Abstract

This paper describes the results of a project on passenger cars to evaluate the effectiveness of idle adjustment at commercial repair facilities. This effort involved a total of 222 passenger cars tested by Automotive Testing Laboratories (ATL) & Automotive Environmental Systems, Inc. (AESI) during 1979 and 1980. These vehicles were a subset of 1225 vehicles tested in St. Louis, Washington D.C., Phoenix and Los Angeles as part of the FY 77 and FY 79 Passenger Car Emission Factor Programs. Only vehicles which arrived for testing without limiter caps were eligible to participate in the survey. After the complete laboratory test, a contractor employee took each vehicle to a service station, independent garage or dealer and asked simply that the idle mixture and speed be adjusted to manufacturer's specifications. Upon return to the laboratory, the work performed by the facility was evaluated using a tachometer and garage-type emission analyzer. The sequence was completed when the contractor's mechanic performed the idle adjustments to the best of his ability. The data obtained illustrates the inability or unwillingness of the majority of commercial repair facilities to properly set idle mixtures. The results of this project point to the need for mechanic training in reducing vehicle emissions through correct maintenance procedures.

Background

According to the Clean Air Act and its Amendments, the Environmental Protection Agency (EPA) is required to encourage and implement programs which will assure that properly maintained vehicles will meet their emission standards throughout their useful life. Inspection/Maintenance programs are the primary force behind this effort to control emissions from in-use vehicles with the work to be performed by the commercial repair industry. It is well known that a substantial number of in-use vehicles will not meet their emission standards when tested in an as-received condition (Reference 1 and 2). One of the major reasons is that the idle mixture and speed has been mal-adjusted. In order for these vehicles to meet their emission standards, these adjustments must be made correctly. The typical places for these adjustments to be made include dealerships, service stations, and independent garages.

Purpose

This study was designed to evaluate the ability of the commercial repair industry to set idle adjustments to manufacturer's specifications.

Selection and Test Procedures

Vehicles selected for this project were recruited primarily from the FY79 Passenger Car Emission Factor Program. Vehicles which arrived at the contractor's facility missing their idle mixture limiter caps were chosen for this study. Two hundred and twenty-two such vehicles out of a total of 1225 passenger cars tested were taken to commercial facilities by various persons in the contractor's organization (secretaries, engineers, technicians, etc.). The following procedures were employed:

Before leaving the contractor's facility - Vehicle identification information was recorded on worksheets provided by EPA. Idle readings (CO, HC, RPM) were also measured and recorded. Any evidence that the vehicle was in a testing program (e.g., data packets or exhaust connectors) was removed from the vehicle. A repair facility was contacted to set up an appointment to have idle mixture and speed adjusted. If possible, all adjustments were to be performed while the driver waited. No reference was made to any affiliation with an emission testing lab or that this was to be part of an EPA study.

At repair facility - The driver requested that the idle mixture and speed be adjusted to manufacturer's specifications. If questioned why, it was stated that they had heard that this is a very important adjustment from a number of standpoints, such as fuel economy and engine performance. If the mechanic insisted that other maintenance be performed, the driver stated that he wanted only the idle adjusted at this time to see what difference it made. If the mechanic said that he did not know how to set it to specifications, he was asked to set it as best he could. Notes were made (although not in the mechanic's presence) of any of his comments and actions. Observations regarding instruments and tools used as well as cost data were also recorded on the worksheets.

After returning to the contractor's facility - ICO, IHC, and IRPM were measured and recorded, as were the number of $\frac{1}{4}$ turns necessary to lightly seat the idle mixture screws. The mixture screw settings were not measured prior to sending the vehicle to the commercial repair facility in order not to disturb the as-received settings. Idle parameters were then adjusted to manufacturer's specifications by contractor mechanics and the location of the idle mixture screws relative to the lightly seated position was recorded. ICO, IHC and IRPM were again measured and recorded. New limiter caps were installed in the center position. The vehicle was then returned to its owner.

Discussion

Idle Test Results - The results of each of the 225 vehicles involved in this project are listed in the Appendix. The contractor for St. Louis, Washington, D.C. and Phoenix was Automotive Testing Laboratories (ATL), while Automotive Environmental Systems, Inc. (AESI) was the contractor for Los Angeles. The results for each city are summarized below.

St. Louis - Eighty three 1975-1979 model year passenger cars were taken to commercial repair facilities. The results of these adjustments are summarized in Figure 1. After adjustment at commercial repair facilities, idle HC concentration increased by 87% and idle CO increased by 30%. The engine RPM values, representing the average absolute difference from manufacturer's specifications, were essentially unchanged. The average cost for these adjustments was \$4.97. A histogram showing the number of $\frac{1}{4}$ turns required for proper adjustment of the idle mixture screws after return from the commercial repair facility is also included in Figure 1.

Washington D.C. - Sixty one 1977-1980 model year passenger cars were taken to commercial repair facilities. Their results are summarized in Figure 2. After adjustments at commercial repair facilities, idle HC concentration increased by 23% and idle CO remained unchanged. Again, the engine RPM values, representing the average absolute difference from manufacturer's specification were virtually unchanged. The average cost was \$4.67. A histogram showing the number of $\frac{1}{4}$ turns required for proper adjustment after return from the commercial repair facility is also included in Figure 2.

Phoenix - Forty eight 1975-1978 model year passenger cars were taken to commercial repair facilities. The results of these adjustments are summarized in Figure 3. After adjustment at commercial repair facilities, idle HC concentration increased by 40% and idle CO decreased by 7%. The engine RPM values, representing the average absolute difference from manufacturers specifications, decreased by 28%. The average cost of these adjustments was \$5.32. A histogram showing the number of $\frac{1}{4}$ turns required for proper adjustment of the idle mixture screws after return from the commercial repair facilities is also included in Figure 3.

Los Angeles - Thirty 1975-1978 passenger cars tested in 1979 by Automotive Environmental Systems Inc. as part of the FY 77 Emission Factor Program are included in this report. These thirty passenger cars were also taken to commercial repair facilities for adjustments. The results of these adjustments are summarized in Figure 4. After adjustment at commercial repair facilities, idle HC decreased by 38% and idle CO decreased by 28%. The engine RPM values, representing the difference from manufacturer's specifications, decreased by 18%. The repair facilities in Los Angeles appeared to do a much better job than in the other cities. On the other hand the average cost of repairs in Los Angeles was \$16.76. This is substantially higher than in the other cities. The factors of cost and quality may be due to California's licensing of mechanics and repair facilities.

Results of the Federal Test Procedure - Although the Federal Test Procedure (FTP) was not performed on these vehicles after they returned from the repair facility, the FTP emissions for the fleet were collected and averaged based on the presence of limiter caps upon arrival at the laboratory. These averages are listed in Table 1. The values here indicate that vehicles without limiter caps have average HC and CO emission levels which exceed those where the limiter caps are intact.

Conclusions

1. Only minor adjustments would be required to allow most vehicles to pass a basic I/M test.
2. The commercial repair industry does not currently adjust idle mixture and speed properly.
3. A lack of training and proper equipment (tachometers and exhaust analyzers) is apparent in the performance of this type of maintenance.
4. In order to conduct successful Inspection/Maintenance programs, some incentives and a major effort in mechanic training will be required to ensure that idle adjustments are made properly.
