiency of the soil venting process. However, in some cases, this neither practical, nor cost-effective. An alternative approach is the use of air sparging (injection) wells to inject hydrocarbon-free air into the saturated zone below the areas of contamination. The contaminants dissolved in the groundwater and adsorbed on the soil partition into the advective air phase, effectively simulating an in situ air stripping system. The stripped contaminants are transported in the air phase to the vadose zone, within the radius of influence of the vapor extraction system. The contaminant vapors are drawn through the vadose zone to a vapor extraction well where they are treated utilizing standard vapor extraction off-gas control system(s).

This paper presents a case history of the application of air sparging as a complimentary technology to vapor extraction in the remediation of residually saturated soils below the water table at a gasoline spill site in Rhode Island.

INTRODUCTION

In 1985, remedial activities were implemented at a gasoline spill site in Pawtucket, Rhode Island. The engineering company contracted to perform the remedial activities designed, installed and operated a free gasoline product recovery and groundwater pump-and-treat system. An air stripping tower was utilized to removed volatile organic hydrocarbons (VOCs) dissolved in the groundwater. Gasoline hydrocarbon vapor migration into nearby basements was controlled through the operation of a soil gas venting system (SVES), also installed in 1985. The groundwater treatment and free product recovery systems were shut down in May 1987; however, the soil venting system remained in operation, and additional vacuum wells were installed to remediate gasoline-contaminated vadose zone soils and to recover hydrocarbon vapors in the vicinity of the spill location. Approximate locations of the monitoring wells, vacuum wells and treatment equipment existing on the site as of May 1987 are shown in Figure 1.

The Rhode Island Department of Environmental Management (DEM) set closure limits of 10,000 parts per billion (ppb), 500 ppb, and 500 ppb total BTEX for monitoring wells MW-3, MW-11 and MW-12, respec-tively. While BTEX levels at MW-11 and MW-12 have remained below the closure limit prior to VAPEX's involvement at the spill site, levels at MW-3 have fluctuated around 25,000 ppb total BTEX with a relative deviation of 16% over the period from July 1988 through July 1989, displaying a high of 29,000 ppb in July 1988 and a low of 19,000 ppb in October 1988. The last sample reported during that period was 21,000 ppb in July 1989.

VAPEX were contracted in August of 1989 to evaluate site conditions for the purpose of developing a specific strategy to meet the DEM's total BTEX closure limits for MW-3. An evaluation of the existing soil gas venting system concluded that the SGVS was influencing and had achieved remediation of the vadose zone soils in the area of concern. It was concluded that the local source of groundwater contamination was located on the soils below the water table level in that area.

Under non active remediation conditions, transport of immiscible phase hydrocarbons from the saturated zone to the vadose zone requires dissolution of the hydrocarbons into the aqueous phase followed by diffusion/dispersion of the dissolved hydrocarbons through the aqueous phase to the air-water interface, where volatilization into the vadose zone occurs. The hydrocarbon vapors are then removed from the vadose zone by the SGVS. Where total hydrocarbon concentrations in the saturated zone are moderately low, as was the case at this site, and conditions are relatively static, the intraphase transport of hydrocarbons occurs very slowly, requiring long periods of time for hydrocarbon source reduction. Therefore, the utilization of the soil gas venting system alone would be expected to be a very inefficient means of achieving the DEM closure criteria at MW-3.

VAPEX performed a cost/benefit analysis on three potential treatment methodologies to achieve the DEM Closure Criteria in the vicinity of MW-3. The three proposed treatment methods were: (1) re-activate the existing groundwater pump-and-treat system, (2) install and operate a new pump-and-treat system centrally located within the area of concern and (3) in conjunction with the existing soil gas venting system, install and operate an air sparging system centrally located within the area of concern. As a result of the cost/benefit analysis, VAPEX proposed that an air sparging system be designed, installed and operated at the site. The air sparging process involves the introduction of hydrocarbon-free air to the saturated zone below the contaminated soils in order to expedite transfer of saturated zone hydrocarbons to the SGVS influenced vadose zone.

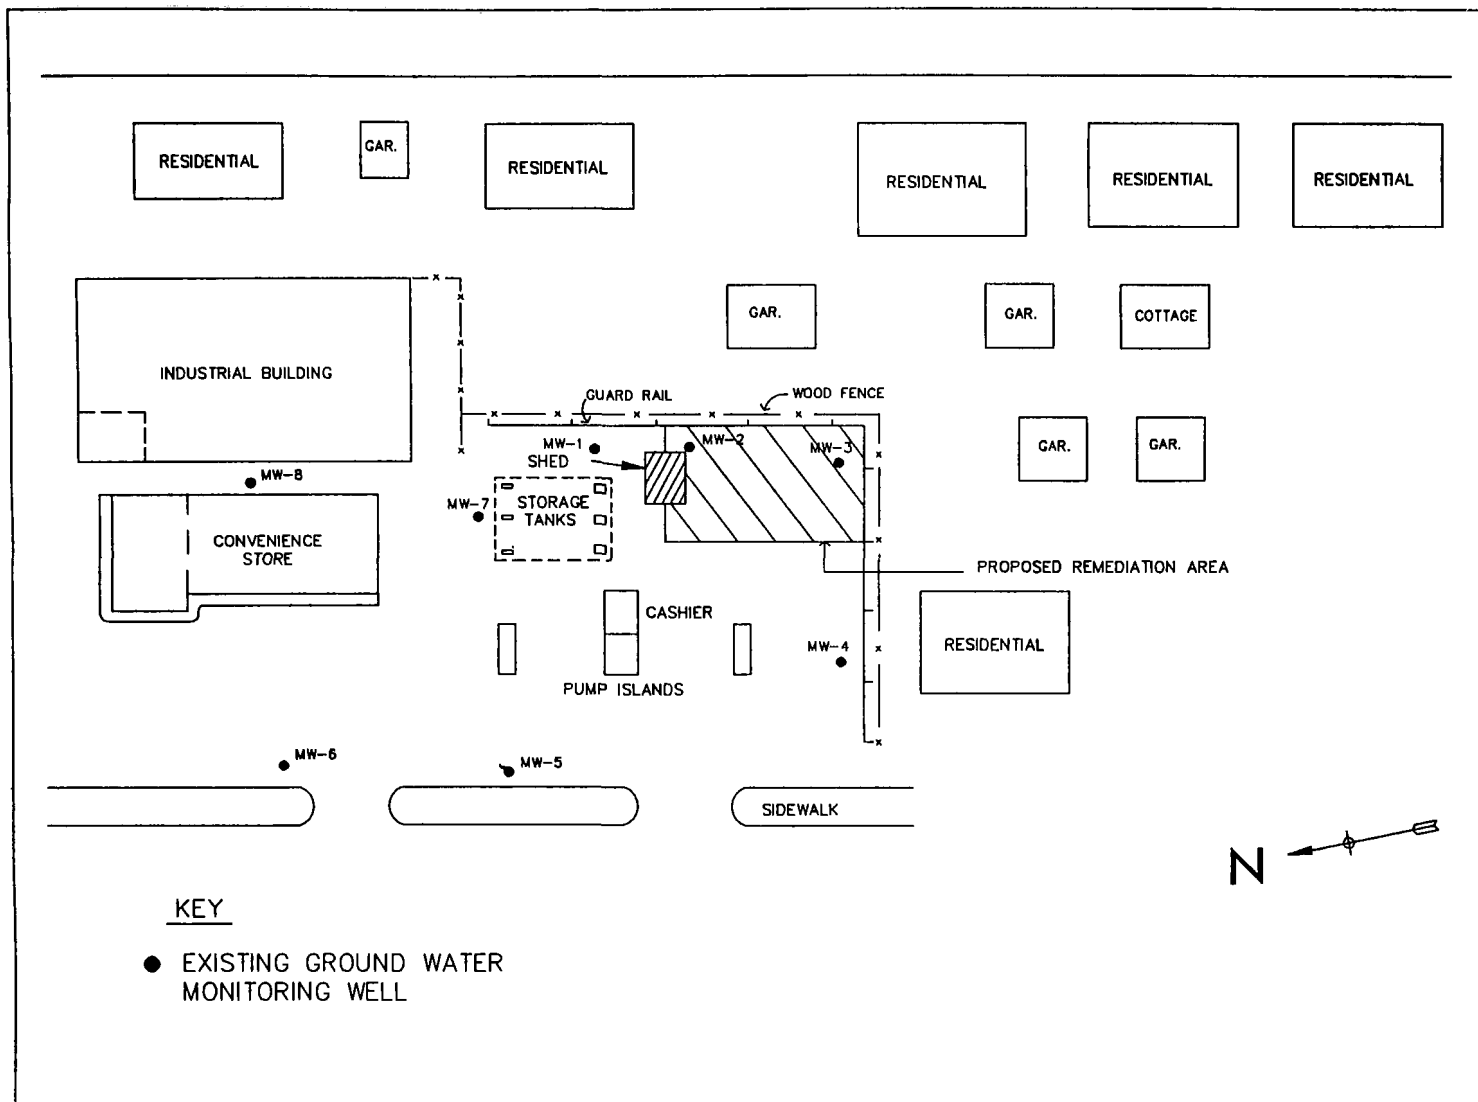
The air sparging process involves the introduction of hydrocarbon-free air to the saturated zone below the contaminated soils in order to expedite transfer of saturated zone hydrocarbons to the SGVS influenced vadose zone. Air flow in a previously water-saturated soil involves a displacement process. The air displaces the water filling the soil pore spaces. When a continuous air phase through the previously water-filled


Figure 1
Site Plan
May, 1987

pores is attained, the air permeability of the soil will be a function of the degree of water saturation of the pore as shown in Figure 2.

Before the air can pass as a continuous phase through the contaminated soil, the air pressure must attain a minimum value termed the air entry pressure (pe). Figure 3 displays a typical porous media capillary pressure curve depicting the related value of the air entry pressure. The sparging system would be designed to ensure that the air would pass through the contaminated soils providing the hydrocarbons with a more efficient transfer pathway to the vadose zone.

SYSTEM INSTALLATION AND OPERATION

Site Geology

The general stratigraphy of the investigated area is defined by a fine to coarse brown sand with no silt and 5 to 15% fine to medium gravel extending from grade to 19 to 20 feet below grade. The coarse, highly permeable material is underlain by a much less permeable brown/grey, well sorted, dense, fine sand. Groundwater was observed at 15.5 to 16.0 feet below grade and displays and approximately 3 feet seasonal fluctuation in level.

Design Parameter Evaluation

To verify the presence of the contaminated soils below the water table

level and to develop design parameters for a full-scale air sparging system, eight borings were advanced in the proposed remediation area. Soil samples were taken during the advance of the borings and were analyzed utilizing U.S. EPA Method for volatile aromatics. The results of the analysis confirmed the presence of low levels of weathered gasoline components on the saturated soils from 15 feet down to approximately 25 feet below grade. BTEX compounds detected ranged in concentration from 835 micrograms per kilogram (ug/kg) to nondetectable, with levels generally decreasing with depth.

Two test air injection wells, (AIW1S and AIW2S) and three monitoring points (VP-1, VP-2 and VP-3) were installed at the site where the soils analyses had indicated the presence of relatively high levels of hydrocarbons in the soil and/or groundwater. The approximate locations of the test injection wells and monitoring points are shown on Figure 4.

Major design parameters to be evaluated were: achievable contaminant removal rates, air entry and operation pressure requirements at the injection wells, achievable injected air flow rates, achievable effective radius of influence of the injection system and an evaluation of pulsed versus continuous air injection.

A 1-day pilot test was performed on the test wells (screened from 18 feet to 20 feet below surface grade). Pressures and achievable air flow rates were measured at each well and monitoring point during the pilot test. The discharge from the SGVS was monitored prior to, during

and after the pilot test.

A portable gas chromatograph (HNU Model 321, equipped with a photoionization detector) was utilized to analyze the discharge data from the soil gas venting system. Prior to the initiation of the injection test, the background discharge reading from the soil gas venting system was 13 parts per million by volume (ppm-v/v) as gasoline. During the injection tests, the discharge from the soil venting system reached a maximum level of 300 ppm-v/v. The SGVS was operating at an air flow rate of approximately 100 cubic feet per minute, while injection air flow rates varied between 10 and 20 cfm, providing a minimum withdrawal to injected air flow ratio of five to one. SGVS discharge concentrations, generally, decreased relatively rapidly during the conduct of the injection test at a well. Approximately 0.7 pounds of gasoline range hydrocarbons were removed from the groundwater and saturated zone soils during the short-term test.

Relatively low air entry and operation pressures of 1 to 2 pounds per square inch (psi) were required to achieve air injection flow rates of 5 to 10 cfm. As expected, during the air injection process, slight positive pressures were measured at the monitoring points in the vadose zone and a rise (0 to 1 inches) in the water table level was detectable within the area local to the injection well. As the shallow injection well screen was located 3 to 5 feet below the water table level in a coarse sand, it was anticipated that the radius of influence of the injection wells would be relatively small. Based on the air pressure readings at the monitoring points and the local water table rise, the radius of influence was calculated to be approximately five feet. No significant differences were observed in mass removals during the injection test under pulsed versus continuous operation. However, with respect to energy conservation and to prevent the development of short-circuiting pathways for the air flow under continuous operation, pulsed injection was considered to be the most advantageous mode of operation.

Full-Scale System Installation and Operation

Based on the parameters evaluated during the pilot test, VAPEX designed and installed a full-scale air sparging system. The full-scale system consisted seven shallow air injection wells and six deep injection wells enveloping the area of concern. Figure 4 shows the remediation area layout. The deep air injection wells were screened from 25 feet to 27 feet below grade in the fine sand material. Two 2.5-hp Ingersoll-Rand oil-less compressors were utilized to provide the hydrocarbon-free air supply to the injection wells. The shallow air injection wells were operated on a 3 hours on, 9 hours off schedule, at an air pressure of 1 to 2 psi and 3 to 6 cfm air flow rates. The deep injection wells were operated on a 6 hours on, 6 hours off schedule, at an air pressure of 6 to 8 psi and 2 to 6 cfm air flow rates.

RESULTS

The operation of the full-scale air sparging system consisted of a 60-day run time within the period from March 21, 1990 through July 14, 1990. During that period, approximately 5 to 10 pounds of gasoline range hydrocarbons were removed from the groundwater and soils within the remediation area. Groundwater samples were collected and analyzed utilizing U.S. EPA Method 602 prior to, during and after the operation of the full-scale air sparging system. The results of the groundwater analysis are presented in Table 1. In Table 1 it can be seen that following 2 to 3 weeks of operation, the level of BTEX in the groundwater had declined in non-detectable levels with the area of concern.

One to two weeks prior to groundwater sampling, the system was shut off to allow the system to come to equilibrium. Dissolved oxygen levels within the area of concern rose from an average level of 1.4 milligrams per liter (mg/l) to approximately 6 to 8 mg/l, reflecting the aer-

ation of the groundwater within the zone of influence of the air sparging system. As determined by pressure measurements in the vadose zone, the air sparging system as designed displayed an effective radius of influence that enveloped the area of concern.

CONCLUSIONS

An air sparging system was designed, installed and operated at a gasoline spill site in Rhode Island. Formerly, the site had undergone five years of remediation utilizing a combined system of groundwater pump-and-treat and a soil gas venting system. While the soil gas venting system was effective in remediating the vadose zone soils, gasoline con-tamination remained on the soils below the water table level and the DEM closure criterion of 10,000 ppb at MW-3 was not achieved.

Following 60 days of operation of the air sparging system, approximately 5 to 10 pounds of gasoline range hydocarbons were stripped from the groundwater and water saturated soils. Within 2 to 3 weeks of operation the closure criteria were achieved at MW-3 and the site is now on a quarterly groundwater monitoring program to ensure that the closure levels are maintained.

The results of the case study demonstrate the potential for air sparging to be utilized as a complimentary technology to vapor extraction (SGVS) to attain a cost-effective, turnkey solution for remediation of gasoline spill sites.

On-site Vapor Extraction—Demonstrated Effectiveness

James B. Plunkett
Thomas P. Simmons
J.B. Plunkett Associates, Inc.
Winchester, Massachusetts

ABSTRACT

Vapor extraction technology has been successfully used to remediate soils contaminated with volatile organic compounds (VOCs). The majority of vapor extraction remedial actions have involved application of a vacuum to contaminated soils in situ.

Soil pile venting employs vapor extraction to reduce VOC levels in soils that have been excavated and stockpiled on the site. Soil pile venting has been used as a successful remedial response action at sites contaminated with VOCs, however, limited published information on design requirements and demonstrated effectiveness is available. Additionally, most of the previous applications have not involved use of a closed system.

A former paint and varnish manufacturing facility in Massachusetts which stored bulk petroleum hydrocarbons and other organic chemicals underground served to demonstrate the effectiveness of vapor extraction in an on-site, above ground, closed system. The application involved excavation of soils containment with toluene, ethylbenzene, xylenes, MEK and vinyl acetate as a of leaking underground tanks and piping.

Soils were excavated during underground storage tank and piping removal placed containment in a closed system for application of vapor extraction technology. The system was comprised of a specifically designed sand bed overlain by an impervious liner; stockpiled contaminated soils on top of the liner in a specifically designed structurally competent manner; vapor vent and vapor extraction piping systems; condensate collection system; and complete enclosure of the stockpiled soils with an impervious liner using extrusion welding processes and attachment of a vapor extraction system blower, a thermal oxidizer vapor treatment system, sampling ports, monitoring devices and electronic controls. A description of the design, including system monitoring requirements and results, perimeter air monitoring results and a cost effectiveness analysis are provided.

INTRODUCTION

This paper discusses an on-site, aboveground treatment technology for remediating soils at a paint and varnish manufacturing site contaminated with esters, ketones, aromatic and halogenated organic compounds. The volatile nature of these compounds allows them to be stripped from soils by inducing a negative pressure over the soil particles surface area. An effective negative pressure can be maintained by connecting a vacuum blower to a piping system installed in the contaminated soils. Vapor extraction, or soil venting as it is also known, has been successfully applied to soils contaminated by releases of gasoline, degreasing solvents and dry cleaning solvents. Soils with grain sizes down to silty fine sands have been effectively remediated by this cleanup technology.

The majority of vapor extraction remedial designs have been applied in situ. Source removal becomes increasingly important where groundwater contamination is present or there is a significant threat of pending groundwater contamination. The operational period of an in situ vacuum extraction system may be greater than desired to remediate a contaminant source in an environmentally sensitive area. On a limited number of sites, contaminated soils have been excavated and stockpiled for above ground remediation using vapor extraction. As a result of a risk assessment performed at Paint and Varnish Site, it was recommended that leaking underground piping and contaminated soils be excavated for above ground, on-site treatment. The excavated soil was stockpiled on a high density polyethylene liner. The liner was folded over the stockpile and extrusion welded along three edges, encapsulating the contaminated soil. Vapor extraction and air intake piping were installed in the soil pile during construction.

SITE DESCRIPTION AND HISTORY

The Paint and Varnish Site comprises approximately three acres in Central Massachusetts, and contains buildings, paved areas and woods (Fig. 1). The main manufacturing building was used to store and mix oil-based primers and paints. An adjacent laboratory building was used to develop and test paint and varnish products. Both buildings were connected to a pump house by underground product distribution lines. The pump house distributed product from 14 underground steel storage tanks ranging in volume from 2,500 to 5,000 gallons each. A list of each tank, its contents and estimated age is presented in Table 1. The site also contained a 55 gallon drum burial area in the southwest, wooded area of the site.

The majority of the site topography slopes to the east towards a nearby residential community. The topography is influenced by the underlying bedrock which outcrops in the northwest corner of the site. The southern half of the site is mainly wooded.
The site has been vacant since late 1985. In late 1986 and early 1987, 14 underground storage tanks were removed. The associated underground piping transferring product to the laboratory and main building was left in place. In June 1987, approximately 80 55-gallon drums were excavated from the drum disposal area in the southwest corner of the site. J.B. PLUNKETT ASSOCIATES, INC. has been involved with the site since August 1988.

SITE GEOLOGY

The geology observed during subsurface exploration programs is fairly consistent beneath the site. A surface soil layer consists of light brown silty fine sand with little amounts of coarser materials. This one to two foot layer has been classified as fill material due to the presence of metal and wood debris. Underlying this unit is a dark brown silty fine sand approximately one foot thick. Beneath this stratum to an average

three foot depth is an orange silty fine sand layer containing angular rock fragments. Below approximately three feet, down to the weathered bedrock surface, the soil consists of brown to gray medium to fine sand with secondary amounts of coarse sand, silt and boulders. The silt content of this layer increases with depth. The bedrock surface exposed in the northwest property corner was encountered at approximately 24 feet along the eastern border of the property. The bedrock has been identified as a moderately fractured, biotite granite.

PRIMARY CONTAMINANTS

The results of previous soil and groundwater sampling associated the primary source of contamination with the former underground storage

tank farm and the existing underground piping. The primary contaminants identified in the soil excavated from these areas and stockpiled on the liner include xylenes, toluene, ethylbenzene, methyl ethyl ketone (MEK) and vinyl acetate. Total concentrations of volatile organic contaminants as high as 70 ppm in groundwater and 380 ppm in soils have been found.

A review of the physical/chemical properties of the primary contaminants in soil identified vapor extraction as a feasible on-site treatment alternative.

Physical/chemical vapor phase properties for the primary contaminants at the site are listed in Table 2. [2]

Henry's Law Constant is an expression of the distribution of a volatile compound or solute at equilibrium between liquid and vapor phases. A review of available literature on vapor extraction systems suggests chemicals with a Henry's Constant greater than 0.01 can be remediated effectively using this technology.[1] While Henry's Law describes the proportion of a compound in the gaseous phase at equilibrium, vapor pressure describes the pressure exerted by the compound in the vapor state.

Figure 2
Cross-sectional View of Liner and Soil Pile

SOIL PILE CONSTRUCTION

The soil pile dimensions after construction are 36 feet by 140 feet by six feet high (Fig. 2). The sides of the soil pile are graded at a 2 to 1 slope for stability. The pile pitches at a 10% grade towards the blower. The liner consists of Permalon® Ply, X-210 high density poly-

ethylene laminate (18 mil). Each laminae is oriented at 45° in succession to provide increased strength. The liner material was selected for its tear resistance, low vapor permeability, contaminant compatibility and photodegradation resistance. The contaminated soil was piled on the liner in sections which minimized contaminant loss through volatilization. The piping was built into the pile at the specified heights and locations as each section was under construction.

Four vent pipes installed at the corners along the pile length consist of 4 inch diameter Schedule 40, PVC slotted screen (Fig. 2). Each vent pipe is slotted in widths of 0.020 inch. A four inch PVC extraction pipe installed lengthwise through the pile center is slotted in widths of 0.010 inch to distribute the vacuum pressure equally over the length of the pipe. The smaller openings provide a more uniform draw on the contaminated soils. Each pipe is surrounded by approximately six inches of filter stone with a median grain diameter of 3/8 of an inch. The vent pipes and the extraction pipe extend through the liner at both ends. The piping configuration is designed to draw contaminated soil vapor atmosphere air radially inward through the pile, flushing the contaminated soil vapor towards the extraction pipe. The vapor flushing method will improve and increase recovery rates and volumes.

The vent pipes at the bottom corners of the pile also function as condensate traps. The vent pipes pitch at a 10% slope towards solid, clear PVC pipe which will collect condensate buildup inside the line. Ball valves installed on the ends of the clear pipe allow the condensate to be drained off. An identical ball valve also has been placed on the downgradient end of the extraction pipe to permit regulation of vapor flow from the pile.

SOIL VAPOR TREATMENT

Contaminated vapor extracted from the pile will be treated to maintain atmospheric air quality standards. A preliminary design has been completed. (Fig. 3).

The estimated maximum influent vapor concentrations of the primary contaminants are: 74 ppm vinyl acetate, 58 ppm methyl ethyl ketone, 38 ppm total xylenes, 14 ppm ethylbenzene, and 5 ppm toluene. These values represent the maximum concentration of the compounds in soil samples collected from the soil stockpile prior to heat sealing the liner.

A blower flow rate between 150 and 350 scfm will be selected which will extract the volume of contaminated vapor in the soil pile every 15 to 45 minutes. These air flow rates will produce the desired vacuum pressure of approximately 40 inches of water.

The vapor stream drawn out of the pile will be directed to a thermal oxidizer which will incinerate the VOCs in a ceramic burner chamber at 1400°F. The minimum destruction efficiency of this unit for these compounds is 95%. Increased destruction efficiency can be obtained by reducing the air flow rates. The estimated operation time of the system to remove the contaminants from the soil stockpile at 250 scfm is 13 weeks.

COST ANALYSIS

Depending upon the objective, excavation and on-site treatment or in situ treatment may prove to be the most cost-effective alternative for remediation of contaminated soils at the site. Typically, the excavation and on-site treatment option is more effective when limited data on subsurface site conditions and occurrence of contaminants are available,

especially when excavation of a subsurface storage facility is planned. The cost-effectiveness of this option is obtained through advance planning and preparedness. This goal is accomplished by a system design such as that described in this paper which can be constructed during the excavation operations.

For soils contaminated with hazardous substance list compounds, only four alternatives (other than no action) are available: (1) excavation and on-site treatment, (2) in situ treatment, (3) excavation and off-site disposal or (4) excavation and off-site incineration. Table 3 details a breakdown of costs for these four alternative.

The on-site vapor extraction treatment costs were derived using data on expenditures made during design and construction of the vapor extraction system discussed in this paper. The in situ treatment costs were derived from a vapor extraction design project being performed by JBP at a different site. Although site conditions for the in situ system are different, the design is comparable to what would have been required to remediate soils in situ at the Paint and Varnish Site. The operation costs for the on-site system and the in situ system were based on manufacturer information and the costs of propane and electricity usage associated with a three month operating period for the thermal oxidizer. The off-site alternative costs were derived directly with communications with licensed contractors. All figures are 1990 dollars.[3]

As shown, the off-site alternatives are substantially more expensive than the on-site alternatives. The on-site costs shown for the system described in this paper, in our opinion, represent a near worst case scenario due to the levels of contamination which occurred in the soils, the types of material excavated and the difficulty of the excavation process due to the high levels of vapors.

CONCLUSIONS

Soil contaminated with VOCs can be excavated and encapsulated on-site with an impermeable liner, resistant to chemical and photochemical degradation, secure from human contact and infiltration of precipitation, and designed so that no uncontrolled releases of vapors or leachate occur. Encapsulation is an effective method for temporarily isolating contaminated soils from the environment. Installation of a piping network during soil pile construction prior to encapsulation allows access to contaminated soil vapors inside the liner. By attaching a vacuum source to the piping, the contaminated vapor can be extracted from the enclosed pile, treated and released to the atmosphere. Including vent pipes at strategic locations during the soil pile construction will permit enhanced vapor recovery.

This remediation design is a low cost on-site alternative to soil remediation at sites contaminated with VOCs. This design has particular merit when applied to locations in highly environmentally sensitive areas (i.e., sole source aquifer) where rapid contaminant source removal is the foremost priority. This design also is appropriate in high water table areas or in areas where soil moisture contents are high.

Brown and Caldwell Consultants
Irvine, California

ABSTRACT

An overview of the principles and use of soil vapor extraction, or SVE, is presented. In many cases, SVE provides an economical and practical approach to mitigating hydrocarbon-contaminated soils.

The implementation of SVE measures are demonstrated for both silt-sized, very fine grained sands and for coarse grained soil matrices, for shallow water table as well as dry (moist) soil conditions and for volatile and semivolatile contaminants. Special emphasis is placed on the soil conditions, contaminant characteristics and SVE system operating variables.

Two case histories are presented to demonstrate the effectiveness and simplicity of an SVE system as well as the importance of design and operating considerations. In the first case history, gasoline contamination of a shallow water table aquifer resulted from a leaking underground storage tank located in southeastern Canada. The site was mitigated in 1982 using SVE. Though site conditions were not optimum for SVE application, the shallow water table coupled with a very fine grained soil matrix produced a 'wick effect' which enhanced the impact of SVE on residual gasoline in the capillary fringe.

The Canadian case shows the effect of marginal soil permeability and a high water table/capillary fringe condition on the volatile organic compounds (VOC) removal efficiency of a typical SVE system. The impact of induced, atmospheric air recharge to the SVE system also was evaluated and was determined to have little or no impact on the SVE system efficiency. However, the subject SVE operation successfully extracted approximately 7 gallons of gasoline per day from the SVE impact zone.

The second case history, recently completed in California, involved both light-end volatile chemicals and heavier semivolatiles in a dry, generally coarse, permeable soil matrix. In the California case, a 40-foot thick unsaturated soil zone afforded excellent SVE pressure distribution and effect. The VOCs were removed over a 9-month period of SVE operation, while the majority of the semivolatiles were biodegraded in conjunction with the SVE-induced aeration of the contaminated soils. Approximately 5 gallons per day of product were removed from the impact zone.

INTRODUCTION

Soil vapor extraction (SVE), or soil venting, has been commonly used to remediate hydrocarbon-contaminated sites since the late 1970s. As current trends indicate, SVE is fast becoming the in situ soil treatment method of choice for many sites contaminated by hydrocarbons and other volatile organic compounds (VOC). Two decades of using SVE for soil air containment and interception and for soil remediation have provided the engineer and scientist with many examples of effective site cleanup and mitigation.[2]

In general, SVE is the removal of volatile constituents from unsaturated soils using a vacuum, or negative pressure source. The SVE equipment (exhaust pump or blower, production wells, piping, vapor aftercooler and knockout drum, and granular activated carbon (GAC) canisters, if required) is easily deployed and installed. The appropriate SVE deployment and operating requirements for a specific site are determined from pilot studies which are used to define the design criteria.

Following regulatory approval of the system operation and configuration, VOC contamination can be mitigated within a matter of months. Contaminant concentration gradients which may threaten the public health (ambient air, adjacent structures, the groundwater quality, etc.) may be effectively reversed shortly after implementation of the SVE program.

SVE is a generally nondisruptive, cost-effective technology which can be coupled with conventional pump-and-treat methods to remove adsorbed contaminants from unsaturated soils. Free product removal is an attainable goal, while containing and extracting the VOC contaminant, restricting hydrocarbon migration to the water table and minimizing overall cleanup time[1,5] are attractive results of SVE implementation. Moreover, while removing soil vapor, the negative pressure created within the soil zone also enhances the extraction and removal of carbon dioxide generated during the dieoff of bacterial growth within the soil pores.

These biomasses are associated with biodegradation of the 'heavy-end' semivolatiles,[8,16] those hydrocarbon molecules having carbon numbers greater than C_{12} or C_{14}. Aeration of the biomass stimulates biodegradation while withdrawal of the carbon dioxide waste product permits active biomass regrowth.

SVE is commonly used to extract lighter volatile compounds from the vadose and capillary zones of the subsurface soils (the unsaturated zones lying above the water table). The SVE procedures also effectively minimize secondary contamination of the water table due to percolation of groundwater downward through contaminated soil zones. SVE also aids in reducing floating hydrocarbons on the water table by enhancing volatilization from the surface of the floating product, often as a result of the wick effect encountered in fine grained capillary fringes.[4]

Factors influencing desorption of a compound from the soil, diffusion into the soil air and into the atmospheric air are the soil's adsorptivity, the soil-water partition coefficient and the solubility, vapor pressure and Henry's Law constant for the VOC molecule. The speed with which this desorption and diffusion takes place is a function of the soil porosity, grain size, moisture content and bulk density and the chemical characteristics of the compound and the operating characteristics of the SVE system.[14,15] The next section of this paper describes

these variables and the diffusion mechanism in detail.

PRINCIPLES OF SOIL VAPOR EXTRACTION

Basically, SVE is the volatilization of a chemical compound from a soil matrix. The physical and chemical processes by which this occurs comprise a co-dependent suite of actions and reactions which determine the rate and degree of volatilization and subsequent success of an SVE project.

Volatilization, the basic mechanism of SVE, relies on the ability of a compound to evaporate or volatilize to the soil-air atmosphere from a nonvapor environment. Various mathematical models and procedures have been developed which help to evaluate this process.

These methods of analysis permit the estimation of chemical concentrations in the soil as well as the volume of the compound diffused to the soil air and subsequently to the SVE system discharge. Such analytical methods should be used as indicative tools and are considered reliable only when corroborated by the results of field conditions as defined by pilot studies, performance results and field and laboratory measurements.[21]

Mobility Factors

Volatilization of a compound from a soil particle requires desorption of the compound from the soil and subsequent migration of the compound to the surface of the soil particle or soil layer. The rate of movement of the compound to the soil surface significantly impacts the length of time required to remediate a site and the cost-effectiveness of an SVE program.

A successful SVE program is defined by attaining a controlled rate of soil vapor extraction by which an appropriate chemical vapor concentration is maintained at the soil surface. An equally appropriate rate of removal of that vapor occurs such that the flux of chemical vapor away from the soil surface to the atmosphere neither limits nor reduces the ability of the compound to continue to migrate from the soil surface and into the soil moisture surrounding the particle with subsequent diffusion into the soil vapor.

The relative volatility of VOCs when not adsorbed on a soil particle or soil layer can be determined from the vapor pressure and water solubility of the subject compound. VOCs of low water solubility will volatilize quickly from water if little or no sediment is present; likewise, colloidal materials, if present, will limit such volatility. Thus, volatilization of compounds from a water-atmosphere interface is a relatively simple process; VOC volatilization from a soil-water-air interface is more complex.

The equilibrium distribution of the soil-water-air matrix is affected by the inherent saturated vapor pressure of the compound; the vapor pressure at the soil surface; the compound solubility; the adsorption coefficient; the various soil-water, compound-water and compound-air partition coefficients; Henry's constant; and the rate of movement of the compound to the soil particle or soil layer surface.

The two processes most critical to SVE success are the movement of nonvapor and vapor from the soil particle to the particle surface (or from a layer of soil particles to the layer surface) and the movement of vapor away from the soil surface to the atmosphere. The two most common mechanisms of VOC movement to the evaporating surface (the surface of the soil particle or soil layer and the thin layer of soil moisture which lines the soil pores), include molecular diffusion and convection.

Both convection (mass flow in the evaporating soil moisture) and advection (soil vapor transport within the soil pores) as well as molecular diffusion (within the soil and at the soil surface) often occur together during SVE processes.[13] These factors are addressed in the following two sections which describe the transport mechanisms of VOCs to the soil particle surface and from the particle surface to the soil air.

VOC Flux within the Soil Layer

The initial volatilization rate of a compound from the soil surface will depend on the compound's vapor pressure at the soil surface. This is determined by the adsorptive interaction of the compound with the soil[19] and by the presence or absence of soil moisture. Where water is not present and able to evaporate from the particle or layer surface,

molecular diffusion dictates the rate of compound movement.

Thus, the presence of soil moisture on and within the soil layer enhances the volatilization of a compound; it increases the desorption rate of the compound, subsequently increasing the vapor pressure of the compound within the soil pores. Conversely, the evaporation of soil moisture increases the adsorption of the compound to the drying soil, thereby reducing the volatilization rate. Without soil moisture, molecular diffusion must occur and the VOC concentration must be sufficiently high whereby the VOC can migrate to the soil surface in a nearly pure form.

As well, the soil bulk density, percent compaction and effective porosity are important factors in the effective transport of VOCs from the soil surface to the soil vapor and to the atmosphere. The chemical characteristics of the subject compound are also particularly important as the vapor pressure, water solubility, basic structure and molecular charge affect such critical factors as adsorptivity and volatile fraction.

VOC Flux from the Soil Surface to the Soil Air

The flux of VOC as a vapor and nonvapor from the soil particle or soil layer surface to the soil vapor within the soil pores is a diffusion-controlled mechanism. The compound moves into the soil moisture or through a thickness of soil water of at least one monolayer (a one-molecule thick layer of water surrounding the particle) and into a solution phase and thence to the soil air in the vapor phase.

As described in the preceding section of this paper, the absence of soil moisture of less than one surrounding water monolayer minimizes the compound volatility. In such circumstances, the compound concentration must be sufficiently large that adsorption to the soil surface is exceeded by direct vapor-phase diffusion of the compound from the soil surface to the soil air. Diffusion pathways of a VOC usually include a vapor-phase and/or as many as three nonvapor phases. The three nonvapor or liquid-phase diffusion pathways include water-to-water, air-to-water and water-to-soil.[21]

These nonvapor phases or pathways are significantly slower than vapor-phase diffusion. However, significantly greater volumes of compound are usually found in the liquid phase (adsorbed to the soil particles or layers and in solution in the soil water contained in the capillary fringe of the unsaturated zone).

Moreover, the rate of vapor-phase diffusion is generally higher than liquid-phase diffusion; the vapor-phase diffusion coefficient is approximately 10,000 times greater than the solution) or liquid-phase coefficient.[21] Thus, a soil water-soil vapor partition coefficient of 1 x 10^{-4} (the distribution of the VOC in grams per cubic centimeter in soil water divided by the distribution of the VOC in the soil air in grams per cubic centimeter) defines the approximate point where vapor/nonvapor phase diffusion becomes dominant.

Thus, the partition coefficient of a compound (soil water-soil air) can be used to predict diffusion pathways. Partition coefficients much less than 1 x 10^{-4} indicate diffusion pathways in the vapor phase whereas compounds having partition coefficients much greater than 1 x 10^{-4} will likely diffuse in the solution phase.[21]

Vapor phase diffusion, which would dominate SVE-induced effects, is inversely proportional to the soil vapor pressure.[6] That is, a decrease in the ambient soil air pressures between the soil particles produces a proportional increase in the diffusion of the compound vapor from the soil-water phase to the soil-air phase.

Moreover, without at least one water monolayer about the soil particles to permit such diffusion, the volatilization rate of the compound once again depends on the compound concentration and subsequent liquid-phase diffusion to the soil surface. Liquid-phase diffusion is much slower than vapor-phase diffusion and reportedly occurs at a rate of only a few centimeters per month.[21]

Nevertheless, total mass transport of the compound by vapor-phase diffusion often equals that of the total transport of compound through the three nonvapor, or liquid phases.[21] The application of negative SVE soil air pressures (decreased ambient soil air pressures) has been demonstrated to significantly enhance the total mass transport of the vapor-phase compound.[3,4]

Release Mechanisms

Adsorption of the VOC to the soil is a critical factor affecting the release of the compound to the soil air during SVE operations. The adsorptivity of the soil matrix (organic fraction; clay content; relationship to compound charge and structure; and the general available surface area of the soil) will affect the chemical activity of the compound and subsequently reduce the vapor density and volatilization rate. Adsorption will reduce the soil-water partition coefficient and limit the amount of available compound for partitioning between the water monolayer and the soil air.

The concentration of the compound in the soil air will depend on this soil-water partition coefficient which in turn is dictated by other previously mentioned parameters, including:

- The soil/soil vapor temperature
- Soil moisture content
- Molecular diffusion coefficient
- Vapor-phase diffusion coefficient
- Solution-phase diffusion coefficient
- Compound partition coefficient
- Ambient and atmospheric vapor pressure
- Soil characteristics (grain size, density, porosity, etc.)
- Rate of air flow over the evaporating surface
- Soil particle geometry and roughness coefficient
- Compound structure (polar/nonpolar, charge, etc.) as well as the changing physical environment induced by the SVE process itself

Upon desorption of the compound from the soil to the soil water, the VOC can then move from the soil water to the soil air depending on its partition coefficient. The concentration of the compound in the soil water will determine the vapor density of the compound in the soil air surrounding the soil particle.

The general formula for VOC partitioning into an adsorbed, solution and/or vapor phase when spilled or leaked to the soil zone has been expressed by Spencer[19] and Jury (University of California, Riverside) as:

$$C_T = (p_A) + (\theta)(C_L) + (a)(C_G) \qquad (1)$$

where

C_T = the total quantity of compound per soil volume
C_A = the adsorbed chemical concentration in ug/g
C_L = the dissolved compound concentration in ug/cm^3
C_G = vapor density in ug/cm^3
p_b = soil bulk density in g/cm^3
θ = volumetric water content
a = volumetric air content

Henry's constant is expressed as C_G divided by C_L; i.e., vapor density divided by dissolved chemical concentration. This constant is dimensionless (ug/cm^3 over ug/cm^3).

Thus, Henry's constants may be used to predict the partitioning and mass transfer effects of VOCs in the soil/ soil-water/soil-vapor system. Calculated or laboratory values such as the distribution coefficient, K_D, and the organic carbon partition, or adsorption coefficient, K_{OC}, can then be used to determine relative vapor-pressures and densities in the soil air surrounding the soil particles. The relative volatility of the compound in the soil given specific physical conditions can then be calculated using the compound's vapor pressure, solubility and adsorption coefficient. Both Spencer[19] and Ehlers[6] have demonstrated this procedure for calculation of lindane volatilities in various soil matrices.

Other factors affecting the release of VOCs to the vapor phase include the polarity of the compound itself. Organic compounds that are weakly polar (nonionic) require low concentrations of the compound in the soil to achieve a saturated vapor phase. Moreover, the weakly polar compounds will volatilize much more easily than strongly polar compounds given equivalent increases in temperature and chemical concentration. Note that the compounds that exhibit weak polarity are also significantly affected by decreases in the soil moisture content; a soil

moisture film less than one monolayer thick significantly reduces the vapor pressure of that compound in the soil pores.

For VOCs that are weakly polar, the organic carbon partition coefficient (or adsorption coefficient) is a significant factor in the release of VOCs to the vapor phase. An increase in the organic matter in the soil increases adsorptivity and decreases vapor pressure; thus, the potential volatility of the compound also is reduced.

Highly polar compounds which exhibit ionic molecular bonds are more affected by the presence of clay minerals rather than organic matter. The ionic VOCs may exhibit reduced vapor pressures and volatilities due to a high adsorptivity on specific clay minerals. The majority of the more volatile compounds are not ionic, are weakly polar and exhibit high adsorptivity on organic matter.

Other physical factors which affect the release of VOCs to the soil-water and subsequently the soil-vapor phase include temperature and rate of air flow across the soil surface. Increased temperature increases vapor pressure and thus volatility. Temperature also affects the soil-water adsorption/desorption equilibria whereby increased temperature will accelerate molecular diffusion and mass transport of the compound to the soil surface.

In general, Henry's constant will increase significantly with increasing temperature (the more volatile compounds are less soluble in warmer water [soil moisture] and therefore produce greater vapor concentrations and densities with increased temperatures). Therefore, with increased temperatures, vapor-phase diffusion increases while mass transport of the compound and liquid-phase diffusion remain stable or decrease.

However, increased temperature and, in a similar manner, excessive airflow across the soil surface will dry out the soil moisture. Reduction of the soil water to less than one monolayer inhibits vapor-phase diffusion and volatilization. Vapor density is decreased and volatilization is reduced. Note that induced airflow across the soil surface enhances vapor-phase removal through ambient pressure reduction and encourages biomass growth and VOC biodegradation if appropriate airflow rates are applied.

An important consideration when discussing air flow effects is the occurrence of a stagnant boundary layer of soil vapor adjacent to the soil particle through which molecular diffusion of the compound must occur. With SVE-induced soil air flow, this stagnant boundary layer is replaced by a moving face of turbulent soil air. The geometry of the soil (effective porosity, granularity and tortuosity) determines the effectiveness of the induced air flow.[17]

The following table demonstrates the relationships of the various release and attenuation factors as well as volatility characteristics of specific VOCs.[9,10] Some of these characteristics are discussed in the succeeding sections of this paper which describe two SVE case histories.

COMPOUND	HENRY'S CONSTANT (atm-m^3/mole)	VAPOR PRESSURE (mm Hg at 25 C)	ADSORPTION COEFFICIENT*
vinyl chloride	1.07×10^{-2}	2660	0.40
acetone	3.67×10^{-5}	231	very low K_{oc}
benzene	5.43×10^{-3}	95	32 – 143
trichloroethylene	1.03×10^{-2}	69	100
toluene	5.94×10^{-3}	28	37 – 178
dichlorobenzene	1.80×10^{-3}	2.3	300 – 2500
naphthalene	4.83×10^{-4}	0.082	400 – 1000

* based on a 'standard soil' type

Given the above Henry's constants and vapor pressures, it is apparent that compounds such as vinyl chloride and acetone have excellent volatilities and are amenable to SVE. Their low adsorption coefficients also reduce the potential for attenuation to the soil matrix.

In general, the extraction of these and similar compounds is easily accomplished by minimal generation of negative soil air pressures within the pore spaces of the soil and continuous movement of soil air across the soil/soil-water surface. High pressure soil air extraction as opposed to low) and moderate-pressure extraction, usually is not required unless the soil matrix is poorly permeable.

The implementation of SVE for compounds like trichloroethylene

and toluene is well suited to granular soil matrices (moderate to good permeabilities with minimal amounts of clay and/or organic matter). The vapor pressures of these compounds are moderate; they have appropriate Henry's constants. However, their adsorption coefficients are also moderate, thus there is an advantage to an extraction site which exhibits a low percent of clay and organic matter in the soil matrix. The presence of such clay and organic matter may increase the potential for attenuation of these compounds which will subsequently limit their potential volatilization.

Also, as suggested by the above table, SVE of dichlorobenzene and naphthalene generally is not cost-effective given the low vapor pressures of these compounds and their comparatively high adsorption coefficients. If organic soils and clays are present, the potential for effective volatilization of these compounds is severely limited. In general, the biodegradation effects generated in the soil matrix due to the aeration of the soils will have a more significant impact on the concentrations of these and other heavy-end VOCs than the SVE process itself.

OPERATING REQUIREMENTS AND VARIABLES

Based on the discussions presented above, the applicability of a cost-effective, efficient SVE program will depend on the chemical nature of the compound involved and the physical environment in which the compound has been introduced. The physical environment may be modified by the operation of the SVE system to increase the volume of VOC extracted from the soil; conversely, inappropriate operation may reduce volatilization rates to ineffective levels. The factors which most significantly impact the operation of SVE systems are described below.

Site Conditions

A site investigation carried out prior to SVE implementation establishes the site history and general site conditions. The investigation addresses the general amount of contaminant believed lost to the soil and the distribution of VOCs and other compounds in the soil (and groundwater if appropriate), the depth to groundwater and the local geologic variations encountered at the site.

The site condition factors which are most important to the successful operation of an SVE program include:

- The areal extent and distribution of the VOCs in the subject area
- The depth to groundwater (shallow vs. deep water table)
- Rainfall and infiltration rate (migration of surface water into the unsaturated soil zone)
- Location of soil matrix heterogeneities (clay and/or organic matter, grain size changes, etc.)
- Ambient temperature and atmospheric pressure
- Location and type/use of nearby structures

During the site investigation phase of a SVE design, these factors are evaluated in an effort to determine the applicability and cost-effectiveness of the proposed SVE mitigation measure. These conditions must be evaluated as the investigation proceeds to maintain an overall understanding of the project as well as to develop the most appropriate SVE design.

Sound engineering principles and practices are then applied to the SVE designs and implementations to assure cost-effective mitigation of soil contamination. The use of equally sound hydrogeologic and geologic principles insures implementation of an appropriate SVE system design which accommodates the specific soil type, condition and other environmental factors of the subject property.

Soil Properties

Typical soil properties defined during the site investigation include particle size distribution, soil structure, porosity and permeability. These properties, which are used to determine the depositional environment of the subject soils, sometimes reveal preferential soil-vapor flow patterns that may permit 'short-circuiting' of the SVE pressures. This short-circuiting may result from layers or zones of coarser-grained sediments and similarly intervening layers of less permeable clays and silts. Thus,

the distribution of fine-grained soils (very fine sands, coarse silts and clays) will not only impact contaminant distribution, but also will deflect and direct SVE pressure distributions.

As addressed earlier, one of the dominant factors determining the success of any SVE system is the soil moisture content. This factor has a significant impact on the ability of the soil to permit diffusion from the soil particle, through the surrounding soil moisture and into the soil vapor between the soil particles. However, soil moisture also impacts soil plate count (the quantification of existing microorganisms that may biologically degrade the VOC) and influences soil pH. The pH of the soil can significantly affect microbial populations. In general, a healthy microorganism biomass is dependent on the subject VOC concentrations, the soil moisture and pH, and the soil/soil vapor temperature.[8]

Thus, where the subject VOC is marginally acceptable for SVE (exhibits ionic bonding and is not weakly polar, has a low vapor pressure and has a high adsorption coefficient, etc.) the presence of natural microbial populations in the soil may enhance the removal of these compounds. Moreover, where natural populations of such microbes are lacking, they may be artificially introduced and subsequently encouraged through addition of soil nutrients and soil moisture.

Control Variables

Following the decision to use SVE as a mitigative measure, existing blower configurations with appropriate pressure and flow ratings should be selected. Numerous companies prepare explosion proof skid-mounted blowers, filters, condensate collection bowls and electrical switches required for SVE implementation.

SVE design parameters include installation of the extraction well near the center of the soil contamination. Generally, the SVE effect is to enhance migration of soil air from adjacent areas across and into contaminated soils thus minimizing cross-contamination of the adjacent soils.[17,18]

Piping, valving and well materials should be chemically resistant to the soil vapor being extracted. Air flow control valves should have Teflon or Viton seals for prolonged use while other piping materials may include stainless steel or fiberglass.

A particularly important SVE factor which affects operation efficiency is the type of surface cover. During SVE, coarse-grained, nonvegetated soils can channel atmospheric air around well installations as well as directly through the ground surface thus impairing system efficiency. In such cases, the soil may be covered with plastic sheeting or an asphalt surface. This cover will also minimize surface water infiltration and pore space reduction in areas having abundant rain.

The operating requirements of an SVE system include accurately monitoring pressures and VOC concentrations at the negative (or inlet) pressure side of the blower and at the positive or outlet pressure side of the blower. Pressure and VOC measurements prior to and after an emissions treatment unit are also required.

These measurements are then used to demonstrate regulatory compliance; i.e., these measurements verify that the SVE operation is functioning as designed and that VOC emissions to the atmosphere are controlled (where required). The analytical information subsequently is used to calculate product recovery rates as well as to determine when termination of the SVE program is appropriate.

Response Variables

In some geographical locations, vapor emissions must be controlled to minimize degradation of the atmosphere. This factor is especially important in California where most air quality management districts require an operating permit. Included in these permits are strict guidelines for monitoring effluent concentrations, installing and operating soil vapor extraction equipment and implementing effluent treatment measures. Additional permits may include electrical, plumbing, excavation or extraction well permits.

Parameters that should be monitored are pressure gradients within specific soil regimes in the vertical and lateral directions from the SVE well. Additional SVE program verification parameters include the final

areal and vertical distribution of VOCs, final moisture content and volume of VOCs removed.

CASE HISTORIES

The application of SVE programs to the mitigation of VOC-contaminated sites can be aptly demonstrated by the following two case histories. The first example involves the remediation of gasoline-contaminated soils in the vadose zone of a shallow water table aquifer located in southeastern Canada. The SVE program was implemented in May 1982. The SVE measure was implemented as the final phase of groundwater and soil cleanup at the subject property.

Case 1: VOC Extraction from a Shallow Aquifer Vadose Zone

The subject property is located in southeastern Canada near the Lake Ontario shoreline. The site was a former service station located near residential and commercial properties. Attention was focused on the service station property as a source of leaking hydrocarbons when reports of gasoline odors in the station and adjacent structure prompted a site investigation. Implementation of free-phase product removal and SVE procedures followed the completion of the site investigation.

The SVE program was originally designed to intercept gasoline vapors migrating from the free-phase product pools floating on the shallow water table. The hydrogeologic conditions at the site were appropriate for groundwater/product recovery wells and SVE production wells. Though the aquifer in which the gasoline leak occurred was comprised of coarse silt-sized aeolian (windblown) sand and was subsequently very

fine-grained, the permeability of the unit was, nevertheless, acceptable for SVE.

The shallow water table (12 to 14 feet below grade) limited the vertical extent of the SVE pressure generation and the unsaturated aquifer thickness available for well screen installation. However, the shallow depth to water and the height of the capillary fringe were not significant problems in this specific application.

SVE System Design

The design of the SVE testing and implementation program included the construction of four gas production, or hydrocarbon recovery, wells located as shown in Figure 1. The wells consisted of 8 feet of 2-inch diameter schedule 40, polyvinylchloride (PVC) pipe and 4 feet of 2-inch diameter stainless steel well screens. Each pipe/screen assembly was placed in an augered 6-inch diameter borehole and backfilled with coarse sand to 3 feet below grade. The remaining borehole/PVC pipe annulus was then filled with a cement/bentonite seal.

The recovery wells were connected to a simple forced-draft blower system (12-in. water column, negative pressure exhausters) installed on the roof of the subject service station. The blowers and piping configurations are shown in Figure 2.

Figure 2
Wells and Fan piping Configurations
Canadian Case History

Figure 1
Location of Gas Production Wells
Canadian Case History

The blowers were operated in sequence or in parallel depending on the need for increased negative SVE pressures or for increased soil-air volume. Two fans operating in parallel produced an approximate doubling of the flow volume of the system with minimal reduction in negative inlet pressure. Connecting the exhausters in series approximately doubled the static pressures at the exhauster inlet while maintaining minimal volume reduction. No emissions treatment or monitoring of soil vapor concentrations was required by the local agency.

Given the comparatively poor permeability of the silt-sized sands at the site, increased negative SVE pressures were desirable. Connecting

the two exhausters in series achieved this effect.

The SVE program included various consecutive phases of pilot testing. These phases were designed to determine the most appropriate method of VOC extraction from the shallow vadose zone of the water table aquifer.

The Canadian SVE pilot tests included:

- A Phase 1, short-term extraction of gasoline VOCs and soil vapor from the vadose zone with limited soil air recharge
- A Phase 2, long-term SVE test coupled with induced atmospheric air recharge
- A Phase 3, long-term SVE test coupled with natural soil air recharge

The following discussion describes the results of the Phase 2 testing of the system. In this phase, SVE was coupled with enhanced recharge of atmospheric air along the site perimeter.

The program was restricted to a circular area having a 20-foot radius from a centrally located group of soil air extraction wells. The perimeter of the test area was a natural soil vapor recharge boundary created by opening to the atmosphere the vadose zone wells located immediately outside the 20-foot radius.

The unsaturated thickness of the soil zone above residual gasoline (floating product) was 12 to 14 feet. The capillary fringe containing water, gasoline and soil air immediately above the water table was calculated to be 3.4 feet thick.

The following equation was used to calculate height of capillary rise.

$$h_k = 0.45 \times (\frac{1-\sigma}{\sigma}) \times (\frac{1}{d_{10}}) \qquad (2)$$

where

h_k = height of capillary rise
σ = porosity
d_{10} = average effective diameter of the soil particles as defined by grain size distribution curves and as measured in millimeters

In the uniform, silt-sized very fine aeolian sand deposits of the subject property,

σ = 0.3
d_{10} = 0.1

therefore

h_k = 3.4 feet

Estimated Hydrocarbon Removal Rates

Using a height of capillary rise of 3.4 feet, a gasoline vapor recovery area of 1,260 square feet (with a radius of 20 feet) and the data measured during the Phase 2 pilot test, the volume of gasoline recovered per day was calculated.

Two methods of calculation were employed. The first calculation, based on mass diffusivity and mass flux laws in a binary gas system,[7,18] was used to calculate theoretical gasoline vaporization in the 40-foot diameter test circle. The second calculation, using standard gas coefficients and measured SVE volumes and vapor concentrations, was used to calculate actual gasoline volumes generated.

In the first method, calculation of mass diffusivity and flux in a binary gas system, where the system was assumed to contain air and n-hexane at 1 atmosphere (atm) pressure, 80% relative humidity, and 60 °F, the following equation was used:

$$D_{AB} = 0.0069 \frac{T^{\frac{3}{2}}}{P(M_A^{\frac{1}{3}} + M_B^{\frac{1}{3}})^2} \sqrt{\frac{1}{m_A} + \frac{1}{m_B}} \qquad (3)$$

where

T = Degrees Rankin
P = 1 atmosphere
M_A = molecular volume of n-hexane C_6H_{14} in ft^3 /lb mole
M_B = molecular volume of air in ft^3 /lb mole
m_A = molecular weight of n-hexane C_6H_{14}
m_B = molecular weight of air

Upon calculation,

$$D_{AB} = (6.9 \times 10^{-3}) \frac{(520)^{\frac{3}{2}}}{[1][(140.6)^{\frac{1}{3}} + (29.9)^{\frac{1}{3}}]^2} \sqrt{\frac{1}{86.2} + \frac{1}{27.4}} \qquad (4)$$

D_{AB} = 0.26 ft^2/hr

With these calculated values, mass flux N was determined using the fictive film theory and mass transfer process:

$$N = \frac{\rho D_{AB}}{\delta} \ln \frac{P_a}{P_a - P_g} \qquad (5)$$

where

D_{AB} = coefficient of diffusion in ft^2/hr
σ = density of air in lb$_m$/ft^3
δ = film thickness in feet (capillary equation h_k)
P_a = pressure of 1 atm (14.7 lb/in.^{2})
P_g = vapor pressure of gasoline = 2 lb/in.^{2}

Using the above calculated and assumed factors,

$$N = \frac{(0.076)(0.26)}{3.4} \ln \frac{14.7}{12.7} \qquad (6)$$

therefore

N = 8.5 x 10^{-4} lb$_m$/hr-ft^2

The gallons of gasoline vaporized in the system over a period of one day can then be calculated. Using an average density of gasoline of 6 lb$_m$/hr-ft^2, the value of N was calculated to be 8.5 x 10^{-4} lb$_m$/hr-ft^2. Thus, the volume of gasoline volatilized in gpd as V can be calculated:

$$V = \frac{(t)(A)(N)}{\rho_g} \qquad (7)$$

where

t = time in hours
A = area of film surface in ft^2
N = mass flux in lb$_m$/hr-ft^2
ρ_g = the average density of gasoline in lb$_m$/gal

By substituting these variables and constants in the equation for V,

$$V = \frac{(2.4 \times 10^1)(1.26 \times 10^3)(8.5 \times 10^{-4})}{6} \qquad (8)$$

approximately 5 gallons per day (gpd) of gasoline are theoretically recoverable from the SVE impact zone.

A second method for calculating V, the volume of gasoline recovered per day, was used as a check on the validity of the above calculations. Using measured flowrates and gasoline vapor (as hexane) concentrations recorded during the pilot study, the following calculations were made:

Q_{AB} = discharge rate of air and n-hexane mixture at exhaust stack of gas extraction unit in ft^3/min

C = concentration of n-hexane vapors in discharge as a percent total sample volume

ρ_{AB} = density of air/hexane mixture in lb/ft^3 at a discharge temperature of 80 °F, a relative humidity of 80%, and a pressure drop of 1 inch Hg induced within the fan

ρ_g = average density of gasoline in lb/gal

Given the above values, the calculated value of V is

$$V = (Q_{AB})(C)(F)(\rho_{AB})(\frac{1440}{6}) \qquad (9)$$

V = (70)(0.02)(0.3)(0.070)(1440)/6

and the calculated recovered gasoline volume was determined to be approximately 8.5 gal/day.

The calculated values obtained from the two methods used to estimate the volume of gasoline, V extracted per day from the SVE impact

zone are approximately 5 and 8.5 gal/day, respectively. These values suggest an average gasoline recovery rate of approximately 7 gal/day.

Results

The Canadian case history demonstrated the effectiveness of SVE for removal of VOCs (in this case, volatiles associated with a gasoline spill) from a silt sized, fine-grained unsaturated sand as well as from the capillary fringe. The effectiveness of SVE in similar soil and site conditions has been documented by Hutzler.[11,12]

Of particular note, is the volume of gasoline vapor that was removed from the soils at a moderate SVE pressure. Even with fine-grained soils and a system configuration such that atmospheric air was allowed to recharge the perimeter of the SVE area, effective VOC removal was achieved. If the atmospheric air recharge had been eliminated (as it was during subsequent full-scale operation of the system), the areal extent of the negative soil-vapor pressures would have been increased and the volatilization rate enhanced. Soil-vapor pressures within the pore spaces would have become more negative, thus increasing the flow of soil air across the particle surface and allowing more compound to volatilize into the pore space.

The increased negativity of the soil air pressures also would have encouraged greater extraction of VOCs from the capillary fringe due to the shallowness of the water table and the significant rise of water and floating product into the fringe area (a result of the very fine-grained character of the soil and the wick effect enhanced by the SVE). The following case history further demonstrates this general advantage of limiting atmospheric air recharge to a SVE system.

Case 2: VOC Extraction from Thick Unsaturated Soils

In accordance with a California county's (County) guidelines for the monitoring of underground storage tanks (UST), a site investigation was conducted on the subject property. The subject investigation indi-
Figure 4

Figure 3
Pilot Test Well and Monitor Location Grid,
California Case History

Figure 5
Soil Vapor Pressures at One Hour after SVE Startup,
California Test

cated hydrocarbon leakage from one UST and possible leakage and/or spillage in other localized areas of a UST facility. Chemical analyses of soil samples collected near the USTs indicated that the hydrocarbons present were generally light-end to moderate and heavy-end oils (not gasoline) with low levels of aromatic compounds.

The County approved SVE as an acceptable mitigation procedure if such hydrocarbon volatilization could be verified by: (1) development and demonstration of a degradation curve showing a leveling-off of total VOC concentrations in the soil-air extracted from the subsurface soils (2) by final verification samples of the subsurface soils showing reduc-

tion in the amount of hydrocarbons in the soil as originally documented at the site.

Soil samples collected during the site UST excavations and prior to SVE implementation indicated the presence of hydrocarbons in the soil at concentrations of 10,000 to 100,000 milligrams per kilogram (mg/kg) in three general areas of approximately 10,000 square feet each. Upon facility closure and initiation of a SVE pilot program, three hydrocarbon recovery wells were installed in the highest soil contamination areas.

In addition to recovery well installation and subsequent pilot testing, an air quality management agency permit process for the control of VOC emissions was implemented. A formal risk analysis was performed and County approval was received. The potential risk to the public health generated by the pilot test emissions was assessed and the risks (with emissions treatment) were accepted as reasonable. The results of the pilot study indicated that effective VOC removal and treatment could be accomplished at the site using SVE. The results of the pilot test are demonstrated by Figures 3 through 5. The pilot test generated an appropriate SVE impact zone which encompassed the site.

Regional and Site Geology

The property of concern is located in an area of continental deposits of coarse gravels and fine-to-medium sands and silts. The local geology near the site has been defined through various test drilling programs conducted during earlier UST investigations as well as during the SVE program.

The surficial sediments in the subject area generally consist of moist, poorly graded sand with minor clay/silt interbedding. These granular surface deposits appear to average 35 feet in thickness and are reportedly separated from an underlying, deeper sand and gravel unit by 55 feet of silty clay.

On the property, surface water infiltration is inhibited by the concreted plant surface area and by the paved surfaces surrounding the plant. No water table has been observed in the shallow sand deposits. All monitoring and recovery wells which were installed to the aquiclude contact at 35 feet below grade evidenced dry to moist soils (no standing water).

SVE System Design

The SVE system employed the basic fundamentals of volatilization; i.e., the extraction of hydrocarbons from the soil surface and from liquids contained within the soil pores. The soil-air extraction system provided the impetus to promote volatilization of the VOCs through generation of negative pressures in the soil pores and enhanced movement of soil-air across the soil particles and adsorbed VOCs. The soil-air extracted from the SVE impact zone was ultimately directed through granular activated carbon where the VOCs were adsorbed before discharge to the atmosphere.

Factors which directly affected the degree and rate of hydrocarbon volatilization included the equilibrium distribution of the VOCs in the soil air, the amount of soil moisture and the type of soil matrix as well as the vapor pressure, solubility and adsorption coefficient of each VOC. SVE not only increased the rate of VOC volatilization from the contaminated soils, but also enhanced the growth of naturally occurring aerobic and facultative bacteria which, in turn, increased natural biodegradation of the heavy-end (C_{12} to C_{14} range and up) spectrum of the hydrocarbon compounds.[3]

System Components

The SVE system included two 4-inch diameter recovery wells screened from 15 to 35 feet below grade. The recovery well locations were selected based on their location in the center of the inactive UST facility and the contaminated area.

The recovery wells were connected to a SVE centrifugal blower/exhauster via buried 4-inch polyvinylchloride (PVC) pipe. Soil vapor extracted from the wells and containing the volatilized VOCs was pumped through a vapor aftercooler (to lower the vapor temperature), a knockout drum (to collect condensed water vapor) and a backdraft valve (to prevent desorption of the granular activated carbon [GAC] during system shutdown).

Ultimately, the extracted soil air passed through two 1,000-pound GAC canisters connected in series to the SVE system. The cleaned soil vapor was exhausted to the atmosphere via a 2-inch diameter PVC pipe leading from the final GAC canister to a discharge point located above the existing plant roof line.

Field Monitoring

The effectiveness of the SVE system was monitored using four distinct methods. These methods consisted of GAC canister breakthrough monitoring, measurement of VOC concentrations at numerous vadose zone monitoring wells, soil vapor pressure response measurement

Contour Interval = 40 ppm

SCALE 1":40 feet

throughout the subject property and periodic monitoring of the system's flowrate.

Using an organic vapor monitor (OVM), the VOC concentrations in the surrounding vapor monitoring wells were monitored to track the effectiveness of the SVE system over time. Prior to the testing and sampling of the ambient soil vapor monitoring wells, each well was purged and sampled with the OVM and the maximum VOC concentration was recorded. Contour maps illustrating the OVM data are included in Figures 6 and 7.

The negative soil-air pressures created by pumping the vapor extraction wells were initially measured on a daily basis (subsequently reduced to weekly measurements) to determine the radius of influence of the soil-air extraction system. The soil-air pressures were measured in inches of water using a low pressure gauge.
Parameters impacting the soil-air pressures included the pump discharge (or flow rate) and the atmospheric pressure. Barometric pressures and influent vapor temperatures were recorded hourly.

The pump discharge rates (volumes of soil vapor extracted) were measured using an anemometer inserted at the exhaust stack outlet located on the roof of the plant structure. Flowrates recorded during the SVE operation averaged approximately 30 cubic feet per minute.

Soil vapor samples were collected at the exhaust inlet and outlet of the SVE system to enable correlation between OVM field measurements and laboratory analyses. Also, laboratory samples were collected as required by the County's permit for construction and operation of an SVE system.

Each vapor sample was analyzed for total hydrocarbons (TH) as methane and for volatile priority pollutants (U.S. EPA Method 8240). Additional influent soil-air samples were also analyzed for TH as methane on a weekly basis.

Results

The soil-air pressure data were evaluated using the pressure measurements obtained prior to system initiation, at one month after system initiation, prior to system flow rate increase, and after this flow rate increase. Figures 8 through 11 present the soil-air pressure configurations as pressure contours for the specific periods cited above. These soil vapor pressures were consistently negative in the wells nearest the VOC recovery or impact zone.

Moreover, the soil-air pressures decreased as the distance from the recovery well increased. These data reflected the expected diminishing radius of influence of the SVE impact zone as distance from the pumping source became greater.

In an effort to demonstrate the reduction in VOC concentrations in the system exhaust over time, the analytical measurements of TH were compared to flowrate; i.e., TH per unit of flow expressed as ppm/scfm was graphed versus time in days since pump startup (Figure 12). Field measurements of VOCs as determined using the OVM were also plotted versus time as shown in Figure 12. Additionally, the total VOCs expressed as TH (methane) were graphed versus time since pump startup (Figure 13).

The heavy-end, lower volatility hydrocarbons remaining in the sub-surface soils at the subject property appeared to be essentially kerosene and mineral oil types having low vapor pressures and moderate adsorption coefficients. These heavy hydrocarbons also appeared to be susceptible to enhanced, natural biodegradation in the soil.

Estimated Hydrocarbon Removal Rates

The estimated hydrocarbon removal rate between GAC canister changeouts was established based on the total operating time between GAC changeouts, average system flow, average TH concentration of the inlet vapors between changeouts, and average molecular weight of the inlet vapor. The following calculation was used to determine V_r, the vapor recovery rate per day:

$$V_r \text{ (lb/day)} = (V_c)/(1 \times 10^6 \text{ ppm}) \times (103.5 \text{ lb/lb-mole})$$
$$\times (1.0 \text{ lb-mole}/385 \text{ scf}) \times (Q \text{ scf/day}) \qquad (10)$$

or

$$V_r \text{ (lb/day)} = (V_c) \times (Q) \times (2.69 \times 10^{-7})$$

where

V_r = vapor recovery rate (lb/day)
V_c = vapor concentration in ppm (by volume)
Q = venting rate (scf/day)

The hydrocarbon removal rates estimated between carbon canister changeouts were then converted to gpd using an assumed liquid hydrocarbon density of approximately 7 pounds per gallon. From system startup through the third GAC changeout, the estimated hydrocarbon removal rate was approximately 1.1 gal/day. Between the third and fourth GAC canister changeout, the estimated removal rate was approximately 5.5 gal/day.

The hydrocarbon removal rate from each GAC changeout was also estimated based on moisture and VOC content in the spent GAC as reported by the GAC recycler. The recycler's analytical results (in percent VOCs) reported for the GAC canisters was multiplied by 2,000 pounds of GAC per changeout (two canisters per occurrence). The total pounds of VOCs were then converted to gallons. This value was subsequently divided by the total number of days between changeouts. The estimated average VOC removal rate was estimated to be approximately 4.5 gal/day.

Results

The California case history demonstrated an application of SVE to
Figure 11
Soil Vapor Pressures at Three Months Operation,
California Case History

Figure 12

California Program

Figure 13
Total Hydrocarbons per Elapsed SVE Operating Time,
California Program

an ideal unsaturated aquifer situation (granular soil, thick deposits with generally moist but unsaturated soil conditions, paved surface cover, etc.): i.e., the physical conditions for SVE were ideal. However, the chemical conditions (i.e., compound volatility) were not totally suitable for direct SVE impact.

The results of the project indicated that the light-end VOCs (C_{12} to C_{14} and less) were volatilized and extracted during SVE operation while subsequent soil sampling showed that the heavier hydrocarbons were also affected by the SVE induced biodegradation. The heavy-end hydrocarbons were effectively biologically degraded and their concentrations were reduced.

CONCLUSIONS

The foregoing discussion and case histories demonstrate the applicability of SVE for many different types of soil conditions and remediation requirements. Of particular importance in all cases, however, is the need for a soil type which is amenable to soil vapor flow and movement; a contaminant type which can be volatilized or, at least, biodegraded during SVE operation; and soil moisture which can be controlled and/or replenished by manipulation of the natural soil conditions.

There are a multitude of ways to judge the success of an SVE operation. The surest evidence of a successful site mitigation and soil cleanup is demonstration of:

• Effective SVE pressure generation (appropriate negative pressure contours in the SVE impact zone)
• Measurable volumes of VOCs extracted and discharged to the treatment system
• Reproducible evidence of decrease and/or consistent reduction in VOC concentrations in the SVE emissions

- Acceptable levels of the VOC and other regulated contaminants in the subject soils

These methods, as described in the above case histories, were used to meet regulatory requirements and to demonstrate effective mitigation of hydrocarbon-contaminated sites.

Reverse Osmosis for Leachate Treatment Case Study: V.A.M., Wijster, the Netherlands

Friedrich Peter Logemann, M.Sc.
Stork Friesland B.V.
The Netherlands

ABSTRACT

Reverse osmosis installations for leachate processing have already operated for several years. The large unit installed at VAM's waste disposal site in the Netherlands has proven that reverse osmosis is a reliable and useful technology for treating this leachate.

Field experience gained over 2 years with this installation at a processing capacity of 102.5 gpm (154 gpm after expansion) is as follows:

With a two-section system high retention rates can be achieved:

BOD   98.8 %
COD - 99.9 %
N.Kj. - 99.5 %
Cl⁻   - 99.8 %

High retention rates are also achieved for heavy metals and extractable organic halides.

On average, the following effluent quality was achieved:

BOD   2 mg/L
COD - 8 mg/L
N.Kj. 10 mg/L
Cl⁻ - 45 mg/L

The operating costs are roughly consistent with the design and are approximately 1.7 cents per gallon of purified water, or approximately 1.3 cents per gallon of leachate.

The use of cellulose acetate tubular membranes in the first section has proven its worth. A service life of approximately one year was achieved. Using the spiral-wound composite membrane in the second section has also proven its worth, although the achieved service life of approximately 1.5 - 2 years is not yet optimal.

INTRODUCTION

For some years, installations utilizing the reverse osmosis principle have been used for waste disposal site leachate treatment in Europe. A reverse osmosis installation has been operational since 1984 at the waste disposal site in Uttigen, Switzerland, where 13,000 gpd of leachate are processed. The installation is operating in batch mode as a single-pass unit. The RO unit has 1075 ft² of tubular composite membranes. The daily production is approximately 10,500 gpd of permeate and 2,500 gpd of concentrate; the latter stream is returned to the waste disposal site.

Currently, another installation is being constructed for the new waste disposal site in Trliachen, Switzerland.

In Western-Germany, an RO plant has operated at the Rastatt disposal site since 1986. Here, a 5-stage single section unit with a total membrane area of 5920 ft² is being used to treat leachate. The unit processes approximately 50,000 gpd in a fully automatic cycle.

In the Netherlands, there are now two operational units and a pilot

plant. A mobile pilot plant was installed in 1985 at the Bavel disposal site. Since 1987, a two-section installation has been used at the Wieringermeer disposal site, where building and industrial waste is dumped. There is also an on-site composting plant. This RO unit produces approximately 38,000 gpd of dischargeable permeate. The installation at the VAM disposal site went on stream in 1986. More details of this plant are reported in the following section of this paper.

VAM DISPOSAL SITE

N.V. Vuil Afvoer Maatschappij (VAM) is a waste processor, of which the Dutch state is the sole shareholder. Currently, VAM's workforce consists of 170 employees. In 1986, well over 1,000,000 tons of waste from nine provinces and more than 88 municipalities were collected and processed. VAM is one of the largest waste processors in the Netherlands. There has been large-scale waste processing at VAM's disposal site at Wijster in the Netherlands since 1930. Until 1980, the waste was mainly composted, but in the last few years mechanical waste separation is rapidly gaining ground. In the years ahead, developments will focus on the composting of biological waste (> 50,000 tons/year) and processing of residual waste partly to produce RDF (refuse derived fuel), which will be used as a fuel for power generation plants.

The Problem of Water

Until 1975, there was an annual water shortage because of the water consumption of the composting process. Since then, this shortage has gradually changed into a water surplus as a result of some operational adjustments, for instance:

* Lower water consumption in the composting process
* Enlarging the disposal site area
* Improved drainage and other actions which were taken for environmental protection.

Since 1979, the framework governing the overall water issue has been structured. This structuring, as a result of government regulations, resulted in the following package of measures:

* Reorganization in order to limit volume of wastewater. The following were created based on the quality of wastewater streams: white, grey and black water. Buildings were disconnected and work was started to cover the site.
* Determination of the ultimate wastewater stream
* Research into the purification potentials of various processes.

In anticipation of the findings of a research project, a temporary solution was found in the off-site discharge of the wastewater to the sewage treatment plants at Beilen and Hoogeveen. Additionally, the equalization (holding) capacity was enlarged to 26,400,000 gal. and a simple prepurification process was installed.

A water management plan was prepared, in which the annual wastewater stream to be purified was calculated to be approximately 63,400,000 gallons. This figure was based on:

- The operating conditions as they will probably be in 1996
- A wet year every other year.

Searching for an Appropriate Purification Method

In 1984, research was done to develop a purification technology which would be suitable for wastewater. Several systems and system combinations were checked for:

- Quality of the effluent that would allow it to be discharged into a regional sewage water treatment plant or into surface water
- Optimum and maximum conditions (capacity and retention)
- Operational at high and low temperatures.

The following systems were investigated:

- Submerged nitrification system
- Activated sludge plant
- Denitrification plant (with addition of methanol)
- Activated sludge with nitrification and denitrification
- Physico-chemical treatment (precipitation with flotation)
- Reverse osmosis installation

Some of the findings are shown in Table 1.

Table 1
Survey of Systems, Effluent Grades and Costs
(VAM Wijster)

System	Effluent (ppm)					Costs (1985, $cts/gal)
	COD	BOD	NH4-N	NOx-N	SO4	
Discharge into surface water						
Activated sludge + physico-chemical post-purification	1500	5	<2	<5	500	1.2
Two-section RO	10	1	8	<1	<1	1.2
Single-section RO + activated sludge	40	2	2	2	11	1.1
Discharge into the sewerage						
Activated sludge + physico-chemical post-purification	1500	50	100	<100	500	1.0
Single-section RO	75	10	240		11	1.1

This research shows that:

- Systems not working on the reverse osmosis principle are unsuitable for the production of dischargeable water
- The biological purification method unsuitable, because many substances cannot be sufficiently biologically degraded
- When used alone, reverse osmosis is relatively expensive, but it produces a dischargeable effluent
- The costs are in the region of 1 to 1.2 cents per gallon. of clean water at a capacity of 127,000 gpd (on the 1985 price basis).

Selection of Purification Method

The selection criteria for the purification system were as follows:

- Discharge requirements, i.e. Cl- and COD (Table 3)
- Water quality and cost of treatment systems
- Availability of relatively inexpensive energy (landfill gas)
- System flexibility (uprating, disconnection, etc.)
- Avoiding odor
- Guarantees for reliable operation, etc.
- Area required for installation

In the end a two-section reverse osmosis system, with tubular mem-branes in the first section and spiral-wound membranes in the second section, was selected.

Design

Together with Grontmij consulting engineers, Stork Friesland has designed a purification installation for VAM's wastewater. The inlet capacity is 102.5 gpm; 79 gpm can be discharged off into the surface water as permeate. In its basic configuration, this installation is suitable for being enlarged to an inlet capacity of 154 gpm and a purified and dischargeable effluent capacity of 119 gpm (which was achieved in 1988).

Process Description

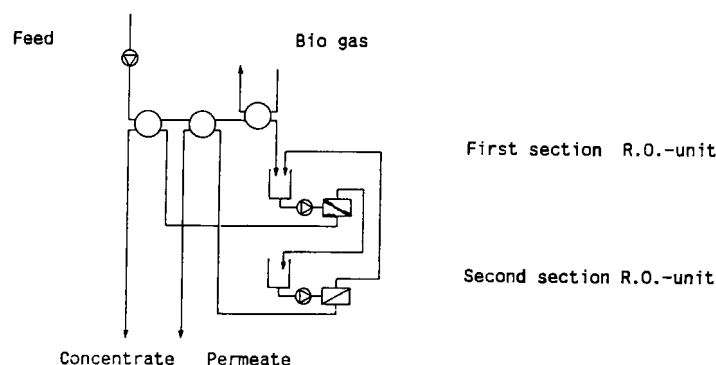
The RO process is shown in Figure 1. The water is filtered in a reversible flow filter (200 μm), so the largest dirt particles are removed to protect the high pressure pumps. Subsequently, the water is heated to approximately 25 C in three heat exchangers. In the feed tank, the leachate is mixed with the concentrate from the second section and the pH is lowered to approximately 6.7 by the addition of sulphuric acid. The first section is fed from this feed tank by a plunger type pump. The pressure is approximately 500 psig. There are six stages to separate the feed into dirty and clean water streams. The concentrate generated in the first section (dirt) is temporarily returned to the disposal site. The clean permeate from the first section is sent into the second section. The second pass is fed from a buffer tank and through two filters (10 μm). The concentrate from the second section is returned to the feed tank of the first section. The permeate from the second section is discharged into the surface water. Further data are given in Table 2.


Figure 1
Process Concept: Reverse Osmosis Process

Table 2
Design Data of the RO Installation

	Design (1986)		After enlargement (1988)	
	First section	Second section	First section	Second section
System	tubular	spiral	tubular	spiral
Number of stages	6	4	7	6
Membrane area sqft	15,540	4,960	22,900	7,440
Leachate gpm	102		154	
Feed RO gpm	126	102	187	151
Permeate gpm	102	79	151	119
Concentrate gpm	23	23	35	32

Tubular cellulose acetate membranes are used in the first section of the RO unit, because of the:

- Presence of undissolved substances in the feed
- Possible deposition in the concentration process
- Minor.risk of tubular membrane clogging
- Ability to be mechanically cleaned

- Potential for chlorine disinfection
- Low membrane replacement cost

Spiral-wound composite polyamide membranes are used in the second section, because of the:

- Good quality of the permeate coming from the first section
- Small space required for fitting the spiral modules
- Low cost (investment and power consumption)
- High retention rate

FIELD EXPERIENCE AT VAM, WIJSTER

Feed and Permeate Quality

Since January 1987, data on the quality of the feed and effluent of the RO installation have been collected. Each week COD and BOD, Kjeldahl-nitrogen and chloride contents as well as the pH have been established. Figure 2 shows the COD results as a function of time since 1987. Generally, the COD is rising. The fluctuations are not consistent with particular periods, i.e., summer or winter. The chloride content shows the same fluctuations and the same trend as the COD. The average composition over the period January 1987 to February 1988 is shown in Table 3, which also indicates the average permeate quality. The calculated standard deviations for both parameters are also given.

Figure 3
COD Concentration of the Influent and Permeate of the RO System

Figure 2
Variation of COD and Chlorine of the Influent Leachate
Figure 4
Chloride Concentration of the Influent and Permeate of
the RO System

Table 3
Leachate and Permeate Composition

Value		Leachate		Permeate		Requirement
		Average	Standard deviation	Average	Standard deviation	
pH		8.2	0.2	5.6	0.4	6.5 - 8.5
COD	ppm	1,600	500	8	9	< 100
BOD	ppm	60	55	2	2	< 5
N-Kj	ppm	480	185	10	7	< 10
Cl⁻	ppm	2,250	470	45	30	< 50

Figures 3 and 4 show the weekly trends in influent and effluent concentrations for the COD, N-Kjeldahl and chloride contents, on a logarithmic scale.

A comparison between the effluent and the allowable concentrations, which are proscribed in VAM's discharge permit (Table 3), shows that the average effluent quality (Table 4) satisfies the discharge conditions.

In 1988, the average permeate figures shown in Table 4 were worse for the following reasons:

- Poorer membrane quality
- Higher concentration of influent than envisaged at the design stage

Table 4
Leachate and Permeate Composition

Value	Average annual figures					
	1987		1988		1989	
	Leach-ate	Permeate	Leach-ate	Permeate	Leach-ate	Permeate
pH	8.1	5.6	8.2	5.6	8.3	5.2
COD ppm	1258	4	1726	12	2859	3
BOD ppm	40	2	59	2	217	2
N.Kj ppm	386	8	495	13	955	5
Cl⁻ ppm	2068	32	2287	60	3156	7

The pH-value of the permeate is declining. Generally speaking, the pH of the effluent from the installation has decreased too much. Therefore, before being discharged into surface water, the effluent is passed through a bed with calciferous material and spray aerated. This process increases the pH to 6.5.

Table 5 shows the feed design figures on which the guaranteed performance figures rates have been based. the data also include the concentrations measured in the periods July 1984 to December 1984

(approximately 40 samples), January 1987 to December 1988 (approximately 104 samples) and January 1989 to February 1989 (8 samples).

Table 5
Leachate Composition

Value		Design	7-12/1984	1/87-12/88	1/89-2/89
pH			8.4	8.2	8.3
COD	ppm	3,000	2,870	1,510	2,860
BOD	ppm	300	218	50	220
N.Kj.	ppm	800	750	440	960
Cl⁻	ppm	2,000	2,900	2,180	3,160

In the first two months of 1989, the concentrations (except for the chloride content) are consistent with those of 1984 (measured during the tests done at VAM's pilot plant) and with the design figures. The system performance in this period met the guaranteed performance (Table 6).

Table 6
Comparison of Retention Rates

Parameter		Guarantee	1/89-2/89	1/87-12/88
COD	%	99.8	99.9	99.5
BOD	%	99.7	98.8	95.7
N.Kj.	%	97.4	99.5	97.4
Cl⁻	%	98.4	99.8	97.9

In addition to the above analyses, heavy metal and organic micropollutant concentrations are measured every three months. Since January 1987, eight samples have been analyzed. The average figures are shown in Tables 7, and 8 and Figure 5.

Table 7
Heavy Metal Concentrations (µg/L)

Parameter	Feed		Effluent		Discharge requirement	Retention rate %
	Average	Standard Deviation	Average	Standard Deviation		
Zinc	630	440	27	16	200	96
Copper	170	45	17	14	50	90
Lead	100	15	3	1.5	50	97
Chromium	170	60	2	1	50	99
Nickel	150	40	15	0.5	50	99
Total	1220	600	50		200	96
Cadmium	1.3	0.7	0.4	0.3	25	67
Arsenic	12	4	3	3	10	73
Mercury	0.5		< 0.1		0.5	> 80

All effluent concentrations are lower than the requirements specified in the discharge permit. The heavy metal concentrations expressed as the total of zinc, copper, lead, chromium and nickel are shown in Table 7, which relates to the feed and effluent since 1987.

Capacity and availability of installation

The installation has been designed for the flowrates shown in Table 9. In November 1988, the installation was expanded to its current capacity.

The permeate produced since January 1987 is shown in Figure 6. In the second quarter of 1987, the permeate production was lower, because work was carried out on the installation. In this period some membranes in the first section (stages 4, 5 and 6) were replaced because of fouling. At the same time some adjustments were made to reduce the pH of the feed to 6.7.

Table 8
Concentrations of Organic Micropollutants (µg/L)

Parameter	Feed		Effluent		Discharge requirement
	Average	Standard Deviation	Average	Standard Deviation	
EOCL *	4.9	3.6	0.7	0.6	10
Mineral oil	380	210	<40	-	100
Total PCA**	8.3	6.8	0.6	0.6	10

* = Extractable organic chlorides

** = Polychlorinated aromatics

Reduction of Heavy metals Concentrations as a Result of Treatment in the Reverse Osmosis Unit; Summation of Concentrations of Zn, Cu, Pb, Cr and Ni

Table 9
Design Capacities of the RO Installation

		Initial capacity	Uprated
Feed	gpm	102	154
Permeate	gpm	79	119
Concentrate	gpm	23	35
Figure 6
Total Flow Through the Reverse Osmosis System in 1987
Figure 7
Total Flow Through the Reverse Osmosis System in 1988

In Figures 6 and 7 and the cumulative permeate capacities for 1987 and 1988 are compared with the target figures. The number of operating hours in 1987 and 1988 is shown in Table 10, which also indicates the hours spent on cleaning, maintenance and other outages.

Table 10
Survey of Operating Hours

	1987	1988
- Production	7,158	6,764
- Cleaning		365
- Maintenance]	1,260	374
- Miscellaneous	340	1,257*

In 1987, the availability of the installation was approximately 82%, or, when the downtime for equipment installation is disregarded, approximately 86%. The total production of purified permeate was 34,600,000 gallons.
In 1988, the availability of the installation was approximately 78%, or, when the outage for expansion (580 hours) is not considered, approximately 83%. The total production of purified permeate was 35,000,000 gallons.

CONSUMPTION FIGURES

Power

The installed power of the installation is:
- 1987 182 kw
- 1988 225 kw (after uprating)

The average power consumption per gallon of permeate produced is 0,0044 kwh/gallon. Additionally, gas is needed to heat the leachwater and the building.

Chemicals

The average consumption of chemicals needed to acidify the feed to pH 6.7 was 0.3-0.7 gallon of H_2SO_4/1,000 gallons of leachate.
The total consumption was as follows:
- 1987 79 tons of H_2SO_4 (98%)
- 1988 146 tons of H_2SO_4 (98%)

The consumption of chemicals for cleaning and disinfection of the installation were the following: Ultrasil 53--approximately 220 lb/cleanup--and the disinfectant active Oxonia--approximately 90 lb/cleanup. Moreover, to avoid bacterial growth in the second section,

4.5 lb of active Oxonia are injected daily. The total consumption was as follows:

	Ultrasil (lb)	Oxonia (lb)
• 1987 :	5500	2750
• 1988 :	7700	4200

Manpower Costs

The manpower costs incurred by VAM are shown in Table 11.

Table 11
Manpower and Maintenance Costs

		1987	1988
- Operation	USD	40,000.-	30,000.=
- Maintenance	USD	20,000.-	10,000.=
Total	USD	60,000.-	40,000.=

Membranes

As described, this is a two-section reverse osmosis installation, where the permeate from the first section is subsequently purified in the second section (Table 12).

Table 12
Installed Membrane Area

	First section		Second section	
	Stages	sq.ft.	Stages	sq.ft.
December 1986	6	15,500	4	5,000
December 1988 *)	7	22,900	6	7,400

*) Expansion from 102,5 gpm to 154 gpm.

For membrane replacement, VAM has concluded a multiyear contract with the membrane producer, Stork Friesland. A fixed annual payment is made and as many membranes as are deemed necessary are replaced, by the contractor to ensure optimum system operation and to meet the guaranteed quality and capacity.
The following conclusions can be drawn from the membrane replacements which have taken place so far:

- The membrane replacement in 1987 was caused by premature calcium deposition in the last three stages, which was due to temporarily insufficient acid dosing of the feed.
- The need for the membrane replacement in the second section may partly be explained by a too low retention rate in the first section. The higher concentrations of calcium and organic substances may have contributed to the attack and/or fouling in the second section.
- The service life of the membranes in the first two years proved to be as follows:
  First section, tubular membranes: approximately 1.0 years
  Second section, spiral-wound membranes: approximately 1.5-2 years

It seems as if the service life in the first section of the RO unit is mainly governed by the chemical attack and/or accelerated hydrolysis of the substances contained in the leachate. The length of the service life in the second section seems to be dominated by the combination of:

- A flux decline as a result of fouling caused by bacteria and/or deposits
- A drop in retention rate due to mechanical and/or chemical attack

Membrane Cleaning

Generally, the membranes in the first section can be cleaned without any trouble.
Cleaning procedure:

- Frequency: every 1-2 weeks
- Cleaning agent: Ultrasil 53: 160-220 lb/cleanup
- Disinfection: Oxonia active: 70 lb/cleanup

Mechanical cleaning the first section appears to have little effect, when it is used for leachate processing. It is rarely possible to clean the spiral-wound membranes in case of severe fouling and/or depositing.

Standard cleaning procedure for the spiral-wound membranes:

- Frequency: every 1-2 weeks
- Cleaning agent: Ultrasil 53: 70 lb/cleanup
- Disinfection: active Oxonia: 4 lb./clean up

Costs

The project was implemented in the period from May to December 1986.

Building costs and Investment costs (based on 1 U.S. dollars = 2 Netherland guilders)

RO installation, complete	$1,300,000
Buildings	$220,000
Infrastructure	$230,000
Engineering	$110,000
Total amount	**$1,860,000**

The following investments were needed for the expansion in 1988:
Uprating of the RO installation $500,000

Operating Costs

Based on the operational results described in this paper, the following operating cost calculation was made by VAM. This calculation relates to the RO installation only (Table 13). The following costs were not considered: leachate gathering and concentrate processing.

FURTHER DEVELOPMENTS

Leachate Quality

To improve the feed (leachate) quality, a study is being conducted

Table 13
Operating Costs in U.S. Dollars of the
VAM WIJSTER Reverse Osmosis System

	DESIGN 1986	1987	1988
A. OVERHEAD	230,000	265,500	275,000
B. RUNNING COSTS			
- MAINTENANCE	45,000	40,000	60,000
- MEMBRANE REPLACEMENT	115,000	115,000	115,000
- GAS (7,6 cts/1,000gal.	10,000	10,000	10,000
- ELECTRICITY (5 cents/kWh)	75,000	65,000	65,000
CHEMICALS	10,000	25,000	55,000
- COST OF ANALYSIS	25,000	25,000	25,000
- OPERATION	35,000	40,000	30,000
	315,000	320,000	360,000
TOTAL	545,000	585,500	635,000
C. PRODUCTION OF PURIFIED WATER gpd	98,000	95,000	96,000
COSTS PER GALLON OF LEACHATE ($ CENTS)	1.2	1.3	1.4

into the optimization of nitrification processes in the storage tanks. This may result in lower BOD and NH_4-N-contents in the feed, which may have a positive effect on the permeate capacity and the concentration factor for the RO installation.

Using Tubular Composite Membranes

Based on the tests which were conducted in the Netherlands, Western Germany and Austria in 1988/1989 on the composite membrane for leachate processing, it may be expected that tubular composite membranes will be more widely used for this application, for the following reasons:

- Improved chemical resistance and, thus, an increased life expectancy
- Higher retention rates at the same flux rate.

Table 14 shows retention rate of composite versus cellulose acetate membranes for leachate processing.

Table 14
First Section, System Retention Rate (%)

	Composite	Cellulose acetate
Conductivity	> 90	60 - 80
COD	> 98	80 - 97
BOD-5	> 99	90 - 95
NH4+	> 90	60 - 80
Cl-	> 90	50 70

Concentrate Processing

According to the original plan, the concentrate was to be returned to the waste disposal site, which was actually done in 1987 and 1988. As VAM's waste disposal site does not completely meet the Dutch IBC-criteria (isolation, management and inspection) and a survey in 1988 proved that the water buffer capacity of the waste disposal site is insufficient for returning the concentrate to the waste disposal site for many more years, research was started for a different solution.

According to VAM's plans, a waste-to-energy plant will go on stream in 1995. A portion of the waste that is unfit for composting will be burned in this plant. The residual substances (approximately 450,000 tons/year) will be discarded.

With a view to this development, a final solution for the complete wastewater stream is being sought, which includes processing of the concentrate.

Other options, such as evaporation, steam stripping, drying and nitrification will also play a role in the selection process. In 1988, tests were conducted to investigate the various options for concentrate processing. Table 15 shows the effluent quality that can be achieved.

Table 15
Effluent from Concentrate Processing

	COD ppm	N.Kj ppm	Cl- ppm
RO concentrate (feed)	13,000	3,500	13,000
Evaporation/stripping	100	50	65
Nitrification/evaporation	125	225	65
Nitrification/physico-chemical	6,200	160	13,000

During the evaporation tests, the concentration was up to 15% dry solids. Further concentration by evaporation is possible. In the Netherlands, research is being done into drying of this evaporated concentrate. After mixing with the dried product, the concentrate is introduced into a superheated steam circuit. The product is pneumatically transported through the installation at high speed (65-130 ft/sec.) and the drying process is complete within 5-10 seconds, producing a product with 96% TS. This drying system may offer the following advantages:

- A well-proven technique for a large variety of products and waste streams
- Minimum risk of fouling and corrosion
- A closed system, thus avoiding air pollution
- A sterile end product.

In the preliminary cost calculations for existing leachate projects with a capacity from 20-45 gpm the operating costs for leachate processing in a combined system featuring:

- *Reverse osmosis* (2 sections) with concentrations from approximately 0.5% to 2.5% dry solids
- *Evaporation* with concentrations from approximately 2.5% to 30% dry solids
- *Drying* from 30% to above 96% dry solids are calculated at 5 cents/gallon of leachate. This amount does not include the cost of discharging the end product. These costs are for Europe estimated at 1 to 2 cents per gallon of leachate.

Solidification/Stabilization Treatment of Lead Battery Site Soils

INTRODUCTION

One of the most frequently detected metals at uncontrolled hazardous waste sites is lead. A major source of this contaminant is former lead recovery operations such as battery cracking. Lead, like any other metal, cannot be destroyed; it can only be converted to another form and will remain in the environment. Therefore remediation schemes should consider lead recovery processes for reuse such as thermal techniques or acid extraction. Residual lead may still be leachable and poses a threat to groundwater. The remediation scheme must then consider technologies which reduce lead mobility such as solidification/stabilization and vitrification. This paper will focus on the evaluation of stabilizing lead-contaminated soil and debris from battery cracking operations.

Lead recovery from battery cracking operations generally consisted of casing cracking, acid drainage and smelting. Residues include chips of casings (ebonite and polyethylene), metal fragments (lead oxide), lead sulfate sludge and slag. These residuals contaminated soil particles and are also categorized as debris.

Recovery operations should be evaluated before any immobilization process is undertaken. Several problems have been encountered in the evaluation of solidification systems applied to battery sites such as lead particles being isolated (unavailable) in fine casing cracks and lead debris fragments being the same particle size as the cleansed soil and being retained on the same screen.[1,2] These processes are being improved.

The goal of solidification/stabilization processes is the reduction of mobility of heavy metals. This immobilization is accomplished by chemical reaction and encapsulation of the metal by a binding agent such as cement. One of the problems of stabilizing lead battery waste may be that the presence of sulfate or lead interferes with the formation of concrete.[3,4]

DISCUSSION

Several variables will affect the results of the stabilization process evaluation. These variables are the type of leach test utilized, the size of the filter used to separate particulate lead from dissolved lead, the type of binding agent utilized and the size and amount of lead particles in the waste. Several leaching test procedures are available to evaluate stabilization including the EP TOX, TCLP, MEP and ANSI 16.1.

Table 1 presents the results of leach tests on stabilized waste from Lead Battery Site A. Substantial decreases in the leaching of lead were obtained by utilizing cement and kiln dust or cement and fly ash. However, the addition of sodium silicate, a common binding agent, shows little mobility reduction (after accounting for dilution).

Table 2 presents the results of leach tests on stabilized waste from Lead Battery Site B. Several binding agents at various binder to soils ratios were evaluated. The data generally show that lead concentration is a function of pH, which is a function of the binder utilized. The cement and lime fly ash binders are capable of reducing leachate concentrations as long as the proper binder to soil ratio is utilized. Cement kiln dust was not effective at all.

Table 3 presents the results of stabilizing soils from Lead Battery Site C. Three different soil types were stabilized with a constant binder to soil ratio of cement. The data show a substantial decrease in lead mobility as evaluated by the TCLP.

Table 4 contains data from Site B with the stabilized waste sub-

Table 1
Lead Battery Site A Stabilization: TCLP Test Data

Binder	E.P. Toxicity (ppm of Pb)
Raw Waste	478.00
Cement + Kiln Dust	0.08
Cement + Kiln Dust	0.09
Cement + Fly Ash	0.30
Cement + Fly Ash	0.20
Cement + Sodium Silicate	318.00
Cement + Sodium Silicate	307.00

Table 2
Lead Battery Site B Stabilization: TCLP Test Data

Binder	Treated Waste Conc. (ppm)	pH
Cement(10%)	500	11.1
Cement(30%)	<0.05	11.4
Cement(60%)	<0.05	11.6
Cement Kiln Dust(10%)	37-150	12.3
Cement Kiln Dust(30%)	16-94	12.6
Cement Kiln Dust(60%)	48-63	12.6
Lime/Fly Ash(10%)	600-700	11.9
Lime/Fly Ash(30%)	<0.05	12.5
Lime/Fly Ash(60%)	2-3	12.5

Table 3
Lead Battery Site C Stabilization: TCLP Test Data

Binder	TCLP (Mg/l of Pb)	pH
Raw waste	287	3.7
Cement (25%)	<0.5	10.6
Raw waste	210	3.6
Cement (25%)	<0.5	10.7
Raw waste	175	3.6
Cement (25%)	<0.5	10.7

Table 4
Lead Battery Site B Stabilization Data from MEP Test Extraction (kng/L Pb)

Extract	1	2	3	4	5	6	7	8
Sample 1	2.9	2.8	25.1	37.5	33.1	40.3	107.3	103.4
Sample 2	3.0	6.1	8.4	5.9	2.4	14.8	39.0	38.2

jected to the MEP procedure. The MEP procedure is designed to mimic continual exposure to acid rain conditions. The test challenges the buffering capacity of the binding system. No clear trend in the data is evident.

ANSI 16.1 test leaching data from these sites were similar to the other leaching tests in that lead concentrations in the extracts were dependent on pH.

Figure 1 illustrates the dependence of lead concentrations on extract pH. These data were derived from both the TCLP and MEP tests on stabilized waste that originated from a metal salvaging operation that did not involve batteries.

(showing that pH is a major factor in Lead Solubility)
Figure 1
Lead TCLP and MEP Data
(Showing that pH is a major factor in Lead Solubility)

Stabilization Chemistry

The stabilization results from these studies will now be explained chemically. During the solidification/stabilization process of lead with cement, the lead is most likely converted into its most insoluble form, namely lead hydroxide $Pb(OH)_2$ as shown in the following equilibrium equation:

$$Pb(OH)_2 \rightleftharpoons Pb^{2+} + 2\ OH^- \tag{1}$$
The solubility product constant is then given by the equation:

$$K_{sp} = \frac{[Pb^{2+}]\ [OH^-]^2}{[Pb(OH)_2]} \tag{2}$$

Therefore, K_{sp} is unity since it is a solid.

$$K_{sp} = [Pb^{2+}]\ [OH^-]^2 \tag{3}$$

The literature value for K_{sp} of $Pb(OH)_2$ is 1.2×10^{-15}

Any cement-based binder normally produces a pH of approximately 12 in aqueous solution during mixing with water.

$$\text{Then the } P^{OH} = 14 - pH \tag{4}$$
$$= 14 - 12 = 2$$
$$\text{Hence, } [OH^-] = 0.01 \text{ moles/L}$$

substituting this value in the K_{sp} equation we get:

$$1.2 \times 10^{-15} = [Pb^{2+}]\ [0.01]^2$$
$$\text{Or, } [Pb^{2+}] = \frac{1.2 \times 10^{-15}}{[0.01]^2}$$
$$= 1.2 \times 10^{-11} \text{ moles/L}$$
$$= 1.2 \times 10^{-11} \text{ moles/Kg}$$
$$= 1.2 \times 10^{-11} \times 207.2 \text{ g/Kg}$$
$$= 2.48 \text{ PPT}$$

In essence, only 2.48 ppt of lead can exist in solution (or be environmentally available) at a pH of 12. This calculation clearly reveals that any cement-based binder can immobilize lead readily. On the other hand, when a weak acid-slurry base salt such as

$$Na_2SiO_3 + H_2O \qquad 2NaOH + SiO_2 \tag{5}$$
The free NaOH increases the OH^- concentration drastically. This in turn results in the formation of plumbate $[PbO_2]^{2-}$ (6)

$$[Pb(OH_4)]^{2-} \longrightarrow PbO_2^{2-} + 2\ H_2O \tag{7}$$
The anionic lead can leach out easily as sodium plumbate which is very soluble in water. The acidity of the leachate in many leaching tests does not impact the pH of the stabilized material.

The dependence of metal solubility on pH as well as the pE of a system is explained in several geochemical textbooks.

One limitation in interpreting metal treatment data is that particulate matter such as colloids may be filtered out before analysis. These colloids can contain metals that may be mobile in a groundwater environment.[5] Small size particulates in drinking water supplies may also be filterable.[6]

CONCLUSIONS

Metal migration from soil and debris from lead battery sites was decreased using various binding agents as evaluated by several leaching tests. The key process variable to control is pH, and one of the key disposal conditions to control is pE. A limitation on data interpretation is particulate lead versus dissolved lead.

Determination of Ultimate Compliance at an NPL Pump-and-Treat Site

GeoTrans, Inc.
Boulder, Colorado

ABSTRACT

The Western Processing Superfund site is a former industrial waste processing facility located in Kent, Washington, approximately 20 mi south of Seattle. Listed among the 50 most contaminated sites in the nation by U.S. EPA in 1983, an emergency removal and RI/FS identified more than 90 contaminants, predominantly volatile and semivolatile organic compounds and heavy metals in soils, groundwater and surface water.

A Consent Decree for a Phase I surface cleanup was entered in U.S. District Court in August 1984, with more than 200 signatory PRPs. A Consent Decree was entered in U.S. District Court in April 1987 addressing the Phase II subsurface cleanup. The Scope of Work outlines key elements of the remediation and establishes performance criteria for ultimate cleanup and long-term monitoring, including a rigorous 3-year milestone remediation evaluation that was successfully achieved by April 1990.

The 16-acre site is presently undergoing groundwater extraction and treatment, with 200 extraction wells enclosed within a slurry-wall hydraulic barrier that extends from ground surface to more than 40 ft below grade. Extracted groundwater is piped to an on-site treatment plant prior to discharge or infiltration.

Ultimate compliance at the site, as defined in the Consent Decree, revolves around meeting U.S. EPA chronic Ambient Water Quality Criteria (AWQC) in Mill Creek, which bounds the western margin of the site. The Consent Decree requires that the slurry wall be breached after pumping has ceased in order to maintain Mill Creek as a viable location for the evaluation of long-term compliance at the site. However, long-term benefits can be realized by keeping the slurry wall intact after pumping ceases, because it serves as an effective barrier to the transport of contamination toward Mill Creek. Recognizing this, the recent letter from the regulatory agencies overseeing the cleanup to the Court (acknowledging that the consenting defendants have successfully achieved the 3-year compliance milestone) includes a proviso for the development of an alternative means of evaluating ultimate compliance at the site.

Tetra Tech and its subsidiary GeoTrans have been tasked with the development of an alternative means of determining ultimate compliance at the site that will satisfy all involved parties, including methods that can be used to evaluate potential system shutdown scenarios. Quantitative analyses are currently underway to provide constraints on contaminant transport and partitioning mechanisms that will directly effect any evaluation of ultimate compliance at the site. The analyses involve complex interactions of a broad range of contaminants with several media, including contaminant partitioning and transport between subsoils, groundwater and surface water (Mill Creek). Whenever possible, data will also be used to enhance the efficiency of the ongoing

remediation process, including the possible development of enhanced extraction techniques and/or methods for the stabilization/fixation of mobile contaminant constituents.

INTRODUCTION

Western Processing is a former industrial waste processing facility that provided chemical reclamation, recycling and disposal services to more than 400 public and private customers between 1957 and 1983. During its more than 20 years of operation as one of the only approved disposal facilities in the region, Western Processing received wastes from a wide variety of sources. These wastes included fuels, oils, sludges, paints, animal byproducts, brewer's yeast, metal finishing solutions, battery acid and chips, fly ash, cyanide and other waste products. Much of these wastes were reclaimed, recycled, or processed at the site into glue, animal feed supplements, fertilizers, fire retardants, paint pigments, fuels and other saleable products. However accidental releases and spills and the permitted storage of wastes at the site in lined and unlined surface impoundments, aboveground storage tanks, waste piles and other structures, eventually resulted in the contamination of soils, subsoils, surface water and groundwater at the site.

Investigations at the site have identified more than 90 contaminants, primarily volatile and semivolatile organic compounds and heavy metals. The more prevalent contaminants of concern at the site include lead, zinc, cadmium, phenols, toluene, methylene chloride, oxazolidinone (a synthetic fuel component and paint additive) and a variety of chlorinated and nonchlorinated solvents.

Setting

Western Processing is located in an industrialized area within the City of Kent, approximately 20 miles south of Seattle (Fig. 1). The site lies within the Green River valley and is bounded on its western margin by Mill Creek (Fig. 2), which flows in a northerly direction into the Green River, a tributary of the Duwamish River; the Duwamish flows northward, entering Puget Sound at Elliott Bay in an industrialized portion of Seattle.

The Western Processing site is located on flood plain deposits of the Green River that are comprised of complexly interbedded silts and sands. These flood plain deposits overlie similar unconsolidated fine-grained sediments that were deposited in a marine embayment. Together, these deposits house an unconfined alluvial aquifer that extends to a depth exceeding 150 ft below ground surface.

Depth to groundwater in the vicinity of the site varies between 5 and 10 ft below ground surface. Shallow groundwater to a depth of approximately 30-35 ft is in communication with Mill Creek in areas adjacent to the creek; below this level, groundwater moves along a regional gradient in a northwesterly direction at the rate of approximately

100 ft/year. The aquifer reaches its lowest annual levels in the months of August and September, prior to recharge that accompanies the onset of the rainy season, which typically extends from fall through spring. No water supply wells are located in the immediate area.

Extraction/Infiltration System Layout and Slurry Wall Trace

REGULATORY AND REMEDIATION HISTORY

Emergency Removal Response

The U.S. EPA closed the site and initiated an emergency removal response in April 1983 to mitigate the threat posed to the public and the environment by the approximately 6,000 drums, 70 bulk storage tanks, 10 surface impoundments, several waste piles and other various structures containing wastes that were present at the site. Drummed wastes included many different acids, bases, solvents, organics, inks and more than 8,000 tons of zinc oxide. Storage tanks containing more than 400,000 gal of liquids, including synfuels of unknown composition, formaldehyde, chlorinated and unchlorinated solvents and other materials were integrity tested and sampled. Surface impoundments for paint sludges, waste solvents, pickling liquor, acid, caustic and cyanide wastes were present, some unlined and others with leaking plastic sheet liners. A large unlined pond containing sludges of varying origin was also present. Waste piles included more than 10,000 tons of fly ash containing heavy metals and 4,000 tons of battery chips.

The Washington State Department of Ecology (WDOE) installed storm water controls to minimize contaminant releases to Mill Creek, which is immediately adjacent to former disposal areas. Hazardous wastes were variously tested and batched for removal, stabilized on-site and shipped off-site for proper disposal over a 75-day period.

Phase I Surface Cleanup

A Consent Decree was entered in U.S. District Court in August 1984, initiating the Phase I surface cleanup at Western Processing. The Phase I cleanup involved the removal of all structures, equipment, tanks, drums and wastes from the surface of the site. More than 2,400 truckloads of various wastes were transferred off-site for treatment or disposal. The site was graded and a stormwater collection and treatment system was installed. A 7,400-gal tank of dioxin-contaminated oily water was treated on-site using a mobile treatment unit that employed a potassium polyethylene glycol chemical process in a low-temperature, low-pressure reaction. The process involved no air emissions or water discharge; a relatively small volume of residual sludge requiring incineration was shipped off-site for treatment. The Phase I cleanup was completed in 1986 after significant delays involving the search for, and application of, the dioxin treatment system.

Phase II Subsurface Cleanup

During implementation of the Phase I surface cleanup, planning for the Phase II subsurface cleanup was undertaken. The Phase II subsurface cleanup planning presented a number of unique challenges, a function of the large number of PRPs; the number, concentration and extent of contaminants in various media at the site; the lack of a well-established experience base regarding large-scale pump-and-treat remediation to draw from; and the resulting absence of an established regulatory history to guide negotiations. Many of the remedial technologies employed at the site were not fully developed or were unproven at the time.

The consenting defendants were organized and led by the Boeing Company, the largest single contributor of wastes to the site. A coordinating committee of Consent Decree signatories (the Trustees) was formed to design a system for cost allocation that attained broad acceptance among the signatory PRPs. This committee was active during the nearly 4 years time that lead to the approval of the Phase II subsurface cleanup plan and remains active in the ongoing remediation. The Phase II cleanup approach was developed by the combined cooperative efforts of the Trustees, U.S. EPA, WDOE and their respective consultants.

The Phase II cleanup was developed and potential remedial alternatives were assessed in accordance with the RI/FS framework outlined in the NCP. The primary elements of the Phase II cleanup were agreed upon and approved by U.S. EPA Region 10, WDOE and, following a public comment and review period, the document was lodged in the form of a Consent Decree with the U.S. District Court on April 10, 1987.

The essential framework outlining the numerous aspects of the cleanup is contained in a Scope of Work included as Attachment B to the Phase II Consent Decree. The Scope of Work establishes critical performance

criteria and standards and outlines the key elements of the project without stipulating the exact design of the subsurface cleanup. The specifics of the Phase II cleanup were established in 30 technical work plans that were subsequently developed to address all aspects of the subsurface cleanup. Each of the work plans underwent separate review and approval by U.S. EPA and WDOE, an iterative process that was ongoing as early work plans were being implemented at the site. This approach allowed the integration of data as it became available, enhancing and refining the quality of the overall remedial approach while allowing cleanup to proceed.

The Scope of Work establishes performance based criteria for the Phase II cleanup, with ultimate compliance revolving around meeting freshwater chronic Ambient Water Quality Criteria (AWQC) in Mill Creek. The following section describes the critical elements of the existing remediation system, which is followed by a brief description of off-site wells and a review of the approaches being taken to evaluate ultimate compliance at the site.

PHASE II REMEDIATION DESIGN AND OPERATION

The Phase II Consent Decree required that a groundwater extraction and treatment system be operated at the site for a minimum of seven years to remedy groundwater contamination beneath the site. In order to achieve this goal, low-permeability wastes present in the subsurface, predominantly fine-grained sludges that originated from surface impoundments, were targeted for removal to permit successful soil flushing.

A drilling, trenching and sampling program was conducted to characterize subsurface contaminants and geology and to define areas requiring removal. Samples were analyzed for hazardous constituents and treatability studies were performed on the subsoils. A specific waste excavation was then conducted prior to the installation of the groundwater extraction system to remove those wastes that would seriously hinder the designed remediation. Over a three month period, a total of 21,900 yd³ of specific waste had been excavated and transported to a U.S. EPA-approved hazardous waste landfill in Arlington, Oregon for disposal. Excavated areas, some extending more than 15 ft below grade, were backfilled with natural permeable materials from both on-site and off-site sources, resulting in subsoil characteristics that would allow successful operation of a soil leaching/flushing system.

Groundwater Extraction/Infiltration/Treatment System

An extraction/infiltration system comprised of more than 200 extraction wells was installed more than a 16-acre area. The extraction wells and infiltration galleries (Fig. 2) were arrayed with respect to subsurface conditions and contaminant concentrations. The extraction cells are arranged in groups comprising seven pumping cells. Within each cell, extraction wells are aligned in rows, with each row separated from adjacent rows by an infiltration gallery. A vacuum pumping system provides draw that can be controlled at several levels: within cells, along a row and at each individual well point. Individual well points are installed to a depth of 30 ft within a casing that is slotted over a 5-ft length and is surrounded by an annular sandpack that includes the screened interval and extends above it approximately 15-20 ft.

Groundwater removal from the extraction wells is piped to an on-site treatment system consisting of two components: (1) a water treatment plant for metals and semivolatile organic compounds removal and (2) an air pollution control unit for VOC removal from the exhaust gas. The water treatment system includes phenol reduction by aqueous oxidation using hydrogen peroxide; heavy metals precipitation/clarification utilizing individual process vessels for pH adjustment, flocculation and clarification; and dewatering of thickened clarifier underflow using a recessed-plate filter press.

Treated groundwater is then pumped to the second component of the treatment process, the air abatement system, where VOCs are removed by hot-air flushing in a stripping tower and are then destroyed in a thermal oxidizer. Fumes from the thermal oxidation unit are cleansed in a wet scrubber prior to discharge to the atmosphere. Effluent water is given a final polish using activated carbon to remove oxizolidinone prior to discharge to a POTW or being pumped into the infiltration galleries located between the rows of well points. The infiltration

galleries consist of perforated pipe surrounded by coarse gravel set in filter-cloth lined trenches.

Slurry Wall

The entire groundwater extraction/infiltration area is surrounded by a slurry wall that extends from ground surface to a depth of 40 to 45 ft below grade. The slurry wall was installed by excavating a trench approximately 30 in. wide and 40-45 ft deep and backfilling with excavated subsoils augmented with bentonite clays and water to form a dense slurry. The slurry wall provides a hydraulic barrier to the lateral movement of contaminated groundwater outward from the extraction/infiltration area, including the entire depth zone of groundwater interaction with Mill Creek. The slurry wall also increases the efficiency of the remediation by preventing the lateral movement of uncontaminated groundwater into the extraction area.

The presence of the slurry wall requires the maintenance of an inward-directed hydraulic gradient along its base to prevent the escape of contaminated groundwater from the extraction area. This is monitored by a piezometer system that includes groundwater measurements obtained from both inboard and outboard of the slurry wall along its entire perimeter (Fig. 3). Piezometers located within the extraction area and at selected locations along the slurry wall trace are completed at different depths to provide the data necessary to calculate vertical hydraulic gradients. These data provide excellent documentation of groundwater behavior at the base of the slurry wall in particular and at the interface between the extraction/infiltration area and the underlying portion of aquifer in general.

Redesign and refitting of the on-site water treatment plant was completed in the fall of 1989, increasing the treatment system capacity from ap!proximately 100 gpm to more than 200 gpm. Strong inward-directed hydraulic gradients have been consistently maintained along the base of the slurry wall since that time, as have upward-directed vertical gradients along the inboard edge of the slurry wall and within the extraction area overall. Downward-directed vertical hydraulic gradients along the outboard edge of the slurry wall have accompanied this trend. The maintenance of beneficial hydraulic gradients at the site is a Consent Decree requirement.

Off-site Wells

In addition to the extraction/infiltration system, four off-site wells are used to capture a VOC-contaminated plume (characterized by cis-1,2-dichloroethene) that extends to the northwest along the regional groundwater gradient (Fig. 3). These wells have a combined pumpage of 40 gpm which is piped directly to the air abatement system, where the VOCs are removed in a dedicated stripping tower prior to discharge or infiltration in the extraction area. The pumping rate from these wells is designed to create overlapping cones of influence to capture the plume; this effect has been documented by aquifer tests.

A series of barrier wells is located west of Mill Creek to prevent off-site migration of contamination (Fig. 3). These wells are present as a contingency in the event that the remediation system cannot prevent contamination from moving off-site; their use has never been required. The barrier wells are presently used as downgradient groundwater monitoring points.

A series of long-term groundwater monitoring wells is located both upgradient and downgradient of the site (Fig. 3). These wells are used to monitor the efficacy of the cleanup and will be points of long-term compliance after groundwater remediation has ceased. Most of these wells are arrayed in clusters of three to four separate completions and are used to monitor multiple depth intervals at the same location. Monitoring well depth intervals in feet below ground surface are: 10-35 ft, 35-70 ft, 70-110 ft and 110-150 ft. The shallow interval corresponds to the zone of interaction of groundwater with Mill Creek; below this level, water travels to the northwest along the regional groundwater gradient as underflow.

The installation of all three of the well systems described above was stipulated in the Consent Decree. A "bank" of several long-term groundwater monitoring wells is held in reserve for future installation at yet

to be prescribed locations to address off-site compliance issues if they arise.

ULTIMATE COMPLIANCE EVALUATION

Geochemical Modeling

The general task assigned to the Tetra Tech/GeoTrans team by the Western Processing Trustees is to estimate the time that the treatment activities must be continued in order to meet the long-term criteria for remediation of groundwater at the site. In order to provide a basis for this estimate, it is necessary to understand the geochemical controls on removal of metals from the subsoils beneath the site, particularly zinc and cadmium. As a first step in this process, water samples were recently collected from selected well points in Cells 5 and 6, the most highly contaminated portions of the area being remediated and are being analyzed to provide information with which to perform geochemical modeling of the groundwater.

These samples are being analyzed for many more inorganic consti-

tuents than have previous samples because of the special needs of geochemical modeling. A list of these parameters is provided in Table 1. Many different redox couples [e.g., Fe(II) and Fe(III), NH_4 and NO_3, Cr(III) and Cr(VI)] are being measured so that the redox state of the water can be determined. It is anticipated that these data will not be consistent, but that, because of kinetic effects, a range of pe values will be computed (pe is the negative log of the electron activity, which is related to Eh). Still, the data will serve as indicators of the approximate redox environment at the site.

Table 1
Inorganic Chemical Parameters for Geochemical
Analysis of Well Point Groundwater Samples

Field Parameters:

    pH, Temperature, Specific Conductance, Hexavalent Chrome

Metals (total and dissolved):

Al	Cr^{+4}	Mn
As	Cu	Mo
Ba	Fe^{+2}	Na
Ca	Fe^{+3}	Ni
Cd	K	Pb
Cr^{+3}	Mg	Zn

Nonmetals (unfiltered):

Alkalinity	Fluoride	Phosphate
Ammonia	Nitrate	Sulphate
Chloride	Nitrite	Sulphide

Total Dissolved Solids

Total Organic Carbon

The analytical data will be used to perform geochemical speciation calculations, using either PHREEQE[1] or MINTEQ.[2] These computer codes calculate the distribution of elements among inorganic species, indicators of the state of saturation of the water with respect to many minerals. Qualitative estimates of the columbic sorptive behavior of metals can subsequently be made based on the charge of the dominant species and on knowledge of the general behavior of common minerals or sorption substrates. Specific sorptive behavior is more difficult to estimate.

Whether precipitation/dissolution reactions are important is commonly estimated based on the value of the Saturation Index (SI) calculated by the model for a number of mineral species. If the SI is approximately 1, then precipitation or dissolution of the indicated mineral may be controlling the water chemistry. Commonly, the rate at which a mineral precipitates or dissolves is too slow to maintain the SI near unity. Because the water sampled had a relatively short contact time (i.e., infiltrated water has a relatively short residence time), the samples are not likely to be saturated (SI less than unity) with respect to, for example, the zinc phases of interest [$Zn(OH)_2$ and $Zn(CO_3)$].

Future steps in this analysis are unclear until the geochemical modeling has been completed and the results analyzed. It may prove beneficial to compare the mass of metals removed against the mass present in the soils before groundwater remediation began, if the preremediation data are adequate. However, because not all of the metals in the subsoil may be mobile, it will not be necessary or possible to obtain 100% removal. The geochemical model also can be used to investigate the feasibility of either increasing or decreasing the mobility of the metals (enhancing metals extraction or causing metals fixation) through adjustment of the chemistry of the infiltration water. If the results are favorable, laboratory testing will be performed to confirm the results.
Because of the impact of changes of water chemistry on the treatment plant and perhaps on the pumping systems, changes to the chemistry of infiltration water must be carefully and thoroughly investigated prior to implementation.

The well point sample locations were selected to provide information over a range of concentrations of inorganic constituents and organic compounds. The extraction wells selected for the analysis include well points known to have similar concentrations of metals and a range of concentrations of organic compounds. This will allow the analytical results to be used to determine if significant ligand binding of metals to organic compounds is occurring in the extraction area, a potentially important factor regarding metals transport.

Pertinent Consent Decree Requirements

Ultimate compliance at the site, as detailed in the April 1987 Consent Decree, hinges on: (1) compliance with 1986 fresh water chronic AWQC for Mill Creek waters; and (2) the reduction of VOCs in the contaminant plume that extends off-site to the northwest to a level below 70 ug/L for the cis- and trans-1,2-dichloroethylene isomers. The Consent Decree stipulates a 30-year monitoring period, beginning when groundwater extraction and treatment is terminated, during which the above compliance criterion must be met.

The intent of long-term monitoring is to evaluate possible contaminant rebound effects. The Consent Decree requires that the Trustees submit an application to the agencies overseeing the cleanup (U.S. EPA and WDOE) requesting that the remediation be terminated. This request cannot be made less than 5 years after groundwater extraction and treatment began and must be accompanied by compelling evidence that long-term compliance has been achieved.

A further requirement in the Consent Decree is that the slurry wall be breached following cessation of remediation in order to maintain Mill Creek as a viable measuring point for long-term compliance.

Recent Developments

Four Key Consent Decree elements that had to be achieved at the site within 3 years of the date the Consent Decree was entered (i.e., by April 10, 1990) include:

* The achievement of fresh water chronic AWQC in Mill Creek
* The creation of beneficial groundwater gradients at the base of the slurry wall that encloses the groundwater extraction area
* The establishment of a hydraulic barrier on the regionally downgradient (western) margin of the site to prevent the off-site migration of contamination beneath the Mill Creek groundwater capture zone
* The reduction of contaminant concentrations within the plume of contamination that extends off-site and is characterized by the presence of cis- and trans-1,2-dichloroethylene isomers

U.S. EPA and WDOE (the Governments) submitted a letter to the U.S. District Court dated August 27, 1990 stating that the trustees had successfully achieved the 3 year compliance requirements listed above. This is a significant milestone for the Phase II cleanup, demonstrating the appropriateness of the overall remediation design and the concerted effort made by the Trustees to achieve the stipulated goals.

Included in the letter from the Governments to the Court are provisions for the establishment of the alternative means of demonstrating long-term compliance for the project. The letter further acknowledges that the slurry wall provides a significant barrier to the migration of contamination toward Mill Creek, an obvious short and long-term goal of the remediation effort.

The Tetra Tech/GeoTrans team is presently evaluating a spectrum of potential approaches that will lead to the establishment of an alternative plan for the demonstration of final compliance that is protective of human health and the environment, is cost-effective and which complies with the intent of the NCP cleanup goals, principles and expectations as well as those of the yet-to-be finalized Washington Model Toxics Control Act. The option for alternative establishment of ultimate cleanup criteria is such a recent development that few aspects of such a plan can be stated with surety. One obvious option is the placement of an impermeable cap on the area enclosed by the slurry wall to limit recharge and the hydraulic impetus for contaminant migration into the underlying aquifer. The results of the geochemical speciation modeling detailed in the previous section will provide a basis for further study and evaluation, potentially leading toward enhanced extraction of contaminants prior to in situ immobilization/fixation.

Heavy Metal-Contaminated Soil Remediation at High Throughput

George J. Trezek, Ph.D.
Greenfield Environmental and University of California at Berkeley
Berkeley, California

ABSTRACT

The technical and operational aspects of the on-site remediation of 100,000 tons of heavy metal-contaminated soil is considered. This treatment project has been completed at a former scrap metal processing yard located at the Port of Los Angeles. The soil was treated at the rate of 100-125 tons/hour using a polysilicate technology in a processing system developed by Solid Treatment Systems Inc. (STS). The efficacy of the treatment is embodied in the transformation of a metal or more commonly the metal oxide into a metasilicate structure such as lead oxide to a form of lead metasilicate. Relatively small quantities of polysilicate and cementitious material are required resulting in a small volume increase after treatment. Further, the process renders a friable soil which can be moved with conventional loading equipment and is suitable for backfilling or other reuse. Although the process is versatile with respect to the nature of its utilization of silicates, the Lopat K20 potassium silicate blend was used for this particular project, where the principal heavy metals of concern were lead, cadmium, copper, zinc, nickel and chromium. Typically, the soluble (STLC) levels of these metals as measured by the California Wet Extraction Test, in the range of several hundred milligrams per liter, were reduced by one to two orders of magnitude by the treatment.

After treatment, the soil, being rendered nonhazardous, was backfilled on the site in compliance with local water board requirements. The unique features of the technology are discussed; the process allows soil to be treated cost-effectively at heretofore unachievable throughput rates. The details and results of this chemical treatment technology are presented, along with a discussion of the relation between total (TTLC) and soluble (STLC) concentrations and their relation to soil treatment.

INTRODUCTION

A heavy metal-contaminated 23.5 acre site involving more than 100,000 tons of soil has been successfully cleaned up using a polysilicate technology. This area, which is part of the Port of Los Angeles, was the site of an extensive metal salvaging operation dealing with a variety of operations which included ship breaking. As a result of these activities, the soil was contaminated with lead, zinc, cadmium, nickel and copper.

In addition to dealing with the heavy metals in the soil, the treatment process had to produce a friable material which could be readily backfilled and compacted on the site. The project schedule imposed a further constraint on the treatment. Basically, material had to be processed at the rate of at least 1000 tons/day in order to meet the project's deadline and avoid the payment of a $2000/day penalty. Thus, in addition to the reliability of the technology, the sequence and performance of unit operations involved in the soil preparation and treatment were a critical part of the overall system.

The mobile nature of the system, owned and operated by Solid Treatment Systems Inc. (STS), allowed it to be erected and operational within 3 working days after arriving on the site. A transportable treatment unit (TTU) permit was obtained from the California Department of Health Services (DHS). An additional permit was required by the Air Resources Board for dust control and operation of the loaders. Because the treated material was to remain on the site, the Water Quality Control Board was required to issue a permit governing the backfilling and subsequent sampling.

Consideration will be given to details of the technology, the processing system and the results of the treatment.

NATURE OF THE TECHNOLOGY

The polysilicate technology used in this project commercialized in 1986 is known as the STS process. The technology provides a reliable, cost-effective mitigation of heavy metals in a solid or semisolid matrix such as soil, residues, ash, baghouse dust, various types of sludges, etc. Several features distinguish this technology from other so-called solidification/stabilization (S/S) processes which are commercially available. The majority of these systems utilize proprietary reagents which are said to form crosslinks with waste components, micro-encapsulate hazardous compounds, absorb contaminants, neutralize constituents, etc. Further, many of these systems are characterized by large (double) volume increases and a final material form which resembles a concrete-like mass.

The STS process is considered to be a chemical treatment technology; that is, not a typical S/S type of process. Three steps are involved in this treatment: (1) the initial formation of a metal metasilicate resulting from the thorough wetting of the material with a polysilicate water blend; (2) the addition of a cementitious material which produces a pozzalonic reaction; and (3) curing or drying. Only small amounts of silicate and cementitious material are required for effective treatment. A previous field evaluation of the technology conducted by the DHS showed that the overall dilution factor was less than ten percent. Typically, one half to 0.75 gallon/ton of silicates and approximately ten percent cementitious material are required. The exact quantities of chemicals are a function of the types of metals and their concentrations. The type of cementitious material determines the required quantity. Curing produces a friable soil-like material which is easily moved and backfilled with conventional earth moving equipment.

The silicates are the critical component of the treatment. An optimum blend can be developed for a particular waste stream. This project used the Lopat K20 silicate blend which is manufactured in two parts; i.e., part A is a blend of three different viscosity potassium silicates and part B contains a catalyzer and dispersing agent.

METHODS AND MATERIALS

The project location was in the Terminal Island District of the Port of Los Angeles, to the rear of Berths 212-215 on the north side of New Dock Street. Basically, the site was a flat or level area consisting of approximately 23.5 acres. According to the analytical results of the initial site characterization, approximately 18 to 24 inches of top soil material would require treatment. Thus, the port engineering surveys estimated that on the order of 60,000 tons of soil would require treatment. In actuality, 106,700 tons of soil were treated in the overall project.

A clean area was prepared on the site for the mobile equipment treatment operations. The contaminated layer was removed in a 300- by 300-foot area, stockpiled in an adjacent location on the site and replaced or backfilled with clean decomposed granite soil. This area provided a working pad for the equipment and the curing of treated material.

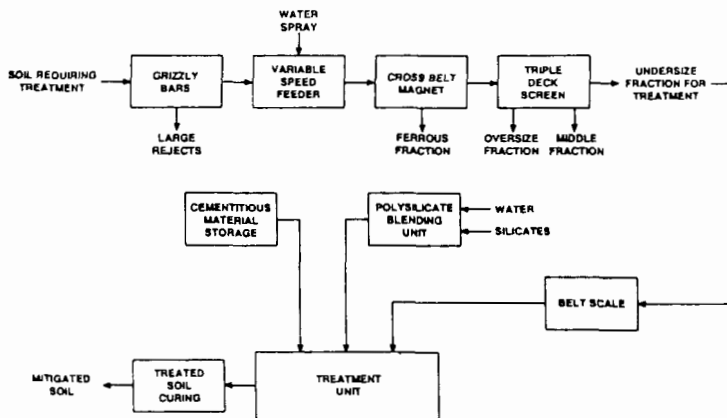
The principal elements of the treatment system, shown schematically in Figure 1, consist of the feeder, magnet, screen, pug mill mixing plant and the polysilicate blending unit. These unit operations were operated as an inline continuous system with a throughput of 100 to 125 tons/hour. The material requiring treatment was not typical soil. Because of the prior metal salvaging activities, the material contained a variety of ferrous and nonferrous metals, rocks and stones, pieces of wood and asphalt and other miscellaneous items. The size distribution of these materials spanned several orders of magnitude ranging from less than one inch to several feet. Occasionally, various parts of ships (i.e., riveted and welded beams, parts of anchors, sections of mechanical equipment, etc.) were uncovered in the excavation of the site and found their way into the stockpiled material for treatment. Consequently, the heterogeneous nature of the material dictated the type of preprocessing unit operations prior to mitigating the heavy metals.


Figure 1
Schematic Diagram of Soil Treatment System

A brief description of the system follows. Soil requiring treatment was taken from the stockpiled material with a front-end loader and fed into the variable speed feeder equipped with a set of grizzly bars to remove large tramp material. Occasionally, metal and other objects would fall through the grizzlies, causing tears in the feeder belt and jams in the feeder, causing excessive equipment maintenance and downtime. This problem was corrected by prescreening the stockpiled material prior to loading into the feed hopper. The prescreen was a mobile unit with a short residence time intended to remove only large objects. After the material exited the feeder, it passed under a cross belt magnet to remove the ferrous fraction. The material then entered the triple deck screen where the large oversize fraction consisting of pieces of concrete, asphalt, wood, etc. was removed on the top deck. After the middle fraction (i.e., smaller-sized rocks, stones, nonferrous metals etc.) were removed, the remaining material was the undersize soil which was suitably conditioned for treatment. A certified belt scale

recorded the feedrate of the material entering the feed hopper on the treatment unit.

The polysilicate additives and mixing process employ two mobile treatment units. The mixing unit consists of two feed hoppers, a twin screw pug mill, a cementitious material storage silo and a discharge conveyor. The silo, capable of storing approximately 50 tons of material, is hydraulically elevated after the unit arrives on the site. Although a diesel engine generator system is mounted on the mixing trailer to provide a self-contained source of power, the demands of the ancillary equipment required the use of a separate mobile system on the site. The polysilicate delivery system is contained on a separate trailer. A 2,000 gallon buffer tank allows the polysilicate-containing water blend to be delivered to a spray nozzle system at the point where the soil enters the pug mill. The polysilicates are added to the buffer tank by means of calibrated metering pumps connected to four, 250 gallon tanks. Polysilicate in fifty-five gallon drums can be directly pumped into these tanks from outside the trailer. Water directly enters the buffer tank from an on-site hydrant.

Appropriate instrumentation allows for the measurement of all water and chemical flow rates entering and exiting the chemical delivery system. Thus, along with the measurement of the soil throughput, a complete mass balance can be performed on the system.

During operation, material requiring treatment enters the rear of the twin screw pug mill. The diluted polysilicate blend is sprayed onto the feed soil. Intensive wetting of the soil with the polysilicates occurs in the first half portion of the mixer. The cementitious material is introduced at the midpoint of the mixer. The feedrate can be adjusted by controlling the variable speed drive on the silo rotary vane feeder. The residence time in the mixer is controlled by the blade angles. For soil, a 22° blade angle is used in the first half of the mixer to enhance retention, (i.e., increase the contact time between the silicates and the material). In the section after the cementitious material is added, the blade angles are set at approximately 45° to enhance mixing and removal of the treated material from the chamber. As the treated material exits the pug mill unit, a radial stacking conveyor piles the material. The process is complete after the material has cured in the stockpiles. The treated stockpiles typically are turned with a front-end loader on a daily basis for several days. Recently, the use of a Bomag unit has simplified the turning and curing of the treated piles.

Although the project was permitted to operate from 6:00 a.m. to 6:00 p.m. 5 days/week, the South Coast Air Quality District imposed the added restriction that all operations including the operation of rolling stock cease by 5:00 pm. Consequently, the effective daily treatment window was approximately ten hours or less depending upon downtime. A period of at least one hour was required for cleanup, maintenance, moving piles, etc. at the end of each shift. Thus, in order to meet the project schedule, a nominal 1000 tons of material/day had to be processed within these time constraints.

Material requiring treatment was arranged in 1000-ton, 30- by 150- by 8-feet high stockpiles on the site adjacent to the clean soil equipment zone. Samples of this material for laboratory analysis of heavy metals were taken as the piles were generated. These data were used to supplement the original site characterization data and provide guidance in establishing the daily treatment protocols. The sampling protocol also involved the collection of samples of untreated and treated material at fifteen minute intervals during operation. These samples formed a daily composite which was split for independent certified laboratory analysis. After receipt of the laboratory report and acceptance by the Port inspectors, the material was backfilled on the site. Additional samples of the in-place material were also taken.

TREATMENT LEVELS

Testing of the contaminated soil for all 17 metals revealed that only five had elevated levels requiring treatment. The range of these metals in terms of both the soluble (STLC) and total (TTLC) concentrations is summarized as follows: (1) lead, STLC—11 to 121 mg/L, TTLC—27 to 1500 mg/kg; (2) zinc, STLC—14 to 320 mg/L, TTLC—242 to 3130 mg/kg; (3) cadmium, STLC—0.1 to 1.9 mg/L, TTLC—2 to 12 mg/kg;

(4) nickel, STLC—0.2 to 7 mg/L, TTLC—30 to 600 mg/kg; and (5) copper, STLC—2 to 96 mg/L, TTLC—70 to 2610 mg/kg. The soluble concentrations were determined by the CAM wet extraction method which involves milling to pass a No. 10 standard sieve and followed by 48 hours of extraction in a sodium citrate solution.

The relationship between the total and soluble concentrations, summarized in Figure 2 shows the respective ranges for each metal. In effect, the treatment process must deal with metals whose concentrations cover a range of four orders of magnitude. It should be noted that the values of lead shown in Figure 2 are plotted as Pb/100 to aid in pattern recognition. Thus, the concentrations of lead are in the same general band as copper and the lower range of zinc.
Figure 2
Relation Between Soluble and Total Concentration
Levels in Untreated Soil

The correlation between soluble and total concentrations can be seen in Figure 2. For example, on the average, the soluble concentrations of these metals would be 16 to 47 times less than the total concentrations. In terms of the specific metals, these reductions would be as follows: (1) lead—20.2, (2) zinc—17.5, (3) cadmium—15.9, (4) nickel—47.2 and (5) copper—22.7. It is interesting to note that with the exception of nickel, the soluble concentrations of the other metals are about 20 times less than the total concentrations.

TREATMENT RESULTS

The actual treatment activities began on Oct. 9, 1989 and terminated on Apr. 12, 1990. The treatment of the initial 60,000 tons of material was completed by the contracted schedule date of Jan. 15, 1990. The project period was then extended to treat the additional 47,000 tons of soil. Approximately 16,000 tons of nonhazardous oversize material was removed in the screening operation. With the exception of the ferrous metals, this fraction was disposed of in a Class III landfill.

The quantities of polysilicates and cementitious material were adjusted to coincide with the concentrations of metals in the in feed material. For a combination of logistical, economic and treatability considerations, cement was used as the cementitious material. Throughout the course of the treatment, the addition of cement ranged from 10.14 to 11.08 percent. Even with the wide range of STLC concentrations of the various metals, the usage of polysilicates varied over a relatively narrow band which ranged from 0.513 to 0.59 gallons/ton of soil. The relation of silicate usage as a function of STLC level in the in feed material requiring treatment is given for the five metals, (lead, zinc, cadmium, nickel and copper) in Figures 3 to 7, respectively. In each case, the treatment achieved at least a 99 percent reduction in STLC level. The data suggest a general trend of increasing silicates with STLC level. A particular group of data lie in the range of 0.578 to 0.59

gallon/ton. In this situation, the silicate addition rate was increased in anticipation of high STLC levels in the in feed material. In actuality, the in feed levels were not excessively high, so that the subsequent STLC concentrations in the treated material resulting from the increased silicate usage were all nondetectable.
Figure 3
Polysilicate Usage for Lead Treatment
Figure 4
Polysilicate Usage for Zinc Treatment

CONCLUSION

The STS polysilicate technology is an effective and relatively low cost method of treating heavy metal-contaminated materials. Because of its straightforward manner of application, material can be treated at rates exceeding 100 tons/hour, thereby allowing the achievement of very favorable economies of scale. Further, the treatment yields significant reductions in soluble (STLC) levels of metals with minimal increases in volume or weight, (i.e., dilution factors of less than ten percent).

The polysilicate blend and the formation of a metasilicate is a critical element in the treatment technology. As shown in the literature, treatment process using only cementitious materials are unlikely to have long-term metal retention properties. In these cases, certain metals may have an adverse effect on the cementitious matrix which negates their immobilization.
Figure 5
Polysilicate Usage for Cadmium Treatment
Figure 7
Polysilicate Usage for Copper Treatment
Figure 6
Polysilicate Usage for Nickel Treatment

This technology also has a mitigating effect on the total (TTLC) concentrations of the metals. Typically, the size distribution of the treated material, particularly soil, will be increased or shifted toward larger particle sizes. The mean particle size of the treated material is increased by at least an order of magnitude which greatly reduces the dispersion of total metal concentrations in airborne particulates.

In Situ Treatment: When Does It Apply?

Daniel S. Schleck
Environmental Remedial Action Division
Chemical Waste Management, Inc.
Oak Brook, Illinois

ABSTRACT

As more and more abandoned hazardous waste sites are investigated, specifications designating in situ remedial activities for soil and groundwater are becoming more common. Advantages of in situ treatment technologies include reduced cost and ease of implementation when compared with intrusive types of remedies. In situ treatment technologies such as soil vapor extraction, bioremediation, soil washing/flushing and air/steam stripping are applicable to many hazardous waste site needs. However, a close examination and evaluation of all factors must be considered prior to consideration of these technologies.

Upon initial appraisal, in situ technologies may appear to possess wide applicability. Unfortunately, in-depth evaluations indicate these techniques cannot be used in all instances and in some cases should not be specified. Differences in geology, cleanup criteria and remedy implementation time constraints may preclude their use. Some of the difficulties with in situ type remedies include; confirmation of compliance and length of time for remedy implementation.

Given the many recommendations for these technologies at remedial actions, the need for some "Rules of Thumb" on using these techniques arises. This paper attempts to set forth guidelines for the applicability of in situ treatment technologies to the remediation of hazardous waste sites.

INTRODUCTION

Recently, the burden of hazardous waste site investigation and cleanup has shifted to the private sector. At the same time, in situ treatment technologies are becoming more popular. In situ treatment technologies are defined by the U.S. EPA as those treatment processes "that can be applied to treat the hazardous constituents of a contaminated environmental medium where they are located and are capable of reducing the risk posed by these contaminants to an acceptable level or completely eliminating that risk."[1]

In general, all of the currently used in situ treatment technologies can be placed into the four general categories listed in Table 1.

Table 1
General Categories for In situ Treatment Technologies

1. Vapor Phase Treatment Technologies
2. Liquid Phase Treatment Technologies
3. Bioremediation
4. Stabilization/Solidification

Virtually all of the in situ techniques currently used fit into one of these classifications. For example, in situ soil vapor extraction (SVE) can be classified as a vapor phase treatment technology. Along these same lines, soil flushing can be classified under this system as a liquid phase treatment technology.

In situ technologies do have many uses. In many cases they can be less costly than intrusive remedial techniques. Unfortunately, they are not useful in all cases. This paper describes many of the in situ technologies in brief detail and generates some general guidelines for their use in the field.

TECHNOLOGIES

There are many different types of in situ treatment technologies that are currently being investigated. Presented below are a few fundamental technologies that are currently being tested and, in some cases, employed on a large scale. By no means is this list complete: it simply serves as beginning point for discussion of the issues considered when specifying their use.

Soil Vapor Extraction

Soil Vapor Extraction (SVE) is a process used to remove VOCs from soil. This technology has very effectively removed fuel from soil (for example, contamination found during removal of underground storage tanks). SVE is a mechanism whereby wells are installed in close proximity to an area contaminated with VOCs. A vacuum is induced on approximately one half of the wells, and the other wells are left open for air induction (Fig. 1). As a vacuum is induced in the interstices of the soil, the VOCs tend to volatilize and are removed with the vapor stream and subsequently can be condensed from the vapor stream for disposal or treatment. SVE can be classified as a Vapor Phase Treatment Technology.
Figure 1
Soil Vapor Extraction

Steam or Air Stripping

Stripping of VOCs from contaminated soil is also a technology that can be used in situ also. This process utilizes basically the same type of setup as SVE, except that injection wells are used in place of induction wells. In this process, steam or hot air is injected into the soil while a small vacuum is concurrently induced at the extraction wells. The steam or hot air heats the soil and increases the vapor pressure of the organic contaminants in the soil. This vaporization of the contaminants separates them from the soil, facilitating removal with the extracted vapor stream. Steam stripping has been more effective than hot air on some higher boiling point semivolatile compounds.[2] Like SVE, Steam/Air stripping can also be classified as a Vapor Phase Extraction Technology.

Soil Washing/Flushing

Soil Washing/Flushing is a Liquid Phase Treatment Technology very similar to steam stripping. Basically, a circulating system is set up in which contaminated groundwater is extracted downgradient of the contaminated area. This water is treated to remove contaminants. The treated water is then recycled to infiltrate back into the contaminated area (Fig. 2). This process is similar to a solvent extraction process. As clean water comes in contact with contaminated soil, there is a contaminant concentration gradient driving contaminants into the water. This gradient induces contaminants to desorb from the soil and move into the liquid phase. This technology can effectively remove inorganic contaminants from the soil and can be improved by adding chelating agents.
Figure 2
Soil Flushing

Chemical Degradation

Another form of Liquid Phase in situ treatment is chemical degradation. In this process, chemically reactive compounds are injected upgradient of a contaminated area. In theory, as these compounds—which can be oxidizers or reducing agents—come in contact with the contaminated soil, they will react with and render harmless the contaminants. Groundwater usually is extracted downgradient of the site to help maintain proper gradients. This process can be controversial due to public perception that injection of certain chemicals into the subsurface is not acceptable no matter what the outcome. These issues must be carefully investigated prior to commencement of any type of injection of chemical degradation additives.

Bioremediation

In situ bioremediation utilizes the same basic biological degradation process as ex situ bioremediation techniques. In situ bioremediation is perhaps the most common type of in situ treatment now being employed for remediation of hazardous waste sites contaminated with organic wastes. The process is similar to chemical degradation treatment except microorganisms and/or nutrients are added to the liquid injection stream rather than chemical degradation agents. In many cases bioorganisms are stimulated by adding basic nutrients such as oxygen, nitrogen and phosphorus. In other uses of in situ bioremediation, hybrid

organisms are introduced to the injection stream along with the nutrients. Groundwater downgradient of the site is monitored and nutrient levels are compared to initial loadings to determine biological degradation rates.

Stabilization/Solidification

Stabilization and Solidification are processes in which contaminants are immobilized, rendering the waste nonhazardous. This process too, can be accomplished in an in situ manner. The most common system uses a series of hollow, vertical augers to dig into the soil. Stabilization additive mixtures are injected through the augers and blended with the contaminated medium. The augers are transported and stabilization takes place in an overlapping fashion (Fig. 3). This technique can be employed to immobilize contaminants either in soil or groundwater. At the same time the soil is being stabilized, an impermeable groundwater barrier can be built to aid in other parts of full facility remedial action.
Auger Pattern
Figure 3
In Situ Stabilization

In situ Vitrification

In situ Vitrification (ISV) is a process that utilizes electricity to melt soil and solid materials into a glass-like inert product. Electrodes are placed into the ground in a box-shaped pattern. A starter path of flaked graphite and glass frit is placed on the surface between the electrodes. As current is applied, the molten path (at approximately 1600°C) progresses from the surface downward (Fig. 4). After the desired melt mass is achieved, the electricity is turned off and clean backfill is used to fill the subsidence volume. As the molten material cools, it takes on the characteristics of Obsidian (Volcanic glass). The solidified mass

has virtually no leachability, has great strength and should last forever.

This brief overview of some of the more popular in situ treatment technologies will aid in later discussions of the principles under which these technologies can and should be applied.
Figure 4
In Situ Vitrification

GUIDELINES FOR USE

With the large amounts of money being spent on remedial actions, there are some important points that must be considered in the specification of in situ remedial measures for hazardous waste sites. These issues must be carefully evaluated in order to insure the success and cost-effectiveness of remedial activities.

The first key issue in dealing with the selection of a remedial technology—not just in situ—is how to confirm the remedial technology will achieve the cleanup standards desired. This is especially true in the use of in situ cleanup technologies.

In an intrusive type of remedial effort, it is much easier to take samples of the treated material and determine if the appropriate cleanup criteria are being achieved. Because in situ remedies basically occur remotely, it is more difficult to take samples; the targeted material is often below the surface and is inaccessible to sampling. Consequently, method of sampling must be devised at the beginning the remedial design to determine how compliance will be monitored. Borings can be taken periodically and the extracted material tested. If frequent borings must be taken, the costs of the overall remedy can increase dramatically.

In some cases, soil cleanup data can be inferred from down-gradient groundwater quality. This method, however, is indirect and may introduce a large error into the data. This point is of great importance—an acceptable method of monitoring compliance must be determined before beginning any cleanup.

It is also important to establish an achievable cleanup standard prior to commencement of the remedy. Many times these cleanup standards are risk-based or are set by a governing agency. Small changes in this standard can have large impacts on final remedy cost.

Third, a projection of the remedy implementation time interval must

be made. This is a difficult task in which many assumptions come are made. In some cases—such as excavation and removal—an intrusive remedy will take a much shorter time period than an in situ remedy. All of the parties involved must have some understanding of the length of time involved in implementing an in situ remedy. In many cases in situ remedies, while cheaper, take a longer time for completion. This time-frame must be considered in the cost/benefit analysis of any remedy.

After reviewing these important general points, there are some in-depth questions to contemplate for specific in situ remedies. For example, in attempting to use a vapor phase in situ treatment technology for the treatment of contaminated soils, clearly, there must be a vapor phase to treat. If the water table of a particular site is too close to the surface, there will be no vadose zone from which to extract vapor. An artificial vadose can be induced using dewatering wells and this has been done very successfully in the past. However, the water table proximity to the surface can still pose a problem if a site has large fluctuations in its water table. In the opposite sense, there can also be a problem if liquid phase treatment is attempted in an area with a very low water table. Consequently, thorough understanding of the site water table characteristics must be obtained prior to investigation of an in situ remedy for the site.

As was mentioned earlier, one of the key considerations in any remedial activity is the estimated length of time for treatment completion. Two variables that will significantly impact the cleanup time for in situ remedies are: (1) permeability of the soil and (2) the magnitude of the groundwater gradient. In the instance of in situ chemical degradation or bioremediation (3) small groundwater gradients will cause nutrients and chemicals to move at a slower pace; thus the cleanup will also occur at a slower pace. This problem also occurs with vapor movement in low permeability soils such as clay. Vapor phase remedies will take longer in this material. Fractures in a geological unit may "short circuit" the flow creating preferential flow channels, bypassing much of the contamination and creating a compliance assurance problem. Nonhomogeneity of soil may cause localized differences in permeability as well. Groundwater gradients can be controlled by pumping and there are ways of increasing permeability, but these modifications all add costs to the final remedy. All of these points lead to one conclusion; in any in situ type remedy there must be a consistently reliable method to reach the contaminants with liquid, vapor, bioorganisms or stabilization agents in a reasonable period of time.

CONCLUSION

In situ treatment technologies have many issues that must be considered prior to their use (Table 2). Initially, these technologies may appear to possess wide applicability. Unfortunately, they cannot be used in all instances and in some cases should not be specified. Differences in geology, cleanup criteria and available time for remedy implementation may preclude their use. Some of the difficulties with in situ type remedies include: (1) confirmation of compliance and (2) length of time required for remedy implementation.

Table 2
Summary of Issues to Consider for In Situ Remedy Selection

1. How will compliance of the remedy with specified goals be monitored?
2. What are the cleanup criteria?
3. What is the estimated time for remedy implementation and completion?
4. Is movement of the water along the groundwater table gradient fully understood?
5. What is the magnitude of the groundwater gradient?
6. What are the permeability characteristics of the soils in the contaminated zone?

Although not applicable to all remedial situations, in situ remedies definitely do have a place. Many successful in situ remediations projects have been completed. These remedies have been successful because planners have carefully considered the six points listed above and applied them to the hazardous waste sites' specific geological and hydrogeological characteristics while keeping in mind cleanup criteria, compliance confirmation and time constraints imposed. Investigation and understanding of these points will lead to many more effective in situ remedies in the future.

ABSTRACT

Lockwood, Andrews & Newnam, Inc. (LAN) has been contracted by the Texas Water Commission to conduct an RI/FS for the Petro-Chemical Systems Superfund Site in Liberty County, Texas. A portion of this work includes Treatability Studies on the contaminated material from the site. The Treatability Studies are required to demonstrate the effectiveness of selected treatment technologies on clay soils containing volatiles, semivolatiles and heavy metals.

The Petro-Chemical Systems site is a 312-acre tract of land located in primarily rural Liberty County, Texas. The site received various chemical wastes in the early 1970s and was placed on the NPL in 1984. Subsequent investigation has revealed dumping activities in three areas of the site and contaminant concentration for heavy metals to 500 ppm, semivolatile hydrocarbons to 4000 ppm and volatile hydrocarbons to 1000 ppm.

Removal of volatile and semivolatile contaminants in the clay soils by a solvent extraction technique will be investigated. Chemical and microbial evaluation, as well as laboratory simulations, will be conducted during this study. The bioremediation treatability study will also attempt to determine the contribution to contaminant removal associated with degradation vs. volatilization. High concentrations of chromium and lead are localized at the site. Inhibition of bioremediation by heavy metals will also be evaluated.

The treatability studies will attempt to determine operating conditions, process requirements, power requirements and chemical requirements. Estimates of treatment costs and treatment schedule will also be determined.

The paper will discuss the process used to select the treatability studies, the results of both treatability studies and their impact on the remediation at the site.

INTRODUCTION

The Petro-Chemical Systems site is a 312 acre tract of land located approximately 65 mi east of Houston, Texas (Fig. 1). The site is approximately 7 mi north of Interstate 10 and 15 mi southeast of Liberty along Farm to Market Road (FM) 563 (Fig. 2). Frontier Park Road provides access to the site from FM 563.

Unpermitted waste disposal operations at the site may have started in the late 1960s. Disposal of waste oils is documented from 1971 when an application for a commercial disposal permit in the name of Petro-Chemical Systems, Inc. was granted by the Texas Water Quality Board. Waste oils were apparently deposited in pits throughout the site and spread on Frontier Park Road as a dust abatement measure.

Opposition to the disposal activity developed, and legal action resulted in the permit being revoked in 1974. The site was then subdivided into 5-to 15-acre tracts and sold for residential development. Five families currently live on these tracts.

Attention brought by local residents in the early 1980s resulted in the site being placed on the NPL. In 1985, the Texas Water Commission contracted with Lockwood Andrews & Newnam, Inc. (LAN) to perform a Remedial Investigation and Feasibility Study on the site. The first task consisted of performing a focused RI/FS on Frontier Park Road, the access road for the site which had been contaminated with waste oils. The road was remediated and the contaminated soil was stored in a RCRA vault on-site pending selection of a remedy for the entire site. The RI/FS for the remaining site was completed in 1990.

REMEDIAL INVESTIGATION RESULTS

The primary contaminates found on-site were volatile and semivolatile organics, chromium and lead. Indicator chemicals were selected during the Risk Assessment and were used throughout the RI to define the extent of contamination and to estimate the volume of contaminated material on site. The indicator chemicals were:

- Benzene
- Ethylbenzene
- Xylene
- Naphthalene
- Benzo (a) pyrene
- Lead

TREATABILITY STUDIES

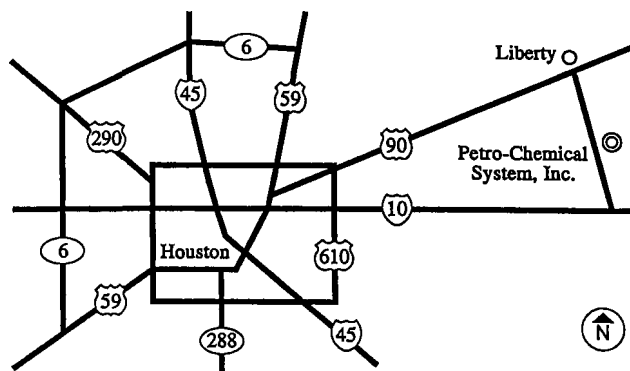
Two technologies were selected to evaluate remediating the contaminated soils. These were bioremediation and solvent extraction.


Figure 1
Site Location Map
Figure 2
Site Vicinity Map

BIOREMEDIATION

Bioremediation of the contaminated soils was simulated by Harding Lawson Associates, a member of the RI/FS team. Prior to commencing the actual laboratory simulation, chemical and microbiological evaluations of the soil were performed. Of prime interest is the ratio of hydrocarbon degrading microorganisms to total microorganisms. This ratio ranged from 12% to 26% and is considered a suitable subpopulation with which to start the test. A soil chemistry profile was conducted to determine nutrient requirements for the treatment process. The chemistry profile indicated that ammonia and phosphorous were the limiting nutrients and required supplementation in a form readily available to the microorganisms. The soil pH was determined to be too low and had to be adjusted with lime.

Treatment Simulation

A laboratory-scale treatment system was constructed to simulate conditions under which the bioremediation process would be implemented in the field. The treatment system (Fig. 3) consisted of a polyethylene-lined treatment bed within an air-tight glove bag enclosure. Air that was pretreated through a carbon trap was supplied to the enclosed treatment unit at a rate between 20 to 40 ft³/hr. Exhaust air leaving the treatment system was filtered through three individual 100 gram carbon traps in series to capture volatile compounds that were released during the treatment process. Nutrient supplementation, mechanical aeration and soil sampling procedures were performed within the treatment system via a pair of side arms with gloves attached to the enclosure. Soil samples were removed from the system via a sampling port.

A composite soil sample weighing approximately 120 lbs was placed into the laboratory-scale treatment system to a depth of approximately 12 inches. Base line parameters, which include BTEX, PNAs, chromium and lead, were measured for the soil. During a six week treatment period, the soil was amended with a nutrient formulation on a weekly basis and mechanically aerated three times per week to provide oxygen for microbial metabolism. Additionally, weekly soil samples were obtained and analyzed for BTEX and microbial populations. Following

Figure 3
Biological Treatment

the treatment period, soil samples were obtained and analyzed for the same base line parameters as previously described.

Study Results

The initial concentration of BTEX in soil was reduced approximately 99.8% (Table 1) during the treatment period. Additionally, the hydrocarbon-utilizing microbial population increased four orders of magnitude indicating that soil conditions conducive to biological metabolism of the hydrocarbons were present during the treatment period. The calculated half-life for BTEX during the treatment period was approximately 5.0 days. The initial concentration of PNAs in the soil was reduced approximately 94% during the treatment period (Table 2). The calculated half-life for PNA during the treatment period was approximately 8.3 days. These data indicate that biological treatment is effective in significantly reducing the concentrations of BTEX and PNAs in soils at the Petro-Chemical Systems site.

Table 1
Biodegradation of BTEX Compounds Petro-Chemical Systems

| Compound | Treatment Period in Weeks | | | | | | | Percent Removal |
	0	1	2	3	4	5	6	
	Concentration in ug/kg

Anthracene	4.2	.7	83.0
Fluoranthene	4.8	1.1	77.0
Pyrene	10.5	3.9	63.0
Total PNA	277.3	15.4	94.0

Petro-Chemical Systems

Activated carbon from the exhaust carbon canisters was extracted with carbon disulfide and the resulting extract was analyzed for BTEX. BTEX compounds volatilized and absorbed to the carbon traps during the period amounted to approximately 3% of the total mass of BTEX present in the soil.

Conceptual Design

The results of a bioremediation treatability study indicate that biological treatment is a technically feasible and effective method for reducing BTEX and PNA concentrations in soils at the Petro-Chemical Systems site. Although the actual design of the full-scale system will be based on site-specific factors, a brief description and conceptual design of a full-scale bioremediation treatment system is presented below.

Soil that requires treatment would be excavated and placed in the treatment facility. A conceptual design of the biotreatment facility is presented in Figures 4 and 5. The biotreatment facility will be an enclosed, above-grade, lined treatment bed capable of treating approximately 2,000 yd³ of soil. It is estimated that the biotreatment will extend over an area of approximately 1.5 acres. The biotreatment facility
will also be equipped with air emissions control system including a vapor phase carbon unit to remove any VOCs that are released during the treatment process.
Figure 4
Bioremediation Conceptual Layout
Figure 5
Typical Bioremediation Section
Figure 6
B.E.S.T.® Process Flow Diagram

Before beginning the treatment process, homogenization of the soil into a uniform consistency may be necessary. Following soil homogenization, base line soil samples would be collected to ascertain organic chemical concentration, microbial population, soil pH and moisture. The nutrient formulation would be applied at an estimated dose of 1.5 to 3.0 gallons/yd³. The nutrient formulation may be applied through several mobile sprinkler nozzles placed within the treatment area. It is estimated that two to four nutrient applications would be performed during the treatment period.

The soil would be mechanically aerated with a tractor-mounted rototiller or discing equipment. The frequency of aeration is estimated to be three times per week during the treatment period. The treatment period for each soil unit volume (2,000 yd³) is estimated to be 8 to 12 weeks. The treatment period is based on the results of the bioremediation laboratory simulation and operating experience with similar pro-

jects. Generally, for projects of this type, the soil treatment cost is estimated to be $84 to $130/yd³.

SOLVENT EXTRACTION

The solvent extraction treatability study was conducted by Resource Conservation Company using their B.E.S.T.ᴿ process. This process uses triethylamine (TEA) to separate sludges, soils and sediments into their oil, water and solid fractions. The physical properties of TEA are ideal for this purpose. TEA is a powerful solvent for organic compounds and has unique water miscibility properties. The key to the success of amine extraction is the property of inverse miscibility. This unique property allows TEA to solvate oil and water simultaneously, resulting in very high extraction efficiency of organic contaminants.

At temperatures below 60°F, TEA is perfectly miscible with water. Above this temperature, TEA and water are only partially miscible. This physical property can be used by the realization that cold TEA can simultaneously solvate oil and water. In the B.E.S.T.ᴿ system, this principle is exploited by performing the extractions in the temperature region where the solvent is miscible with both oil and water, creating a single-phase extraction medium.

Once the extraction of the sample is complete, soil particulates are removed by either gravity settling or centrifugation. The cold, single-phase solution of TEA, water and oil is then heated to 130°F. Heat drives the solution into the temperature region where TEA and water are only partially miscible. The TEA/oil fraction is then easily separated from the water fraction by decanting off the water.

Bench Scale Study

Soil samples were collected from site locations selected on the basis of the first phase RI data. The samples were shipped on ice in four one-liter containers. The samples were kept cold until the initiation of the test.

Initial examination of the sample indicated a soil pH of 3.1. Due to the basic nature of TEA, the pH of the feed for the process must be controlled to a level of 10 or higher. It was determined by titration that 21 mL/kg of 50% caustic soda (NaOH) of feedstock would be required to adjust the pH to the required range.

Based on this information, a prechilled, 600 gm portion of the soil sample was pH adjusted by adding 13 mL of 50% caustic soda at the same time that three liters of chilled TEA were added. Mixing was performed by an air-driven prop mixer in an open top beaker.

As expected, the solvent became colored, indicating that oil extraction was taking place. Mixing time was extended from the standard 30 minutes period to 42 minutes to ensure that all the sample was adequately mixed with the TEA. After mixing ceased, heavy particles immediately settled to the bottom of the beaker. Fine particulates did not readily settle to the bottom of the beaker indicating that gravity settling alone would not be sufficient to remove all the particulates from the extraction mixture. As a consequence, centrifugation was used to remove the particulates between each extraction stage.

The cold centrate recovered from centrifugation was decanted from the particulate solids at this point and retained for further processing. The remaining solids were placed back into the extraction flask in preparation for the next two extraction stages.

Two more stages were performed for a total of three extraction stages. The recovered soils from the centrifugation of the previous stage were mixed with the same amount of TEA, 3.0 liters, for the second and third stages. No additional caustic was added. After 30 minutes of mixing, centrifugation was performed as before. After the third stage centrifugation was completed, the solids were dried.

The centrate recovered from the first extraction stage was separated into its aqueous and organic components. The TEA/Oil/Water mixture was heated to approximately 140°F to effect the separation of the two phases. The hot centrate was permitted to stand and separate for 30 minutes in a four-liter separatory funnel immersed in a hot water bath.

Separation of the organic and aqueous phases was immediate, with no rag formation. After the 30-minute standing period, the aqueous phase was decanted off the bottom of the organic phase and retained

for further treatment. The organic phase was then ready for the TEA Recovery/Oil Stripping process.

Only the centrate from the first extraction stage had a significant amount of water in solution; therefore, only the centrate from the first extraction stage was decanted.

Analysis showed the organic fraction contained only 2% fugitive water, which is the minimum achievable concentration in a pure triethylamine/water system. The concentration of fugitive triethylamine in the aqueous fraction was also low, namely, 2.8%.

Recovery of product oil was accomplished in three steps. First, the bulk of the TEA was removed by simple distillation. Second, the residual TEA was stripped from the oil by steam distillation. Third, the oil was heated to the further reduce the residual levels of TEA and water. No foaming was observed during the above operation and no TEA odor was apparent in the oil at the completion of the steam stripping step.

Due to the extremely low oil content of the feedstock, very little oil was recovered. The amount of oil recovered was not sufficient to perform any laboratory analysis.

Removal of triethylamine from the decant water was accomplished by heating the water on a hotplate, while insuring an elevated pH was maintained. The elevated pH was necessary to insure that the majority of the triethylamine was in the volatile molecular form. Additional caustic was required, 0.4 mL/L 50% NaOH decant water, to maintain the elevated pH. No foaming was observed during the stripping.

Study Results

Prior to starting the test, an initial sample was analyzed to provide a base line for comparison. Sample characteristics are shown in Table 3.

Table 3
Feed Compositional Analysis

Oil	0.99%
Water	9.0%
Solids	70.0%
Ash	65.0%
Cyanide	0.54 ppm

The remaining laboratory results are presented in Tables 4 through 6. The tables show the initial and final concentration for each analyte with the calculated percent removal.

Table 4
Volatile Organic Compounds

ANALYTE	RESULT, MG/KG		
	INITIAL	FINAL	% REMOVAL
Methylene Chloride	14	0.06	99 6
Acetone	<28	3.2	88.6
2-Butanone	<42	1.9	95.5
Benzene	<5.6	0.016	99.7
2-Hexanone	6.5	0.022	99.7
Toluene	13	0 032	99.8
Ethylbenzene	15	0.008	99.9
Styrene	35	0.024	99.9
Xylene	43	0.053	99.9

In selecting a chemical extraction method, we were concerned with metals treatment and ultimate on-site disposal of the residual solids. To address this concern, we requested that a leachate test, EP Toxicity, be run on the residual solids to give us a feel for the expected final characteristics of these solids. Table 6 gives the initial and final total metals analysis by Method TCL 6010-7000 and the EP Toxicity concentration of the eight targeted metals.

Summary

Superfund Site was suitable for processing with the B.E.S.T.[R] solvent extraction process. There were no significant problems observed during testing of the samples and consequently, full-scale processing should be straightforward. Key observations concerning the test results include the following:

- The oil was chemically compatible with triethylamine.
- The oil in the sample was readily extracted from the soil. The soil and grease residual in the product solids was 470 ppm, compared to 9,900 ppm in the feedstock, yielding a 95% extraction efficiency in three extraction stages.
- All semivolatile compounds were below detection limits in the treated solids. However, two volatile compounds, acetone and 2-butanone (MEK), were quantified above 1 ppm in the product solids. Thus the treatment objective of 1 ppm or less volatile organic compounds in the treated soil was not achieved.
- The product solids readily passed the EP Toxicity Leaching test for metals.
- The separation of TEA/oil from water by heating and gravity decantation was very effective in that it was immediate and minimal concentrations of fugitive water and TEA/oil remained in the decant TEA/oil and decant water fractions, respectively.

- The untreated product water contained 41 mg/L oil and grease and also contained very low concentrations of metals. Both oil and grease content and heavy metals content could be further reduced by post-treatment if desired.

Conceptual Design

The contaminated soil could be treated in a 110 yd³/day B.E.S.T.ᴿ transportable processing unit. The unit would operate 24-hours per day during the processing period with an average utilization rate of 80%.

The estimated unit cost for this treatment system is $160-$210/yd³.

CONCLUSIONS

Both of the technologies studied can successfully treat the contaminated soils at the Petro Chemical Systems Site. The bioremediation alternative may have a cost advantage over the solvent extraction technology; however, confirmation of this preliminary conclusion will be based on a more detailed economic comparison.

Design Modifications to Improve Granular Activated Carbon Treatment System Performance

Brandon R. Ball

Tacoma, Washington

James I. Michael
Black & Veatch
Denver, Colorado

ABSTRACT

Improvements were recommended and designed for the South Tacoma Channel Groundwater Treatment System. The treatment system was implemented to assist with remedial cleanup activities at this NPL site in Tacoma, Washington. The existing treatment system utilizes liquid-phase, granular activated carbon (GAC) treating 150 gpm of groundwater to remove volatile chlorinated hydrocarbons. Current GAC performance for contaminant breakthrough and competitive adsorption was accurately simulated with a plug-flow pore and surface diffusion model for multicomponent, fixed-bed mixtures. The model was also used to estimate GAC performance at higher influent loading rates, which would occur if a new proposed groundwater extraction well were added to the system in the future.

The recommended design improvements included the addition of an air stripping process at the end of the GAC system to remove vinyl chloride. The air stripping tower was designed to remove only vinyl chloride, which is weakly adsorbed and quickly displaced from the GAC by other competing organics, resulting in high overall carbon usage rates. An analysis of air stripping design was performed with a computer model based on a two-resistance approach using Onda correlations. The modified treatment system configuration of GAC combined with air stripping, as simulated by computer models, was shown to be capable of surpassing performance requirements for air and water discharge. An economic evaluation showed that the modifications could pay for themselves in approximately two years based on savings associated with carbon replacement if more stringent vinyl chloride discharge standards were adopted in the future.

INTRODUCTION

The South Tacoma Channel Well 12A site is located in Tacoma, Washington, within the Commencement Bay drainage area. Well 12A is part of an alluvial well field providing a supplemental potable water source for the City of Tacoma. Chlorinated hydrocarbon compounds have been detected in the groundwater withdrawn from Well 12A at concentrations high enough to preclude its use in the water system without first receiving treatment to remove contaminants. To cleanup the aquifer, a groundwater extraction and GAC treatment system was installed at the contaminant source location in 1988. The treatment system consists of two GAC adsorbers operated in series. The overall objectives of the extraction and treatment system are to remove and treat groundwater contaminants at their sources and to restore the quality of the aquifer to acceptable drinking water standards.

The GAC treatment system, which has operated continuously since 1988, is capable of reducing influent VOC concentrations to below standard detection levels available by GC/MS analysis for all compounds except vinyl chloride. Vinyl chloride is weakly adsorbed onto GAC and

quickly displaced by other, more strongly adsorbing organic compounds. The displacement of vinyl chloride routinely produces an effluent vinyl chloride concentration from the treatment system that is higher than the influent concentration. To address the issue of vinyl chloride, the U.S. EPA tasked Black & Veatch to evaluate the technical and economic feasibility of applying air stripping treatment to the existing GAC system to reduce the effluent levels of vinyl chloride. Although vinyl chloride is not effectively removed by GAC, it has properties of high volatility and low molecular weight that make it very suitable for removal by air stripping.

For purposes of the evaluation, the following discharge goals and operating criteria were proposed by the U.S. EPA and the Washington State Department of Ecology:

- No displacement standard. This discharge goal requires that effluent vinyl chloride concentrations be no greater than the average influent concentration.
- Carbon replacement in the lead bed based on 300 $\mu g/L$ breakthrough of 1,2-dichloroethene (1,2-DCE) in the lead bed effluent. This operating criterion allows full breakthrough and displacement of vinyl chloride in the effluent but maintains all other contaminants below detection levels by using 1,2-DCE as a precursor.

For comparison, the evaluation also investigated the feasibility and cost of meeting a discharge goal of 2 $\mu g/L$, which is the drinking water maximum contaminant level (MCL) for vinyl chloride. In addition, the evaluation considered the impact of adding another extraction well to the system, which would increase the influent hydraulic and contaminant loading rates.

The current treatment requirements for vinyl chloride are based on meeting U.S. EPA Marine Water Quality Criterion of 525 $\mu g/L$. The existing GAC system can meet this standard even with the displacement of vinyl chloride. However, if a no displacement standard were adopted in the future, the operating costs of the system would increase substantially because of the very high carbon usage rates required to remove vinyl chloride. Therefore, significant cost savings would be achieved by modifying the system with an air stripping tower to selectively remove vinyl chloride.

DESCRIPTION OF EXISTING GAC TREATMENT SYSTEM AND OPERATING PERFORMANCE

The operating performance of the GAC treatment system is summarized in Table 1. As shown in the table, all VOCs are routinely removed to below detection limits by GAC, with the exception of vinyl chloride. Treated effluent is discharged through a storm drain into Puget Sound. The current discharge standards, which are based on U.S. EPA Marine Water Quality Criteria, are continuously met for all compounds including vinyl chloride which has a standard of 525 $\mu g/L$.

Monthly Flow (Mgal)	5.9	5.0-7.2		

U = Compound was analyzed for but not detected at the given detection limit.

The existing treatment process consists of two carbon adsorption vessels with identical dimensions: 10 feet in diameter and approximately twelve feet high. Each vessel contains approximately 20,000 lbs. of 12 by 40 standard sieve GAC, which is used in a pressurized, downflow operational mode. The maximum flow capacity of the system is rated at 500 gpm. The flowrate is presently limited to 150 gpm because of hydraulic restraints of the groundwater well extraction system. This production rate is the maximum that currently can be sustained without pumping the well dry. At 150 gpm, the empty bed contact time (EBACT) within each adsorber is 36 minutes.

During normal operation, the vessels are operated in a series configuration. Exhaustion of the activated carbon in the lead bed is based on reaching a concentration of 300 μg/L of combined cis- and trans-1,2-dichloroethene (1,2-DCE) in the effluent from the lead vessel. 1,2-DCE is the second-weakest adsorbing component and is used as a precursor to the breakthrough of other contaminants. When the 1,2,-DCE concentration has approximately reached this breakthrough level, the lead bed is taken out of service, and the spent carbon is replaced with fresh carbon. After the carbon is replaced in the first vessel, the valve sequence is manually changed, and the bed is returned to service as the second bed in series.

At 150 gpm, the treatment system operates at only 30% of its maximum hydraulic loading capacity. The U.S. EPA tentatively plans to install a new extraction well directly below the primary source of groundwater contamination. The purpose of the new well will be to speed up groundwater remediation by extracting groundwater having the highest contamination concentration. If installed, the new well would add approximately 150 gpm to the system, for a total flowrate of approximately 300 gpm. It is expected that the new well will contain the same VOC contaminants that the system currently processes, but at roughly 10 times higher concentration.

For purposes of the air stripping process evaluation, the maximum emission allowance for vinyl chloride was set at 1 lb/day. This value was based on the local air pollution control standards for Tacoma-Pierce County, which were in effect at the time of this study.

DESCRIPTION OF PROCESS MODELS

The mathematical models used to simulate GAC performance and to assist with design of the air stripping treatment process are complex, and a full description would require a separate technical paper. Therefore, this paper will present only a brief description of the models with references to the literature for a more complete description and theoretical basis.

Air Stripping Process Model

The computer model used to perform the air stripping analysis is based on a two-resistance approach using Onda correlations to determine liquid) and gas-phase mass transfer coefficients. The model considers both liquid-phase and gas-phase resistance to mass transfer and has been found to offer significant improvement over single-phase models in predicting volatilization of trace VOCs in the air stripping process.

The rate of mass transfer across an air-water interface in the stripping process is controlled by the sum of resistances in the liquid and gas-phase boundary layers. Assuming that Henry's Law describes the chemical equilibrium conditions between the air and water phases (a valid assumption for low concentrations of VOCs in groundwater) the overall rate constant is given by:[1]

$$K_L a = [(1/k_L a) + (1/k_G a \, H_c)]^{-1} \qquad (1)$$

in which K_L is the overall mass transfer coefficient (m/sec), k_L and k_g are the mass transfer coefficients for the liquid and gas phases (m/sec), a is the specific interfacial area of packing m^2/m^3 and H$_c$ is the Henry's Law constant (dimensionless). The product of $K_L a$ is equivalent to the first order, transfer rate constant. Values for k_L, k_G and a (area) were determined by correlations developed by Onda et al.[2]

By incorporating the overall transfer rate constant into mass balance equations based on influent and desired effluent contaminant concentrations, important design parameters such as packing height and air-to-water ratio were determined for the air stripping process.

GAC Process Model

The computer program used to perform the GAC analysis was developed by John C. Crittenden at Michigan Technological University and is commonly referred to in engineering literature as the plug-flow pore and surface diffusion model (PFPSDM).[3]

The PFPSDM is used to predict effluent concentration profiles and carbon usage rates for multicomponent mixtures treated by a fixed-bed GAC adsorber. The model considers mass transfer resistances due to both pore and surface diffusion. Once contaminant molecules have diffused from the bulk solution to the outside surface of the adsorbent grain, they then diffuse to the inside of the porous adsorbent because of the high internal surface area of the adsorbent. The internal transfer step can proceed in the liquid-filled pores, which is referred to as pore diffusion, or along the walls of the pores as adsorbed molecules, which is referred to as surface diffusion. Although most adsorbents used to remove organic compounds from water have very heterogeneous and porous structures, the PFPSDM assumes that the adsorbent grain is a spherical particle of homogeneous structure such that the solid-phase contaminant concentration, adsorbent density and surface depend only on the radial location in the particle.

The assumptions incorporated into the PFPSDM are as follows:

- The liquid-phase flux may be described by a linear driving force
- Local equilibrium exists throughout the adsorbent phase
- The adsorption equilibria may be described by the Freundlich isotherm equations and ideal adsorbed solution theory
- The intraparticle mass flux is given by both surface and pore diffusion
- There are no solute-solute interactions in the diffusion process
- Solute transport in the axial direction is by advective flow
- The effects of radial dispersion are negligible

To make predictive calculations with the PFPSDM, the following five parameters must be determined for each contaminant: Freundlich capacity parameter K_f; Freundlich intensity parameter, 1/n; film transfer coefficient; surface diffusion coefficient; and pore diffusion coefficient.

The program solves a system of simultaneous partial differential equations by converting them to a system of ordinary differential equations using the orthogonal collocation method then integrating by the Dgear method. The PFPSDM program accurately predicts the competitive adsorption effects in multicomponent mixtures and can be used to determine the elution order and effluent breakthrough profiles of contaminants and the highest effluent concentrations due to displacement from competitive adsorption.

EVALUATION PROCEDURES FOR GAC

The Freundlich isotherm constants used in the process model were reduced to account for a reduction in GAC adsorption capacity because of fouling by influent total organic carbon (TOC). The adverse effect of TOC loading on the performance of the GAC treatment system is due to the significant differences in adsorption behavior between trace VOCs and natural organic matter (measured as TOC). Within an adsorption vessel, the chlorinated hydrocarbons build up in a well-defined mass transfer zone, which migrates slowly through the carbon bed with increased running time. The large humic molecules that comprise the majority of TOC constituents have slow adsorption kinetics, which leads to a rapid migration velocity and a long mass transfer zone. This, in turn, yields a fast breakthrough of TOC in the effluent of adsorption vessels designed specifically for trace VOC removal. The effect of this TOC preloading is a substantial reduction of carbon adsorption capacity over time. For modeling the existing treatment system, TOC preloading reduced the Freundlich constants to approximately 70% of the adsorption capacity of virgin carbon. The value for each adjusted Freundlich constant is shown in Table 2.

TOC (mg/l)	6		
Water Temperature C	12		
Average Monthly Flow, Mgal	5.2		

The results of the modeling predictions are compared with the observed monitoring data for the treatment system for displacement of vinyl chloride in Figure 1 and breakthrough of 1,2-DCE in Figure 2. As indicated in the figures, the modeling results agree very closely with the actual treatment system performance observed at the site. The increased vinyl chloride concentration in the treated effluent is due to competitive displacement occurring in the carbon beds between compounds of different adsorption strength. The competitive displacement or desorption process occurring within the carbon beds at the Well 12A treatment system can be described as an interaction between the compounds vinyl chloride and 1,2-DCE. Both of these VOCs are being fed simultaneously to the treatment system and 1,2-DCE has a higher adsorption affinity and migrates more slowly than the vinyl chloride as these compounds move through the carbon beds. Consequently, the weakly adsorbing component (vinyl chloride) migrates through the bed faster than the more strongly adsorbing component and saturates the bed as if it were present as a single component. This phenomenon leads to a solid-phase concentration for the vinyl chloride in the deeper part of the bed that exceeds the solid-phase concentration that results when 1,2-DCE is also present. Accordingly, the weakly adsorbing component is displaced by 1,2-DCE in a manner in which the displaced concentration exceeds the influent concentration.

Under the current operating conditions and discharge standards, the most efficient utilization of carbon can be attained by rotating the carbon bed sequence upon depletion and by allowing the lead adsorber to saturate completely with 1,2-DCE before replacement. Bed satura-

tion is achieved for a given contaminant when the bed effluent concentration becomes equivalent to the influent concentration. Because the discharge standard (1.85 μg/L) for cis- or tans-1,2-DCE is only slightly above the analytical detection level, concentrations of this compound must remain below detection levels in the effluent at all times. The adsorption capacity and breakthrough data obtained with the PFPSDM model indicate that, for both the current and potential future treatment system operating conditions, the lead vessel can be saturated with 1,2-DCE without 1,2-DCE or any other VOCs (with the exception of vinyl chloride) being detected in the effluent from the second vessel. Furthermore, there is a minimum time period of approximately one month between 1,2-DCE saturation of the lead carbon bed and the beginning of 1,2-DCE breakthrough of the second carbon bed. This time period should provide a sufficient safety factor to ensure that carbon replacement in the lead vessel will occur before 1,2-DCE is detected in the system's discharge.
EVALUATION AND DESIGN PROCEDURES FOR THE AIR STRIPPING PROCESS

Optimum Configuration

The alternative configurations that were reviewed for placing an air stripping tower in the treatment process included:

- After the groundwater extraction well and before the carbon adsorp-

tion vessels
- Between the first and second carbon adsorption vessels
- At the end of the GAC process after the second carbon adsorption vessel

The capital cost of either of the first two configurations would exceed the cost of the third alternative because a new pumping station would be needed to pump effluent from the air stripping tower through the downstream carbon adsorption vessel(s). The first alternative would also air strip other VOCs besides vinyl chloride, resulting in VOC emissions in excess of the local standard of 1 lb/day for total chlorinated hydrocarbons. The second alternative, locating an air stripping tower between the first and second carbon adsorption vessels, could be operated in a manner that would eliminate excess VOC emissions by allowing only vinyl chloride removal. However, the operating criteria necessary to achieve this goal would adversely impact the treatment system's cost-effectiveness because the first carbon bed would require replacement as soon as 1,2-DCE was detected in the air stripping tower's influent.

Placement of an air stripping tower located after the second carbon adsorption vessel (the third alternative) was chosen for further detailed evaluation. Only vinyl chloride is removed by the air stripping tower in this alternative and carbon usage in the lead vessel is maximized by completely saturating the carbon in the lead vessel with 1,2-DCE.

Design Criteria

Design criteria for the air stripping tower were evaluated and selected using the previously described air stripping computer model. The design of the air stripping tower was based on the most conservative parameters projected for the treatment system, including addition of the new groundwater extraction well. The treatment objective was based on meeting the most stringent discharge goal of 2 μg/L of vinyl chloride. This goal would require removing 99.33% of the vinyl chloride displaced from the GAC system. Based on the displacement concentration projected by the GAC model, a maximum vinyl chloride concentration of approximately 300 μg/L could be present in the effluent from the carbon adsorption vessels. Removing at least 99.33% would also result in air emissions consistent with the local air pollution control standard of 1 lb/day for total chlorinated hydrocarbons.

The modeling analysis showed that a minimum height of packing material required to achieve 99.33% removal of vinyl chloride would be approximately 18 feet for a tower 5 feet in diameter and an air-to-water ratio of 30. Figure 3 shows the relationship between packing height and air-to-water ratio. At an air-to-water ratio between 20 and 30, the curve starts to flatten out and packing height decreases little for further increases in the air-to-water ratio. The packing height approaches an asymptote at high air-to-water ratios because the liquid loading decreases, which in turn decreases the overall mass transfer coefficient
Figure 4
Relationship Between Packing Height and Percent Removal
(Air-to-Water Ratio = 30)

in Equation 1. Although the gas-phase loading and, thus, gas-phase mass transfer is increased, the overall mass transfer coefficient is reduced because most of the mass transfer resistance is in the liquid phase. Figure 4 shows the packing height versus percent vinyl chloride removal for a 5-foot-diameter tower and an air-to-water ratio of 30. The figure indicates that the packing height increases rapidly as percent removal increases beyond the required removal rate of 99.33%.

Table 3 summarizes the design criteria developed for the air stripping treatment system. The air stripping process was designed to meet the lowest discharge goal of 2 μg/L. However, the system could meet other less stringent goals, such as a no displacement standard for vinyl chloride, if the air-to-water ratio were lowered.

Table 3
Air stripping Tower Design Criteria

Design Parameter	Design Value

COST ANALYSIS

Carbon Usage Rates

The impact of alternative discharge goals on the annual carbon usage rates and carbon replacement costs for the existing treatment system are indicated in Table 4. The predicted carbon usage rates and resulting costs were based on treatment system breakthrough performance as estimated by the PFPSDM GAC model for meeting each of the different discharge goals. The carbon usage rate indicated in the table for

Figure 3
Relationship Between Packing Height and A/W Ratio
(93.33% Vinyl Chloride Removal)

meeting the current discharge standard of 525 µg/L vinyl chloride assumes optimum carbon utilization by allowing the lead bed to fully saturate with 1,2-DCE before replacement. Based on the analysis, adoption of a no displacement standard for vinyl chloride, compared to the current 525 µg/L discharge standard, would increase carbon replacement costs by $70,000/yr. For comparison, Table 4 also lists carbon replacement costs for achieving a discharge goal of 2 µg/L vinyl chloride. The table shows carbon replacement costs under the current operating criterion of 300 µg/L of 1,2-DCE from the lead bed effluent.

Table 4
Impact of Alternative Discharge Criteria
on Annual Carbon Replacement Costs

Conditions	Discharge Criteria VC (ug/l)	Carbon Usage Rate (lbs/1000 gal)	Annual Carbon Replacement Cost* ($)
Existing Conditions With 1 Extraction Well			
Marine Discharge Standard	525	0.77	66,000
No Displacement Standard	28.8	1.59	136,000
300 ug/l 1,2-DCE (Lead Bed)	>30	0.85	73,000
Safe Drinking Water Act MCL	2	1.75	150,000
Future Conditions With 2 Extraction Wells			
Marine Discharge Standard	525	0.98	168,000
No Displacement Standard	158	1.75	299,000
300 ug/l 1,2-DCE (Lead Bed)	>30	1.35	231,000
Safe Drinking Water Act MCL	2	1.92	329,000

*Based on actual carbon replacement cost of $1.37 per pound. Cost calculation assumes a total flow of 62.4 million gallons with one extraction well and 124.8 gallons with two extraction wells.

Based on the accuracy of the GAC computer model in simulating the performance of the existing treatment system, process modeling was performed to evaluate the performance of the treatment system in the event that a new groundwater extraction well was installed. As a basis for comparison, it was assumed that the new extraction well would add 150 gpm to the existing influent and contain 10 times the current concentration of each VOC and TOC. The modeling analysis used an approach similar to the method described for the existing treatment system except that, because of the higher VOC loading rates and corresponding increased carbon usage rates, the TOC preloading effects were slightly reduced and, therefore, the Freundlich constants were estimated to be 80% of the adsorption capacity predicted by virgin carbon. Based on the vinyl chloride and 1,2-DCE breakthrough curves predicted by the PFPSDM model for the future treatment system with higher loading, the impact of alternative discharge goals on the carbon replacement costs were evaluated. Table 4 indicates the projected carbon usage rates and annual carbon costs for meeting each of the alternative discharge goals in the event that a new groundwater extraction well was added to the treatment system. The results indicate that adoption of a no displacement standard would increase carbon replacement costs by $131,000/yr.

Air Stripping Treatment Costs

Total construction costs for the air stripping tower were estimated to be $122,000. These costs include the air stripping tower, foundation, installation, startup and testing, contingencies and engineering. The cost for the air stripping tower and associated equipment were estimated to be $50,000, which includes the tower structure, 18 feet of packing material, the blower, electrical controls and all necessary piping. Annual operation and maintenance (O&M) costs including power consumption of the blower were estimated to be $3,000/yr.

Present Worth Analysis

A present worth analysis was conducted to determine the benefits,

if any, of installing an air stripping tower to remove vinyl chloride from the GAC treatment system's effluent. The analysis was based on the design criteria developed for both the existing treatment system and the future treatment system, which includes a new groundwater extraction well. As a basis for comparison, a no action alternative was developed that considers the cost requirements for meeting a lower discharge standard with the existing GAC system. The no action alternative's carbon replacement costs were based on the carbon usage rates estimated as necessary to meet the discharge requirements that would result from the adoption of a no displacement standard.

The no action alternative's costs were then compared to the costs associated with meeting the same discharge standard by adding an air stripping tower at the end of the existing GAC treatment system. For the analyses, carbon replacement costs and O&M costs were escalated annually over the life of the project at a 3% rate of inflation. A discount rate of 8% was assumed for the present worth calculations. The present worth analysis for the current treatment system operating with one extraction well is summarized in Table 5. The net savings indicated in the table are based on three primary considerations:

- The economic analysis uses the no action alternative's carbon replacement costs and associated 28.8 µg/L vinyl chloride discharge standard as the basis for comparison. Carbon usage rates are based on values given in Table 4 for meeting the 28.8 µg/L standard.
- An air stripping tower is included to achieve the 28.8 µg/L vinyl chloride effluent limitation. Capital and O&M costs for addition of the air stripping tower are based on the costs developed in the previous subsection.
- The carbon usage rates associated with the modified treatment system with air stripping are based on values given in Table 4 for meeting the 525 µg/L discharge standard for vinyl chloride.

The results of the present worth analysis show that the modifications associated with adding an air stripping unit would pay for themselves

within two years based on cost savings associated with carbon replacement. For the first 15 years, the present worth of the net savings of air stripping vinyl chloride over continued carbon treatment exceeds $3.3 million.

A second present worth analysis was conducted for the case of a future treatment system operating with two extraction wells. The same no action alternative used as a basis for comparison in the first present worth analysis was also used in the second analysis. The carbon replacement costs were based on the values shown in Table 4 for operation with two extraction wells. The air stripping system was designed to handle either high- or low- influent loading conditions. Therefore, the costs associated with adding the air stripping unit were the same as those used in the first analysis. Because of the higher influent loading conditions and reduced capacity of the GAC, the second present worth analysis indicated an even shorter payback period of one year and a 15-year present worth net savings in excess of $7 million.

CONCLUSIONS

The PFPSDF model can be used as an accurate predictor of full-scale GAC performance under the conditions of multicomponent competitive interactions observed at the Well 12A treatment system. The modified treatment system configuration of GAC followed by air stripping, as simulated by computer models, was shown to be capable of meeting existing discharge requirements for air and each proposed discharge goal for water. By applying air stripping treatment at the end of the GAC system to selectively remove vinyl chloride, more efficient carbon utilization may be achieved by allowing 1,2-DCE to saturate the lead adsorber. If more stringent water discharge standards for vinyl chloride were adopted in the future, such as a no displacement standard, significant carbon replacement cost savings could be achieved by modifying the existing GAC system with an air stripping tower.

The displacement and early breakthrough of certain organic contaminants is not uncommon with GAC treatment. The design and analysis procedures described in this paper can be applied similarly to other water treatment systems employing GAC.

Key Mixed Waste Regulatory and Policy Issues

Steven C. Goldberg, Esq
Columbus, Ohio

INTRODUCTION

This paper contains a discussion of the key regulatory and policy issues regarding mixed waste (waste containing both radioactive and nonradioactive hazardous chemical constituents). This includes a brief discussion of relevant NRC and U.S. EPA regulatory and policy requirements. The key regulatory and policy issues addressed in this paper are: (1) NRC-U.S. EPA regulatory consistency, (2) the land disposal ban effect and (3) Federal-State regulatory complexity. It concludes with some key observations and recommendations.

BACKGROUND

According to the U.S. EPA, there are approximately 30 Department of Energy (DOE) installations that generate mixed waste and approximately 26,000 Nuclear Regulatory Commission (NRC) licensees [see 54 FR 48372, 48492 (Nov. 22, 1989)]. The U.S. EPA states that 13 of the 30 DOE installations generate the majority of the mixed waste containing high-level, low-level and transuranic radioactive waste.

The NRC licensee mixed waste generators include hospitals, universities and nuclear power plants. The radioactive waste in this mixed waste consists largely of low-level radionuclides. The principal nonradioactive hazardous constituents include solvents, lead, chromium and other hazardous elements generated by the biomedical and nuclear power industries. The U.S. EPA estimates that commercially generated mixed waste represents approximately 2-3% of the low-level radioactive waste generated annually.

The U.S. EPA notes that there are inadequate government or industrial facilities licensed by both the NRC and the U.S. EPA to dispose of mixed waste. According to the U.S. EPA, most mixed waste is being managed by either recycling (mixed waste containing lead, for example) or incineration (scintillation cocktails containing solvents, for example). Most mixed waste is stored by generators under hazardous waste storage permits.

MIXED WASTE REGULATION AND POLICY

Commercially generated mixed waste is subject to federal regulation by NRC (radioactive waste constituents) and U.S. EPA (hazardous waste constituents) or states federally delegated or exercising independent, regulatory authority.[1] DOE generated mixed waste is subject to self-regulation regarding the radioactive waste constituents and U.S. EPA or state regulations regarding the hazardous waste constituents.[2]

NRC regulates the management of radioactive waste under the AEA, Nuclear Waste Policy Act (high-level waste) (NWPA) (42 USC sec. 10101-10226) and Low-Level Radioactive Waste Policy Act (LLRWPA) (low-level waste) (42 USC sec. 2021b-2121d) and implementing regulations. This paper concentrates on low-level mixed waste. NRC low-level waste regulations govern generation, treatment, storage, disposal

(10 CFR Parts 20, 30, 40, 50, 61 and 70) and transportation (10 CFR Parts 20, 71 and 73).

Under NRC regulations, the on-site treatment and storage of low-level radioactive waste is authorized as part of nuclear reactor and radioactive materials possession licenses. Both nuclear reactor and radioactive materials possession licensees are subject to various regulatory requirements regarding, among other things, on-site and off-site radiological exposure limits, operating procedures, environmental reviews and facility and equipment tests and inspections [see 10 CFR sec. 50.34 and 50.34a (reactor) and 10 CFR Parts 30, 40 and 70 (materials)]. The on-site disposal of low-level radioactive waste, such as incineration, requires additional authorization (see 10 CFR sec. 20.302). The off-site disposal of low-level radioactive waste requires an NRC license for the disposal facility operator (see 10 CFR Part 61). Low-level radioactive waste facility licensees are subject to various regulatory requirements regarding, among other things, waste classification siting, design, radiological performance objectives, environmental monitoring, closure and post-closure (see 10 CFR Part 61).

U.S. EPA regulates the management of hazardous waste under the Solid Waste Disposal Act, as amended by the RCRA (42 USC sec. 6901-6991k), and implementing regulations. These implementing regulations govern hazardous waste generation (40 CFR Part 262), transportation (40 CFR Part 263), treatment, storage and disposal (TSD) and cleanup and compensation (10 CFR Parts 264, 265 and 270). Hazardous waste includes U.S. EPA-listed waste (40 CFR Part 261) or waste that exhibits one or more of the following characteristics: ignitability, corrosivity, reactivity or toxicity. Characteristic waste can be determined either on the basis of known properties or testing (see 40 CFR sec. 261.3 and 261.20). RCRA cannot be applied in a manner inconsistent with the AEA. (see 42 USC 6906).

Under RCRA and regulations, bulk or containerized liquid hazardous waste, free liquids containing hazardous waste, specified concentrations of certain listed hazardous waste (including solvents and dioxins), "California list" waste and other listed and characteristic hazardous waste are prohibited from land disposal unless the U.S. EPA determines that such prohibition is unnecessary in order to protect human health and the environment [see 42 USC sec. 6924(c)-(g)]. An application for such a determination by an interested party must demonstrate, to a reasonable degree of certainty, that there will be no migration of hazardous constituents from the disposal unit or injection zone as long as the waste remains hazardous [see 42 USC sec. 6925(d)]. The land disposal ban extends to landfills, surface impoundments, waste pits, injection wells, land treatment facilities, salt dome formations and underground mines or caves [see 42 USC sec. 6924(k)]. Land banned waste can only be stored for the purpose of resource recovery, treatment or disposal [see 42 USC sec. 6924(j)].

Minimum technological requirements exist for new and interim status landfills or surface impoundments and new incinerators [see 42 USC sec. 6924(o)]. Interim status mixed waste disposal facilities are those in existence on July 3, 1986 and for which a partial (part A) permit application was submitted by March 23, 1989 [see 53 FR 37045 (September 13, 1988)].

Minimum technological requirements for landfills and surface impoundments include double liners, leachate collection systems and groundwater monitoring [see 42 USC sec. 6924(o) and 40 CFR sec. 264.221 (surface impoundments), sec. 264.301 (landfills) and sec. 264.97 (groundwater monitoring)]. Requirements for incinerators include compliance with minimum destruction and removal efficiency standards. Double liners and a leachate collection system are not required if the TSD operator can demonstrate that alternative design and operating practices, together with location characteristics, will prevent the migration of any hazardous constituents into the groundwater or surface waste as effectively as liners and leachate collection system [see 42 USC sec. 6924(o)(2)]. New TSD facility location standards, including criteria for identifying areas of vulnerable hydrogeology, are pending [see 42 USC sec. 6924(o)(7)].

Under RCRA regulations, hazardous waste can be stored on-site for 90 days without an interim status or full-scale TSD permit (see 40 CFR sec. 262.34). TSD permitees are subject to various regulatory requirements regarding, among other things, waste analysis, siting, design, manifesting, equipment and facility inspections, groundwater monitoring, corrective action, closure and post-closure procedures.

The NRC and the U.S. EPA have issued three policy memoranda describing their positions on commercial mixed waste definition, disposal facility siting and disposal facility design. The first memorandum defines mixed waste as waste that meets the definition of low-level waste under the LLRWPA and contains hazardous waste that is either a U.S. EPA-listed waste or characteristic waste.[3] The memorandum presents a method for generators to use in identifying characteristic mixed waste. The memorandum stated further that, if a generator normally segregates radioactive and hazardous waste, there is no need to assume that hazardous waste has inadvertently mixed with radioactive waste so as to form mixed waste or to inspect each container or receptacle to ensure that inadvertent mixing has not occurred.

The second policy memorandum identifies 11 siting criteria deemed acceptable for the selection of a mixed waste disposal site pending issuance of U.S. EPA's new location standards.[4]

The third policy memorandum presents a conceptual design approach that meets the U.S. EPA's minimum technology requirements for liners and leachate collection systems and NRC requirements for minimization of contact of waste and water while also assuring long-term stability and avoidance of long-term maintenance which are required by both agencies.[5] The policy states that, depending on the particular type of conceptual design selected by an NRC licensee, the U.S. EPA may permit variances to the double liner and leachate collection system requirement.

In a September 1988 the U.S. EPA mixed waste policy statement, the U.S. EPA indicated that the NRC and the U.S. EPA were exploring the possibility of issuing a joint licensing-permitting policy [see 53 FR 37045 (September 23, 1988)].

In a January 19, 1990, letter from NRC Chairman Carr to Congressman Udall, NRC indicated that consideration is being given to the issuance of guidance documents on waste characterization, inspection and storage. It states that the waste characterization guidance will address occupational exposures during sampling and testing. The sampling and testing guidance will provide NRC regional, NRC agreement states, U.S. EPA regional and U.S. EPA-authorized state inspectors with background information on mixed waste licensing and permitting, inspection planning and coordination, cross-training and conduct of mixed waste inspections. The storage guidance will combine the NRC radioactive waste storage recommendations with U.S. EPA storage requirements.

KEY MIXED WASTE REGULATORY AND POLICY ISSUES

NRC-U.S. EPA Regulatory Consistency

Under RCRA section 1006, RCRA cannot be applied in a manner inconsistent with the AEA. The September 1988 U.S. EPA mixed waste policy statement contained a commitment by the U.S. EPA to minimize the impact of RCRA regulation of mixed waste by developing a strategy for the least burdensome dual regulation of mixed waste. The U.S. EPA indicated that, where NRC and U.S. EPA regulations were duplicative, compliance with NRC regulation might achieve a level of environmental protection commensurate with that of U.S. EPA regulations and that, in such instances, it would accept information submitted in an NRC waste disposal license application when processing a U.S. EPA mixed waste permit application.

The U.S. EPA stated that a U.S. EPA and NRC staff review found no inconsistences in the agencies' respective regulations although U.S. EPA regulations were more prescriptive in some instances and differed in stringency. The U.S. EPA requested that any cases of actual inconsistency be brought to its attention for future rulemaking or policy consideration.[6] The 1990 NRC letter of Congressman Udall also stated that the NRC knew of no AEA-RCRA regulatory inconsistencies.

The January 1987 version of the NRC-U.S. EPA joint policy memorandum on mixed waste definition and identification provided that a RCRA-AEA regulatory inconsistency would exist in a situation where satisfying both sets of regulations would increase the radiation hazard, would be technically infeasible or would violate national security interest. It stated that variances from the RCRA requirements could be granted to generators, transporters and facilities that treat, store or dispose of mixed waste. The 1987 policy stated that NRC licensees could petition for variances from a RCRA requirement when they believe the application of such requirement would be inconsistent with the AEA. The policy did not identify any NRC regulatory process or procedure for considering inconsistency variance petitions. There is no discussion in the policy of how U.S. EPA permittees could obtain an inconsistency determination. It is not clear whether the NRC licensee variance petition is to be submitted to the NRC and/or the U.S. EPA. The inference appears to be that NRC decides inconsistency variance petitions for NRC licensees. The 1987 policy stated, for example, that NRC licensees should discuss any inconsistency with NRC prior to submitting a variance petition. If this interpretation is correct, it raises a jurisdictional question since the U.S. EPA, not the NRC, has RCRA implementation responsibility.

RCRA section 1006 is not discussed in the October 1989 final version of this policy memorandum. It is, thus, unclear whether the 1987 passage continues to represent the NRC or the U.S. EPA position on section 1006.

The September 1988 U.S. EPA mixed waste policy statement sheds some additional light on the meaning of the term inconsistency from the U.S. EPA viewpoint. The U.S. EPA stated that differing or more stringent regulations do not necessarily constitute inconsistent regulations. At the same time, it noted that dual regulation could result in instances where compliance with both sets of regulations may be both undesirable and infeasible. It is not clear whether the U.S. EPA would regard such an instance as one of regulatory inconsistency. In the written materials for the U.S. EPA mixed waste training course given to familiarize U.S. EPA mixed waste permit reviewers and inspectors with mixed waste issues, it is provided that an inconsistency exists when compliance with one set of regulations would cause noncompliance with the other.[7]

In my opinion, there are no substantive NRC-U.S. EPA regulatory inconsistencies per se although differences exist. With regard to mixed waste generators, a primary difference is that a RCRA permit is required for the treatment or storage of mixed waste which would not otherwise be required for the treatment or storage of radioactive waste by an NRC materials or reactor licensee. NRC regulations permit on-site treatment or storage by NRC licensees without further regulatory approvals. The

on-site treatment or storage of mixed waste subjects NRC licensees to a wholly new permitting scheme and regulatory authorities with which they are unfamiliar. In addition, since there are no off-site treatment or disposal facilities, generators must obtain some form of regulatory relief in order to overcome mixed waste storage and land disposal restrictions. These are discussed later.

Additionally, mixed waste characterization and analysis requirements arguably conflict with the NRC requirements to maintain occupational radiation exposure as low as reasonably achievable (ALARA) and remain a potential dissimilarity at least until the promised NRC-U.S. EPA policy guidance on the subject is issued.

With regard to mixed waste disposal facility operators, in my opinion, there are five major regulatory dissimilarities. First, since the NRC relies heavily on natural site features to control the migration of hazardous constituents, existing NRC siting regulations are more detailed than existing U.S. EPA siting regulations. However, the joint NRC-U.S. EPA siting guidance alters this and reduces any adverse impact from this fact. New U.S. EPA siting regulations are pending with an indeterminate impact at this writing.

Second, NRC regulations provide general design criteria which, along with siting, operation and closure measures, must permit the site to meet performance objectives regarding radiological exposure, prevention of inadvertent intrusion and post-closure site stability, as well as minimize wastewater contact and assure long-term stability and post-closure maintenance. NRC design details can be developed during the licensing process. U.S. EPA regulations (as required by RCRA) contain prescriptive design requirements for a double liner and leachate collection system. However, as already noted, RCRA permits a party to recommend an alternative facility design upon a demonstration of equivalent disposal facility performance. This also is addressed in the NRC-U.S. EPA design guidance document.

The third dissimilarity is in the area of groundwater monitoring. U.S. EPA regulations are far more prescriptive and extensive than NRC regulations in this area. Both NRC and U.S. EPA regulations require monitoring during site operation and the post-closure surveillance periods. Under NRC regulations, monitoring must be capable of detecting radiological releases before they reach the site boundary. Monitoring plan details are not specified and are left for development in individual license applications. U.S. EPA groundwater monitoring regulations, on the other hand, are quite detailed and include specific requirements for well locations, construction, sampling and data handling.

The fourth dissimilarity is in the area of sampling and inspections. U.S. EPA regulations require sites to be inspected weekly and after storms to detect any evidence of deterioration or malfunction of the run-on and run-off systems, proper functioning of the wind dispersal control system and the presence of leachate in the leachate collection system. NRC has no specific inspection regulations. Any such license requirements would be developed as part of the operating plan for individual applications. The potential for additional occupational radiation exposure exists from the U.S. EPA inspection requirement. This subject has already been touched upon.

The fifth and final dissimilarity of note is in the area of post-closure. NRC regulations require 5-year post-closure observation and maintenance by the licensee unless site-specific conditions necessitate a shorter or longer period. Following the required transfer of the site to a federal or state entity, an institutional control period of at least 100 years is required, which includes site monitoring and surveillance and limited custodial care. U.S. EPA regulations do not require transfer to a government agency and require a 30 year period of post-closure care by the permittee, which includes monitoring, reporting and maintenance. Accordingly, the institutional care period required by NRC is longer than required by the U.S. EPA and different bodies (the federal or state government for the NRC and the permittee for the U.S. EPA) are responsible for activities during this period. Both NRC and U.S. EPA regulations, however, provide that shorter or longer post-closure periods can be established on a case-by-case basis depending on site-specific conditions.

In summary, and despite the noted dissimilarities, statutory and regulatory means exist to obtain relief from any or all of the noted requirements on a case-by-case basis. For example, as already noted, RCRA prohibits inconsistent RCRA and AEA application. How a party can obtain such a determination, as also noted, is not clear. NRC licensees can also seek to obtain a regulatory exemption from a given NRC requirement upon a certain specified showing [see 10 CFR 30.11, 40.14, 70.14 (materials licensees), 50.12 (reactor licensees), 61.6 (disposal facility licensees)]. Although there is no comparable U.S. EPA regulation, the U.S. EPA has the inherent authority to grant relief from its own regulations. Both agencies are also on record as committed to eliminate consistencies if present and to otherwise harmonize the two sets of regulations. The results of ongoing discussions regarding future guidance documents should reveal the sincerity of this commitment and its achievability.

Land Disposal Ban Effect

As noted above, the RCRA land ban and associated storage restriction precludes the storage of untreated mixed waste. Since there is virtually no national mixed waste treatment capability and no mixed waste disposal capability, there is no alternative but to store mixed waste indefinitely. But such storage is prohibited, thus exposing generators to U.S. EPA or state enforcement action. There are 4 options for obtaining regulatory relief from the RCRA land disposal and storage ban: (1) no-migration petition, (2) national capacity variance, (3) case-by-case extension and (4) treatment variance.

The no-migration petition option was discussed earlier. A national capacity variance may be granted by the U.S. EPA when it determines that there is insufficient treatment or recovery capacity for a particular waste type. During the period a capacity variance is in place, land banned waste can only be land disposed in a facility that meets the RCRA minimum technology requirements (namely, a double liner and leachate collection system). Most mixed waste is characteristic hazardous waste for which a national capacity variance has been proposed by the U.S. EPA in its 1989 proposed rulemaking containing proposed treatment standards and prohibition effective dates for all characteristic hazardous waste and some listed waste (the third-third rule) [see 54 FR 48372 (Nov. 22, 1989)].

A case-by-case extension may be granted by the U.S. EPA upon a demonstration that a binding contractual commitment exists to construct or otherwise provide alternative capacity and the capacity cannot be available by the effective date because of circumstances beyond the petitioner's control (see 40 CFR sec. 268.5). During an extension period, land banned waste can only be disposed of in facilities meeting the minimum technology requirements. A treatment variance may be granted by the U.S. EPA by rulemaking on a generic or site-specific basis. A variance petition must demonstrate that: (1) because the physical or chemical properties of the waste differ significantly from the waste evaluated by the U.S. EPA in establishing the treatment standard, the waste cannot be treated to the level or by the method specified by the treatment standard or (2) that such standard or method is inappropriate for the waste. A site-specific treatment variance may be granted but it has no generic application to wastes at other sites (see 40 CFR sec. 260.20).

Varied Federal-State Regulation

The complexity and rigors of federal mixed waste regulation is compounded by the fact that some states exercise some or all NRC or U.S. EPA mixed regulatory authority and may additionally have hazardous waste laws that are more stringent than RCRA. NRC agreements state radioactive waste laws cannot be more stringent than NRC requirements. Thus, compliance with NRC and U.S. EPA mixed waste regulatory requirements may not be enough and regulated parties are subject to the interpretation and application of State laws with which they may have less familiarity and for which there may be less compliance guidance and consistency.

CONCLUSION

The NRC and the U.S. EPA take the view that there are no NRC-U.S. EPA regulatory inconsistencies relative to mixed waste regulation. Both agencies appear committed to address such inconsistencies brought to their attention. The process for resolving regulatory inconsistencies is unclear. Some existing and prospective NRC-U.S. EPA policy statements could eliminate real or perceived regulatory inconsistencies. In order to effectively eliminate real or perceived regulatory inconsistencies, it would be preferable to vest one agency or the other with exclusive or primary jurisdiction over mixed waste. Accomplishing this designation could require a legislative change. No such legislation is pending.

The RCRA hazardous waste land ban and storage restrictions place mixed waste generators in a quandary. Untreated mixed waste may not be stored or disposed of. There are inadequate mixed waste treatment and disposal facilities. Although some covered waste is not land banned until May 1992 under the third-third rule national capacity variance, the situation may not be much different then. Thus, mixed waste generators must obtain some form of regulatory relief or face potential regulatory enforcement action.

The fact that some states exercise NRC mixed waste regulatory authority, that some state exercise the U.S. EPA mixed waste regulatory authority, that some states exercise the U.S. EPA hazardous waste but not mixed waste regulatory authority and that some states exercise independent hazardous waste regulatory authority not derived from RCRA, creates a potential patchwork of mixed waste regulatory programs at the state level. State radioactive waste regulatory policies may differ from NRC radioactive waste regulatory policies. Therefore, the degree to which a particular state exercises delegated federal mixed waste regulatory authority or its own state regulatory authority will dictate how certain mixed waste regulatory requirements are interpreted and applied. Thus, the mixed waste generator must be aware of the regulatory policies in the state in which it operates. It cannot rely solely on federal regulatory policies which may or may not have been adopted by the state.

FOOTNOTES

1. See 42 USC sec. 2224 (NRC agreement states) and 42 USC sec. 6926 (U.S. EPA-authorized states). State hazardous waste regulation may exist independent of EPA delegation. State radioactive waste regulations may exist independent of NRC delegation.

2. The Atomic Energy Act (AEA) (42 USC sec. 2011-2296) and DOE Act (42 USC sec. 7101-7375) authorize DOE to govern its own nuclear activities through the issuance of orders to protect public health, life and property, which could include standards controlling the design, location and operation of facilities associated with these activities. See 42 USC sec. 2201(i) (3). Doe nuclear activities include nuclear weapons production, uranium enrichment and nuclear research.

   DOE low-level radioactive waste management policy is contained in DOE Order 5280.2A and includes provisions on waste form acceptance criteria, site selection criteria, design criteria, operating procedures (including training, environmental monitoring, testing, site access and emergency planning) and closure and post-closure (including periodic surveillance and maintenance provisions). DOE hazardous and mixed waste management policy is contained in DOE Order 5400.3 and essentially invokes applicable U.S. EPA and state requirements.

Remediation of Solvent Contaminated Soils by Aeration

Andy Davis, Ph.D.

Camp, Dresser and McKee
Denver, Colorado

ABSTRACT

A bench-scale box test was performed to evaluate the feasibility of rototilling to remediate excavated soils contaminated with tetrachloroethylene (PCE), trichloroethylene (TCE) and 1,1,1-trichloroethane (1,1,1-TCA). Two soils containing different concentrations of the target analytes were tested. PCE in Soil A decreased from 25,000 μg/kg to 5,053 μg/kg within the first 24 hours (an 80% decrease of the initial concentration) and to 834 μg/kg after 407 hours. PCE in Soil B decreased from 8,881 μg/kg to 500 μg/kg (a 94% loss) after 96 hours. The initial TCE concentration in Soil A was 1,100 μg/kg, decreasing to 30 μg/kg after 408 hours. The initial TCE concentration in Soil B was 1,573 μg/kg decreasing to 37 μg/kg (a 98% loss) after 192 hours. The maximum PCE concentrations in the off-gas were 1.5 ng/mL and 0.8 ng/mL above Soils A and B respectively, during the first 24 hours of exposure. Subsequent air samples all were below 0.1 ng/mL (the detection limit). Concentrations of TCE in the air above the soils were below the detection limit (> 0.1 ng/mL) throughout the experiment. Maximum 1,1,1-TCA air concentrations were 0.14 ng/mL during the first 24 hours in Box A.

INTRODUCTION

Chlorinated industrial solvents, e.g., tetrachloroethylene (PCE), trichloroethylene (TCE) and 1,1,1-trichloroethane (1,1,1-TCA), are among the most common contaminants found at hazardous and industrial waste sites.[5] Remediation of soils contaminated with these compounds using techniques such as solidification/stabilization, incineration, soil vapor extraction, soil flushing or in situ biodegradation are expensive and time-consuming alternatives.[2,8] This contamination problem, requires a simple and effective remedy; one such alternative is enhanced solvent volatilization by excavation and rototilling.

A major concern with this option is the ensuing media transfer of contaminants from the soil to the urban atmosphere. However, once exposed to ultraviolet radiation, these compounds readily photolyze in the atmosphere (e.g., TCE $t_{1/2}$ = 5.2 days[3]); while in the troposphere, the unsaturated double bond is highly reactive, rapidly degrading to HCl, CO, CO_2 and carboxylic acid with a rate constant of $3x10^{12}cm^3/$ sec for TCE and $1.3x10^{12}cm^3$/sec for PCE.[11] Consequently, volatilization followed by degradation of the chlorinated compound in the atmosphere and troposphere appears to be a simple, safe and effective remedial option for soils contaminated with chlorinated solvents.

This study was designed to evaluate the efficacy of a proposed aeration technique (excavating, rototilling and exposing contaminated soils to the atmosphere) in terms of the concentrations of solvents released into the atmosphere under ambient atmospheric conditions and the time required to volatilize a significant (<90%) proportion of the contaminants. To quantify removal rates of PCE, TCE and 1,1,1-TCA from

the contaminated soils, a bench-scale aeration test was performed in an experimental environment similar to the anticipated field conditions. Another facet of the investigation was to calculate the maximum mass of PCE, TCE and 1,1,1-TCA potentially released to the atmosphere over the course of the experiment.

This study was undertaken to provide practical data on solvent volatility from contaminated soils. Although the physical characteristics of the three target compounds are well known, to date there has been little investigation into their volatility from soils and water surfaces. The only research that has been reported[12] focused on the release of PCE from soil immediately following application. No work appears to have been undertaken using soil that has been contaminated with PCE for several years.

MATERIALS AND METHODS

The aeration test apparatus consisted of two wooden boxes (60 cm long, 30 cm wide and 15 cm deep) lined with aluminum foil to prevent contaminant loss to the wood. Two rectangular openings were cut at each end, one a portal for a shaded pole fan and the other for an exit vent. The fan was used to provide a constant 10 km/hr breeze over the soil (characteristic of average wind speed conditions at the site) monitored at each box exit using a hand-held anamometer.

Two clay rich test soils were evaluated with Soil A containing >100 mg/kg VOCs and Soil B containing 10 to 20 mg/kg VOCs. After sampling, the soils were shipped to the laboratory on ice in coolers and maintained at 4 °C until the start of the experiment. Each box was filled with uncompacted soil to a depth of 30 cm, broken into clods 2.5 to 4 cm in diameter. These conditions were thought to be representative of a realistic depth and the likely size fraction resulting from rototilling the soil. Samples from each box were then taken in order to establish initial soil conditions. After sampling, the boxes were closed and placed in a ventilation hood. The box fans were turned on and air samples were collected immediately. Every 24 hours the entire soil column was overturned and soil samples were collected after rototilling.

The greatest variable in the soils was the moisture content of the clods, determined using ASTM D2216-80,[1] so this factor was incorporated into the sampling strategy. After the soil had been tilled, four clods, apparently representing the range of moisture observed in the soil at the time of sampling, were selected from each box. The clods were aggregated and the blended soil was analyzed. Due to the volatile nature of the compounds of interest, processing was performed quickly and the composited samples were placed in a glass vial containing as little head space as possible. To evaluate solvent diffusion out of the clods, the interior and exterior (rind) of Soil A clods were sampled on four occasions. These samples were collected by removing and compositing the exterior one centimeter from each of three clods. Moisture, PCE

and TCE were measured in both rind and interior samples.

Each representative sample weighed approximately 80 grams. Of this amount, 30 grams were used for moisture analysis, 30 grams were split into three 10-gram aliquots for chemical analyses and the rest was discarded. At the time of sampling, the relative humidity, wind speed and temperature of the air in the box were recorded.

Air sampling commenced immediately after the soils were placed in the boxes. Air samples were obtained using a 5-mL syringe through the exit port at hourly intervals for the first 4 hours and then again after 30 hours. The fan on Box A was turned off overnight after the second day and the box was sealed tightly in order to test the buildup of gas over Soil A. Subsequently, air samples were collected before the fan was turned on, 15 minutes after and again after rototilling. To characterize air quality over Soil B, three samples were collected over a 1.5-hour period on the first day and over a 1.5-hour period on the second day. Between samples, the syringes used to collect the samples were flushed 10 times with air.

Three separate 5-gram aliquots of soil were extracted in reagent grade methanol following U.S. EPA method 5030, the extracts were analyzed separately and the results averaged or the extracts combined and analyzed together or the soil splits were combined prior to extraction. The extracts were analyzed for PCE, TCE and 1,1,1-TCA using a Purge and Trap/Temperature Programmable Gas Chromatograph with a Hall detector in the halogen specific mode (following U.S. EPA method 8010a).

Quality assurance for the measurement of halogenated compounds was monitored four ways: by relative percent difference (RPD) of duplicate analyses, by soil spiking, by adding blanks and by introducing of a surrogate compound. To ensure analytical replicability, one duplicate sample was run from Soil A each day. For soils, the acceptable RPD limit is +/-35%.[10] With the exception of one TCE data point at a low soil concentration, the duplicate extractions all met this criterion.

A blank was run to test for: (1) cross contamination of soils during the extraction step, (2) contaminants in the methanol extractant, (3) contaminants on the glassware and (4) other contamination introduced during analysis. No contamination was detected in any blank over the course of the bench test. Each day a split of blended Soil B was spiked with a 1-mL mixture of the halogenated compounds of interest to determine a percent recovery for each analyte. The spike concentration decreased with time to reflect the decreasing soil analyte concentration in the unspiked soil. The spike recovery range for all analytes fell between 60-140%, also meeting the criteria established by the U.S EPA.[10]

To ensure that the purge/trap extraction mechanism and the Hall Detector were working properly, 100 ng of dichlorobromomethane were added to each extract and the percent recovery of the surrogate was calculated. The acceptable surrogate recovery range for soil methods is 75-125%.[10] The percent recovery of surrogate from these samples ranged from 82 to 110% and averaged 95%.

RESULTS AND DISCUSSION

Both soils were clay rich ranging in color from dark brown when moist to light brown when dry. The soil dried into clods that were very difficult to break. Soil moisture averaged 18% at the start of the experiment, decreasing to 2% after 7 days (Fig. 1). Percent moisture values for rinds and interior samples fell below bulk percent moisture values for both soils, although the rind and interior values measured after 24 hours lie within a similar percentage range. These data are indicative of the heterogeneity of the soil clods in contrast with the more homogenized sample used for the bulk soil test.

The highest analyte concentrations determined were PCE, followed by TCE and 1,1,1 TCA. Concentrations decreased most rapidly within the first 24 hours, approaching an asymptote after approximately 150 hours. The initial PCE concentration in Soil A was 25,000 μg/kg, decreasing to 5053 μg/kg within 24 hours; a loss of 80% of the initial concentration (Fig. 2). The PCE concentration decreased to 3330 μg/kg (an 87% decrease) after 48 hours and to 1000 μg/kg after 192 hours (a 96% decrease).

In Box B, the initial PCE concentration was 8880 μg/kg (Fig. 2),

decreasing to 6290 μg/kg after 24 hours (a 29% decrease), to 2410 μg/kg after 48 hours (a 73% decrease) and to 500 μg/kg after 192 hours (a 94% decrease). For both the rind and interior PCE analyses, the rind concentration was less than the average clod concentration, which was less than the interior PCE concentration. These data suggest that a diffusive mechanism controlled release of PCE from the interior of the clod (Fig. 2).
Figure 1
Soil Moisture Content
Figure 2
Concentration of PCE in Soils A and B

TCE in Soil A was initially 1100 μg/kg (Fig. 3) decreasing to 144 μg/kg after 24 hours (an 87% decrease) and to 25 μg/kg after 192 hours (a 98% loss). In Soil B, the initial concentration of TCE (1573 μg/kg) was higher than Soil A. An 84% loss of TCE (to 250 μg/kg) was measured in the first 24 hours. After 192 hours, the concentration had decreased to 25 μg/kg (a 98% loss).
Figure 3
Concentration of TCE in Soils A and B

Soil A) to 8.1% (TCA in Soil B). PCE had the highest refractory fraction of the total mass, consistent with its high K_{ow}. Research by Zytner et al.[12] demonstrated that the volatilization rate of pure PCE after a recent soil application is 4 to 5 times slower than PCE dissolved in water, indicating that the volatilization rate of PCE from soil also depends on the form in which PCE enters the unsaturated zone. In addition, Petersen et al.[6] found that TCE partition coefficients were higher for dry soils than for moist soils, while Smith et al.[7] in a field study at Picatinny Arsenal, New Jersey, also demonstrated that TCE sorption was highly dependent on the soil humidity.

Both rind and interior samples taken after 24 hours contained less TCE than the bulk sample soils. Soil A clods collected after 48 hours, however, spanned the bulk concentration (Fig. 3).

1,1,1-TCA in Soil A behaved in a similar fashion to both TCE and PCE, decreasing from 793 μg/kg to 211 μg/kg (a 73% loss) after 24 hours and to 47 μg/kg (a 94% loss) after 194 hours. A similar concentration of 1,1,1-TCA (883 μg/kg) was found in Soil B. The evaporative rate loss was similar; 87% after 24 hours and 96% after 194 hours.

The initial PCE in Soil A air was 1.5 ng/mL and 0.8 ng/mL in Soil B air. Air samples taken 24 hours after initial rototilling measured less than 0.1 ng/mL (the detection limit) for both boxes. The fans were then turned off for 12 hours to allow a build-up of gas. An air sample was collected before the fans were turned on (PCE = 4.0 ng/mL) and fifteen minutes after the fan was turned on, at which time a concentration of < 0.1 ng/mL PCE was measured. No TCE concentrations above detection limits (0.1 ng/mL) were measured at any time. Initial 1,1,1-TCA soil gas concentrations were 0.14 ng/mL in Box A and < 0.1 ng/mL in Box B. The 24 hour air sample was below the detection limit (0.1 ng/mL). After gas accumulated over the 12 hour period, 1,1,1-TCA was 0.18 ng/mL, but was below the detection limit 15 minutes after the fan was turned on.

Calculation of the mass flux of solvents from the soil to the atmosphere on a daily basis demonstrates that the bulk of PCE, TCE and 1,1,1-TCA is released over the first 24 hours (Table 1), after which the solvent flux decreased substantially.

The initial rapid loss of volatiles followed by a slow, longer term decline in solvent concentrations suggests a dual release mechanism. The initial rapid decrease in soil concentrations probably corresponds to evaporation of interstitial water containing high solvent concentrations, a "labile" fraction. Solvents in this fraction would be lost to the atmosphere at a rate governed by the vapor phase concentration and the gaseous diffusion. These parameters are well-known from Henry's Law constant and the diffusivity coefficient, so it is not surprising that PRZM accurately simulated the initial volatilization rate.

The more tightly bound "refractory" fraction comprises only a small percent of the total solvent mass, but is responsible for the asymptotic behavior of the soil concentration curve after the labile fraction has volatilized. This refractory solvent content ranged from 2.7% (TCE in

All these investigations support the labile/refractory hypothesis advanced here. The practical effect of the dual volatilization mechanisms on the simulated soil concentrations is to overestimate solvent degassing, hence underestimating residual soil concentrations after volatilization of the labile solvent fraction. However, it is important to note that the refractory solvent fraction is invariably less than 10% of the total concentration, so that the error introduced in the simulations is not great.

Table 1
Loss of Solvents From Soils A and B

	PCE		TCE		1,1,1-TCA	
	Day 1	Day 2	Day 1	Day 2	Day 1	Day 2
Soil A	1.30	0.16	0.06	0.01	0.04	0.003
Soil B	0.46	0.07	0.08	0.01	0.05	0.004

ABSTRACT

The purpose of this paper is to provide an analysis of the effectiveness of treatment technologies for contaminated soil and debris in response to the recommendation in the 1989 U.S. Environmental Protection Agency Superfund Management Review to "carefully evaluate the impact of RCRA land ban and other rules on the use of alternative technologies." This analysis provides support to Regional decisions to employ treatability variances for complying with the RCRA Land Disposal Restrictions as applicable or relevant and appropriate requirements (ARARs) for Superfund actions involving contaminated soil and debris.

INTRODUCTION

The 1989 Superfund Management Review (also known as the 90-Day Study) by the U.S. Environmental Protection Agency acknowledged that Superfund response actions may not be able to meet treatment standards based on "best demonstrated available technology" (BDAT) under the Land Disposal Restrictions (LDRs). This regulation may limit the potential treatment technologies available for Superfund cleanups, with technologies such as soil washing, stabilization and biological treatment being precluded because they may not meet the highest level of performance required by LDRs. In contrast, the 90-Day Study encouraged the greater use of innovative technologies and urged the reduction of nontechnical barriers, such as regulatory and policy constraints, that inhibit the use of treatment technologies, while preserving the intent and spirit of applicable RCRA regulations.

Office of Solid Waste and Emergency Response (OSWER) program offices recognized the potential limitation on treatment technologies for Superfund actions and developed a process to use LDR treatability variances for soil and debris. Guidance was issued to the Regions through the Superfund LDR Guide 6A, "Obtaining a Soil and Debris Treatability Variance for Remedial Actions," (OSWER Directive 9347.3-06FS) in July 1989 and revised in September 1990.[3] Superfund LDR Guide 6B, "Obtaining a Soil and Debris Treatability Variance for Removal Actions," (OSWER Directive 9347.3-07FS) was issued in December 1989 and revised in September 1990.[4] These guides describe the treatability variance process, include alternate treatment levels to be obtained under treatability variances and identify treatment technologies which have achieved the recommended levels. OSWER recognizes that the use of treatability variances represents an interim approach and is currently in the process of acquiring additional data for developing a regulation on treatment standards for contaminated soil and debris.

On November 30, 1989, the Office of Emergency and Remedial Response (OERR) issued a memorandum on the "Analysis of Treatability Data for Soil and Debris: Evaluation of Land Ban Impact on Use of Superfund Treatment Technologies," (OSWER Directive 9380.3-04).[2] This memorandum was in response to the concern in the Superfund Management Review regarding limitations to the use of alternative technologies at Superfund sites: it included an analysis summarizing the effectiveness of treatment technologies applied to soils and other environmental wastes. The memorandum provides support for decisions by the Regions to use treatability variances, when appropriate. The analysis identifies some of the key technical considerations to be evaluated in obtaining a treatability variance when there is a reasonable doubt that a technology operated at full-scale cannot consistently meet the BDAT treatment standards for the soil and debris to be treated.

ANALYSIS OF TREATMENT EFFECTIVENESS

An extensive effort was undertaken during 1987 and 1988 to collect data on the treatment of soil, sludge, debris and related environmental media. The results from several hundred studies were collected and reviewed. All applicable treatment information from 67 studies was extracted, loaded into a data base and analyzed to determine the effectiveness of technologies to treat different chemical groups (Summary of Treatment Technology Effectiveness for Contaminated Soil, U.S. EPA, EPA/540/2-89/053).[1]

Although some of the data on which the analysis is based have limited quality assurance information, the data, nevertheless, do indicate potential effectiveness (at least 90% to 99% reduction of concentration or mobility of hazardous constituents) of treatment technologies to treat Superfund wastes. Some reductions in organic concentrations or organic mobility of more volatile compounds may actually represent the removal of those compounds as a direct result of volatilization. Technologies where this is most likely to occur include dechlorination, bioremediation, soil washing or immobilization, and consideration of appropriate emission controls is required. Percentage removal reductions (removal efficiencies) are not always a good measure of effectiveness, especially when high concentrations remain in the residuals. Some of the performance observations are based upon a relatively small number of data points and may not extrapolate well to the broad array of soils requiring treatment.

Based on this analysis, a number of technologies commonly used in the Superfund program provide substantial reduction in mobility and toxicity of wastes as required in Section 121 of the Superfund Amendments and Reauthorization Act (SARA) of 1986. For example:

- Thermal destruction has been proven effective on all organic compounds, usually accomplishing well over 99% reduction of organics.
- Although the data indicate that PCBs, dioxins, furans and other aromatic compounds have been dechlorinated to approximately 80%, more recent data indicate that removal efficiencies may approach 99.9%.
- Bioremediation successfully treats many halogenated aliphatic compounds, nonhalogenated aromatics, heterocyclics and other polar compounds with removal efficiencies in excess of 99%.
- Removal efficiencies for low temperature thermal desorption have been demonstrated with averages up to 99% for nonpolar halogenated aromatics and with treatment often exceeding 90% for other polar organics.
- Soil washing data on organic compounds indicate average removal efficiencies of approximately 90% for polar nonhalogenated organics and 99% for halogenated aromatics, with treatment often exceeding 90% for polynuclear aromatics. The chemical extraction process, with optimized solvent selection, has demonstrated removal efficiencies often exceeding 90% for volatile and nonvolatile metals.
- Immobilization processes, while not actually destroying the organic compounds, reduce the mobility of contaminants an average of 99% for polynuclear aromatic compounds. Immobilization may not effectively stabilize some organic compounds, such as volatile organics, and the long-term effectiveness of immobilization of organics is under evaluation. Immobilization can achieve average reductions in mobility of 93% for volatile metals, with reductions in mobility often exceeding 90% for nonvolatile metals.

A more detailed summary of the data follows, extracted from the "Summary of Treatment Technology Effectiveness for Contaminated Soil."

TECHNOLOGY LIMITATIONS TO BE CONSIDERED

The data available suggest that the treatment of soil and debris with organic contamination by technologies other than thermal destruction will not consistently achieve BDAT standards. Therefore, other technologies should be used for those wastes only if approved under a treatability variance.

The residual concentrations in contaminated soil treated by technologies other than thermal destruction are highly dependent upon the concentrations in the untreated soil. Therefore, when evaluating technologies other than thermal destruction, the ability of those technologies to treat high concentrations of organics should be considered.

Site conditions and characteristics must be carefully considered when designing and operating materials handling, pretreatment and treatment requirements. High variability in contaminant concentrations of untreated soil may have an adverse effect on the ability to achieve treatment levels using technologies other than thermal destruction. Consideration should be given to the need for blending wastes. In selecting technologies for contaminated soils and sludges, the number and types of contaminants must be carefully screened, and, in some cases, different technologies may be necessary for soils and sludges.

UNIQUE CONSIDERATIONS OF SOIL TREATMENT

The complex nature of solid waste matrices, such as contaminated soil from a Superfund site, severely complicates the treatment process. Soil is a nonhomogeneous living medium and the proportion of clay, organic matter, silt, sand, debris and other constituents can affect the treatability of a contaminated soil. In addition, the distribution of contaminants often is also nonhomogeneous and is dependent on patterns of contaminant deposition and transport. Collectively, these conditions make the treatment of contaminated

soil a formidable technical challenge. Discussions of some important considerations relevant to the selection of soil treatment processes follow.

A critical element in soil treatment is materials handling. Special approaches to waste transfer throughout the treatment system are particularly important for solids and viscous sludges where traditional conveyance methods are frequently ineffective. Slugs of material or debris tend to jam treatment equipment, resulting in breakage, downtime and the potential for uncontrolled releases to the environment. Materials handling equipment should be tested on the waste as part of any treatability testing program. Experiments should be conducted on an untreated waste as well as on any intermediate mixtures exhibiting changes in viscosity, particle size, density, etc.

The preprocessing of waste to maximize homogeneity and modify the waste characteristics is important to successful treatment technology operation. Any treatment technology will operate most efficiently and cost effectively when it is designed and utilized to treat a homogeneous waste with a narrow range of physical/chemical characteristics. If contaminant types and concentrations, waste viscosity, BTU content, moisture content, acidity, alkalinity, etc. vary widely, control of the system can be difficult and costly to maintain. Many of these waste characteristics can be modified and improved with appropriate preprocessing.

In addition, the most effective technology performance is achieved when the soil particle size is small and the maximum amount of surface area is exposed. This condition facilitates intimate contact between the contaminant sorption sites and the driving force of the technology (i.e., microorganism, solvent, warm air, etc.). The key to achieving this contact, and subsequent contaminant destruction, transfer to another medium or bonding, is often achieved only through significant preprocessing.

Materials handling and preprocessing technologies with potential application for soil are currently in use in the construction, agriculture and mining industries. All of these industries routinely handle large quantities of soil or rock. The use of technologies from these industries should be considered during all soil remediation activities. Materials handling and preprocessing techniques should also be incorporated in treatability testing programs. The results of such tests will better define the range of waste characteristics which the actual treatment technology will have to address.

CONCLUSIONS REGARDING SOIL TREATMENT TECHNOLOGY EFFECTIVENESS

Contaminated soils can be treated through three basic mechanisms: (1) destruction of the contaminants through chemical alteration to a less toxic compound (e.g., thermal destruction, dechlorination and bioremediation); (2) physical transfer of the contaminants to another waste stream for subsequent treatment or recovery (e.g., low temperature thermal desorption and chemical extraction and soil washing); and (3) permanent bonding of the contaminants within a stabilized matrix to prevent future leaching (e.g., immobilization). In general, the destruction technologies effectively reduce the toxicity of many organic contaminants. The physical transfer technologies reduce the toxicity and often the volume of selected organic and inorganic contaminants. While the bonding technologies most effectively reduce the mobility and, therefore, the toxicity of inorganic contaminants, some increasing effectiveness is being demonstrated on selected organic contaminants as well. Figure 1 presents a summary of these basic conceptual conclusions. A more detailed discussion follows.

The technologies that have been widely demonstrated on soils are thermal destruction for organic contaminants and immobilization for inorganic contaminants. While these two technologies may be highly effective in treating particular classes of compounds, neither provides an ideal solution to complex mixtures of organic and inorganic contaminants which are common at Superfund sites. The inherent difficulty in treating contaminants in a soil matrix, where

waste conveyance and mixing are in themselves complicated unit operations, contributes to the need to find special solutions. Other issues, such as landfill capacity and cost, cross-media impacts and natural resource conservation, also support the need to develop and use alternative and innovative treatment technologies for contaminated soil.

Figure 1
Soil Treatment Effectiveness - Conceptual Approach

Because of the U.S. EPA's ultimate goal of developing LDRs for contaminated soil and debris, this study evaluates a number of treatment options that are applicable to excavated soils. In situ soil techniques, such as some types of bioremediation, soil vapor extraction, in situ immobilization and combined groundwater and vadose zone soil treatment were not included in the scope of this evaluation. In situ techniques should also be considered when researching remediation measures for a contaminated soil problem. When in situ technologies are used at Superfund sites, the LDRs may not be applicable because the waste has not been excavated and subsequently "placed" in a landfill or other RCRA unit.

Based upon the data collected and evaluated by OERR from more than 200 soil treatment tests, conclusions were developed regarding the effectiveness of six soil treatment technology groups on each of 11 contaminant treatability groups. For destruction and physical transfer technologies applied to organic contaminants, the removal efficiency was analyzed. This evaluation factor was replaced by the reduction in mobility for immobilization for organics and inorganics, and for chemical extraction and soil washing of inorganics.

In Figure 2, "Predicted Treatment Effectiveness for Contaminated Soil," summary information is provided for each of 11 contaminant treatability groups and six treatment technology categories. For each treatability group, the effectiveness of various technologies is evaluated using the following ratings:
- Demonstrated Effectiveness: A significant percentage of the data, at least 20%, is from pilot- or full-scale operations, the average removal efficiency for all of the data exceeds 90% and there are at least 10 data pairs.
- Potential Effectiveness: The average removal efficiency for all of the data exceeds 70%.
- No Expected Effectiveness: The average removal efficiency for all of the data is less than 70% and no interference is expected to this process as a result of this group.
- No Expected Effectiveness: Potential adverse effects to the environment or the treatment process may occur. For example, high concentrations of metals may interfere with biological treatment.

In some cases, a different rating was selected when additional qualitative information and engineering judgment warranted. Two ratings were selected if the compounds within a treatability group were so variable that a range of conclusions could be drawn for a particular technology.

Figure 2
Predicted Treatment Effectiveness for Contaminated Soil

Thermal Destruction (See Figure 3)

Principle of Operation
- Thermal destruction uses high temperatures to incinerate and destroy hazardous wastes, usually by converting the contaminants to carbon dioxide, water and other combustion products in the presence of oxygen.

Effectiveness on Organics
- This technology has been proven effective on all organic compounds, usually accomplishing well over 99% removal.
- Thermal destruction technologies are equally effective on halogenated, nonhalogenated, nitrated, aliphatic, aromatic and polynuclear compounds.
- Incineration of nitrated compounds such as trinitrotoluene (TNT) may generate large quantities of nitrous oxides.

Effectiveness on Inorganics
- Thermal destruction is not an effective technology for treating soils contaminated with high concentrations of some metals.
- High concentrations of volatile metal compounds (lead) present a significant emissions problem which cannot be effectively contained by conventional scrubbers or electrostatic precipitators due to the small particle size of metal-containing particulates.
- Nonvolatile metals (copper) tend to remain in the soil when exposed to thermal destruction; however, they may slag and foul the equipment.

Dechlorination (See Figure 4)

Principle of Operation
- Dechlorination is a destruction process that uses a chemical reaction to replace chlorine atoms in the chlorinated aromatic molecules with an ether or hydroxyl group. This reaction converts the more toxic compounds into less toxic, more water-soluble products. The transformation of contaminants within the soil produces compounds that are more readily removed from the soil. An evaluation of the end products is necessary to determine whether further treatment is required.

Effectiveness on Organics
- PCBs, dioxins, furans and other aromatic compounds (such as pentachlorophenol) have been dechlorinated to approximately

Figure 4
Final Conclusions by Treatment Technology - Dechlorination

80% removal, with more recent data indicating that removal efficiencies may approach 99.9%.
- Other limited laboratory data suggest potential applicability to other halogenated compounds including straight-chain aliphatics (such as 1,2-dichloroethane). The removal indicated by the data may be due in part to volatilization.
- Although no data were available for halogenated cyclic aliphatics (such as dieldrin), it is expected that dechlorination will be effective on these compounds as well.
- When nonhalogenated compounds are subjected to this process, volatilization may occur.

Effectiveness on Inorganics
- Dechlorination is not effective on metals, and high concentrations of reactive metals (such as aluminum), under very alkaline conditions, hinder the dechlorination process.

Bioremediation (See Figure 5)

Principle of Operation
- Bioremediation is a destruction process that uses soil microorganisms including bacteria, fungi and yeasts to chemically degrade organic contaminants.

Effectiveness on Organics
- Bioremediation appears to successfully treat many halogenated aliphatic compounds (1,1-dichloroethane), nonhalogenated aromatics (benzene), heterocyclics (pyridine) and other polar compounds (phenol) with removal efficiencies in excess of 99%; however, the high removal implied by the available data may be a result of volatilization in addition to bioremediation.
- More complex halogenated (4-4'DDT), nitrated (triazine) and polynuclear aromatic (phenanthrene) compounds exhibited lower removal efficiencies, ranging from approximately 50% to 87%.
- Polyhalogenated compounds may be toxic to many microorganisms.

Effectiveness on Inorganics
- Bioremediation is not effective on metals.
- Metal salts may be inhibitory or toxic to many microorganisms.

Low Temperature Thermal Desorption (See Figure 6)

Principle of Operation
- Low temperature thermal desorption is a physical transfer process that uses air, heat and/or mechanical agitation to volatilize contaminants into a gas stream, where the contaminants are then subjected to further treatment. The degree of volatility of the compound rather than the type of substituted group is the limiting factor in this process.

Effectiveness on Organics
- Removal efficiencies have been demonstrated by these units at bench, pilot and full scales, ranging from approximately 65% for polynuclear aromatics (naphthalene) to 82% for other polar organics (acetone) and 99% for nonpolar halogenated aromatics (chlorobenzene).

Effectiveness on Inorganics
- Low temperature thermal desorption is not effective on metals.
- Only mercury has the potential to be volatilized at the operating temperatures of this technology.

Chemical Extraction and Soil Washing (See Figure 7)

Principle of Operation
- Chemical extraction and soil washing are physical transfer processes in which contaminants are disassociated from the soil, becoming dissolved or suspended in a liquid solvent. This liquid waste stream then undergoes subsequent treatment to remove the contaminants and the solvent is recycled, if possible.
- Soil washing uses water as the solvent to separate the clay particles, which contain the majority of the contaminants, from the sand fraction.
- Chemical extraction processes use a solvent which separates the contaminants from the soil particles and dissolves the contaminant in the solvent.

Effectiveness on Organics
- The majority of the available soil washing data on organic compounds indicates removal efficiencies of approximately 90% for polar nonhalogenated organics (phenol) to 99% for halogenated aromatics (chlorobenzene), with lower values of approximately 71% for PCBs to 82% for polynuclear aromatics (anthracene).
- The reported effectiveness for treatment of these compounds could be due in part to volatilization for compounds with higher vapor pressures (such as acetone).
- This process is least effective for some of the less volatile and less water soluble aromatic compounds.

Effectiveness on Inorganics
- The chemical extraction process, with optimized solvent selection, has demonstrated removal efficiencies of 85% to 89% for volatile metals (lead) and nonvolatile metals (copper), respectively.

Immobilization (See Figure 8)

Principle of Operation
- Immobilization processes reduce the mobility of contaminants by stabilizing them within the soil matrix without causing significant contaminant destruction or transfer to another medium.
- Volatile organic compounds will often volatilize during treatment, therefore an effort should be made to drive off these compounds in conjunction with an emission control system.

Effectiveness on Organics
- Reductions in mobility for organics range from 61% for halogenated phenols (pentachlorophenol) to 99% for polynuclear aromatic compounds (anthracene).
- Immobilization is also effective (84% reduction) on halogenated aliphatics (1,2-dichloroethane).
- Some organic mobility reductions of the more volatile compounds may actually be removals as a direct result of volatilization during the exothermic mixing process and throughout the curing period.
- The immobilization of organics is currently under investigation, including an evaluation of the applicability of analytical protocols (EP, TCLP and total analysis) for predicting long-term effectiveness of immobilization of organics. The preliminary available data indicate that significant bonding takes place between some organic contaminants and certain organophilic species in the binding matrix; however, immobilization may not effectively stabilize some organic compounds, such as volatile organics.

Effectiveness on Inorganics
- Immobilization can accomplish reductions in mobility of 81% for nonvolatile metals (nickel) to 93% for volatile metals (lead).

REGULATORY IMPLEMENTATION

The data indicate potential limitations of technologies that are used to treat Superfund wastes when attempting to meet existing BDAT standards for industrial process wastes. Superfund LDR Guide 6A outlines the treatability variance process for Superfund soil and debris and identifies alternate treatability variance levels. The levels in LDR Guide 6A (Figures 9 and 10) should be followed, when appropriate, until OSWER completes a regulation with treatment standards for contaminated soil and debris. The limitations on technologies identified here should be taken into account when evaluating, selecting, designing and implementing Superfund response actions.

TREATABILITY GROUP	NUMBER AND SCALE OF AVAILABLE DATA	AVERAGE CONCENTRATIONS (ppm) AND % REMOVALS		GENERAL OBSERVATIONS
NON-POLAR HALOGENATED AROMATICS (W01)	68 PAIRS 95 % BENCH 5 % PILOT 0 % FULL	AVERAGE CONCENTRATIONS (ppm) UNTREATED 2.9 TREATED 0.79	AVERAGE REMOVAL EFFICIENCY 53 %	• This technology is not effective for all contaminants in this class; however, there is potential for effectiveness for low initial concentrations with further development. • The presence of these contaminants at low concentrations is not expected to interfere with the treatment of applicable wastes. • The effectiveness of this technology may be different than the data imply, because the initial concentrations in these tests were so low.
PCBs, HALOGENATED DIOXINS, FURANS, AND THEIR PRECURSORS (W02)	1 PAIRS 0 % BENCH 100 % PILOT 0 % FULL	AVERAGE CONCENTRATIONS (ppm) UNTREATED 2,000 TREATED 0.12	AVERAGE REMOVAL EFFICIENCY 99 %	• The lone data pair is PCBs. • Ongoing research suggests that this technology may be potentially effective for this group.

AVAILABLE TECHNOLOGY TRANSFER ASSISTANCE

It is recommended that treatability studies be conducted for each site containing soil and debris which requires treatment. To assist in the process of planning and performing these treatability studies, a number of sources of pertinent current information exist. In terms of guidance documents and technical resources, the following are important sources of information:

- Summary of Treatment Technology Effectiveness for Contaminated Soil, U.S. EPA, EPA/540/2-89/053
- Superfund Treatability Clearinghouse Abstracts, U.S. EPA, EPA/540/2-89/001
- Technology Screening Guide for Treatment of CERCLA Soils and Sludges, U.S. EPA, EPA/540/2-88/004
- Guide for Conducting Treatability Studies Under CERCLA, U.S. EPA, EPA/540/2-89/058
- Inventory of Treatability Study Vendors, U.S. EPA, EPA/540/2-90/003a
- Various Superfund Innovative Technology Evaluation (SITE) Program Reports

In addition to the abovementioned references, there also is a valuable network of U.S. EPA and other Agency, university, vendor and consulting engineering personnel focusing on the challenging technical issues of waste treatment. Some elements of this network include the following:

- Superfund Technology Support Project (TSP)
- Superfund Technical Assistance Response Teams (START)
- OSWER Technology Innovation Office (TIO)
- National Advisory Council for Environmental Policy and Technology (NACEPT)

CONCLUSION

The data and conclusions presented in this paper represent the most current information available in the Superfund program. The U.S. EPA recognizes that with each additional treatment test performed, more valuable information will be generated regardless of whether the test was successful or unsuccessful. Timely and complete technology transfer is the key to establishing the necessary justifications for treatability variances as well as to developing appropriate land disposal restrictions for contaminated soil and debris based upon best demonstrated available technologies. Therefore, the U.S. EPA continues to seek all treatment results for evaluation for regulatory development and for timely technology transfer.

In order to participate in this important technology transfer process, please send all available information on the treatment of contaminated soil and debris to U.S. EPA OERR or to CDM Federal Programs Corporation at the following addresses:

Weathering Resistance of Stabilized Petroleum Sludge

Stephen Zarlinski

Bucknell University
Lewisburg, Pennsylvania

ABSTRACT

A multiyear research project has been undertaken to investigate the stabilization/solidification of a petroleum sludge. Recent papers have presented the results of short-term testing (TCLP) of the stabilized material. In order to evaluate long-term environmental effects, durability testing was conducted on samples of the stabilized petroleum sludge. Conclusions and recommendations based on these durability tests are presented in this paper.

Under current laboratory procedures, the stabilized sludge samples cure in a humid environment for 2 weeks before further testing. A study was conducted to determine whether the test results were significantly affected by the curing time. Individual samples were tested at daily and weekly intervals up to 4 weeks and monthly thereafter. Results indicate that the maximum unconfined compressive strength occurs at approximately 28 days. Depending upon the stabilization reagents, the total organic carbon (TOC) concentration in the extract increased or remained unchanged with increased curing time beyond 28 days.

To further study long-term environmental effects, a wet/dry study was conducted. Each sample was placed in a bath of water for 24 hours and oven-dried for 24 hours. This 48-hour cycle was repeated 12 times on each sample. Very limited physical degradation was apparent for each mix during cycles of wetting and drying. The sludge stabilized with cement kiln dust was not as resistant to wet/dry testing as sludge stabilized with a mixture of attapulgite, fly ash quicklime and cement.

Since the project is located in the mid-Atlantic region, the stabilized material may also be subjected to freeze/thaw stresses. The freeze/thaw samples were frozen for 6 hours and thawed for 42 hours. The process was repeated for 12 cycles on each sample.

Consolidation data are used to predict the total settlement and time-rate of deformation due to an applied load of overlying material. Although additives used to solidify the sludge are cementitious, the resulting strength and stiffness is not that of concrete. The compression indices indicate that the stabilized mass has the properties of a stiff clay.

Permeability tests were performed to determine the rate of transport of fluids through the stabilized sludge. The average hydraulic conductivity of the material is 2×10^{-6} cm/sec. The TOC of the effluent was an order of magnitude greater than the influent concentration indicating a release of encapsulated organics due to permeation with tap water.

INTRODUCTION

The refinery processes used in the past to produce lubricating oil from crude oil generated significant quantities of acidic petroleum sludge. The common practice was to dispose of this sludge in open lagoons. In the early 1970s, the manufacturing process was altered to eliminate the production of acidic sludge—but the lagoons remained.

Among the alternative remediation techniques identified for these sludge lagoons is stabilization/solidification, the subject of the research reported in this paper. Remedial technologies are sought which result in more permanent solutions than landfilling. Such solutions include bioremediation, incineration, vitrification and stabilization/solidification. A multiyear research project has been undertaken to evaluate the effectiveness of stabilization/solidification for the acidic petroleum sludge.

Stabilization is a process employing additives to reduce the hazardous nature of a waste by converting the waste and its hazardous constituents into a form that: (1) minimizes the rate of contaminant migration into the environment or (2) results reduced toxicity. Solidification is the process of improving the engineering properties of a material through the addition of stabilization reagents. This paper will use the term stabilization to denote both stabilization and solidification processes.

The first year of the research included a review of existing literature and the development of the laboratory testing procedures. A survey of stabilization vendors also was conducted. The second year included laboratory testing of 250 stabilized test mixes. Laboratory testing included unconfined compression and Toxicity Characteristics Leaching Procedure (TCLP). The final phase of the project will include a field study of sludge stabilization.

The laboratory testing focused upon two aspects of stabilized sludge performance. The first aspect was short-term evaluation of the toxicity reduction and engineering properties of the stabilized samples.[1] The second aspect of laboratory testing, the focus of this paper, studied the durability of the stabilized monolith under weathering conditions including freeze/thaw and wet/dry stresses.

STABILIZATION REAGENTS

Reagents for the stabilization of the acidic petroleum sludge were classified into two groups: binders and sorbents. Binders include those materials which, when added to the contaminated material, improve the strength of the material. Fly ash and lime, cement and kiln dust are binders used for the solidification studies described in this paper.

Sorbents for the stabilization of the organic waste were added in order to reduce the contaminant transport rates from the treated waste. The sorbent materials used in the studies described in this paper include bentonite, attapulgite and organically modified clays.

LABORATORY TESTING PROGRAM

Physical Property Tests

Each stabilized sample was mixed using a 500-gram sample of untreated sludge. Upon sampling, the density, moisture content, loss on ignition and pH were determined for the untreated material. A mechanical rotary mixer was used to mix the reagents with the untreated

material. The samples were then compacted into a 2.8-in. diameter cylindrical mold using standard proctor energy. The compacted samples were allowed to cure in a humid environment for 2 weeks.

After the 2 week cure period, the samples were extruded and tested in unconfined compression. The specimens were tested to their maximum unconfined compressive strengths, or 15% axial strain, whichever occurs first. The pH of the sludge averaged 3.2 with an average loss on ignition of 78.2% and an average water content of 45.6%. Thus, the sludge is both very acidic and very organic.

Chemical Tests

Once the sample was crushed in unconfined compression, it was further disaggregated by passing the material through a 3/8-in. sieve. The disaggregated material was extracted using a modified form of the Toxicity Characteristic Leaching Procedure (TCLP). The test procedure has been modified to use sulfuric acid instead of acetic acid as the extraction acid. This modification allows for the measurement of the total organic carbon concentration (TOC) in the extract. Studies have shown that no significant difference exists between the use of sulfuric acid in place of acetic acid for these sludges.[2]

Samples of the extract were analyzed for TOC and metals. A 1-L aliquot of the remaining extract was used for a methylene chloride acid/base extraction. The extract was then condensed to 1 mL for injection into a Hewlett-Packard gas chromatograph/mass spectrometer. The concentrations of individual organic contaminant present in the sludge was then measured. The TCLP extract was found to have varying concentrations (depending upon the stabilization mix) of several organics including phenol, methyl phenol and naphthalene. The average TOC in the extract from all stabilized mixes was 187 mg/L.

CONCLUSIONS AND RECOMMENDATIONS BASED ON LABORATORY TESTING

Candidate mixes for the stabilization of the acidic petroleum sludge were selected from these studies.[3] For the durability studies reported in this paper, the following two types of mixes were used: (1) cement kiln dust and (2) fly ash, quicklime, cement and attapulgite. For the second type of mix, that with fly ash, quicklime, cement and attapulgite, two mix formulations were used with different sludge to attapulgite ratios. As measured in the extraction fluid from the TCLP, the following parameters were selected to evaluate stabilization effectiveness:

- Total organic carbon concentration
- Phenol
- Methyl phenol
- Naphthalene
- Chromium
- Lead
- Mix cost
- Unconfined compressive strength
- Volume increase

DURABILITY TESTS

The laboratory analyses discussed above effectively evaluated the mixes in the short-term. The test parameters are effective for initial evaluation of the stabilized/solidified mixes. It is recognized that under long-term environmental stresses (i.e., weathering), physical and chemical degradation of the samples may occur. The remainder of this paper discusses the evaluation of the effects of long-term stresses upon the stabilized samples.

Results of the short-term testing have been previously presented.[1,4,5] From these results, three candidate mixes were selected for the long-term durability analysis. The mix proportions are shown in Table 1. The following section of this paper describes the tests conducted on each of the samples and discusses the results of these tests.

DURABILITY TESTING PROGRAM AND RESULTS

Curing Time Study

The short-term laboratory procedure had employed a 2-week cure

time. A study was conducted for each of the selected test mixes to evaluate the characteristics and property changes of the stabilized monolith as a function of time. For each of the three candidate mixes, samples were tested at curing times of 1, 7, 14, 21 and 28 days, and 2 and 3 months. With the exception of the curing time, the laboratory procedures remained unchanged for these replicate samples.

Shown in Figure 1 is the relationship between the curing time and the unconfined compressive strength for the three candidate mixes. For each test series, the unconfined compressive strength increases by approximately 300% from 1 day to 28 days of curing. Series I used cement kiln dust as the solidification agent; it exhibited the lowest strength of the three tested. Series II and III both used attapulgite, fly ash, quicklime and cement in the solidification process. Series II had an attapulgite to sludge ratio of 0.6, whereas Series III had an attapulgite to sludge ratio of 0.4. The higher attapulgite to sludge ratio resulted in higher strengths as expected, although the increase is not dramatic.

Table 1
Mix Ingredients and Proportions (by weight)

Sludge/cement kiln dust (S/CKD)	1/1.5
Sludge/attapulgite/fly ash/quicklime/cement (S/A/FA/QL/C)	1/.6/.75/.25/.5/.3
Sludge/attapulgite/fly ash/quicklime/cement (S/A/FA/QL/C)	1/.4/.75/.25/.5/.3
Figure 1
Relationship Between Unconfined Compressive Strength and Curing Time

The reduction in the TOC of the extract was studied as a function of curing time as shown in Figure 2. In the case of the cement kiln dust-stabilized sample, the reduction in TOC (in the extract) decreased as curing time increased. For the candidate mixes using attapulgite, curing time has little effect upon the TOC in the extract. The data also show that cement kiln dust was not as effective as the attapulgite mixes in reducing the TOC of the extract in the TCLP.

Wet/Dry Testing

Wet/dry testing was conducted to quantify the resistance of the stabilized materials to degradation as a result of wet/dry cycles following the procedure outlined in ASTM D-4843. The samples were mixed, compacted using standard proctor energy, allowed to cure for 1 week and extruded for testing. For each candidate mix, three test samples and three control samples were formed. The test samples were sub-

jected to 12 cycles of wetting in deionized water for 24 hours and drying at 60°C for 24 hours. Each 48-hour segment of wetting and drying constituted one cycle.
Figure 2
Relationship Between TOC Reduction and Curing Time

The corresponding control samples were not subjected to the stress of drying. Instead, these samples were placed in a humid environment for 24 hours. The total material loss was obtained by drying and weighing the material which spilled off the sample. The relative material loss is the difference between the total material loss for the test samples and the total material loss for the control samples. Samples were tested for metal and organic contamination using the modified TCLP described above.

Results of wet/dry testing are presented in Table 2. As shown in Table 2, the total material loss was greatest for the cement kiln dust-stabilized sample. The total material loss was least for the sample having an attapulgite to sludge ratio of 0.4., although the sample having an attapulgite to sludge ratio of 0.6 was similar in magnitude. Since the relative material loss is quite small when compared with the total material loss, the tests demonstrated that the material degradation was primarily a result of the wetting cycles with little impact from the drying cycles. All mixes were quite resistant to physical degradation due to wetting and drying as indicated by the low values of material loss. Failure usually is defined as a relative material loss of 30%.

Table 2
Wet/Dry Test Results

Stabilization Mix & Proportions	Total Material Loss (%)	Relative Material Loss (%)	TOC Reduction (%)
S/CKD (1/1.5)	1.81	0.15	72.3
S/A/FA/QL/C (1/.6/.75/.25/.5/.3)	1.09	0.26	66.9
S/A/FA/QL/C (1/.4/.75/.25/.5/.3)	0.90	0.28	71.0

Freeze/Thaw Testing

Freeze/thaw testing was conducted to evaluate the resistance of the stabilized materials to cycles of freezing and drying. The literature indicated that freeze/thaw cycles often are more destructive than the wet/dry cycles. Samples for the freeze/thaw testing were mixed and compacted into plexiglass cylinders 1.75 inches in diameter and 3.00 inches in length. As with the wet/dry analyses, test and control samples were prepared for each candidate mix. Samples were cured in a humid

environment for 1 week. After curing, test samples were placed in the freezer for 24 hours at a temperature less than −20°C. This freeze period was followed by 24 hours of thawing in deionized water.

The results of the freeze/thaw testing are shown on Table 3. As with previous data, the cement kiln dust-stabilized samples did not perform as well as the samples stabilized with fly ash, quicklime, cement and attapulgite. The reduction in TOC was greatest for the sample having an attapulgite to sludge ratio of 0.6, which was only slightly better than an attapulgite to sludge ratio of 0.4. The material loss was greatest for the sample stabilized with cement kiln dust and essentially the same for the attapulgite-stabilized samples. Since the relative material loss is quite large when compared with the total material loss, the tests demonstrate that the material loss is primarily due to the freezing cycles.

A comparison of the freeze/thaw test results with the wet/dry test results indicates that the freeze/thaw stresses are more critical than the wet/dry stresses with respect to physical degradation. With respect to TOC, the wet/dry stresses are more critical.

Table 3
Freeze/Thaw Test Results

Stabilization Mix & Proportions	Total Material Loss (%)	Relative Material Loss (%)	TOC Reduction (%)
S/CKD (1/1.5)	6.46	5.22	72.4
S/A/FA/QL/C (1/.6/.75/.25/.5/.3)	2.69	1.62	91.4
S/A/FA/QL/C (1/.4/.75/.25/.5/.3)	2.41	1.43	89.6

One-Dimensional Compression

In order to assess the time rate and magnitude of the settlement of the stabilized mass, consolidation tests were run on the three candidate mixes. For this test, a 1-in. thick by 2.5-in. diameter specimen of the cured stabilized material is subjected to increasing vertical pressure and constrained from lateral deformation (one-dimensional compression). Loads were applied to stress the samples to 0.25, 0.5, 1, 2, 4, 8 and 16 tons per square foot. The samples were then unloaded to stresses of 8, 2, 0.5 and 0.001 tons per square foot. The time rate of deformation was recorded for all loading increments. The compressibility is indicated by the compression index, defined as:

$$Cc = de/d\log\sigma'_v \qquad (1)$$

where
de = change in void ratio
$d\log\sigma'_v$ = change in applied stress

The results of the consolidation testing are summarized in Table 4. Note that the values of the compression index are in the range of those typical for stiff clays. The data also show a significant apparent preconsolidation pressure for the samples stabilized with attapulgite. Thus, stabilized materials loaded in the field at stresses less than these values will not be subject to large deformations.

Table 4
Consolidation Test Results

Stabilization Mix & Proportions	Pre-Consolidation Pressure (tsf)	Compression Index
S/CKD (1/1.5)	0.6	0.218
S/A/FA/QL/C (1/.6/.75/.25/.5/.3)	4.5	0.217
S/A/FA/QL/C (1/.4/.75/.25/.5/.3)	3.5	0.475

PERMEABILITY

Permeability tests were conducted on the stabilized monoliths in order to assess the hydraulic conductivity of the materials and to examine the contaminant transport from the stabilized material as a result of water infiltration. Triaxial permeability tests were conducted at an effective consolidation pressure of 10 psi, a backpressure of 50 psi and a differential seepage pressure of 5 psi. The permeant was potable tap water with a TOC of 10 mg/L. Chemical analyses were conducted on the effluent to determine the extent of transport from the sample.

Presented in Figure 3 are the permeability test results for a sludge sample stabilized with cement kiln dust. The hydraulic conductivity, which was initially 3×10^{-6} cm/sec, decreased to 2×10^{-6} cm/sec after 5 days. The slight decrease in conductivity is typical of cementitious materials which continue to hydrate with time after mixing.
Figure 3
Hydraulic Conductivity Test Results
Figure 4
TOC of Hydraulic Conductivity Test Effluent

Chemical analysis of the effluent (Figure 4) show an initially high (>100 mg/L) TOC decreasing with time, i.e., pore volume displacement. It is postulated that the initially high TOC is the result of free organics within the stabilized matrix. The lower TOC reflects a steady-state diffusion from the stabilized matrix to the permeating water.

CONCLUSIONS

As a result of the studies of the stabilization of acidic petroleum sludges described herein, we have concluded that:

• The unconfined compression strength increases with curing time to approximately 28 days with little increase beyond that time.
• The initial TOC reduction decreased with increased curing time.
• No significant physical degradation occurred due to wet/dry testing
• Freeze/thaw testing resulted in greater physical degradation of the samples than wet/dry testing.
• Mixes containing fly ash, quicklime, cement, and attapulgite were more effective in stabilizing the acidic petroleum sludge than cement kiln dust.
• Compression characteristics of the stabilized sludge are similar to those of stiff clays.
• The hydraulic conductivity of the stabilized materials is low (in the range of 2×10^{-6} cm/sec).
• Permeation with tap water caused release of organics from the stabilized monolith.
• The release of organics decreased with the duration of permeation.

ABSTRACT

The U.S. EPA provides a number of tools for decision-makers who must evaluate technologies to remediate contaminated soils and groundwater. This paper provides a "road map" to guide the reader through the variety of U.S. EPA resources available on innovative treatment technologies.

Some of the available resources include screening guides that assist site managers in matching waste types with appropriate technologies; a bibliography, entitled *Selected Alternative and Innovative Treatment Technologies for Corrective Action and Site Remediation*, listing relevant and current U.S. EPA reports on remedial technologies and how to obtain them; the ROD System (RODS) data base, which contains information on technologies selected for individual sites; Superfund Innovative Technology Evaluation (SITE) reports, which provide performance data on innovative technology demonstrations; and the Alternative Treatment Technology Information Clearinghouse (ATTIC), which is a computerized library of treatability studies.

Additional resources to be available in the near future include information on technologies used at removal and remedial sites and their implementation status; an expert system to help select appropriate biological treatment processes for remedial sites; and an enhancement of ATTIC with treatment technology case histories from the Department of Energy, the Department of Defense and the Department of the Interior.

INTRODUCTION

SARA mandated the use of permanent remedies at Superfund sites. By definition, these remedies reduce the toxicity, mobility and volume of contamination. As noted in the *Management Review of the Superfund Program* (commonly referred to as the 90-Day Study), decision-makers are hesitant to select newly developed or innovative technologies for a variety of informational, institutional and economic reasons. The Technology Innovation Office (TIO) was created in 1990 within the U.S. EPA's Office of Solid Waste and Emergency Response (OSWER) to identify and remove impediments to the broader application of innovative technologies to hazardous waste remediation. One of TIO's primary goals is to assist those who select hazardous waste cleanup technologies to identify and use new or innovative technologies when remediating contaminated soils and groundwater.

A principal impediment to the use of innovative and alternative treatment technologies is the lack of up-to-date, objective data with which to initially evaluate a technology's performance and cost. Such data must be available early in the remedy screening process in order for an innovative technology to be fully considered during the feasibility study. In an effort to overcome this particular roadblock, the U.S. EPA has created a number of reference sources for use by U.S. EPA

employees and others. These resources include computerized data bases, a reference library, numerous publications and the availability of dedicated groups of technical experts. Many of these resources are available to the general public with no user fees.

The purpose of this paper is to publicize these computerized, bibliographic and technical resources, to encourage their use and to present a "road map" or logical approach to their efficient application. The "Practitioner's Guide to Identifying Innovative Technologies"

  OSWER Directive 9200.5-254-FS (Fact Sheet)

(Fig. 1) provides an ordered approach to using the various data bases, publication sources and technical experts currently available from the U.S. EPA. This Guide can be used as a first step in identifying potential technologies that may be applicable to a specific contaminated site, as well as serving as a final check on available cost and performance data concerning various innovative remediation technologies that have already been identified through other means.

THE FIRST STEP

The streamlining of the Superfund remedial program in recent years requires the identification of remedial technologies during the early data gathering phases of the RI. During the early identification of technologies in the RI, the analyst needs to sift quickly through available information and identify what might be worth examining in more detail. A similar analysis may be conducted when time permits an engineering evaluation prior to a removal action.

The U.S. EPA has prepared several screening documents which support an initial assessment of the possible application of technologies at sites. These documents (Table 1) provide an overview of potential technology use based on physical site characteristics and contaminant information. This information will help the analyst begin to identify potentially feasible technologies, to identify interfering waste and/or site characteristics and to identify process limitations. The screening guides should help focus attention on important technical issues and help identify key words or phrases for use during computer searches. Following this initial screening, data bases may be searched to identify useful references.

The U.S. EPA has created four data bases that are useful places to begin bibliographic technology research: ATTIC, the Hazardous Waste Collection Data Base, RODS and COLIS. The most recently developed of these four data bases, and likely the most pertinent to a technology search, is ATTIC—the Alternative Treatment Technology Information Clearinghouse. ATTIC is the primary technology transfer mechanism for disseminating information concerning the Superfund Innovative Technology Evaluation (SITE) program and also contains abstracts and executive summaries from more than 1,500 technical documents and reports from states, industry, NATO, DOD, DOE other countries, Superfund RODs and various Superfund treatability studies. ATTIC can be accessed through modem-equipped personal computers or through a systems operator. The system is designed to search for key words with minimum effort, a site manager can receive short abstracts and summaries of possible applicable technologies. Should these summaries seem relevant, full copies of reports can be obtained through several sources including the U.S. EPA Library. Access to the on-line ATTIC system is available through the ATTIC system operator. Technical information requests also can be made by calling the system operator at (301) 816-9153.

The second data base of potential use during an early technology search is the Hazardous Waste Collection Database (HWCD), housed within the U.S. EPA Headquarters library. The HWCD, established in 1986 to support the information needs of the U.S. EPA's Superfund office, is a bibliographic data base containing abstracts of U.S. EPA and other government agency reports, trade books, policy and guidance directives, legislation and regulations concerning hazardous waste. Although the subject matter of HWCD is far more wide-ranging than the topic of innovative technologies, it is searchable by subject, reference title and key words using a menu. A data base thesaurus is available to aid users in designing efficient searches. One may contact Felice Sacks, the U.S. EPA Headquarters Head Hazardous Waste Superfund Librarian, at (202) 382-5934 for more information concerning the HWCD system.

A third useful data base is the Records Of Decision System (RODS) data base. The RODS data base contains the text of the signed Superfund Records of Decision. It facilitates comparing technologies used at sites with similar physical characteristics and waste conditions. The data base is menu-driven and provides rapid information searches. A search can be conducted on such fields as site name, remedy, key contaminants or the full text of the ROD. RODS is maintained on the U.S. EPA's IBM mainframe computer, which is located in Research Triangle Park, North Carolina. The RODS data base is available to the general public through the CERCLIS Hotline at (202) 252-0056 or the RODS staff at (202) 245-3770.

The fourth data base of interest is COLIS—the Computerized On-Line Information Systems. COLIS is part of the U.S. EPA's Risk Reduction Engineering Laboratory's (RREL) Technical Information Exchange. Three COLIS data bases are currently in operation:

- Case History File: This file contains information on site characteristics, respond methods, costs and cleanup problems related to spills, waste sites and underground storage tank management.
- Library Search System: This subsystem allows free form searching through catalog cards and full length abstracts of documents in the TIX library. Users may conduct their own literature searches using their own key words—they are not limited to a standard set of key words.
- SITE Application Analysis Report File: This subsystem allows free form searching of reports containing cost and performance data gathered from the U.S. EPA's SITE demonstration program. The reports are on-line in their entirety.

COLIS is accessible through the ATTIC system, or the system operator can be contacted at (201) 906-6871.

In addition to data bases services, the U.S. EPA also has prepared two brochures that will help identify U.S. EPA documents concerning the use of innovative and alternative remedial technologies. These brochures are titled *Selected Alternative and Innovative Treatment Technologies for Corrective Action and Site Remediation* (EPA/540/8-90/008, Oct. 1990) and *Selected Technical Guidance for Superfund Projects* (EPA/540/8-89/004, May 1989). Each of these two brochures lists more than 70 U.S. EPA documents relating to Superfund and remedial technologies. Both of these brochures are available free from the U.S. EPA's Center for Environmental Research Information (CERI) at (513) 569-7562.

FOCUSING IN

Each of these four computerized information sources allows users to gather a large number of potentially useful references in a relatively short period of time. The next step, therefore, is to pare down the reference list to those documents truly of interest. The technology screening guides listed in Table 1 should be helpful in this regard by assisting site managers to obtain a sense of the relevancy of individual references. The U.S. EPA and other sources also make available technology-specific publications and technical experts that can be consulted for detailed information regarding potentially useful remediation technologies.

Technology Specific Publications

By using general knowledge of site characteristics and an overview of potentially effective treatment technologies obtained from the screening guides mentioned above, the site manager has at this point identified references to a relatively small number of remediation technologies that are potentially useful. The next step is to locate and review documents concerning these technologies so that these few technologies can be compared with each other.

During the review of screening documents and technical literature, the analyst may become aware of important site characteristics which will determine the feasibility of some treatment processes. These factors may concern the physical or chemical character of the waste and suggest the need to promptly gather additional site data. Thus, an iterative process may develop where additional site data will be necessary to thoroughly assess technologies prior to conducting treatability studies.

Technical Experts

One of the challenges facing site managers is the need to assess the value of an innovative technology for the specific characteristics of a site. When reviewing the literature and considering technologies, the analyst should be aware of the developmental status of different technologies. By definition, innovative technologies are neither fully commercialized nor ready for "off-the-shelf" use. These technologies have limited performance and cost data and lack extensive field experience. The status of these processes may rapidly change, and new information is constantly being generated as demonstration projects and treatability studies are completed. Therefore, especially for new technologies, personal contact with technical experts, experienced peers and technology vendors is very important.

The U.S. EPA's Risk Reduction Engineering Laboratory (RREL) and Robert S. Kerr Environmental Research Laboratory (RSKERL) have experts on numerous treatment technologies that can quickly steer a site manager to pertinent and relevant information. The U.S. EPA sponsors several programs through each laboratory to provide this type of consultation. At the RREL, the U.S. EPA has established:

- The Engineering and Treatment Technical Support Center
- The Treatability Assistance Program
- The Superfund Technical Assistance Response Team

These three programs offer expertise in contaminant source control particularly in: above ground treatment units; materials handling; treatment of soils, sludge and sediments; and treatment of aqueous and organic liquids. They are intended to serve U.S. EPA site managers primarily, but are available to the public on a limited basis. For further information regarding these programs, one can contact Ben Blaney at (513) 569-7406.

Similarly, at the RSKERL, the U.S. EPA has established a Technical Support Center to deal with in situ biorestoration of soils and technologies affecting groundwater. For further information concerning these programs, one can contact Richard Scoff at (405) 332-8800.

The U.S. EPA has published reference guides to help identify ongoing programs and individuals who are working in specific technical areas. These guides are listed in Table 2. In addition, the SITE program has ben actively working with developers of innovative technologies for the last 4 yr. The program has a technology transfer effort intended to provide support to those in the hazardous waste site remediation community. The annual SITE Program brochure lists the U.S. EPA Office of Research and Development project managers and their associated

technologies of interest. For additional information, one can contact John Martin at (513) 569-7758.

The five Hazardous Substance Research Centers are another source of technical expertise funded by the U.S. EPA (Table 3). These university-based centers, each of which has established special relations with a pair of U.S. EPA Regions, focus on problems common within their geographic regions, with emphasis on a specific area of research. These areas of specialization include groundwater remediation, incineration, bioremediation, recovery of metals and other physical and chemical treatment of surface and subsurface contaminants. The centers perform long- and short-term research on all aspects of hazardous substance generation, management, treatment and disposal. The centers are committed to technology transfer, as well. The activities of these centers are described more fully in *Hazardous Substance Research Center: Annual Report FY 1989* (January 1990). For a copy of this report or more information regarding these research centers, one can contact Karen Morehouse at (202) 382-5750.

GETTING SPECIFIC

After identifying innovative treatment technologies with a potential for success at a site, treatability studies will likely be necessary to ascertain the effectiveness of technologies for the given site conditions and waste characteristics. The U.S. EPA provides several services to help make this task easier. The most basic are the publications entitled *Treatability Studies Under CERCLA: An Overview* (OSWER Directive 9380.3-02FS) and *Guide for Conducting Treatability Studies Under CERCLA, Interim Final* (EPA/540/2-89/058). These publications

are available through the Superfund Docket and CERI, respectively (Table 2).

Through the Risk Reduction Engineering Laboratory, the U.S. EPA sponsors the previously mentioned Treatability Assistance Program. This program offers a list of contractors available to perform treatability studies, a comprehensive data base of all aqueous treatability studies and brief bulletins describing the applicability of various technologies. The Treatability Assistance Program is also in the process of developing generic technology specific treatability study protocols.

CONCLUSION

The U.S. EPA is assembling a comprehensive set of materials to make hazardous waste site managers aware of the resources available concerning innovative remedial technologies and to help steer them toward use of innovative remedial technologies. A logical approach to use of these materials is:

- To reference screening guides and assess overall technology potential
- To conduct a series of comprehensive data base searches
- To consult available bibliographies
- To screen the computer-generated reference lists, abstracts and bibliographies and obtain those publications and documents identified as having direct relevance to the project
- To contact recognized experts in the field of hazardous waste site remediation and engineering
- To conduct treatability studies using site-specific conditions and wastes

The Technology Innovation Office continues it's efforts to make more technology-specific information available to the hazardous waste site remediation community. Future plans call for the development of an innovative technology vendor data base, the expansion of the ATTIC system to include other data bases (thereby offering one-stop shopping), the development of a computerized expert system to assist in the selection of appropriate types of biological treatment and an expansion and improvement of SITE program information availability.

A critical factor in the success of the innovative technology information systems is the timeliness of the information it contains. "Innovation" by definition means "new," and all data in the U.S. EPA systems need to be continually updated or the system becomes simply one more impediment to using innovative technologies. Data and information concerning innovative technologies must be made widely available before these technologies can be fully evaluated and their potentials realized.

The U.S. EPA's Technical Innovation Office would also like to integrate information from outside sources, such as remediation contractors, other federal agencies and private industry, into its various technology transfer mechanisms. We have begun an outreach program designed to help collect and collate cost and performance data for innovative remediation technologies wherever it is available.

DISCLAIMER

The opinions expressed in this article are those of the authors, and do not necessarily reflect the policy position of the U.S. EPA.

Considerations in the Design of Pump-and-Treat Remediation Systems

James W. Mercer, Ph.D.
David C. Skipp, M.S.
GeoTrans, Inc.
Sterling, Virginia

ABSTRACT

A common means to contain and/or remediate contaminated groundwater is to extract the water and treat it at the surface. This process is referred to as pump-and-treat technology. Practical considerations in the design of pump-and-treat systems are reviewed, with emphasis on the "pump" portion of the technology. Pre-design analysis and post-implementation monitoring also are emphasized. Basic guidance is given on how to use hydrogeological and chemical data to determine when, where and how pump-and-treat technology can be used successfully.

Factors which affect the time required to achieve a specific groundwater cleanup goal also are discussed. These factors include certain combinations of hydrogeological conditions and geochemical properties. The variables also include the presence of nonaqueous phase liquids (NAPLs), chemical desorption from the soil matrix and media that exhibit significant spatial variability. Such conditions and properties result in longer remediation performance periods for all corrective actions, including pump-and-treat technologies.

Case studies illustrate the proper design of pump-and-treat technology. As with any remedial technology, limitations at various sites may require that different remedial technologies be combined to improve remediation performance.

INTRODUCTION

Sources of groundwater contamination can range from leaky tanks, landfills and spills to the less obvious, such as chemicals in the soil dissolving from nonaqueous phase liquids (NAPLs) or chemicals desorbing from the soil matrix. Several options can be used to attempt containment and/or cleanup of groundwater contamination.

First, however, a distinction needs to be made between source removal and groundwater cleanup. Source removal typically refers to excavation and removal of wastes and/or contaminated soil. It also can include vacuum extraction. Source containment includes chemical fixation or physical encapsulation; if effective, its result is similar to source removal in that it eliminates the potential for continued chemical transport from the waste source to groundwater.

Groundwater containment/cleanup options include physical containment (e.g., construction of low-permeability walls and covers), in situ treatment (e.g., bioreclamation) and hydraulic containment/cleanup (e.g., extraction wells and intercept trenches/drains). To ensure complete cleanup, several methods may be combined to form a treatment train. This paper focuses only on hydraulic containment/cleanup, in particular, pump-and-treat technology.

In a pump-and-treat system, contaminated groundwater or mobile NAPLs are captured and pumped to the surface for treatment. This process requires locating the groundwater contaminant plume or NAPLs in three-dimensional space, determining aquifer and chemical proper-ties, designing a capture system and installing extraction (and in some cases injection) wells. Monitor wells/piezometers used to check the effectiveness of the pump-and-treat system are an integral component of the system. Injection wells are used to enhance the extraction system by flushing contaminants (including some in the vadose zone) toward extraction wells or drains. A pump-and-treat system may be combined with other remedial actions, such as low-permeability walls, to limit the amount of clean water flowing to the extraction wells, thus reducing the volume of water to be treated.

Whether the objective of the pump-and-treat system is to reduce concentrations of contaminants to an acceptable level (cleanup) or to protect the subsurface from further contamination (containment), the system components are:

- A set of goals or objectives
- Engineered components such as wells, pumps and a treatment facility
- Operational rules and monitoring
- Termination criteria

Each of these components must be addressed in the design and evaluation of a pump-and-treat technology.

Pump-and-treat technology is appropriate for many groundwater contamination problems.[1,2] However, the physical-chemical subsurface system must allow the contaminants to flow to the extraction wells. Consequently, the subsurface must have sufficient hydraulic conductivity to allow fluid to flow readily and the chemicals must be transportable by the fluid, thus making the use of pump-and-treat systems highly site-specific.

One way to evaluate the effectiveness of a remediation technology is through a study of case histories. Lindorff and Cartwright[3] discuss 116 case histories of groundwater contamination and remediation. The U.S. EPA [4,5] presents 23 case histories of groundwater remediation. More recently, groundwater extraction has been evaluated via case histories.[6] Based on these reviews, conditions which inhibit the easy flow of contaminants to pumping wells include:

- Heterogeneous aquifer conditions where low-permeability zones restrict contaminant flow toward extraction wells
- Chemicals that are sorbed or precipitated on the soil and slowly desorb or dissolve back into the groundwater as chemical equilibrium changes in response to the extraction process
- Immobile nonaqueous phase liquids (NAPLs) that may contribute to a miscible contaminant plume by prolonged dissolution (e.g., a separate phase gasoline at residual saturation)

The main limitation of pump-and-treat technology is the long time that may be required to achieve an acceptable level of cleanup. Limitations are discussed further in Mackay and Cherry[7] and Mercer et al.[2] For these limitations, modifications to pump-and-treat technology, such as

pulsed pumping, may be appropriate. Pump-and-treat technology also may be combined with other remedial alternatives, such as vacuum extraction and/or bioremediation. One should realize that no single technology is a panacea for subsurface remediation under complex conditions.

CONCEPTUAL DESIGN AND LIMITATIONS

When to Select Pump-and-Treat Systems

Figure 1 presents a decision-flow diagram for groundwater contamination. For groundwater contamination, the first decision concerns whether a remedial action (G3) is necessary. If a risk assessment shows the need for a remedial action, then the options shown in Figure 1 are containment (G4), in situ treatment (G5) or pump-and-treat (G6). If G5 is selected, then other decisions are necessary but not discussed here. If G4 is selected, then the containment can be either physical (G7) or hydraulic (G8). Physical containment generally has not worked well[8] and is not discussed further; hydraulic containment is achieved by pump-and-treat technologies (G11). As indicated previously, if the source of the groundwater contamination is not removed, then containment may be necessary as opposed to G5 or G6.

If pump-and-treat (G6) is selected, the next decision is whether to use wells (G9) or drains (G10). If the hydraulic conductivity is sufficiently high to allow flow to wells, then select wells. For low-permeability material, drains may be required. If wells have been selected, a decision must be made whether to use extraction wells (G12), injection wells (G13) or a combination. Injection wells will reduce the cleanup time by flushing contaminants toward the extraction wells. For the extraction wells, decisions need to be made concerning continuous pumping (G16), pulsed pumping (G17) and/or pumping combined with containment. Continuous pumping maintains an inward hydraulic gradient; pulsed pumping allows maximum concentrations to be extracted efficiently; containment can be used to limit the inflow of clean water that needs to be treated. The injected water can be treated water (G19); for biodegradable contaminants, it can contain nutrients and/or electron acceptors (G20) to enhance in situ biodegradation; or, for NAPLs, it can consist of enhanced oil recovery (EOR) materials (G21). For problems involving groundwater contamination, some form of pump-and-treat technology almost always will be used.
Figure 2
Liquid Partitioning Limitations of
Pump-and-Treat Effectiveness (from Keely[20])

Limitations of Pump-and-Treat Systems

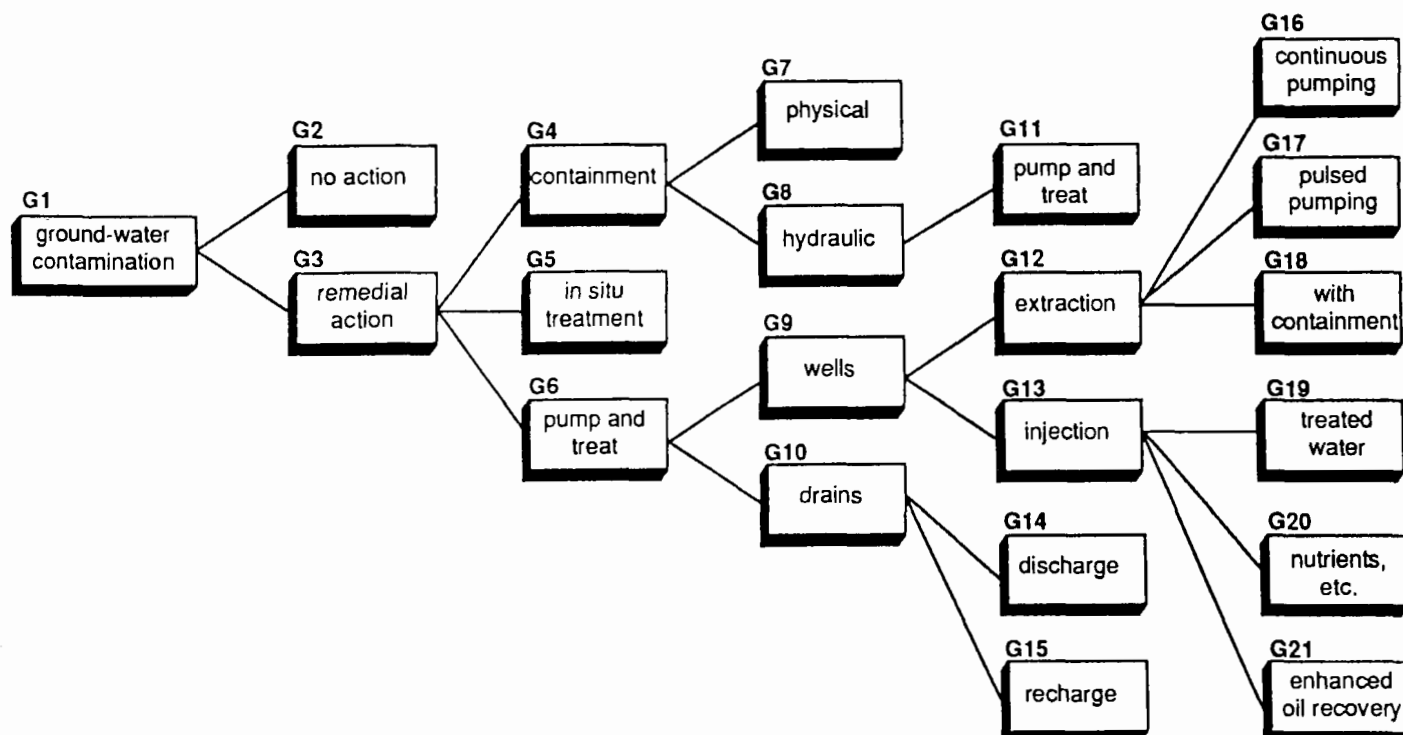
For pump-and-treat technology to remediate an aquifer in a timely fashion, the contaminant source must be eliminated. Otherwise, unremoved contaminants will continue to be added to the groundwater


Figure 1
Decision-flow Diagram for Groundwater Contamination

system, prolonging cleanup. Excavation is one of several options available for source removal. NAPLs at residual saturation are one of the most difficult sources of groundwater contamination with which to deal. Particular difficulty is posed by substances such as halogenated aliphatic hydrocarbons, halogenated benzenes, phthalate esters and polychlorinated biphenyls (PCBs) which, in their pure form, are DNAPLs. When NAPLs are trapped in pores by interfacial tension, diffusive liquid-liquid partitioning controls dissolution. Flow rates during remediation may be too rapid to allow aqueous saturation levels of partitioned contaminants to be reached locally (Figure 2). If insufficient contact time is allowed, the affected water may be advected away from the residual NAPLs before approaching chemical equilibrium and replaced by water from upgradient. Because groundwater extraction generally does not efficiently clean up this type of source, some other remedial action may be required.

Mobile chemicals may be treated using pump-and-treat technology. For sorbing compounds, however, the number of pore volumes that will need to be removed depends on the sorptive tendencies of the contaminant, the geologic materials through which it flows and the groundwater flow velocities during remediation. If the velocities are too rapid to allow contaminant levels to build up to equilibrium concentrations locally (Figure 3), then the affected water may be advected away before approaching equilibrium. Efficiency in contaminant removal may be low and will tend to decrease with each pore volume removed.

The hydrogeological conditions favorable to pump-and-treat technology are high permeability (greater than about 10^{-5} cm/sec) and homogeneity. If the hydraulic conductivity is too low (less than about 10^{-7} cm/sec) to allow a sustained yield to a well, groundwater extraction via pumping wells is not feasible. Determining pump-and-treat feasibility is site-specific; a hydraulic conductivity range that works at one site may not work at another site. For example, if the plume is small and the natural hydraulic gradient low, a pump-and-treat system pumping at a very low rate in a low-permeability unit may be feasible.
Figure 3
Sorption Limitations to Pump-and-Treat
Effectiveness (from Keely[20])

However, this same permeability may result in containment failure at another site.

For heterogeneous conditions (Figure 4), advected water will sweep through zones of higher hydraulic conductivity, removing contamination from those zones. Although heterogeneous conditions only are illustrated in the vertical in Figure 4, they are generally a three-dimensional phenomenon. Movement of contaminants out of the low hydraulic conductivity zones is a slower process than advective transport in the higher hydraulic conductivity zones. The contaminants either are slowly exchanged by diffusion with the flowing water present in larger pores or move at relatively slower velocities in the smaller pores. A rule of thumb is that the longer the site has been contaminated and the more lenticular (layered) the geologic material, the longer will be the tailing effect. The water and contaminants residing in the more permeable zones are those first mobilized during pumping. Thus, pump-and-treat technologies work in heterogeneous media, but cleanup times will be longer and more difficult to estimate than for similar systems in more homogeneous media.
Figure 4
Effect of Geologic Stratification on Tailing
(from Keely[20])

Using Models for Pump-and-Treat Design

At many sites it is advantageous to have multiple extraction wells pumping at low rates rather than one well pumping at a high rate. Analytical or numerical modeling techniques are used to evaluate alternative designs and help determine optimal well spacings, pumping rates and cleanup times.[9] For example, a generic modeling study examining the effectiveness of various restoration schemes is presented in Satkin and Bedient.[10] There also are approaches combining groundwater models with linear and nonlinear optimization.[11] Fluid pathlines and travel times in groundwater systems also can be estimated from particle tracking codes.[12] In addition, there are numerous analytical solutions that may be used to estimate pumping rates and well spacings once aquifer properties are known. These solutions are included in Ferris et al.,[13] Bentall,[14] Walton[15] and Jacob.[16] In the following examples, both numerical and analytical models were used to estimate well spacings, pumping rates and cleanup times.

Numerical Model Example

A proposed pump-and-treat system for a hazardous waste site was evaluated using a numerical model and described by Ward et al.[17] The goal of the pump-and-treat system was to contain and clean up contamination. The results of the transport simulations are summarized in Figure 5. This figure shows the distribution inventory of the mass of volatile organic compounds (VOCs) at the site over time. At any given time, the initial VOC mass can be distributed in three categories: (1) mass remaining in groundwater, (2) mass removed by the extraction system and (3) mass leaving the domain unremediated. The mass in groundwater diminishes with time. However, some mass leaves the system uncaptured by the proposed corrective action. Thus, this pump-and-treat system will fail to contain the contamination.
Figure 5
Calculated VOC Inventory versus Time
(from Ward et al.[17])

To assess the effect of increasing discharge and injection rates on plume capture, simulations were performed in which the total extraction and injection rates were doubled. The increased pumping rates reduced the VOC mass left in groundwater, but still failed to contain a portion of the plume (indicated by the dashed line in Figure 5). Thus, final pumping rates will need to be even greater. These results show the importance of plume capture analysis and emphasize the need for performance monitoring and the use of a model in monitoring program design.

The analysis of the above pump-and-treat system indicated declining contaminant concentration at the seven proposed extraction wells with time (Figure 6). Most wells exhibit a decreasing trend after a few weeks of operation. For each tenfold increase in the time of system operation, the concentration of VOCs decreases by a factor of ten. Some wells exhibit a temporary increase in concentration as zones of contamination are flushed toward the extraction wells. The effect of sorption also was examined with the model. A nearly linear relationship exists between retardation and time of remediation for a specific level of contaminant.

Analytical Model Example

Scoping calculations to estimate the pumpage required to capture a plume in a confined aquifer may be performed using the semi-analytical model RESSQ.[18,19] RESSQ is applicable to two-dimensional contaminant transport subject to advection and sorption (no dispersion, diffusion or degradation can be considered) in a homogeneous, isotropic, confined aquifer of uniform thickness when regional flow, sources and sinks create a steady-state flow field. RESSQ calculates groundwater flow paths in the aquifer, the location of contaminant fronts around sources at various times and the variation in contaminant concentration with time at sinks.
Figure 6
Calculated Extraction Well Concentrations versus Time
(from Ward et al.[17])

For example, the site is located in glacial deposits and consists of a leaking landfill with an associated plume (Figure 7). The goal is to design a capture well network for the plume. The site is more complex than the conditions simulated with RESSQ. A sand lens (not shown)

causes the plume to narrow with distance from the landfill. For these scoping calculations, the flow system considered is at the front of the plume where the wells are placed. For this location, a groundwater velocity of 0.205 ft/day (75 ft/yr) was estimated using Darcy's equation. The aquifer is 30 feet thick and the plume width is approximately 600 feet. The regional flow rate is 600 ft x 30 ft x 0.205 ft/day = 3690 ft³/day or 19.2 gpm. The total pumping rate of the wells will need to be approximately 20 gpm to capture the plume.
Figure 7
Simulation to Capture Front of the Plume:
10 Wells, 25 Feet Apart, Pumping at 2 gpm Each

Next, the maximum pumping rate that is sustainable without the wells going dry must be determined. The computation of drawdown at a single well in a multiple-well installation is not precise when a single water table aquifer of infinite extent is assumed. For 10 wells pumping at 2 gpm each, the maximum drawdown is calculated using the Theis solution and superposition[15] as 32 ft. This is an overestimate, as the leakage from the layers below and other sources (e.g., delayed yield) in the vicinity are not considered. Therefore, 10 wells at 2 gpm is considered acceptable from the considerations of drawdown. An optimum well spacing of 25 ft was determined based on guidelines provided by Javandel and Tsang.[19]

Streamtubes representing uniform regional flow were generated using RESSQ (Figure 7). The streamtubes trace the movement of the contaminants in the plume by advective transport. To ensure that contaminants do not escape between wells, the two streamtubes at the middle of the plume were divided into 5-foot wide spacings. The resulting calculations using RESSQ confirmed that the proposed pumping system would effectively capture the plume.

OPERATION AND MONITORING

Whatever remediation system is selected for a particular site, the following need to be described clearly:

- Performance standards (remedial objectives)
- Monitoring program
- Contingencies (modification to the existing remediation)

Remedial action objectives are the goals of the overall remediation. To ensure that these are met, appropriate monitoring must be conducted. If the monitoring indicates that the goals are not being met, then contingencies must be specified concerning changes to the remediation system that will ensure that the goals are reached or will specify alternate goals where original goals cannot be practically achieved.

According to Keely,[20] numerous compliance criteria and compliance point locations are used as performance standards. Compliance criteria can be divided into three categories: chemical, hydrodynamic and administrative control. Chemical compliance criteria are risk-based[21] and include Maximum Contaminant Limits (MCLs), Alternate Concentration Limits (ACLs), detection limits and natural water quality. Hydrodynamic compliance criteria may include demonstrated prevention or minimization of infiltration through the vadose zone, maintenance of an inward hydraulic gradient at the boundary of the contaminant

plume, or providing minimum flow to a surface water body. Administrative control compliance criteria range from reporting requirements, such as frequency and character of operational and post-operational monitoring, to land-use restrictions, such as drilling bans and other access-limiting restrictions.

Once the remedial action objectives are established and a remedial system is designed to meet these standards, the next step is to design a monitoring program that will evaluate the success of the remedial system. The monitoring criteria will be important in establishing the required monitoring program. Water quality monitoring is important; water-level monitoring also is important and is less expensive and subject to less uncertainty.

The location of monitor wells is critical to a successful monitoring program. For pump-and-treat technology, extraction and injection wells produce complex flow patterns locally, where previously there were different flow patterns.[20] Another possibility is that previously clean portions of the aquifer may become contaminated. Thus, monitor well locations should be based on an understanding of the flow system as it is modified by the pump-and-treat system. Modeling techniques discussed previously can be used to help in site-specific monitoring network design.

To determine the flow system generated by a pump-and-treat system, field evaluations must be made during the operational phase. Consequently, in addition to data collection for site characterization, data need to be collected during and after pump-and-treat system operation. Post-operational monitoring is needed to ensure that desorption or dissolution of residuals do not cause an increase in the level of contamination after system operation has ceased. This monitoring may be required for approximately 2 to 5 years after system termination and will depend on site conditions.

Because of the uncertainties involved in subsurface characterization, a pump-and-treat system may require modification during the initial operational stages. Modifications may result from improved estimates of hydraulic conductivity or more complete information on chemistry and loading to the treatment facility. Other modifications may be due to mechanical failures of pumps, wells or surface plumbing.

Switching from continuous pumping to pulsed pumping is one modification that may improve the efficiency of contaminant recovery. Pulsed pumping is the intermittent operation of a pump-and-treat system. The time when the pumps are off can allow the contaminants to diffuse out of less permeable zones and into adjacent higher hydraulic conductivity zones until maximum concentrations are achieved in the latter. For sorbed contaminants and residual NAPLs, this nonpumping period can allow sufficient time for equilibrium concentrations to be reached in local groundwater. During the subsequent pumping cycle, the minimum volume of contaminated groundwater can be removed at the maximum possible concentration for the most efficient treatment. The durations of pumping and nonpumping periods (approximately 1 to 30 days) are site-specific and only can be optimized through trial-and-error operation. By occasionally cycling only select wells, possible stagnation (zero or low flow) zones may be brought into active flowpaths and remediated.[20]

If plume capture must be maintained, it will be necessary to maintain pumping on the plume boundaries and perhaps only use pulsed pumping on the interior of the plume. Termination of the pump-and-treat system occurs when the cleanup goals are met. In addition to meeting concentration goals, termination also may occur when optimum mass removal is achieved and it is not practical to reduce contaminant levels further.

Application of Innovative Treatment Technologies At NPL Sites

Walter W. Kovalick, Jr., Ph.D.
John Kingscott

United States Environmental Protection Agency
Washington, D.C.

INTRODUCTION

SARA fundamental changes in the U.S. EPA's approach to hazardous waste site remediation by providing a clear preference for the use of permanent remedies. The NCP[1] codifies the U.S. EPA's policy preference for treatment as well. Consistent with this direction, the Agency has made significant progress in this area. For the last 2 fiscal years (FY 88 and FY 89), more than 70% of our RODs for source control remedies included provisions for treatment of some portion of the waste at sites. These treatment technologies include several well-known technologies which are available for "off the shelf" use on contaminated soils and sludges such as rotary kiln incineration and solidification/stabilization. However, concerns regarding the costs or effectiveness of these methods under a variety of site conditions have caused the Agency to actively seek the development of new and innovative technologies to remediate hazardous waste sites.

Our ability to develop and use new technologies leading to more cost-effective site cleanups may well determine the eventual success of the nation's efforts to implement the Superfund and RCRA corrective action programs. The Agency's recent Superfund Management Review (90-Day Study)[2] recognized the importance of this issue and called for the creation of a separate U.S. EPA office charged with the responsibility of stimulating the use of new technologies at Superfund sites. The Technology Innovation Office was created by the U.S. EPA this year to work with both the public and private sectors to accomplish this goal.

The goals of this Office support a strategy to overcome impediments that restrict the broader use of new technologies. These impediments are regulatory, institutional and informational in nature.

Regulatory impediments relate primarily to regulatory and permitting requirements under RCRA. The evaluation of new hazardous waste treatment technologies is an unusual area of new product engineering which requires a permit to develop such technologies in addition to a permit for operation. The recently completed RCRA Implementation Study[3] highlights areas for attention which will make it easier for technology developers to perform testing with hazardous wastes not on Superfund sites.

Institutional impediments have their roots in human nature: people are reluctant to take unnecessary risks. U.S. EPA project managers may not see sufficient advantage in trying something new, or private consulting engineering firms may not be willing to risk their reputations and company assets on untried technologies. PRPs and owners/operators do not want to pay twice for solutions. The Technology Innovation Office will be sponsoring a number of outreach initiatives to provide more training and create incentives to overcome these barriers.

Informational impediments concern both technical and market issues. The Agency's Office of Research and Development has an ongoing program to assist vendors in developing innovative and emerging technologies. The Superfund Innovative Technology Evaluation (SITE) program provides an opportunity for developers to demonstrate their capabilities to the U.S. EPA. The program produces performance and cost data which are necessary for the engineering evaluation of new technologies. The Technology Innovation Office is also undertaking initiatives to develop a computerized vendor information system and to better define the hazardous waste remediation market. These efforts will help foster greater communication between firms that are developing new technologies, the financial community and potential users.

MARKET FOR CONTAMINATED SITE REMEDIATION

The potential market for new and innovative technologies is very broad and rapidly evolving. In addition to problems at Superfund sites, which are discussed later in the paper, a recent Congressional Budget Office report[4] estimates a future obligation of nearly $150 billion over the next 30 years to remediate hazardous waste problems at federal facilities. These facilities primarily include Department of Defense and Department of Energy sites. Federal facilities may present unique opportunities for innovative technology because of the unusual nature of the sites. Often these sites are contaminated with pollutants related to the production of munitions or nuclear devices not commonly found on sites owned and operated by individuals. These sites may contain very large quantities of contaminated material if they were operated for long periods of time.

In addition, all facilities issued a RCRA permit after November 8, 1984, must take corrective action for contamination at or from the facility, including releases that result from past disposal. The primary responsibility for corrective action belongs to the owner/operator of the individual facilities. In the recent RCRA Implementation Study, the U.S. EPA estimates that approximately 80% of 4,700 treatment storage or disposal facilities may require some form of corrective action.

Leaking underground storage tanks represent another potential market for innovative technologies. Estimates of the number of leaking underground tanks vary, but current data suggest at least 10% of more than 2 million tanks may be leaking. Based on information supplied from states, approximately 50% of these sites are petroleum product retailers and 5% involve hazardous waste.

Moreover, some individual states have site inventories which rival the number on the Federal NPL. Non-NPL sites include those that the U.S. EPA or states have assessed and found to be ineligible for the NPL, unassessed or unscored sites that may or may not be eligible for the NPL, sites that states have not reported to the U.S. EPA and undiscovered sites. Accurate data are not available on the number of non-NPL sites, since many still have not been identified. A December 1987 GAO report[5] stated that neither states nor the U.S. EPA has identified all potential sites. The report estimates that between 130,000 and 425,000

sites may eventually have to be evaluated for possible cleanup action. Some states have active site discovery programs underway, while other states rely solely on citizen reports of potential sites.

The contamination problems at this broad array of sites vary widely with various combinations of volatiles, semivolatiles, metals and radioactive mixed waste. In addition, assumptions regarding cleanup levels vary depending on whether Federal or state agencies are responsible for remediation. As a result, no single technology is expected to dominate the cleanup market. Combinations of technologies with several unit processes in series will often be required, but narrow market niches will also develop. This suggests an overall market capable of supporting a variety of technologies.

MAKING INNOVATING TECHNOLOGY MORE AVAILABLE

Interest in the hazardous waste site remediation market on the part of technology developers is evident from the response to SITE program requests for proposals. Approximately 115 proposals were received from five solicitations for the SITE innovative demonstration program, while 210 proposals were received from four solicitations for emerging technologies program.

The Technology Innovation Office is interested in achieving an increase in the supply of new technologies to help satisfy the diverse and growing demand for remediation services. In the Superfund program, innovative technologies are being chosen with increasing frequency. In FY 1987, almost 80% of the treatment technologies chosen for source control were conventional. By contrast, in FY 89 less than 50% of the chosen technologies were conventional. At present, however, relatively few innovative technologies have been employed in actual cleanup efforts. It is obviously important to have firms with commercial equipment available to bid competitively for work when it is advertised. Improving the balance between supply and demand for new technologies can be enhanced through better communication between technology developers, investors and site managers.

The Technology Innovation Office is initiating an effort to provide an opportunity for innovative technology developers to display information about the performance and status of their units. A series of questions are being compiled to profile new technologies for source control and in situ groundwater remediation. Vendors will provide information to the U.S. EPA which will be entered into an on-line data base and made available through ATTIC, the Office of Solid Waste and Emergency Response Electronic Bulletin Board and other sources. The system will help PRPs, government representatives and their consultants keep informed about the latest information on new technologies.

A second initiative to increase communication involves a compilation of information on the market or potential demand for new technologies. This market assessment is intended to help developers and investors make long-term strategic decisions and to help alert the remediation community to upcoming opportunities to bid on specific projects. The analyses will be published periodically in monographs devoted to this subject. The analysis which follows was prepared as part of the initial effort in this area.

SUPERFUND TECHNOLOGY SELECTION

Table 1 provides an overview of Superfund source control remedies by fiscal year since the 1986 Amendments. The table shows an increase in the selection of treatment remedies and in the number of RODs specifying innovative treatment technologies.

Figure 1 provides a more detailed look at the chosen technologies. The data are derived from RODs and anticipated design and construction activity. A comparison of similar compilations prepared separately for FY 87, FY 88 and FY 89 shows a trend away from the selection of solidification/stabilization and incineration (both on-site and off-site). Correspondingly, the largest increases are in the selection of vapor extraction and bioremediation technologies.

SITE CHARACTERIZATION

Table 2 groups NPL sites into 14 categories. Since sites may fall into multiple categories, the total number of sites given exceeds the NPL inventory of 1218 which was used for this analysis. The table also gives

Table 1
Overview of Source Control Remedies
FY 1987-1988

FY	RODs Signed	Source Control RODs (Final & Interim)	RODs Selecting One or More Treatment Technologies for Source Control	RODs Selecting Innovative Treatment Technologies for Source Control
87	77	50	25	8
88	151	99	70	31
89	143	104	70	43

ROD=Record of Decision

Treatment Technologies Specified - 210
Number of RODs - 165

* Sources include solids, soils, sludges and liquid wastes; waste sources do not include ground water or surface water
** Also includes sites where location of incineration is to be determined
( ) Number of times this technology was selected
Figure 1
Source Control Treatment*
Fiscal Year 1987-1989

the categories for sites with signed RODs through FY 89. These figures include RODs for groundwater and source control.

Table 3 provides background on the criteria used to develop this classification system. Waste source, site description and constituent information primarily come from site summaries which are prepared when sites are proposed for inclusion on the NPL. Data for the five primary contaminants come from ROD Summaries. All this information has been placed into a new data base which provides technical characteristics for NPL sites.

Table 4 shows the distribution of selected innovative technologies for the site categories. However, when sites are categorized by the presence of a specific compound, that compound may not necessarily be targeted by the selected technology. Table 5 provides a summary of the occurrence of contaminated media for the different site categories.

Table 2
Number of NPL Sites in Each Site Category
(Total Number of Sites with RODs = 465)
(Total Number of NPL Sites = 1218)

Category	Number of sites with RODs	Total number of sites

PESTICIDES	31	3	6
OTHERS	10	1	2

At the time of writing this paper, additional analyses were being conducted to be presented verbally at the Superfund '90 Conference. Some of the additional work will include: total volumes of waste to be remediated will be determined by media. These data will include waste volumes for all technologies specified in RODs including land disposal, incineration, solidification/stabilization and innovative technologies. Average volumes will then be calculated for each site category leading to an estimate of total volumes by category and media. The CERCLIS data base will then be used to determine the status of remedial design and remedial action activities. This information should help vendors better understand the market and plan for commercializing their technologies.

ABSTRACT

On behalf of U.S. EPA, PEI Associates, Inc. performed laboratory screening level treatability studies to support the ongoing RI/FS for the Halby Chemical site in Wilmington, Delaware. These studies were designed to address the applicability of solidification/stabilization and xanthate flotation for treatment of metals in soils. In addition to these technologies, low-temperature thermal desorption was evaluated as a pretreatment step to remove compounds in soils that may impede the solidification/stabilization process and biological treatment was evaluated for treatment of carbon disulfide and those thiocyanate compounds that were present at high levels in soils and groundwater.

The results from these studies indicate that: (1) aerobic and anaerobic carbon disulfide- and aerobic-thiocyanate degrading organisms are present in soils and biodegradation of carbon disulfide and thiocyanate compounds (as indicated by microbial growth and oxygen consumption) can occur in the laboratory with the indigenous microbial population under aerobic conditions and sufficient amounts of nutrients; (2) while low-temperature thermal desorption may not be needed as a pretreatment step prior to solidification/stabilization, it can successfully remove most volatile and semivolatile organic compounds in soils at temperatures between 300° and 500°F and between 15 and 30 minutes residence time; and (3) the soils, themselves, do not leach appreciable amounts of metals under TCLP test conditions and of the two binders studied (asphalt and cement), asphalt appears to be the better binder for reducing leachate concentrations of arsenic and copper. Significant flotation/separation of metals from soils using xanthates was not achieved in our limited laboratory studies; however, further studies may be needed to more fully evaluate the applicability of this technology for removing heavy metals from soils. Additional feasibility and treatability studies are recommended prior to remedy selection.

INTRODUCTION

Since the enactment of SARA, RI/FS have included detailed evaluation of treatment alternatives for soils and groundwater. Recently, the U.S. EPA developed general procedures and guidelines for conducting treatability studies during the RI/FS as part of the remedy selection process reported in the U.S. EPA's ROD documents.[1] This guidance document, entitled *Guide for Conducting Treatability Studies Under CERCLA* (Interim Final), established three general levels of treatability testing that can be used to provide the necessary technological information to support the FS and remedy selection process.

This paper presents results from laboratory screening level treatability studies performed on soils contaminated with volatile and semivolatile organic compounds, as well as heavy metals and inorganic compounds.[2] This work was conducted by PEI Associates, Inc. on behalf of U.S. EPA, Office of Research and Development under the U.S. EPA

Contract No. 68-03-3413, Work Assignment No. 2-60. The overall approach for these studies was modeled after the policies and guidelines given in U.S. EPA's guidance document.[1]

Four treatment technologies were evaluated for treatment or removal of organic and inorganic compounds found in soils collected from the Halby Chemical Site in Wilmington, Delaware. They are low-temperature thermal desorption, solidification/stabilization, xanthate flotation and biological treatment. Each technology was evaluated as a primary treatment step, except low-temperature thermal desorption, which was evaluated as a pretreatment step prior to solidification/stabilization. The biological treatment study was conducted as a critical first step to evaluate the feasibility of biological treatment for selected compounds. Xanthate was evaluated as a flotation/separation agent to remove heavy metal particles from other soil material. All four technologies were evaluated at the laboratory screening tier, as defined in the U.S. EPA treatability study guide.[1]

SITE DESCRIPTION

The Halby Chemical site covers approximately 14 acres in a highly industrialized area in Wilmington, New Castle County, Delaware. As Figure 1 illustrates, the site is situated in a tidal marshland that is bordered on the north and west by Interstate 495, on the east by Conrail Railroad and on the south by Terminal Avenue. The Christina River and adjacent marsh area are located east of the site.

The Halby Chemical Company and the Witco Chemical Company produced sulfur compounds from 1948 to 1977. Specific raw materials used in the manufacturing process are shown in Table 1 and the products and associated byproducts known to have been produced at the plant are shown in Table 2. The principal chemicals that were manufactured or used at the chemical facility include carbon disulfide, ammonium thioglycolate (ATG), isooctyl thioglycolate (IOTG) and ammonium thiocyanate. In addition to these compounds, pyrite ore (iron sulfide) with trace amounts of heavy metals and coke piles have been stored on and adjacent to the site.

From 1948 to 1964, the wastewater, cooling water and surface run-off were discharged into an unlined lagoon. The lagoon waters discharged to the Christina River through a drainage ditch connected to Lobdell Canal southeast of the site. The lagoon presently receives run-off from the railroad tracks on the east side of the site and from the highway northwest of the site. Currently, a drainage ditch along I-495 drains the lagoon waters during tidal fluctuations into the Christina River. Although chemical production activities stopped in 1977, the site is still used for storage of carbon disulfide in above ground tanks. Areas adjacent to the site also are used for storage of coke piles (north of the site) and for truck washing (west of the site).

SOIL CONTAMINATION

The site soils and sediments are contaminated by a complex chemical mixture of VOCs (including carbon disulfide, chlorinated ethylenes and benzene compounds), semivolatiles (including pyrene, benzo[a]pyrene, phenanthrene, fluorene, chrysene, fluoranthene and acenaphthene) and inorganic compounds (ammonium thiocyanate, arsenic, copper, cobalt, lead, manganese, mercury, vanadium and zinc) at widely varying concentrations ranging from approximately 100 ppb to 1%. In the sediments and surface soils, the highest concentrations of these compounds appear to be located at the southern end of the site near the tanks and chemical plant building, with lower levels in the northern and eastern portions. Subsurface soils are also contaminated with similar VOCs, semivolatiles and inorganic compounds to a depth of approximately 10 feet.

The lateral and vertical extent of contamination at the Halby Chemical site is complex and variable. The coexistence of various classes of com-

pounds means that several treatment technologies, either as operable units or combined in treatment trains, may need to be evaluated in the feasibility study. In addition, because the area is primarily industrial, the use of in situ treatment methods for remediating soils and ground-water may be evaluated in the RI/FS.

TECHNOLOGY DESCRIPTIONS

Several soil treatment technologies were identified by PEI and the U.S. EPA for further study during the technology screening stage of the RI/FS. Of these, solidification/stabilization and xanthate flotation were evaluated for applicability as primary treatment processes for treatment of the metals in the soils. Low-temperature thermal desorption was tested as a pretreatment step prior to solidification/stabilization. Microbial activity on site was assessed as an indicator of the site's potential for supporting bioremediation of organic contaminants, especially carbon disulfide and thiocyanate compounds that are present at high levels in soils and water.

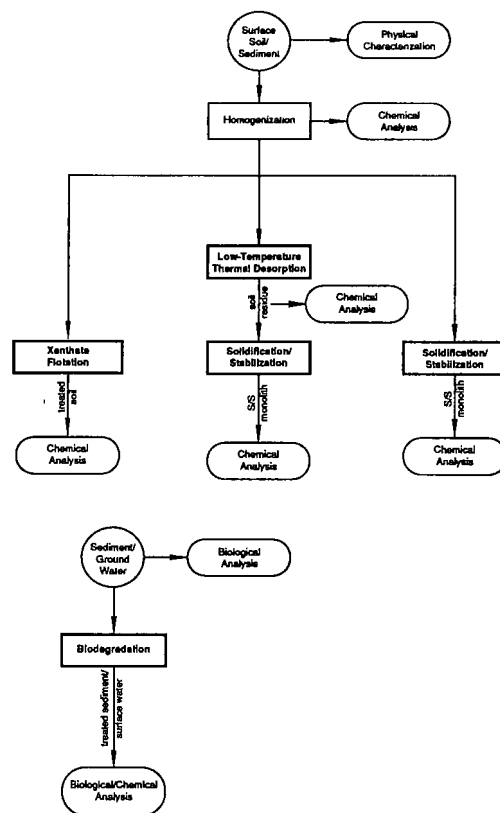
Figure 2 presents the overall treatability scheme for this project and Table 3 presents the experimental plan. Table 4 summarizes the analytical testing program for the soil, groundwater and treatment residual fractions. Soil collected from the Halby Chemical site was subjected to physical, chemical and biological characterization tests to delineate the soil characteristics that may influence treatment effectiveness. Each separate soil sample (surface soil and sediment) was homogenized prior to chemical analysis and testing to ensure that representative samples are tested for each technology and that the results from those technologies with similar starting matrices can be compared. The soil was analyzed for a select list of indicator compounds (Table 4) to provide initial concentration data for determining the effectiveness of the technologies.


Figure 2
Overview of Treatability Scheme

The low-temperature thermal desorption studies were performed at two temperatures (300° and 500°F) and two residence times (15 and 30 minutes). The VOC, semivolatile and inorganic/metal indicator compounds were measured in the soil residues from all tests. The tests were

conducted using soil that contained high levels of VOCs and semivolatile contaminants.

Table 3
Experimental Plan

	Matrix	Test conditions	No. of repli-cates	Total No. of test runs
Low-temperature thermal desorption	Surface soil/sediment	3 temperatures x 2 residences	2	6
Solidification/stabiliza-tion	Thermal residues	2 binders x 2 mix + ratios + 4 blanks	2	12
Solidification/stabiliza-tion	Surface soil/sediment	1 binder x 2 mix ratios	2	4
Xanthate flotation	Surface soil/sediment	1 reagent + 1 reagent/frother	2	4
Biodegradation	Sediment/ground water composite	2 treatments + 2 controls	2	8

The solidification/stabilization studies were performed on thermally-pretreated soils from the low-temperature thermal desorption (500°F and 30 minutes) test run and on soil samples that were not thermally treated. For the thermally-pretreated soils, two binders (asphalt and portland cement Type II) were evaluated each at two binder/waste mix ratios (0.25 and 0.4 for cement and 0.5 and 1.0 for asphalt). Asphalt was considered as a binder agent, because an asphalt plant is located near the site. For the previously untreated soils, only cement was evaluated at the same two mix ratios used for the thermally-pretreated soils (i.e., 0.25 and 0.4). The starting materials and the stabilized products were subjected to leach testing using the U.S. EPA's TCLP test

and the extracts were analyzed for the metal indicator compounds. In addition, unconfined compressive strength tests were run on the stabilized products.

Xanthates are the reaction products of carbon disulfide and alcohol and an alkali-metal hydroxide. The initial alcohol/hydroxide reaction forms an alkoxide, which then reacts with carbon disulfide to give the alkali-metal xanthate. Alkali metal xanthate salts are soluble in water and readily decompose in acidic environments to liberate carbon disulfide and the corresponding alcohol. Xanthates are used extensively. in the minerals processing industry as collectors in the selective separation of nonferrous metal sulfide ores from gangue (mixtures of undesirable ores, silicates and non-ore material).

This process exploits a surface chemistry phenomenon, where the xanthate compound selectively coats the metal sulfide particle increasing its hydrophobicity and affinity to gas bubbles. The bubbles lift the metal sulfide particles to the surface where they can be skimmed off and collected in a separate vessel. The degree of flotation accomplished is dependent upon the particular xanthate chosen and the presence of activators, such as cupric sulfate, or depressants, such as cyanide salts. Frothing agents can be added to enhance the life of the bubbles and allow for a more efficient separation.[3] Although this process has been previously used in the mining industry, it has not been previously demonstrated on contaminated soils. Nevertheless, the presence of high concentrations of carbon disulfide in the surface soils and in above ground tanks on-site caused us to consider testing this mining process at the laboratory screening level using a pre-formulated xanthate reagent (potassium amyl xanthate) with a frothing agent (2-ethylhexanol). The soil and the recovered froth would be analyzed for the metal indicator compounds.

Table 4
Summary of Analytical Testing

Parameter	Low-temperature thermal desorption		Solidification/ stabilization		Xanthate flotation		Biological studies	
	Untreated soil	Treated soil	Untreated soil	Treated soil	Untreated soil	Treated soil	Water	Composite

[a] TCLP extracts analysis.

[b] Because no visible separation occurred, these analyses were not performed.

The biological studies involved an initial assessment of the biological and chemical characteristics of site soil and groundwater, followed by a series of treatments evaluating the degradative activity of the indigenous microbial population. Microbial growth and oxygen consumption were measured to evaluate the potential for biological treatment of carbon disulfide and ammonium thiocyanate in soils and groundwater.

PROJECT OBJECTIVES

The objective of these treatability studies was to determine the applicability of the four treatment technologies to treat or remove the organic and inorganic indicator compounds in soil. For low-temperature thermal desorption, the specific test objectives were to remove semivolatile organic compounds and those compounds, such as carbon disulfide, ammonia and cyanide/thiocyanate compounds, that may impede the solidification/stabilization process. For biological treatment, the test objectives were to identify and evaluate conditions under which indigenous microorganisms will degrade carbon disulfide and thiocyanate compounds. The test objective for xanthate flotation was to reduce inorganic indicator compounds from soils and the objective for solidification/stabilization was to reduce the leachate concentration of inorganic indicator compounds. Table 5 includes specific target levels for the semivolatile organic indicator compounds for the low-temperature thermal desorption and metal indicator compounds in soils for xanthate flotation. These target levels are based on site-specific human health and environmental risks. Under the solidification/stabilization studies, the preliminary target levels for metals indicator compounds in TCLP leachate is 1 mg/L.

Table 5
Treatment Objectives for Treatability Studies

Indicator compound	Soil[a]	TCLP extract[b], mg/L
Semivolatiles (low-temperature thermal desorption studies)

EXPERIMENTAL DESIGN AND PROCEDURES

The following discussion summarizes the experimental design and testing procedures, including sample collection and preparation, biological treatment, xanthate flotation, low-temperature thermal desorption treatment and solidification/stabilization studies. A discussion of the analytical results and interpretation follows this section.

Sample Collection and Preparation

Samples of surface soil and sediment were collected at two locations in the process plant area of the Halby Chemical site. These surface soil and sediment samples were combined in a 30-gallon steel drum and used for the low-temperature thermal desorption, solidification/stabilization and xanthate flotation studies. A separate, sterilized container was used to collect the sediment sample for the biological

studies. Groundwater from well SMW-01 was collected in three sterilized, 1-gallon, amber glass jars for the biological treatment study. Prior to groundwater sampling, four well volumes were bailed from the well. In addition to these samples, subsurface soils were collected at two locations in the lagoon area (Fig. 1) in anticipation of performing additional treatability studies.

The sediment and groundwater samples for biological studies were packed in ice and sent to the bioremediation testing laboratory (IT Corporation, Knoxville, Tennessee) for analysis and treatability testing. The 30-gallon drum containing surface soils and sediments was manifested as hazardous waste and shipped to the U.S. EPA T & E facility in Cincinnati, Ohio, for treatability testing. Upon receipt at the T & E facility, the 30-gallon drum was placed in an insulated drum overpack with dry ice for proper storage in the hazardous waste storage area prior to testing.

Soil/sediment samples were withdrawn from the drum using an aluminum scoop and homogenized by hand for 10 minutes in a stainless steel pan under a laboratory hood. Large fragments and debris were removed by hand from the pan during mixing and placed back in the steel drum. The soil was mixed until uniform in color and texture. Homogenized soil used in all the treatability studies was stored in a 5-gallon stainless steel container at 4 °C. Stainless steel spoons were used to transfer the soils from the container to the testing apparatus and appropriate sample containers for analysis.

Biological Studies

Prior to testing, the sediment and groundwater samples were stored at 4 °C. Water samples were taken by pipette. Sediment samples were homogenized and pulverized with a mortar and pestle, with large-sized particles removed by sieve.

The biological studies involved an initial biological characterization step followed by a series of treatment test runs. Under the biological characterization step, the sediment and groundwater were tested for the following parameters:

- Microbial enumeration of heterotrophic bacteria, as well as specific thiocyanate- and carbon disulfide-degrading bacteria
- Nutrient analysis for nitrogen (as ammonia) and orthophosphate compounds in groundwater and lagoon sediment
- Ph of soil and groundwater
- Total organic carbon (TOC) in groundwater

Under the treatment test runs, a composite sample consisting of 1 part sediment and 10 parts groundwater (by volume) was subjected to one of four treatments:

- Treatment 1 (nutrients and oxygen) -- Restore™ 375 brand microbialnutrients (1000 mg/L) were added to the treatment vessel. The head space, which constituted 50% of the total volume, was filled with air.
- Treatment 2 (oxygen only) -- No nutrients were added; the head space was filled with air.
- Treatment 3 (nutrients only) -- 1000 mg/L of Restore™ 375 brand nutrients were added; the head space ambient air was purged and replaced with helium.
- Treatment 4 (biologically inhibited) -- 100 mg/L mercuric chloride was added to inhibit all biological activity.

The treatment vessels were sealed with Teflon® -lined silicon septa. Sulfide and thiocyanate compounds were added to the composite treatment runs. Oxygen levels were measured at frequent intervals for a period of 14 days by taking 50 μl of head space gas with a gas-tight syringe and injecting the gas sample into a quantitative oxygen sensor. Injections of air were also made at each sampling point. Microbial growth was also monitored at the start and finish of the two-week period.

Xanthate Flotation

Soil was homogenized and a portion was sampled for analysis of the metal indicator compounds. The homogenized soil was then mixed with deionized water and potassium amyl xanthate in a 4-liter glass beaker. A frothing agent, 2-ethylhexanol, was added to the beaker. The mix-

ture was stirred and air was bubbled through to facilitate flotation of the insoluble metal sulfides present. Figure 3 illustrates the xanthate flotation process evaluated in the study. The froth was then skimmed from the surface and collected in sample containers for analysis of metal indicator compounds. The liquid was decanted and the remaining soils were collected for analysis of metal indicator compounds.
Figure 3
Xanthate Flotation

Low-Temperature Thermal Desorption

Thermal treatment of homogenized soils was performed by placing approximately 800 g of soil in a 4-liter reaction flask with a stirring paddle and heating indirectly and gradually until the soils reached the target temperature (300 °F or 500 °F). Figure 4 illustrates the testing apparatus used in the study. The soil was then heated at that temperature (± 7%) for 15 or 30 minutes. The reactor vessel was continuously purged with nitrogen gas to reduce the possibility of fire or explosion. After completion of the test run, the heating mantle was turned off and the sample allowed to cool to ambient temperatures, prior to transferring the solid residue to sample containers for analysis. Eight samples (two temperatures x two reaction times x two replicate runs) were generated at the end of the experiments. To prepare samples of thermally-treated soil for solidification/stabilization, additional 800-g soil samples were heated at 500 °F for 30 minutes. The evolved gases from the 500 °F and 30 minute test runs were condensed in a cold-finger condenser, collected in a 1-liter volumetric flask and composited for analysis of the indicator compounds.

Solidification/Stabilization

Portland cement Type II was added to the thermally-pretreated and untreated soil samples at binder/waste mix ratios of 0.25 and 0.4 (by weight). Sufficient water (approximately 25% by weight of total solids) was added to the mixtures to pass the slump test. In the case of the thermally-pretreated soils, petroleum-based asphalt was pre-heated to approximately 140 °C and soils were heated to 60 °C and then added at binder/soil mix ratios of 0.5 and 1.0 (by weight). In addition, blank samples were prepared by mixing clean sand and the binder (cement or asphalt) at the above mix ratios. The mixtures were poured into rigid plastic molds and allowed to cure in zip-lock storage bags for a minimum of 14 days. A total of 12 stabilized products (two binders x two mix ratios x two replicates + four blanks) for the thermally treated soils and 4 stabilized products (one binder x two mix ratios x two replicates) for the untreated soils were generated and subjected to unconfined compressive strength and TCLP tests for metal indicator compounds.
Figure 4
Diagram of Desorption Vessel

RESULTS AND DISCUSSION

The following paragraphs summarize the analytical results and discussions for each of the four treatment technologies. Overall conclusions concerning the applicability of these technologies for remediation of the soils are presented in the following section.

Biological Studies

The initial biological characterization produced the following results (Tables 6 to 9):

- Ph of the groundwater is within acceptable range for bioremediation and the soils are only slightly acidic
- Groundwater is deficient in orthophosphate
- Aerobic carbon disulfide and thiocyanate degraders were present in sediment samples; however, the microbial population in groundwater is low. Aerobic thiocyanate) and carbon disulfide-degrading microbes comprised approximately 10% of the total aerobic microbial population found in the sediment and water
- Anaerobic carbon disulfide degraders were detected in sediment and groundwater. A relatively high concentration of anaerobic carbon disulfide degraders was found in the sediment sample. No anaerobic thiocyanate degraders were observed in sediment or groundwater
- Metabolic activity and microbial growth were observed on the organic carbon contained in the site water samples.

Based on these results, we conclude that site soils contain adequate amount of aerobic and anaerobic carbon disulfide degraders and aerobic thiocyanate degraders. Site groundwater contains lower levels of both aerobic and anaerobic carbon disulfide degraders, but little or no thiocyanate degraders.

The results from the four treatment runs are shown in Table 10 and Figure 5. The results of these experiments indicate that addition stimulates the growth and metabolism of carbon disulfide- and thiocyanate-degrading microbes (Treatments 1 and 2). A deficiency of s appears to inhibit the growth of thiocyanate degraders, only (Treatment 2). The results for microbial population density in Treatment 3 are not valid because of a leak in the treatment vessel that introduced oxygen to the system. The presence of oxygen in Treatment 3 probably inhibited the growth of anaerobic microbes. The increased population density of heterotrophs and carbon disulfide degraders observed in the killed control treatment (Treatment 4) may be indicative of the presence of mercury-resistant organisms. Based on these results, thiocyanate degraders appear to be able to grow only in the presence of oxygen and nutrients; carbon disulfide degraders are able to grow under aerobic conditions with or without nutrients.

Xanthate Flotation

Although several attempts were made to encourage long-lasting frothing action, no significant froth was observed and, therefore, no apparent separation of metal particles from the soil. Consequently, no chemical analysis was performed on the treated and untreated soils.

The negative results from the study may have occurred as a result of one or several of the following factors:

- Inadequate equipment for mixing and bubbling action
- Too great a liquid to solids mix ratio
- Presence of too little (or no) metal sulfide particles in the soil for flotation
- Too small particle size or too little xanthate reagent to effect reaction between xanthate and metal particle
Figure 5
Oxygen Consumption Data by Water-Sediment Slurries. Air Control is a Standard Obtained by Quantifying the Oxygen Content in Air at Each Sampling Point

Further jar studies may be necessary in order to determine whether the flotation process did not work as a result of the equipment and experimental design or because of a lack of chemical reaction between the xanthates and metals in soils. While we assumed that metals in the soil were present in a sulfide form on the basis of site operating history, they may actually be in other forms.

Low-Temperature Thermal Desorption

Table 11 and Figures 6 through 8 give a comparison of contaminant concentrations in untreated and thermally-pretreated soils. Together, these table and figures illustrate several findings:

- The concentrations of volatile and semivolatile organic compounds and total cyanide decreased significantly after thermal treatment at 500 °F for 30 minutes
- The concentration of metals and inorganic compounds remained fairly constant (concentrations varied within normal range of variability expected for analyses) in the soils throughout the thermal studies

The apparent increase of certain VOCs (i.e., toluene, methylene chloride and 2-butanone) after thermal treatment at 300°F may be the result of high moisture content of the raw soils, which reduced the analytical recovery and quantitation of these soluble compounds. The low percent recoveries (30 to 40%) of these VOC compounds in the matrix spike samples of the raw soils give some support for this theory. Other possible explanations for the apparent increase in VOC concentrations may be degradation of other organic compounds during thermal treatment.

In addition to analyses of soils, condensate collected in the flask from the 500°F and 30 minute test runs was composited and analyzed for the organic and inorganic indicator compounds. The analytical data indicated that semivolatile and metals are present at or below their solubility limits and that most VOCs are not present above detectable levels. The absence of VOCs in the collected condensate may have been due to the fact that noncondensable vapors and some of the condensate were drawn through a vacuum line that was located below the condenser. Therefore, it is expected that the VOC concentrations in the off-gases from low-temperature thermal desorption will actually be much higher than indicated in these analyses.

Solidification/Stabilization

Table 12 and Figure 9 give the results of TCLP leachate analysis for metals from cement-based solidification/stabilization of thermally-pretreated soils (500°F and 30 minutes runs) and untreated soils. Table 13 and Figures 9 and 10 present the TCLP leachate data for metals from cement- and asphalt-based solidification/stabilization of the thermally-pretreated soils. From these tables and figures, the following conclusions can be made:

- TCLP leachate concentrations of arsenic, chromium and mercury from the thermally-pretreated soils and untreated soils are well below the TCLP regulatory levels that are used to classify wastes as characteristically hazardous (40 CFR Part 261.24). In addition, for these unsolidified soil samples, leachate concentrations of all metal indicator compounds are at or below the treatment target level of 1 mg/L.
- Although leachate concentrations are low, those for arsenic and copper are significantly reduced by asphalt binder at both mix ratios; the cement binder did not perform as well as the asphalt and in the case of arsenic and copper, it resulted in increased concentrations.
- Both the asphalt and cement binders significantly reduced concentrations of zinc in the leachate.
- Increased chromium concentrations observed in leachate from cement-based products may have resulted from chromium in either the portland cement material or the tap water used during the mixing process, since the levels are comparable to those found for the two blank samples. Chromium is generally known to leach more readily under basic conditions such as those created by the cement process. Chromium is present at levels near or below detection limits in the leachate from the asphalt-based products.
- Leachate levels of the metal indicator compounds are similar for the cement-based products of thermally-pretreated soil and untreated soils.

As shown in Table 11, the moderate to high concentrations of metals (between 200 and 150 mg/kg) present in the thermally-pretreated and untreated soils apparently do not readily leach in appreciable amounts under TCLP test conditions. Leachate concentrations of these metals may be much greater, however, in multiple extraction tests or other leach tests that are designed to address long-term leaching rate over time. The need for solidification/stabilization of soils should be investigated by conducting additional leach testing of the soils.

While the asphalt appears to be the better binder of the two studied for arsenic and copper, the lower leachate levels reported for the asphalt-based products may be partially due to higher dilution by asphalt than by cement (i.e., higher binder to soil mix ratios). In addition, several issues should be evaluated further prior to selecting asphalt as the solidifying/stabilizing agent for previously untreated soils: (1) need for dewatering of the soils prior to mixing, (2) potential VOC emissions during mixing and (3) potential leaching of volatile and semivolatile organic compounds. Therefore, additional feasibility analyses and bench-scale studies may be warranted to evaluate these issues, if solidification/stabilization is deemed necessary for reduction of metals leaching from soils to surface and ground waters.

CONCLUSIONS AND RECOMMENDATIONS

Based on these preliminary studies, the following overall conclusions are drawn:

- Bacteria capable of degrading carbon disulfide and thiocyanate are present in the soils under aerobic conditions with sufficient nutrient supply. The presence, growth and metabolism of aerobic carbon disulfide and thiocyanate degraders suggests the possibility of using an above ground bioreactor treatment system.
- Xanthate flotation/separation of heavy metals from soils was not successful under the limited experimental conditions tested.
- While low-temperature thermal desorption at temperatures between 300° and 500°F and between 15 and 30 minutes residence time can successfully remove VOCs and semivolatile organic compounds from soils, it may not be needed as a pretreatment step prior to solidification/stabilization.
- The soils, themselves, do not leach metals at appreciable levels under TCLP test conditions. However, among the two binders tested, asphalt binder appears to be the much better binder material for reducing

The following additional studies are recommended prior to selecting a final remedy for soils at the Halby Chemical site:

• Conduct a full-scale microbial treatability study to confirm initial findings from this study and to select the treatment scenario best suited to the site conditions and cleanup goals.
• Further xanthate floating laboratory studies examining the effects of: (1) mixing speeds, (2) particle size, (3) water to solids mix ratio,

(4) xanthate flotation agent and concentration and (5) frother concentration/bubbler flow speeds.

- Additional TCLP or other leach testing (preferably a multiple waste extraction test or long-term leach study) of soils to adequately determine the need for solidification/stabilization to reduce the leaching of metals from the soils to the surface and groundwaters.
- Upon determining the need for solidification/stabilization of soils, perform feasibility analysis comparing costs for cement-based and asphalt-based solidification/stabilization processes taking into account the need for dewatering prior to using asphalt. Upon determining the more feasible solidification/stabilization process perform additional banch-scale studies evaluating leachate levels of semivolatile and metal indicator compounds and VOC emissions during mixing, at binder to soil mix ratios between 0.5 and 0.25 (for asphalt) or between 0.25 and 0.40 (for cement).

These additional studies could not be performed under the existing scope and budget, but they are needed to build upon data presented in this paper and to help further refine the design, cost and performance for soil treatment alternatives.

ABSTRACT

A detailed bench-scale treatability study of acid extraction and chemical fixation was conducted on the metal-contaminated (cadmium, nickel and cobalt) soil at the former battery plant grounds of Marathon Battery Company Superfund Site situated in the Village of Cold Spring, New York. For acid extraction, five variables, including leaching solvent, pH, soil concentration, contact time and number of extraction stages, were studied. In addition, other related treatment processes, including base recovery, settling and dewatering, also were studied. For chemical fixation, a proprietary reagent consisting of Portland cement, silicate and other additives was used. The most optimum reagent ratio was determined through a screening procedure. TCLP and MEP were performed on the chemically-fixated soils to determine the leachability and persistence. The objective of this paper is to present the treatability study results so that the findings and conclusions can be used to support the remediation of other Superfund or hazardous waste sites with similar contamination.

INTRODUCTION

As part of the RI/FS performed on the former battery plant grounds portion of the Marathon Battery Company Superfund Site, acid extraction and chemical fixation were evaluated for the remediation of the metal-contaminated soils.[1,2] Extensive bench-scale tests were designed and conducted to confirm the applicability and treatability of these two remedial technologies. This paper presents the treatability test methods and results. It is hoped that the findings and conclusions presented in this paper can be used to support the remediation of other Superfund or hazardous waste sites with similar contamination.

BACKGROUND

The Marathon Battery Company site, situated in the Village of Cold Spring, Putnam County, New York, is located across the Hudson River and slightly north from the United States Military Academy at West Point. The site is approximately 40 miles north of New York City. The Marathon Battery Company site is comprised of three study areas: Area I, which consists of East Foundry Cover March and Constitution Marsh; Area II, which encompasses a former batter manufacturing facility, its grounds and the adjacent residential yards; and Area III, which includes East and West Foundry Coves and the Hudson River in the vicinity of the Cold Spring pier (Fig. 1).

EXTENT OF CONTAMINATION

Cadmium, nickel, and cobalt, contamination have been detected in the sediments (Areas I and III) and soils (Area II) in all three areas.[1-8] The source of the contamination is the former Ni-Cd battery manufacturing plant (located in Area II) which operated from 1952-1979.

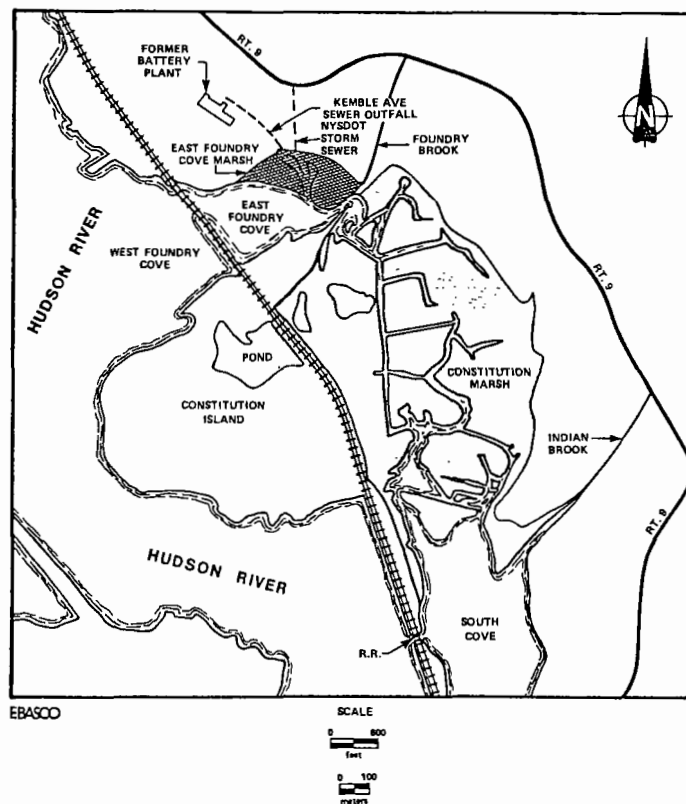
The measured concentrations of Cd, Ni and Co in the Area II soils are 10 to 5,580 mg/kg, 26 to 2,046 mg/kg and 7 to 161 mg/kg, respectively. Only the surface soils, i.e., upper 2 to 3 ft, are contaminated with these heavy metals. Generally, the soil which is closest to the surface has the highest metal concentrations. The concentration distribution patterns of these metals are very similar. Based on the results of a risk assessment[1] and the recommendation of the Agency for Toxic Substances and Disease Registry, a Cd cleanup level of 20 mg/kg was selected for the site (while Ni and Co contamination are also present, Cd was used in the analysis since it is the most toxic of the three metals). Employing the 20 mg/kg cadmium remediation level, the total volume of metal-contaminated soil requiring remediation was estimated to be 5,250 yd³.


Figure 1
Marathon Battery Site
East Foundry Cove Marsh and Constitution Marsh

TCLP tests were conducted on the soil samples with cadmium concentrations ranging from 114 to 5,580 mg/kg.[1] The results indicate that cadmium concentrations ranging from 3.9 to 97.6 mg/L in the extracts exceed the regulatory limit of 1.0 mg/L. Therefore, the cadmium-contaminated soil at the former battery plant grounds may be considered hazardous under the RCRA. There are no TCLP limits for nickel and cobalt.

TREATABILITY TEST METHODS

Both acid extraction and chemical fixation bench-scale tests were conducted in a U.S. EPA mobile laboratory located on the former battery plant grounds. Acid extraction tests were performed by Ebasco Services Incorporated (Ebasco) and the liquid and solid samples generated during the tests were analyzed by Hittman-Ebasco Associates Incorporated (HEAI). Chemical fixation tests were performed in the on-site laboratory by Chemfix Technologies, Inc. (Chemfix) and the fixated soil samples were shipped to an off-site Chemfix laboratory for further testing and analysis. For conducting these bench-scale tests, a total of approximately 4.0 kg of soil were collected from the area showing the highest levels of Cd, Ni and Co contamination. In order to determine the metal concentrations in the collected soil, 20 samples were taken and analyzed for Cd, Ni and Co. The results indicate that the concentration ranges for Cd, Ni and Co are 856 to 2,873 mg/kg, 585 to 1,829 mg/kg and 40.3 to 84.2 mg/kg, respectively and their corresponding average concentrations are 1,420 mg/kg, 1,060 mg/kg and 52.4 mg/kg, respectively. These results also show that the metal concentrations are quite variable in the soil and therefore, for the acid extraction tests, metal concentrations must be determined for both liquid and solid phases in order to make an accurate evaluation of the effectiveness of this treatment process.

Acid Extraction Test

Acids have often very successfully extracted and recovered metals. The primary purpose of this bench-scale treatability test was to identify an acid which could effectively extract the metals from the contaminated soil so that the metal residual concentrations in the soil would meet the remediation level.

Several variables can affect the amount of metals extracted from a given contaminated soil. For this test, the following five major variables were selected to determine their effects on acid extraction:

- Leaching Solvent: Six leaching solvents were evaluated (i.e., hydrochloric acid, sulfuric acid, nitric acid (HNO_3) and three mixed solutions of sulfuric acid and ferric sulfate designated as M1, M2 and M3 and defined in Table 1).

- pH: Three pH levels were evaluated (i.e., pH of 1, 2 and 3).
- Soil Concentration: Three soil concentrations were evaluated (i.e., 5%, 10% and 15% by weight).
- Contact Time: Six contact times were evaluated (i.e., 1, 2, 4, 12, 24 and 48 hours).
- Number of Extraction Stages: Six extraction stages were evaluated.

Table 1 summarizes the testing conditions used to evaluate the effects of the aforementioned variables on the effectiveness of acid extraction. As indicated in the table, when one variable was evaluated, the other variables were held at preset constant conditions.

Each acid extraction test was carried out by simply mixing a leaching solvent with the metal-contaminated soil at the preset testing conditions of pH, soil concentration, contact time and number of extraction stages (Table 1). The mixing continued until the specified contact time was reached and the mixture was then separated into liquid and solid phases by vacuum filtration. Samples were taken from both the filtrate and filtered solids for analyses to determine the mass distributions of Cd, Ni and Co in the liquid and solid phases. The percentage of a metal extracted from the soil was be calculated by the following equation:

$$\text{Percent Metal Extracted } (\%) = \frac{MML}{(MML + MMS)} \times 100\% \quad (1)$$

where: MML = Metal Mass in the Liquid Phase (or leaching solvent)
MMS = Metal Mass in the Solid Phase (or soil)

For the cases of multiple stages of extraction, no samples were taken from the solid phases during intermediate stages. In addition, fresh leaching solvent was used at each stage of the multiple stages of extraction.

As a part of the acid extraction treatability test, a base recovery test was conducted to examine the possibility of recovering the metals from the spent leaching solvents through precipitation at higher pH levels. Sodium hydroxide was used to raise the pH and three pH levels, i.e., 7, 9 and 11, were evaluated by running a jar test. In addition, zone settling rate tests and Buchner Funnel vacuum filtration tests were performed on the metal sludge generated during the base recovery tests to determine the settleability and dewaterability of the metal sludge. The testing procedures for conducting these tests can be easily found elsewhere[9,10] and are not discussed in this paper.

Chemical Fixation Test

The purpose of this bench-scale test was to confirm whether the metals present in the soil could be chemically stabilized and/or physically encapsulated in the soil so that the metal-contaminated soil could be transformed into a material which:

- Would not exceed maximum allowable concentration in sample leachate when subjected to the RCRA TCLP
- Would satisfy the Multiple Extraction Procedure (MEP) which has been used to estimate the long-term stability of chemically fixated soil under conditions simulating 1,000 years of acid rain

If successful, the metal-contaminated soil would be considered nonhazardous and suitable for disposal in a nonhazardous waste landfill.

The reagent used by Chemfix to chemically fixate the metal-contaminated soil consisted of Portland cement, silicate and other proprietary additives. The optimum reagent ratio was determined by first running a screening test on ten 100-gram soil samples, each mixed with a different reagent ratio. Unconfined compressive strength (UCS) readings were performed at various time intervals during the curing process of these ten mixtures. Once UCS trends were established, three of the best reagent ratios were selected. New samples of these three selected reagent ratios were made and shipped to an off-site Chemfix laboratory for UCS and TCLP tests. The mixture which passed the TCLP test and yielded the best UCS readings was selected for the MEP test. If the mixture passed the MEP test, the associated reagent ratio would be considered as the optimum one to chemically fixate the metal-contaminated soil. A duplicate soil sample was thus made with the

Table 1
Acid Extraction Bench-Scale Treatability Test
Testing Conditions

Variable Evaluated	Leaching Solvent	pH	Soil Concentration (% by wt.)	Contact Time (Hrs.)	Number of Extraction Stages
Leaching Solvent	HCl, H₂SO₄, HNO₃, M1*, M2* & M3*	1.0	5	1	1

	M2	20 gr H₂SO₄ + 10 gr Fe₂(SO₄)₃
	M3	50 gr H₂SO₄ + 2 gr Fe₂(SO₄)₃

** One hour contact time per extraction stage

optimum reagent ratio and it was tested again for UCS, TCLP and MEP to confirm the reproducibility of the results.

TREATABILITY TEST RESULTS

The results of the bench-scale treatability tests of acid extraction and chemical fixation on the metal-contaminated soil are discussed below.

Acid Extraction Test Results

All of the leaching solvents tested achieved greater than 90% extraction of cadmium from the contaminated soil (Table 2). For nickel and cobalt, H_2SO_4, M1, M2 and M3 appear to be more effective than HCl and HNO_3 to leach out these two metals from the contaminated soil. Since cadmium was the most hazardous contaminant among the three metals of concern and since the cleanup requirement for cadmium was the most stringent, the effectiveness in extracting cadmium from the contaminated soil became one of the important factors in selecting a leaching solvent. The other factors considered were chemical cost and number and amount of chemicals used. After evaluation of these factors, HCl and H_2SO_4 were selected and the remaining variables were studied using only HCl and H_2SO_4.

Table 2
Effect of Various Leaching Solvents On
Acid Extraction of Metal-Contaminated Soil

Leaching Solvent	Percentage of Metal Extracted, %**		
	Cadmium	Nickel	Cobalt
HCl	92.8	63.8	59.9
H_2SO_4	91.0	81.0	74.3
HNO_3	91.5	68.4	56.1
M1*	90.9	82.9	76.0
M2*	92.5	88.5	83.0
M3*	91.1	82.2	75.8

* See Table 1 for definition.
** Average values of two tests.

The pH levels can significantly affect the effectiveness of a leaching solvent (Fig. 2). A high percentage of metal extraction was achieved when the pH levels were maintained at 1.0 or lower. For HCl, 96.4% Cd, 81.2% Ni and 95.9% Co were extracted from the contaminated soil and for H_2SO_4, 90.3% Cd, 85.6% Ni and 96.3% Co were extracted. It should be mentioned that Figure 2 was plotted based on the final pH levels measured during the tests. For those tests with an initial pH of 3.0, it seemed that the pH levels could not be held at 3.0 throughout the tests.

Under the mixing condition used during testing (i.e., 100 rpm; Phipps and Bird multiple mixer Model No. 7790—300), the effectiveness of the leaching solvents was not affected when soil concentration was up to 10% by weight (Fig. 3). At 15% by weight soil concentration, the percentage of metal extracted was generally decreased. This result could be due to inadequate mixing. Localized soil settlement was observed during the testing of the 15% by weight soil concentration.

Increasing the contact time between soil and the leaching solvents generally increased the amount of metals leached from the contaminated soil (Fig. 4). After 12 hours of contact, no significant increase in metals leached from the soil was observed. After 12 hours of contact, approximately 96% Cd, 93% Ni and 87% Co were extracted from the soil.

Increasing the number of successive extraction stages increased the amount of metals being leached from the contaminated soil (Fig. 5). After three successive extraction stages, no significant increase in metals leached from soil was observed. Approximately 95% Cd, 83% Ni and 78% Co were leached from the soil after three successive extraction stages.

By combining the optimum conditions of the tested variables, it is estimated that at least 94% Cd, 84% Ni and 75% Co can be removed

of Metal-Contaminated Soil
Figure 6
Effect of pH on Metal Removal from
Spent Acid Extraction Solution

from the contaminated soil by using either HCl or H_2SO_4.

Figure 6 indicates that more than 99% of the Cd, Ni and Co in the spent leaching solvents can be removed (or recovered) at pH 11. As the pH level decreased from 11 to 7, the percentage of metal removal decreased. The settling test results indicate that the sludge generated during the base recovery tests was completely settled within 30 minutes. The solids concentration of the settled sludge ranged from 3.4 to 6.3% by weight. The filterability test results indicate that the sludge can be further dewatered by vacuum filtration or the like and the solids concentration can be increased to 15% by weight in the dewatered sludge. The calculated specific resistance is in the range of 10^9 to 10^{10} sec/gr; therefore, chemical additives may be required for assistance during sludge dewatering.

Since the cleanup level for cadmium was 20 mg/kg, the contaminated soil with Cd concentration greater than 330 mg/kg would not be cleaned up to the desired level at the leaching efficiency of 94%. It was estimated that approximately 40% of the metal-contaminated soil had a cadmium concentration greater than 330 mg/kg. Thus, additional treatment may be needed for that volume of the metal-contaminated soil. Therefore, based on the above treatability test results, acid extraction was determined not to be a viable remedial technology for cleanup of the contaminated soil at the site.

Chemical Fixation Test Results

Tables 3 through 5 and Figure 7 summarize the chemical fixation test results. These results are discussed below.

The results of the TCLP test on the three selected reagent ratios (i.e., A, B and C) indicate that a very low quantity of metals leaches from the fixated soils (Table 3). For the three metals of concern, the concentrations of Cd, Ni and Co in the leachates from the TCLP tests were <0.005 to 0.29 mg/L, 0.33 to 0.41 mg/L and <0.05 to 0.06 mg/L, respectively. The Cd concentrations were all less than the TCLP Cd limit of 1.0 mg/L. The fixated soils using reagent ratio B were selected for the MEP test and the results indicate that a very small amount of

metals leaches from the fixated soils during each of the ten leaching steps (Tables 4 and 5). The concentrations of Cd, Ni and Co in the leachates from the MEP tests were <0.005 mg/L to 0.29 mg/L, <0.04 to 0.53 mg/L and <0.05 mg/L, respectively. Again, all the Cd concentrations were less than the TCLP Cd limit of 1.0 mg/L.

Figure 7 shows that the unconfined compressive strength (USC) increased rapidly as the curing time increased. With a curing time of 10 hours, the USC can reach 1500 lb/ft^2 and at the end of two-day curing time, the USC can reach approximately 5 tons/ft^2.

During the application of the Chemfix fixation process to treat the metal-contaminated soil at the former battery plant grounds, 70% by weight of water had to be added into the soil-reagent mixture. After curing, the final volume of the fixated soil was approximately double the original volume of the contaminated soil.

The above treatability test results indicate that the Chemfix fixation process is capable of treating the metal-contaminated soils at the former battery plant grounds. The extraction procedures performed (TCLP and MEP) on the fixated soil samples resulted in leachate contaminant con-

centrations well within the regulatory limits. This chemical fixation treatment can change the hazardous characteristics of the metal-contaminated soil to become nonhazardous.

CONCLUSIONS

Based on the results of the above-described bench-scale treatability tests, the following conclusions are made:

- Since the selected soil cleanup level for the Area II portion of the Marathon Battery Company site is 20 mg/kg Cd, acid extraction is not a viable stand-alone remediation approach for this site.
- Chemical fixation (e.g., the Chemfix fixation process) is capable of eliminating the hazardous characteristics of the metal-contaminated (Cd, Ni and Co) soil at the former battery plant grounds.

Extraction and Washing Contaminated Soils Using High Pressure Jet Grouting Techniques

George R. Grisham

Offenbach, West Germany

ABSTRACT

Contamination in the ground, particularly under a structure on a congested urban site, poses a unique problem requiring a unique solution. A small site in Hamburg, Germany, presently occupied by three old factory buildings, was contaminated with phenol, a chemical substance which was used in the manufacture of disinfectants. The old factory buildings had subsequently been renovated and are now occupied by a community center and various commercial enterprises.

An extensive site investigation revealed contamination concentrated between and under the buildings. Since off-site disposal of contaminated soils in Germany is difficult and cost-prohibitive, it was necessary to develop reliable methods of removal and on-site treatment of the contaminated soils. Remedial measures on this site required decontamination of soils adjacent to and under the structure while providing adequate ground support of the foundations.

An on-site pilot program was devised using jet grouting techniques to extract and wash contaminated soils. This process utilizes a high pressure air/water jet which erodes and washes away the contaminated substance from the granular soils. Contaminated soil was displaced to the surface where it was collected and cleaned of phenolic contamination by oxidation in a completely self-contained unit. After decontamination, the cleaned material was separated according to composition and then filtered. Cleaned soils were mixed with cement and replaced. The City of Hamburg's Environmental Commission performed tests that indicated levels of phenol in the soil were well below the maximum acceptable limits.

This process, using the combination of jet grouting technique, on-site soil washing and recycling of clean materials has proven successful on this project.

INTRODUCTION

Thousands of hazardous waste sites are known to exist in North America and Europe. Evaluations of many of these sites and their potential for damage (or further damage) to the environment have produced a vast array of remedial techniques. Traditionally, excavation and transport of the contaminated soil to an off-site landfill has been the most commonly used method of site remediation. However, due to land ban legislation and the extremely high cost of off-site disposal, there has been an industry shift to containment and/or on-site/in situ treatment of contaminated soils.

Congested urban areas with contamination in the ground pose particularly difficult challenges for the remediation contractor. Remediation of contaminated soils must make sure that all contaminated soils, even in difficult to access areas (i.e., under developed sites), can be decontaminated while the planned use of the area and integrity of the existing structures is retained. This paper explains how one proven geotechnical technique, jet grouting, was adapted and combined with a new technology, soil-washing, to address a unique environmental problem.

CONTAMINATED SITE

An urban site in Hamburg, West Germany, was occupied by a small manufacturing facility that produced disinfectant until the beginning of the 1960s. The site, with an area of approximately 5,000 square meters, is bordered by a canal on the south side. Three old, but renovated, factory buildings exist on the site, one of which is used as a community center. The other two buildings are occupied by various commercial enterprises. Because of the production and improper handling methods used, the soil and groundwater became contaminated with various concentrations of phenol. West Germany currently has no national approach to establishing cleanup goals for contaminated land. Cleanup control is by provincial governments with use of the "Dutch List" for general guidance and screening.[1]

An extensive site investigation program was undertaken to determine the type and extent of contamination. The soil structure was basically horizontal with layers of peat and sand over a layer of mud at approximately 7 meters below the surface. The center of the contaminated area was located in front of, and underneath, the former disinfectant plant, as shown in Figure 1. Phenol concentrations were determined in both the groundwater and the soil. The highest concentration of contamination was determined to be approximately 2 to 3.5 meters beneath the surface.[2] When the highly concentrated chemicals came into contact with air, they produced an intense odor which made excavation of the soils in this urban area impractical.

The spread of contamination underneath the structures posed a major problem because the integrity of the buildings and the soils they were resting on had to be maintained. It was necessary to find a suitable method of treating the contaminated soils under the structures.

TREATMENT REQUIREMENTS

This complex site required the development of treatment methods that met the following criteria:

- Little or no contact with the contaminated material
- No air emissions during the decontamination process other than properly filtered air
- No open pit excavations
- The program should be able to extract and decontaminate soils underneath the buildings without compromising the support of the structure
- No groundwater lowering could be allowed because you would potentially have to treat large volumes of contaminated water and the dewatered peat layers would likely cause settlement of the structure
Figure 1
Extent of Contamination
with Respect to Structures

Figure 2
Triple System Jet Grouting

- Little or no off-site transportation and disposal of contaminated materials would be required

Several remedial methods were considered. Because of the high concentration of phenols and their considerable odor, on-site techniques using open-pit excavation methods were neither practical nor did they address contamination underneath the structure. Biological treatment, which was attempted in a prior project, was unsuccessful because of the differing soil conditions (sand and peat with different organic contents and thickness) and rapid changes in contamination concentrations.

TREATMENT SYSTEM

A geotechnical process known as jet grouting by the triple system method was combined with an on-site soil-washing process. Jet grouting is a Ground Modification system used to create in situ cemented geometries of soil (soilcrete). This system was developed primarily for underpinning and/or excavation support but also has been adapted for stabilization of soft soils and more recently has been used for pollution control projects. The triple system (or a triple rod system as it is also known) of jet grouting uses the combination of high pressure water (5,000 to 6,000 psi) shielded in a cone of air to cut and lift the soil to the surface (Fig. 2). In underpinning applications, the void created is simultaneously tremie filled with a pre-engineered backfill (usually a cement slurry).[3]

The water jet is surrounded by a concentric collar of compressed air which concentrates the jet, particularly below the water table. This high pressure water and air stream was designed to erode the surrounding soil but also washes certain contaminants from the coarser grained soils. This medium also becomes the source for the air lift system for displacement of spoil to the surface where it could be collected at the top of the drill hole. This controlled soil removal and washing capability was selected for a full-scale pilot program on the Hamburg site.

Five test columns were installed to monitor and analyze the success of the procedure. The subsoil to be cleaned is made air-tight with a surface sealing work pad over the planned boring area. After advancing the drill through the work pad to the desired depth of treatment, high pressure water and air are forced through the drill rods. The drill rods are rotated and retracted at a predetermined rate. The high energy cutting stream leads to a displacement of the treated soil within a certain distance from the opening in the drill rod. In this case, the treated volume of the soil columns had an effective diameter of approximately 1.5 meters. The soil is eroded and intensely cleansed and mixed with the outflowing water.

The radius of the eroded column can be regulated by altering stream velocity, rotary velocity and suction velocity. This process allows variance in the system to account for differing soil conditions. This cleansing process continues to the surface or upper limit of contamination.
During and after the production process, the stability of the column walls is maintained by the pressure of the suspended material in the column. The use of additives in the cutting water (i.e., bentonite slurry) can be used, if required.

The diameter of the column (i.e., the treated volume of soil) can be mechanically measured at the end of the operation by means of a folding screen which is inserted in the column filled with suspended material. This usually is done in the first test column(s) in order to set parameters for the production work.

The contaminated material consisting of water and soil coming out of the drill hole through the work pad is fed directly into an enclosed soil washing decontamination system (Fig. 3). An oxidation process was used to degrade the phenols.[4] After decontamination, the cleaned material was removed, leaving the fine soil which was separated into dry material and filtrate.

This soil washing process can be repeated as often as desired. The process results in very little contaminated material that has to be disposed of in a secure landfill.

The suspended material remaining in the test column now has to be exchanged for an uncontaminated mixture in the next step of the process.

The clean materials were mixed with purified filtrate water and a bonding agent (in this case cement) to form a competent filling material. This material was then reinjected into the open column displacing the suspended medium which is collected at the surface and treated and reused in the next column.

Soil extraction and treatment was continued in alternating columns refilling one column before jetting the adjacent column. This procedure is standard practice in conventional underpinning and prevents undermining of the structure. The columns are over[lapped to ensure decontamination of the entire volume of soil targeted.

CONCLUSION

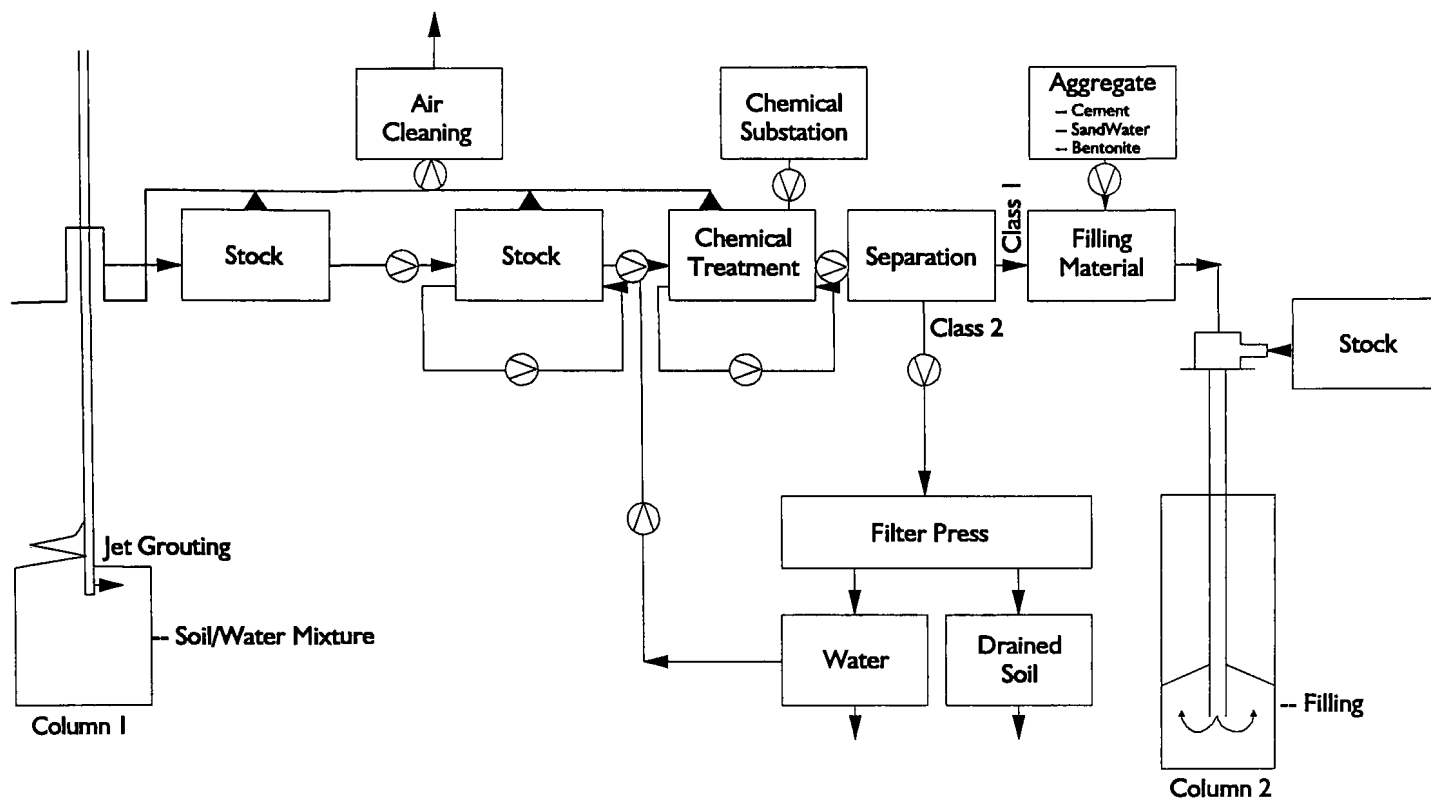
This method of contaminated soil extraction and on-site treatment in a closed system proved quite successful in this pilot project. The final product showed a 98% reduction in the level of phenol. Confirming tests by the regulating authority showed that the levels of phenol found in the soil were well below required levels. The combination of the jet stream procedure for eroding and washing the contaminated soil


Figure 3
Technology of High Pressure Washing and Treatment

followed by a direct decontamination and recycling of the resulting displaced mixture has several advantages:

- Site access is not as significant an issue as it would be in an excavation and replacement procedure; the triple rod system method of jetting can be done with small jet grouting rigs, if necessary, to access very restrictive locations
- The procedure also has the potential of targeting pockets of contamination in deep or otherwise in accessible locations such as under existing structures
- Due to the closed system of treatment, there is very little contact of the contaminated materials with the surrounding environment
- No lowering of the groundwater is necessary
- The process results in very little off-site disposal of contaminated soil
- The process can potentially be adjusted to treat specific contaminants

Care must be taken during the extraction process not to increase the amount of contaminated water in the treatment zone. Properly staging and planning the remedial program will minimize this problem. Potential chemical reactions of the treatment reagents with the soils and contaminants must be carefully considered. Since most hazardous waste sites contain a mix of contaminants. A treatment approach that may neutralize one contaminant may render another more toxic or mobile.[5]

Jet grouting techniques can be used to support structures while contaminants are removed beneath them and to wash the coarser soil particles in-place and bring the fines with the contaminants to the surface for additional treatment.

Further development of this technique includes using hot water and/or adding steam to the flushing and cutting jet to greatly increase the degree of decontamination of particular pollutants. Addition of a biologically active substance to the jet stream is also a viable option under consideration.

Research Triangle Park, North Carolina

ABSTRACT

Air stripping is a proven technology that frequently is used at Superfund sites to treat groundwater contaminated with certain volatile organic compounds (VOCs). It may be desirable or required by regulations to control the air emissions from air strippers when emission rates of VOCs exceed certain levels. The cost of controlling these air emissions is of interest to the U.S. EPA and others involved in evaluating costs of remedial technologies. This study evaluated cost trends for air stripping with vapor-phase carbon adsorption controls and graphically presents the control costs in terms of dollars per ton of pollutant removed versus groundwater concentration for various treatment rates.

Cost data on existing air stripping operations at Superfund sites are generally very limited in terms of uniformity of data reported and lack of cost category. To produce consistent results, preliminary air stripper and carbon adsorber designs were developed and estimated costs were calculated based on some simplifying assumptions. Three compounds, 1,1-dichloroethylene (DCE), trichloroethylene (TCE) and 1,2-dichloroethane (EDC), were used at various concentrations in groundwater for the purposes of this study. These compounds are commonly found at Superfund sites and have small maximum contaminant levels (MCLs) used as cleanup standards. They represent a range of Henry's Law constants and each may be adsorbed in vapor phase by activated carbon at different holding capacities. VOC inlet flow rates investigated varied from 0.05 to 10 lb/hr and liquid flow rates varied from 500 to 3500 gal/min at a fixed air-to-water ratio. Air strippers were designed using the Sherwood-Holloway Model and vendors supplied design and cost data for the carbon adsorption units. Both regenerative and nonregenerative carbon systems were evaluated.

Estimated capital costs, operation and maintenance costs and annualized costs are presented for the air strippers, carbon adsorption units and the combined systems. Control costs are presented and trends are discussed in terms of cost per ton of VOC adsorbed and cost/1000 gallons of groundwater treated.

INTRODUCTION

PEI Associates, Inc. (PEI) was asked by the U.S. EPA to evaluate the cost of controlling air emissions from air strippers used in groundwater remediation at Superfund sites. This study was initiated to provide additional data for the Office of Emergency and Remedial Response's (OERR) Air Stripper Control Policy in terms of evaluating control costs per ton of pollutant removed. The study also was useful as a tool in evaluating cost trends for air stripping and vapor-phase carbon adsorption controls.

Cost data on existing air stripping operations at Superfund sites have been found to be very limited in terms of uniformity of data reported and lack of cost breakdowns. To produce consistent uniform results for

this study, it was necessary to develop preliminary air stripper and carbon adsorber designs and to calculate estimated costs based on some simplifying assumptions.

The results of the control cost analysis are summarized in Figure 1. Figure 1 is a plot of the cost per ton of volatile organic compound (VOC) adsorbed on the activated carbon versus the groundwater concentration for three different treatment rates. For regenerative carbon adsorption systems at air concentrations greater than 4 ppm, the costs per ton are very similar for the three chemicals investigated because equipment costs predominate. Therefore, one set of lines represents the 500, 1500 and 3500 gal/min flow rates. The inlet pollutant rates (0.5 lb/hr to 10 lb/hr) for the regenerative systems also are shown in Figure 1. Below 4 ppm the nonregenerative carbon adsorption systems show different costs per ton for each chemical because the different carbon use rates control these costs. Best fit lines have been plotted for the nonregenerative carbon adsorption systems used to control each pollutant at low air concentrations.
Figure 1
Cost per ton of VOC Adsorbed vs. Groundwater Concentration

CHEMICAL SELECTION

Three chemical compounds were selected for the study based on logical criteria. These chemicals are VOCs commonly found in con-

taminated groundwater at Superfund sites and the groundwater cleanup levels required are significantly small for each chemical. Both air stripping and vapor-phase activated carbon adsorption are technically feasible treatment methods for each chemical. The three chemicals represent a high, medium and low range of Henry's Law constants (a measure of a compound's ability to be stripped). Trichloroethylene (TCE) was selected first because it is a VOC frequently found at Superfund sites, it is a common target for air stripping and it has a midrange Henry's Law constant. Selection of the other two chemicals was aided by consulting the chemical data table in the *Superfund Public Health Evaluation Manual* (SPHEM)[1] and reviewing the Superfund Records of Decision System (RODS) data base.[2] 1,1-Dichloroethylene (DCE) was selected as the VOC with a higher range Henry's Law constant and 1,2-Dichloroethane (EDC) was selected as the VOC with a low-range Henry's Law constant that could be removed from groundwater by air stripping. Tables 1 and 2 present selected data for each chemical. In this study, VOC concentrations in groundwater up to 40,000 μg/liter were investigated.

Table 1
Data on Three Compounds Selected for
Study of Air Stripper Control Costs

Compound	Molecular weight	Henry's Law constant	Vapor pressure, mm hg
1,1-Dichloroethylene (DCE)	97	3.4×10^{-2}	600
Trichloroethylene (TCE)	131	9.1×10^{-3}	57.9
1,2-Dichloroethane (EDC)	99	9.8×10^{-4}	64

Table 2
Typical Concentrations at Superfund Sites

Compound	Frequency[a]	Range of concentrations, μg/liter		Approximate mean concentration, μg/liter	MCL[b], μg/liter	WQC[c] μg/liter
DCE	6	1.7	52,000	400	7	0.033
TCE	18	8	70,000	1,600	5	2.8
EDC (DCA)	4	5	7,000	200	5	0.94

[a]Number of times compound was identified as a contaminant in RODs data base at 28 sites with air stripping.
[b]MCL = Proposed maximum contaminant level for drinking water.
[c]WQC = Water quality criteria (for 1 x 10-6 cancer risk).

ASSUMPTIONS USED FOR PRELIMINARY DESIGN AND COST ESTIMATES

This section presents the assumptions and data items used in the design and cost analysis. The following assumptions were used to design the air stripper and the outlet results were used to size the carbon adsorber:

- The carbon adsorber and air stripper designs were produced for treatment of three chemicals independently: TCE, DCE and EDC.
- The VOC flow rates investigated ranged from 0.05 to 10 pounds/hour in the liquid influent. The inlet rates were assumed to be constant. No "safety factor" for variation in concentration or nonideal effects was included.
- Liquid flow rates of 500, 1500 and 3,500 gal/minin were investigated.
- The air-to-water ratio used in each case was 35 to 1. This ratio was found to provide an adequate air stripper design for the cost estimates on a comparative basis.
- The outlet water concentration was set at 5 micrograms/liter. This parameter also controls the air stripper design efficiency.
- Air and water temperatures were assumed to be 60° F.

With these parameters, the air stripper was designed for optimum height and diameter using the Sherwood-Holloway Model.[3] An assumption used in designing the air stripper was that column dimen-

sions would allow operation at 50 percent of the flooding loadings of water and air. In some cases, there was no feasible single air stripper design and multiple parallel air strippers were used. Once the optimum designs were identified, vendors were contacted to obtain prices for the accompanying carbon adsorbers. The capital costs for the air stripper were calculated from the PDQ$ costing program.[4] The cost for the 1.5 inch Berl saddles packing was obtained from Peters and Timmerhaus.[5] The operation and maintenance costs for the air strippers were assumed to be 62 percent of the capital costs. The operation and maintenance costs for the carbon adsorbers were individually calculated based on carbon use and other factors.

Carbon adsorber costs were obtained from vendors for both regenerative and nonregenerative carbon systems. The regenerative unit is fully automated and has low operating costs (mostly utilities). On the other hand, the nonregenerative unit has a low initial capital cost, but a large cost for off-site regeneration of the spent carbon. The total annualized costs for each type of system were compared to determine whether a regenerative or nonregenerative system should be used.

The annualized costs for both the stripper and the carbon adsorber were obtained by assuming a 10-year project life (operating life and capital recovery period) and a 10 percent interest rate. Costs presented are in 1989 dollars. A number of assumptions were made in determining the adsorber and stripper costs including: the site is accessible and utilities are available, minimum site work is necessary for installation, the system is in continuous operation, operating labor requirements are minimal, the salvage value or disposal cost for the recovered VOC is negligible and there is no salvage value for the used equipment at project end.

The vendors supplied details and costs of exchangeable carbon adsorption units (carbon tanks) and steam-regenerative systems based on air flow volume. General adsorption capacities of carbon for the three chemicals at 4 ppm were used to calculate carbon use for the nonregenerative units. These estimated capacities were reduced by 50 percent at VOC concentrations below 1 ppm. The annualized cost of the carbon adsorber was divided by the tons of VOC removed/year, based on an assumed efficiency of 92 percent, to obtain the cost per ton of VOC removed.

The capital and operating costs estimated include basic installed equipment costs, minimum expected operation and maintenance costs and minimum operating labor requirements. Many other direct or indirect costs associated with groundwater cleanup may be applicable to Superfund site remediation depending on site-specific conditions. Items that were not included in the cost estimates include design, engineering, treatability studies, shipping costs, installation of utilities, groundwater collection systems, auxiliary equipment, heating of gas stream (if required), unscheduled repairs and administrative costs.

It is important to note that if all the above cost factors are considered, the cost of the basic air stripping operation may be a small portion of the total site remediation costs.

TECHNICAL AND ECONOMIC FEASIBILITY OF CARBON REGENERATION OF ADSORBERS TREATING AIR STREAMS WITH LOW VOC CONCENTRATIONS

When treating air streams with low VOC concentrations, carbon adsorbers that make one time use of the carbon (nonregenerative systems) and carbon adsorbers that regenerate the carbon on-site for reuse are competitive from both a cost and technical standpoint. Vendors were contacted in an effort to learn at what VOC concentrations nonregenerative carbon use becomes preferable on both technical and economic grounds. One area of agreement was that boundaries were very situation-specific and the information presented is strictly a generalization.[6,7] The specific comparisons cited are only good for the 10 year operating life.

Economic Considerations

Regenerative systems have a much higher initial capital cost and, therefore, incur large fixed costs due to capital recovery, maintenance, taxes, insurance, etc., whether or not the system operates. Variable costs, i.e., operating labor (the system is essentially automated and small)

and steam for carbon regeneration, are low.

The nonregenerative systems have low initial capital costs, mainly for fans and ductwork, but operating costs are high due to the cost of carbon. Large air flows favor regenerative systems because carbon adsorber costs do not vary linearly with size. For example, a system handling 12,000 cfm has only twice the costs of a system handling 2,300 cfm.

Regenerative systems appear to be less costly at VOC concentrations of approximately 3 ppm at 2,300 and 7,000 cfm and approximately 2 ppm at 12,000 and 16,000 cfm. The technical feasibility of on-site steam regeneration of carbon beds at these low concentrations, however, has been questioned by the carbon system vendors.

The minimum cost of a small (300 to 800 cfm) regenerative carbon adsorber is approximately $80,000. Minimum requirements also include instrumentation and controls and metal fabrication work. Allowing for an additional cost of 50 percent for installation and $5,000 for a steam generator and air compressor, the minimum cost of a regenerative carbon adsorption system of this type is $125,000. Therefore, due to fixed costs such as capital recovery, maintenance, taxes, insurance, etc., a nonregenerative system would be preferable if annualized costs are $35,000 or less.

Technical Considerations

There was agreement among carbon vendors that nonregenerative systems should be considered at concentrations below 10 ppm as well as at higher concentrations. The technical feasibility of a regenerative system was questioned at or below 3 ppm. The dividing line is somewhere between 4 and 10 ppm with the considerations being: (1) the hydrocarbon being adsorbed, (2) the air flow rate and (3) the temperature and relative humidity of the air stream being fed to the adsorber.[6,7] For the purpose of this analysis, if the air concentrations were 4 ppm and below, a nonregenerative system was selected because a regenerative system may not be technically feasible.

In a regenerative system, more VOC is adsorbed on virgin carbon than on carbon that has been regenerated by stream. This operational phenomenon occurs because steam stripping only removes part of the adsorbed VOC, thus reducing the capacity of subsequent cycles. For example, if virgin carbon can adsorb 10 percent of its weight in VOC, then that is considered to be the capacity of the carbon. But steam regeneration may remove only 70 percent of the VOC from the carbon, leaving 0.03 pounds of VOC/pound of carbon still on the carbon. Because the carbon capacity remains at 0.10 pounds of VOC/pound of carbon, the working capacity of the carbon is 0.10 - 0.03 or 0.07 pounds of VOC/pound of carbon. For the purpose of analysis, it was assumed that the regenerative systems lost one-third of their capacity due to the inability to completely regenerate the carbon beds.

RESULTS AND DISCUSSION OF COST ESTIMATES

This section of our paper presents the design results and cost data for air stripping and vapor phase carbon adsorption. The costs per ton of VOC removed by stripping and adsorption are discussed as well as the costs/1000 gallons of groundwater treated.

Air Stripping

Table 3 shows the estimated air stripping costs for the chemicals TCE, DCE and EDC. The stripper dimensions shown are inside packing dimensions. The values reported are based on the results of the Sherwood Holloway packed column model. Other models exist that are more complex and would give somewhat different tower dimensions. In addition, design practice would dictate rounding tower diameters to convenient increments for manufacturing and recalculating packing height and mass transfer rates based on actual dimensions. The total column height used for cost estimates includes five extra feet for internal distribution at column inlet and outlet.

The capital costs, annual operation and maintenance (O&M) costs and annualized costs for air strippers generally increase as the air flow and the inlet water concentrations increase. For TCE the capital costs range from $35,000 to $216,000, and the O&M costs range from $22,000 to $134,000/year. The annualized costs range from $28,000 to $169,000.

For DCE, the air stripper costs are only slightly higher than for TCE by 2 to 4 percent. The air stripper costs for EDC are highest, at 1.2 to 2 times the costs for TCE.

The costs per ton of TCE removed from groundwater by air stripping range from $1900/ton up to $430,000/ton. These unit costs decrease as the quantity of TCE being treated increases and as the size of the air stripper (air flow) is reduced. The costs per ton of DCE and EDC removed are higher as compared to TCE, in the same proportions as the air stripper costs for those chemicals.

Carbon Adsorption

Table 4 shows estimated costs for the carbon adsorption controls for the chemicals TCE, DCE and EDC. The costs presented are additional control costs to be added to the cost of air stripping. Both regenerative and nonregenerative carbon systems were used in this study. The regenerative systems were more economical for treating highly concentrated outlet air streams. For cases where the outlet air concentrations were lowest, the nonregenerative systems were found to be more economical. Nonregenerative systems were used in all cases at or below 4 ppm air concentration because of the performance concerns regarding regenerative systems as previously discussed.

The capital costs for the carbon adsorbers are the same for all three chemicals under the same operating parameters. The nonregenerative capital costs range from $14,000 to $24,000, while the regenerative capital costs range from $207,000 to $453,000. The operating costs for the nonregenerative systems depend mainly on the carbon replacement costs. The nonregenerative operating costs/year for TCE range from $24,000 to $475,000. For DCE the range is $62,000 to $547,000. For EDC the range is $51,000 to $443,000. The operating costs for

regenerative systems depend on fixed costs and steam and vary by 5 to 20 percent between different chemicals. Annual operating costs for regenerative systems for the three chemicals range from $20,000 to $54,000. The total annualized costs for controlling TCE range from $26,000 to $479,000. The range for DCE is $54,000 to $551,000 and the range for EDC is $53,000 to $446,000. Except for the cases where nonregenerative systems were chosen over regenerative systems for technical reasons, costs are reduced when the system size is reduced and the quantity of VOC treated is reduced.

Cost per ton of VOC Adsorbed

The costs per ton of VOC controlled by the carbon adsorber range from a low of $2100/ton to highs of $219,000/ton for TCE, $605,000/ton for DCE and $498,000/ton for EDC. The costs per ton decrease as the quantity of VOC being treated increases and the system size decreases.

As previously noted, Figure 1 shows the cost per ton of VOC adsorbed plotted against the groundwater concentration on a log-log scale. For the regenerative systems at air concentrations greater than 4 ppm, the costs per ton are very similar for the three chemicals. These have been plotted as one set of lines for the 500, 1500 and 3500 gal/min in flow rates. The VOC inlet rates for the regenerative systems are also shown, from 0.5 lb/hr to 10 lb/hr. It can be seen that for a given groundwater concentration, the cost per ton decreases when the water flow rate is increased because the VOC quantity being adsorbed also increases. Below 4 ppm, the nonregenerative systems show different costs per ton for each chemical because of the different carbon use rates. Best-fit lines have been plotted to show the general cost trends for these systems.

Combined System Costs

Table 5 shows the calculated annualized costs for air stripping, carbon adsorption controls and the combined systems. The control costs per ton of VOC adsorbed are shown for the three chemicals.

The annualized costs for the air stripper and the carbon adsorption systems were discussed in the previous sections. In comparing these costs, the additional costs for controls were found to range from 36 percent of the air stripping cost up to 426 percent of the air stripping cost for the extreme case. The smaller percentage additional control costs are generally found in the larger regenerative systems. It can be seen that the total cost of air stripping with controls generally increases as the system size and ground-water concentration increases. These total annualized costs range from $54,000 to $628,000 for TCE, $92,000 to $707,000 for DCE and $95,000 to $637,000 for EDC. Costs for the air stripper, carbon adsorber and the combined system were lowest for TCE. The highest costs for the air stripper and combined system were for EDC, while the highest carbon adsorber cost was for DCE.

Cost Estimates by Volume of Groundwater Treated

In evaluating the costs of groundwater treatment technologies, as well as drinking water and wastewater treatment technologies, the cost/volume of water treated frequently is used as a basis for comparison. Table 5 shows these costs in $/1000 gallons of groundwater treated. It can be seen that the costs range from 8 cents 31¢/1000 gallons for air stripping alone. When carbon adsorption controls are added, the total costs range from 14 to 70¢/1000 gallons.

The costs per 1000 gallons of water treated generally is reduced when the size of the stripping operation is increased and the groundwater concentration is reduced. This trend is opposite from the trend indicated by the cost per ton of VOC treated. The cost/1000 gallons may be a better indicator for evaluating system costs because the treatment rate

for groundwater is constant and variations in groundwater concentration do not drastically affect these costs. The costs per ton of VOC treated, however, are directly affected by the groundwater concentration, which is likely to fluctuate. In many applications, groundwater is moving through an aquifer and it is impossible to accurately predict the quantity of VOC that will be removed over a given period of time. When an air stripping system is only removing a fraction of a ton of VOC/year of operation, the cost per ton of VOC treated becomes a large, abstract number that does not necessarily reflect the actual cost of the system.

DATA LIMITATIONS AND CONCLUSIONS

The cost data generated are based on simplified assumptions and theoretical models and are valid only for the single chemicals in groundwater. The adsorption capacity of carbon actually varies with varying chemical concentration and can vary with different brands of carbon. This variation in treatability can have a significant impact on carbon use and the cost for the nonregenerative units. The design of a practical air stripping system with vapor phase carbon adsorption controls at a specific Superfund site would require a more detailed analysis than was possible to include in this study. For example, the costs generated by PDQ$ for the air stripping columns are for carbon steel. In many cases an FRP (fiberglass reinforced plastic) or a stainless steel column may be more desirable, at a different cost. Most Superfund sites contain a variety of different chemical contaminants. The air stripper must be designed for the chemical with the worst stripping characteristics, while the carbon adsorption system must be designed for chemical com-

binations with potentially complex adsorption relationships. The air stripper also should be designed for the lowest expected operating temperatures.

The cost per ton of VOC removed is extremely sensitive to the tons/year of VOC adsorbed. A minor variation in tons/year of VOC at low concentrations will produce a significant change in the cost per ton of VOC removed. The system with the lowest VOC input and lowest annualized cost can also have the highest cost per ton of VOC removed.

The cost data presented may be used as relative indicators of cost trends for air stripping and carbon adsorption control systems. Real world systems at Superfund sites may vary widely from these numbers depending on a variety of site-specific conditions.

ABSTRACT

Irradiation of water with high energy electrons results in the formation of three reactive free radicals: $e^-(aq)$, $H\cdot$ and $OH\cdot$. Once formed, these free radicals react with organic solutes in aqueous solution. Full-scale experiments, conducted at our Electron Beam Research Facility, will be compared to parallel bench-scale studies, conducted at a ^{60}Co facility, for the removal of chloroform and carbon tetrachloride from aqueous solutions. Additional results obtained at the E-Beam facility will describe removal efficiencies obtained for chemicals of interest in site remediation. The results of these studies have led to a better understanding of the factors affecting the removal of the organic compounds of interest to Superfund.

INTRODUCTION

Soils, sediments and groundwater have been contaminated with hazardous compounds in many areas of the country, many of which may persist for considerable periods in the environment. Because of this contamination and the recalcitrant nature of many of the chemicals, it is of interest to develop processes which will effectively and efficiently remove these compounds from aqueous solutions. Effective technology might be defined as that technology which results in the ultimate disposal of the chemicals, not merely a transfer from one environmental compartment to another. Efficiency should consider not only the cost question, but also the overall effectiveness of the process in solving the problem.

High energy electron irradiation is an innovative treatment process which is being developed as an ultimate disposal process for toxic and hazardous organic chemicals. Experiments conducted to date have focused upon their removal from aqueous solutions of varying water quality, i.e., raw wastewater to potable water. Recently, experiments have been initiated which indicate that the process also will work well on sludges.

Table 1 outlines the most frequently found hazardous chemicals at Superfund sites in the United States. Table 2 outlines organic compounds recently added to the list of compounds to be regulated as hazardous. Many of the organic compounds on these lists have been studied at the Electron Beam Research Facility in Miami, Florida. It is possible to use ^{60}Co gamma irradiation to simulate the high energy electron irradiation process. The advantage of conducting studies using gamma irradiation is that smaller volumes can be used and the solutes can be studied in distilled water and in aqueous solutions of defined composition. Reaction byproduct analyses can be conducted much easier in a well-defined aqueous medium and the results confirmed at full-scale and in natural waters.

This paper focuses upon the results of full-scale high energy electron irradiation and batch ^{60}Co gamma irradiation for the removal of chloroform and carbon tetrachloride from aqueous solutions. Studies conducted at both the ^{60}Co and the Electron Beam Research Facility will be compared and a quantitative relationship defined to relate removal efficiency under both conditions.

RADIATION CHEMISTRY OF NATURAL WATERS

The purpose of this section is to provide an overview of aqueous-based radiation chemistry. This brief introduction should assist the reader in understanding the application of high energy electron irradiation to the treatment of toxic and hazardous organic wastes in natural waters.

Table 1
25 Most Frequently Identified Substances At 546 Superfund Sites Adapted from McCoy & Assoc., "Haz. Waste Consult." 3:2(1985))

2,4,6-Trichlorophenol	2.0
Vinyl Chloride	0.2

The literature relating to radiation chemistry most often reports experiments conducted in pure water. The extrapolation of pure water data to natural waters is complicated by the presence of inorganic and organic matter (primarily humic substances) found in natural waters. These compounds may interact with the reactive species formed during irradiation and lead to side reactions not observed in pure water. Examples of these processes are the reactions of hydroxyl radical with carbonate and halide ions.

Irradiation of pure water with fast electrons has been studied extensively with numerous excellent reviews on the subject.[1-3] The fast electrons can be generated either by ^{60}Co or by electron accelerators. It is thought that the initial radiation process (10^{-16}-10^{-14} sec) results in the formation of excited molecules H_2O^*, H_2O^+ and e^- [4] As these excited state molecules and electrons interact and transfer their energy, several secondary reactive species are formed:

$$H_2O -/\backslash /\backslash /\backslash-> e^-(aq) (2.6), H\cdot (0.55), OH\cdot (2.7), H_2 (0.45), H_2O_2 (0.71), H_3O^+ (2.7) \quad (1)$$
The efficiency of the conversion of energy from ionizing radiation to chemical energy is described by G values. G is defined as the number of radicals, excited states or other products, formed (or lost) in a system absorbing 100 eV of energy. The G value for the formation of the secondary products of irradiation are indicated in parenthesis in Equation (1).

The three free radicals formed are the most reactive species. The $e^-(aq)$ and H· are reducing radicals and the OH· is an oxidizing radical.[5-8] Of these radicals, the aqueous electron and hydroxyl radical account for greater than 90% of the reactive species. Thus, the chemistry of primary interest in this process is that of these two species. However, it is possible that the presence of H_2O_2 may also contribute to the removal of organic toxic and hazardous wastes.

Aqueous Electron

The reactions of the aqueous electron, $e^-(aq)$, with specific organic and inorganic compounds has been studied extensively.[4-6,9] The $e^-(aq)$

is a powerful reducing reagent with an $E°$ ($e^-(aq) + H \longrightarrow \frac{1}{2}H_2$) of 2.77. The reactions of the $e^-(aq)$ are single electron transfer, the general form of which is:

$$e^-(aq) + S^N \longrightarrow S^{N-1} \quad (2)$$

The $e^-(aq)$ reacts with numerous organic chemicals and of particular interest to the field of toxic and hazardous wastes are the reactions with halogenated compounds. A generalized reaction is shown below:

$$e^-(aq) + RCl \longrightarrow R + Cl^- \quad (3)$$

Thus, reactions involving the $e^-(aq)$ may result in the dechlorination of organohalogen compounds. Further reaction of the organic radical formed could result in the complete destruction of the compound and specific examples are given below. The $e^-(aq)$ also reacts with other organic compounds and would contribute to the removal of these compounds from aqueous solutions. Examples of the rate constants of reactions of interest in this area are presented later in this paper.

Hydrogen Radical

The reactions of H· with organic and inorganic compounds have also been summarized.[10] The hydrogen atom accounts for approximately 10% of the total free radical concentration in irradiated water. The H· undergoes two general types of reactions with organic compounds, hydrogen addition and hydrogen abstraction.

An example of a typical addition reaction with an organic solute is that of benzene:

$$H\cdot + C_6H_6 \longrightarrow \quad (4)$$

The second general reaction involving the H· is hydrogen abstraction:

$$H\cdot + CH_3OH \longrightarrow H_2 + CH_2OH \quad (5)$$

Since most natural waters likely to be encountered will be oxygenated, the predominate reaction for H· will be:

$$H\cdot + O_2 \longrightarrow HO_2 \quad (6)$$

This reaction has a second order rate constant of 2.1 x 10^{10}/m. sec. Therefore, it is assumed that the H· is of minimal importance in the removal of toxic and hazardous organic compounds from oxygenated aqueous solutions.

Hydroxyl Radical

Reactions of the hydroxyl radical, OH·, with inorganic and organic compounds has been well-documented.[6] Compilations of rate constants have been published.[7,10] OH· can undergo several types of reactions with chemicals in aqueous solution. The types of reactions that are likely to occur are addition, hydrogen abstraction, electron transfer and radical-radical recombination.

Addition reactions occur readily with aromatic and unsaturated aliphatic compounds. The resulting compounds are hydroxylated radicals:

$$OH\cdot + CH_2=CH_2 \longrightarrow HOCH_2-CH_2 \quad (7)$$

Hydrogen abstraction occurs with saturated and many unsaturated molecules, e.g., aldehydes and ketones:

$$OH\cdot + CH_3-CO-CH_{33} \longrightarrow CH_2COCH_3 + H_2O \quad (8)$$

Reactions involving halogen ions (X⁻) may also be significant:

$$OH\cdot + X^- \longrightarrow X + OH^- \quad (9)$$
$$X + X^- \longrightarrow X_2^- \quad (10)$$

The X_2 can further react with organic molecules possibly forming halogenated organic compounds. The halogens of most interest are Cl⁻ and Br⁻.

Another inorganic radical likely to be involved is the carbonate radical, CO_3^-. CO_3^- is formed by OH· reaction with CO_3^{2-}. The importance of the carbonate radical is as yet unknown, but because of its relatively

low reactivity with organic compounds, it probably will play a relatively unimportant role in their removal from aqueous solution. However, the presence of high concentrations of CO_3^{2-} may have a positive effect on the effective concentration of $e^-(aq)$ by removing OH^- from solution. This situation would result in an increased removal efficiency of compounds which primarily react with $e^-(aq)$.

Hydrogen Peroxide

In oxygenated aqueous solutions, the reactions of O_2 with $e^-(aq)$ and H^- occur and compete for the reactive intermediates formed in Equation 1. Both of these reactions result in the formation of reduced oxygen:

$$e^-(aq) + O_2 ----> O_2^- \tag{11}$$
$$H^- + O_2 ----> HO_2 \tag{12}$$

The products of Equation (11) and (12) are in equilibrium, with a pK_a = 4.5. These products also lead to the formation of additional H_2O_2:

$$2O_2^- + 2H^+ ----> H_2O_2 + O_2 \tag{13}$$
$$2HO_2 ----> H_2O_2 + O_2 \tag{14}$$
One of the interesting reactions that has been studied is the following:

$$e^-(aq) + H_2O_2 ---> OH + OH^- \tag{15}$$

with a second order rate constant of 1.2-1.4×10^{10}/m. sec. In our study, with the high and continuous radiation dose, it appears that H_2O_2 might serve as a secondary source of OH^-.

ELECTRON BEAM RESEARCH FACILITY

Plant Description

The Electron Beam Research Facility is located at the Virginia Key (Central District) Wastewater Treatment Plant. It was originally installed as a substitute technology for heat-treatment disinfection of sludge and was declared operational on September 25, 1984. The actual project construction costs at that time were approximately 1.7 million dollars.

The accelerator is a horizontal 1.5 MeV electron beam, rated at 50 mA. The beam current is continuously variable from 0 to 50 mA, providing doses of 0 - 850 krads.

The research facility was designed to treat 460 L/min (120 gpm); however, experiments have been conducted using flows of up to 610 L/min. The minimum flow is approximately 380 L/min (100 gpm). Originally designed to disinfect digested sludge, 2-8% solids, the present configuration allows for several influent streams. The influent streams directly connected to the plant are potable (drinking) water, a secondary wastewater effluent and anaerobically digested sewage sludge. The secondary wastewater is the effluent of an extended (pure oxygen) aeration process. The effluent is chlorinated immediately (0.5 - 1 min.) prior to the intake of the electron beam.

In addition to the three flow streams described above, we have the capacity to conduct large-scale (22,400 L) batch experiments using tank trucks. Batch experiments may be used for groundwater and any other source of contaminated water for which treatability studies are desired. The minimum batch experiment is 7,600 L.

The electron beam (E-Beam) research facility has been instrumented to continuously monitor and record various operating parameters; accelerating voltage, beam current, water flow and absorbed dose. The absorbed dose is measured using five resistance temperature devices (RTDs). The five RTDs are mounted in the influent (2 sensors) and effluent (3 sensors) stream immediately before and after the beam. All of the variables are connected via an interface board (Strawberry, Inc.) to a portable computer (Compaq, Inc.) which continuously reads and records temperatures.

Measurement of Absorbed Dose

Absorbed dose is a measure of energy transfer to the irradiated material, in this case, water. In a continuously flowing aqueous system, the absorbed dose can be estimated by measuring the temperature difference of the water stream before and after irradiation as follows:

$$1000 \text{ Krad} = 1.0 \times 10^8 \text{ erg/g} = 2.39 \text{ cal/g} \tag{16}$$

By converting cal/g to temperature in degrees centigrade, 1000 Krads is equivalent to a temperature change of 2.39°C. Therefore, the total absorbed dose (D_t) in pure water is calculated using the equation:

$$D_t = K(t_2 - t_1) \tag{17}$$

where t_1 and t_2 are the before and after irradiation water temperature of the flowing stream in °C, respectively; and K is the constant of proportionality:

$$K = 418 \text{ krads/°C} \tag{18}$$

The measurement of D_t provides an estimate of absorbed dose in natural waters. A slight error results from the deviation from unit density (pure water) of the natural waters. The application of temperature difference to estimate the absorbed dose in irradiated sludges would result in an error which would increase with increasing solids content.

Electron Utilization Efficiency

It is possible to estimate the electron utilization efficiency of the system at the Electron Beam Research Facility described above. Assuming that the system is operated at full power, i.e., 1.5 MeV and 50 mA, total beam power of 75 kW and a flowrate of 470 L/min, then the efficiency may be determined as follows:

$$1 \text{ W} = 860 \text{ cal/hr} \tag{19}$$
$$75 \text{ kW} = 6.45 \times 10^7 \text{ cal/hr} \tag{20}$$

Assuming that 1 cal results in a 1.0 C increase in temperature per gram, complete conversion of electrical energy (beam power) to heat would result in a D_t of:

$$D_t = 6.45 \times 10^7 \text{ cal/hr} / 2.73 \times 10^7 \text{ mL/hr} = 2.36°C \tag{21}$$

We observed a 1.54°C increase in temperature (645 krads). Therefore, the efficiency of the conversion of beam energy to heat was:

$$\text{efficiency (\%)} = 1.54°C/2.36°C \times 100 = 65.3 \% \tag{22}$$

In limited experiments at high water flowrates, 610 L/min the dose was unchanged, i.e., 645 krads or 1.54°C increase in temperature and the efficiency approached 86%. The reasons for the increase in efficiency probably were related to the more complete absorption of the fast electrons in the solution (increased depth of the water) and at the higher flowrate, the water cascaded over the weir nearer to the electron gun window, reducing energy losses in the air between the window and the water.

^{60}Co GAMMA SOURCE RESEARCH FACILITY

More than 20 years of research have demonstrated the reduction of chemical and microbiological contaminants from aqueous-based systems with ^{60}Co-Gamma radiation.[11,12] ^{60}Co represents an unstable nucleus of cobalt. ^{59}Co, when placed in a reactor, will absorb a neutron and become ^{60}Co:

$$^{59}\text{Co} + {}^1\text{n} ----> {}^{60}\text{Co} \tag{23}$$

As the ^{60}Co returns to a stable condition, it releases mass-energy in the form of one beta particle and two gamma rays. This process results in the stable isotope ^{60}Ni.

$$^{60}\text{Co} ----> {}^{60}\text{Ni} + \beta^- + 2\tau \tag{24}$$

Beta (β) particles are electrons and have very little penetrating ability when released from ^{60}Co.[13] When ^{60}Co is encapsulated in stainless steel, all of the beta particles are stopped and only the highly penetrating gamma rays escape into the surrounding medium. Gamma rays are not deflected by an electric or magnetic field and have no charge. They are electromagnetic waves with extremely short wavelengths and are very penetrating.

Gamma rays in water produce a decomposition of water similar to that observed with high-energy electrons. Interaction of gamma rays and water is on the molecular level and not on the nuclear level. Gamma

rays must possess at least 1.50 MeV of energy to enter a nucleus and even at this elevated energy level, photonuclear cross sections are extremely small.[14] Because gamma rays from ^{60}Co are emitted at energies of 1.17 and 1.33 MeV, residual nuclear activity in the water or wastewater is not observed.

^{60}Co Reactor Description

The ^{60}Co reactor is a 5000 Ci gamma source located at the University of Miami Radiation Control Center. The gamma source is located at the center of concentric circles of 10, 20, 30, 40, 50, 60, 70 and 100 cm. A linear regression of a ln/ln plot of distance versus dose rate was generated to determine the dose rate at any distance from the ^{60}Co source:

$$\ln \text{(dose rate)} = -1.958 \times \ln \text{(distance)} + 13.356 \qquad (25)$$

REMOVAL OF SELECTED ORGANIC CHEMICALS IN AQUEOUS SOLUTION

We have conducted numerous experiments on organic chemicals that may be of interest in: water treatment, trihalomethanes; groundwater contamination, halogenated ethanes and ethenes; leaking underground storage tanks, benzene and substituted benzenes; as well as other organic chemicals now regulated as hazardous wastes. Before presenting removal efficiencies, a brief discussion and summary of the rate constants is presented for the compounds that have been studied or are of interest in the area of toxic and hazardous wastes.

Rate Constants

The rate constants of interest are those for the reaction of the reactive intermediates formed when water is irradiated (Equation 1), e^-(aq), H· and OH·. with toxic and hazardous organic chemicals and inorganic chemicals likely to be found in natural waters. A review of the literature[10] for selected rate constants applicable to toxic and hazardous wastes is summarized in Table 3.

Removal Efficiencies

Most of the results shown below, conducted on a large-scale treatment facility, appear to be qualitatively explained using available rate constants. However, other results do not fit the available rate data. These differences are not surprising given that the rate data reported in the literature usually are obtained in pure solutions under controlled experimental conditions. Thus, there may be several reasons for the apparent discrepancies. First, all of the experiments have been conducted in raw or secondary treated wastewater or potable water. These waters are of widely varying (water) quality and present a complex matrix for detailed examination of removal data. Secondly, not all of the applicable rate constants are known for the compounds of interest.

To date, the only compound which has been studied at both the Electron Beam Research Facility and the ^{60}Co Research Facility is chloroform. Chloroform is listed as the sixth most frequently identified substance at 546 Superfund Sites (Table 1). Others have reported studies using electron and gamma irradiation of aqueous solutions of chloroform.[15,16] We have observed removal efficiencies of CHCl$_3$ of approximately 99.9% in distilled water (Figs 1 and 2) using ^{60}Co irradiation. This removal was not affected by the initial concentration of CHCl$_3$ when it was varied from 125 to 1250 ug/L. At the electron beam research facility, similar studies were conducted using potable water (Figs. 3 and 4). Experiments not shown in secondary and raw wastewater have shown removal efficiencies of 85 - 95%.

A proposed mechanism for the decomposition of CHCl$_3$ and the formation of reaction byproducts has been suggested:[16]

$$e^-(aq) + CHCl_3 \quad \longrightarrow \quad Cl^- + CHCl_2 \qquad (26)$$
$$H + CHCl_3 \quad \longrightarrow \quad H_2 + CCl_3 \qquad (27)$$
$$\longrightarrow \quad HCl + CHCl_2 \qquad (28)$$
$$OH + CHCl_3 \quad \longrightarrow \quad H_2O + CCl_3 \qquad (29)$$
$$CHCl_2 + H_2O \quad \longrightarrow \quad CHO + 2HCl \qquad (30)$$
$$CCl_3 + 2H_2O \quad \longrightarrow \quad COOH + 3HCl \qquad (31)$$
$$COOH + COOH \quad \longrightarrow \quad HOOC\text{-}COOH \qquad (32)$$

$$\longrightarrow \quad HCOOH + CO_2 \qquad (33)$$
$$CHO + HCCl_3 + H_2O \longrightarrow CHCl_2 + HCOOH + HCl \quad (34)$$
$$H + CHCl_3 \quad \longrightarrow \quad CH_2Cl_2 \qquad (35)$$
$$CHCl_2 + CHCl_2 \quad \longrightarrow \quad CHCl_2CHCl_2 \qquad (36)$$
$$CCl_3 + CHCl_2 \quad \longrightarrow \quad CCl_3CHCl_2 \qquad (37)$$
$$CCl_3 + CCl_3 \quad \longrightarrow \quad CCl_3CCl_3 \qquad (38)$$
$$H + CHO \quad \longrightarrow \quad HCHO \qquad (39)$$
and in solutions with high O_2 concentrations the following reactions are also possible:

$$CHCl_3 + O_2 \quad \longrightarrow \quad O_2CHCl_3 \qquad (40)$$
$$CCl_3 + O_2 \quad \longrightarrow \quad O_2CCl_3 \qquad (41)$$
with the exact fate of these radicals unknown.

The major differences between the work which resulted in the above reaction mechanism[16] and our work are: (1) the concentration of the CHCl$_3$ was 70 mm, whereas the concentration range we have been studying is 1000-fold less and (2) the irradiation doses we use are up to 100-fold higher. In our studies, conducted at low solute concentrations, none of the halogenated reaction byproducts have been observed. The liquid-liquid extraction method used for the quantification of the CHCl$_3$ would also have determined the presence of the chlorinated ethanes at detection limits of 0.01 μL. The authors[12] found that the presence of O_2 enhanced the decomposition of the CHCl$_3$. This finding is important because many of the systems in which this process potentially will be used involve solutions which will have been aerated or at least contain some O_2.

Table 3
Rate Constants (1/m. sec.) of Selected Organic Chemicals and the Free Radicals Formed in Irradiated Aqueous Solution[10]

Compound	$e^-_{(aq)}$	$H\cdot$	$OH\cdot$
Benzene	9.0×10^8	9.1×10^8	7.8×10^9

p-Xylene	NF	3.2×10^9	7.0×10^9

Many experiments conducted at low pH.
NF = not found.

Whether the above mechanism describes the actual breakdown process in natural waters will never be known quantitatively. The importance of the above mechanism (Equations 26-41) is that it provides a point of departure for determining other possible reaction products. We have observed, in preliminary research, that oxidized organic compounds, such as formaldehyde, are formed. Continuing research is underway using analytical methods for the determination of very low concentrations of aldehydes and carboxylic acids.

Another group of organic chemicals that have been studied at our treatment facility are the halogenated solvents. The compounds most commonly found are trichloroethylene (TCE) and tetrachloroethylene (PCE). Radiation-induced decomposition of TCE in aqueous solutions has been the subject of several recent studies.[17-22] An example of the removal efficiency we have obtained in raw wastewater is shown in Figure 5. In most of the referenced studies conducted to date, the complete destruction of TCE was observed. Although the preliminary data indicated a relationship between removal efficiency and second order reaction rate constants of OH·, it is also possible that the e⁻(aq) may be in part responsible for the removal of TCE. We have also conducted studies on the removal of tetrachloroethylene in secondary chlorinated wastewater (Figure 6).

POTABLE WATER

Figure 3
Removal of CHCL$_3$, using ^{60}Co, at several irradiation doses in distilled water at an initial concentration of approximately 100 ug/L (error bars indicate one standard deviation from mean, where no error bars are seen the error is within the data point)
DISTILLED WATER

Figure 1
Removal of CHCL$_3$, using ^{60}Co, at several irradiation doses in distilled water at an initial concentration of approximately 125 ug/L (error bars indicate one standard deviation from mean, where no error bars are seen the error is within the data point)

POTABLE WATER
Figure 4
Removal of CHCL^3, using the Electron Beam Research Facility, at several irradiation doses indistilled water at an initial concentration of approximately 600 ug/L error bars indicate one standard deviation from mean, where no error bars are seen the error is within the data point)

DISTILLED WATER

Figure 2
Removal of CHCL$_3$, using ^{60}Co, at several irradiation doses in distilled water at an initial concentration of approximately 1250 ug/L (error bars indicate one standard deviation from mean, where no error bars are seen the error is within the data point)
RAW WASTEWATER

Figure 5
Removal of TCE at several irradiation doses in raw wastewater (error bars indicate one standard deviation from mean, where no error bars are seen the error is within the data point)
Figure 6
Removal of PCE at several irradiation doses in
secondary wastewater (error bars indicate one standard
deviation from mean, where no error bars are seen the error
is within the data point)

Considerable research has also been reported on the irradiation of aqueous solutions of PCE.[17-20, 22-25] As with TCE, it appears that complete destruction occurs as evidenced by chloride ion mass balance. This observation, insofar as loss of the parent compound PCE, has been confirmed in our studies in potable water. In secondary wastewater, removal was < 95% while in raw wastewater the removal was > 95% (Fig. 6). It is remarkable that there is little, if any, difference in the removal efficiency of PCE in raw and secondary wastewater. A possible explanation of this phenomenon is that the presence of relatively high concentrations of organic compounds in these two waters results in less recombination of the e⁻(aq) and OH⁻. By reducing the recombination of these two species, their effective concentrations in solution increase and result in similar removal efficiencies. Mechanisms for the destruction of both TCE and PCE have been proposed and presently are under investigation in continuing studies.

Another example of a removal efficiency using high energy electron irradiation is shown in Figure 7 for carbon tetrachloride. This chemical is persistent in subsurface environments and is not effectively treated using other oxidation processes. High energy electron irradiation appears to be an excellent choice for its destruction.
Figure 7
Removal of carbon tetrachloride at several irradiation doses in
secondary wastewater (error bars indicate one standard
deviation from mean, where no error bars are seen the error
is within the data point)

A third group of compounds which we have studied are benzene and substituted benzenes. Numerous studies have been reported on the effect of irradiation of aqueous solutions of benzene.[26-33] In other studies

we have also shown that benzene is very effectively removed from an oxygenated secondary wastewater effluent. Shown in Figures 8 and 9 are the removal efficiencies of chlorobenzene and ethylbenzene in secondary wastewater. We have shown that at low irradiation doses, phenols are formed. However at higher doses, these compounds are removed with a net removal of total phenols of approximately 50%. We also were able to identify formaldehyde and glyoxal in sub-μM concentrations in several samples. Several other aldehydes were observed, but the structures of these reaction products have not yet been determined. Additional studies are underway to determine all of the reaction byproducts.
Figure 8
Removal of chlorobenzene at several irradiation doses in
secondary wastewater (error bars indicate one standard
deviation from mean, where no error bars are seen the error
is within the data point)
Figure 9
Removal of ethylbenzene at several irradiation doses in
secondary wastewater (error bars indicate one standard
deviation from mean, where no error bars are seen the error
is within the data point)

CONCLUSIONS

The results reported here are part of an ongoing project which will extend the data base to other chemicals of concern to Superfund. The use of high energy electron beam irradiation appears to be an efficient process for the destruction of all organic compounds of interest in site remediation.

ABSTRACT

This paper discusses the design and initial operation of the U.S. EPA's Mobile Volume Reduction Unit (VRU) for soil washing. Soil washing removes contaminants from soils by dissolving or suspending them in the wash solutions (which can be treated later by conventional wastewater treatment methods) or by volume reduction through simple particle size separation techniques. Contaminants are primarily concentrated in the fine-grained (0.0025 inches) soil fraction. The VRU is a pilot-scale mobile system for washing soil contaminated with a wide variety of heavy metal and organic contaminants. The unit includes state-of-the-art washing equipment for field applications.

The VRU equipment was originally conceived by the U.S. EPA. It was designed and fabricated by Foster Wheeler Enviresponse, Inc. under contract to U.S. EPA's Risk Reduction Engineering Laboratory (RREL) in Edison, New Jersey, with the following objectives:

- To make available to members of the research community and to the commercial sector the results of government research on a flexible, multistep, mobile, pilot-scale soil washer capable of running treatability studies on a wide variety of soils
- To demonstrate the capabilities of soil washing
- To provide data that facilitate scale-up to commercial size equipment

The design capacity of the VRU is 100 lb/hr of soil, dry-basis. The VRU consists of process washing equipment and utility support services mounted on two heavy-duty semitrailers. The process trailer equipment accomplishes material handling, organic vapor recovery, soil washing, coarse soil screening, fine particle separation, flocculation/clarification and steam generation via a boiler. The utility trailer carries a power generator, a process water cleanup system and an air compressor. The VRU is controlled and monitored by conventional industrial process instrumentation and hardware.

Shakedown operations are currently in progress, and future plans include testing U.S. EPA-produced synthetic soil matrix (SSM) spiked with specific chemical pollutants. The addition of novel, physical/chemical treatment processes, such as sonic/ultrasonic cleaning and acid leaching, will expand the VRU's extraction capability in soil decontamination.

INTRODUCTION

Section 121(b) of the CERCLA mandates the U.S. EPA to select remedies that "utilize permanent solutions and alternative treatment technologies or resource recovery technologies to the maximum extent practicable" and to prefer remedial actions in which treatment "permanently and significantly reduces the volume, toxicity, or mobility of hazardous substances, pollutants and contaminants as a principal element."

In most cases, soil washing technologies are used in conjunction with other remedial methods for the separation/segregation and volume reduction of hazardous materials in soils, sludges and sediments. In some cases, however, the process can deliver the performance needed to reduce contaminant concentrations to acceptable levels and, thus, serve as a stand-alone technology. In treatment combinations, soil washing can be a cost-effective step in reducing the quantity of contaminated material to be processed by another technology, such as thermal, biological or physical/chemical treatment. In general, soil washing is more effective on coarse sand and gravel; it is less successful in cleaning silts and clays.

A wide variety of chemical contaminants can be removed and/or concentrated through soil washing applications. Removal efficiencies depend on both the soil characteristics (e.g., soil geology and particle size) and the processing steps contained within the soil washer. Experience has shown that volatile organics can be removed with 90+% efficiency. Semivolatile organics are removed to a lesser extent (40-90%). They usually require the addition of surfactants to the washwater. Surfactants are surface-active or wetting agents that reduce the surface tension at the interface between the hydrophobic contaminants and the soil, thereby promoting release of the contaminants into the aqueous extraction medium.

Metals which are less soluble in water often require acids or chelating agents for successful soil washing. A chelating agent, such as ethylenediaminetetraacetic acid (EDTA), bonds with the metal and facilitates solubilization in the extraction medium.

The VRU process can be applied to the treatment of soils contaminated with hazardous wastes such as wood preserving chemicals (pentachlorophenol and creosote), electroplating residues (cyanides and heavy metals), organic chemical production residues and petroleum/oil residues. The applicability of soil washing to general contaminant groups and soil types, which is shown in Table 1, has been reproduced from a U.S. EPA report, "Treatment Technology Bulletin - Soil Washing," dated May 1990.

The U.S. EPA has developed the VRU to meet the following objectives:

- To make available to members of the research community and to the commercial sector the results of government research on a flexible, multistep, mobile, pilot-scale soil washer capable of running treatability studies on a wide variety of soils
- To demonstrate the capabilities of soil washing
- To provide data that facilitate scale-up commercial size equipment

The U.S. EPA plans to investigate other extraction processes which may be added to the VRU at a later data. The addition to the VRU of novel physical/chemical treatment processes, such as sonic/ultrasonic

cleaning and acid leaching, will expand its overall extraction capability in soil decontamination.

□ Not Applicable: Expert opinion that technology will not work

SYSTEM DESCRIPTION

The VRU is a mobile, pilot-scale washing system for stand-alone field use in cleaning soil contaminated with hazardous substances. The VRU is designed to decontaminate certain soil fractions using state-of-the-art washing equipment. The total system consists of process equipment and support utility systems mounted on two heavy-duty, semitrailers.

Figure 1, General Block Diagram, shows the VRU basic pilot plant subsystems as follows:

- Soil handling and conveying
- Organic vapor recovery
- Soil washing and coarse screening
- Fines/floatables gravity separation
- Fines flocculation/water clarification and solids disposal
- Water treatment
- Utilities - electric generator, steam boiler and compressed air unit

The generator, air compressor, water heater, water filters/carbon adsorbers, recycle water pump, gasoline tank (for the generator) and delisting tank are located on the utility trailer. All remaining equipment is located on the process trailer. The VRU system is controlled and monitored by conventional industrial process instrumentation and hardware, including safety interlocks, alarms and shutdown features.

PROCESS DESCRIPTION

Figures 2, 3 and 4 present the Process Flow Diagram for all VRU subsystems in terms of their process equipment functions.

Soil Handling and Conveying

Raw soil is delivered from battery limits to a vibrating grizzly that separates the particles greater than 0.5 inches into a drum for redeposit and collects the smaller particles (-0.5 inches +0) for transfer to the feed surge bin. (The maximum particle size that can be handled in the miniwasher is 0.5 inches, but smaller screen sizes may be selected.) From this bin, the soil less then 0.5 inches in size is conveyed through a steam-jacketed screw conveyor where the volatile organics and water are vaporized. Both live steam and jacketed steam can be introduced so that the efficiency of the steam extraction can be determined. The conveyor flow is adjusted by a speed controller on the conveyor motor. The solids pass through a motor-operated rotary valve (which prevents air infiltration), then into the feed hopper of the mini-washer.

Organic Vapors Recovery

Volatiles stripped from the soil in the screw conveyor are either collected in the VOC condenser and fall by gravity into the process condensate seal tank or are adsorbed in vapor-phase activated carbon containers located upstream of the vent blower.

The spent carbon will be periodically replaced based on vent gas analyses. The vapor train is maintained under vacuum by an induced draft blower. The vacuum level is adjusted by manual admittance of atmospheric air upstream of the blower to maintain a slight negative pressure on the vapor system. Clean vapors, leaving the blower, vent to the atmosphere.

Soil Washing and Coarse Screening

Soil is fed to the miniwasher at a controlled rate of approximately 100 lb/hr by the screw feeder. Filtered washwater, which can be heated to 150 °F (maximum), is added to soil in the feed hopper and also sprayed onto an internal slotted trommel screen (with a 10-mesh (0.079 inches) slot opening) miniwasher. Five manually controlled meters can control the flow up to approximately 10:1 overall weight ratio water to soil. Hot water should be more efficient in extracting contaminants, but heating is optional. When required, dilute surfactant/detergent and/or caustic can be metered at a controlled rate into the feed hopper.

Two vibrating screens, equipped with antiblinding devices, are provided to continuously segregate soil into various size fractions. These screened fractions can be collected to measure the effectiveness of contaminant removal for each soil fraction recovered and to determine the effectiveness of soil washing in cleaning a particular contaminated soil fraction to achieve sufficient volume reduction.

Miniwasher overflow, containing the coarser solids, falls onto the first 10-mesh (0.079 in/2 mm) vibrascreen. First vibrascreen overflow (-0.5 inches + 10 mesh) solids flow by gravity down to a recovery drum. The underflow is pumped at a controlled rate, using a progressing cavity pump, onto the second 60-mesh (0.0098 in/0.25 mm) vibrascreen where it is joined by the miniwasher underflow.

The overflow from the second vibrascreen (- 10-mesh + 60-mesh), is gravity fed to another recovery drum. Second vibrascreen underflow (a fines slurry) drains into an agitated tank. The VRU is designed with the following flexibility:

- The mesh sizes for both the miniwasher and vibrascreens can be varied [i.e., the screen size could be 20- or 30-mesh (0.033 inches or 0.023 inches)].
- Additional soil cleaning by use of water sprays or steam sprays will be evaluated for each vibrascreen.
- Screened soil fractions, collected in the recovery drums, can be redeposited if sufficiently cleaned or further cleaned by addition of rinse water, followed by reslurrying and pumping the slurry back over the screens (recycle mode). In the future, these soil fractions will be sent for treatment by various extraction units currently under development by U.S. EPA's RREL in Edison, New Jersey.

Fines/Floatables Gravity Separation

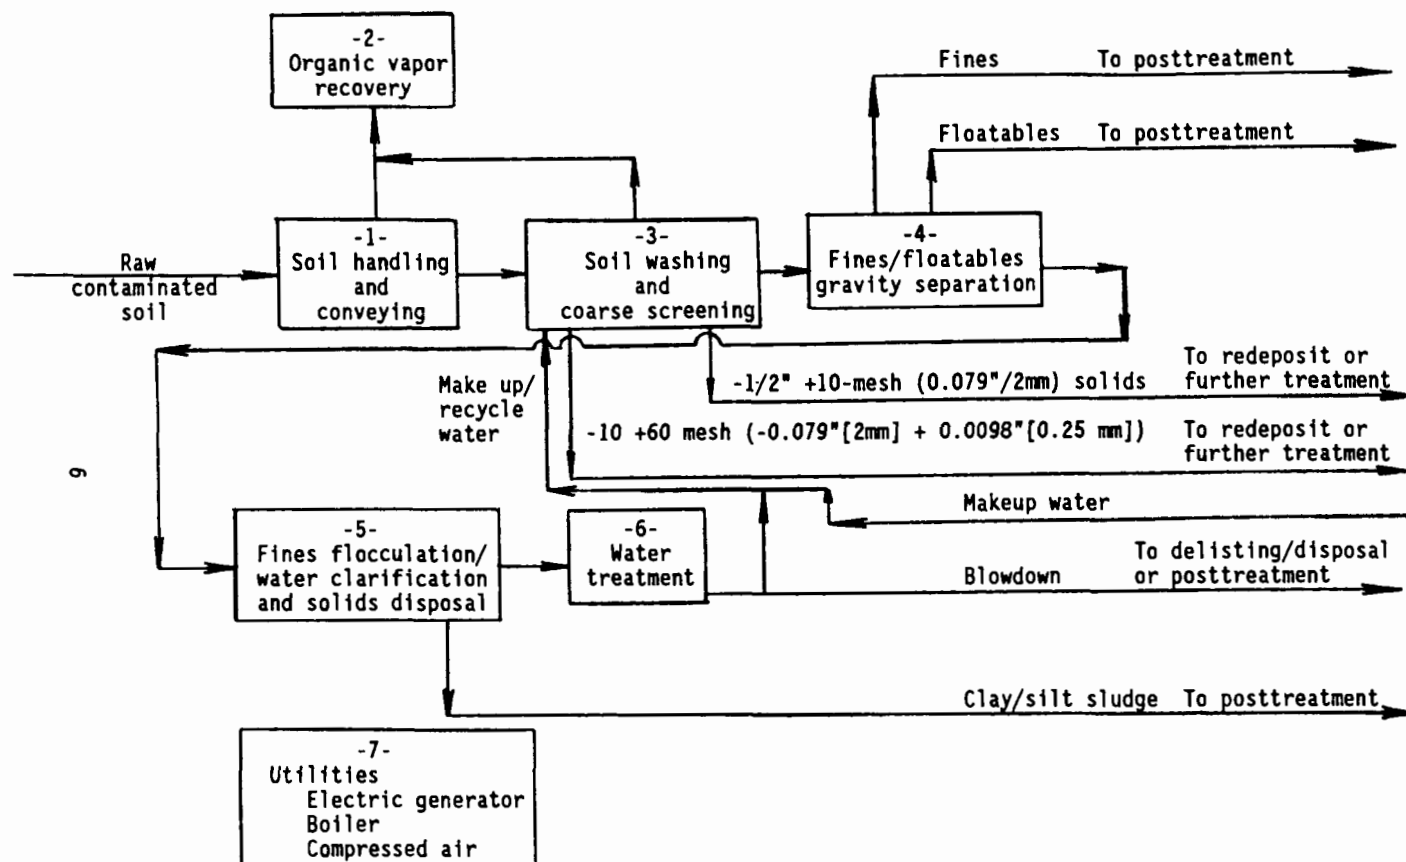
Slurry from the second screen (fines slurry) tank, containing particles less than 60-mesh (0.0098 inches/0.25 mm) in size, is pumped to a Corrugated Plate Interceptor (CPI). Material lighter than water


Figure 1
General Block Diagram

(floatables such as oil) will overflow an internal weir, collect in a compartment within the CPI and drain by gravity to a drum for disposal. CPI-settled solids [soil particles - 60- to about 400-mesh (- 0.0098 inches to about 0.0015 inches)] will be discharged by the bottom auger to a recovery drum. The VRU has the flexibility to redeposit or further clean these settled soils, if required, by addition of rinse water followed by pumping the slurry back through the CPI. As mentioned above, these soils could also be sent, in the future, to an extraction unit.

Fines Flocculation, Water Clarification and Solids Disposal

Aqueous slurry, containing fines less than about 400-mesh (34 um/0.0014 inches), overflow the CPI and gravity feed into an agitated tank. The slurry is then pumped to a static flash mixer located upstream of the floc clarifier's mix tank. Flocculating chemicals are introduced into this static flash mixer. Typically, liquid alum and aqueous polyelectrolyte solutions are metered into the static flash mixer to neutralize the repulsive electrostatic charges on colloidal particles (clay/humus) and promote coagulation. The fines slurry is discharged into the floc chamber which has a varispeed agitator for controlled floc growth (sweep flocculation). Sweep flocculation refers to the adsorption of fine particles onto the floc (colloid capture) and continuing floc growth to promote rapid settling of the floc and its removal from the aqueous phase. The floc slurry overflows into the clarifier (another corrugated plate unit). Bottom solids are gravity fed by an auger to a drum for disposal, or to the sludge slurry tank (depending on solids concentration) for subsequent concentration in a filter package unit. Concentrated cake from the filter is discharged to another drum for disposal. This system has the ability to clarify the process water and dewater the sludge. The efficiency of solids dewatering can be determined and cost savings estimated, for trucking waste sludge to a disposal/treatment site.

Water Treatment

Clarified water is polished with the objective of reducing suspended solids and organics to low levels that permit recycle of spent washwater. Water is pumped from the floc settler overflow tank at a controlled rate through cartridge-type polishing filters operating in parallel, in order to remove soil fines greater than 10-um (3.94×10^{-4} inches). One um (3.9×10^{-5} inches) cartridges are available, if required.

Water leaving the cartridge filter flows through activated carbon drums for removal of hydrocarbons. The carbon drums may be operated either in series or parallel and hydrocarbon breakthrough monitored by sampling. A drum will be replaced when breakthrough has been detected.

In order to recycle water and maintain suitable dissolved solids and organic levels, aqueous bleed (blowdown) to the boiler delisting tank may be initiated at a controlled rate. Delisted material will be sealed in drums and sent for disposal in accordance with respective state and local regulations. Treated recycle (recovered) water is sampled for analysis before it flows into the process water storage tank. Supplementary water is fed into this tank from a tank truck. Recovered and added water is pumped by the water recycle pump (and optionally fed to the water heater) for subsequent feed to the miniwasher. A side stream from the water recycle pump is utilized as cooling water in the VOC condenser and either returned to the process water storage tank or sent to the sewerage system.

Utilities Systems

The VRU is equipped with a steam boiler, electric generator and a compressed air system.

Field Operations

While in the field, the VRU would be supported by a decontamina-

tion trailer, a mobile treatability laboratory/office and a storage trailer for supplies, spare parts, miscellaneous tools, etc.

SUMMARY OF VRU FEATURES

Listed below are the various features, operational parameters and capabilities of VRU:

- The VRU is a mobile, pilot-scale washing system for field use in cleaning soil contaminated with hazardous materials, using state-of-the-art washing equipment and support utilities.
- The unit has the ability to remove VOCs by steam heating and stripping.
- It is capable of washing with water (in combination with surfactants/detergents) up to a 10:1 water to soil ratio while also varying water temperature from ambient to 150°F.
- The miniwasher screen and vibrascreens can be varied in mesh size. Additional use of soil cleaning by water or steam sprays on the vibrascreen decks can be evaluated.
- Four screened soil fractions (including CPI-settled solids) can be further cleaned by slurrying with the addition of rinse water and recycling the slurry over the vibrascreens or the CPI.

- The floc-clarifier system has the ability to clarify the process water and dewater the sludge.
- Additional treatment of the clarified process water through polishing filters and activated carbon should allow, in most cases, reuse of this water as recycle to the washing circuit.
- Side streams from the VRU will be treated using various physical/chemical extraction units currently under development by U.S. EPA.
- The VRU offers a unique method for conducting treatability studies on various contaminated soils.

Baird and McGuire Superfund Site:
Design of a GWTP Fume Collection and Treatment System

Cinthia L. Rudasill, P.E.
Mary E. Doyle
Metcalf and Eddy, Inc.
Hazardous Waste Division
Wakefield, Massachusetts

ABSTRACT

A groundwater extraction system and treatment plant has been designed by Metcalf and Eddy to restore groundwater quality at the Baird and McGuire Superfund Site in Holbrook, Massachusetts. The site, which formerly housed chemical mixing and batching operations, currently ranks 14th of 989 sites on the NPL.

The groundwater at the site has been contaminated with metals, (including arsenic and lead), volatile and semivolatile organics and pesticides. Included among the VOCs found in the groundwater are vinyl chloride, methylene chloride, trans-1, 2-dichloroethane, benzene, toluene and xylenes. The groundwater treatment plant will treat 200 gpm of contaminated groundwater by a series of unit operations including metals precipitation, biological treatment, filtration and granular activated carbon adsorption.

Due to the high concentration of VOCs present in the groundwater, the need for collection and treatment of contaminated air from the process tanks located inside the treatment plant building and from the biological aeration tanks located outside was assessed to ensure the safety of the treatment plant operators and the surrounding community. In order to determine whether collection and treatment of the air would be necessary, the OSHA permissible exposure limits (PELs) of the contaminants and Henry's Law constants were reviewed. Additionally, samples of air emissions were collected during bench-scale treatability testing and submitted to an analytical laboratory for VOC analysis by GC/MS. Test results confirmed the need for collection and treatment of air from all process tanks through the treatment train up through biological aeration.

Two methods of off-gas treatment were considered; fume incineration and vapor-phase carbon adsorption. Fume incineration was selected since this process provides essentially complete destruction of the VOCs without producing a waste byproduct. An air collection system was designed to collect the contaminated air from the plant and aeration tanks and feed it to a 1,000-cfm incinerator. The incinerator will be fueled by natural gas and operate at a minimum temperature of 1,400°F.

INTRODUCTION

The Baird and McGuire Superfund site currently ranks 14th of 989 sites on the NPL. Baird and McGuire, Inc., operated a chemical mixing and batching facility in Holbrook, Massachusetts, for more than seventy years. Operations at the facility included production of household and industrial products such as floor waxes, wood preservatives, pesticides and solvents,[1] and resulted in widespread contamination of the Baird and McGuire property, and the surrounding property by numerous toxic organic and inorganic compounds. In September, 1986, following a number of investigations, the U.S. EPA issued the ROD for the Remedial Alternative for the site. Included in the ROD was remediation of con-

taminated groundwater by metals precipitation, biological treatment and carbon adsorption. The ROD also included remediation of soil by incineration.

Site Contamination

Investigations have been conducted at the Baird and McGuire site by several parties including consultants for Baird and McGuire, Inc., the town of Holbrook, the U.S. EPA, the Massachusetts Department of Environmental Quality Engineering, Goldberg-Zoino Associates[2] and GHR Engineering Associates. Most recently, Metcalf and Eddy conducted a comprehensive groundwater sampling effort to provide support for design activities. The analytical data from this sampling round documented extensive groundwater contamination by metals, semivolatile and VOCs and pesticides.

VOCs were of special interest in the design of the groundwater treatment plant since the need for fume collection and treatment, as well as removal of these constituents from the groundwater, had to be assessed. The VOCs detected in the groundwater during the most recent phase of sampling are shown in Table 1.

DESIGN OF THE GROUNDWATER TREATMENT PLANT

As part of the Baird and McGuire site remediation, Metcalf and Eddy designed a groundwater treatment plant (GWTP). The plant was designed to produce an effluent which will meet drinking water stan-

dards as is required for infiltration to the aquifer. The standards are specified by the federal Safe Drinking Water Act (SDWA) Maximum Contaminant Levels (MCLs) or the Massachusetts Groundwater Quality Standards, whichever is lower. The plant was designed to treat 200 gpm of groundwater contaminated with metals, volatile and semiVOCs and pesticides. Treatment processes include two-stage metals precipitation, biological treatment by activated sludge process, filtration and granular activated carbon adsorption.

During predesign activities conducted by M and E to confirm or develop design parameters, it was determined that the need for controls to eliminate volatile emissions during GWTP operations had to be assessed. This measure was not required to comply with the ROD since, unlike off-gas from an air stripper, off-gas from a biological aeration tank does not require treatment under Massachusetts regulations.

Predesign Activities

The predesign activities, which were conducted as part of the design effort, included a groundwater pumping test and a bench-scale treatability study. These investigations developed data for the design of the groundwater extraction system and confirmed the ability of the proposed treatment processes to meet the discharge limitations; the treatability study developed treatment system design data. Water produced during the pumping test was temporarily stored on-site in an open 300,000-gallon above ground tank. Due to past odor problems, community concern and the potential for health impacts, a review of the need for temporary controls to prohibit release of VOCs from the tank to the atmosphere was conducted at this time.

The review was conducted to evaluate airborne VOC concentrations in the vicinity of the tank and at the property boundary. Henry's Law was used to estimate the concentration of contaminants in the air at the air/water interface, and a simple U.S. EPA dispersion model was used to estimate contaminant concentrations at the property boundary. The estimated air concentrations were then compared with OSHA permissible exposure limits (PELs) and what was then called Massachusetts proposed allowable ambient levels (AALs). Only organic contaminants that had been defined as critical in the public health risk assessment, conducted as part of the Feasibility Study,[4] and which had been detected in the groundwater were included in the evaluation. Conservative assumptions were used in this comparison, including maximum measured contaminant concentrations, high ambient temperature for the time of year the pumping test would run (77 °F) and low wind speeds (1 m/sec to 2 m/sec). In addition, comparing a water/air interface concentration with an OSHA PEL is very conservative, since the concentration where workers are exposed should be lower.

The evaluation determined that five contaminants were greater than the OSHA PELs indicating the potential to exceed PELs in the vicinity of the tank and that 12 to 14 of the compounds exceeded the AALs. The estimated property boundary concentrations were as high as 1,000 times the state AAL. This evaluation was based on very conservative assumptions; however, concentrations up to 1000 times the state's AALs indicate the potential for contaminants to volatilize from an uncovered tank at concentrations above AALs even under less conservative conditions than those used in the models. The results of this evaluation, as well as the concern for potential odors, indicated the need to install a floating cover on the 300,000-gallon tank. The evaluation also indicated a need to incorporate emissions controls into the design of the full-scale treatment plant. A program for measuring loss of volatiles from the groundwater to the air was incorporated as part of an ongoing bench-scale treatability testing program. The goal of the sampling program was to quantify volatile contaminants that would pose a threat to the operators of the proposed GWTP and the surrounding community.

Two methods were used to determine quantities of volatiles being transferred from the water to the air. The first calculation involved a simple mass balance around a batch aerated tank. Loss of volatiles to the air was determined by measuring VOCs in the waste before and after aeration over a 4-hour test period.

The second method involved the collection of air samples from two covered tanks, one unaerated and one aerated, over a measured period

of time. An aeration tank containing biomass from activated sludge test was used as the aerated test vessel. The biomass was added to the tank in order to help account for loss of VOCs due to biodegradation. Contaminated groundwater was added to the tank and a sample of the contaminated air was collected using a volatile organic sampling train (VOST).

The VOST consists of a series of vapor traps, condensers and a vacuum pump that allow vapor to flow through the apparatus and capture organic contaminants in a trap containing a carbon medium. The apparatus was set up to draw samples from an exhaust stack stemming from each of the enclosed tanks. Air was sampled for 0.5 rh at a rate of 1 L/min, which equaled the diffused air flow rate into the test aeration tank. A vent in the tank cover allowed the flow of air into the test apparatus.

The results of the mass balance around the aerated tank are shown in Table 2. These data indicate that at an air flow rate of 1 L/min, 15 L of waste yield 82.5 mg of volatile compounds over the 4 hour test period. This amount equals 344 mg/m³ of VOCs leaving the aeration tanks. Analytical results could not be obtained for the samples collected by the VOST method since VOC concentrations on the carbon collection media were higher than the GC/MS calibration limits for the test. This result indicated that the air VOC concentrations were extremely high.

Table 2
VOCs Concentrations in Groundwater
Before and After Aeration

Parameter	Concentration (ug/l)(*)	
	Raw Groundwater	Aerated Groundwater
Trans-1,2-dichloroethane	1100	21
Benzene	160	1.6
Toluene	900	9.6
Ethylbenzene	660	4.5
Total Xylene	2700	33
Total Volatiles	5520	69.7

* Only volatile organics detected in the test sample have been reported.

Test Conclusions

Results of the mass balance indicated that loss of VOCs to air would be high enough to warrant the collection of fumes off the GWTP aeration tanks and the application of Best Available Control Technology to the contaminated air collected from the tanks. In addition, since all process tanks that precede the activated sludge process were to be located inside a building, a decision was made to cover the tanks and collect the contaminated air in the tank head-space for treatment as well, in order to ensure operator safety.

Design of the Fume Collection and Treatment System

Based on the test results and the sampling data presented in Table 1, a fume collection and treatment system was designed. Two methods of off-gas treatment were considered for the full-scale GWTP; fume incineration and vapor-phase carbon adsorption.

The two alternatives were evaluated based on their ability to remove or destroy the contaminants of concern, their applicability to the Baird and McGuire site and cost. A technical evaluation of the two alternatives indicated that carbon has low adsorption capacity for several of the contaminants of concern, including methylene chloride and vinyl chloride. This finding was of particular concern due to the potential for high concentrations of some of these organics in the air. Incineration, under proper operating conditions, will result in virtually complete destruction of all the organics of concern, regardless of concentration.

An additional consideration evaluated was community reaction to the two alternatives. Due to the low adsorption capacity of carbon for some of the contaminants and the potentially high concentrations expected in the air stream, frequent carbon replacement or on-site steam regeneration would be required. Replacement or regeneration would result in additional traffic to and from the site through the bordering residential area, either delivering and removing carbon, or removing the concen-

trated solvent waste that would result from regeneration. The community's reaction to another incinerator on the site was of concern.

Table 3
Cost Comparison

	Carbon Adsorption	Incineration
Design Basis:	1,000 cfm 1,000 lbs carbon/adsorber	1,000 cfm 1,400 °F
Capital Cost	$110,000[1]	$ 90,000
Annual Operating Cost	$ 45,000	$ 20,000
Net Present Value[2]	$452,000	$242,000

1. Includes adsorbers and steam regeneration system
2. Present value assumes an annual interest rate of 10% over a 15 year project life.

However, it was found that any increase in traffic, particularly if the vehicles would be transporting hazardous materials, seemed to be of

groundwater into the air, the tendency of some of the VOC contaminants found in the groundwater to deplete the capacity of carbon at a high rate and the need for disposal or on-site regeneration of carbon with regenerant disposal, the fume incineration option was selected. This option will provide essentially complete VOC destruction without producing a waste byproduct requiring disposal.

All process tanks preceding and including the biological aeration tanks and clarifiers were covered, and exhaust gas from these tanks were vented at a rate of 800 to 1000 cfm through FRP ductwork and fans to a fume incinerator located outside the treatment plant building. FRP was selected due to the presence of chlorinated organics. Vents were included in the tank covers to allow air to be drawn by two induced-draft fans to the incinerator. A process flow diagram is shown in Figure 1.

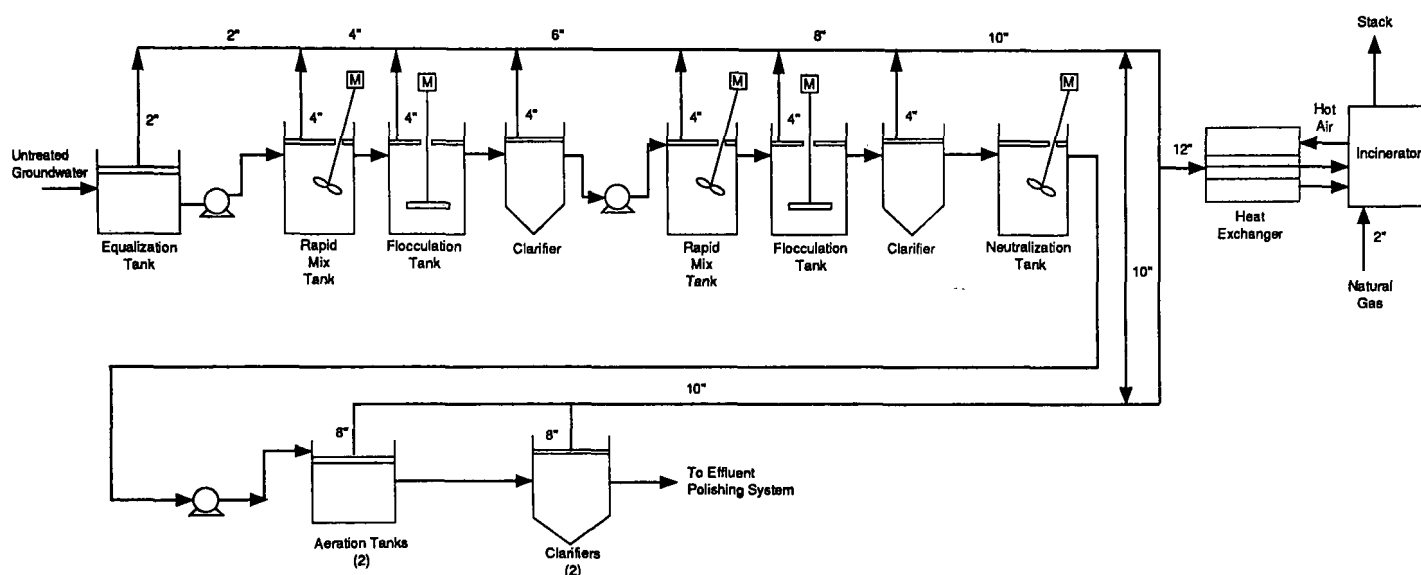
Due to the low BTU value of the contaminated air and aeration tank off-gas, an air-to-air heat exchanger was included to recover heat from the incinerator stack gas to preheat the incoming air to approximately 700 °F. The VOC contaminants will be thermally oxidized in the incinerator at a minimum temperature of 1400 °F. The system is design to achieve 99.99% destruction of organics. The incinerator burner will be fueled by natural gas.


Figure 1
Process Flow Diagram

greatest concern to the surrounding community.

Finally, incineration was found to be the more economical solution for treating the contaminated air at this site. Although equipment costs of the two proposed alternatives are comparable and both use fairly low maintenance equipment, the need to frequently replace or regenerate the carbon drives up the operating cost of this process. A cost comparison is presented in Table 3.

CONCLUSIONS

Due to the potentially high concentration of VOCs removed from the

Chemical Oxidation of Dissolved Organics Using Ultraviolet-Catalyzed Hydrogen Peroxide

Frederick E. Bernardin, Jr.
Emery M. Froelich
Peroxidation Systems, Inc.
Tucson, Arizona

INTRODUCTION

The development of the perox—pure™ UV/Peroxidation process was started in the late 1970s. Today, while there are more than 30 full-scale treatment units in operation or in the final stages of design and installation, the development and improvement of the process is continuing.

This advanced oxidation process using ultraviolet (UV) light-catalyzed hydrogen peroxide is a cost-effective treatment for a wide array of organic compounds found in contaminated groundwater, toxic waste leachates and industrial wastewaters. Recent improvements in the perox-pure™ Process have reduced the operating cost for total destruction of these toxic organics by up to 50%. In addition, the oxidation rate of many of the "difficult to oxidize" compounds such as 1,1,1-trichloroethane (TCA), 1,1-dichloroethane (DCA), chloroform (CHCl₃) and methylene chloride (MeCl) have been increased up to three-fold. These advances increase the cost-effectiveness of on-site destruction processes versus transfer technologies and broaden the applicability of chemical oxidation as the technology of choice.

perox-pure™ PROCESS

In this process, UV light converts the hydrogen peroxide (H_2O_2) in solution to hydroxyl radicals (HO·) and "activates" many of the organic molecules to make them easier to oxidize. The photolysis reaction which forms HO· can be shown as follows:

$$H_2O_2 \xrightarrow{\text{UV}} 2\,HO\cdot \tag{1}$$
The activation of the organic molecules can range from direct oxidation by UV absorption and disassociation to the formation of organic radicals or other reactive intermediates. With enough time and reactants, organic compounds can be completely destroyed to CO_2, H_2O and, if present, the appropriate inorganic salt.

Most early UV oxidation processes used low pressure mercury vapor lamps combined with ozone (O_3). The perox-pure™ Process utilizes a proprietary high intensity UV lamp combined with H_2O_2. This provides a number of advantages for chemical oxidation of aqueous solutions.

Three process considerations which manifest advantages include:

- *UV Intensity* - The higher intensity allows for a more compact equipment design as well as lower capital cost. In addition, the higher UV intensity gives better penetration in wastewater or high concentration waters and allows for treatment of a wider range of applications.
- *UV Spectra* - Since activation of organic compounds plays a key role in the destruction process, the broad spectra of the high intensity lamps are better suited for most applications than the narrow spectrum low pressure mercury lamps.
- *Hydrogen Peroxide* Because H_2O_2 is completely miscible with water, it can easily be added in any desired concentration. This wide range of permissible concentrations combined with high intensity lamps allows for simplicity of reactor design and short reaction times for both groundwater and wastewater applications. In addition, there are no toxic gas emissions or stripping of volatile organics into the air.

BENCH-SCALE TESTING

Over the last 5 years, Peroxidation Systems, Inc. (PSI) has tested hundreds of water and wastewater samples from clients using bench-scale equipment. In addition, an ongoing research and development program has contributed to the large body of information available on the oxidation of organic compounds by UV peroxidation. These data are stored in a computerized data base that can be used to generate preliminary process design and cost estimates for a given set of influent and effluent specifications. Table 1 is a partial listing of the compounds in the data base.

PROCESS CONSIDERATIONS

Like most other chemical oxidations, the UV/Peroxidation process is dependent upon a number of reaction conditions which can affect both performance and cost. Some process variables are inherent to the properties of the contaminated water while other process variables can be controlled by the treatment system design and operation. Some of the more important process variables are summarized in Table 2.

Table 2
UV/Peroxidation Process Variables

* Variables related to the contaminated water:
    * type and concentration of organic contaminant
    * light transmittance of the water
      (color/suspended solids)

* Variables related to treatment process design and operation:
    * UV and H2O2 dosages
    * pH and temperature conditions
    * Use of catalysts

TREATMENT EQUIPMENT

While the UV/Peroxidation process is based on well-known chemistry, the equipment and the use of a high intensity UV source such as is embodied in the perox-pure™ equipment is a more recent development. Figure 1 presents data which illustrates the relationship between the UV power employed and the oxidation rate for trichloroethylene (TCE).

As is shown, the reaction rate improves significantly and is more than 10 times faster for the high output UV sources employed in the perox-pure™ equipment than for the older conventional sources. In practice, for UV/Peroxidation reaction, this relationship results in a four-lamp 80-gallon reactor being able to provide equivalent treatment to a system requiring 200 lamps in a 1500-gallon reactor. The increased lamp power costs are more than off-set by the much simpler and lower capital cost equipment.

This smaller, simpler design has significance with regard to space requirements, the number of potential replacement parts and the corresponding maintenance costs. A schematic design of a high intensity UV/Peroxidation system is shown in Figure 2.

In practice, H_2O_2 stored on-site in polyethylene or aluminum tanks at 50% concentration is fed via small chemical metering pumps directly into the incoming water. The solubility of H_2O_2 in water obviates any need for mixing or dispersion devices other than the inlet piping. The mixture passes into the bottom of the oxidation chamber and then upward over horizontally mounted UV lamps. Mechanical design and hydraulic principles ensure mixing during the oxidation process. The unit contains no moving parts, further minimizing maintenance problems.

Individual oxidation chambers can contain up to 15 lamps which can be controlled in increments which match the UV dosage to the treatment needs based on the incoming flow and organic concentration. As treatment flow increases or higher concentrations are treated, the modular oxidation chambers are mounted in series or parallel depending on whether longer contact times or higher flow capacities are required.

Modular systems have been constructed which have hydraulic capacities up to 1500 gpm. As shown schematically in Figure 2, the majority of equipment on each skid-mounted system is devoted to the electrical feed and control system which provides output readings on lamps, power controls, alarm readouts and the option for remote and automatic operation and control.

Figure 1
Effect of UV Intensity on Destruction Rate

FULL-SCALE OXIDATION

Of the 30 full-scale perox-pure™ systems in operation or final construction/installation, approximately 10 are treating wastewaters with organic concentrations between 10 mg/L and 1%. The remainder of the 30 on-line units are treating groundwater. Table 3 shows a partial list of the organic compounds being treated by these installations. Operating costs for these treatment systems range from approximately $0.25/1000 gallons for low concentration groundwater containing TCE and DCE to approximately $0.12/gallon for the highest concentration wastewaters.

APPLICATION OF THE PROCESS

Examples of treatment systems and their performances are presented below to illustrate the application of the process.

Because of the low flow estimated for treatment (25-50 gpm) and the bench-scale success, the smallest perox-pure™ production model, an LV 60, was chosen for the on-site demonstration. Specifications for the LV 60 are shown in Table 4. Other process components included an air stripper, equalization tank, piping and well pumps.

In order to make maximum use of both air stripping and the UV/Peroxidation system, the treatment system was plumbed to allow UV/Peroxidation first followed by the air stripper. Data from this treatment sequence are presented in Table 5. As is shown, the UV/Peroxidation destroyed virtually all contaminants with the exception of TCA which is subsequently reduced to below 2 μg/L by the air stripper. The result of this sequence is higher quality effluent water as well as much lower atmospheric emissions of chlorinated hydrocarbons.

Comparison of UV/H$_2$O$_2$ and GAC

Contaminant	GAC[1] Influent (ug/l)	GAC[1] Effluent (ug/l)	GAC[2] Influent (ug/l)	GAC[2] Effluent (ug/l)
TCE (Ave. 6 Mos)	756	3.8	4016	<1

1. GAC usage 1.2 lbs./100 gal., Contact time 50 min.
2. H202 usage 50 mg/l, oxidation time <1 min.

The perox-pure™ system on this site is being operated on a Full Service Contract which eliminates capital expenditure and includes regular service, all parts and labor for maintenance, delivery of H_2O_2 and a guarantee of system performance. The cost to destroy the organics as shown with the perox-pure™ system is approximately $2.69/100 gallons treated including capital amortization, chemicals, electricity and all maintenance parts and labor, but excluding air stripping costs.

OTHER EXAMPLE INSTALLATIONS

In order to illustrate the range of treatment applications, two more sets of performance data are presented. Table 6 shows treatment of water principally contaminated with hydrazine with other trace organics present.

While it is notable that all treatment objectives were met, it also is interesting to note that the total organic carbon (TOC) content of the water was reduced more than 93% indicating that most of the organics have been converted to CO_2.

Table 7 is a comparison of 6 months of averaged data on a TCE-contaminated site which operated both a granular activated carbon (GAC) and UV/Peroxidation system.

The principal difference in the operation was that while the GAC system was operated on a production well, the UV/Peroxidation system operated on a monitoring well with nearly six times higher concentration. Twelve months of operating data showed the UV/Peroxidation

system capable of producing a significantly better effluent at an operating cost of $0.83/1000 gallons compared to $3.05/1000 gallons for GAC.

CONCLUSION

The use of chemical oxidation and particularly the use of ultraviolet light-catalyzed hydrogen peroxide systems, is a proven, very effective technology for removal of organic contamination from water. It is economically competitive with adsorption and operationally simpler than other technologies which may produce sludges, air emissions or other secondary disposal problems. The UV/Peroxidation process is relatively easy to evaluate and demonstrate and should be included in any evaluation of treatment technology alternatives.

Hazardous Material Control Versus "End of Pipe" Disposal

Alvin F. Meyer, PE
A.F. Meyer and Associates, Inc.
McLean, Virginia

ABSTRACT

This paper describes current industrial interest in the subject of pollution prevention, gives some historical perspectives on it and then addresses, as a case study, a program of the U.S. Navy to reduce hazardous waste by 50% during the next five years. An overview of the specifics of key elements of the Navy's Hazardous Material Control and Management Program is presented as an example of one approach that brings together all the elements of environment, safety and health by a life-cycle approach to management.[1]

INTRODUCTION

This paper presents a brief overview of the regulatory maze governing pollution control, the resulting philosophies of regulatory action and compliance and associated economic implications. It then addresses concepts and approaches developed by the U.S. Navy to reduce the amounts and costs associated with using hazardous materials and the disposal of their ultimate waste.

At the outset it must be understood that in both industry and in the defense establishment there always will be processes, systems and operations that require the use of materials with properties hazardous to human health safety and/or the environment. As J. Clarence Davies stated in his remarkable text almost twenty years ago, "We can not stop all the activities which introduce potentially dangerous substances into the environment, because to do so would be to sacrifice most of the benefits of modern society."[3] He also pointed out that the prevailing philosophy then was we could build treatment plants and install control devices if money and political power were brought to bear on the problem. From an economic viewpoint, it is interesting to note that in 1970 it was estimated that the control costs to bring down air, water and solid waste pollution to the then acceptable levels was $300 billion in 1970 dollars over a thirty year period.

Events and costs have overtaken the political, social and engineering/technical philosophies that national environmental goals can best be met through control technology. Environmental control procedures have been based on the premise that the best solution will come from ever increasingly stringent codes, standards and regulations directed at requiring achievement of the best available technology. A recent article on occupational hazard illustrates that this approach is rapidly being recognized as bad policy.

A rethinking of these traditional approaches began in the early 1980s. Waste minimization as an alternative to disposal has rapidly become a recognized industry objective. That process is defined by DuPont as "reducing the quality and toxicity of materials to be wasted by end-of-the-pipe treatment."[2] While large companies and government agencies have been committed to source reduction and waste minimization, the large outlay of funds that may be involved results in many small and medium size companies concentrating on treatment and disposal procedures with all of the associated permit requirements.

Beginning in 1986, the U.S. Navy began to address the questions of both hazardous material control and hazardous waste minimization. After extensive study of ongoing efforts in several naval activities, including the Naval Aviation Depot Pensicola, Florida, broad-scale investigations led to the development and issuance of the Navy directive on Navy Hazardous Material Control and Management. This approach has been recognized by the General Accounting Office as being a unique approach worthy of being emulated by other Federal agencies. The principles and procedures are applicable to the private sector as well as the Defense and Aerospace community.

BACKGROUND OF REGULATORY REQUIREMENTS AND ECONOMIC IMPLICATIONS

Among the driving forces affecting the widening recognition that a true preventive management and engineering approach is needed for hazardous materials and hazardous waste is the high cost of complying with the wide variety of Federal, State and local regulations. Significant also are the regulations' indirect impacts.

Among these indirect impacts are the costs of training the people working with hazardous materials to meet the Hazardous Communication Standard of OSHA; the costs associated with installation of ever increasingly complex new equipment to meet such requirements as Fossil Organic Compound Controls; medical examinations for personnel routinely working with hazardous materials and hazardous waste; and the sharply increasing costs of storage facilities. The General Accounting Office has estimated that it costs the Defense establishment approximately $1.10 for waste disposal for each $1.00 actually spent in procuring a hazardous material. Thus economic implications begin to take a major role in a search for alternatives to pollution control technology.

FUNDAMENTAL CONCEPTS OF HAZARDOUS MATERIAL CONTROL AND MANAGEMENT

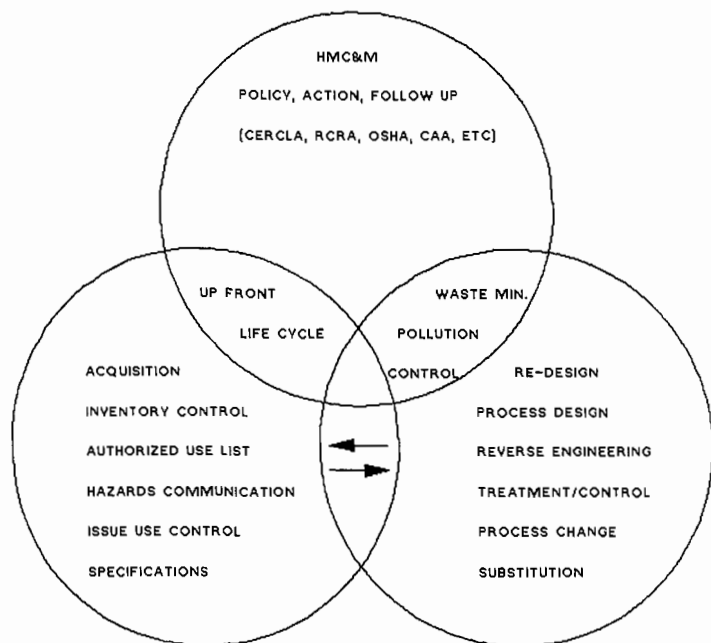
As envisioned by the U.S. Navy, Hazardous Material Control and Management is not waste minimization alone. Waste minimization is an element of a multifaceted approach bringing together all of the requirements associated with environment, safety and health. As shown in Figure 1, it is a program which provides for policy, action and followup by all of the interested and affected elements of the Navy structure. It recognizes that there is a relationship between the life-cycle control and management of acquisition procurement and use of hazardous materials and the control and waste minimization efforts and procedures. Highlights of the most important elements of the Navy policy embodied in its directive, OPNAV Instruction 4110.2, Hazardous Material Control and Management, are provided below.[6]


Figure 1
HMC&M Concept/Inter Relationship

Figure 2
Life Cycle of System and Requirement

Policy and Goals

The basic Navy policy is that the Navy will control and reduce the amounts of hazardous material used and hazardous waste generated through a life-cycle approach. A central element of the policy is the establishment of an integrated effort encompassing the health and safety of Navy workers and procedures to protect the environment. A firm goal of achieving a 50% reduction in weight of hazardous waste generated by the Navy by 1992 is also established. In view of the fact that some observers are looking at a 25% reduction of waste from most generators by the year 2000, this goal may seem overly optimistic, but at least it represents a reasonable target.

The Life-Cycle Approach

In essence, the Navy program calls for institution of hazardous material control and management procedures and actions throughout two related life-cycles of Navy systems and equipment. The first of these relates to the life-cycle of systems and equipment as shown in Figure 2. Consideration of the need for use of hazardous material and resulting hazardous waste reduction must begin from the time of conception to the new system of procedure throughout its research, engineering development, production, installation, use and ultimate disposal. The systematic application of hazardous material control and management studies and analyses as part of system development is intended to result in inputs to the Navy's authorized use list discussed later in this paper.

There is another life-cycle which is also recognized in the Navy process. It is described in Figure 3. A second life-cycle is at the activity or installation level. It involves the local facilities' ordering of materials, their receipt, storage, distribution, use and ultimate disposition. In a manufacturing installation or other similar commercial facility, this same life-cycle exists. It involves raw materials, transportation and handling; plant and process operations; storage, distribution and transportation of the finished product; and use by an ultimate consumer. It also includes final disposition of the waste streams in the manufacturing process and of the finished products distributed in commerce.

In effect, in both the military installation and the civilian situation, there are two distinct phases in controlling a hazardous material. The first control phase is the in-plant one involving exposures of personnel, equipment and facilities to the hazards associated with the materials. The second control phase involves the external environment using a systems engineering process. These process must be addressed con-

currently. The approach taken by the Navy and its Hazardous Material Control and Management Plan clearly recognizes these interfaces and provides for them in a cohesive fashion.
Assignments of Actions and Responsibilities

Any program for comprehensive hazardous material control bringing together environmental safety and health concerns requires a clearly defined assignment of actions and responsibilities from the top level of management to the lowest operating level. The Navy directive does this in unmistakable terms. Responsibilities are assigned commanders of systems command and fleet commanders in chief, and additional specific assignments are provided to those elements concerned with systems development, acquisition and research for education and training and to commanders of Navy facilities.

A key element to ensure the program's success is to assign the Naval Inspector General to make the project a special interest item. Past experience has indicated that this action will result in the necessary responsiveness at all echelons of the organizational structure.

Authorized Use List Concept

The OSHA Hazard Communications Standard (29 CFR 1910.1200) requires that employers (and the Navy, as well as other Federal agencies, is considered an employer) must maintain inventories of hazardous materials in the workplace and provide workers with material safety data sheets on those materials. Literally tens of thousands of hazardous materials are currently in use throughout American industry and the Navy is no exception.

As in industry, many of the materials used by the Navy used are specified by plant process, production and operational design staff. Far too often, little or no consideration has been given or had to be given to whether or not a less hazardous material than the one called for might be more suitable.

Instead of approving the use of hazardous materials on an uncontrolled basis or operational need, the Navy is now changing its method of dealing with this problem. It is requiring an "up front" analysis and control at the earliest possible moment. The objective is to help the Navy avoid excessive costs associated with hazardous waste disposal and the acquisition of hazardous materials.

To that end, the Navy directive calls for the establishment at activity level and at the Navy level of "Authorized Use List." Such a program has been adopted by the Navy for its forces afloat and is now being carried over into the entire Navy establishment. Accomplishment of hazards analysis, risk assessment and economic analysis of an appropriate level of detail to the intended usage is required as part of the decision process involved in the selection and use of hazardous materials.

Recognizing that there are many specifications and standards calling for the use of hazardous materials applicable to existing systems and equipment, the Navy program provides for a 36 month time period for the establishment and implemention of plans to take the necessary actions to review these and develop plans and procedures for the substitution of less hazardous materials as appropriate. One unique procedure now being investigated by the Navy is the use of reverse engineering/value engineering techniques to determine if existing

requirements for the use of hazardous materials can be changed or modified.

Plan of Action Requirement

In addition to the inspection program through the Naval Inspector General, an important feature of the Navy's program which is directly applicable in a civilian sector is the requirement for a formal plan of action and milestones for implementation of the program and overview of progress in meeting the requirements by the "Corporate Headquarters," namely the office of the Chief of Naval Operations.

PERCEIVED OUTPUTS/BENEFITS

Although the primary objective of the Navy program is to reduce hazardous waste by 50% in a finite time period, there are many other perceived outputs and benefits of the Navy program which are applicable to the civil sector as well as to other Federal agencies. Some of these benefits have already been cited in this presentation. In addition, the following are of critical importance:

- Avoidance of both resources (dollars and time) to deal with litigation, citations and fines associated with environmental impacts or violations and/or occupational safety and health requirements.
- Avoidance of the costs of new control equipment to comply with the requirements of the pending Clean Air Act and OSHA permissible exposure limit regulations.
- Reduction in impacts on productivity because of requirements for use of personal protective equipment, preventive measures, etc.
- Reduction in the costs for compensation for occupational injuries and illnesses.
- Cost containment associated with accident and emergency response requirements.
- Lessened technical administrative and management needs to deal with

hazardous materials.
- Reduction in specialized hazardous materials/hazardous waste storage facilities.
- Improve public and worker perception of the organizations policies, procedures and actions.[4]

SELECTION PROCESS FOR HAZARDOUS MATERIALS

One major need associated with the Navy program and similar hazardous material control and management programs in the civilian sector (in this author's view) is the lack of uniformly acceptable procedures for evaluation and selection of the least hazardous material to achieve specific needs. While the concept of substitution of lesser hazardous materials has been a longstanding philosophy of industrial hygiene and environmental engineering, no definitive guidance currently exists. In addition to toxicological and other environmental, occupational health and safety and public health hazard information (for example, fire and explosion potential), such considerations as the number of persons exposed, the frequency and duration of exposure and the circumstances of use need to be taken into account.

While there is a lot of literature relating to "risk analysis" in relation to environmental impacts[5], there is a need to compare the use of one solvent with another in a particular industrial setting. A number of methods currently used to evaluate occupational exposures may be utilized to meet this need. Among these are the procedures for "deriving risk assessment codes for health hazards" developed by the U.S. Army Environmental Hygiene Agency and adaptations to include environmental concerns total Air Force Occupational Safety and Health Standard 161-11,"Work Place Monitoring."[7] These both use numerical rating systems which allow a comparative analysis of the potential hazards and other concerns associated with the specific workplace situation. This is an area which requires much more study within the hazardous materials control community.

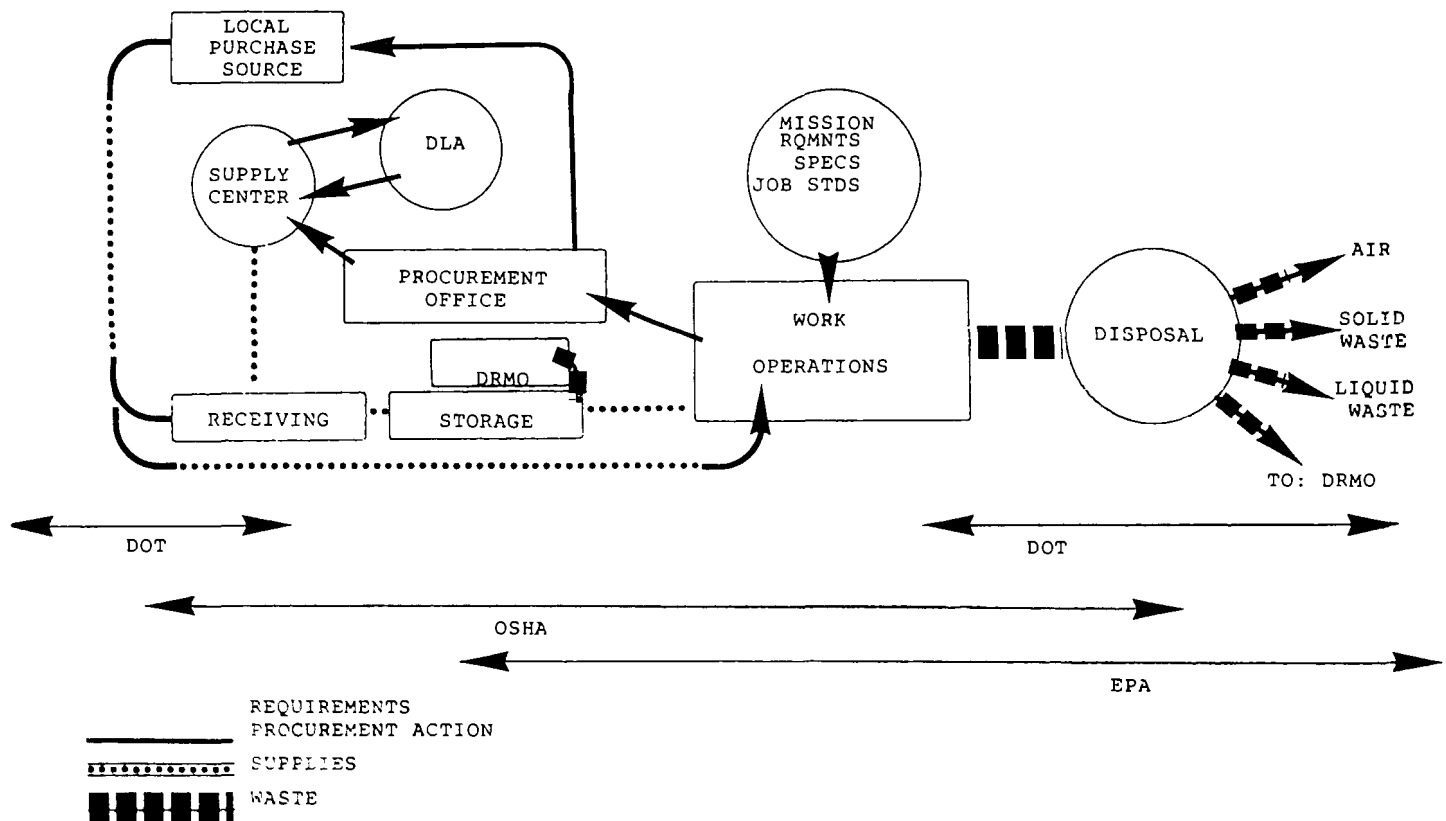
REQUIREMENTS
PROCUREMENT ACTION
SUPPLIES
WASTE


Figure 3
Hazardous Material Management Regulatory
Requirements and Life Cycle Concept

CONCLUSION

The end-of-the-pipe air, water pollution and solid waste control solution still is required for many waste streams. Hazardous materials control by "up-front" procedures is not a panacea, but it is essentially more cost-effective and less wasteful than the former mode of operation. From an overall national economic viewpoint, addressing a requirement for waste minimization and process control, when conducted in conjunction with measures to improve productivity and modernization of production processes, has built-in benefits as an important element in improving American competitiveness.

M. Neal Guentzel
Joy Hudson
The University of Texas at San Antonio
San Antonio, Texas

ABSTRACT

Following a diesel fuel spill of approximately 1,400 gallons a portion of the contaminated soils was obtained for studies of bioremediation with an indigenous microbial consortium. These soils were characterized for existing microorganisms and hydrocarbon concentration. The predominant microbial species found in the diesel-contaminated soils consisted of *Pseudomonas putida, P. fluorescens, Acinetobacter calcoaceticus* var. *anitratus, A. calcoaceticus* var. *Iwoffi* and other *Pseudomonas* species. The initial total heterotrophic bacterial population was 2×10^5 CFU/g, the final population was 6×10^8 CFU/g and the soil contained approximately 14,000 $\mu g/g$ of diesel fuel.

In 150 days of treatment, approximately 87% of the hydrocarbons were mineralized to carbon dioxide and water. In another reactor where additional oil-degrading microbes were added along with the nutrients, the degradation of diesel fuel was 84%. A degradation study with oxygen consumption was also conducted with a six-reactor respirometer. Mineralization of 97% of initial concentrations of 100 and 300 ppm of diesel fuel was obtained in 60 days.

INTRODUCTION

Human and animal populations have demonstrated chronic and acute toxicity to organic chemicals.[1-3] Stricter federal and state regulations for organic pollutants have required owners to clean up their toxic wastes from the contaminated environment.[4-6] Although incineration technology often is the optimum choice for destruction of toxic and concentrated organic wastes, it is not economically feasible for organics sorbed to soils over a wide area.

The cleanup of persistent organic contaminants that have been strongly adsorbed to soils is difficult and expensive. One promising and economically feasible approach is through in situ biodegradation of the organic contaminants.[7-11] Theoretically, any organic compound can serve as a carbon source for microorganisms. Metabolism of organics with naturally existing living microorganisms may be encouraged by adding nutrients, oxygen and minerals. When naturally-occurring degradative microorganisms are absent or low in numbers, preacclimatized cultures may be added along with nutrients to the environment.

The specific objectives of the research were: (1) to evaluate the capability of a fertilizer formulation to serve as a nutrient source for promoting indigenous bioactivities, (2) to determine the indigenous microorganisms present in degrading diesel fuel and (3) to compare the biodegrading capability among the indigenous microorganisms, as well as the activated sludges obtained from an industrial wastewater treatment plant and a municipal wastewater treatment plant.

EXPERIMENTAL

In Situ Bioreactor

The soil samples obtained from the site were separated into two portions and placed into two 55-gallon glass reactors called AQUA-1 and AQUA-2. The design of the reactors is shown in Figure 1. AQUA-1 was designed to use naturally existing microbes for degrading the diesel fuel. A mixture of Pseudomonas, Enterobacter, Acinetobacter, Klebsiella and Bacillus was added along with the nutrient during injection into AQUA-2. The nutrients were applied during treatment of the soils in both reactors and the soils were continuously aerated with the PVC pipe. The excess nutrients were recycled back to the container. The nutrient was a fertilizer containing urea as a nitrogen source, phosphoric acid as a phosphorous source and metals.
Figure 1
Design of In Situ Bioreactor for Degrading
Diesel Fuel in Contaminated Soil

Closed System Bioreactor - The Electrolytic Respirometer

The reaction vessels used in the study were 1-L flasks with side openings so that septa were easily inserted into them allowing sampling of the reaction mixture. The experiments consisted of duplicate flasks of two concentrations of diesel fuel (100 mg/L and 300 mg/L) in each flask. The indigenous microorganisms were isolated from the contaminated soils. Besides the indigenous microorganisms, mixed con-

sortium inocula also were obtained from an industrial wastewater treatment plant at Kelly Air Force Base, San Antonio, Texas and the San Antonio City Municipal Wastewater Treatment Plant. The seed inocula were suspended in a nutrient mixture containing ammonium chloride, calcium chloride, potassium phosphate, sodium phosphate and trace metals (magnesium sulfate, ferric chloride, sodium molybdate, cobalt chloride, copper sulfate, zinc sulfate) as nutrients. The respirometric control system consisted of (1) nutrient/substrate control (diesel fuel/sterile water/nutrient) and (2) nutrient/substrate/inoculum control (diesel fuel/nutrient/inoculum). At specified times, 25-mL aqueous samples were removed from the respirometer vessels and analyzed for diesel fuel aliphatic, aromatic compounds and related metabolites using gas chromatography/mass spectrometer (GC/MS). When necessary, the pH was adjusted to ensure that the environment remained optimal for microbial growth. The electrolytic respirometer was developed as a means of providing a more accurate and complete measurement of the BOD than normally is obtained by the standard dilution BOD methods. The BOD is determined by precise measurement of the oxygen uptake reaction. This system eliminates many technical problems encountered with other methods for determining oxygen demand and the rate at which it is exerted.

The electrolytic respirometer consists of three basic components: (1) a reaction vessel, (2) an electrolysis cell and (3) an electronic control unit. Together, these components comprise a large-volume respirometer which provides continuous and automatic adjustment of the oxygen pressure within the enclosed reaction vessel.[12]

As oxygen is consumed by the biological reaction within the reaction vessel, metabolically produced carbon dioxide is absorbed in a KOH scrubber solution. A slight vacuum is thereby created, causing a decrease in the electrolytic level in the outer chamber of the electrolysis cell. When an approximate 1-mm change in electrolyte level has occurred, the outer electrolyte surface breaks contact with the switch electrode. This signal activates the electronic control unit and causes a controlled direct current to flow through the electrolyte. Oxygen is produced at the positive electrode according to Faraday's Law. This oxygen is added to the reaction vessel in precise increments until the original internal pressure is reestablished and electrolyte contact is made at the switch electrode. Oxygen production is monitored electronically by counting the increments of input needed to equalize the pressure. Hydrogen produced at the negative electrode is vented to the atmosphere at the outside top of the electrolysis cell.

Microbial Analyses of Soil Samples

Soil samples were collected in sterile vials and refrigerated immediately upon receipt. These diesel fuel contaminated soil samples were used to characterize the indigenous microbial population growth. Serial tenfold dilutions of the soil samples were made using sterile 0.85% saline solution. Aliquots (0.1 mL) of the dilutions were spread plated onto plate count agar, MacConkey's agar, Pseudomonas agar P and Sabouraud dextrose agar plates.

Gram-negative isolates were identified using the API-20E system (Analytab Products, Plainview, New York). The system contains dehydrated chromogenic substrates that are activated with the addition of the bacterial suspension. The reactions are assigned numbers according to the result that occurs, and a seven or eight digit combination of these numbers is then decoded in the data base. The methodology used to detect the other microbial parameters was that described in the latest edition of Bergey's Manual of Systematic Bacteriology, Volumes I and II.[13] The techniques selected for identification were those which should yield the greatest degree of sensitivity for the samples examined.

RESULTS AND DISCUSSION

Oxygen Uptake

Results of the respirometry experiments were based on the oxygen uptake from each reactor vessel (containing 100 and 300 ppm, respectively) and the mineral nutrients.

1) 100 ppm diesel fuel/nutrients in sterilized water
2) 100 ppm diesel fuel/nutrients/industrial aerobic sludge

3) 100 ppm diesel fuel/nutrients/indigenous microbes
4) 300 ppm diesel fuel/nutrients/industrial aerobic sludge
5) 300 ppm diesel fuel/nutrients/indigenous microbes
6) 300 ppm diesel fuel/nutrients/municipal microbes

The oxygen uptakes are shown in Figure 2. The figure displays cumulative oxygen consumption with respect to duration time illustrated by oxygen uptake kinetics. Oxygen uptake in the nutrients with the 100-ppm diesel fuel began after approximately 2 days lag time and leveled off at approximately 180 mg/L through 30 days. In the substrate/nutrient/inoculum control studies, inocula obtained from the industrial wastewater treatment plant showed a better initial bioactivity comparing the indigenous and municipal wastewater cultures. The activity of the industrial inoculum could be traced to the acclimation and selection of the inoculum to hydrocarbons at the treatment plant.
Figure 2
Cumulative Oxygen Consumption in Respirometry Experiments

Oxygen consumption showed a cumulative oxygen uptake plateau at 780 mg/L at a 300-ppm initial diesel fuel concentration in the industrial inoculum culture. The maximum oxygen uptake values for the indigenous soil microbe inoculum were 320 mg/L and 450 mg/L at 100

ppm and 300 ppm initial diesel fuel concentration for 60 days incubation. Figure 2 only shows 30 days of incubation.

Microorganism Analysis

Growth data indicated significant increases of growth of the indigenous oil degrading microorganisms at the end of the 60-day incubation period.

Plate counts demonstrated that the number of organisms increased from 2.1×10^5 cfu/mL on the soil samples to 6×10^8 cfu/mL after 60 days of incubation in the respirometric reactors. The total heterotrophic bacteria count seemed to level off after the first 2-3 weeks of incubation.

hydrocarbons degrading capability in the literature.[7-11] An attempt to characterize the aerobic activated sludges obtained from Kelly Air Force Base, Texas, and the San Antonio Municipal Wastewater Treatment Plant is shown in Table 2.

Gas Chromatographic/Mass Spectrometry Analysis Information

Table 2 illustrates the GC/MS analysis in culture samples obtained from respirometric vessels. This analysis demonstrates almost complete mineralization of the aliphatic and aromatic hydrocarbons in these experimental systems at the end of 60 days incubation in Reactions 2-5. Significant biodegradation of diesel fuel at 100 mg/L and 300 mg/L occurred with inocula obtained from the industrial wastewater treatment plant and acclimated indigenous soil microbiota. This result also shows that higher concentrations of diesel fuel in the inlet stream of municipal treatment plant may upset the activated aerobic sludge of the plant. The blank control experiment in Vessel 1 using the respirometric approach provided evidence that more than 90% of the diesel fuel remained in the sample at 60 days post-inoculum.

The Fourier transform infrared analysis technique was applied to analyze the samples obtained at 60 days. These samples were extracted by Freon 113 and hydrocarbons monitored at 2930 nm.

Biodegradation data for diesel fuel contaminated soils at approximately 14,000 μg/g are shown in Table 3. Control studies were conducted with air aerated at 10 psig throughout the soil for 10 days. Soil samples obtained from the reactors on the 3rd, 6th and 10th days demonstrated that the high molecular weight aliphatic (mle = 57) and aromatic (mle = 91) hydrocarbons are strongly absorbed by the soil matrix. The concentrations remained at a homogeneous level with 2,900 ppm of aliphatic hydrocarbons and 13,000 ppm of aromatic hydrocarbons for reactor AQUA-1 and 3,100 ppm of aliphatic hydrocarbons and 13,000 ppm of aromatic hydrocarbons in reactor AQUA-2.

On the 11th day, sprinkle-type injection systems were set up on both aerated reactors and the soil moistures were controlled to near 40-60%. For reactor AQUA-1, only buffered fertilizer medium was applied to the soils while hydrocarbon preacclimatized microbes were added into the buffered fertilizer medium to enhance the degradation rate of the AQUA-2 soils. During applications, the nutrient conditions were monitored and maintained at pH 7 and room temperature. The samples obtained after 30 days showed a drastic drop in concentrations of the residual diesel fuels. In AQUA-1 60% and 50% of the initial aliphatic and aromatic hydrocarbons, respectively, were degraded; at the same time the soil samples obtained from AQUA-2 demonstrated 74% and 62% degradation of the aliphatic and aromatic hydrocarbons, respectively. In both reactors, the recycled nutrients in the bioreactors do not

5. 300 ppm Diesel Fuel/Nutrient/Indigenous Soil Inoculum	300	192	179		7.3
6. Diesel Fuel/Nutrient/Muncipal Wastewater Inoculum	300	392	207		86

As shown in Table 1, the inoculum composition was characterized for the component and microbial species. The contaminated soils contained *Pseudomonas aeruginosa, Pseudomonas fluorescens, Pseudomonas putida, Acinetobacter calcoaceticus var. anitratus* and *Acinetobacter calcoaceticus var. lwoffi. The organisms have established*

contain any hydrocarbons. In the total population counts, a 50% increase in bacteria density was obtained in both reactors. In 150 days of treatment, approximately 87% of the hydrocarbons were mineralized to carbon dioxide and water in AQUA-1. In AQUA-2, the degradation of diesel fuel was 84%. It is anticipated that the soils will be cleaned

up in another 4 months.

Analytical respirometry and the in situ bioreactor technique were shown to be a valuable experimental approach for testing biodegradability of the diesel fuel formulations in contaminated soil matrices.

CONCLUSIONS

Respirometric and bioreactor biodegradation data have demonstrated a significant enhancement of biodegradation of diesel fuel with the use of fertilizer and mineral nutrients. In situ stimulation of the growth of indigenous microbes from diesel-contaminated soil with nutrients permitted the mineralization of hydrocarbons to environmentally acceptable products, carbon dioxide and water. Inoculum from an industrial wastewater treatment plant were an alternative source of microbes permitting degradation of hydrocarbons. The results of this experiment have promoted an on-site pilot study of the diesel fuel spill site. We anticipate the cleanup of the contaminants will be accomplished within a year.

Biodegradation of Aromatic Compounds

William R. Mahaffey, Ph.D.

ECOVA Corporation
Redmond, Washington

ABSTRACT

An overview of current knowledge on the capacity of microorganisms to degrade polycyclic aromatic compounds (PAH) will be reviewed. Bioremediation of PAH compounds such as pentachlorophenol (PCP), creosote, naphthalene and phenanthrene will be demonstrated through case histories.

A former railroad tie-treating plant on the NPL list is contaminated with creosote in soil and groundwater. PCP, naphthalene and phenol have migrated from site ponds and have contaminated shallow groundwater beneath the site and a nearby river. Contamination at the site ranges from oil-saturated sands and gravel to groundwater containing $\mu g/L$ concentrations of dissolved contaminants.

ECOVA conducted a 20-month treatability study and process development program to evaluate the effectiveness of oil recovery and develop advanced in situ soil washing and bioremediation treatment techniques. Laboratory bench-scale studies provide a thorough analysis of site soils, and a series of micro-column studies determined the effectiveness of bioremediation. The results confirm that the PCP can be rapidly degraded in the highly contaminated soil and water at this site. This study confirmed that the PAHs could be successfully biologically remediated in the contaminated soil and water. The rates of loss are extremely rapid in a soil slurry system, with concentrations reaching nondetectable levels in four weeks in some cases. Similarly, water biotreatment can be extremely rapid and complete. Finally, the compounds can be effectively (90%) removed from soil by simulating in situ soil washing which has tremendous potential for hastening on-site remediation of heavily-contaminated sites.

The Brio Refining Superfund Site has a large volume of soil containing styrene still bottom tars and chlorinated hydrocarbon solvents. The site, located adjacent to a housing development, contains approximately 60,000 yd^3 of waste. VOCs, ethylbenzene, styrene and toluene, were detected at maximum concentrations of 4,400 ppm, 240 ppm and 510 ppm, respectively. The contaminant of particular concern is phenanthrene, detected in ranges from 0.44 to 170 ppm. ECOVA conducted a process development and treatability study to bioremediate the soil.

A site assessment and laboratory study demonstrated that phenanthrene could be degraded to <1 ppm using biological techniques. A four-month pilot demonstration of solid-phase bioremediation was conducted. The treatment area was enclosed into greenhouse-type enclosures to capture vapor emissions during treatment and eliminated the need to control or treat rainwater. An overhead spray system distributed water, nutrients and inocula. Organic vapor emissions were controlled by adsorption on carbon and the greenhouse helped control dust. Approximately 200 yd^3 of contaminated soils were successfully treated during the 94 days of operation. VOCs were reduced by more than 99%. Semivolatile organic compound concentrations were reduced an average of 89%, and phenanthrene concentrations reduced an average of 84%. the average phenanthrene half-life was 33 days, significantly less than reported half-life values of 69-298 days in other solid-phase bioremediation systems. The data indicated that approximately 131 days would be required for the phenanthrene concentration to reach 0.33 ppm, the analytical detection limit using U.S. EPA-approved procedures.

INTRODUCTION

Bioremediation is the controlled use of microbiological agents, commonly bacteria and fungi, to reclaim soil and water contaminated with substances which are deleterious to human health and the environment. The biological agents are often indigenous microorganisms inhabiting the polluted matrix. However they also may be seed organisms which have been isolated from another environment on the basis of their ability to degrade a specific class of substances. It is due to the wide diversity of microbial metabolic potential that bioremediation is possible.

PAHs represent a class of organic compounds which are ubiquitous in the environment. They are present in fossil fuels and are formed during the incomplete combustion of organic material. Creosote has been used extensively to treat wood products against fungal and insect attack or to impart fire resistance. The creosote found in wood treatment wastes is a coal tar distillate boiling from 200 to 400°C. Chemically, creosote is a complex mixture predominantly of PAHs, plus a minor fraction of phenolic substances. The major PAH constituents are 2-, 3-, 4- and 5-ring compounds, including; naphthalene, acenaphthene, fluorene, anthracene, phenanthrene, fluoranthene, pyrene, benzopyrene and methyl derivatives of these compounds. PAHs, as a class of organic compounds exhibit low volatility and low aqueous solubility. As the molecular weight of these compounds increases, there is an exponential decrease in both solubility and volatility. PAHs exhibit a strong tendency to adsorb onto soils and sediments due to their hydrophobic character, which is an intrinsic function of molecular size.

The microbial degradation of individual PAHs by pure cultures[1] as well as mixed populations is well documented.[2] In addition, the degradation of PAHs has been evaluated in complex mixtures such as petroleum refining wood preserving wastes. Numerous laboratory studies have been performed which demonstrate the biodegradability of these compounds under a wide range of soil types and environmental conditions.[4,5,6]

Generally, the factors which seemed to have the greatest influence on the rates of biodegradation were moisture content of soils, pH, inorganic nutrients, loading rates, initial concentrations and the presence of an acclimated microbial population.

Feasibility studies are an essential component for the development of a bioremediation strategy. These studies are performed in a phased testing program which is designed to accomplish a number of objec-

tives. These objectives include:

- Establish the existence of an indigenous microbial population with the appropriate degradative potential on-site contaminants
- Define the rate limiting factors for enhanced microbial degradation of the contaminants
- Perform process optimization studies to define the optimal treatment in terms of rates and cleanup levels attainable
- Develop design parameters for field operations

The first half of this paper presents a case study on a feasibility testing program and the implications of the results for the development of a site-specific remediation strategy. The second half will present a review of a pilot-scale demonstration program treating soils containing styrene still bottoms and chlorinated hydrocarbon solvents presented at this conference in 1987.[7]

CASE HISTORY: TREATABILITY STUDY

The site is a former wood treating facility which was in operation for almost 100 years. Wood preserving agents used in the process included zinc chloride, creosote oil and pentachlorophenol. Wastes were disposed of at the plant according to the standards of the era, resulting in approximately 100 acres at the site becoming contaminated by present standards. Contamination consists largely of an immiscible, denser than water mixture of creosote and PCP. The principal compounds of concern are PCP and PAHs. The range of site contamination varies from oil-saturated sands and gravel to groundwater with $\mu g/L$ concentration of dissolved phenols, PCP PAHs and other petroleum hydrocarbon fractions.

The site was secured with a contaminant isolation system installed on-site. Actions over the past three years have focused on cleanup of the site through on-site contaminant removal and biotreatment technologies. Due to the tightness of the bedrock formations and the high porosity of the soils, this site is well-suited to in situ bioremediation techniques.

RESULTS

Phase 1: Microbial Biotreatability Evaluation

A microbiological evaluation was performed to determine whether the microorganisms currently present in the soils and groundwater at the site were capable of degrading the site contaminants under conditions conducive to biodegradation. Soil and water samples were incubated under aerobic conditions with sufficient nutrients for 4 weeks. The loss of contaminants was monitored by GC/MS. Half of the samples received growth factors and a surfactant to determine whether these chemical treatments could enhance biodegradation.

The results indicated that substantial biodegradation of contaminants could be achieved in all of the areas sampled. Contaminant reduction was greatest in the groundwater samples (93%), followed by the saturated soils (80%) and the unsaturated soils (66%). The percent reduction in individual target contaminant levels was not related to the initial concentrations in all samples. However, the total biodegradation was related to total contaminant concentration in all samples. The residual hydrocarbon after a 4-week incubation appeared to be related to the inherent biodegradability of the contaminants present in a given sample. Most of the individual compounds were readily biodegraded. The average loss of 2 - 3 ring polynuclear aromatic hydrocarbons (PNAs) was 80 to 90%. In those sites showing residual hydrocarbon, the compounds were those showing slower rates of biodegradation such as pentachlorophenol (PCP) and the 4 - 6 ring PAHs (approximately 65% loss on average). No effect of the growth factor and surfactant addition was observed.

Although the results indicate substantial biodegradation of contaminants, it was necessary to confirm that microorganisms present at the site are capable of mineralizing the contaminants (i.e., convert organic carbon to carbon dioxide). To confirm mineralization, selected ^{14}C-labeled compounds were incubated with enrichment cultures selected during the previous activity and mineralization was monitored by measuring the evolved $^{14}CO_2$.

The results showed that the 2 - 3 ring PAHs tested (naphthalene,

phenanthrene and fluorene) were rapidly mineralized by most of the enrichment cultures when present as sole carbon source. The 4- and 5- ring PNAs tested (pyrene and benzo(a)pyrene, respectively) were not mineralized when present as the sole carbon source. However, $^{14}CO_2$ was evolved by some enrichments when contaminated soil (containing additional hydrocarbon substrate) was added. This is evidence that mineralization of 4- and 5-ring PNAs may be achieved through cooxidation by stimulating microbial activity on other organic substrates (i.e., microbes are growing related simpler contaminants). PCP was mineralized when present as sole carbon source only by enrichments from some of the surface and unsaturated soil samples. Microorganisms responsible for mineralizing PCP appeared to be lacking from the groundwater and saturated soil samples. The apparent lack of this metabolic potential in these areas probably is due to the lack of oxygen. An acclimated culture capable of PCP mineralization was under development and testing.

The initial studies have shown that the site contains microorganisms capable of extensive biodegradation of all target contaminants. Many of the simpler compounds can be biodegraded as sole carbon source and these apparently can induce the production of enzymes capable of degrading the more complex compounds as well. These bacteria apparently are not distributed evenly throughout the site. Thus, the extent of biodegradation of PCP or more complex PNAs was highly variable between samples and there was no conclusive evidence that the microorganisms present in any one sample could degrade all of the contaminants. However, the results establish the potential for in situ biological treatment for both contaminated groundwater and soils at the site.

The following conclusions can be drawn from this work:

- The total contaminant concentration at the site varies with sampling site (location) and/or medium (groundwater, surface, subsurface soil).
- The potential to biodegrade all of the contaminants present in the soil and water exists in the metabolic capabilities of the microorganisms present at the site.
- The fraction of the total contaminant load which was biodegraded in a given time period was related to the location of the sample (groundwater > saturated soil > unsaturated soil).
- The total contaminant biodegraded in a given time period was related to the total concentrations of contaminants as well as the concentration of 4 - 5 ring PNAs or PCP.
- The amount of contaminant biodegradation achieved was not increased by addition of growth factors or surfactants.
- Inoculation of microorganisms or substrates may be necessary to redistribute the biodegradation potential at the site to achieve total bioremediation.
- Mineralization of most the compounds tested can be achieved by microorganisms present in the site.
- Cooxidation or the addition of specific organic substrates may stimulate the biodegradation of other compounds (4 - 5 ring PNAs and PCP).

Phase 2: Bioremediation Process Optimization

From the Phase 1 studies it was concluded that the indigenous microorganisms possessed the contaminant biodegradation potential required for an effective in situ bioreclamation process. The focus for the Phase 2 studies was on determining how best to use these capabilities in a site-specific bioreclamation process and on preliminarily evaluating the cleanup levels that can be achieved over time.

Several specific in situ bioreclamation processes were developed and tested. These processes include surface bioreclamation, in situ subsurface bioreclamation after free product recovery and in situ subsurface bioreclamation following soil washing using an alkaline polymer surfactant (APS). Each process relies on stimulating the contaminant biodegradation activity of native microorganisms by managing the soil environment. Process specific techniques include altering and maintaining pH and moisture levels within a preferred range, supplementation with inorganic nutrients that would otherwise be present in limiting concentrations and providing sufficient oxygen for optimal aerobic

activity. Laboratory results suggest that surface bioreclamation following primary product recovery and in situ subsurface bioreclamation following soil washing each has potential as a viable, cost-effective remediation technique.

Surface Bioreclamation

Surface bioreclamation is based on the microbial degradation of organic contaminants in soils in a land surface treatment system. Surface bioreclamation essentially consists of stimulating contaminant degradation in a relatively shallow (< 18 inch) surface soil layer. Contaminant biodegradation is stimulated by providing an environment conducive to optimal microbiological activity. Aerobic conditions are maintained by optimizing atmospheric contact and oxygen diffusion through surface soil and may be aided by soil tilling methods. Inorganic nutrients and other soil amendments can also be tilled into the soil while the moisture content is maintained within a range conducive to microbial activity.

The most effective surface bioreclamation methods were evaluated by measuring contaminant reduction in soils treated by different methods in microcosm studies. The surface bioreclamation microcosm studies were carried out in small open pans containing approximately 3 kg of soil spread to a depth of approximately 10 cm. Daily tilling and watering were carried out to maintain soil moisture content at approximately 50% to 70% of the water holding capacity. Treatments evaluated in these studies included the following:

- Soil amendment with inorganic nutrients
- Amendment with various levels of manure
- Inoculation plus amendment with nutrients

Figure 1 illustrates the results obtained for the biodegradation of the PAH fraction in the surface soils under evaluation for surface bioreclamation.
Figure 1
PAH Removal Results for Laboratory Simulation of Surface
Soil Bioreclamation

The contaminant removal kinetics observed in these studies were on the high end of the range obtained in similar studies reported in the available literature. Similar results were observed for the oil and grease component of the site contamination. As observed in other studies, the higher ring PAHs (i.e. > 4-rings) exhibit degradation rates which are lower than for the 2-to 3-ring PAHs. This results in a lower overall biodegradation efficiency of the larger PAHs during the study period (Table 1). Given the limited duration of these studies (i.e., 8 weeks), the rates should be considered initial rates at best for the higher ring PAHs and therefore the residual contaminant levels achievable for these compounds cannot be accurately assessed.

These laboratory simulations suggest a number of factors that may be important for surface bioreclamation pilot studies. For example, it appears that while the addition of manure did not significantly enhance the rate of biodegradation, it did enhance the physical character of the soil making it easier to till. This operational factor alone warrants the use of manure for field pilot studies. The laboratory studies also suggest

Table 1
Residual Contaminant Levels Achieved in Surface Bioreclamation Pan Studies

that it may be beneficial to add nutrients in small multiple increments.

The most important implication of the laboratory soil pan studies is that surface bioreclamation does indeed appear to be a viable means of reducing the contaminant levels in the surface soils. It should be further investigated in field pilot studies.

Soil Washing

Laboratory column studies, which are designed to simulate an in situ treatment process, have provided data on the effectiveness of the APS soil washing process. These studies confirm the contaminant removal effectiveness of the APS soil washing technique as summarized in Table 2. Generally, better removal efficiencies (>89%) were observed in the more heavily contaminated Trench 4 soil.

Table 2
Contaminant Removal in APS Soil Washing Studies

In situ soil washing is a two-step process consisting of delivery of the APS solution followed by an aquifer reequilibration step designed to purge residual polymer and surfactant and to establish base line pH conditions. The high pH values subsequent to the APS wash are not conducive to microbial activity. In addition, the alluvium will contain high residual concentrations of polymer and surfactant. This contamination may contribute to an increased oxygen demand and result in the preferential biodegradation of this material over the target contaminants.

As part of the laboratory studies, various treatment evaluations were performed on soil columns that had been subjected to the APS washing process. One series of columns was treated by flushing the soil with 0.001 N phosphoric acid solution to return the soil to near neutral pH. The other series of columns was treated by flushing neutral pH, oxygenated water through the columns to slowly reequilibrate the soil. As summarized in Table 3, higher concentrations of polymer, surfactant and target contaminants were leached with neutral water solution than with the acid solution. This suggests that aquifer rehabilitation will be most effectively accomplished with non-pH-adjusted water.

Table 3
Contaminant Removal During Simulated Aquifer Rehabilitation

Subsurface Bioreclamation

Subsurface bioreclamation may be implemented in two distinct soil environments. One scenario is implementation immediately following primary oil recovery in which case the soil environment would be heavily contaminated. In the second scenario, primary oil recovery would be followed by in situ soil washing with in situ bioreclamation as the polishing step to achieve final cleanup levels. The soil environment would be characterized by much lower target contaminant levels, the presence of residual polymer and surfactant from the wash step and potentially altered microbial populations and metabolic capabilities.

Laboratory studies were performed to evaluate in situ bioreclamation in both washed and unwashed soils. The discussion of the results from this study is therefore presented in two sections: bioreclamation in unwashed soils and bioreclamation in washed soils.

Studies performed to evaluate in situ bioreclamation in unwashed soils were designed to answer the following questions:

* Considering the toxicity of certain site contaminants, could microbial degradative activity be stimulated in the heavily contaminated soils present after primary oil recovery?
* What specific treatments are required to most effectively stimulate activity in these soils?
* What cleanup levels are achievable as a function of time in the specified process?

The ability to stimulate microbial activity in heavily contaminated unwashed soils was evaluated in column studies designed to simulate in situ subsurface bioreclamation. Soils from two site locations, Trench 1 and Trench 4, were used in these studies. Trench 4 soil had the highest contaminant levels, approximately four times greater than Trench 1 soil. Approximately 400 g of soil were placed in columns 20 cm long with a diameter of 5 cm. Simulated groundwater containing combinations of treatment agents (e.g., oxygen, nutrients, peroxide and inoculum) was then passed through the saturated soil column. Data were obtained
Figure 2
Contaminant Reduction in Trench 4 Soil During Column Studies

through influent and effluent analysis and through analysis of soil from sacrificed columns.

Results from the column studies demonstrated that microbial contaminant degradation could be stimulated in heavily contaminated Trench 4 soils. Oxygen consumption in the columns is indicative of aerobic microbial activity since the aerobic biodegradation of the contaminants will exert an oxygen demand on the system. Oxygen supplied to the columns was generally rapidly and completely utilized in the columns. The data suggested that higher oxygen delivery rates resulted in increased contaminant biodegradation or removal. The greatest degree of contaminant reduction occurred in columns which received elevated oxygen levels and inorganic nutrients. This result is illustrated in Figure 2 which presents a summary of results obtained in studies conducted in the soil columns.

The level of cleanup achievable using in situ subsurface bioreclamation and the time required to attain a given cleanup level will be two criteria that will determine the feasibility of this technique for site cleanup. The most pertinent data generated in the bioreclamation laboratory studies for cleanup levels are the data on contaminant concentrations in column leachates at the conclusion of the tests. These data provide a measure for organic groundwater quality achievable as subsurface contaminants are removed and biodegraded.

Leachate from the columns was evaluated after 15 weeks of delivering oxygen and nutrients to saturated soil columns. No PAHs or PCP were detected in the column leachate at a detection limit of 10 µg/L. Levels of total petroleum hydrocarbon (TPH) were below the detection limit of 1.0 mg/L. Another measure of the degree of cleanup achievable with in situ bioreclamation immediately following primary oil recovery is the degree to which specific contaminant concentrations in column soils are reduced. Table 4 contains data on soil contaminant levels at the beginning and after 15 weeks of treatment in select column studies.

It is apparent from these data that significant reductions in all contaminants were observed; however, this result was not considered representative of the ultimate degree of cleanup attainable. Most of the oxygen being supplied to the columns was still being consumed in the columns at the time these data were collected.

Select columns were operated through 92 weeks of treatment before the columns were sacrificed and analyzing soil samples were analyzed for residual contaminant levels. Generally, oxygen consumption had subsided considerably and nutrient levels in column effluents approached those of the influent. This was taken as an indication that microbial degradative activity had subsided. Trench 1 soils continued to exhibit further reductions in all PAHs. In the more heavily contaminated Trench 4 soil columns, further reductions in contaminant levels were observed only in those columns receiving inorganic nutrients and aerated groundwater. Columns receiving additional oxygen in the form of hydrogen peroxide showed no significant reductions in PAHs after the first 15 weeks of treatment. The indication is that treatment with hydrogen peroxide can substantially reduce the time frame of in situ bioreclamation and achieve the maximum cleanup levels attainable. Table 5 provides a summary of the results obtained for specific bulk contaminant parameters such as COD, oil and grease, TPH and total PAHs. These data suggest that while though peroxide treatment resulted in optimal PAH removal during the first 15 weeks of treatment, further significant reductions in COD and TPH could be achieved through longer treatment times. The data can also be interpreted to indicate that PAHs are preferentially biodegraded in comparison to the total organics. Table 6 provides a summary of the reductions obtained in specific target contaminant levels for Trench 1 (low PAH) and Trench 4 (high PAH) at various treatment times. The results tend to indicate that the use of hydrogen peroxide yielded optimum reduction of all PAHs during in the shortest treatment interval (15 weeks). When treatment consisted of supplying oxygen via aerated groundwater, then both Trench 1 and Trench 4 soils exhibited substantial reductions in PAHs with extended treatment periods.

Laboratory studies were performed to evaluate in situ subsurface biodegradation of contaminated subsurface soil following in situ soil washing with an APS solution. These studies were designed to answer the following questions:

- To what extent will microbial populations and metabolic capabilities be altered by the APS soil washing process?
- What measures are required following soil washing to restore microbial degradative activity towards site contaminants?

- What cleanup levels are achievable using in situ subsurface bioreclamation following in situ soil washing?

A major concern about the in situ soil washing process followed by in situ bioreclamation as a polishing step was the potential adverse effect of the APS solution on microbial populations and metabolic capabilities towards site contaminants. The saline, alkaline, APS solution could drastically reduce microbial numbers and metabolic capacity during the washing cycle. It was hypothesized that a soil washing agent that effectively liberates and displaces oil from the subsurface soils could flush the associated microbial biomass from the soils as well.

The degree to which microbial populations and metabolic capabilities were altered by the soil washing process was evaluated in a series of column experiments. Approximately 400 g of Trench 4 soil were placed in columns 20 cm long with a diameter of 5 cm. Four pore volumes of the APS solution were then passed through the columns. After soil washing, various treatments for rehabilitating the soil were evaluated. Simulated groundwater containing combinations of treatment agents (i.e., phosphoric acid, oxygen, nutrients, peroxide and inoculum) were then passed through the saturated soil column. Data were obtained through influent and effluent analysis and through analysis of soil from sacrificed columns. Evidence of restoration of microbial activity can be divided into three categories:

- Oxygen consumption in the columns
- An increase in microbial numbers during the bioreclamation phase
- Contaminant removal during bioreclamation

After the soil washing process, Trench 4 soil samples exhibited a reduction in microbial populations from 2×10^5 viable heterotrophic bacteria per gram of soil to less than 10^4 gram of soil. Trench 2 soil showed a more drastic reduction in microbial populations from 3×10^7 to 1×10^5/gram of soil (Table 1). Subsequent to cycling water containing oxygen and nutrients through the soil columns, microbial counts increased to 2×10^7/gram of soil. This increase in numbers is another indication that microbial activity can be reestablished in soils after APS washing.

The effect of the simulated soil washing process on microbial biodegradation capabilities was evaluated by measuring phenanthrene mineralization during incubation of soils subjected to the soil washing process. Mineralization was measured using a ^{14}C - radioisotope of phenanthrene and monitoring for the production of $^{14}CO_2$.

As can be seen by the results presented in Table 7, phenanthrene mineralization was reestablished in Trench 4 soils but apparently was not reestablished in Trench 2 soil.

Nearly all oxygen supplied to the columns was consumed during the bioreclamation phase. In columns with an influent dissolved oxygen of 12 mg/L, the effluent dissolved oxygen was always less than 1.5 mg/L.

Table 7
Reestablishment of Biodegradation Potential After APS Soil Washing

Sample	Percent of 14-C as CO2 (mg/kg total phenanthrene)		
	Week 2	Week 4	Week 6

Although these data suggests that significant microbial activity was restored, there is no certainty whether the target contaminants (PAHs) or residual polymer surfactant were being degraded.

As part of this study, replicate columns were sacrificed and the soil was analyzed at the conclusion of the soil washing and again at the conclusion of the bioreclamation process. Although it is possible to state, based on these data, that aerobic microbial degradative activity was restored in these columns, it is difficult to conclude to what degree the capability of soil microorganisms to degrade target contaminants was affected.

This conclusion is due in large part to the excellent contaminant removal efficiencies attained in the soil washing phase. The concentration of target contaminants (PAHs and PCP) in the column soils at the conclusion of soil washing was generally near nondetectable levels. Some further reduction in target contaminant concentrations was achieved during the bioreclamation phase of the study (Table 8). It is not possible to differentiate between contaminant loss resulting from microbial activity in the column and contaminant loss resulting from the leaching of a mixture of residual polymer, surfactant and target contaminants.

It is important to note that the lowest contaminant levels were attained in the soil columns that were not subjected to rapid pH adjustment with phosphoric acid. These columns were simply treated by cycling oxygenated groundwater through the column.

CONCLUSIONS

The most important conclusion from the bioreclamation column studies described previously is that in situ subsurface bioreclamation is a viable process under either of the following scenarios:

- Directly following primary oil recovery where very high contaminant levels will be present
- Directly following soil washing with an APS solution as a polishing step.

Microbial contaminant biodegradation was stimulated in soils containing relatively high residual contaminant levels. Providing sufficient oxygen appeared to be the most important parameter for stimulating microbial degradative activity. Supplementation with nitrogen and phosphorous as inorganic nutrients was also beneficial, but only if sufficient oxygen was provided.

In situ, subsurface bioreclamation following soil washing also appears to be a viable treatment scenario. Although the APS soil washing process did have some impact on microbial populations, the laboratory study results suggest that microbial contaminant biodegradation activity can be restored and stimulated. In the laboratory column studies, bioreclamation following soil washing successfully lowered the residual concentrations of target contaminants (PAHs and PCP) in the soil to levels near or below the analytical detection limit.

Preliminary indications of the time required to achieve cleanup were obtained in the column studies. It is believed that the time required to achieve cleanup by in situ bioreclamation may be determined primarily by the rate at which oxygen is delivered to the subsurface. The laboratory studies suggest that the subsurface oxygen demand that must actually be met to achieve cleanup may be substantially less than the predicted oxygen demand based on in situ mineralization of the gross organics present. Thus, depending upon the oxygen delivery rate actually achievable under field conditions, actual cleanup times could potentially be lower than theoretical predictions.

As previously stated, the laboratory results suggest that in situ bioreclamation is a viable treatment alternative for the remediation of this site and field pilot testing was recommended. Based on the laboratory results, it was suggested that one of the major objectives of the field program should be the correlation of oxygen delivery with contaminant removal. Developing the correlation will require determining the relative extent of contamination reduction through several mechanisms. Monitoring the following parameters will be critical tasks in field pilot studies:

- Mass of oxygen delivered
- Mass of oxygen consumed and definition of the zone of aerobic treatment
- Contaminant reduction in the aerobic zone
- Contaminant reduction in anoxic zones
- Nature and extent of contaminant removal through leaching from the subsurface

CASE HISTORY: PILOT-SCALE DEMONSTRATION

A pilot-scale, solid-phase air stripping and biological treatment facility was constructed at the Brio Refining Superfund Site, Texas, in order to demonstrate the feasibility of bioremediating affected soils and organic residues on-site. The site has a large volume of affected soils containing

styrene still bottom tars and chlorinated hydrocarbon solvents.

The biodegradability of the site material was determined by Microtox testing. Of 11 areas tested, two areas were found suitable for biodegradation without dilution. Of these two areas, the one with the lowest concentration of volatile organic compounds was selected as the source of material for the pilot-scale biodegradation demonstration. This area was designated as Pit O during the RI/FS. Additional samples of the Pit O backfill were collected in order to conduct a bench-scale evaluation of the biodegradability of the organic compounds present in the backfill. This testing indicated that the ketones, short-chain chlorinated hydrocarbons, chlorinated aromatic hydrocarbons and aromatic hydrocarbons found in the pit backfill could be removed by air stripping or biologically destroyed by indigenous microorganisms. On this basis, the decision was made to undertake a pilot-scale demonstration of biodegradation of backfill material from Pit O.

The treatment facility consisted of an enclosed, lined treatment bed containing 200 yd^3 of affected soil from one of the backfilled storage lagoons located at the site. The liner was an 80-mil HDPE synthetic membrane with heat-welded seams. A sand drainage layer was placed on top of the liner and a 6-inch thick layer of affected soil was placed on top of the sand. Nutrients and inoculum were applied to treatment bed through an overhead spray system. The treatment bed was tilled daily to increase soil surface area and provide aeration. Volatile emissions from the treatment bed were contained by a plastic-film greenhouse and routed to carbon adsorption units.

Following construction of the treatment facility, approximately 200 yd^3 of soil were transferred to the treatment facility. The excavated soil was placed on top of the prepared treatment bed. Due to the cohesiveness of the clay soil, the pit backfill material was allowed to dry before final grading. For several days the tracked front-end loaders were run back and forth over the pit backfill to break up large blocks of soil and distribute material evenly over the treatment bed. After 3 days of manipulation, the clay was amendable to tillage by a power rototiller attached to a tractor. Soil moisture content was low enough after 6 days to add nutrients.

The soil treatment bed was divided into four lanes so that different methods of optimizing microbial activity and biodegradation rates could be evaluated. A control lane, which received only tilling and water additions, was established to provide a base line for evaluating the effectiveness of the following three treatment processes: (1) nutrient addition, (2) single microbial inoculation and (3) multiple microbial inoculations.

The pilot-scale treatment facility was operated for 94 days. The soil in the treatment facility was tilled daily to optimize contact between microorganisms and the organic constituents present in the pit backfill material and to ensure adequate aeration for microbial activity. Tilling also facilitated the air stripping of VOCs. Soil moisture content, soil temperature and soil pH were monitored to ensure that they remained within ranges conducive to microbial activity. Water, nutrients and inocula were added as required to the treatment bed through the overhead spray system.

Sample Collection Analysis

Soil samples were collected on Day 0, Day 21, Day 58 and Day 94. Soil samples were analyzed for volatile and semivolatile organic compounds in order to determine the rate of organic compound degradation and measure the effectiveness of the three treatment processes. In addition, the soil samples were analyzed for soluble ammonium, nitrate and phosphate to determine if the concentrations of these nutrients were sufficient to ensure maximum microbial growth and organic compound degradation.

Removal of Volatile Organic Compounds

The predominant VOCs detected in the Pit O backfill material placed in the treatment facility were ethylbenzene, styrene and toluene. These compounds were detected at maximum concentrations of 4,400 ppm, 240 ppm and 510 ppm, respectively. Methylene chloride and 1,1,2-trichloroethane were also detected but at lower concentrations. Methylene chloride concentrations ranged from 0.53 ppm to 20 ppm.

while 1,1,2-trichloroethane concentrations ranged from 0.52 ppm to 110 ppm. Acetone; 2-butanone; chlorobenzene; 1,1-dichloroethane; methylene chloride; 1,1,2,2-tetrachloroethane, 1,1,2-trichloroethane; and xylene were detected at concentrations ranging from 3.1 to 88 ppm; 3.7 to 54 ppm, 3.4 to 26 ppm; 2.3 to 200 ppm; 0.53 to 20 ppm; 4 to 5.1 ppm; 0.52 to 110 ppm and 0.55 to 180 ppm, respectively.

The concentrations of the volatile organic compounds in the treatment facility were reduced by more than 99% over the 94 day period of operation (Table 9). Most of this reduction occurred within the first 21 days of operation and was predominantly due to air stripping. Volatile compounds of both high and low volatility were removed with equal efficiency. For example, the concentrations of methylene chloride and 1,1,2-trichloroethane, both highly volatile compounds, were reduced by more than 99%. The concentrations of ethylbenze and styrene, both low volatility compounds, also were reduced by more than 99%.

Two methods were used to estimate the amount of volatile organic compounds removed from the affected soils by air stripping: (1) concentration of volatile compounds adsorbed in the activated carbon units and (2) air emissions data collected during facility operation. The amount of volatile compounds air stripped from the affected soils ranged from 137 kg to 159 kg, a removal rate of approximately 7 kg per day.

Table 9
Volatile Organic Compound Removal, Pilot-Scale Bioremediation, Brio Refining Site, Friendswood, Texas

Total Volatile Organics (PPB)

Lane	Day 0	Day 21	Day 58	Day 94	Reduction*
Control	25,972	81	17	29	99.69%
Nutrient Adjusted	39,460	40	14	12	99.90%
Single Inoculation	273,184	13	16	25	99.99%
Multiple Incoluation	101,868	10	19	27	99.9%
* Reduction After 21 Days of Operation					

Degradation of Semi-Volatile Organic Compounds

Phenanthrene was the predominant semivolatile organic compound detected in the Pit O backfill material placed in the treatment facility. Phenanthrene concentrations ranged from 0.44 to 170 ppm and the average phenanthrene concentration was 36.3 ppm. 2-Methylapthalene concentrations ranged from 6.2 to 170 ppm, with an average concentration of 50. ppm. Naphthalene concentrations ranged from 0.13 to 96 ppm and the average concentrations was 19.5 ppm. Over the 94 day operation of the pilot-scale biological treatment facility, semi-volatile organic compound concentrations were reduced an average of 89% (Table 10).

Table 10
Semi-Volatile Organic Compound Degradation, Pilot-Scale Bioremediation, Brio Refining Site, Friendswood, Texas

Total Semi-Volatile Organic Compounds (PPB)

Lane	Day 0	Day 21	Day 58	Day 94	Reduction
Control	18,900	9,346	6,078	2,928	84.51%
Nutrient Adjusted	16,100	6,999	5,325	1,402	91.29%
Single Inoculation	56,983	4,610	3,967	2,023	96.45%
Multiple Inoculation	18,496	6,028	6,611	2,800	83.03%

Phenanthrene Degradation

Due to its predominance in the affected soil from Pit O, phenanthrene was used to determine the effect of the various treatment processes on the degradation rate of semivolatile organic compounds. Over the 94 days of facility operation, phenanthrene concentrations were reduced an average of 84% (Table 11). During the first 21 days of operations, phenanthrene degradation occurred at a relatively rapid rate. For the remainder of the demonstration project, the phenanthrene degradation rate was approximately 124 μg/kg/day. At this degradation rate, approximately 131 days would be required for the phenanthrene con-

centration to reach 0.33 ppm, the analytical detection limit using the U.S. EPA-approved procedure.

Table 11
Phenanthrene Degradation, Pilot-Scale Bioremediation, Brio Refining Site, Friendswood, Texas

Phenanthrene Degradation, Pilot-Scale Bioremediation, Brio Refining Site, Friendswood, Texas				
Phenanthrene Concentration (PPB)				
Lane	Initial Day 0	Final Day 94	Reduction	Half-life (Days)
Control	27,850	5,725	79.44%	40.8
Nutrient Adjusted	19,400	2,712	86.02%	33.0
Single Inoculation	73,600	5,750	92.19%	25.7
Multiple Inoculation	24,360	5,275	78.35%	43.3

Phenanthrene half-life values for the control, nutrient-adjusted, single inoculation and multiple-inoculated lanes were 40.8, 33.0, 25.7 and 43.3 days, respectively. A statistical analysis of the data demonstrated that there was no significant difference in the rate of phenanthrene degradation in the different treatment lanes; the initial phenanthrene concentration was apparently the parameter controlling the rate of phenanthrene degradation. The data collected during this demonstration project suggested that aeration and the amount of contact between the microorganisms and the affected soil also were parameters that governed the rate of phenanthrene degradation.

Since there was no significant difference in the rate of phenanthrene degradation observed in the different treatment lantes, all of the date were pooled to determine the rate of phenanthrene biodegradation in the treatment facility. The average half-life was 33 days, significantly less than reported half-life values of 69 to 298 days in other solid-phase biodegradation systems.

CONCLUSION

The pilot-scale biological treatment facility constructed at the Brio Refining Superfund Site conclusively demonstrated that target compounds such as 1,2-dichloroethane, 1,1,2-trichloroethane and phenanthrene could be removed effectively from soils using an on-site treatment technology other than incineration. The process removed volatile organic compounds by air stripping and destroyed semivolatile organic compounds by biodegradation.

ABSTRACT

Red water generated during the manufacture of trinitrotoluene (TNT) is an environmental concern because it contaminates ground surfaces and groundwaters. Past methods for the management of this hazardous waste stream either did not meet pollution compliance or were not cost-effective. Biodegradation of TNT by bacteria has been reported, but no conclusive evidence supports its biotransformation to harmless products or its complete mineralization to CO_2 and H_2O. The lignin peroxidase (ligninase) secreted by the white rot fungus (*Phanerochaete chrysosporium*) has been shown to degrade a broad spectrum of organic pollutants. In this study, the efficacy of treating red water with the *P. chrysosporium* system was investigated.

INTRODUCTION

Red water is a waste stream generated during the manufacture of explosives. During TNT purification, a red colored waste water is produced that is rich in sodium sulfite (sellite) and sulfonates of various isomers of TNT. Red water has been classified by the U.S. EPA as hazardous and has been an environmental concern not only to U.S. Army ammunition plants, but also to the general public because it can contaminate ground surfaces and groundwaters.

Disposal of untreated red water by direct discharge into waterways and sewer systems is not acceptable. Tighter pollution regulations have prevented paper mill companies from recycling the red water for its sodium and sulfur content for use in pulping operations.[1] The conventional method of disposal by incineration is expensive and energy-intensive, and the ash accumulated from incineration can cause a leachate problem when it is landfilled.[2] The Sonoco process,[3] which converts red water into a sellite solution for reuse in TNT purification, has been tried in several operations, but the capital cost of the equipment and the cost of plant operation are astronomical. In addition, the quality of the recovered sulfite remains questionable.

An average Army ammunition plant, such as the Joliet Army Ammunition Plant (JAAP), generates red water at rates of approximately 80,000 gal of liquid per day and 250,000 lb solids per day during full operation. Samples taken from different sites at JAAP indicated that past operations have caused contamination of the soils, sediments, surface water and groundwater. Until a solution for effective red water treatment is found, all United States ammunition plants must be maintained in a standby mode, and no TNT may be produced.

One of the most cost-effective methods for on-site remediation is microbial biodegradation. However, the effectiveness of this treatment depends heavily on the survival, adaptability and activity of the microorganisms. Initial efforts at biological treatment of wastewater containing TNT were not satisfactory. Bacteria generally reduce nitro groups of the TNT, but no conclusive evidence exists that they cleave the aromatic ring. In addition, the bacterial transformation created a sludge disposal problem and produced an effluent that was more toxic to fish than the untreated samples.[4] Therefore, an economical and environmentally safe method needs to be developed to treat red water.

Direct enzyme treatment of hazardous compounds and environmental contaminants is a relatively new concept. Lignin peroxidase (ligninase) secreted by a white rot fungus has been shown to nonspecifically break many aromatic and substituted aromatic rings.[5] Ligninases play a key role in the degradation of a broad spectrum of organic pollutants including DDT, polychlorinated biphenyls, benzopyrene, pentachlorophenol and dioxins.[6] In this study, red water samples were treated with ligninase prepared from the fungal culture or with the fungal culture itself, under various conditions. Different analytic and toxicologic parameters were tested to evaluate the efficacy of the various treatment protocols. The best biotreatment protocol can be used as the basis for further development of field application and on-site, large-scale demonstrations.

EXPERIMENTAL

The red water samples obtained from Canadian Industries, Limited (McMasterville, Quebec) are representative of waste streams from continuous production lines in the U.S. Army ammunition plants. The "as received" (AR) red water was refrigerated, and the solid precipitate (identified as Glauber's salt, $Na_2SO_4 \cdot 10\ H_2O$) formed upon refrigeration was removed to yield the salt-reduced (SR) form.[7] Both AR and SR red water samples were treated with the fungal system.

The white rot fungus *P. chrysosporium* (BOK-f-1767, ATCC 24725) originally from T.K. Kirk (U.S. Department of Agriculture, Forest Products Laboratories, Madison, Wisconsin) was cultured according to the procedures of Tien and Kirk.[8] The ligninase activity secreted into the fungal culture media during the ligninolytic phase of fungal growth was extracted. The ligninase activity was measured at room temperature by monitoring the increase in absorbance at 310 nm.[9] One unit of ligninase activity (U) is defined as that which catalyzes oxidation of one micromole of veratryl alcohol to veratryl aldehyde (which absorbs intensely at 310 nm) per minute under specified conditions.

The extracted ligninase preparation was concentrated by Amicon CH2PRS and 8200 concentrators (Amicon Division, W.R.

Grace & Co., Danvers, Massachusetts) using a membrane with a cutoff at 10,000 molecular weight. Dialysis of the concentrated ligninase preparation (CLP), removal of mucilagenous materials after the CLP was frozen or partial purification of the extracellular enzyme followed, depending on the experimental design. The stability of the ligninase activity was evaluated at various temperature to ensure that the storage and activity of the enzyme preparation were proper for laboratory use or for long-term field application.

The CLP collected from several batches of shake flask culture of *P. chrysosporium* was used in various biotreatment incubations. Both the AR and the SR red water, undiluted and diluted (1:10 - 1:20), were incubated with CLP at 25° C. The whole fungal culture was sampled when peak ligninase activity was observed. The peak fungal broth (PFB) was used to treat the SR red water sample at 39° C. The biodegradation rate of the whole fungal culture treatment was compared to that of the direct enzyme (CLP) treatment. Biotreatment controls (with no CLP or no red water) were also set up for proper comparison.

An aliquot of the SR red water was preexposed (at room temperature) for three days to a Philips back-light lamp (with greater than 96% of its energy peaked at 365 nm) from four directions in a sealed structure made in-house. Ultraviolet light (UV) exposure is known to cause photolysis and to weaken the structure of the organic ring. The effects on biodegradation of UV pretreatment and the addition of veratryl alcohol (known to stabilize the ligninase activity) were also tested in the SR red water.

Treated sample aliquots were taken from the incubation mixture at 4 hr, 1 day, 3 days and 7 days. These samples were stored at −20° C until the time of assay. Samples collected from various biotreatment plans were analyzed for decolorization and ligninase activity and by UV spectral analysis, high-performance liquid chromatography (HPLC) metabolite analysis and Microtox™ bacterial toxicity screening.[10]

Two different HPLC column systems with UV detection (230 nm) were developed to analyze specific reactants in the red water and their biodegradation products. The Supelcosil LC-8 column (4.6 mm x 33 mm, 3-um packing, from Supelco, Inc., Bellefonte, Pennsylvania) was heated at 30° C. Sample (20 ul) was injected onto the column through a 0.5-um pore stainless steel precolumn frit filter. Standards of structures similar to the organic compounds commonly found in red water were chosen to calibrate the column. The standards, used in 95% glacial acetic acid (GAA) were 2,4,6-trinitrobenzenesulfonic acid (picrylsulfonic acid, PSA), TNT, 2,4-dinitrotoluene (2,4-DNT) and 2,6-DNT. The column was eluted for the first 4 min with 100% 1 mM GAA (at 0.5 mL/min) and for the next 10 min with a solvent system consisting of 30% of 1 mM GAA (at 2 mL/min).

The second HPLC system, developed to analyze biodegradation metabolites, used a longer column (Beckman Ultrasphere Octyl 5-um column, 4.6 mm x 250 mm, from Beckman Instruments, Inc., San Ramon, California) and a longer elution time (30 min) for better resolution of the earlier peaks derived from the treated samples. Samples (20 uL), diluted in 1 mM GAA, were injected onto the column at 40° C. From 0 to 7 min, a 10% solution 2% THF in methanol in 90% water was used as mobile phase at a flowrate of 0.3 mL/min. From 7 to 30 min, the mobile phase was changed to 30%:70% and the flowrate increased to 2.5 mL/min.

To get even better resolution of the major sample peaks, samples were run isocratically on the Beckman column at 40° C for 25 min. The mobile phase used was a 10% solution of 2% THF in methanol in 90% water at a flowrate of 0.3 mL/min.

Samples collected at different time points of the biotreatment incubation were screened for biotoxicity with the Microtox bioassay (Microbics Corporation, Carlsbad, California). This assay involves exposing luminescent bacteria to red water and measuring any decrease in light output, which is indicative of the degree of sample toxicity. When the treated red water is subjected to the same test, an increase in light output over that for the untreated

sample reflects degradation and detoxification of the red water. The Microtox test was conducted on a Luminescence Biometer (DuPont Instruments, E.I. DuPont deNemours & Co., Wilmington, Delaware).

RESULTS AND DISCUSSION

Stability of Ligninase

In vitro stability of ligninase is important in determining the economic and technical feasibility of its application in bioremediation or industrial uses. The ligninase activity of two different CLPs was compared at 25° C. The high-activity (3580 U/L preparation, without mucilagenous material, showed a slow decrease in activity, finally staying at 70% of its original activity at 7 days. However, the low-activity preparation (750 U/L), containing mucilagenous material, dropped to only 3% of its original activity in 24 hr. Ligninase activity of a CLP (1540 U/L, mucilates removed) first decreased and then stayed at 70 to 80% of its initial activity over a period of 7 days when it was stored at 25° C (Fig. 1) or 39° C (Fig. 2). When the original enzyme activity (1540 U/L, 1X) was diluted to 0.2X, 0.1X or 0.02X, the stability pattern remained the same. The same ligninase stability pattern was also observed with a CLP of 1050 U/L (mucilates removed) stored at −70° C, −20° C or 4° C for 28 wk. If the mucilagenous material is removed from the crude enzyme preparation, the ligninase activity apparently will remain at 70 to 80% of its original value at starting activity levels ranging over two orders of magnitude (30 to 3500 U/L). The polysaccharides or protease present in the mucilates may have detrimental effects on the ligninase activity.

Decoloration and UV Spectral Analysis

The red color intensity was measured in all samples by absorbance at 400 nm. A loss of red color suggests that biotransformation of the red water has occurred. The red color intensity was

reduced in all samples from 30 to 0% of the original value after only 1 day of treatment with the fungal system. The diminished absorbance in the region 200 to 300 nm may result from UV spectral changes associated with the reduction of NO_2 groups of TNT isomers, a general bathochromic shift and the degradation of aromatic rings by enzyme hydrolysis. The decoloration of treated red water (Figs. 3A, 4A and 5A) corresponds with changes in the UV spectral profile (Figs. 3B, 4B and 5B). Figure 3 (A and B) shows that red color and UV absorbance (at 200 to 300 nm) were reduced when SR red water received UV treatment before enzyme (CLP) treatment. When SR red water was treated at two different temperatures, the 39° C incubation caused more biodegradation than the 25° C incubation as decoloration (Fig. 4A) and UV spectral results (Fig. 4B) demonstrate. Both red color intensity data (Fig. 5A) and UV spectral analysis (Fig. 5B) demonstrated that the fungal enzyme degrades AR red water more effectively than SR red water.

More decoloration was observed (Fig. 6) when SR red water was treated with whole fungal culture (PFB) than with the fungal enzyme (CLP). The addition of veratryl alcohol (V-OH), a substrate for ligninase, further reduced the red color.

The decoloration and UV spectral results both suggested that SR red water is more toxic (see following toxicity data) and less biodegradable than AR red water. The UV pretreatment makes the SR red water more amenable to fungal biotreatment. The salt

that was removed from the AR red water may be important to the enzyme activity and the biotreatment regime.

HPLC Analyses of Red Water Biodegradation Metabolites

Data from HPLC analyses revealed that biotreatment with fungal enzymes altered red water components. An aliquot from the 4-hr sampling of the CLP-treated (at 25° C) SR red water was spiked with 0.1% PSA, 77 mg/L TNT, 109 mg/L 2,4-DNT and 93 mg/L 2,6-DNT and the mixture was applied to the Supelcosil column. The elution profile with its respective retention time (min) is given in Figure 7. Five distinct peaks were recovered from the treated red water sample. The applied PSA standard was resolved into three earlier peaks (PSA-A, PSA-B and PSA-C) which were mingled with the five peaks derived from the treated sample. The TNT, 2,4-DNT and 2,6-DNT peaks appeared toward the end of the elution.

The calibrated Supelcosil column system was used to analyze samples taken from biotreatment incubations. The results are summarized in Table 1. All samples initially had low levels (less than 0.5% of the total peak height) of TNT isomers. After CLP

[a]Retention times are 0.78, 0.83, 1.19, 1.89, 2.15, and 3.74 min, respectively, for peaks Pk1-Pk5.

[b]Abbreviations: AR, as-received red water; SR, salt-reduced red water; CLP, concentrated ligninase preparation; 25, 39, red water sample treated at 25°C or 39°C; 4 hr, 1 wk, sample aliquots taken at 4 hr or 1 week of red water biotreatment incubation; UV, SR red water subjected to UV pretreatment for 3 days before biotreatment.

treatment, 0% peak height of TNT isomers was found. In general, the percent peak heights of all resolved peaks from the AR red water, the SR red water and the UV-pretreated SR red water were identical. When the SR red water was treated with CLP (at 25° C), Peak 1 appeared with a corresponding decrease in Peak 2 in both the 4-hr and 7-day samples (Table 1A). A decrease in percent peak height was also found in peak PSA-B in those two samples. Similar changes in percent peak height were observed when the UV-treated SR red water was further treated with CLP at 25° C (Table 1B). The 25° C and 39° C incubations were identical when SR red water was treated with CLP for 7 days (Table 1B).

The HPLC elution profile for the Beckman column is in Figure 8. The AR red water was spiked with PSA (19 ug), TNT (0.15 ug), 2,4 DNT (0.22 ug) and 2,6-DNT (0.19 ug). The elution pattern and the retention times for each peak are different from those of the Supelcosil column. Three peaks were resolved for the PSA standard (PSA-A, B and C). The treated sample aliquot was again resolved into five distinctive peaks, and TNT, 2,4-DNT and 2,6-DNT were eluted toward the end of the run.

The changes in metabolite peaks observed in the Beckman column HPLC profile, using isocratic conditions, are summarized in Table 2. Under these conditions, PSA peaks do not overlap with sample peaks. The patterns of percent peak height for the AR and SR red water are not significantly different (Table 2A), as in the Supelcosil column peak distribution. However, even though in both HPLC analyses, organic components in AR and SR red water had the same percent peak heights, the UV spectral analysis and toxicity data suggested that the AR and SR red waters and their biodegradabilities with the fungal system are different. A shift from Peak 2 to Peak 1 and the appearance of Peak 3 (less than 5% of the total peak height) were observed in all CLP-treated SR red water samples (Table 2). Profiles for the 25° C and 39° C treatment are similar (Table 2C). Peak 1 does not appear until the UV-pretreated SR red water is further treated with CLP at 25° C (Table 2D).

The combination of HPLC and nuclear magnetic resonance (NMR) analysis can further demonstrate ring hydrolysis and changes between organic aromatic and aliphatics in the treated samples.

Toxicity Screening

The degree of toxicity, as derived from the Microtox data for various biotreatment protocols, is summarized in Table 3. No

toxicity was found in the control incubation (CLP only). The degree of toxicity is equal to $(1/EC50) \times 100$, where EC50 is the concentration of a compound that causes a 50% reduction in light production in luminescent bacteria exposed to it. The degree of toxicity of the SR red water is set at 100%, and the data obtained for the other samples are expressed as a percentage of the value for SR red water.

The AR red water showed less toxicity than SR red water. After UV treatment, the toxicity of the SR red water was reduced to one third its original value (Table 3A). The ligninase (CLP) treatment reduced toxicity in both AR and SR red water and further reduced the toxicity of the UV-pretreated SR red water (Table 3B). Toxicity decreases with time of biotreatment, i.e., less toxicity is observed in samples treated for 7 days than in samples treated for 4 hr (Table 3C). Direct enzyme treatment seems to be more effective in reducing toxicity of the SR red water than whole fungal culture (PFB) treatment, and the addition of veratryl alcohol (V-OH) resulted in additional detoxification of the PFB-treated red water (Table 3D).

CONCLUSIONS

Preliminary studies suggested that the white rot fungal system is effective in biodegrading the red water waste stream during 7-day laboratory incubation with the whole fungal culture or with

the extracellular ligninase preparation. Certain aromatic components of the red water waste were biotransformed, and the red color intensity and biotoxicity were reduced after the biotreatment. The ligninase activity was stable (at 70 to 80% of its original level) for a minimum of 7 days at 25°C or 39°C. Pretreatment of the red water with UV seems to make the waste more sensitive to biodegradation.

ABSTRACT

A laboratory, batch biodegradation study was conducted to evaluate the biodegradation potential of soil from a hazardous waste site containing chemicals associated with polystyrene waste. The study focused on: (1) total waste biodegradability; (2) quantitative losses of certain volatile compounds added, i.e., 1,2-dichloroethane (DCE) and 1,1,2-trichloroethane (TCE); and (3) kinetic removal rates for all chromatographable organic compounds in the waste.

Sixteen nonvolatile chromatographable compounds were monitored in seven bioreactors in a 14-day study. The experimental design consisted of two open bioactive reactors, a sealed bioactive reactor, two sterile open control reactors to measure abiotic degradability and two open reactors not exposed to wastes as background controls for quality control. All bioreactors were spiked with DCE and TCE to quantitate losses due to volatility.

High resolution GC/MS analyses indicated that a major fraction of the organic components was biodegraded with reaction half-lives ranging from 24 hours to 72 hours. All nonvolatile chromatographable compounds were reduced to less than the limit of detection (1.0 ppm). Difference between the volatile and nonvolatile chemicals was successfully measured. Organic chemicals with GC retention times shorter than biphenyl, including DCE and TCE were rapidly volatilized. Enumeration of microorganisms confirmed an active microbial consortium present at all times of the study except in the control reactors. Acute toxicity analysis using Microtox confirmed a decrease in toxicity of extracts from the bioactive reactors over time.

INTRODUCTION

Hazardous wastes produced by industry must be disposed of in a manner which is both environmentally acceptable and cost-effective.[1,3,6,7,15] The waste disposal problem includes past disposal sites that now must be cleaned up. The remediation method chosen for each site is a key factor affecting the cost of any site remediation project.[7] Since the reauthorization of CERCLA, incineration has been the primary technique for waste site remediation of organic contaminants. Incineration may be cost-effective and efficient in specific instances where wastes contain high levels of organic components and high BTU content. However, when the site consists primarily of soil containing less than approximately 5% organic components, microbial treatment is a viable and cost-competitive alternative to incineration. It has been demonstrated that, under favorable environmental conditions, biodegradation of contaminated organics such as hydrocarbons and oily sludges may occur in soils.[6,7,8,13]

Since most hazardous waste sites contain mixtures of many chemicals, a microbial technology must demonstrate the removal of all listed chemicals to acceptable levels. This paper summarizes results from a laboratory-scale biological treatment study which was conducted to demonstrate the feasibility of biologically treating soil contaminated with polystyrene tars. The objectives of this study were: (1) total waste biodegradability; (2) measurement of quantitative vapor losses of certain volatile compounds added, i.e., 1,2-dichloroethane (DCE) and 1,1,2-trichloroethane (TCE) and (3) kinetic removal rates for all chromatographable organic compounds in the waste.

MATERIALS AND METHODS

Experimental Design

Seven glass bioreactors (2-L beakers) were used to conduct the study. Each bioreactor, except reactor D, contained 1450 mL of soil-water slurry. Reactors A and B were duplicate vessels to which 300 mg of $HgCl_2$ (Granular, Mallinckrodt Chemical Works, St. Louis, Missouri) were added on Day 0 and again on Day 10. The absence of microbial activity in these reactors should provide information about abiotic degradation processes. Reactor C contained all components except the waste to provide quality control. Reactor D was sealed with no headspace to eliminate volatility and demonstrate quantitative recovery of the chemicals at the end of the experiment. It consisted of a 1-L glass bottle filled up to the neck in order to eliminate all headspace and sealed with a foil-lined cap. Reactors E and F were bioactive duplicates of A and B and were the key reactors for monitoring biodegradation of the waste chemicals. Reactor G served as secondary control for analytical purposes and contained only well water, DCE and TCE. All reactors except C and G were amended with nutrients and a surfactant. Previous research has shown that nutrient supplementation may enhance biodegradation of organics[4,9] and that soils contaminated with hydrophobic or slightly hydrophilic organics have been previously treated with surfactants.[7]

Procedures

All waste and surface soils were collected from the waste site and characterized as containing polystyrene tar polymers and chlorinated organics.[18] Two duplicate composite soil mixtures containing 20% total solids (wet wt/vol) were used to prepare the test soil water slurry. The mixtures were homogenized in small increments with a blender. The first mixture was then transferred into a 4-L Erlenmeyer flask and further stirred with a spatula. The second mixture was further handmixed in a 6-L Erlenmeyer flask. Equal volumes of each mixture were transferred into 2-L beakers and allowed to stir on heavy duty magnetic stirrers for 18 hr in a closed environmental chamber (Vollrath, River Falls, Wisconsin) at 22 °C. During this mixing period, a portion of the styrene polymers contained in the waste was visibly adsorbed to the stir bars. The stir bars coated with styrene tars were removed and a new stir bar was added to each reactor prior to test initiation. After

stirring, the mixtures were transferred back into the large Erlenmeyer flask and rehomogenized with a Talboys Model 101 homogenizer (Cole Parmer Instr., Chicago, Illinois). Aliquots of 1450 mL were then transferred into 2-L open glass vessels. The first batch provided the slurry for reactors A and E, and the second for B, D and F.

Assuming a total organic carbon content of 1% of the soil slurry, nutrients (K_2HPO_4 and NH_4NO_3) were added at a C:N:P ratio of 100:10:1. Surfactant, Triton x 100 was added at a concentration of 200 ug/mL, and DCE and TCE were both added at 61.1 ug/mL to all reactors but D to which 86.8 ug/mL were added. The pH was adjusted to pH 7.8 for all reactors. All reactors were incubated on heavy duty stirrers in a closed environmental chamber at 22 °C. A light source consisting of 50% Gro-Lux and 50% Cool White fluorescent bulbs provided a light intensity of 175 ftc ±5% at reactor liquid level. A 16 hour light period was alternated with an 8 hour dark period. The lack of humidity control in the environmental chamber necessitated daily adjustment of the liquid level in all reactors but D, which was sealed.

Samples for analytical work were withdrawn for Volatile Organics, Gas Chromatography/Mass Spectrometry (GC/MS) Extractables, acute toxicity as measured with Microtox and enumeration of microorganisms.

Enumeration of Test Organisms

Microorganisms were collected from contaminated surface soil from the site (0 to 6 in. depth). This soil was used to prepare a soil slurry of 20% waste (wet weight/vol) with well water. The soil slurry was placed in an open glass container and continuously stirred on a heavy duty magnetic stirrer and periodically amended with nutrients and waste for a period of 2 months. This slurry was used as inoculum for the present study. Thirty mL of the slurry was used as an inoculum for each flask. Enumeration of microorganisms was performed using disposable presterilized Millipore Total-Count™ Water Testers.[17] Each sample was plated in duplicate using serial dilutions of the waste. Two sterile controls with autoclaved distilled deionized dilution water were also plated to test for contamination in plates, pipettes and dilution water. The Total-Count™ samplers were incubated at 35 °C for 24 hours. Growth of heterotrophic bacteria was determined by visual detection of colonies or turbidity. Results were reported in colony forming units per mL (CFU/mL).

Isolation of Microorganisms

Microorganisms were isolated from reactors using an enrichment medium consisting of minimal inorganic salts[14] supplemented with wastes containing the mixture of organics (0.02% total organic carbon) as the sole source of carbon. A series of 500-mL Erlenmeyer flasks containing 200 mL of this medium was prepared, autoclaved, inoculated with 1 mL of slurry from reactors E and F and incubated at 22 °C. Control flasks lacking wastes were also inoculated. Bacterial populations in the flasks were measured by plating onto minimal inorganic salts solidified with purified agar and on nutrient agar (Bacto, Difco Laboratories, Detroit, Michigan). Nineteen microbial isolates were obtained from the plating studies. Pure cultures of each microbial isolate were examined with a Zeiss Axioskop light microscope (Zeiss, West Germany) for cellular morphology and gram stain reactions. The isolates were further characterized and identified with a Vitek AMS microbial identification system (McDonnell Douglas Health Systems Co., St. Louis, Missouri) using the gram-negative GNI identification card (Vitek No. 51-1306).

Acute Toxicity

One method of defining the potential toxicity of chemical residues is the use of bioassays such as the Microtox™ test. A major advantage of microbial toxicity testing over chemical analysis is the direct assessment of potential biotic impact without extrapolation from chemical analysis of uncertain completeness.[12] A Beckman Model 2055 Toxicity Analyzer (Beckman Instruments, Inc., Microbics Operations, Carlsbad, California) was used to measure the toxicity of the liquid fraction of the wastes to the marine bioluminescent bacterium Photobacterium phosphoreum in a temperature-controlled photometer (15 °C). The procedure for the assay is detailed in the Microtox™ System Operating

Manual. Bioreactor sample aliquots (7 mL) were placed in 20-mL scintillation vials on Days 0, 7 and 14 and stored in the refrigerator at 4 °C until analysis. A statistical analysis method was used to determine the percent normalized light decrease for all dilutions.[10] The decrease in toxicity is reported as normalized percent light decrease.

Method of Analysis

Instrumental analysis methods (GC/MS) were developed to quantify the major volatile and nonvolatile extractable chromatographable compounds in the waste from each bioreactor. Since some of the wastes at the site contained large amounts of DCE and TCE, which were absent in the present samples, 70 uL of these two compounds were added at day 0 to all bioreactors. This addition resulted in a beginning concentration of 61.1 ug/mL of DCE for all reactors but D, which contained 86.8 ug/mL. The beginning concentration for TCE was 70 ug/mL for all reactors but D, which contained 99.5 ug/mL. Reactor D was the only vessel that was sealed immediately after spiking; therefore no loss of chemical occurred before the time zero samples could be collected.

Volatile Organics Analysis

Duplicate samples were collected and analyzed at each sampling period. A 10-mL aliquot of bioreactor sample was pipetted into a 14-mL Pierce vial, and 1 mL of n-dodecane was added to each vial. The vials were sealed with Teflon-lined caps. The samples were vortexed for approximately 2 min and the phases were allowed to separate. The vials were then stored at 4 °C until further extraction. The extraction was completed after bringing the vials to room temperature, shaking them and withdrawing 0.5-mL samples, which were placed in 1.6-mL autosampler vials. An aliquot of this extract was placed with an equal volume of n-dodecane which contained 100 ug/L benzene-d6 internal standard. The samples were analyzed by split injection on an HP 5985 Capillary GC/MS. The chromatographic column used was a 30-meter fused silica J&W DB-5 (250 u) with a wide bore (0.32-mm I.D.). Column temperature program was held at 10 °C for 4 min and then increased at 8 °C/min to the final temperature of 300 °C. Typically, data were acquired for 40 min. Masses were monitored from 10 to 250 Atomic Mass Units. The concentrations of DCE and TCE were determined by using an internal standard quantitation method. Relative response factors for these compounds were determined by analyzing a standard solution containing these two compounds. Samples for volatiles were not collected after day 3 because analysis showed 100% removal by day 1.

Extractables Analysis

Ten mL of bioreactor sample were pipetted into a 40 mL Pierce vial and serially extracted with 20 mL of methylene chloride three times. After each 20 mL addition, the vial was agitated and the methylene chloride was removed. The three methylene chloride extracts were combined and concentrated to a final volume of 10 mL. An aliquot of this extract was added to an equal volume of methylene chloride which contained 100 ug/mL anthracene-d10 internal standard. The samples were analyzed by splitless injection using an HP 5985 Capillary GC/MS as previously described. Column temperature program was held at 50 °C for 4 min and then increased at 8 °C/min to the final temperature of 300 °C. Typically, data were acquired for 40 min. Masses were monitored from 10 to 500 Atomic Mass Units. The concentrations of the major extractable compounds were calculated by dividing the total ion areas of the organic compounds by the total ion area of the anthracene-d10 internal standard and by performing the same calculation using the selected ion areas. All values are reported on a wet weight basis and are not corrected for extraction efficiency.

The experimental design required that 16 compounds, in seven biodegradation reactors, at 10 different days, be analyzed in duplicate. This requirement resulted in the analysis of 16 compounds in approximately 100 reactor samples. Approximately two-thirds of these samples contained the 16 compounds of interest, with the remaining one-third being method blanks, reactor blanks and QA/QC samples which did not contain the total array of analytes. This procedure resulted in the generation of 3,200 concentration values and 4,800 additional values

which required summing, averaging and displaying in an efficient manner. Thus the GC/MS study was divided into a data acquisition part collecting data in the MS system, and a data analysis part transferring the data to Lotus 1-2-3 and performing calculations. Both parts of the process were designed to be interrelated and to produce high quality data in a cost-effective manner.

Analyte concentrations were calculated by using the total ion (or selected ion) areas of the analytes, the total ion (or selected ion) area of the internal standard and the concentration of the internal standard to calculate the "Total Ion Concentrations" or "Selected Ion Concentrations." Detailed compound identification can be accomplished best only after all possible isomers of identified compounds are obtained and retention times of authentic standards are compared to the retention times of the components in the waste. However, this detailed identification was not considered critical to the present study since degradation profiles of compounds and relative changes in concentration, were of primary concern. Therefore, compounds which were not uniquely identified by standard library search algorithms were identified by molecular formula and/or molecular weight, when possible.

GC/MS Quality Control

False Positives

Bioreactors C and G served as Quality Control reactors to which no wastes had been added. Therefore, analysis of these bioreactor samples would indicate whether contamination was occurring which would have resulted in the reporting of false positive values. In addition, extraction method blanks were prepared and analyzed in order to detect any source of contamination in the extraction of samples. No method blanks contained any of the analytes. Finally, either methylene chloride or n-dodecane was analyzed using capillary GC/MS to identify whether instrument contamination could be causing the measurement of false positives. Again, no analytes were detected in any of the instrument blanks analyzed.

False Negatives

An instrumental analysis protocol was developed which assured that adequate levels of detection and system performance were maintained so that the incorrect reporting of analytes did not occur. This analysis protocol included the analysis of a system performance standard which contained compounds of wide volatility to evaluate chromatographic performance, and decafluorotriphenylphosphine which evaluated mass spectrometer performance. In addition, all bioreactor extracts were analyzed at random times so that there could be no systematic bias produced in one set of bioreactor samples. Therefore, in a given set of analyses, there would be Day 7 extracts from Reactors A and B which showed the presence of a large number of components which were present on Day 0, and also Day 7 extracts from Reactors E and F which showed the absence of almost all of these components. These data were analyzed in a blind manner so that no bias would result in human interpretation where preconceived biasses may exist.

RESULTS

Biodegradation of Chromatographable Chemicals

Analytical measurements indicated rapid removal of all chromatographable compounds in the bioactive reactors (Table 1). The data for the average total ion (TI) concentrations for duplicate samples for Bioreactors A, B, D, E and F are shown in Figure 1. Reactors C and G are not included in this Figure, since they served as quality control reactors and did not contain any of the analytes of interest. Three disappearance patterns are evident. Reactors A and B, sterile duplicates, showed some degradation within the first 7 days of the experiment. This degradation may be due to unidentified abiotic loss, but is thought to be partially due to microbial activity, as evidenced by an increase in microbial cell counts (Table 2). It is believed that these microorganisms contributed to the overall TI removal of 49.5% for Reactor A and 48.8% for Reactor B. The second addition of HgCl$_2$ eliminated further degradation in both reactors.

* A control was plated using sterile dilution water.

Reactor D showed 27.3% TI removal. Since it was sealed, volatile components were prevented from escaping and reoxygenation was eliminated. The minor degradation which did occur could be attributed to microorganisms utilizing the dissolved oxygen in the aqueous fraction as an electron acceptor for the metabolism of some of the organics.

Reactors E and F showed TI removal rates of 99.5%. A lag phase required by the microbiota to adapt to the system explained the low degradation rates during the first day. Almost linear degradation rates were observed from Days 2 to 5. Since neither the sealed nor the sterilized reactors exhibited similar removal rates under equal conditions, the degradation was interpreted as being microbial.

Reasonably good agreement was obtained between the TI and SI chromatographable measurements. The response factors for the SI concentrations are slightly lower than for the TI concentrations (Fig. 2). The detection limits were 1 ug/mL for TI and 0.1 ug/mL for SI concentrations. Seventeen compounds were identified with Selected Ion Mass (Table 1). The first compound, anthracene-d10, was used as an internal standard in all cases. Biphenyl (Compound #02) was completely removed in Reactors A, B, E and F, however at different rates. While 6 and 5 days were needed in Reactors A and B, respectively, to remove biphenyl >99%, it degraded in 3 and 2 days, respectively, in the Bioactive Reactors E and F to below the detection limit. The total TI removal of biphenyl in Reactor D was 61.0%. Since volatilization was excluded in this system, it is assumed that biphenyl was microbially degraded in Reactor D. However, biphenyl may have partially degraded and/or partially volatilized in Systems A, B, E and F. Compounds #2-12 and compound #15 (elemental sulfur) were removed 100% in Reactors E and F, while they partially persisted in Bioreactors A, B and D.

Plots of the chemical concentrations over time are presented for 2-phenylnaphthalene and phenanthrene as typical examples demonstrating the biodegradation of all 16 chromatographable compounds (Figures 3 and 4). 2-Phenylnaphthalene and phenanthrene degraded rapidly below the detection limit. Previous literature reports indicate the ability of bacteria and fungi to utilize naphthalene and phenanthrene as a source of carbon.[2,3,13] It was expected, therefore, that these compounds or isomers would be biologically oxidized. The two compounds typically were not removed in the sterile and sealed bioreactors with the exception of phenanthrene in sterile reactor B which exhibited significant microbial activity by Day 7. This result clearly indicated that the compound was biodegraded and not volatilized. The estimated half-life under the given environmental conditions was less than 36 hours. If one takes into consideration the fact that the experiment consisted of a batch microbial system with a small amount of inoculum, the initial lag phase where no degradation occurred is not unex-

pected. Therefore it appears possible to design a system that would reduce the lag phase and the amount of time required to degrade the chemicals.
Figure 2
Average Total Ion and Selected Ion (TI and SI)
Concentrations for All Bioreactors

The presence of elemental sulfur was monitored by GC/MS (Fig. 5). It was observed to rapidly disappear from the bioreactors containing bacteria. Sulfur is required as an essential constituent for bacterial cell growth and used in the synthesis of amino acids. Most bacteria assimilate sulfur in the form of soluble sulfates or reduced organic sulfur compounds, but elemental sulfur can be utilized.[5,16] The process of the oxidation of elemental sulfur has been studied in detail.[5] In all the reactors containing bacteria (D, E and F), elemental sulfur was completely removed, while it persisted in the Sterile Controls A and B (Fig. 5). Some sample variability for Reactors A and B may be due to the fact that elemental sulfur is insoluble, but it was consistently observed in all studies that it was removed in active bioreactors. It is thought that the sulfur was microbially converted to a form which was not chromatographable.

The data obtained on the removal of volatile compounds (DCE and TCE) indicate that these chemicals are in fact removed by volatilization and not biodegradation under the conditions of this test (Fig. 6). Concentrations of both chemicals in Bioreactors A, B, E and F dropped to less than 10 ug/mL (initial concentration was 70 ug/mL) after 1 hour. However, the concentrations of both DCE and TCE in Bioreactor D were only slightly below the initial concentration of 99.5 ug/mL. This result was interpreted as evidence that these two compounds were volatilized and not biodegraded. No data are shown for DCE, Reactors B and F, in Fig. 6, because the values were less than the method limit of detection (1 ug/mL).

Enumeration of Microorganisms

The enumeration of microorganisms in Bioreactors E and F increased approximately two orders of magnitude from Day 1 to Day 7 and

remained in the order of 10^7 CFU/mL over the last 7 days (Table 2). The highest enumeration of heterotrophic bacteria occurred in Reactors E and F and correlated with the highest compound removal in these reactors. All other reactors that had received the same initial nutrient amendment as E and F did not exhibit such high cell counts. These data indicated that the bacteria in Reactors E and F used the organics present in the waste as a carbon source for cell growth. Reactor D exhibited a steady increase in enumerations of microorganisms over the time of the experiment. The biomass in this reactor doubled from the first to the last day of the experiment, suggesting that nutrient sources were available to support growth. The microbial population in Reactor G also increased over time but remained below the reactors containing waste.

Acute Toxicity

The Microtox™ test measures the toxicity of chemicals to a phosphorescing bacterium by measuring a loss in its ability to produce light. The Bioactive Reactors E and F exhibited 82.2% and 78.2% light loss, respectively, on Day 0, while on Day 14, the percent light loss was only 13.9% and 18.1%, respectively. Thus, these reactors showed the highest reduction in toxicity over time. These data correlated well with results obtained using GC/MS which showed the largest reduction in chemicals for these two reactors. Reactor G, like Reactor C, served as a quality control. The only difference between Reactors C and G consisted in the amount of surfactant added. Reactor C received the same amount of surfactant as all other bioreactors; Reactor G did not receive surfactant. This difference explains the lack of toxicity and light loss over time in Reactor G while Reactor C exhibited some toxicity at Day 0 as evidenced by a 57.4% light loss. However, this light loss dropped to 23.2% on Day 14, suggesting metabolism of the surfactant by bacteria in the reactor.

(*)   ND= Not Determined
Figure 6
Concentrations of Volatile Compounds One Hour
After the Study Started

The normalized percent light decrease for Days 0, 7 and 14 is presented in Table 3. Both sterile controls, Reactors A and B, exhibited a 100% light decrease on Day 0 due to the presence of HgCl₂. The toxicity of these samples decreased 20% to 25% by Day 7, which indicates a lack of complete sterility and correlates well with the microbial growth in these bioreactors and the degradation shown in Fig. 1. A second addition of HgCl₂ on Day 7 was necessary to insure sterility during the remaining 7 days. Reactor D showed a minor decrease in toxicity correlating with a small amount of degradation occurring in this reactor.

Characterization of Microorganisms

After approximately 3 to 5 weeks of enrichment, a clear difference in growth and number of colonies between the plates from the test flasks (with waste) and plates from the control plates (no waste) was evident. Nineteen microbial isolates were initially obtained and studied by light microscopy. Colonial morphologies ranged from yellow to white and from oval to circular with a predominance of round white and bright yellow colonies. All isolates were nonfermenting obligate aerobes and gram negative short rods with the exception of one strain which was a gram positive rod. This gram positive strain, however, was always found in combination with a gram negative culture and could not be isolated into a pure culture.

Four of the isolates were tentatively identified as Acinetobacter calcoaceticus (98%, 98%, 91% and 99% probability), two strains as Pseudomonas vesicularis (96% and 99% probability) and one strain as Pseudomonas paucimobilis (99% probability). Tentative identification of the other strains showed 49% probability for Flavobacterium sp. and 23% probability for Pseudomonas stutzeri. Eight isolates could not be identified by the Vitek system.

DISCUSSION

The concept of using biological treatment as a remediation technology for contaminated waste is an attractive idea because of the potential cost savings. Additionally, bioremediation offers the advantages that the chemicals of interest are destroyed, future liability is eliminated and the remediation can be done on-site. The present study has demonstrated that 16 chemical constituents associated with styrene tar polymers can be removed in a biological treatment system to acceptable levels. Acceptability of this process is based on: (1) reduction of key chemical constituents to acceptable levels; less than 1.0 mg/kg was achieved for 16 chromatographable compounds, (2) significant reduction in the toxicity of the soil slurry to Photobacterium phosphoreum as measured in the Microtox test; (3) demonstration that biodegradation is the primary route of degradation, not volatilization for most of the 16 chromatographable chemicals; (4) rapid growth of microorganisms in the active treatment reactors; and (5) demonstration of removal rates that are rapid enough to allow for this bioprocess to be scaled up and used on a field scale.

It is recognized under the test conditions used that chlorinated solvents were most likely air stripped and the lower molecular weight organics such as biphenyl were at least partially air stripped. Full-scale use of this technology would most likely require carbon adsorption of the bioreactor gasses.

It was demonstrated in this study that the indigenous microflora was adapted to the system and capable of rapidly metabolizing the major chromatographable compounds present. The persistence of most of the compounds in the sterile control reactors and the sealed reactor was interpreted as proof that losses of these compounds in the reactors containing the bacteria can best be explained by biodegradation and not volatilization. No new chromatographable components were detected during the study, indicating that no new chromatographable degradation products were produced during biodegradation. It is not clear, however, if one or several dominant species were responsible for the metabolism or if cometabolism played a major role. It is not known what role the individual isolates played in the overall degradation processes, but it does warrant further investigation. Since cometabolism may play a significant role, chemical degradation may be dependent on the presence of all or a mixture of some members of the consortium.

The data presented in this paper have been used to justify a field pilot study for a biodemonstration of this method. The data suggest that adequate treatment could be achieved on a full-scale level using a 4-day batch treatment of a 20% soil/water slurry.

In Situ Bioremediation of TCE and Other Solvents

Michael J.K. Nelson, Ph.D.
John A. Cioffi
Harlan S. Borow
ECOVA Corporation
Redmond, Washington

ABSTRACT

In situ bioremediation of industrial solvents, hydrocarbons, and pesticides has been demonstrated as an effective alternative to aboveground treatment using physical processes such as air stripping and carbon adsorption. These competing physical cleanup methods do not destroy the compounds of concern but merely transfer them from one medium to another. Biological treatment is an alternative treatment process that could result in complete destruction of TCE, hydrocarbons and related compounds. As an overview, in situ biological treatment techniques will be presented followed by a discussion of several field case histories.

Chlorinated solvents such as TCE are ubiquitous and persistent groundwater contaminants. Currently, physical processes such as air stripping and carbon adsorption are used to remove these compounds.

Biological degradation was demonstrated by ECOVA in a continuous-flow bioreactor with influent TCE concentrations of 1 to 5 mg/L being degraded to below detectable levels. The results indicate the utility of the system for field applications using surface bioreactors in pump-and-treat processes. Subsequent laboratory studies identified conditions that would maintain TCE and thus be suitable to use in situ. Utilizing these conditions, ECOVA tested a pilot system in the field for developing and maintaining TCE-degradative activity within an aquifer. Initial concentrations ranged from 2500 to 3500 ug/L TCE. After 24 hr of treatment, a downgradient monitor well had less than 500 ug/L TCE; the concentration decreased less than 100 ug/L TCE after 7 days of operation. The test results indicate that in situ biological removal of TCE can be achieved in subsurface aquifers.

ECOVA has designed and installed an in situ bioremediation system for groundwater contaminated with 4-chloro-2-methyl-phenol (4C2MP). Prior to the design and installation of the bioremediation system, hydrogeological and microbiological evaluations were conducted to determine if in situ bioremediation was a viable treatment technology for the contaminated groundwater. The microbiological evaluation demonstrated that the groundwater contained a high existing 4C2MP biodegradation potential. Under laboratory conditions, the existing microorganisms in groundwater samples removed from the site generally reduced the 4C2MP concentration by more than 90% after 7 days of incubation. The hydrogeological evaluation demonstrated that aquifer permeabilities and subsurface mass transport parameters were amenable to in situ bioremediation. A groundwater model for the site was developed to determine optimum spacing of the groundwater recovery and reinjection wells. The in situ bioremediation system consists of aeration and recycling of recovered groundwater to stimulate the existing microorganisms to degrade the 4C2MP. In the initial 3 mo of operation, the total contaminated plume exhibited a 25% to 35% reduction in size; after 6 mo, a 50% reduction was observed.

In situ biotreatment is being implemented in a multicomponent

cleanup program currently underway at a former marketing fuel terminal in the Western United States. Two separate zones of contamination are being treated in situ via series of trenches and wells for recovery and recharge of groundwater contaminated with petroleum hydrocarbons at a mean concentration of 2,660 mg/L. The primary contaminants are weathered gasoline and diesel. Recovered water is pumped to the surface bioreactor where free product is reclaimed, contaminant concentrations are reduced and the treated water is amended with oxygen and specific nutrients and recharged into the subsurface. Soil oxygenation is also being used to provide oxygen to the zones where in situ treatment is underway and remove limited amounts of volatile compounds from the shallow unsaturated soil above the in situ biotreatment zone. This remedial program will reduce total petroleum hydrocarbon contamination from the mean concentration of 2,660 ppm to less than 15 ppm cleanup criteria for groundwater. To date, the in situ system operation is effectively producing biodegradation in the subsurface.

INTRODUCTION

Groundwater beneath industrial sites is commonly contaminated with a variety of organic chemicals.[1] The contaminants originate from surface lagoons, tanks and pipelines and percolate into aquifers where they migrate in both the free and dissolved phase. The standard approach for solving this problem is to install a series of recovery wells which pump the contaminated groundwater to above ground treatment systems. The most commonly used treatment systems are air strippers and/or activated carbon filters.

Both of these treatment methods are really transfer technologies; that is, they transfer the contaminants from the water into either the atmosphere or onto the carbon. Alternatives to this standard approach are required for two reasons: (1) transferring the contaminants merely results in contamination of another medium, and (2) pump-and-treat technology fails to achieve site cleanup goals. The U.S. EPA has recognized that while pump-and-treat systems are generally effective in containing contaminant plumes, full system optimization (pumping rates, screened intervals and well locations) and cleanup goals have not been attained.[2] The in situ biological removal of organic groundwater contaminants addresses both concerns. The contaminants are degraded (not transferred to another medium) and, thus, more efficiently removed from the subsurface.

The successful implementation of in situ degradation systems requires an in-depth understanding of the subsurface environment generally followed by a three-phased development program: (1) laboratory treatability evaluation, (2) pilot-scale demonstration and (3) full-scale system implementation. This approach ensures that only the most effective treatment program is implemented for full-scale remediation.

THE SUBSURFACE ENVIRONMENT

The subsurface groundwater environment consists of three components; physical, chemical and biological. Each component plays an integral part in the evaluation, design and implementation of in situ treatment systems. The physical system governs the rate at which groundwater contaminants move through the subsurface and the ease with which they will be removed. Contaminant chemistry defines the geometry and behavior of the contaminant plume while an assessment of subsurface microbiological activity determines the presence of contaminant degrading microorganisms and the subsurface oxygen conditions. To engineer an effective in situ biotreatment system, each of these components must be defined and understood.

Hydrostratigraphy

Subsurface geological strata are defined by drilling soil borings and collecting soil/rock samples. Stratigraphic profiles are developed that delineate various hydrostratigraphic units: water bearing aquifers and low permeability aquitards. Measurements of hydraulic gradients and conductivity are used to determine groundwater flow velocities and the rate of contaminant plume migration.

Hydrochemistry

The chemical compositions of the aquifer matrix and the groundwater are defined through the analysis of soil and groundwater samples. The ability of the contaminants to dissolve and migrate through the aquifer is determined together their ability to absorb on the solid matrix.

Hydrobiology

Microorganisms represent the biological component of the subsurface environment. To survive, they must obtain a variety of inorganic substances, carbon and a source of energy. When these conditions are met, the microbial population flourishes and in so doing transforms the chemical contaminants to harmless byproducts.

IN SITU BIOTREATMENT

In situ bioremediation is the controlled management of microbial subsurface processes. In situ systems generally utilize aerobic processes and involve the introduction of oxygen, nutrients and sometimes specific microorganisms, to the subsurface. Two key criteria for in situ treatment are: (1) a permeable matrix to allow rapid oxygen and nutrient transport and (2) contaminant-degrading microorganisms.

In situ treatment systems involve either: (1) pumping the contaminated groundwater to the surface from a downgradient recovery well, passing it through a surface treatment unit, amending it with nutrients and oxygen and reinjecting it into the subsurface via an upgradient injection well; or (2) directly stimulating microbial activity in the aquifer via direct injection.

PROGRAM DEVELOPMENT

The key to successful in situ biotreatment of contaminated groundwater is to understand the complete hydrobiological system. For example, some hydrogeologic environments may contain sufficient nutrients, others may not require the addition of oxygen (if anaerobic conditions are preferred), or low permeability may cause accumulation of biomass in the treatment zone. An in situ program generally involves three steps: (1) laboratory treatability study, (2) pilot program and (3) full-scale implementation.

Treatability Studies

The purpose of a treatability study is to determine the:

* Biodegradability of the groundwater contaminants
* The rate at which they degrade
* The amounts of oxygen and nutrients required to sustain the reaction
* The interaction between the degrading compounds and the aquifer media (plugging potential).

There are two basic types of treatability studies: (1) the flask study and (2) the column study.

For flask studies, the contaminated groundwater is analyzed for organic, inorganic and metallic compounds. A minimum of three test conditions are generally performed over a period of 6 to 8 wk. During this time, the tests are periodically analyzed to determine the rate of biological degradation. The basic test conditions are: sterile, unamended and nutrient-amended. Typical data are shown in Figure 1. At the completion of the study, a preliminary treatment design is prepared that specifies the anticipated rate of contaminant reduction (cleanup time) and the amounts of oxygen and nutrients required.

Column studies employ the same approach as flask studies with the added benefit of measuring the effect of the aquifer media on the biological reactions. Glass columns are filled with soil samples, and contaminated groundwater is percolated through the columns; sterile and nutrient-amended columns also are evaluated. While the columns do not accurately recreate actual in situ conditions, they do provide an indication of the likely effects of compound adsorption and precipitation.

System Design

Thought must be given to the design of the in situ system such that several key questions are addressed. The treatability study determines if the site contaminants are biodegradable and the rates at which they degrade under laboratory conditions. The next step is to run a field pilot test to confirm these experimental results under "real" conditions, quantify the effects of dilution on contaminant concentrations and evaluate hardware components that will be used in the full-scale system.

Pilot Program

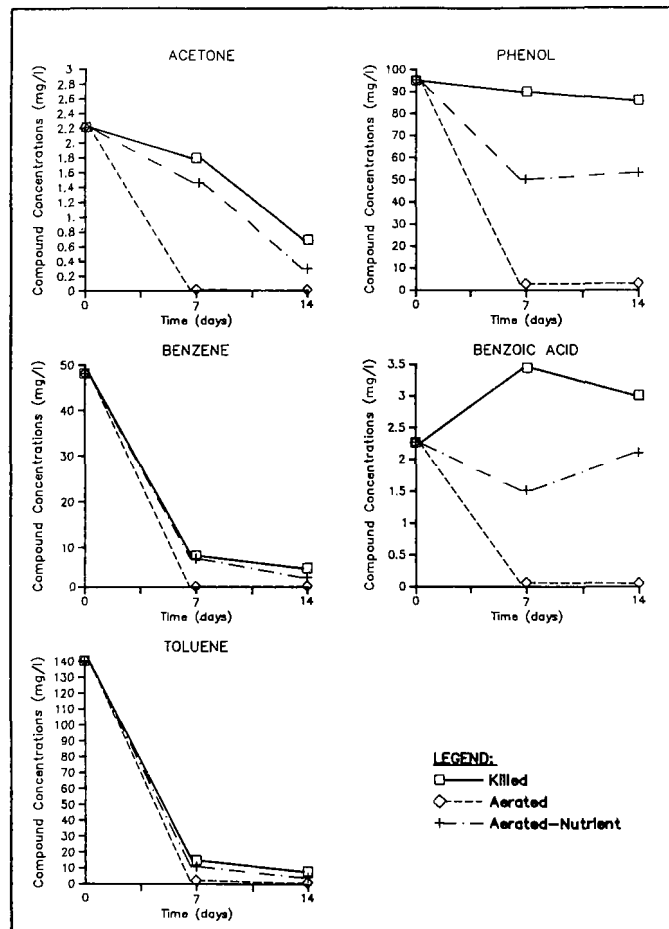
The pilot test must be capable of simulating full-scale operations and yet be brief enough to obtain data that can be fed into the system design. The ideal setup for the in situ program is to monitor groundwater flow and quality up and downgradient of the injection location. The monitoring wells should be located within several days' hydraulic travel


Figure 1
Compound Concentrations in Aerobic Culture Flasks

time of the injection well so that the biological process can be monitored rapidly following injection.

Before performing the biological pilot test, a preliminary test using clean, unchlorinated water should be run without oxygen and nutrients. This test determines the potential effects of water injection (dilution) on contaminant concentrations and is used as a base line against which the effects of biological test are compared. A conservative tracer can be used at this stage to help define groundwater velocities and flowpaths in the vicinity of the injection well and identify potential zones of anisotropy within the aquifer and hence the ability of the feed stock to reach the contaminants.

Full-Scale System

The full-scale system must be capable of degrading the entire plume without causing the spread of contaminants through pumping and injection. For complex sites, this information can be obtained by simulating a variety of scenarios using computer models. The model aids in locating injection and recovery wells and estimating cleanup time.

A series of case histories is presented to illustrate the details of the three steps of an in situ program. Separate projects were selected to illustrate the application to different organic contaminants.

CASE HISTORY: PILOT-SCALE DEMONSTRATION

The aerobic biodegradation of trichloroethylene (TCE) has been demonstrated in laboratory treatability tests.[4] A pilot program was designed to demonstrate the viability of using this process in situ.[5]

The test site is underlain by a thick and extensive sand aquifer (Upper Aquifer) that contains two zones (shallow and deep) contaminated with TCE. The pilot program was performed upgradient of the plant production well N-1. This well pumps 200 gpm from the deep zone of the Upper Aquifer and runs the effluent through a carbon filter before delivering it to the plant water system. An injection well (EI-1) and up (EU-1) and downgradient (ED-1, M-1A) monitoring wells were installed for the test program. Figure 2 shows the locations and layout of the test wells.

A tapline, installed downstream of the N-1 carbon unit, conveyed clean, unchlorinated water to an aeration column, nutrient/bacteria feed system and into the Upper Aquifer via injection well EI-1. To ensure a maximum feed rate, the delivery zone was vertically restricted by means of an inflatable packer. Dedicated, submersible, air-driven sampling pumps were installed in monitoring wells ED-1 and M-1A.

A two-phased pilot program was implemented. Phase 1 involved the injection of TCE-free water containing a sodium chloride tracer into the aquifer to quantify the effects of dilution on groundwater TCE concentrations. Phase 2 involved the injection of oxygen, nutrients and a

strain of TCE-degrading bacteria (G-4) into the aquifer to quantify the effect of in situ microbial degradation of TCE.

Phase 1 - Tracer Test

Sodium chloride was selected as the tracer; an increase in specific conductance in the monitoring wells would indicate the migration of the tracer. The saline solution was fed to the water stream which was injected into the well (EI-1) at a rate of 5 gpm. Before starting the test, base line conductivity measurements were taken in the three monitoring wells; injected water was detected in both the up and downgradient monitoring wells. Groundwater velocity in the lower permeable unit was calculated to range between 2 and 5 ft/hr. This figure was determined by dividing the time taken for the first occurrence of tracer at the two downgradient wells by their respective distances from the injection well.

The issue of dilution is a key point in verifying the validity of the in situ biotreatment process. TCE values were plotted versus conductivity to determine if there was a correlation between TCE and salt concentration. An increase in conductivity would parallel the ingress of the injected water. If the freshwater injection was diluting the contaminated groundwater, then a decrease in TCE levels could be expected to correspond with an increase in conductivity.

By calculating the daily flow of groundwater in injection zone and comparing it with the amount of water injected, it is possible to calculate the expected dilution effect. The receiving zone had a saturated thickness of 14 ft and a width of 20 ft (minimum, based on the appearance of tracer at all monitoring wells), an effective porosity of 25% and a flow velocity of 48 ft/day. Based on these data, approximately 25,000 gal/day (gpd) were flowing through the receiving zone. By comparison, the injection stream was run at a steady rate of 5 gpm (7,200 gpd) representing 29% of the flow into which it was placed. Based on this calculation, a 30% decline in TCE levels could be ascribed to dilution in ED-1, the directly downgradient well. No evidence of dilution was seen in wells EU-1 or M1-A. By contrast, the overall reduction (95%) in TCE values achieved during the subsequent biological test far exceeded the effects of dilution.

Direct measurements of the injected salt concentrations were not made in Salt Test 1 and therefore dilution estimates could only be approximated. In Salt Test 2 influent salt concentration was measured, allowing the calculation of dilution at the monitor wells. The results of the test are presented graphically in Figure 3. The time-weighted average concentration of the saline feed was determined by weighing the data points using the length of time between the readings. Using the time-weighted average smoothed the injection concentration data that would improperly skew the test results.

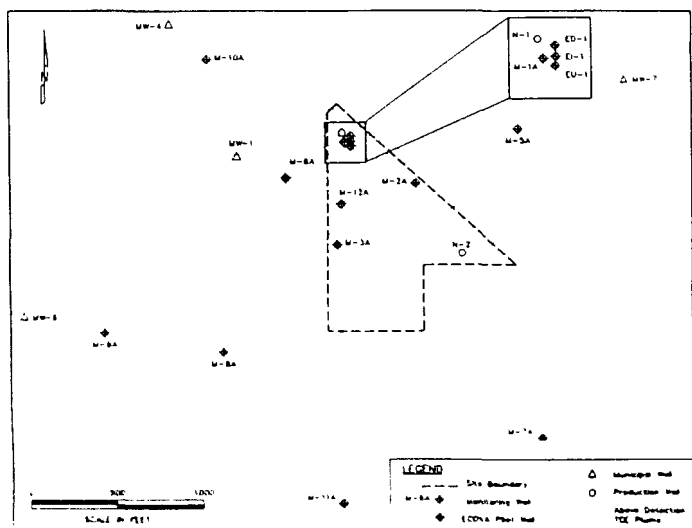
In Salt Test 2, Wells ED-1 and EU-1 recorded the greatest breakthrough of salt solution from the injection well EI-1. Well M1-A showed


Figure 2
Upper Aquifer, Deep Hydrochemistry
Figure 3
Salt Injection Test

very little breakthrough (one peak at 500 mg/L over background). Dilution (of groundwater) was calculated from the following formula:

DILUTION = (SAMPLE CONC.-BACKGROUND CONC./
(INJECTION CONC. BACKGROUND CONC.)   (1)

Figure 4 represents the calculated percent dilution during the test for all the wells. Dilution in the upgradient and downgradient wells (EU-1, ED-1) was the most significant; the greatest calculated dilution was 40% and only then for one sampling. Well M1-A showed only minimal dilution effects of the injected water, less than 13%. These data suggest that dilution is a very localized process and would become insignificant during full-scale operations. The large fluctuations are due to fluctuating water demands by production well N1. Time weighted averages of dilution calculated for wells ED-1 and EU-1 (not including the lag phase) were 23% and 20%, respectively.

From the Salt Test 1 data we calculated that dilution by the injection stream would account for a 29% decrease in TCE plume concentrations. This number was calculated using flowrate ratios between the injection stream and groundwater flow in the aquifer. However, no data were taken during the first test on the exact salt concentrations being injected; therefore, the exact dilution could not be calculated. In the second test, we monitored the salt concentrations being injected throughout the test, this allowing exact concentrations to be calculated.

Phase 2 - Biotreatment Test

The in situ biotreatment system utilized the same injection and monitoring wells and the same injection rate (5 gpm) as the tracer test. Clean unchlorinated water was injected for 1 day; nutrient feeds were initiated the following day. Various additions were made to the recharge water to stimulate degradation of TCE. The water was oxygenated and both inorganic and organic nutrients were introduced into the feed. In addition, a culture of strain G4 was added during the initial phase of the test. Nutrients and oxygen were added continuously for 6 days.

Oxygen Concentrations:

The addition of oxygen to the feed maintained high levels of oxygen downgradient during the test period, ensuring the necessary aerobic conditions for treatment. The range of oxygen concentrations from initiation of the test to termination of feed is summarized in Table 1 for the three monitoring wells. As expected, as treatment continued and microbial activity was expected to increase, the oxygen levels decreased. However, at no time did oxygen concentrations decrease to levels approaching anaerobic conditions.

Table 1
Range of Oxygen Concentrations During the Pilot Treatment Test

Well	Oxygen Concentration (mg/L)	
	Min	Max
ED-1	4.0	14.6
M1-A	4.0	12.3
EU-1	2.8	12.5

Microorganisms:

The monitoring wells were periodically tested for the presence of strain G4 suing a semi-selective plate count method. These results indicate that very low levels of strain-G4-like microorganisms were already present in the aquifer. The results for the following 5 days showed less than 10^3 cfu/mL of organisms in all three monitoring wells.

Detectable increases in G4-like microorganisms were first detected at T=6.2 days, and they were 7.6 x 10^4 and 1.6 x 10^4 cfu/mL in wells M1-A and EU-1, respectively. Similar results were obtained at T=6.9 days, which was the final test for microorganisms. In this instance, all three wells showed significant levels of microorganisms.

TCE Disappearance:

After 24 hr of feed (T=2 days), TCE concentration in the downgradient well (ED-1) had decreased from 2500 ug/L to 466 ug/L. By Day 3 of the test, the concentrations had fallen below 200 ug/L. With the exception of one data point (T=5.8 days), all subsequent concentra-
Figure 4
Salt Injection Test, Percent Dilution

tions were below 300 ug/L. Decreases in the concentration of TCE also occurred in wells M1-A and EU-a. The time of response was longer and the magnitude of the decrease was less than observed for ED-1. These results were consistent with the results of the tracer studies, which showed the most rapid communication between the injection well (EI-1) and well ED-1, followed by well M1-A and finally the upgradient well (EU-1).

Results:

Figure 5 summarizes before (T=0 days) and after (T=10 days) test plume configurations. The effect of treatment continued after termination of the feeds. The pilot test allowed the following important conclusions to be made regarding the in situ treatment of TCE:

• The tracer test confirmed that the injection water spread up and downgradient of the injection well and that groundwater flow velocities within the receiving zone were on the order of 2 to 5 ft/hr. A theoretical dilution of TCE concentrations was calculated based on the ratios between the rate of injection and the flowrate of the receiving zone. Measurable dilution effects were only observed in the downgradient monitoring well ED-1.

• The tracer test was followed by the introduction of TCE-degrading bacteria, organic and inorganic nutrients and oxygen into the lower permeable unit of the Upper Aquifer over a 6-day period. Within 8 hr of initiation, a measurable decline in TCE concentrations was observed. A corresponding decline in oxygen levels was observed, suggesting that microbial degradation had been activated.

• The in situ test demonstrated biological degradation of TCE-contaminated groundwater from a high value of 3,000 ug/L to a mean concentration of 135 ug/L, which was maintained form Day 3 to Day 8. A further decline to a mean value of 78 ug/L was observed over the next 10 days.

The pilot test proved that TCE can be removed from groundwater by in situ aerobic biodegradation. The rapid rates are very encouraging as they indicate that under the right conditions, this contaminant can be significantly reduced within a short time frame.

CASE HISTORY: IN SITU BIODEGRADATION OF HERBICIDES

Shallow groundwater contamination was detected beneath a herbicide formulation facility in 1981. The major contaminants were identified as chlorinated phenols, primarily 4-chloro-2-methylphenol (4C2MP), and were present in a shallow (35ft. thick) glacial aquifer overlying bedrock. A pump-and-treat system (consisting of 11 extraction wells feeding two activated carbon units) was installed in 1983. Effluent from the system was returned to the aquifer via eight injection wells. To achieve a more rapid reduction in contaminant levels, an in situ program was evaluated in 1987.
Figure 5
Pre and Post Test TCE Concentrations

Aerobic laboratory culture techniques were used to assess 4C2MP biodegradation in the site groundwater. High 4C3MP biodegradation potentials were observed in groundwater samples obtained from three site wells (Table 2):

Table 2
4C2MP Concentrations in Aerobic Cultures

Well	C_0 (mg/L)	C_{fc} (mg/L)	C_{ft} (mg/L)
I-4	X = 1133	X = 1133	X = <41
P-4	X = 3400	X = 3800	X = 1380
P-8	X = 710	X = 710	X = <41

X = Average 4C2MP concentration (3 replicates).
C_0 = Initial Concentration.
C_{fc} = Final Control Concentration (7 days).
C_{ft} = Final Test Concentration (7 days).

High 4C2MP biodegradation potentials were observed with no nutrient adjustment. This study showed that only aeration was needed to reduce 4C2MP concentrations in the groundwater. In 1988, the number of recovery wells was increased to 19 and two additional injection wells were installed. Airlift pumps were placed in the recovery wells, thereby increasing the oxygen concentration in the injected effluent.

Results

Within the first year of system operation, the following results were obtained:

• Reduction in off-site contaminant plume size was effected by gradient control of the recovery system.
• Decreased dissolved oxygen concentrations were initially measured in the injection wells; this suggested that phenolic degrading microbial populations had been established adjacent to the injection wells.
• In the initial 3 mo of operation, the total phenol plume exhibited a 25 to 35% reduction in area; after 6 mo, a 50% reduction was observed.

The system has continued to operate successfully and is expected to result in total site remediation within five years of initiation.

CASE HISTORY-IN SITU BIODEGRADATION OF PETROLEUM

A former marketing terminal in the Western United States had been contaminated by losses incurred during the handling of petroleum products during 65 yr of operation. More than 60,000 yd^3 of soil are contaminated with petroleum hydrocarbons at a mean concentration of 2,660 ppm. Groundwater analyses identified benzene as the compound of concern. Ethylbenzene, toluene and xylenes are present at low levels.

A laboratory treatability study evaluated treatment options and cleanup levels achievable through bioremediation. Options studied included excavation and off-site disposal, off-site treatment and on-site treatment focusing on bioremediation. Activities managed in support of the Remedial Action Plan (RAP) included preliminary design of cleanup systems and regulatory liaison and public involvement activities.

Two recommended treatment alternatives, on-site solid-phase biotreatment and in situ biotreatment, were selected because of the destruction of the contaminants and significant cost savings compared to off-site disposal. Bioremediation of the contaminated soil reduces the hydrocarbon contaminant level to below the agreed to cleanup level of 200 ppm. Water cleanup criteria for the contaminants are as follows: total hydrocarbons-15 mg/L, benzene-40 ug/L and ethylbenzene-3.5 mg/L. Once these levels are achieved, the site will be rendered clean and suitable for development.

The site is divided into four areas (Fig. 6). The in situ system plan called for installation of trenches on either side of Area C and either side of Area D. Figure 7 shows the general installation and operation of the two situ systems.

The in situ systems are comprised of extraction and reintroduction trenches/wells and surface bioreactors. Contaminated groundwater is pumped from the extraction trench/well to the surface bioreactor. Baffles on the influent end of the bioreactor separate free product which is pumped to an oil/water separator for further separation and eventual reclamation. The contaminated water flows over a weir into the active zone of the bioreactor. In this zone, oxygen (via diffused air bubblers) and nutrients are added to promote optimal degradation. The residence time of the water in the reactors is controlled to ensure degradation of the contaminants.

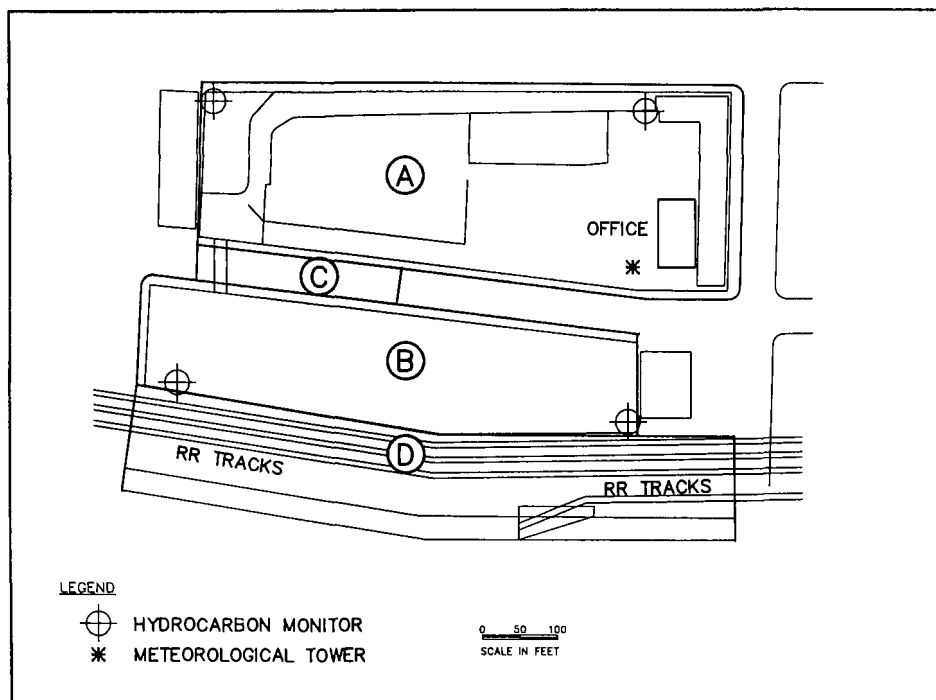
Once the contaminants are degraded, the treated water is pumped from the surface bioreactors through nutrient amendment and oxygenation contactors and reintroduced to the subsurface via the reintroduction trenches. The nutrient additions are monitored to maintain optimal


Figure 6
Site Map

levels. The oxygenation is accomplished with both diffused air bubblers and pure oxygen contactors. The oxygen is supplied by an on-site oxygen generator, thereby avoiding the dangers associated with compressed oxygen storage. The oxygen generator uses a molecular sieve bed that selectively excludes nitrogen from an ambient air stream and allows only oxygen to pass. As a result, a 98% pure oxygen stream can be produced. The molecular sieve uses size exclusion to prohibit the nitrogen flow and is regenerated each cycle.

The in situ system cleans contaminated zones by increasing the flow above normal groundwater flowrates, promotes in situ degradation, promotes mobilization of contaminants and treats unsaturated zones more effectively. The higher flowrate through the zone of contamination promotes soil washing. Any contaminants that are mobilized by the system are captured by the extraction trench and treated in the surface bioreactor. By supplying oxygen and nutrients to the subsurface, organisms present in the soil reach optimal degradation rates and reduce the contaminants

at the source. The enhanced biodegradation also assists in promoting mobilization of contaminants for capture and treatment by the extraction trench and surface bioreactor.

The development of active biodegradation in the subsurface enhances mobilization of contaminants through the action of biosurfactants. The microorganisms produce extracellular proteins (biosurfactants) which liberate contaminant molecules from soil particle surfaces into solution. Once in solution, the microbes can absorb and utilize the contaminant molecule as direct or co-metabolic carbon sources. The active microbial culture is very efficient at producing biosurfactants but not as efficient at capturing and utilizing all of the mobilized contaminant. As a result, with the increased groundwater flowrates and the action of the biosurfactants, soil washing is enhanced and the extraction trench recovers the mobilized contaminants for treatment in the surface bioreactors.

Finally, the reintroduction trench supplies treated and oxygen/nutrient-amended groundwater at a faster rate than the subsurface strata can accept. As a result, the groundwater surface in the area of the reintroduction trench is mounded. This mounding of the groundwater surface saturates previously unsaturated soils and provides a more optimal condition for in situ biodegradation.

The Area C system is comprised of a 300-ft long extraction trench coupled to a 250-ft long reintroduction trench. The pipe invert for the extraction/reintroduction piping is 2 ft below static water surface, or approximately 13 ft below ground surface. The design flow rate for the Area C system is approximately 20 gpm.

The Area D system is comprised of a series of 15 extraction wells on 50-ft centers. The wells were required because of lower permeabilities and restricted access problems. The extraction wells are coupled to a 650-ft long reintroduction trench. The invert elevation for the extraction wells is between 5 to 10 ft below static water levels and the pipe invert for the reintroduction trench is 2 ft below static groundwater levels. The design flow rate for the Area D system is approximately 100 gpm.

Included in the Area C and D in situ system trenches are vacuum lines that induce soil oxygenation in the contaminated zones. Ambient air is drawn into the subsurface from exposed surfaces within the zone of influence of the trench by a vacuum applied to the subsurface piping. The soil oxygenation pipe invert is 6 ft above the groundwater surface and 4 ft below ground surface.
Figure 7
In Situ System

Figure 8 presents some process monitoring data collected during the initial 8 mo of operation. As can be seen from this figure, the in situ system has clearly affected the subsurface. The concentration of ammonia nitrogen has increased consistently since operation of the system began in early 1990. The other parameters, nitrate nitrogen, phosphate and dissolved oxygen also show potential increasing trends but are not as clear as the trend for the ammonia nitrogen. Based on the data collected to date, we project that the cleanup goals will be achieved within 7 yr of initiation of treatment.

CONCLUSIONS

In situ biotreatment of groundwater contaminated with organic compounds is a proven remedial method that may provide an alternative or adjunct to conventional solutions. The method uses naturally occurring microorganisms that are adapted to site conditions to remove groundwater contaminants. Laboratory treatability studies provide an evaluation of the biodegradability of the contaminants. Pilot testing gathers information on the performance of the injection/recovery system and determines the degree of dilution. Full-scale implementation results in terminal destruction of the contaminants and rapid site cleanup.

Technology Applications and Commercialization
Findlay, Ohio

INTRODUCTION

OHM Remediation Services Corp. (OHM) was hired in 1985 by a major Midwestern refiner to provide environmental services for a petroleum refining site. The refinery operations had been previously dismantled, but the site needed further assessment and remedial efforts to address the residual contamination that had originated from the facility. During the last 5 years, OHM has completed the site characterization, provided interim site mitigation measures to prevent further groundwater contamination, performed biotreatability tests, conducted bench-scale tests and completed a detailed design for an integrated treatment system. This system includes a variety of processes, but biological treatment is the cornerstone of the process with carbon adsorption used for polishing effluents.

This paper discusses the tasks related to the development and design of a treatment system to recover and treat benzene, toluene, ethylbenzene and xylene (BTEX) contaminants in groundwater. Over a long period of time these soluble petroleum hydrocarbon components (PHC) had dissolved into the shallow groundwater aquifer. The primary objectives of this project were to:

- Provide a site perimeter groundwater containment system consisting of fully penetrating recovery wells designed to halt the off-site migration of groundwater containing dissolved PHCs.
- Identify the optimal method to treat groundwater containing BTEX and dissolved PHCs to levels suitable for discharge into a surface drain under a NPDES permit.
- Design a full-scale treatment system for the selected remedial process.

The information gained during the prior 4 years of hydrogeological and biodegradation studies was used as a basis for this design.

The significance of this project is that it provides an excellent example of how, by combining technologies, project costs can be reduced while meeting the established cleanup criteria. Although this groundwater cleanup could have been achieved by using either carbon adsorption or biological treatment alone, combining these technologies optimized both the technical results and the cost-effectiveness.

BACKGROUND

The site geology consists of a 75- to 80-foot thick interval of coarse- to medium-grained sands that fine downward and overlay a blue silty clay. The depth to groundwater ranges from 2 to 5 feet below grade. The upper 20 feet of the water table aquifer possesses a hydraulic conductivity of 1,000 gal/day/ft.^{2}

The contamination originated from the oil products that were produced by the refinery. Over the years of refinery operation, these products spilled and were also discharged into ponds which most likely leaked. The result was that the underlying soil and groundwater were contaminated with PHCs.

Table 1 lists the influent parameters and contaminant concentrations for the design basis. Table 2 lists the discharge limitations as outlined in the NPDES permit. The primary hydrocarbon constituents for which regulatory agencies established cleanup criteria are BTEX. Other hydrocarbon constituents are present in the water, but they have not been regulated. The total influent BTEX concentration is 2 mg/L. The treatment criteria establish that the total concentration of BTEX compounds must be reduced to less than 20 parts per billion μg/L (24-hour sample) with a benzene limit of 5 μg/L.

Available on- and off-site hydrogeological, hydrochemical and biological data were used to design a groundwater recovery treatment system. Additional data generated from initial laboratory treatment studies were also utilized to prepare the preliminary design and to estimate operational costs.

Table 1
Design Basis

Parameter	Value
Hydraulic Conductivity	1,000 gallons/day/ft^2
Porosity	0.3
Ground-Water Gradient	0.0026
Saturated Thickness	78 ft
Maximum Influent Flowrate	400 gallons per minute
Normal Influent Flowrate	360 gallons per minute
Ground-Water Chemistry	
Lead	<0.05 ppm
Chromium	<0.05 ppm
BTEX (total)	2 ppm
BOD$_5$	<10 ppm
Total Organic Carbon (TOC)	40 ppm
Total Suspended Solids (TSS)	5 ppm
Dissolved Oxygen (DO)	2 ppm
pH	6.7 SU
Oil and Grease	<10 ppm
Water Temperature	55°F
Nitrogen	3 ppm
Phosphorous	0 ppm

Table 2
Effluent Limitations and Monitoring Requirements

Effluent Characteristics	Discharge Limitations		Monitoring Requirements

pH (Standard Units)	6.5	8.0	Weekly	Grab
Dissolved Oxygen, mg/L	6.0	---	Weekly	Grab

The groundwater extraction wells have already been designed and installed to halt the off-site migration of PHC contamination. The groundwater treatment system design was based upon the flowrate of these wells, which produce a maximum flowrate of 400 gpm.

The following studies and work phases are described in this paper:

- Review of viable treatment processes for groundwater treatment
- Selection of an appropriate biotreatment process
- Bench-scale biotower treatability study
- Detailed design of integrated treatment system

TECHNOLOGIES SELECTION

Several technologies were evaluated as potential treatment methods for destroying or removing the dissolved PHC contaminants from the site groundwater. The following treatment processes were considered:

- Biological treatment
- Ultraviolet (UV) oxidation
- Carbon adsorption
- Air stripping

The advantages of first two processes are that they both would destroy the contaminants, rather than transfer them to another medium. However, at the time this evaluation was performed, UV oxidation was not considered cost-effective for the low level contaminant concentrations present at this site. Also, the water would need pretreatment to remove any turbidity that would interfere with UV light absorption.

Air Stripping/Activated Carbon

Air stripping and carbon adsorption are both effective methods for removing BTEX compounds, but these compounds still must be transferred to another medium. Air stripping would have to be used in combination with vapor phase carbon adsorption.

Carbon adsorption (for the liquid phase) presents definite advantages in that it is tolerant of concentration and flowrate variations and can adsorb a broad spectrum of compounds. However, oil and grease can plug a carbon bed if the concentration is greater than 10 mg/L. Carbon preferentially adsorbs certain organics. Of the BTEX compounds, carbon adsorbs less benzene than the other BTEX components. The primary disadvantages of carbon are the relatively high cost of operation and the need to further treat and/or dispose of the carbon.

A carbon isotherm study was conducted in the laboratory to measure the adsorption of BTEX components onto granular activated carbon (GAC) to assure that contaminant concentrations could be reduced to μg/L levels. The carbon adsorption isotherms demonstrated that for the major contaminant, benzene, the carbon capacity was 0.175 mg/g. The study also addressed total organic carbon (TOC) removal, showing that 1,000 pounds/day of carbon would be required to treat a representative flow of 150 gpm down to low μg/L levels of TOC.

Bioremediation

Bioremediation is a cost-effective treatment process that uses microorganisms to degrade organic materials. This process is enhanced by providing the organisms with the appropriate nutrients (nitrogen, phosphorus and trace minerals) and environmental conditions (Ph, temperature, moisture, etc.) to optimize the reaction rates. Bioremedia-

tion of PHC compounds results in the organics being degraded to carbon dioxide and water; therefore, little or no residual hazardous chemicals result from the treatment process.

The PHC and BTEX compounds present in the groundwater and soil at the site are known to be readily biodegradable. Biological treatment of PHCs is well-documented in the published literature.[1-6] Priority Pollutant phthalates, benzenes and PAHs are included on the Appendix VIII list of hazardous organics under 40 CFR Part 251 and, therefore, are subject to the regulations specified under the RCRA. A report prepared by ERT for the American Petroleum Institute stated that the all Appendix VIII organic compounds that may be present in land-treated petroleum wastes can be degraded in soil under proper environmental conditions.[7] Tabak et al.[8] demonstrated biodegradation of benzene, ethylbenzene and toluene in basal salts-yeast extract enrichment flasks using 5 and 10 mg/L concentrations of each compound as sole carbon and energy sources for microbial growth. A wastewater inoculum was used and adaptation was rapid. Biodegradation of o-, m- and p-xylene is well-documented.[9]

For the above reasons, bioremediation was selected as the primary remedial technology to treat groundwater at the site. A laboratory treatability study had demonstrated the effectiveness of indigenous microorganisms to degrade BTEX to concentrations less than 1 μg/L in groundwater. These studies also provided information on treatment kinetics to allow an order of magnitude estimate of the reactor volume required to treat a given quantity of water.[10]

BIOLOGICAL TREATMENT SELECTION

The aerobic, static (packed) bed, fixed-film process configuration was selected for biological treatment of the contaminated groundwater after considering a number of process configurations including the rotating biological contactor process; the fluidized-bed, fixed-film process; and the powdered activated carbon-activated sludge process. In the aerobic, static-bed process configuration, wastewater flows upward or downward through a bed of media, fixed within the reactor shell. Oxygen, normally in the form of air, is introduced through diffusers located in the bottom of the reactor.

The full-scale process flowsheet would involve a biological treatment system followed by solid-liquid separation and conventional GAC adsorption. Some components of the groundwater, especially benzene, would quickly exhaust the GAC in the treatment system if not degraded in the biological treatment process. A high removal efficiency of benzene and other aromatic components by biological treatment will assure a longer effective lifetime for the carbon. This design will translate into a savings in activated carbon costs over the system's lifetime. The GAC adsorption step is anticipated to play a significant role in assuring effluent quality requirements are met during startup and upsets of the biological treatment system. Once the biological system reaches its design treatment capacity, the GAC adsorption step will polish the water to assure treatment to discharge criteria.

BENCH-SCALE BIOTOWER TREATABILITY STUDIES

A bench-scale study was performed to develop process operation information for full-scale design of a biological system to treat contaminated groundwater. The goals were to determine the treatment removal efficiency achievable for the BTEX components in the groundwater and to establish the minimum temperature and nutrients needed to operate the upflow bioreactor to achieve design effluent concentrations at an influent flow of 200 gpm (1-hour Hydraulic Residence Time [HRT]) to each biotower. In addition, other important treatment system design and operating parameters (e.g., biological reactor oxygen requirements, chemical requirements for pH control, degree of VOC stripping in the reactor, etc.) were established.

The required size or number of biotowers would be dictated by the treatment kinetics associated with the wastewater in question and the mass of active microorganisms which could be developed and maintained in the reactor. Based on a design Biological Oxygen Demand (BOD) loading of approximately 20 pounds BOD_5/1,000 ft^3/day, one reactor would treat 200 gpm of groundwater.

Materials and Methods

The laboratory study involved operation of an upflow, attached film, 5-L, static bed reactor. The upflow operation assured maximum groundwater/biomass contact and a minimum of short circuiting through the bed. The reactor was filled with random packed, plastic pall rings and enclosed to allow complete material balances to be performed. Air was used as an oxygen source during the study to assess the effect of aeration on VOC stripping. If necessary, high purity oxygen could be used to minimize volatilization/stripping of the organics. The reactor was operated on the site water supplemented with appropriate nutrients to support the growth of biomass. The pH of the reactor was maintained in the neutral range. In order to establish the minimum temperature and nutrients needed to achieve design effluent concentrations, two small biotowers were constructed. Biotower I was operated at 70 °F to simulate heated groundwater, while Biotower II was operated at 55 °F to simulate the ambient groundwater temperature.

The biotowers were constructed as 4-inch diameter Plexiglas columns with flanged top and bottom plates. The influent port was located on the column bottom while the effluent was side discharged near the top of the biotower. A port on the biotower top allowed off-gas to escape.

The packed volume of the reactor was 4 liters. Each column was packed to a height of 29 inches, with 5/8-inch nominal Nor-Pac polypropylene media to provide a support medium for biomass growth. One-half inch glass beads were placed below the packing for air dispersion from the influent throughout the column diameter (Fig. 1).

Each reactor was inoculated with activated sludge from the Findlay, Ohio, wastewater treatment plant. A full recycle flow scheme was initiated with an influent feed consisting of BTEX-spiked site water supplemented with acetate. The acetate was the primary carbon source for the developing biomass since TOC and BOD concentrations in the site water were relatively low. Full recycle operation was continued until sufficient biomass had developed on the column media.

For continuous flow operation, site water was pumped from barrels into a header leading to the bioreactor influent port. Also connected to the header was a line to the carbon/nutrient/BTEX source carboy. This mixture contained measured amounts of ammonia-nitrogen and phosphate-phosphorous nutrients for biomass support, a BTEX addition to increase influent concentrations and acetate to be added as a primary carbon source when necessary. The BTEX addition was necessary due to volatilization of these contaminants from the site water
Figure 1
Bench-scale Biowater System

during collection and/or storage. On Biotower I, operated at room temperature to simulate 70 °F (heated) groundwater, a compressed air line was connected to the combined feed header before reaching the column influent port. Biotower II was operated at 55 °F to simulate ambient groundwater temperature. The combined feed was passed through a copper tubing coil immersed in a temperature controlled water reservoir to assure an influent temperature of 55 °F. An aeration line was also connected into the chilled feed line to provide oxygen to the biotower.

Several operating conditions were tested on each biotower from flow initiation to the design 1-hour HRT (Tables 3 and 4). This operating parameter required the adjustment of liquid feed rates and influent concentrations. A period of at least 2 to 3 weeks was allowed for biomass acclimation after operating conditions were changed. Once the performance had stabilized, analytical data were collected over 3 days as representative of steady-state performance (Table 5).

Results and Discussion

Biological removal of BTEX was the primary goal of this study. Greater than 99% treatment removal efficiency was achieved for BTEX during operation of Biotower I at design steady-state conditions during 8 months of operation. An average influent BTEX concentration of 2 mg/L was treated to nondetectable levels in the effluent stream (Limit of Detection [LOD] = 2 μg/L for each BTEX component) (Table 6). A similar treatment efficiency (greater than 99%) has been achieved for BTEX in Biotower II during 5 months operation at design conditions (Table 7). To confirm that microbial degradation was the mechanism responsible for BTEX removal, analyses of the vent gas and biomass solids were performed on both biotowers. The data indicate

that the BTEX components were not detectable in the air or solids process streams (Tables 8 and 9). These data clearly prove the effectiveness of the upflow biotower design for treating BTEX in groundwater.

The total unidentified semivolatiles (total influent concentration = 0.999 mg/L) were not fully degraded by the biotower treatment systems. Biotower I removed an estimated 67% of the semivolatile contaminants while Biotower II removes approximately 31% of these compounds. Volatile or semivolatile compounds were not detected in the biomass

Table 3
Steady State Operating Conditions for Biotower I

(70 Degrees Fahrenheit)

Condition	Hydraulic Residence Time	Influent Total Organic Carbon
1	2 hour	35 ppm site water plus 35 ppm acetate
2	1 hour	35 ppm site water plus 35 ppm acetate
3	1 hour	35 ppm site water plus 17.5 ppm acetate
4	1 hour	35 ppm site water

NOTE: Condition 4 is Design Operating Conditions

Table 4
Steady State Operating Conditions for Biotower II

(55 Degrees Fahrenheit)

Condition	Hydraulic Residence Time	Influent Total Organic Carbon
1	2 hour	35 ppm site water plus 35 ppm acetate
2	1 hour	35 ppm site water plus 35 ppm acetate
3	1.5 hour	35 ppm site water plus 17.5 ppm acetate
4	1.5 hour	35 ppm site water
5	1 hour	35 ppm site water

NOTE: Condition 5 is Design Operating Conditions

sludge indicating these compounds do not bioaccumulate within the reactor.[11]

In addition, acetate addition and the heated water (70 °F) would only be required during the startup process. Once the biotowers were operational, the acetate feed and water heating could be gradually eliminated. The results from this study were used as the basis of the final design.

FINAL FULL-SCALE DESIGN

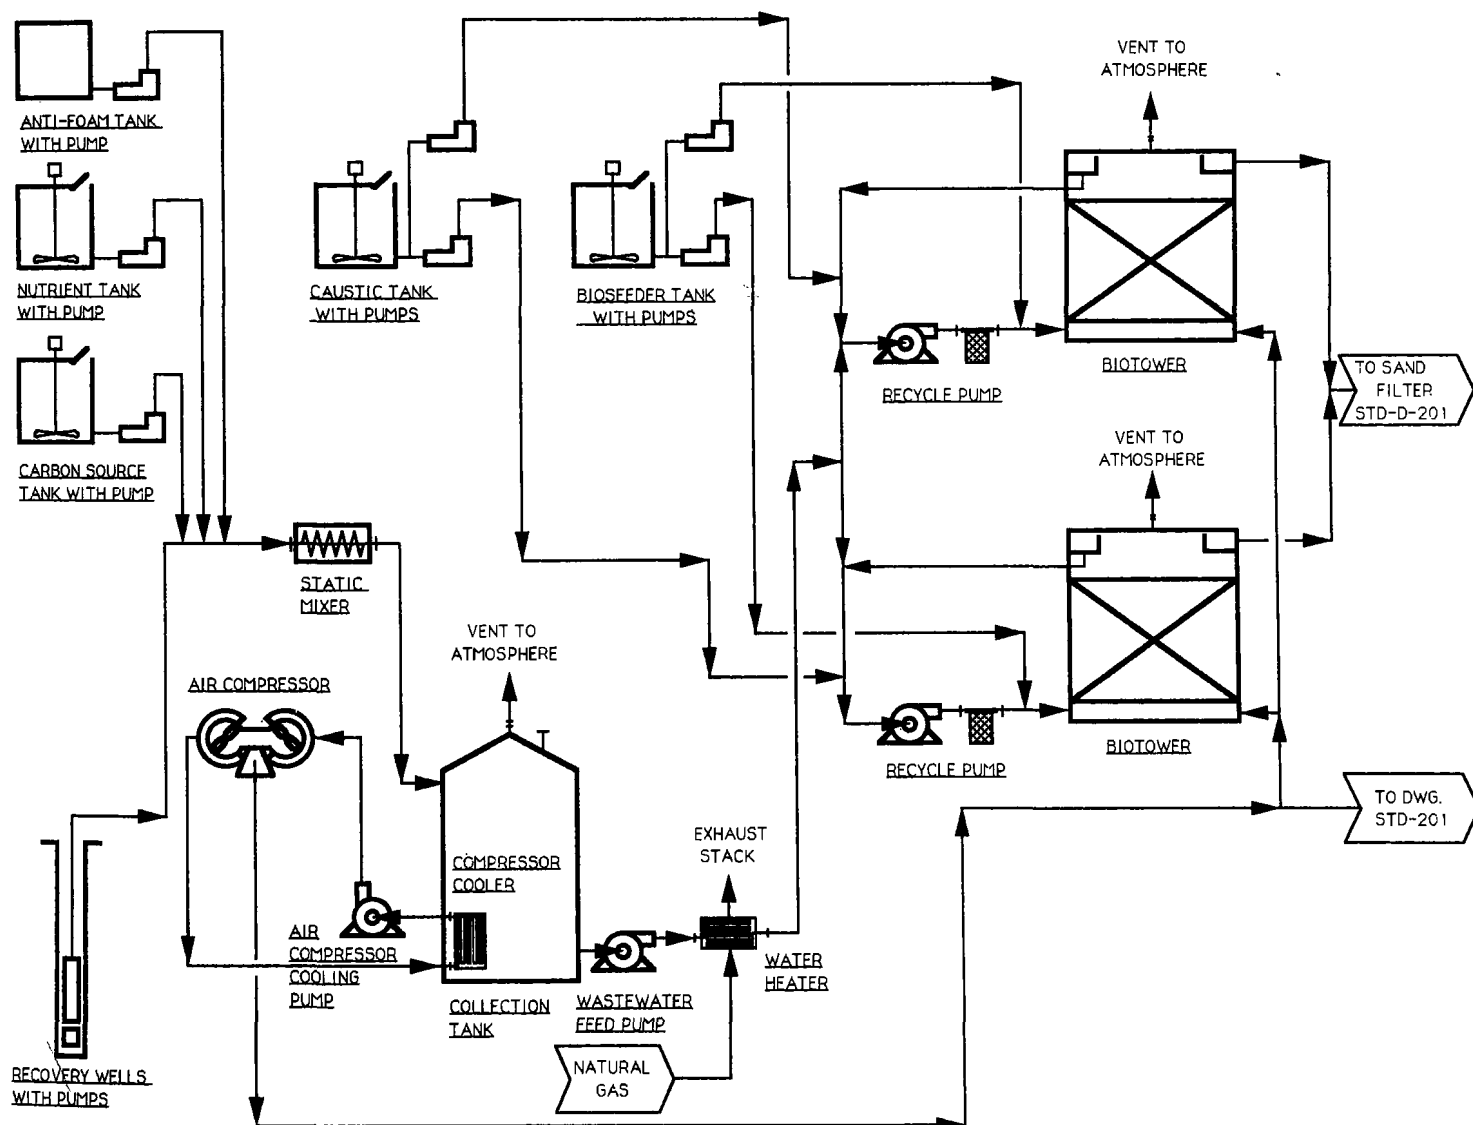
The final treatment system was designed to treat a maximum of 400 gpm to the cleanup criteria previously described in Table 2. The process flow diagrams for the full-scale treatment system are presented in Figures 2 and 3. The treatment system will include the following major systems:


Figure 2
Process Flow Diagram

- Groundwater recovery system
- Pre-conditioning system
- Biological treatment system
- Post-conditioning system
