Organic Chemicals in Drinking Water

Summary of the National Organics Monitoring Survey The United States Environmental Protection Agency (EPA) has conducted the National Organics Monitoring Survey (NOMS) since March 1976, to determine the frequency of occurrence of specific contaminants in drinking water supplies and to provide data for the possible establishment of additional maximum contaminant levels for organic compounds or for a treatment requirement for the control of organic compounds in drinking water.

Included in the NOMS were 113 community water supplies, representing various types of sources and treatment processes. These were monitored three times (phases) during a twelve month period. A fourth phase is currently underway.

The source of these compounds may be: (1) naturally occurring organic matter (e.g. humus); (2) contaminants introduced as a result of treatment (e.g. trihalomethanes); (3) synthetic chemicals from point sources; and (4) chemicals from non-point sources. The naturally occurring substances constitute by far the major portions of the organic chemicals found in drinking water.

Compounds selected for the NOMS study include: chloroform, 1,2-dichloroethane, carbon tetrachloride, bromodichloromethane, trichloroethylene, dibromochloromethane, bromoform, benzene, vinyl chloride, bis (2-chloroethyl) ether, p-dichlorobenzene, 1,2,4-trichlorobenzene, 2,4-dichlorophenol, pentachlorophenol, polychlorinated biphenyls, fluoranthene, 1,12-benzoperylene, 3,4-benzopyrene and indeno(1,2,3-cd)pyrene. These compounds were chosen on the basis of possible occurrence, available toxicological data, and the existence of analytical methodology for their identification and quantification. In addition, several general organic class parameters, such as total organic carbon (non-purgeable), carbon chloroform extract, ultraviolet absorbance and emission fluorescence scan were studied in an attempt to determine a possible relationship between one or more of them and specific compound occurrences. Certain sampling and analytical modifications were instituted in Phase III to take into consideration the findings of the earlier phases. NOMS data for trihalomethanes (THMs) are summarized below. (Table I).

2

TABLE I - Analytical results of chloroform, bromoform, bromodichloromethane, and dibromochloromethane and total trihalomethane in water supplies from NOMS

(Concentrations in milligrams per liter)

۰.

In Phase I, samples were collected and analyzed in a fashion similar to that employed in the National Organics Reconnaissance Survey (NORS). Samples were shipped from the utility and stored at 2-8°C for 1-2 weeks prior to analyses. In Phase II samples were allowed to stand at 20-25°C for 3-6 weeks prior to analyses. Under these conditions THM formation was permitted to proceed to reaction end points (terminal values) generally corresponding to the consumption of free chlorine residual in the sampling vial. All supplies were sampled in Phase III both with and without a chlorine reducing agent present at the time of sampling (quenched and terminal). In addition, samples with a reducing agent added were collected at five points in the distribution system in each of ten cities. A site at a distant point in most systems was sampled. These experiments were incorporated in Phase III in order to more fully understand the distribution of total trihalomethanes (TTHM) concentrations that can reach the consumer, since it is recognized that the extent of THM formation depends on the type and chemical composition of raw water, pH, water temperature, chlorine contact time, treatment method, and in certain cases, season.

The NOMS demonstrated that considerable amounts of THMs could form in the water after it had entered the distribution systems on the way to the consumer's tap. It also showed that THMs far exceeded the concentrations of other synthetic organic contaminants in finished drinking water, and that brominated THMs could also exceed the chloroform concentrations in some situations. Part of the THM concentration variation between Phases I, II and III might also be attributable to seasonal effects.

Other than trihalomethanes, compounds studied in the NOMS are generally present in finished drinking water due to raw water contamination (Table 2). An exception is

4

2,4-dichlorophenol which is produced on treatment by chlorination of phenol, or related precursors.

 Samples were shipped ICLD (4°C), atored at 2°-8°C for 1-2 weeks prior to analyses.
 Samples were preverved with Sodium Thiosulfate at time of mampling, shipped at ambient temperature, atored at 20°-25°C for 3-6 weeks F Samples were preserved and an ambient air temperature, stored at 20°-25°C for 3-6 weeks prior to analyses.
 Bisples were shipped at ambient air temperature, stored at 20°-25°C for 3-6 weeks prior to analyses.

. In general, the data shows that the trihalomethanes (chloroform, bromodichloromethane, dibromochloromethane, bromoform and dichloroiodomethane) are by far the most ubiquitous synthetic organic contaminants in drinking water, and they also occur at the highest concentrations (up to 784 ppb were detected). They are produced by chlorination during treatment of their naturally occurring precursors, probably humus, but algae and other chemicals may also be precursors. Pentachlorophenol was also commonly found in parts per trillion levels.

Although a large number of other synthetic products were also detected in various waters, the concentrations were generally very low (usually sub parts per billion) and the number of occurrances was generally small. The common volatile halogenated solvents and chemical intermediates (i.e. chlorinated ethanes, ethylenes and benzenes) were typical. Carbon tetrachloride when found in finished water was probably a result of contamination of the chlorine. Chemical oxygen demand (COD) and Non-purgeable Total Organic Carbon (NPTOC) correlated reasonably well with the THM formation potential.

Besides the above mentioned organic contaminants, Table 3 lists additional organic compounds that have been detected at least once in the NOMS study.

The EPA has published in the Federal Register on February 9, 1978, proposed regulations to establish a

6

maximum contamination level of 100 parts per billion for THMs and to require the installation of granular activated carbon treatment to control general synthetic organic contaminants.
