Prepared for

OFFICE OF RESEARCH AND DEVELOPMENT U.S. ENVIRONMENTAL PROTECTION AGENCY WASHINGTON, D.C. 20460

November 1974

This report has been reviewed by the Environmental Protection Agency and approved for publication. Approval does not signify that the contents necessarily reflect the views and policies of the Agency, nor does mention of trade names or commercial products constitute endorsement or recommendation for use.

FOREWORD

This document presents the results of a survey of the costs of converting conventional, fossil fueled, stationary combustion equipment to the use of selected coal-derived fuels. The report provides updated information on present-day fuel switching activity, continues with the presentation of equipment conversion costs, and concludes with the formulation of cost models derived from the previously collected data.

The latter four authors of this report, personnel of The Coen Co. in Burlingame, California, performed the boiler modification cost assessments.

Aerotherm extends its appreciation for the valuable assistance provided by Mr. R. C. Carr of the Electric Power Research Institute, Palo Alto, California, and Dr. R. M. Jimeson of the Federal Power Commission, Washington, D.C. Special thanks is given to the diligent members of the Aerotherm Technical Publications Department.

This survey was performed for the Engineering Analysis Branch of the Control Systems Laboratory, U.S. Environmental Protection Agency. Dr. Gary J. Foley was the task officer until July 26, 1974. Dr. Charles Chatlynne was the task officer for the remainder of project's duration. The Aerotherm Project Manager was Dr. Larry W. Anderson. Dr. C. B. Moyer and Dr. H. B. Mason acted as advisors for all phases of the study. The study was undertaken during the months of June to September, 1974.

SECTION 1

INTRODUCTION

The creation of the various combustion-generated chemical species generally regarded as air pollutants can be reduced by a variety of means. Some pollutants, such as "thermal" nitric oxide, lend themselves to reduction by modification of the combustion process. Others, notably the oxides of sulfur, are released in quantities directly proportional to the amount of some contaminant contained in the fuel. Pre- or post-combustion controls are the only feasible means of eliminating combustion systems as sources of SO_X . Therefore, the two leading strategies for controlling SO_X emissions from combustion equipment firing sulfur-containing fuels are: (1) burning desulfurized fuel, or (2) removing the SO_X from the flue gas (Reference 1-1).

For high-sulfur coal, the former method can be effected by burning the products from various gasification and liquefaction processes, while several popular scrubbing techniques exist for stack gas SO_X removal. The choice of the most viable control strategy will be based on cost, among other factors. Such monetary considerations are to be analyzed using detailed, consistent cost models developed by the EPA.

EPA has funded research into several stack gas scrubbing techniques, and has detailed information on the costs of such operations for a given size of installation. The costs associated with typical coal gasification and liquefaction processes are also reasonably well in hand (Reference 1-2). There is not, however, a good source of information on the costs associated with converting oil- and coal-fired equipment to use these "synthetic" gases and liquids as fuels. The purpose of this task order is to provide cost information on the conversion from conventional fossil fuels to selected coalderived gaseous and liquid fuels as a function of equipment type and firing capacity. This study focuses on conventional stationary combustion systems, such as industrial furnaces and utility boilers. The cost figures collected during this study lead to the formulation of generalized equipment conversion cost models, compatible with existing models involving production and transportation of these coal-derived fuels. The results of this task will contribute to EPA's on-going SO_X Control Strategy Analysis.

Specifically, the coal-derived fuels of concern in the context of the present study include Solvent Refined Coal (SRC) and the range of low-Btu (150 Btu/scf) to high-Btu (1000 Btu/scf) content gases. For the gaseous fuels, an attempt is made to treat the range of gases as a continuum, and to incorporate a heating value term in the cost models for gas. Large-scale research and development programs aimed at determining the feasibility of usir these materials as fuels have only recently been initiated. As a result, very little is known about their combustion and handling properties, and certain assumptions were made in this regard in order to make the required equipment modification cost estimates. It will be possible to evaluate these assumptions as more information on these fuels' physical properties becomes available.

The combustion systems of concern include steam-raising boilers in the 10^7 to 1000×10^7 Btu/hr range, encompassing all industrial and utility size equipment. This assures inclusion of the smaller SO $_{\rm X}$ sources, which tend to lack even intermittent controls (i.e., tall stacks) and which may have a significant impact on local air quality.

A future use for these coal-derived fuels for electric power production will be to fire them in combined-cycle plants, rather than solely in converted equipment of conventional designs. Indeed, the ultimate goal of most present-day coal-conversion power system projects is the demonstration on a commercial scale of an economically and environmentally acceptable electric generating plant that links a coal-conversion system with a combined-cycle plant adapted for using these exotic fuels (see References 1-3, 1-4, 1-5). Combined-cycle power plants are not, however, treated in the present study, but it is felt that determining the costs of converting conventional combustion equipment to the use of these fuels will provide support for future system trade-off and cost-effectiveness assessments.

The remainder of the present study is organized in the following manner:

Section 2: Current Fuel Substitution Activity - Conventional to Coal-Derived Fuels

This section attempts to draw together ongoing, practical experiences and state-of-the-art knowledge on the subject of converting the combustion equipment of concern to the use of exotic, coal-derived fuels from more conventional fossil fuels. This investigation was performed in the hope of supplementing the estimates of equipment conversion costs presented later in the study.

Section 3: Characterization of Combustion Equipment

This section presents the justification of the choice of combustion equipment types scrutinized in the study. Brief qualitative descriptions of the equipment are included.

Section 4: Characterization of Substitute Fuels

The study continues with brief discussions of the Solvent Refined Coal process, the notable coal gasification schemes, and their probable importance as fuels of the future. Typical chemical compositions of these fuels are given as well.

Section 5: Selection of Fuel Substitution Options

The manner in which the conversion cost data will be collected is introduced. This consists of a matrix of boiler type versus boiler capacity for a given type of conversion. The cost estimation method involves applying a set of cost data obtained from a similar conversion (i.e., to a lighter fuel oil) to a postulated coal-derived fuel conversion.

Section 6: Documented Boiler Conversion Cost Data

This section contains the estimated equipment conversion cost data for a given boiler type, original fuel and substitute fuel as set forth in the "Equipment Conversion Cost" data sheets. Included also are plots of the cost versus capacity data. Qualitative descriptions of the methodology of each conversion are provided. A discussion of the possible cost models that may be derived from these data is included as well.

Section 7: Conclusions and Recommendations

The significance of the results of the study are summed up, and recommendations for their future application are provided.

The report concludes with the References and the Appendix. The latter section contains the bulk cost data from which the final equipment conversion cost figures were derived. Included also is a tabulation of popular coal gasification processes. The appendix concludes with a table of British to metric conversion factors.

SECTION 2

CURRENT FUEL SUBSTITUTION ACTIVITY: CONVENTIONAL TO COAL-DERIVED FUELS

2.1 INTRODUCTION

Two energy source substitution strategies exist for reducing sulfur oxide emissions from fossil-fueled steam-generation equipment. First, the generating source itself may be replaced, such as switching from a fossil-fueled to hydropower plant. The second option, and by far the more expedient, is substitution of a cleaner fuel. The present study is concerned with a specialized case of the latter method.

Fuel substitution is a common practice in the operation of most large steam raising plants, although its motivation is most often based on fuel availability rather than on air pollution control. Most of these plants were originally designed for dual fuels, and the actual in-plant fuel switching process is usually quite straightforward. As a general rule, however, difficulty in doing so increases when progressing from gaseous or liquid to solid fuels. The material handling problems are worsened, and the possibility of additional combustion erratics arise with reduced fuel heating value.

Among the more promising low-sulfur fossil fuels are the products from coal conversion processes. The current clean fuel shortage has sparked widespread interest in the energy generation potential of these future fuels. the present time, however, no existing industrial or utility boiler is firing these fuels, due mainly to a general lack of sufficient quantities. tion, the combustion and handling properties of these fuels are generally un-The probability is high, however, that some degree of equipment modification will be necessary before these fuels can be utilized in existing equipment. The purpose of this study is to assess the capital costs of converting a variety of boiler designs and capacities to two types of coal-derived fuels; namely, lower-BTU gas (HHV = 150-700 Btu/scf) and solvent refined coal (SRC). Current activities in this area are reviewed in the following subsections. Although for many years it has been the practice of the industrial boiler sector to use waste gases (i.e., coke oven gas) of low heating values as fuels, such occurrences are too varied to be included in this discussion. The principles involved in using such fuels are, however, an integral part of the cost estimation methodology performing during this study.

2.2 CURRENT ACTIVITIES

For the most part, actions in the area of converting boilers to coalderived fuels have been limited to studies, models, and position papers by the utility industry. This lack of actual conversion experience stems, for the most part, from a combination of the following three factors:

- Quantities of these exotic fuels are insufficient even for subscale test purposes, much less for full-scale steam generation.
- Pressure to begin such programs was absent until the energy shortage reached a severe level several years ago. This, naturally, retarded the development of the required new technology.
- The lead time required by the utility industry to implement alterations in electrical generation mode is traditionally long.

However, a discussion of germane literature as well as the current posturing by the utility industry is of interest in the context of this study.

Conversions to Lower-BTU Gas

A recent article by Henry and Burbach of Combustion Engineering, Inc., (Reference 2-1) considered the factors involved when attempting to apply low-Btu gas (130 Btu/scf) to an existing tangentially-fired boiler. The authors' major conclusions were:

- The lower heating value of the gas requires that, compared with natural gas, as much as 12 times the amount of fuel gas (by weight) be handled
- This factor may require a larger combustion volume, and either larger fuel piping or higher supply pressures.
- Operation of the on-site low-Btu gas plant may require that the steam generator be brought on line on its backup fuel (i.e., low sulfur oil) and then transferred to the low-Btu gas. This refers to the "dynamic coupling" difficulties that will be discussed later in this section.

No information on the costs associated with the required modifications were included in the paper. The article also related that Combustion Engineering currently has a four-phase contract with the Office of Coal Research to design a 200 MW pilot plant in combination with 5 ton/hr low-BTU gasification plant.

A recent paper by Frendburg (Reference 2-2) verifies much of the information in the paper by Henry and Burbach, and contains some additional elaborations:

- As the heating value of the fuel gas falls below 300 Btu/scf, the fuel pipes or ducts increase in size making it more difficult to route these pipes or ducts.
- The furnace volume of coal-fired utility boilers are inherently larger than those for either oil or gas, and will, therefore, more readily accommodate lower-Btu gas.
- Unit efficiency may decrease when firing lower-Btu gas, due to increasing heat loss to the stack.

Actual application of lower-Btu gas in power plants is seemingly limited at the present time to some program planning on the part of an electrical utility company in Illinois (References 2-3 and 2-4). Through contributions to the Electric Power Research Institute, the electric utility industry is supporting this development project, which is sponsored by Commonwealth Edison Company. The project's strategy will be to use a Lurgi gasifier to equip the 120 MW Powerton Station. It was determined that using low-BTU gas as a fuel supply possessed two major advantages over stack gas scrubbing:

- The low-Btu gas supply can generate a net excess of electric power by passing the product stream through an unfired expander turbine; this contrasts with the scrubber which uses from 5 to 10 percent of the generated power (Author's comment: it should be noted, however, that generation of low-Btu gas entails the loss of approximately 40 percent of the heating value of the feedstock coal. An overall power generation system energy balance will favor the use of raw coal).
- The associated gas purification process of the gasification system effects cleanup by removing hydrogen sulfide (for which technology exists), and treats less than 5 percent of the volume of gas that would be processed in a scrubbing system.

Detailed information on the present status of this project was not available.

Conversions to Solvent Refined Coal

The practical and economical feasibilities of utilizing solvent refined coal in existing fossil-fueled utility boilers have been analyzed in some depth (References 2-5, 2-6, and 2-7). SRC is a relatively clean fuel, being low in moisture, ash, and sulfur, and its heating value is fairly uniform regardless of the feedstock coal (about 16,000 Btu/lb). On the face of it,

this means that the refined product can be shipped on a Btu basis for proportionately less than raw coal. This factor suggests the location of refining plants near cheap sources of coal. In addition, the paper studies show significant pollution control cost savings through the use of SRC. However, the assumption is made that it can be substituted for either oil or coal without difficulty. As it is the purpose of the present study to evaluate such conversion costs, the validity of this assumption will be tested. Also, the cost of producing SRC must be factored in when comparing costs with stack gas scrubbing.

As is described in detail in Section 4 of this report, the physical properties of SRC are such that some controvery currently exists as to whether it is more advantageous to burn it as a liquid or solid. The original fuel may become a deciding factor.

There are currently two schools of thought on the subject of the applicability of solid SRC to coal-fired plants. One contends that the material is sufficiently similar to coal that existing storage facilities, pulverizers, and fuel handling and combustion equipment can all be used, with no modifications necessary. The opposing theory states the opposite: that solid SRC will melt unless preheat operation is discontinued and appropriate portions of the fuel preparation and handling equipment are externally cooled (References 2-8 and 2-4). As so little is known about the actual handling and combustion properties of this material, considerations from both cases have to be treated. The first would require essentially no cost, while some finite cost will be associated with the second.

It is generally agreed that firing liquid SRC in either oil- or coalfired plants will require some degree of adaptation. SRC's viscosity increases
dramatically below about 500F, which will necessitate, among other factors,
external pipe- and vessel-heating apparatus. The extent and cost of the liquid
SRC handling system will depend to some degree on the location of the SRC
plant with respect to the steam generator. If the plant is located inconveniently far from the site of use, the SRC can be transported as a solid (molded
pellets) to the boiler and subsequently melted. If the SRC plant is adjacent
to the boiler, cooling the material to solid form will not be necessary before
combustion. In either case, the usual liquid fuel handling equipment (piping,
valves, pumps, storage tanks, etc.) will be required in addition to the special
fuel warming equipment. Such considerations will be treated at greater length
in Section 6 of this report.

Actual experience in converting steam raising boilers to the use of SRC has been, at present, restricted to preliminary program planning by some electric utility/oil company consortia in the Midwest and Southeast. In Ohio, the team of Old Ben Coal Company, Standard Oil of Ohio, and Toledo Edison are gearing up for a pilot program in which SOHIO will supply SRC, made from coal supplied by Old Ben, to an Edison generating station. Conversations with the principals involved netted the following (References 2-9, 2-10, and 2-11):

- SRC will be transported like coal in existing hopper cars.
- Heated pulverizers cannot be used; Toledo Edison's operates at about 130F.
- What effect SRC's lower ash content will have on the plant's existing ash collection method is unknown.
- Amount of possible boiler derating is unknown.
- SRC may not be able to be heated to a liquid state and stored for long periods of time; in any case, the heating must be done under pressure and an inert atmosphere, to avoid repolymerization.
- The major advantage of SRC as a substitute fuel over lower-Btu gas is the lessening of "dynamic-coupling" difficulties; i.e., a utility plant's output can vary by as much as ± 5 percent per minute, while a gasification plant's rapid turndown capabilities are far less.

 SRC can be stored easily and its input rate can be modulated readily.

A detailed description of the SOHIO/Toledo Edison/Old Ben enterprise has not yet been published or otherwise made available to the general public.

Additional activity in the area of SRC utilization in power plants is currently taking place at Wilsonville, Alabama. A 6 ton/day SRC pilot plant, sponsored jointly by The Southern Company system and the Electric Power Research Institute, was completed at this location in August, 1973. Pre-liminary plans are being made for applying the SRC obtained from this pilot plant to a Southern Services generating plant (Reference 2-12).

2.3 SUMMARY AND CONCLUSIONS

The motivation for fuel substitution in steam-raising boilers is based on fuel availability and/or pollution control. The continuing shortage of clean substitute fuels will cause reliance on alternate fossil fuels. With the advent of coal-derived fuels, most of which require special handling and

combustion procedures, some effort will have to be expended to convert conventional combustion systems to their use. Of the various coal conversion processes, the products from two of them are considered in this study: solvent refined coal and synthesis gas.

Thus far, activities aimed at converting full-scale utility boilers to the use of either of these types of fuels has been limited to studies, position papers, and preliminary program planning by a few electric utility/oil company consortia in the Southeast and Midwest. For the gaseous coalderived fuels, a Lurgi coal gasifier will be used to supply a 120 MW generating station. Details on the present status of this project were not available.

In another program, solid SRC will be utilized in a coal-fired power plant. It is anticipated by the participants that little or no equipment conversion will be necessary. An additional SRC-related project is underway in the Southeast, where SRC from a 6 tons of coal/day pilot plant will be supplied to an existing generating unit.

A major advantage of solid SRC over lower-Btu gas as a boiler fuel is that, in contrast to the product from an <u>in situ</u> gasifier, SRC can be stored when not in demand by the power plant, thus removing the "dynamic coupling" difficulties prevalent in the gasifier/steam plant strategy.

There is as yet no widespread move to employ either gasified coal or SRC in the industrial boiler sector.

The absence of cost data based on actual experiences in converting to these exotic fuels necessitates that such costs be estimated for this study. The estimation procedure, performed by personnel of The Coen Co., was based on a knowledge of the fuel's physical properties as well as an extensive background of boiler conversions to similar fuels. Section 6 of this report discusses the estimation methods and assumptions used in deriving the cost figures.

SECTION 3

CHARACTERIZATION OF COMBUSTION EQUIPMENT

3.1 INTRODUCTION

The previous section of this report reviewed current activities involving the substitution of various coal-derived fuels for conventional fossil fuels in stationary combustion equipment. The majority of such activity currently centers around full-size utility boilers, with less apparent effort being expended in the industrial boiler sector. Both sectors are, however, obvious candidates for the application of fuel switching as a SO abatement strategy.

The choice of the combustion equipment types and their capacities ultimately considered in this study was based on two factors:

- Determination of the most prolific stationary SO_X sources. According to the 1970 nationwide emission estimates given in Reference 3-1, fuel combustion in stationary sources accounts for 79 percent of the total controllable SO_X emissions. Of that amount, 73 percent is contributed by steam-electric, 18 percent by industrial, 3 percent by commercial and institutional, and 5 percent by residential sources. It appeared that the greatest benefit would be derived from considering only the first two source categories.
- Possible impact on the ambient air quality in the immediate vicin ity of the source. This consideration demanded the inclusion of the smaller SO sources.

These criteria acted to establish the framework for the determination of the types and capacities of combustion equipment to be considered in this report; namely, steam-raising boilers in the 10^7 to 1000×10^7 Btu/hr (1-1000 MW) capacity range, which encompasses all industrial and utility size equipment. Including a wide variety of boilers and capacity ranges increases the probability of arriving at a global relationship between equipment conversion capital cost and capacity.

Boilers used for industrial purposes in the capacity range of interest include the following general types:

- Firetube (packaged)
- Watertube (packaged or field-erected)
- Stoker (field-erected)

Utility boiler types, all of which are field-erected, are categorized mainly by fuel firing mode. These include:

- Face-fired
- Tangentially-fired
- Turbo-fired
- Cyclone-fired

The remainder of this section is devoted to brief descriptions of these types of industrial and utility boilers. Throughout the discussion, it should be noted that the term "packaged" refers to a shop-fabricated boiler which is shipped as a complete unit to the point of use. This fact naturally places an upper limit on physical size; the largest packaged boilers can be transported by barge, and most are sized for railroad flat cars. The opposite fabrication method is described by the term "field erected," meaning the boiler is assembled from its component parts at the site of eventual operation.

Additional, more detailed specifications on the design, construction, and operation of these boilers can be obtained from the references cited.

3.2 INDUSTRIAL BOILER TYPES

3.2.1 Firetube Boilers

Firetube boilers (all of which are packaged) are used where steam demands are relatively small, usually for heating systems, industrial process steam, or as portable boilers. In this design, the hot combustion gases are passed through tubes submerged in a water-containing vessel. The principal types of firetube boilers include Horizontal Return Tubular (HRT), Scotch Marine, and "Short Firebox," the capacities of which fall in the 10^7 to 25×10^6 Btu/hr range.

These three types of boilers will be lumped together under the firetube boiler category, mainly because of similarities in capacities and firing equipment. HRT boilers are not commonly built for industry at present, being more predominant 15 to 20 years ago. The same is true of the short firebox boiler. The Scotch Marine boiler type refers to firetube boilers in general use today for low pressure (15 to 20 psig) saturated steam applications with steam flow capacities in the 300 to 25,000 lb/hr range. Firetube boilers are fired solely on gaseous or liquid fossil fuels. Typical manufacturers are Cleaver Brooks, Superior, and Bryant (References 3-2, 3-3).

3.2.2 Watertube Boilers

This category includes both field-erected as well as packaged units. Common sizes for the former type fall between 50×10^6 and 500×10^6 Btu/hr, while 10^7 to 250×10^6 is the capacity range for the latter. Larger packaged boilers, above 450×10^6 Btu/hr, are currently being designed and supplied, but are not yet common.

As the name implies, watertube boilers are designed to flow water through the heat transfer tubes, instead of combustion products as in the firetube design. Because of the smaller diameter pressurized components and the advantage using tubes gives in accommodating expansion, they are better able to contain the pressure and afford an inherently safer design.

Field-erected boilers are usually balanced draft and therefore require both forced draft and induced draft fans. Field-erected boilers are commonly fired with coal, gas and/or oil. Many such boilers exist today but very few new applications have capacities lower than 200×10^6 Btu/hr, except for pulverized or stoker coal-fired units. This is because of the packaged boiler's domination of the oil- and gas-fired boiler market, which is in turn due to their low capital cost in the sizes between 12×10^6 and 200×10^6 Btu/hr.

Packaged watertube boilers are used for gas and oil firing applications. They are not used for coal firing because they have much smaller furnace volume than are permissible. They are designed to be rail-shipped as a complete, single package with minimum fieldwork. The furnaces are also designed to operate under positive pressure versus the balanced or slightly negative pressure found in coal-fired boilers.

Both types of boilers use similar type firing equipment. The register-type burner is generally used, with burner capacities being between 50 x 10⁶ and 120 x 10⁶ Btu/hr on a field-erected boiler, and up to 350 x 10⁶ Btu/hr on a packaged boiler. Packaged boilers generally have one burner although older units were fitted with multiple burners - usually two. Popular types of industrial watertube boilers, both packaged and field-erected, are manufactured by Combustion Engineering Company, Riley Stoker, and Erie City Company (References 3-2, 3-4, 3-5, 3-6).

3.2.3 Stoker-Fired Boilers

The two major options available for the controlled combustion of coal are suspended firing, in which the fuel is pulverized to a fine dust prior to being combusted in a wall-mounted burner, and bed combustion, which causes oxidation to take place in and above a layer of raw coal. An example of the latter method is found in the traditional hand-fired coal furnace. Mechanical stoker-fired boilers are an improvement over this design.

The general stoker-fired boiler category includes spreader, underfeed, vibrating grate, chain grate, and traveling grate stokers. All terms refer to the method of coal/air introduction and mixing, as well as char and ash removal. Firing capacities generally range from 15×10^6 to 250×10^6 Btu/hr. It is very unusual for a stoker to be designed with less than 20×10^6 Btu/hr capacity. Units above 200×10^6 Btu/hr are also rare.

Stokers are often preferred over pulverized-fired units because of their ability to burn a wide variety of coals and other solid fuels, greater operating range, and lower power requirements.

A major impact on the cost of converting mechanical stoker-fired boilers to a substitute, cleaner fuel will be the required modification of the equipment inside the furnace volume. Pulverized coal-fired units of the same capacity incur no such costs. This effect will be noted in Section 6, later in this report.

3.3 UTILITY BOILERS

Most of the nation's combustion-derived electricity is generated in large fossil-fueled central stations, which consist of watertube boilers operating in the supercritical pressure region serving turbine-generators in the million kilowatt range. Firing capacities of individual burners in utility boilers commonly range up to as high as 125×10^6 Btu/hr. One-thousand MW wall-fired units may require as many as sixty separate burners.

Although there are some differences among utility boiler designs in such factors as furnace volume, operating pressure, and configuration of internal heat transfer surface, the principle distinction is firing mode. This includes the type of firing equipment, the fuel handling system, and the placement of the burners on the furnace walls. The major firing modes, of which equipment conversion costs are a function, are briefly described below.

3.3.1 Wall-Fired Boilers

The multiple burners in wall-fired utility boilers are usually mounted in geometrical patterns on the vertical furnace wall, although some designs employ roof-mounted burners. Depending on the manufacturer and firing capacity, the burners in vertical wall-fired boilers may be mounted either on a single wall or on opposite walls. Figure 3-1 shows cross-sections of these two types of boilers. Vertical-wall burners are usually of the register type, while "intertube" burners are normally used in roof-mounted applications. In any case the burners are fired in a fixed direction normal to the wall. This is in contrast with the tangential firing method which allows some degree of burner "till

Individual burner firing rates lie in the 75 x 10^6 to 125 x 10^6 Btu/hr range; the total heat release rate of wall-fired boilers normally falls between 500 x 10^6 and 10,000 x 10^6 Btu/hr, which corresponds to a generating capacity range of 50 to 1000 MW.

The wall-fired boiler design is capable of utilizing all conventional fossil fuels, including natural gas, fuel oil, and pulverized coal. Well-known manufacturers of this type of boiler include The Babcock and Wilcox and Foster Wheeler Companies (Reference 3-7).

3.3.2 Tangentially- and Turbo-Fired Boilers

Tangentially- and turbo-fired boilers are grouped together because the burner equipment is essentially identical for both boiler types; i.e., both use multiple burners, both fire between the boiler tubes, fuel/air mixing takes place within the boiler furnace itself (as opposed to the burner throat of a register type burner), and they employ a common burner capacity range - 75×10^6 to 125×10^6 Btu/hr.

The boilers are physically quite different. Tangential boilers, as show in Figure 3-2, are fired with groups of 4 burners at the same elevation with eaburner located in a corner of the boiler. Each burner fires along the tangent of a small imaginary circle in the center of the boiler. The resulting spin of the four "flames" creates high turbulence and thorough mixing of fuel and air i the center of the furnace. Additional levels of burners at 6- to 10-foot increments provide additional capacity for larger boilers.

Turbo-fired furnaces, as illustrated in Figure 3-3, provide a similar turbulent mixing of fuel and air in the furnace, but in this case, the burners are mounted in opposing walls of a "bottle neck" type furnace. The walls are tilted towards each other such that opposing burners fire down at a 30° angle towards the center of the lower part of the boiler. The burner sizes mentioned

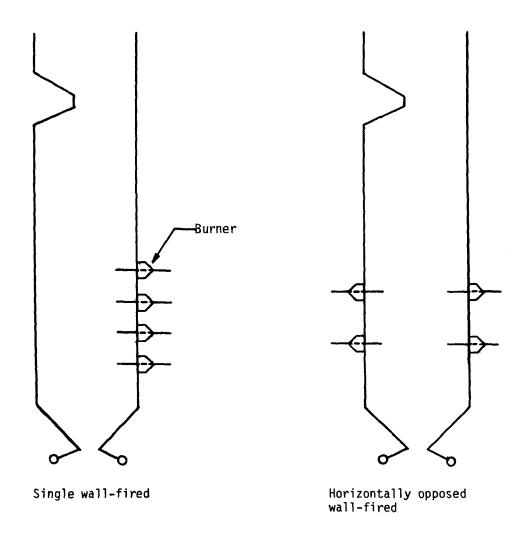

Figure 3-1. Vertical wall-fired utility boiler shapes and burner configurations

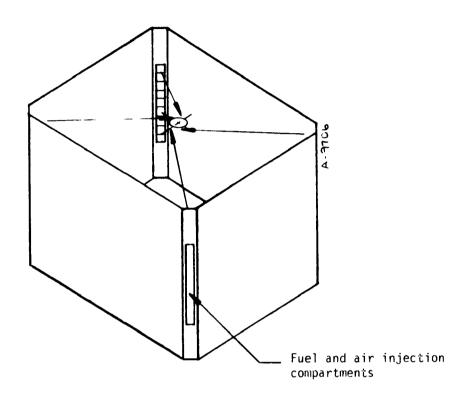

Figure 3-2. Tangentially-fired utility boiler shape and firing pattern

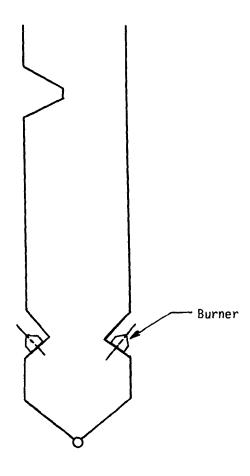

Figure 3-3. Riley ${\sf Turbo}^{\it \tiny (B)}$ furnace shape and burner configuration

above are the same as those commonly found in tangentially-fired boilers. Therefore, higher boiler capacities are attained by increasing the boiler widt and the number of burners.

Turbo-fired boilers are manufactured by Riley Stoker, while most of the tangentially-fired utility boilers are constructed by Combustion Engineering, Incorporated (Reference 3-8).

3.3.3 Cyclone-Fired Boilers

A cyclone boiler is composed of the combination of a watertube boiler and a separate "cyclone" furnace (or series of furnaces) that are themselves water-cooled. Cyclone furnace firing arrangements are depicted in Figure 3-4. This type of furnace is capable of handling coals with high slag viscosities (250 poise at 2600F or lower). The air-conveyed coal and secondary air are injected into the furnace such that a highly swirling "cyclone" flame results. The high heat release of the furnace results in the high gas temperatures that are necessary for the formation of liquid slag. Slag taps permit continuous removal of the molten slag. Typical single furnaces are designed for firing capacities between 100 x 10⁶ and 400 x 10⁶ Btu/hr, with multiple cyclone furnaces being employed for loads above 400 x 10⁶ Btu/hr. Cyclone furnaces are designed primarily for coal-firing, with gas or oil available only for standby operation. For gas operation, the fuel is injected horizontally with the secondary air.

Most cyclone-type boilers are constructed by The Babcock and Wilcox Company or its subsidiaries (Reference 3-7).

SECTION 4

CHARACTERIZATION OF SUBSTITUTE FUELS

4.1 INTRODUCTION

The preceding section provided brief descriptions of the types of SO_X emitting combustion systems for which the costs of switching from conventional fossil fuels to various coal-derived fuels were estimated in this study. The present section attempts to characterize these exotic fuels.

Four distinct coal conversion routes are possible. These include: pyrolysis, hydrogenation, solvation, and production of synthesis gas. The amount, type and quality of the products from each of these methods depend upon the coal properties and process conditions (Reference 4-1).

In pyrolysis, the coal is heated in an inert atmosphere to break it down into solids, liquids, and gases, the amounts of which are proportional to the heating rate.

In hydrogenation reactions, coal and hydrogen are reacted together directly. In the presence of a catalyst at 850F and at elevated pressures, a liquid product is made. If a catalyst is not present, the coal reacts directly with hydrogen at higher temperatures (about 1600F) and pressures (150-300 psi) to form methane.

During solvation, the coal is dissolved and, with the addition of hydrogen at modest pressure, can be filtered and converted into an essentially ashfree and low sulfur solid or liquid.

Synthesis gas is produced by reacting coal with an oxidizing agent and steam. The resulting low heating value gas can then be used to make a high-Btu gas by a methanation step which reacts the purified gas over a nickel catalyst.

The present study concerns itself with the conversion of steam-raising boilers firing conventional fossil fuels to the use of selected products from solvation and synthesis gas coal conversion methods; namely, solvent refined coal (SRC) and lower-Btu gas. Brief summaries of these processes and their products are presented in the following subsections.

4.2 LOW- AND MEDIUM-BTU GAS

The basic process for converting solid coal to a fuel gas comprising principally nitrogen, carbon monoxide, hydrogen, and a certain amount of methane is well understood. In fact, the "town gas" commonly used, especially in Europe, before the general availability of natural gas was produced with earlier versions of present-day equipment. In general, these gases are produced when an insufficient quantity of oxidizer is supplied to the coal at a high temperature, thus preventing the reaction from going to completion to form carbon dioxide and water.

Most gasification processes have in common four basic sequentiallyoccurring reactions. The principal heat-producing reaction is oxidation, which results when oxygen reacts with fuel to form water and carbon dioxide:

$$C + O_2 \rightarrow CO_2$$

$$H_2 + 1/2 O_2 \rightarrow H_2O$$

Next comes the gasification reaction, which is the most endothermic. This reaction occurs when unburned carbon from the fuel reacts with steam and carbon dioxide to form hydrogen and carbon monoxide:

$$\begin{array}{c} c + \begin{pmatrix} H_2O \\ CO_2 \end{pmatrix} \rightarrow CO + \begin{pmatrix} H_2 \\ CO \end{pmatrix} \end{array}$$

The third reaction, hydrogasification, is mildly exothermic and takes place when hydrogen reacts with fuel carbon to give methane:

$$C + 2H_2 \rightarrow CH_4$$

Finally, and sometimes concurrently with the preceding reactions, devolatilization occurs when the fuel is subjected to heating:

Coal + Heat
$$\rightarrow$$
 C + CH₄ + HC

Among the myriad types of gasification processes either operating or contemplated, these four basic reactions can occur simultaneously in a reactor, or each may take place in a particular region of the reactor, or each may be confined to a separate vessel. Most of these processes are designed so that

the heat required by the highly endothermic gasification reaction is supplied by the heat released from the other three reactions. Adjusting the amount of oxidizer lent to the process controls this heat balance. Raw gas leaving the gasifier consists mainly of methane, hydrogen, nitrogen, carbon oxides, and sulfur compounds. The sulfur compounds and other impurities are removed downstream.

The basic gasification process described to this point delivers a product gas whose heating value abides primarily in the carbon monoxide and hydrogen resulting from the gasification step. This product is usually termed "lower-Btu gas." This definition is employed because there are two fuel-gas heating values of potential interest below the SNG level of 900 to 1000 Btu/scf. The first of these is the range of 300 to 700 Btu/scf, which is referred to as medium-Btu gas. The other is the range of 150 to 250 Btu/scf, which is referred to as low-Btu gas.

Two basic motives exist for converting coal to gas, depending on the ultimate application (Reference 4-2):

- If pipeline quality, high-Btu gas is desired, the product gas must go through an additional methanation step. This is an expensive process, whereby additional hydrogen is produced and chemically reacted with carbon monoxide to form methane. Current SNG costs are in the range of \$1.05 \$1.50/10⁶ Btu.
- If the purpose of gasifying coal is solely to remove ash and sulfur so that the fuel gas is nonpolluting when burned, the heating value need only be high enough to maintain a stable flame, with a minimum deleterious effect on plant efficiency. Medium— and low—Btu gases are well suited for this purpose. In most processes, oxygen injected into the gasification step will produce the former gas ("oxygen—blown"), while air injection will produce low—Btu gas ("air—blown"). Medium—Btu gasification saves 10 to 15 percent in coal feed rate, 30 to 35 percent of plant investment, and 25 to 35 cents/10⁶ Btu relative to SNG. Producing low—Btu gas provides an additional savings of 5 to 10 cents/Btu over gases of intermediate Btu heat content.

The attractiveness of lower-Btu gas as a boiler fuel is quite apparent. Studies have shown that the most feasible location for lower-Btu gasification plants is at the point of use, while the product from SNG plants can be economically transported by pipeline over long distances (References 4-3, 4-4, 4-5, 4-21). It is therefore easy to visualize lower-Btu gasification plants

constructed next to a new or existing combustion system, whether the product is destined for the steam-electric utility or industrial boiler sector.

Combustion systems firing conventional fossil fuels, however, will require some degree of equipment modification before these new gaseous fuels can be burned. Assessing the costs of such conversions was the objective of the present study.

For the purposes of the study, certain simplifying assumptions are made about the combustion characteristics of these gases. Table 4-1 shows the chemical compositions of selected lower-Btu gasified coal fuels. These gases are representative of the products of all gasification processes, detailed descriptions of which are given in Appendices A and B. The heating value of the gases range from 170 Btu/scf for the air-blown Lurgi to 780 Btu/scf for the Hydrane process. For the most part, heating value is directly proportional to volume percent of methane.

It will be assumed that the combustion characteristics of these and all lower-Btu gases will depend on heating value alone and be decoupled from specific chemical composition. This will allow the range of gas types to be treated as a continuum. In this way, the equipment conversion costs of substituting for these gases can be related to heating value. Section 6 will describe in more detail the method used for incorporating a heating value term in the conversion cost equations for the gaseous substitute fuels.

4.3 SOLVENT REFINED COAL

In Section 4.2, the feasibility of using coal-derived gases of lower heating values (<1000 Btu/scf) as low sulfur boiler fuels was discussed. Similar advantage can be gained by using the products from coal conversion processes that generate clean fuels that are liquids or solids at room temperature. Examples of the former type are the products from the Bergius - I.G. Farben, Fischer-Tropsch, COED, H-Coal, and Flash Pyrolysis processes. Ample descriptions of these treatment methods, which are essentially pyrolysis or hydrogenation processes, appear in References 4-14, 4-15, and 4-1. Clean solid fuels from solvation processes are exemplified by solvent refined coal (SRC). Cost estimations for converting stationary combustion equipment to the use of this fuel were established in the present study.

Solvent refined coal (SRC) is a name given to a reconstituted coal which has been dissolved, filtered, and separated from its solvent. It is moisture-free, low in sulfur and ash, and can apparently be handled in the liquid as

well as the solid state. In the latter form, it is brittle and easily grindable. The process of pulverization can, however, heat the material sufficiently to cause undesirable agglomeration. Its major advantage is that its heating value remains at 16,000 Btu/lb regardless of the quality of the coal feedstock.

The SRC process has been under development for a number of years. Pittsburg & Midway Coal Mining Company, under the sponsorship of the Office of Coal Research, demonstrated the technical feasibility of the process on a pilot scale in 1964. In 1972, construction was begun on two additional SRC pilot plants. The 6 ton/day Wilsonville, Alabama, facility has been completed and is currently producing small amounts of material for experimental purposes. The project is sponsored by the Electric Power Research Institute and Southern Services. A larger plant, 50 ton/day, is located at Tacoma, Washington, and will be completed in late 1974. In both facilities, emphasis is placed on developing a utility fuel of a quality that will meet environmental standards when burned (Reference 4-3).

The solvent refined coal process is shown schematically in Figure 4-1. SRC is produced by first dissolving coal under pressure in a recycled solvent containing a small quantity of hydrogen. The coal solution is then filtered to remove virtually all of the mineral matter including the pyritic sulfur. Small quantities of hydrocarbon gases and lighter liquids are distilled off. The main product from the process is a heavy organic material which has a melting point of about 350F and, depending on the composition of the feedstock coal, contains less than 0.1 percent ash and less than 0.8 percent sulfur. The yield of solvent refined coal and other liquid products is approximately 90 percent of the original coal (References 4-16, 4-17).

The compositions of typical samples of SRC are presented in Table 4-3, while the analysis of the coal from which they were derived is shown in Table 4-2. These analyses are associated with projects performed by the Bureau of Mines (Reference 4-18), Combustion Engineering, Inc. (Reference 4-19), and The Babcock and Wilcox Company (Reference 4-20), in an effort to determine the combustion characteristics of SRC, samples of which were supplied by the Office of Coal Research. The investigators came to the following general conclusions:

- Based on both the proximate and ultimate analyses, the solid phase material appeared similar to a high volatile bituminous coal except for the reduced sulfur and ash content.
- Thermogravimetric analyses indicate ignition characteristics similar to a high volatile bituminous coal, but for burnout it appears to more closely resemble a semianthracite.

- The grindability index (about 160) indicated that the solid SRC can be pulverized with less power than nonprocessed coal (e.g., grindability for the Kentucky No. 11 coal was 61).
- In pulverized form, firing tests indicated that the material tended to agglomerate in the fuel lines when the primary (coal conveying) air was preheated.
- In the liquid phase, firing tests indicated that the material was similar to No. 6 fuel oil in handling and combustion characteristics. The preheating requirements are greater, however. For good pumpability (viscosity <30 cp) it must be heated above 635F. Because of the expulsion of volatile matter at temperatures above 350F, heating should be carried out under pressure in a closed system.
- When firing in the liquid phase, all fuel handling equipment in contact with the SRC must be heated to above 350F. In addition, steam-atomizing, heavy oil guns are recommended to eliminate the need for heating the gun components with an external heat source.

As implied by these conclusions, there remains some question as to the most advantageous phase in which to handle and burn the SRC. If applied in the solid form to conventional pulverized coal-fired combustion equipment, the retrofit procedure may be straightforward and inexpensive if most of the original equipment can be used and if the fuel handling equipment need not be externally cooled. When heated, by all indications, this material can be fired as an oil. In both cases, however, unforeseen retrofit difficulties may arise. More light will be cast on the situation when the results of additional EPRI-funded combustion tests, currently being performed by Combustion Engineering and Babcock & Wilcox, become available early in 1975.

As was related in Section 2 of the present study, no actual conversions of conventional steam-raising boilers of any capacity to the use of solvent refined coal have yet taken place. This is partially due to a general lack of sufficient quantities of this fuel at the present time. For the purposes of this study, the conversion cost estimation methods described in Section 5 will necessarily be based on past conversion experience involving similar substitute fuels.

4.4 SUMMARY AND CONCLUSIONS

Of the four basic coal conversion routes, pyrolysis, hydrogenation, solvation, and synthesis gas formation, representative products from the latter two processes have been considered in this study.

Solvent refined coal, in its solid state, is brittle and readily grindable into a fine powder. It is low in ash and sulfur, moisture free, and can be melted and handled as a fluid. Its heating value is about 16,000 Btu/lb, regardless (theoretically) of the type of feedstock coal. If its application as a boiler fuel is proven feasible, the major advantages afforded by SRC are:

- Use of plentiful high-sulfur coal reserves would be permitted
- The uniformity of the SRC product would permit power plants to use one "off-the-shelf" boiler design

The production of synthesis gas from coal has a lengthy history, and the technology is currently being revived. Most coal gasification processes have in common four basic reaction steps, ultimately producing a gas of heating value below that of natural gas (150-700 Btu/scf). To produce synthetic natural gas (SNG), the products from most of the gasification processes can be exposed to additional methanation steps. Economics demand that lower-Btu gasification plants be located on the site of use, while it is feasible to pipe SNG over long distances. As lower-Btu gas is less expensive than SNG to produce, is sulfur and ash free, and by all indications is able to produce a stable, trouble-free flame, it shows promise as a boiler fuel.

In order to use either lower-Btu gas or SRC in existing stationary boilers, it will be necessary to convert the combustion equipment from the use of conventional fossil fuels. As this has yet to occur on a large scale for any of these exotic fuels, the conversion costs appearing in this report are necessarily estimations, based on past conversion experience to similar substitute fuels.

SECTION 5

SELECTION OF FUEL SUBSTITUTION OPTIONS

Section 3 of this report described the types of combustion equipment that will be considered as candidates for conversion to cleaner fuels. These consist of all major types of industrial and utility boilers, encompassing a boiler capacity range from 10⁷ Btu/hr to 1000 x 10⁷ Btu/hr. For an estimated 35% thermal efficiency, these heat release rates correspond to an electric generating capacity range of 1 to 1000 MW. Section 4 of this report discussed the various types of clean fuels considered as subsitutes for conventional, high sulfur fossil fuels. These included solvent refined coal, low-Btu gas, medium-Btu gas, and natural gas. The first three are of interest in that they are the products of promising coal-conversion processes. The costs of equipment conversions to natural gas, an operation for which ample experience has already been gained, will act as a reference point for the conversions to the other fuels.

The information contained in Sections 3 and 4 helped to define the logical fuel substitution options available for a given type of boiler firing a given type of original fuel. These options are compiled in Table 5-1. The major points to be gained from this table are the following:

- The initial assumption is that all boiler types are capable of being converted to all of the substituted fuels.
- This number is reduced by the exclusion of certain illogical conversions, based on the following reasons:
 - Nonexistence of coal-fired firetube and packaged watertube boilers
 - Exorbitant cost associated with converting oil-fired combustion equipment to solid SRC (only conversions from solids to liquids or gases, and from liquids to gases are judged practical)
 - Nonexistence of oil-fired stoker and cyclone furnaces

TABLE 5-1
FUEL SUBSTITUTION OPTIONS

| Original Fuel | Boiler Category | Applicable Substitute Fuels | Comments |
|------------------|---|-----------------------------------|--|
| Coal | Industrial Types: | | |
| | • Firetube | None | No coal-fired boilers of this type |
| | Packaged watertube | None | Essentially no coal-fired boilers of this type |

These options were instrumental in the determination of the required equipment conversion cost data, as indicated by the space enclosed within the bold lines in Figures 5-1 and 5-2. These figures are the forms of the master data sheets that were ultimately used to tabulate the cost figures. The two extreme left-hand columns contain the delineation of industrial and utility boiler types, an indication of whether the boiler is packaged or field-erected, and its normal capacity range in units of 10⁶ Btu/hr. The columns between the double vertical lines serve to space out the increments in boiler capacity range. The letters in the rows contained in the extreme right-hand column indentify the cost category entered in the row; "E" denotes equipment cost, "I" denotes installation expense, and "T" is the sum of E and I, or, total capital investment.

Five sheets of the form of Figure 5-1 will contain the costs for converting the appropriate boilers from coal to the use of the five substitute fuels. Similarly, Figure 5-2 indicates that four data sheets will be completed for conversions of oil to the four applicable substitute fuels.

The equipment conversion cost estimations and associated documentation are contained in the following section of this report.

5-5

Figure 5-1. Conversion Cost Data Sheet for Coal-Fired Boilers

Figure 5-1. Conversion Cost Data Sheet for Coal-Fired Boilers

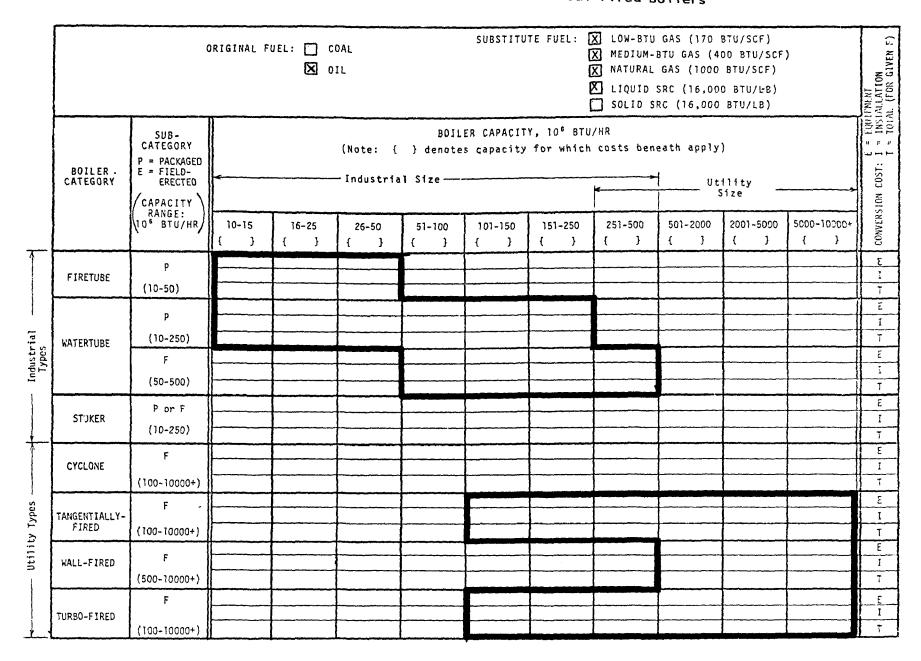

Figure 5-2. Conversion Cost Data Sheet for Oil-Fired Boilers

SECTION 6

DOCUMENTED BOILER CONVERSION COST DATA

6.1 INTRODUCTION

The preceding section served to define the available fuel substitution options for a given type of boiler. The techniques used to compile the cost data were introduced as well. This section begins with a brief discussion of the major considerations associated with the various types of boiler conversion procedures, continues with the actual cost figures presented in both tabular and graphical form, and concludes with a presentation of the proposed cost models that can be derived from the cost data.

6.2 BOILER MODIFICATION CONSIDERATIONS

This subsection is organized into four portions:

- The general equipment modification considerations prevailing for all of the boiler types
- Some specific points pertaining to certain unique boiler types
- A general discussion of the proposed substitute fuel handling systems
- Descriptions of the firing equipment required for the gaseous and liquid substitute fuels.

6.2.1 General Equipment Modification Considerations Applicable to All Boiler Types

The following are general considerations applicable to all boilers of the indicated type:

- The conversion to the new fuel was planned and implemented in such a manner as not to effect boiler efficiency.
- Existing burner registers can be reused; for coal-fired boilers, the coal nozzles are removed to such a position as to allow adequate working space for installation of new burners.

- The burners selected for gas firing are termed "center-fired" gas guns. Each burner assembly includes a burner gun, guide pipe, shield, flame stabilizing device, flex hose, hand valve, and mounting adapter plate.
- Burners for liquid SRC firing are steam atomizing oil burners of the internal mixing type. (Refer to Table 6-1 for the determination of the number of burners required for the individual boiler capacities chosen for the cost estimations.)
- For converting coal-fired boilers to any of the substitute fuels, a burner management system will be required. The type recommended by the NFPA Supervisory Manual was used. The system includes a logic cabinet, safety interlocks, and all interconnecting piping and wiring. Reference 6-1 supplies additional information on this system. For oil-fired equipment, the existing burner management system can be used, but with new limit and safety interlock settings.
- Existing combustion controls can be reused. Each conversion requires a new fuel flow transmitter, fuel flow rate control valve, and miscellaneous relays and valves to be interfaced with the existing panel.
- It was assumed that no modifications to the boilers' wall-mounted heat transfer surfaces, superheaters, or economizers were required. Indeed, one industrial-size boiler manufacturer stated that their boilers' interior designs for the coal-derived fuels would not differ appreciably from designs presently used for more conventional fossil fuels.
- Existing forced draft and induced draft fans can be reused for the new fuels.
- The assumed gas and liquid SRC supply pressures at the burners are given in Table 6-2. In an existing plant, of course, the supply pressures must be chosen on the basis of practical line size and physical space considerations.

6.2.2 Special Equipment Modification Considerations for Unique Boiler Types

The following are some additional fuel substitution program considerations for five unique categories of boilers.

TABLE 6-1

BOILER TYPES, CAPACITIES, AND ASSOCIATED BURNER QUANTITIES FOR GAS- AND LIQUID SRC-FIRING

| Boiler Category | Capacity (10 ⁶ Btu/hr) | Burner Quantity | Capacity (10°Btu/hr) | Burner Quantity | Capacity (10 ⁶ Btu/hr) | Burner Quantity |
|--------------------------|--------------------------------------|--------------------|-------------------------|--------------------|--------------------------------------|--------------------|
| Fire Tube | 12 | 1 | 20 | 1 | 35 | 1 |
| Watertube (field-erect.) | 75 | 1 | 150 | 2 | 350 | 4 |
| Watertube (packaged) | 25 | 1 | 75 | 1 | 150 | 2 |
| Stoker | 25 | 1 | 75 | 1 | 150 | 2 |
| Cyclone | 250 | 2 | 1,000 | 8 | 7500 | 60 |
| Tangentially-fired | 250 | 2 | 1,000 | 8 | 7500 | 60 |
| Wall-fired | 1,000 | 8 | 3,500 | 2º | 7500 | 60 |
| Turbo-fired | 250 | 2 | 1,000 | 8 | 7500 | 60 |

TABLE 6-2

BURNER SUPPLY PRESSURES FOR GASEOUS
AND LIQUID SUBSTITUTE FUELS

| Substitute Fuel Type | Burner Supply Pressure (psig) |
|-------------------------|----------------------------------|
| Low-Btu gas | 35 - 40 |
| Medium-Btu gas | 30 |
| Natural gas | 15 |
| Liquid SRC | 125 |

6.2.2.1 Firetube Boilers

It was assumed that an industrial-type flame safeguard system exists and is reusable. Gas safety interlocks and a fuel selector switch are added. In addition, it was assumed that the existing burner guns are steam- or high pressure air-atomized, and not mechanical atomized.

6.2.2.2 Stoker-Fired Boilers

For the purposes of this study, it was assumed that the mechanical stoker and internal grates would be removed and a new twelve inch-thick refract ory floor would be installed. A completely new windbox-burner assembly would be installed in the lower front wall. The actual number of burners needed depends on the furnace capacity.

In some cases, the more economical approach would be to install the refractory directly on the existing grates, and mount the windbox burner in the boiler's sidewall. However, this would require bending of the heat transfer tubes in the vicinity of the burner to afford clearance for the burner throat. The disadvantages of this approach are operator inconvenience, possible water circulation problems due to the unusual tube bends, and minor problems in adjusting the flame shape to retain a uniform temperature profile across the boiler tube bank or superheater (if employed).

As a general rule, the retrofitted burner can be supplied with an integral fan rather than attempting to reuse the existing combustion air fan. This is because the fan cost is offset by the labor, materials, and engineering required for the installation of a duct from the existing fan to the new burner.

For solid SRC, the only practical conversion strategy would be to install a suspended firing system as is described above. Due to its rather low melting temperature (260F), the SRC would be incompatible with the stoker's grates, which are designed for bed-type combustion with concurrent removal of incombustible ash and char.

6.2.2.3 Cyclone-Fired Utility Boilers

For retrofitting this class of boiler to the gaseous or liquid coalderived fuels, the new burner guns can be installed through the existing coal burner. It was assumed that the average cyclone furnace heat release rate was 250 x 10⁶ Btu/hr. Capacities of larger boilers would be multiples of this figure, and would require a correspondingly larger number of individual cyclone furnaces. It was assumed that on liquid SRC firing above 200 x 10⁶ Btu/hr, two simultaneously-firing oil atomizers will be used, because this heat release quantity is currently the upper limit of a single atomizer as currently designed.

The existing combustion control system can be used, but will require the addition of a fuel flow control valve for each cyclone furnace.

6.2.2.4 Turbo- or Tangentially-Fired Utility Boilers

For oil-fired boilers of these types, retrofit of the gases and liquid SRC will involve the installation of the burners ("gun" design) either in a parallel (tangentially-fired) or an adjacent (turbo-fired) configuration. In coal-fired units, the guns can be substituted in place of the existing coal burner tubes and nozzles.

There may occur a small difference in piping installation costs between the tangentially- and turbo-fired boilers due to running the piping vertically versus horizontally. This variation, however, was considered insignificant in light of the other plumbing costs, such as valve installation.

6.2.3 Fuel Handling Systems

In the determination of piping costs for the gaseous substitute fuels, it was assumed that the amount of piping installed could be grouped into three categories, the length being an arbitrary function of the boiler capacity. Therefore, the piping to the boiler is essentially independent of boiler type. The capacities and respective pipe runs are given in Table 6-3 (A).

The second general assumption made for the gaseous fuel handling systems was that the piping supplied a single boiler. The third and possibly most important assumption was made in regard to the pressures of each type of gas as supplied to the steam plant boundary. This information is given in Table 6-3(B). These pressures were selected because they appeared to be commercially practical, and because the line sizes more closely match existing industrial standards. It is obvious that the variation in the main gas supply pressure could effect the validity of the cost estimates; this is especially true in the case of low-Btu gas.

For solvent refined coal (SRC) in the hot liquid state, complete heating systems are required for both the SRC storage facilities and the burner supply piping system. A liquid heat transfer system using Therminol 77 was selected for these purposes (see Reference 6-2 for Therminol's properties). This heat transfer fluid is heated by firing No. 2 fuel oil in a firetube boiler on the plant premises. The hot Therminol is then used to warm the storage tanks and the day tanks, to supply the suction heaters, and to heat trace all piping and valves. It was assumed that the SRC would be delivered at 450F, all pumping would be done at 1100 centistokes, and that the SRC would arrive at the

TABLE 6-3

GASEOUS FUEL HANDLING SYSTEM PIPING LENGTHS AND SUPPLY PRESSURES

(A) Piping Length, All Gases

| Boiler Capacity Range (10 ⁶ Btu/hr) | Piping Length (ft) |
|---|-----------------------|
| 10-65 | 500 |
| 75-350 | 1000 |
| 500-7500 | 2000 |
| | <u> </u> |

(B) Supply Pressure to Plant Boundary

| Gaseous Fuel Type | Supply Pressure (psig) |
|-------------------|---------------------------|
| Low-Btu | 350 |
| Medium-Btu | 130 |
| Natural | 50 |
| | |

burner at 66 centistokes (640F). Each system includes the following features:

- An unloading pump set of capacity equal to six times the firing rate
- Insulated bulk storage tank(s) for the liquid SRC and No. 2 fuel
 oil, with an estimated thirty day storage capacity
- Tank foundations and firewalls
- Tank suction heater(s)
- Therminol heaters and circulation pumps
- No. 2 oil pump sets
- SRC transfer pump set
- Insulated SRC day tank (two day storage capacity)
- Day tank suction heater
- Final pump and heater set
- All necessary interconnecting piping and valves

For solid SRC, the costs of converting coal-fired boilers will reflect the requirement that various portions of the fuel handling system be externally cooled, by either water or air. It was assumed that the existing coal handling and preparation equipment could be used with no major modifications necessary. Air preheat operation would be discontinued and replaced by a system supplying ambient or chilled air for coal conveying purposes. It was also assumed that the coal supply pipe at the burner would be water-cooled.

6.2.4 Firing Equipment For Gases and Liquid SRC

This subsection contains more detailed information on the replacement firing equipment for the gaseous and liquid substitute fuels, including:

- Burner types
- Burner fuel supply valving
- Burner management systems

For conversions of coal-fired combustion systems to the use of solid SRC, it was assumed that the existing firing equipment with the retrofits described previously would be adequate for the purpose. For these boilers, major modification costs will be associated only with the fuel handling system.

6.2.4.1 Burner Types

For gaseous substitute fuel firing, the burner selected was the centerfired gas gun. Table 6-4 shows the gun sizes chosen for the various gases.

To burn liquid SRC, a burner of the multiple venturi design was deemed practical. This is a steam-atomized burner normally used for heavy fuel oil (No. 6) combustion applications. Table 6-5 lists the model numbers and corresponding heat release rates of a typical commercially-available multiple venturiburner. Similarly-designed burners are available from a number of manufacturer

6.2.4.2 Burner Fuel Supply Valving

The following are typical valve requirements for single and multiple burner applications:

Single Burner, Gas-Fired

Pilot gas cock, pilot gas PRV, two pilot safety shut-offs, one pilot gas vent, main gas safety shut-off, supervisory gas plug cock, and main gas fuel flow control valve.

Single Burner, Liquid SRC-Fired

Main oil safety shut-off, main oil check, supervisory oil cock, steam purge, steam check, manual oil shut-off, manual steam shut-off, oil strainer steam drain, steam trap, steam-oil pressure differential control, and main oil flow control valve; pilot valves are the same as for gas.

Multiple Burners, Gas-Fired

The following valves are required at the header: main gas strainer, manual shut-off, main gas PRV, bypass PRV, main safety shut-off, main gas header vent, two manual gas vent valves, main gas reliefs, pilot gas manual shut-off, pilot gas PRV, and one main gas control valve.

The following valves are required at each burner: burner safety shut-off, supervisory shut-off cock, two pilot gas safety shut-offs, and one pilot gas vent valve.

Multiple Burners, Liquid SRC-Fired

The following header valves are required: manual oil shut off, oil strainer, main oil safety shut-off, oil by-pass PRV, oil return check valve, oil recirculating valve, steam manual shut-off, steam strainer, steam trap, steam PRV, steam bleed check, steam-oil differential pressure, oil flow control valve, manual pilot gas valve, and pilot gas PRV.

TABLE 6-4

GUN SIZES FOR GASEOUS SUBSTITUTE FUEL FIRING
(NOMINAL PIPE SIZE, INCHES)

| Burner Firing Rate Gaseous (10 ⁶ Btu/hr) Fuel Type | 25 | 75 | 125 | |
|---|----|----|-----|--|
| Low-Btu gas | 4 | 6 | 8 | |
| Medium-Btu gas | 3 | 4 | 6 | |
| Natural gas | 2 | 3 | 4 | |

TABLE 6-5

TYPICAL MULTIPLE VENTURI BURNER TYPES FOR LIQUID SRC FIRING (MANUFACTURER: THE COEN CO., REFERENCE 6-3)

| Coen Co. Model Number | Maximum Heat Release Rate (10 ⁶ Btu/hr) |
|--------------------------|--|
| 1 MV | 35 |
| 2 MV | 75 |
| 3 MV | 150 |
| 3-1/2 MV | 350 |
| Dual 3 MV or | > 350 |
| 3-1/2 MV | |

The following valves are required at each individual burner: burner safety shut-off, oil check, supervisory oil cock, steam purge, steam check, steam manual shut-off, two pilot gas safety shut-offs, and one pilot gas vent valve.

6.2.4.3 Burner Management System

Converting from coal to gaseous substitute fuels requires the addition of at least the following safety interlocks: high gas pressure, low gas pressure, forced draft air, purge air, instrument air, fan starter interlocks, damper position switches for the forced and induced draft fans (if used), and steam over-pressure. Converting from coal to liquid SRC requires basically the same except for low oil pressure and temperature limit switches. Atomizing steam pressure and flow switches are also required. For multiple burner applications, such as in utility boilers, header switches are included in addition to the individual burner fuel interlocks.

6.3 BOILER CONVERSION COST DATA AND EVALUATION

6.3.1 Introduction

The previous subsection presented the basic assumptions on which the boiler conversion cost estimations were based. The present subsection contains these cost figures, tabulated on the data sheet first introduced in Section 5 of this report. In order to visualize more clearly the functional relationship between conversion cost and capacity for a given boiler, these data are plotted for each original fuel-to-substitute fuel conversion. A discussion of the data and their concomitant uncertainty factors is given as well.

6.3.2 Boiler Conversion Cost Data

Tables 6-6 through 6-14 are the completed data sheets for all nine possible conversions: coal-fired equipment modified to burn all five coal-derived fuels, and the oil-fired equipment modified to burn four out of the five substitute fuels (excluding solid SRC). It should be remembered that "liquid SRC" refers to the melted solid SRC material. The installation costs are based on 1974 San Francisco Bay Area labor rates. The total capital costs, or required plant investment, indicated on the tables are therefore specific for that metropolitan area. These numbers must be modified by a location factor if the installation costs for another site are desired. This point will be discussed further in subsection 6.3.4. All of these cost figures were reduced from the bulk cost data included in the Appendix of this report. These figures are

sums of numbers from individual modification considerations; the last three digits are not significant.

Associated with each of these tables are the corresponding data plots, Figures 6-1 through 6-9. Table 6-15 presents the uncertainty factors for the conversion costs. These confidence limits are indicated on the plots by the vertical bars on each point. Some error bars, however, are not included since they would have been of insignificant length when drawn on the log-log graph.

Figure 6-10 is the composite of all the data. Superimposed on these points are straight lines showing cost as a function of capacity for all boile types. The overall significance of the conversion cost data is discussed in the following subsection.

6.3.3 Cost Data Evaluation

Within the scatter of the data plotted in Figures 6-1 to 6-9 there is a correspondence between conversion cost and capacity for individual boiler types. In addition, a general correspondence between conversion cost and capacity exists for all boiler types for a given original fuel to substitute fuel conversion. The data appear to be described by power law functional relationships. The following are some additional significant items that require amplification

- For the gaseous substitute fuels, boiler conversion costs increase in proportion to a decrease in heating value of the fuel (Figures 6-1 through 6-3, 6-6 through 6-8). The greatest cost differential exists for 750 MW equipment, for which a 45% cost variance exists.
- In some of the plots, the data points for stoker-fired equipment lie above the correspondence defined by the remaining points (Figures 6-1 through 6-3). This reflects the additional cost incurred as a result of the required internal modifications, a procedure unique to this type of boiler.
- The data points for oil-fired, firetube boilers (Figures 6-6 through 6-9) indicate a slightly different trend than that defined by the remaining points. This reflects certain fixed costs, such as piping common to all types of boilers, which become more noticeable as the boiler's physical size and capacity decrease.
- For all of the original fuel-to-substitute fuel conversions, the costs required to modify the utility boilers differ among the various types of boilers only slightly. This is at variance with the notion conceived previous to compiling the data that conversion cost would be a strong function of utility boiler type. The costs associated with the individual conversion considerations for each type of boiler are contained in the Appendix of this report.

Figure 6-10. Composite of All Conversion Cost Data vs. Capacity

 The differences in conversion costs for the field-erected and packaged watertube boilers are slight. An incrementally higher engineering cost for the latter type accounts for this difference.

Figure 6-10 is the composite of all cost data previously shown in Figures 6-1 through 6-9. Three lines, again appearing to conform to power law functional relationships, have been fared in to illustrate the correspondence between cost and capacity for all boiler types for the three major fuel switching strategies. These are:

Conversion to Liquid SRC

Enabling all coal- or oil-fired boiler types to use liquid SRC is clearly the most expensive fuel substitution option. This cost is dominated by the elaborate fuel handling system that is required.

Conversion to solid SRC

This appears to be the least expensive strategy for abating $\rm SO_{x}$ emissions by way of fuel switching. It does, of course, apply only to boilers that were originally burning coal. The low cost reflects the savings realized through the reuse of existing fuel handling and firing equipment.

• Conversion to the Coal-Derived Gases and Natural Gas

These costs fall between those for liquid and solid SRC. The
option for conversion to gas is open for all boiler types firing
either original fuel. Due to the data scatter, the straight
line in Figure 6-10 representing the costs for this operation is
only one of many that could have been drawn in. It serves, however, to identify the overall trend. A more accurate placement
of the line can be obtained by performing a regression analysis.

6.3.4 Use of Cost Data for Other Locations

As was mentioned previously, the installation costs associated with each type of conversion were based on San Francisco Bay Area labor rates. Therefore, the total plant investment as shown on the data sheets is specific for that metropolitan area. To determine installation costs for other areas, it will be necessary to modify the Bay Area figures by some labor rate factor.

M. W. Kellogg Co. presented location factors for the major U.S. cities in Reference 6-4. These are repeated in Table 6-16. Adjacent to each of these numbers is a corresponding factor as normalized to the Bay Area figure (1.45). With these factors, the installation cost estimates contained in this report can be used to calculate total equipment conversion capital costs for other major cities.

TABLE 6-16
LOCATION FACTORS FOR MAJOR U.S. CITIES

| Location | M. W. Kellogg Location Factor (Reference 6-4) | Location Factor Normalized to San Francisco |
|---------------|---|---|
| Atlanta | 1.10 | 0.76 |
| Baltimore | 1.41 | 0.97 |
| Birmingham | 1.16 | 0.80 |
| Boston | 1.23 | 0.85 |
| Chicago | 1.52 | 1.05 |
| Cincinnati | 1.53 | 1.06 |
| Cleveland | 1.86 | 1.28 |
| Dallas | 1.07 | 0.74 |
| Denver | 1.03 | 0.71 |
| Detroit | 1.73 | 1.19 |
| Kansas City | 1.37 | 0.95 |
| Los Angeles | 1.44 | 0.99 |
| Minneapolis | 1.54 | 1.06 |
| New Orleans | 1.16 | 0.80 |
| New York | 2.08 | 1.43 |
| Philadelphia | 1.82 | 1.25 |
| Pittsburgh | 1.52 | 1.05 |
| St. Louis | 2.01 | 1.39 |
| San Francisco | 1.45 | 1.00 |
| Seattle | 1.21 | 0.83 |
| Houston | 1.00 | 0.69 |

6.3.5 Proposed Cost Models

Interpolation and regression will allow the formulation of the functional relationships suggested by the correspondences between cost and capacity for each type of fuel-to-fuel conversion for each boiler category, as shown in Figures 6-1 through 6-9. Therefore, the most specific cost models would take the following forms:

where

HHV = high heating value for substitute fuel gas (Btu/scf)

F = location factor

and n's, p's and K's are calculated by the regression analysis.

Due to the lack of more than three data points for each boiler type, and the overall scatter of the data, the creation of these elaborate cost models may not be justified. More simplistic cost models can be obtained from the composite of all the data, illustrated previously in Figure 6-10. Thus, the general form of these functions would be the same for the three principal fuel substitution options for all boiler types:

Equipment Cost =
$$(K_e)$$
 (Capacity) n_e
Installation Cost = (F) (K_i) (Capacity) n_i

The total plant investment is the sum of the equipment and installation costs.

SECTION 7

CONCLUSIONS AND RECOMMENDATIONS

The following are this study's major conclusions:

- On the basis of the estimated equipment modification cost data, there appear to be three basic fuel switching options for the abatement of oxides of sulfur emissions from industrial and utility boilers. These include conversions to melted solvent refined coal, solid solvent refined coal, and the gaseous fuels of any heating value.
- Based on the engineering assumptions made during the cost estimation procedure, conversions to hot liquid SRC seem to be the most expensive of the investigated alternatives. The fuel handling system cost is the major portion of the total plant investment. This strategy is open to applicable boiler types firing either oil or coal.
- Converting coal-fired boilers to the use of solid SRC is the least expensive alternative. Considerable cost savings result from the reuse of the existing fuel handling and firing sytems. Modifying oil-fired boilers to enable the use of solid SRC is considered impractical. The costs of such an operation would exceed the costs for converting to liquid SRC.
- Between the costs for converting to SRC in either phase lie those for converting to the gaseous fuels. These costs are generally inversely proportional to the heating value of the substituted gas. This fuel switching option is available for all boiler types firing either oil or coal originally. The sulfur oxide reduction benefit is greater for the gaseous fuels since, unlike SRC, they contain no sulfur.
- There appears to be a correspondence between conversion cost and capacity for the three basic fuel switching options; a power law functional relationship probably best describes this correspondence.

The following are the principal recommendations made in light of the results of this study:

- A regression analysis should be performed for each of the correspondences between conversion cost and boiler capacity for each of the three major fuel substitution options. This procedure will result in the formulation of generalized equipment conversion cost models.
- The results of the ongoing experimental and practical activities in handling and burning solvent refined coal and the lower-Btu gases should be used to periodically update the cost estimations contained in this report.
- The cost estimation methodology used in this study should be employed to evaluate the costs of converting boilers to other coalderived fuels, especially the products from the more promising coal liquefaction processes.

APPENDIX A

PROCESSES FOR LOW AND INTERMEDIATE BTU FUEL GAS (From Reference 4-21 except where noted)

PROCESSES FOR LOW AND INTERMEDIATE BTU FUEL GAS

| Developed or Offered by (and Process Name if any) | Process Comments | Status and Remarks |
|---|--|--|
| Applied Technology Corp. | Coal is continuously gasified by air (without steam) in a molten-iron bath. Reaction with limestone takes out sulfur. | Tested in pre-pilot reactor equivalent to 10 bl/min of coal. Aiming for funding for bigger unit. |
| Applied Technology Corp. (Patgas) | Similar to company's Atgas process (see Appendix B) but without shift conversion or methanation. | Gas intended for, e.g., iron and steel industry |
| Babcock & Wilcox Co. | Coal is entrained in air for feeding to gasifier, which uses no steam. Char is recycled. | Tested in experimental unit. |
| Bituminous Coal Research, Inc. | Gasification in multiple fluidized beds yields a gas stream free of liquids. Btu content of gas depends on whether air or oxygen is fed. | Construction of 100-lb/h unit to begin at Monroeville, PA, this year. |
| Columbia University | Coal's carbon reacts with steam in electric arc at about 10,000°C. Depending on reaction and subsequent quench conditions, process can be used to make low- or high-Btu gas. | As of May 1973, had been tested on batch basis at about 30 kw. Sponsored by Consolidated Natural Gas Co. |
| Combustion Engineering, Inc. | Pulverized coal is entrained in air and steam for feeding to gasifier. | Preliminary tests completed; await funding for 5-ton/h unit. |
| Davy Powergas, Inc. (Winkler) | Fluidized-bed gasification accommodates wide range of particle sizes. Some installations use oxygen instead of air, to obtain higher-Btugas. | Developed in Germany; widely commercial in Europe and Asia; no contracts in U.S. yet. |

APPENDIX B

PROCESSES FOR HIGH BTU PIPELINE GAS (SNG) (From Reference 4-21)

Processes Developed With Their Own Technology for Methanation

| Developed or Offered by (and Process Name if any) | Process Comments | Status and Remarks |
|---|---|---|
| Bituminous Coal Research, Inc. (Bi-Gas) | Gasifier, at 1000 to 1500 psi, has two stages. Char is gasified with oxygen and steam in lower stage; the gas rises, picking up and entraining incoming coal; this stream goes to upper stage, which makes char and enriches the gas. Methanator has fluidized catalyst bed, with imbedded heat-transfer surfaces. | Gasification tested in 100-1b/h continuous unit; methanation likewise sucessfully tested. A 5-ton/h pilot plant for overall process being built at Homer City, PA. |
| Columbia University | Coal's carbon reacts with steam in electric arc at about 10,000°C. Proper reaction and quench conditions enable production of SNG without additional methanation step. | As of May 1973, had been tested on batch basis at about 30 kw. |
| Institue of Gas Technology (Hygas) | After pretreatment by air oxidation or by dilution with char, coal is oil-slurried and fed to top of 1000 - 1500 psi two-stage hydrogasifier, while mixture of steam and hydrogen (generated externally, from leaving hydrogasification) enters at the bottom. Heat in gasifier is supplied by carbonhydrogen reaction. Methanator downstream uses multiple packed-catalyst-bed reactors. | Three-ton/h pilot plant compleated at Chicago in 1971 has operated on lignite, with hydrogen produced from char electrothermally. Now, IGT will run caking bituminous coal, and produce hydrogen via oxygen-combustion as source of heat. |
| Lurgi Gesellschaft für Wärme~ und Chemotechnik mbH. (Lurgi Pressure Gasification) | In pipeline-gas projects, gasifier with lock hopper and grate (see Appendix A) employs oxygen for gasification, producing a raw gas of about 400 Btu/ft ³ . A heterogeneous nickel catalyst is used in the downstream methanation step. | Gasification well established (see Appendix A). Methanation being groomed in demonstration plants. First SNG-from-coal plants in U.S. will use Lurgi technology. |

Processes Developed With Their Own Technology for Methanation (Concluded)

| Developed or Offered by (and Process Name if any) | Process Comments | Status and Remarks |
|--|--|--|
| Stone & Webster Engineering Corp. (Solution/Gasification) | Coal is slurried in a solvent; then a two-step treatment with hydrogen solubilizes the coal and produces pipeline-quality gas without an explicit methanation step. Process does not entail oxygen or steam. | Tested on bench scale. Under new joint venture with General Atomic, nuclear reactors will provide heat for hydrogen generation. Demonstration plant planned. |
| U.S. Bureau of Mines (Synthane) Processes That Will be Com | Coal is pretreated with steam and oxygen in fluidized-bed reactor that is integral part of gasification system. The system operates at high pressures (e.g., 1000 psi). Of methane contained in final gas, 60 percent is made during gasification step. Two variants of downstream methanation with Raney nickel catalyst are under study. | Tested in continuous unit rated at 10 to 20 lb/h. A 75-ton/d pilot plant due completed at Bruceton, PA, in August 1974. |
| Applied Technology Corp. | Coal is injected into 2500°F molten- iron bath; reaction with steam and oxygen produces sulfur-free gas for shift conversion and methanation. Sulfur removed as slag by limestone addition. | Gasification step has been tested in 2-ft-dia. reactor, equivalent to 10 lb/min of coal. Company seeks funds to build 15-ton/h unit. |
| Babcock & Wilcox Co. | Entrained-coal gasifier; char recycled. Methane content of gasifier output can be regulated by selecting pressure and temperature. | Technology commercial in 1950's for making synthesis gas. Now soliciting cutomers for fuel production (including SNG) as well. |
| Babcock & Wilcox Co. | Gasifier employs sulfur dioxide in- stead of oxygen for blowing. | Conceptual. Seeking Funds for testing. |

Processes That Will be Combined with "Outside" Methanation Technology (Continued)

| Developed or Offered by (and Process Name if any) | Process Comments | Status and Remarks |
|--|---|--|
| Cogas Development Co. (Cogas) | Multistage pyrolysis of coal yields gas, oil and char. More gas comes from reacting char with steam, at under 100 psi. Heat for gasification supplied by burning some char in air, in a combustor external to the gasifier. No oxygen needed. | Pyrolysis step demonstrated in COED-Process work of FMC Corp., one of the partners in Cogas Development Co. Two pilot plants will test char-gasification step. |
| Consolidation Coal Co. (CO ₂ Acceptor) | Lignite is gasified with steam in presence of hot, calcined dolomite. This reacts exothermally with the gasification-generated carbon dioxide, removing it while providing heat for gasification. Dolomite regenerated by heating. | Runs have been made in a 30-ton/d pilot plant completed in South Dakota in 1972. |
| Davy Powergas, Inc. (Winkler) | Oxygen-feeding version of process outlined in Appendix A serves as gasification step to precede shift conversion, purification, and methanation. | Developed in Germany; widely commercial in Europe and Asia; no U.S. contracts yet. |
| Exxon Corp. | Air burns char outside of gasi- fier, to provide heat for gasi- fication reactions involving steam. System does not require oxygen. | Tested in 1/2-ton/d unit at Baytown, Tex. Design of proposed 500-ton/d plant nearly completed. |
| Garrett Research & Development Co. (GRD Coal Gasification Process) | A low-pressure (30 to 50 psi) step pyrolyzes coal quickly in the presence of some steam and recycled gas. The pyrolyzer also receives partially burned char (produced externally by air combustion), which supplies the needed heat. | Tested in a 50-lb/h unit (a highly similar liquefaction process has been tested in a 300-lb unit). Now seeking support for a 250-ton/opilot plant. |

Processes That Will be Combined with "Outside" Methanation Technology (Concluded)

| Developed or Offered by (and Process Name if any) | Process Comments | Status and Remarks |
|---|--|--|
| M. W. Kellogg Co. | Coal is contacted with oxygen and steam in a molten-sodium-carbonate bath at about 1700°F. and 1200 psi. The salt serves as catalyst and heat-transfer agent; all operations involving salt take place in the one vessel. Raw gas from gasification is tar-free. Of methane in the final gas, 55 percent to 60 percent is made during this gasification step. | Process development, underway for several years, has included studies in a 5-1/4-in-dia. reactor. Next step will employ a 30-in reactor. Funding sought for building a large continuous pilot plant. |
| Koppers Co. (Koppers-Totzek) | Effluent from gasification des- cribed in Appendix A is suitable for shift conversion, and methanation. | Sixteen commercial plants in Europe and Africa, making ammonia-syntesis gas. |
| Union Carbide/Battelle/Chemico | Two fluidized-bed systems, a combustor and a gasifier, are linked by an agglomerated-ash circuit that transfers heat. Gasifier, at 1800°f and 250-350 psi, is fed coal and steam; the combustor is fed char and air. No oxygen required. | Components of process tested during 1960's by Union Carbide and Battelle. Chemico completing design, for Battelle, for 25-ton/d pilot unit. |
| U.S. Bureau of Mines (Hydrane) | In a first, "dilute" stage, coal particles are heated through their plastic-transition temperature range in a stream of hydrogen and methane from fluidized-bed second stage. Devolatilized coal, mean-while, falls into second stage, where it contacts hydrogen gernerated externally from char, steam and oxygen. Gas leaving dilute stage, at 2000 psi, is 75 percent or more methane. | The two stages have been tested separately at Bruceton, PA. A pilot unit to demonstrate them together has just been built but is not likely to start up during this fiscal year. |

APPENDIX D METRIC SYSTEM CONVERSION FACTORS

Although EPA's policy is to use the metric system in all of its documentation, certain non-metric units are used in this report for convenience. Readers more familiar with the metric system may use the following to convert to that system:

| Non-Metric Unit | Multiplied By | Yields Metric Unit |
|---------------------|-----------------------|--------------------|
| in | 2.540 | cm |
| ft | 0.3048 | m |
| ft² | 9.3×10^{-2} | m² |
| ft³ | 28.317 | liter |
| gal. | 3.785 | liter |
| lb. | 0.454 | kg |
| ton | 907.185 | kg |
| centistoke | 10 ⁻⁶ | m²/sec |
| °F | 5/9(°F-32) | °C |
| Btu | 1.055×10^{3} | joule |
| Btu/ft ³ | 37.256 | joule/liter |

| 15. SUPPLEMENTARY NOTES | | |

The report gives results of a study to identify capital costs associated with converting industrial and utility boilers from conventional high-sulfur fossil fuels to low-sulfur products from selected coal conversion processes. The boilers of concern include all industrial and utility size equipment in the 10 to the 7th power to 10 to the 10th power Btu/hr capacity range. The substitute fuels include solvent refined coal (SRC) in the solid and hot liquid (melted) phases as well as lower-Btu gas. The cost assessment methods used in the study showed that conversion to liquid SRC is the most expensive alternative. Converting coal-fired boilers to solid SRC is the least expensive alternative for these types of boilers. Between the costs of converting to SRC in either phase lie those costs for converting to the gaseous fuels. A significant result of the study is that the costs of all conversion

strategies increase exponentially with boiler capacity: cost appears to be a weak
